Potassium Iodide as a Primary Standard Substance in Permanganimetry

BY I. M. KOLTHOFF, H. A. LAITINEN AND J. J. LINGANE

It was shown in a previous paper from this Laboratory[1] that the potentiometric iodide–silver titration is capable of giving results accurate to within 0.02%, under the proper conditions. The purpose of the present study was to investigate the accuracy of several iodide-permanganate titration methods, with a view to using potassium iodide as a primary standard substance in permanganimetry. For this purpose we have compared the results obtained by standardizing solutions of potassium permanganate against potassium iodide, with those obtained using arsenious oxide and sodium oxalate as standard substances.

Materials

Potassium Iodide.—The potassium iodide used in this work was synthesized from purified potassium bicarbonate and pure hydriodic acid. The hydriodic acid was synthesized directly from purified iodine and hydrogen, using platinized asbestos as catalyst, in the all-glass apparatus shown in Fig. 1. All joints in this apparatus were of ground glass lubricated with a minimal amount of phosphoric acid, except the joint at the absorption bulbs, D, which was sealed with a drop of water. Iodine, purified by repeated sublimation from potassium iodide, was placed in the bulb A and volatilized by immersing the bulb in an electrically heated glycerol bath at 150 to 180°. The iodine vapor and an excess of pure hydrogen, introduced through the short arm, then passed through the porous platinized asbestos plug at B, which was heated to about 400° by a burner at the end close to the bulb while the other end was left unheated. The resulting hydrogen iodide passed through the trap C, which was immersed in a freezing ice–salt mixture to condense a small amount of unreacted iodine, and the gas was then absorbed in conductivity water in the absorption bulbs D to give a concentrated hydriodic acid solution.

Before starting a run and before the catalyst was heated, the apparatus was flushed out with nitrogen for a few minutes to prevent explosive reaction of hydrogen with oxygen from the air at the surface of the platinized asbestos. Hydrogen was then passed through the apparatus for a few minutes before the heating was started, and the rate of hydrogen flow during a run was so adjusted that about 2–3 bubbles per second escaped from the absorption bulbs. The rate of the reaction was controlled easily by regulating the temperature of the iodine bulb A and the rate of flow of hydrogen. In a typical run, 180 g. of iodine was converted to hydriodic acid in six hours with a yield better than 95%.

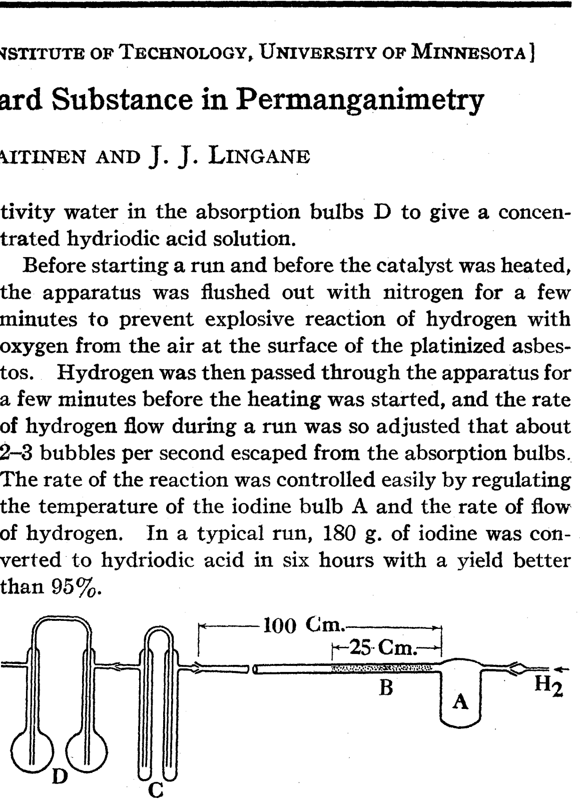

Fig. 1.—All glass apparatus for synthesis of hydriodic acid.

The hydriodic acid solution was treated with a slight deficiency of potassium bicarbonate which had been recrystallized repeatedly from water at 70° in an atmosphere of carbon dioxide, and the resulting solution of potassium iodide containing excess hydriodic acid was filtered and evaporated to crystallization on an electric hot-plate in an Erlenmeyer flask through which a rapid stream of hydrogen was bubbled. The potassium iodide obtained on cooling the solution was filtered off on a sintered glass funnel, freed from excess mother liquor by suction, and finally dried and stored in a desiccator over fused potassium hydroxide.

The salt was prepared for weighing by fusion in a platinum boat in an atmosphere of pure, dry hydrogen, under which conditions there was no trace of decomposition [1]

---

(1) I. M. Kolthoff and J. J. Lingane, THIS JOURNAL, **58**, 1524 (1936).

This method of obtaining very pure potassium iodide will be described in greater detail in a forthcoming volume of "Inorganic Syntheses."

Arsenious Oxide.—Bureau of Standards arsenious oxide was dried in a desiccator over concentrated sulfuric acid to constant weight. A sample of antimony-free arsenious oxide kindly furnished by Professor Foulk[2] was dried similarly.

Sodium Oxalate.—Bureau of Standards sodium oxalate was dried to constant weight at 105°.

Potassium Permanganate Solution.—Stock solutions of potassium permanganate, approximately 0.1 and 0.4 *N*, were prepared from reagent quality potassium permanganate, allowed to stand for two weeks, and filtered through a sintered glass filtering funnel. The stock solutions were checked at regular intervals by potentiometric titration of fused potassium iodide samples. Approximately 0.01 *N* solutions were prepared by diluting weighed portions of the stock solutions in a calibrated volumetric flask. A fresh 0.01 *N* solution was prepared every five days.

Experimental Technique.—The titrations were performed by adding the major portion of the stock solution from a weight buret until an end-point was closely approached, after which the titrations were finished by the use of 0.01 *N* solution delivered from an ordinary volume buret.

Weights and volumetric apparatus were calibrated carefully by standard methods. Weighings were corrected to vacuum using the following densities: brass weights 8.4, potassium iodide 3.13, arsenious oxide 3.86, and air 0.0012 g. per cc.

1. Iodide–Permanganate Titration According to Andrews.[3]—This titration is based upon the oxidation of iodide to colorless iodine monochloride in strong hydrochloric acid medium, the end-point being determined by the use of carbon tetrachloride.

About 25 ml. of water was introduced into a 500-ml. iodine flask and about 1 ml. of concentrated hydrochloric acid was added. Pure potassium bicarbonate was added in small portions until a slight excess was present and most of the air in the flask was replaced by carbon dioxide. A weighed sample of fused potassium iodide in a platinum boat was then introduced, and after solution of the salt was complete, the platinum boat was removed by means of a suitably bent glass rod and washed thoroughly with water. Sufficient concentrated hydrochloric acid (13.3 *N*) was added to obtain the desired acid concentration at the end-point given in Table I, assuming a final volume of 325–350 ml. The solution was cooled in an ice-bath and 6 ml. of carbon tetrachloride was added. The titration was then carried out with 0.4 *N* potassium permanganate from a weight buret until within a few drops of the end-point, and then finished with the 0.01 *N* solution, the end-point being detected by the disappearance of the iodine color from the carbon tetrachloride upon thorough stirring.

The results of titrations carried out at various acidities of hydrochloric acid are given in Table I, and the normality found compared with that obtained in the standardization against pure potassium iodide according to the potentiometric method by oxidation to iodine. It will be shown later in this paper that the latter method gives exact results.

Table I

Titration of Potassium Iodide with Potassium Permanganate According to Andrews

No.	Final concn. HCl, *N*	KI (vacuum), g.	Total $KMnO_4$ soln. added, g.	Normality of $KMnO_4$, g.	Normality of $KMnO_4$ (potentiometrically)	Error of Andrews method, %
1	3.1	1.09311	28.761	0.45783	0.45753	+0.066
2[a]	3.3	1.23485	32.054	.46401	.46460	− .130
3	3.7	1.37193	36.118	.45756	.45753	+ .007
4	3.8	1.35017	35.027	.46433	.46460	− .058
5	4.3	0.99039	26.070	.45762	.45753	+ .020
6	5.1	1.09551	28.421	.46432	.46460	− .060
7	5.8	1.37068	35.564	.46415	.46460	− .097
8[a]	8.2	1.23690	32.490	.45858	.45768	+ .197
9	8.9	1.25115	32.864	.45859	.45768	+ .199
10	9.0	1.07241	28.180	.45841	.45768	+ .160

[a] Titration carried out rapidly (*ca.* 30 ml./min.). In the other cases the titrations were carried out no more rapidly than 10–15 ml./min.

2. Potentiometric Titration of Potassium Iodide by Oxidation to Iodine.—The fused sample of potassium iodide was dissolved in about 50 ml. of water in a wide-mouthed bottle. One ml. of concentrated sulfuric acid was added from a pipet, and a stream of purified nitrogen was bubbled through the solution to provide stirring. The final volume was about 100 ml., and the final sulfuric acid concentration was about 0.36 *N*. The usual potentiometric apparatus with a bright platinum indicator electrode was employed. Care was taken to wait for a steady e. m. f. after each addition of reagent. The end-point, found from the maximum value of $\Delta E/\Delta V$, could be determined with a precision of ±0.005%.

3. Titration According to the Iodocyanide Method of Lang.[4]—In this titration the iodide is oxidized to colorless iodine cyanide in dilute acid solution in the presence of hydrocyanic acid. The accurately weighed sample of potassium iodide (1 to 1.3 g.) was dissolved in an iodine flask in 25 ml. of water and 50 ml. of 4 *N* sulfuric acid and 30 ml. of 0.5 *N* potassium cyanide were added. The mixture was titrated with permanganate until near the end-point. Then 20 ml. of 0.2% starch solution was added and the titration continued with 0.01 *N* permanganate until the solution was colorless. In all titrations this end-point appeared 0.07% too early due to the fact that part of the iodine is present as iodine cyanide which is not reactive with starch and to the limited sensitivity of the iodine starch reaction. After the starch end-point had been reached, 2 drops of 0.025 *M* ferrous phenanthroline indicator were added and the titration continued until the color went from red to practically colorless. The ferrous phenanthroline must not be added before the starch iodine end-point as the indicator reacts with the iodine.

4. Titration by the Acetone Method of R. Berg.[5]—This titration is based upon the fact that the iodine first formed reacts with acetone present in the solution to give colorless iodoacetone.

---

(3) L. W. Andrews, *Z. anorg. allgem. Chem.*, **36**, 76 (1903); This Journal, **25**, 756 (1903).

(4) R. Lang, *Z. anorg. allgem. Chem.*, **122**, 332 (1922).

(5) R. Berg, *Z. anal. Chem.*, **69**, 369 (1926); compare also D. Lewis, *Ind. Eng. Chem., Anal. Ed.*, **8**, 199 (1936).

Instead of using potassium iodate as recommended by Berg, potassium permanganate was used in the following titrations.

The fused sample of potassium iodide was dissolved in 25 ml. of water and 50 ml. of redistilled acetone, 20 ml. of 9 N sulfuric acid and water were added to give a volume of 200 ml. Near the end-point either 5 drops of 0.2% diphenylamine sulfonate or 2 drops of 0.025 M ferrous phenanthroline were added as indicators. The titrations were not well reproducible, indicating an average normality which was 0.55% low. For this reason the results are not tabulated. The poor results are probably due to a low rate of reaction between acetone and iodine.

5. Standardization of Potassium Permanganate with Arsenious Oxide. (a) **Potentiometrically.**—The sample of arsenious oxide (0.8 to 1 g.) was dissolved in 10 ml. of 6 N sodium hydroxide, which was free of reducing agents. Ten ml. of concentrated hydrochloric acid and 100 ml. of water were then added, the solution at the start of the titration thus being about 0.5 N in hydrochloric acid. One drop of 0.0025 M potassium iodate was added as catalyst, together with 1.0 g. of sodium chloride. The titrations with potassium permanganate were carried out using nitrogen for stirring, with care to wait for equilibrium, and the end-point determined from the maximum value of $\Delta E/\Delta V$.

(b) **Visually.**—The titrations were performed as in (a) above but with titration to the point where the first permanganate color was visible. This end-point appeared 0.012% later than the potentiometric end-point. Using ferrous phenanthroline as indicator, the end-point coincided to within 0.003% with the potentiometric end-point.

The results of the various titrations are given in a condensed form in Table II. In the last column the error in the normality is referred to the value obtained by the potentiometric iodide titration.

4	As_2O_3[c]	Potentiometric	3	.45740	± .015	− .028

[a] Ferrous phenanthroline end-point. [b] Bureau of Standards product (99.97% pure). [c] Product from Professor Foulk.

6. Standardization of Potassium Permanganate with Sodium Oxalate.—Since the procedures described for the standardization of potassium permanganate with sodium oxalate are given for 0.1 N solutions, permanganate solutions of the latter strength were prepared and standardized potentiometrically against pure potassium iodide. In the standardization with oxalate the procedures of McBride,[6] of Kolthoff,[7] and of Fowler and Bright[8] were followed closely. In all cases the end-point was found potentiometrically by finishing the titration with 0.01 N permanganate. The calculation of the results is based upon a purity of 99.96% as stated by the Bureau of Standards. The results are given in Table III.

TABLE III

STANDARDIZATION OF 0.09573[a] N POTASSIUM PERMANGANATE AGAINST SODIUM OXALATE

Method used	Differences in normality found, %				Average error
McBride	+0.31	+0.15	+0.16		+0.21
Kolthoff	+ .13	+ .05	+ .22		+ .13
Fowler and Bright	+ .09	+ .09	+ .06	+0.04	+ .07

[a] Normality determined by potentiometric titration against potassium iodide.

Discussion

1. It is known that dependent upon the acidity the results of the Andrews method may be high or low.[9] At a final acidity between 3.7 and 5.5 N the permanganate normality found was on an average 0.04% smaller than that found by the direct potentiometric titration. At the specified acidities the reproducibility is very good. At acidities between 8 and 9 N, the normalities found were about 0.2% too high, indicating that too little permanganate was used for a given amount of iodide. This may be due to an induced air oxidation of potassium iodide during titration or to a slow reaction near the end-point. It may be mentioned that a solution of potassium iodide in 7–8 N hydrochloric acid could be allowed to stand for a considerable time before an iodine color was noticed in the carbon tetrachloride layer upon shaking.

2. The potentiometric titration of iodide with potassium permanganate in dilute sulfuric acid gives exact and precise results, easily reproducible to within ±0.01%. The normality of the permanganate found by this method agreed within 0.03% with that obtained in the standardization with Bureau of Standards arsenious oxide, and with the antimony-free sample of arsenious oxide obtained from Professor Foulk. The titration of iodide according to Lang also gives satisfactory results and can be recommended with the Andrews titration for the standardization of potassium permanganate.

In order to avoid the troublesome fusion of

potassium iodide in a hydrogen atmosphere, experiments were performed using samples dried simply at 200–225°. The normalities obtained with the unfused salt were 0.02 to 0.03% higher than with the fused salt, indicating the retention of a very small amount of occluded water.

3. Although sodium oxalate and oxalic acid are classical primary standards, they are not suitable for the highly exact standardization of potassium permanganate solutions because of side reactions. Theoretical results can be found only by a compensation of errors. In agreement with Fowler and Bright[8] we found in the present work that McBride's procedure gives high normalities (average +0.20%), the precision of the titration being not greater than ±0.1% The procedure recommended by Kolthoff[7] gives slightly better results, although the average error was still +0.13%. The best results were obtained by Fowler and Bright's procedure, although even in this case the average error amounted to +0.07% as referred to potassium iodide. Therefore, potassium iodide and arsenious oxide fulfill the rigid requirements of primary standard substances better than sodium oxalate.

Acknowledgment.—We express our appreciation to the Graduate School of the University of Minnesota for financial aid which enabled us to do this work.

Summary

1. Potassium iodide and arsenious oxide are more suitable for the exact standardization of potassium permanganate than sodium oxalate.

2. The results obtained by the potentiometric titration of pure potassium iodide and of Bureau of Standards arsenious oxide with potassium permanganate agreed within 0.03%.

3. Potassium permanganate may be standardized against potassium iodide by Andrews' method or by Lang's method under the specified conditions. The results were accurate within 0.05%.

4. The results obtained with potassium iodide dried at 200–225° were 0.025% higher than with fused samples of the salt.

[Contribution from the Laboratory of Liquefied Gases of the Karpov Institute for Physical Chemistry]

A Study of Acid Catalysis in Liquid Ammonia

By A. I. Shatenshtein

Brönsted's work cleared up the concept of the acid–base equilibrium in any solvent. The solvent participates together with the dissolved substance in a double buffer equilibrium

$$\text{acid}_1 + \text{base}_2 \rightleftarrows \text{acid}_2 + \text{base}_1 \qquad (1)$$

This unified point of view enables one to correlate phenomena observed in different solvents, and in particular the catalysis of solvolysis reactions in aqueous and ammoniacal solutions.

From experimental results obtained in the catalysis of sugar inversion by concentrated aqueous solutions of acids it is evident[1] that the specific catalytic activity (ratio of the reaction velocity constant to the equivalent concentration of the acid) rises (as the concentration of the acid increases) in the case of perchloric, hydrobromic, hydrochloric and nitric acids (acids given in descending order of specific catalytic activity). This ratio remains constant in a solution of trichloroacetic acid and in solutions of the weaker acids the lower the dissociation constant of the acid the lower it falls.

The sequence of acids shown corresponds to the increasing firmness with which the proton is held in the molecule of acid and at the same time corresponds (for the so-called "strong" acids) to the increase of the interionic forces in their ionized solutions.

The rise in the specific catalytic activity can be attributed[2] to the primary salt effect, which may be more correctly described as the primary auto-salt effect. This is really the influence of the field of forces of the ions surrounding the solvatized protons $(H_3O \cdot nH_2O)^+$ and the reacting molecules. The increase in the concentration of the ionized acid corresponds to an increase in the strength of the field and the decrease in the degree of solvatization of the ions.

Assuming equally complete ionization in concentrated aqueous solutions of all "strong" acids, one might expect greater catalytic activity of

---

[1] A. Hantzsch and A. Weisberg, *Z. physik. Chem.*, **125**, 251 (1927).

[2] J. Brönsted and Bell, This Journal, **53**, 2478 (1931).

those acids in which the interionic forces are greatest. Actually, however, the opposite phenomenon is observed.

The contradiction may be solved by assuming that the reaction of solvolysis (of the sugar inversion type) is catalyzed, in the main, by lyonium[3] ions and that in concentrated aqueous solutions of "strong" acids one has a secondary auto-salt effect, that is to say, an unequally complete displacement of the equilibrium (1) in the direction of forming undissociated molecules of acid. This is confirmed by Raman spectra.[4]

The addition to the acid solution of a neutral salt with a common anion has the same effect on the reaction velocity as raising the concentration of the acid.[5] This confirms the applicability of the term auto-salt effect to the phenomena observed when the concentration of the acid is raised.

Thus one may take it that the change in the specific catalytic activity of aqueous solutions of acids as their concentration increases is the total result of primary and secondary auto-salt effects and depends on which of these predominates.

Assuming this view to be correct and taking into account the properties of ammonia, which is a solvent with a considerably greater affinity for the proton than water and a much lower dielectric constant, one may make a prediction with regard to the acid catalysis of the ammonolysis of organic compounds (ethers, lactones, etc.) in liquid ammonia.

Equilibrium (1) is displaced much farther to the right in solutions of acids in liquid ammonia than in water. The effect of interionic forces is much stronger in liquid ammonia than in water.

From this the following conclusions can be drawn: Reactions of ammonolysis in liquid ammonia should be catalyzed by phenols, amides and imides of acids,[6] and carbohydrates. In concentrated solutions of these acids both a primary and a secondary auto-salt effect occur. The catalytic activity of dilute solutions of ammonium salts of "strong" inorganic and "weak" organic acids should be the same and should be proportional to the analytic concentration of the solvatized protons $(\mathrm{NH_4}\cdot n\mathrm{NH_3})^+$.

When the concentration of solutions of "strong" acids is increased the secondary auto-salt effect is absent.[7] Assuming that the catalytic activity of solvatized protons increases as the field of forces of the anions becomes stronger, one may expect that a series of acids, placed in ascending order of specific catalytic activity, will be antibatic to a series of acids placed in ascending order to electrical conductivity, activity and osmotic coefficients.

The aim of the present work was to test these conclusions.

Experimental Results

The velocity of the reactions was measured by the change in the rotation of the plane of polarization of a solution in liquid ammonia. For this purpose a method was worked out for polarimetric measurements in liquefied gases at room temperature.[8] The reaction velocity constants were calculated according to the equation for a reaction of the first order.

In Table IV time is expressed in hours and in the other tables in minutes. The temperature in all cases was 20 ± 0.2°.

I. Kinetics of Ammonolysis of Santonine.—As Abkin and Medvedev[9] have shown the ammonolysis of santonine in liquid ammonia proceeds quantitatively with the formation of the amide of santoninic acid.

The reaction takes place autocatalytically. The initial value of the reaction velocity constant at 20° is about 0.0004.

A. Catalysis by Ammonium Salts.[10]—In Table I the average values of reaction velocity constants of the ammonolysis of santonine in the presence of ammonium salts are given.

---

(3) Undissociated molecules of an acid can only play a minor part in the catalysis of reactions of solvolysis: the more easily they yield up a proton the greater is the probability of "lyonium" ions being formed.

(5) Spohr, *J. prakt. Chem.*, **32**, 32 (1885).

(6) That solutions of these substances in liquid ammonia act as acids has been shown in numerous researches by Franklin (see E. C. Franklin, "Nitrogen System of Compounds," A. C. S. Monograph Series, 1935).

(7) M. Wolkenstein (*Acta Physicochim., U. R. S. S.*, **5**, 627 (1936)) has actually shown that in the Raman spectra of concentrated solutions of $\mathrm{NH_4NO_3}$ and $\mathrm{NH_4CNS}$ in liquid $\mathrm{NH_3}$ no frequencies are observed which could be ascribed to undissociated molecules. Of course when the concentration is increased a change in the degree of solvatization of ions, including $(\mathrm{NH_4}\cdot n\mathrm{NH_3})^+$ is possible. Between ions in ammonia solutions of organic carboxyl acids, beside electrostatic forces there are also forces of a chemical nature.[14] These would also appear to be present in concentrated solutions of inorganic acids, and this should have an influence on their catalytic activity. Owing to the lack of material this question is not discussed in the present paper.

II. Kinetics of the Ammonolysis of Desmotroposantonine in the Presence of Ammonium Salts.[12]—It may be thought that by analogy with the ammonolysis of santonine an amide of the desmotroposantoninic acid is formed as an end-product.

Table IV gives the average values of the reaction velocity constants in the presence of 1.5-normal solutions of ammonium salts (concentration of desmotroposantonine 0.75 g. per 100 cc. of solution).

TABLE IV

REACTION VELOCITY CONSTANTS OF THE AMMONOLYSIS OF DESMOTROPOSANTONINE

N	NH_4Cl	NH_4Br	NH_4I
1.5	0.024	0.015	0.010

The reproducibility of the constants was within 5 to 10%.

III. Kinetics of the Ammonolysis of Ethyl Tartrate in the Presence of Ammonium Salts.—The reaction took place with the formation of the diamide of tartaric acid. Figure 1 gives an idea of the velocity of the reaction of the ester in the presence of a number of ammonium salts (1.02 *N*). Concentration of ester 15.2 g. to 100 cc. of solution.

Discussion of Results

The experimental material submitted confirms the propositions given above regarding acid catalysis in liquid ammonia.

From Tables I–IV and Fig. 1 it follows that as concentration increases the catalytic activity of

---

[11] The last four results are provisional.

[12] For details see A. Schattenstein, *Acta Physicochim., U. R. S. S.*, **5**, 841 (1936).

ammonium salts of "strong" acids varies with the anion as follows: $ClO_4^- < I^- < NO_3^- < Br^- < Cl^-$.

In the works of Schattenstein and Uskova,[13] Gurjanova and Pleskov[14] it has been shown that the osmotic coefficients and coefficients of electrical conductivity of solutions of ammonium salts in liquid NH_3 follow in the order: $ClO_4^- > I^- > NO_3^- > Br^- > Cl^-$.

Similar data with regard to solutions of halogen salts and nitrates of alkali metals have been published in the works of Linhard[15] and Kraus.[16]

The order of catalytic activity of the amides of carboxyl acids in liquid ammonia corresponds to that of the acids themselves in water ($CH_3COOH < C_6H_5COOH < HCOOH$). There are no quite reliable data for the electrical conductivity of the amides of acids and phenols especially at great dilutions, on a basis of which one can calculate the coefficients of electrical conductivity of these solutions and corresponding dissociation constants. However, the qualitative comparison of our data with the results of Franklin and Kraus' work[17] on the whole confirm the proposition stated above.

Thus to sum up it may be asserted that the experimental material which we have hitherto been able to collect, is in good agreement with the views expressed in the present paper. This makes them quite plausible. However, further research is necessary to establish them on a firmer basis and pass from purely qualitative reasoning to stricter conclusions. Work is still in progress.

Acknowledgment.—The author wishes to thank Prof. A. M. Monossohn for his kind attention and interest in the present work.

Summary

1. The suggestion is made that the change in the specific catalytic activity of acids (including "strong" acids) as the concentration of their aqueous solutions rises is the total result of the primary and secondary auto-salt effects.

2. The conclusions are drawn as regards the acid catalysis of the ammonolysis reaction in liquid ammonia which are tested experimentally in the case of the ammonolysis of santonine, desmotroposantonine and ethyl tartrate.

3. Ammonolysis reactions in liquid ammonia are catalyzed by ammonium salts, amides of acids, phenols and carbohydrates.

4. The differences in catalytic activity of ammonium salts, both of "strong" and "weak" acids are leveled out. In dilute solutions the velocity constant is proportional to the concentration of the solvatized protons. With increase in concentration in solutions of ammonium salts of "strong" acids the antibatic nature of the series of catalytic activity and the series of electrical conductivity, activity and osmotic coefficients is observed.

5. The relationships usual in aqueous solutions of acids are observed in ammonia solutions of acids in which the proton is firmly attached (*e. g.*, the amides of acids).

Notable Differences in the Absorption Curves of Certain Groups of Unsaturated Hydantoins

BY MARGARET K. SEIKEL[1]

A systematic spectrographic study of certain unsaturated hydantoins which have been synthesized in this Laboratory during the course of the past twenty years, now brings to light additional evidence for the assumption that the structural formulas commonly accepted do not serve adequately to indicate their several relationships.[2] The substances investigated are all derivatives of anisalhydantoin and, with the single exception of anisalhydantoin-N-1-acetic acid,[3] were obtained from anisalhydantoin by the direct replacement of the hydrogen atoms in the N-1- and N-3-positions. In each case the structural formulas of these substances were reported in the literature as identical with that represented above except for the fact that the hydrogen atoms in the N-1- or the N-3-position or in both were shown to have been replaced.

It now seems desirable, however, to review the data from a somewhat different angle, since a more extended study of the ultraviolet absorption spectra of a number of related compounds has made it possible to correlate consistent differences in both physical and chemical properties in such a way as to classify these compounds in separate groups. This is illustrated in Figs. 1, 2 and 3.[4] A comparison of the curves represented in Fig. 1 shows for example that the characteristic spectrum of anisalhydantoin remains almost unchanged as the result of substituting a variety of different residues for the hydrogen atom in the N-3-position. This uniformity corresponds to other similarities observed in both physical and chemical properties since all the substances whose absorption curves have been plotted, as well as other N-3-derivatives, possess many characteristics in common. For example, they all agree in being only slightly soluble in most boiling organic solvents, such as CH_3OH, C_2H_5OH, CH_3COCH_3, $CHCl_3$ and dioxane and only moderately soluble in boiling acetic acid. All represent remarkably stable compounds and have resisted every attempt to isomerize them.

On the other hand, the replacement of hydrogen in the N-1-position is accompanied by a distinct change in the absorption curve. This holds true whether the hydrogen atom in the N-3-position has been replaced or not. Here again the substitution of different groups appears to have very little effect upon the character of the absorption, as is evident from a comparison of the curves in Figs. 2 and 3. The latter represent respectively groupings of stable and labile geometrical isomers.[5] Here again the remarkable uniformity in the absorption of quite different compounds corresponds to similarities in other physical and chemical properties. For example, all dissolve readily in cold chloroform and are in general much more soluble than the corresponding N-3-derivatives so that they easily can be separated from them.[6] They are also much less stable.[7] Moreover they isomerize readily.[8]

---

[1] In collaboration with Dr. Dorothy A. Hahn and Dr. Emma P. Carr.

[2] This assumption has long been the subject of informal discussion because of noticeable differences observed in the properties of two distinct groups of such compounds.

[3] This substance was prepared by condensing anisaldehyde with hydantoin-N-1-acetic acid, Renfrew and Johnson, THIS JOURNAL, **51**, 1787 (1929).

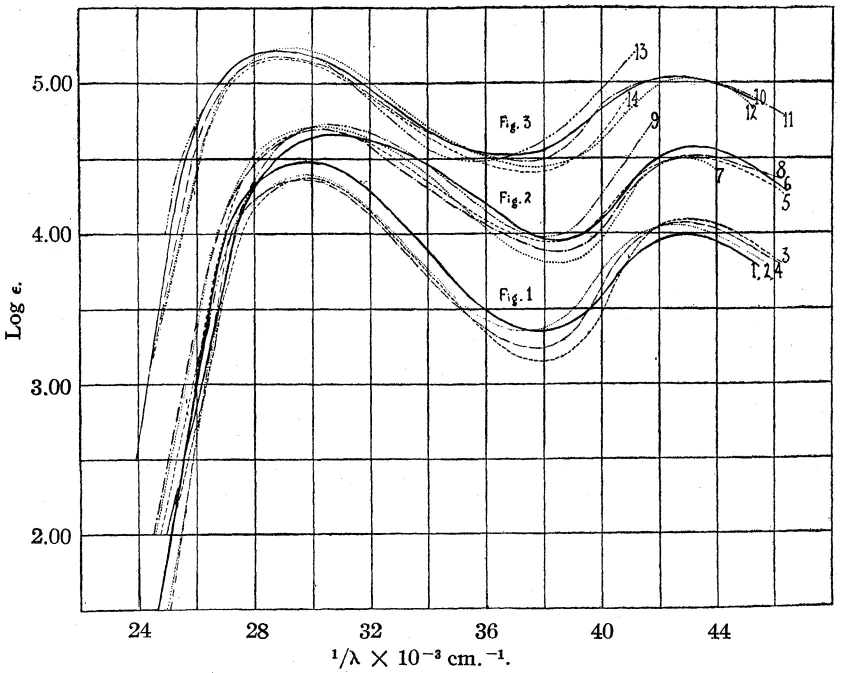
[4] Compare Figs. 1, 2 and 3 in the accompanying chart. For purposes of brevity only a few of the absorption curves which have been plotted were selected, but all which were measured fall into the same classifications.

[5] No curve for the labile isomer of 8 is given because the amount of material available at the time was not sufficient to permit the required number of recrystallizations. All substances in this group isomerize more or less in solution so that losses are sustained during the process of purification. In the case of 14 only one modification of the two possible isomers was obtained by Miss Renfrew. The fact that the absorption curve of this compound belongs obviously in this group, is of considerable importance since it, unlike all the others, contains a *free hydrogen atom* in the N-3-position.

[6] Note the relative differences in the solubilities of N-3-methylanisalhydantoin as compared with ethyl N-3-methylanisalhydantoin-N-1-acetate [Hahn and Renfrew, THIS JOURNAL, **47**, 151 (1925)] or with ethyl N-3-methyl-anisalhydantoin-N-1-phenylacetate [Hahn and Dyer, *ibid.*, **52**, 2498 (1930)]. It may be added that N-1-N-3-dimethyl-anisalhydantoin is also very soluble.

[7] They hydrolyze slowly on standing or rapidly in the presence of even traces of alkali. This is accompanied by the splitting off of groups in the N-1-position and to a lesser extent of groups in the C-5-position.

[8] In most cases the stable isomers are formed as a result of condensation reactions in an alkaline medium and are subsequently isomerized in alcohol solutions under the action of hydrogen chloride [Hahn and Gilman, THIS JOURNAL, **47**, 2953 (1925)]. In the case of 14 condensation in an acid medium resulted in formation of the labile modification. While the latter was the only compound which was separated from the reaction mixture, the fact is significant that only very low percentage yields were obtained since equilibrium mixtures of any two isomers frequently form oils and are then extremely difficult to separate.



All three groups of curves have been plotted on the same coördinates but in order to facilitate their comparison by representing all on one plate, the curves grouped in Figs. 2 and 3 have been raised 1 and 2 spaces, respectively. The values given for log ε therefore apply only to the curves grouped in Fig. 1.

(a) Wheeler and Hoffman, *Am. Chem. J.*, **45**, 375 (1911). (b) Johnson and Nicolet, *ibid.*, **47**, 469 (1912). (c) Hahn and Renfrew, THIS JOURNAL, **47**, 149 (1925). (d) Hahn and Gilman, *ibid.*, **47**, 2959–60 (1925). (e) Hahn and Dyer, *ibid.*, **52**, 2497 (1930). (f) Renfrew and Johnson, *ibid.*, **51**, 1787 (1929).

In comparing the absorption curves of these three groups of hydantoin derivatives, the most pronounced difference is in the greater persistence of the long wave band in the case of the unsubstituted and N-3 substituted compounds (Fig. 1). This fact together with the higher intensity of the maximum of this band serves to differentiate compounds of this type from the N-1 or N-1-N-3 derivatives where the corresponding band is more shallow and the extinction coefficient of the maximum is distinctly lower. In the case of the stable isomers of the latter type (Fig. 2) the absorption curves start at very nearly the same frequency as that observed for the N-3-substituted derivatives but, in general, the maximum of the first band is shifted slightly toward the ultraviolet in the N-1 and N-1-N-3 compounds. The position of the second maximum remains practically unchanged for all three groups of compounds. The absorption curves of the labile isomers (Fig. 3) are very

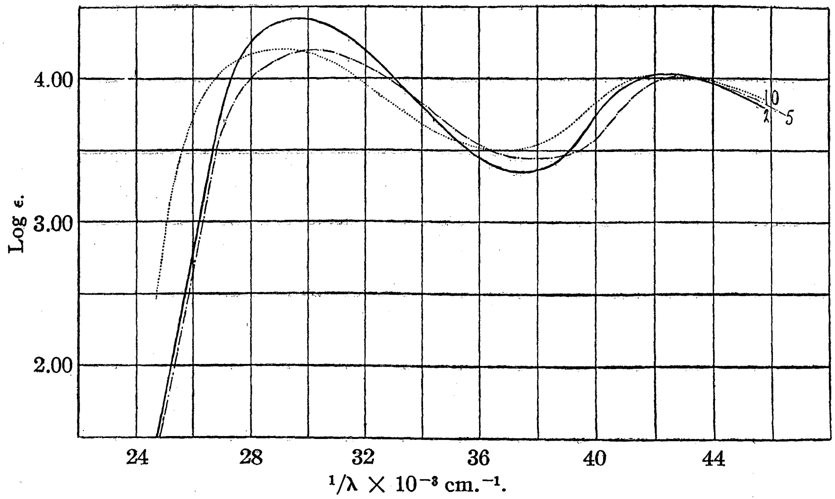

Fig. 4.—A closer comparison of: 2, N-3-methyl-5-anisalhydantoin, Fig. 1; 5, N-1-N-3-dimethyl-5-anisalhydantoin, Fig. 2; and 10, isomer of 5, Fig. 3.

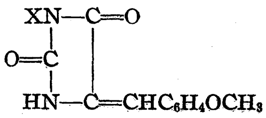
similar to those of the corresponding stable modifications throughout their entire course but are shifted slightly toward the visible. These differences are so well defined that it is possible to identify a given isomer as a stable or a labile modification by means of its absorption curve. The same general relationships hold for the corresponding derivatives of benzalhydantoin  $\begin{array}{l}\mathrm{HN{-}CO} \\ \mathrm{OC} \\ \mathrm{HN{-}C{=}CHC_6H_5}\end{array}$ although the absorption curves of all of these compounds are shifted slightly in the direction of the ultraviolet.[9]

With the single exception of anisalhydantoin-N-1-acetic acid,[10] the compounds referred to in this paper were prepared in this Laboratory[11] and all were carefully recrystallized before using. The determinations of the absorption coefficients were carried out in alcohol solution by the Henri method using a Hilger quartz spectrograph (E 2), the procedure being essentially the same as that described by Hahn and Dyer.[12]

Since differences in absorption are commonly conceded to correspond to differences in molecular configuration and since the absorption of anisalhydantoin and its N-3-substitution products as a group is distinctly different from the absorption of the N-1- and N-1-N-3 derivatives, it seems probable that the two groups possess certain structural differences which are not fully indicated by the commonly accepted general formulas

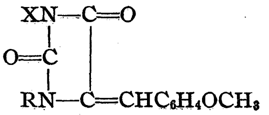
(a)



$\begin{array}{l}\mathrm{XN{-}C{=}O} \\ \mathrm{O{=}C} \\ \mathrm{HN{-}C{=}CHC_6H_4OCH_3}\end{array}$

and

(b)



$\begin{array}{l}\mathrm{XN{-}C{=}O} \\ \mathrm{O{=}C} \\ \mathrm{RN{-}C{=}CHC_6H_4OCH_3}\end{array}$

where X denotes *either* H[13] or R, and where R denotes a hydrocarbon residue. These differences may, however, be understood by assuming that *all* compounds belonging to the first group, *a*, exist chiefly in the form of their *enolic* modifications and therefore possess the molecular configuration

[9] Unpublished work except for Hahn and Evans, THIS JOURNAL, **50**, 809–10 (1928).

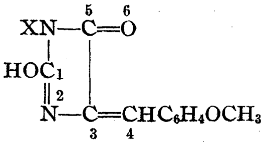
[10] Furnished through the courtesy of Renfrew and Johnson.[3] In this connection it may be noted the absorption curves of free acids are practically identical with those of the corresponding methyl and ethyl esters. For examples see Hahn and Dyer, *ibid.*, **52**, 2507 (1930).

[11] References to the methods used in the preparation of all of these substances together with their respective properties will be found in the footnotes accompanying each figure.

[12] Hahn and Dyer, THIS JOURNAL, **52**, 2511 (1930). It may be noted that the work of Hahn and Dyer was repeated for purposes of comparison and also in order to follow the absorption far enough into the ultraviolet to show the existence of the second absorption band. Eastman No. 40 and Ultraviolet Sensitive Plates were used, and a copper–silver spark. Each curve is based on at least 100 experimental points but these individual points have not been shown on the curves since they are so closely spaced as to give practically a continuous line. A relatively large number of compounds were investigated but the absorption curves of only 14 are represented. These are differentiated by numerals on the charts and in the text.

[13] Although anisalhydantoin-N-1-acetic acid, 14, was the only substance examined which contained a free hydrogen atom in the N-3-position, the fact appears to be highly significant that its spectrum is essentially the same as in cases where the hydrogen in this position has been replaced by a variety of different substituents. This would seem to indicate that the characteristic spectrum of all of these compounds is determined by the presence of a substituent in the N-1-position.

(a^1)



Molecules possessing such a configuration contain a so-called crossed conjugate system of double bonds (1-2-3-4 and 4-3-5-6) and might therefore be expected to show a selective absorption different from that of molecules containing a single conjugate system associated, as in *b*, with an isolated carbonyl group.

Summary

The absorption curves[14] together with other physical and chemical properties of anisalhydantoin and its N-3-substitution products as compared with N-1- or N-1-N-3- derivatives, serve to differentiate these substances into two separate and distinct groups. The suggestion is made that the differences between these groups may be due to corresponding differences in configuration.

A Study of the Magneto-optic Method of Analysis

BY DONALD C. BOND

The magneto-optic method of analysis was proposed by Allison and Murphy in 1930[1] and since that time it has been used by a number of investigators, apparently with success.[2] However, there has been considerable controversy concerning the merits of the method, since many workers have been unable to duplicate the results of Allison and his co-workers. In view of the controversial status of the method, the present work was undertaken in an effort to clarify the situation.

Considerable time was spent by the author in studying the magneto-optic apparatus in use in the laboratory of Dr. T. R. Ball at Washington University, under the direction of Mr. R. E. Wingard. This equipment, which had been copied from that of Allison, was duplicated in as great detail as possible. Since it has been described elsewhere,[2] the apparatus will not be discussed further here.

After certain adjustments had been made, it was found that the Allison effect could be observed. Readings were made in the following manner. Two workers alternately observed and recorded scale readings. Every precaution was taken to prevent psychological factors from causing one scale reading to occur more frequently than another. Although it was found that the observer could seldom return to the initial scale reading or move any desired distance on the scale, even when consciously attempting to do so, nevertheless, the recorder, before each observation, moved the trolley back and forth in order to confuse the observer, finally leaving it at some random setting.

In some cases the observer desired to comment on a given reading. Thus, he might have said that it was questionable, in which case it was given a weight of one-half that of an ordinary reading. Likewise, he might have been so confident about a reading that he would want to give it a weight of two. In any case, such comments were always made *before* the scale light had been turned on and the trolley position read.

According to Allison, the "minima" for cupric chloride are found at 20.48, 20.56 and 20.68 on the scale. In Graph I (heavy line) are shown readings which were taken in the course of some work with cupric chloride solutions. All of the readings taken over a period of two months with solutions of concentration 3×10^{-12} g. of copper per cc., or greater, have been included, without any omissions. Readings taken at smaller concentrations have not been plotted because it is believed that the "minima" for cupric chloride are not present at these concentrations.

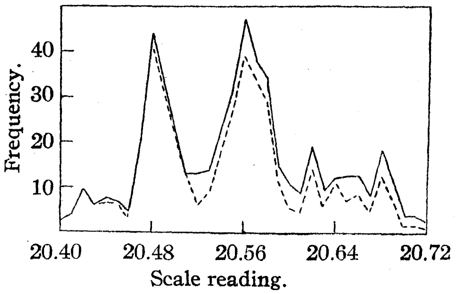
Included in this graph are several sets of readings which are known to be unreliable because it was noticed before they were taken that the line voltage was fluctuating or that the observer's eyes were tired. Although it seems that there is sufficient reason for discarding these sets, this has not been done because it might be objected that one had retained only the data which indicated the existence of an effect. Since there is

---

[1] Allison and Murphy, THIS JOURNAL, **52**, 3796 (1930).

[2] A complete review of the work which has been done with the magneto-optic apparatus is given by Cooper and Ball, *J. Chem. Ed.*, **13**, 210 (1936).

reasonable doubt about these readings, however, they have been omitted in the dotted line in Graph I for the sake of comparison.



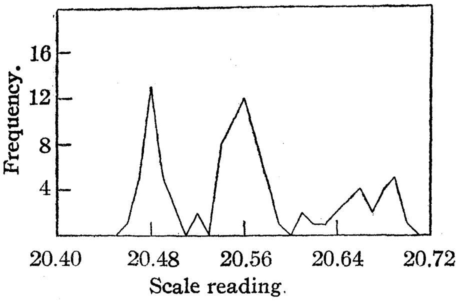
Graph I.—$CuCl_2$ "minima."

In Graph II are shown readings which were obtained with solutions of cupric chloride containing 10^{-9} g. of copper per cc. Here again all of the readings obtained with a given solution have been plotted. This graph illustrates the type of results possible with solutions whose concentrations are not near the "threshold" concentration, (these readings are included in Graph I).

The scale readings of the "minima" were found to change when the distance between the cells was changed, as reported by Allison, so that the effects observed could hardly have been caused by imperfections in the trolley system or other mechanical defects.

The magneto-optic method of analysis was applied with some degree of success to the determination of the amount of copper in a sample of phosphorescent zinc sulfide which had been prepared in these laboratories. The procedure which was used was that employed at Washington University. That is, for each solution investigated each observer moved the trolley back and forth across the position of the cupric chloride "minima" and decided whether or not the "minima" were to be seen and then the two observers compared notes. In addition, for the smaller concentrations, even in those cases in which it was thought that no "minima" could be seen definitely the scale readings of any fleeting effects observed were taken and frequency curves were plotted in the hope that these would reveal "minima" which were difficult to detect.

A number of tests were made with pure water and unknowns were run and at the time the work was done we were convinced that we could tell whether or not the "minima" were present with a given solution. In retrospect, however, it appears that there may be some doubt as to whether or not all of the insidious psychological effects possible were eliminated. While our results indicate that each Allison "minimum" is due to the presence of a certain compound, disappearing when the concentration is reduced to a very small value, we are not yet ready to say that this has been shown conclusively.



Graph II.—$CuCl_2$ "minima," 10^{-9} g. Cu per cc.

A word of apology would perhaps not be out of place here. Every paper which has appeared up to now in which the magneto-optic method has been criticized has concerned itself chiefly with the question of the reality of the "minima" observed with the apparatus. For that reason we have concentrated our efforts upon the question of the existence of the "minima," neglecting for the time a thorough investigation of the more difficult question of whether or not the "minima" disappear when the solution is diluted.

It would be difficult to say how well our observations and results compare in reliability with those of others who have worked with the Allison apparatus. Some idea of this may be obtained, however, by comparing Graphs I and II with similar graphs obtained by Ball and Crane.[3]

Miscellaneous Experiments.—A number of experiments were performed in an effort to throw some light on the behavior of the Allison apparatus and the nature of the phenomenon involved in the magneto-optic method.

A cathode-ray oscillograph was used to study the spark discharge. It was found that for each cycle of the 60-cycle a. c. supply from one to ten discharges occurred, depending upon the capacitance, voltage and gap width used. This is in agreement with the results which Cooper and Ball[2] obtained by another method. Any slight irregularity in the spark discharge is easily detected in the oscillograph, so that it is possible to obtain a much steadier discharge than by the ordinary methods. For this reason it is hoped that the oscillograph will prove a valuable accessory in the adjustment of the Allison apparatus.

A number of photographs of the magnesium spark spectrum were taken, using the color filters employed in the Allison apparatus. It was found that two lines appear, of

---

(3) Ball and Crane, THIS JOURNAL, **55**, 4860 (1933).

about equal intensity. They are: a doublet having a wave length of 4481 Å. and a triplet whose average wave length is about 3830 Å. This result contradicts that of Cooper and Ball,[2] who found that only the 4481 Å. line passed through the filters.

The "Landolt fringe"[4] was found to be present in the Allison apparatus. Probably it is to be observed in any similar apparatus, although it has not been noticed by other workers, so far as can be learned.

When a cell filled with carbon disulfide is placed in one of the solenoids in the Allison apparatus and the solenoid is disconnected, the light from the spark can be completely extinguished by rotating the analyzer to the proper position. However, if the solenoid is connected in the condenser circuit so that the pulse from the spark passes through it, there is no setting of the analyzer for which the light is completely extinguished. That is, for the position of the analyzer which gives the most complete extinction possible, there is still a definite and unmistakable amount of light to be seen. Although this effect is no doubt to be observed in any Allison apparatus, so far as can be learned it has never been mentioned and there has been no speculation as to its cause.

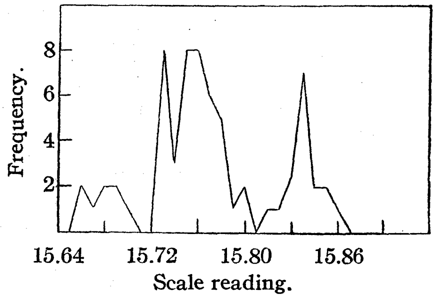
This effect may be explained as follows. The passage of the electric pulse through the solenoid around the carbon disulfide cell causes a Faraday rotation of the plane of polarization of the light passing through the cell. However, the amount and direction of this rotation vary with the time, so that there is no setting of the analyzer for which the light is completely extinguished at every instant. Since the eye integrates the illumination received by it, the net effect is that light is observed at all possible settings of the analyzer.

When a carbon disulfide cell is placed in each solenoid in the apparatus, the following may be observed. If the polarities of the solenoids are in the same direction, the effect described above is greatly increased, while if the polarities are opposed, it is possible to extinguish the light completely by rotating the analyzer to the proper angle. This is, of course, what is to be expected if the above explanation holds.

It will be shown later that there is reason for believing that the light which passes through a single carbon disulfide cell in the Allison apparatus is elliptically polarized. Tests for the presence of elliptically-polarized light were made with a quarter-wave plate, a Brace half-shade,[5] and a Bravais ellipticity half-shade,[6] but none gave any definite results. Since the double refraction expected would be at a maximum in certain quadrants of the cell, the ellipticity tests were repeated on light which passed through these quadrants, without any definite, positive results. It is not surprising that these tests failed, since the double refraction anticipated probably would be as difficult to detect as the Allison phenomenon itself.

Attempts to detect a heating effect in the carbon disulfide cell in the apparatus were unsuccessful. It was estimated that any rise in temperature due to the pulsating field present in the carbon disulfide is less than 0.001° per minute.

Observations were made with the polarity of one of the solenoids in the apparatus reversed and also with the analyzer rotated so that the Nicols were uncrossed. Definite evidence was found for the presence of effects which were located at the same trolley positions as those at which "minima" were ordinarily observed (Graph III). Although Allison, Christensen and Waldo[7] report that either maxima or minima of light intensity may be observed, according to the direction of the magnetic field and the position of the analyzer, we were unable to detect any difference between the appearances of the two phenomena. Considering the intangible character of the effect observed and the very great difficulty of even detecting it, one wonders whether it is possible for anyone to determine definitely whether it is an increase or a decrease in intensity.



Graph III.—HCl "minima," Nicols crossed, fields assisting.

Theoretical Discussion of the Allison Effect

Although the Allison effect was discovered almost ten years ago, the only explanation for it which has been advanced is the original hypothesis of Allison that it is caused by a differential time lag in the Faraday effect. Allison and his co-workers have performed a large number of experiments designed to test the theory of a Faraday time lag and their results support this hypothesis to a certain extent. However, there are several reasons why it is believed this theory is untenable.

In the first place, there is the fact that the results of Abraham and Lemoine[8] contradict this explanation. These results, obtained in a perfectly straightforward method, showed that any time lag in the Faraday effect for carbon disulfide must be less than 10^{-8} second. Allison has found time lags which are less than that of carbon disulfide by more than 10^{-8} seconds, indicating that the lag for carbon disulfide is greater than this.

In the second place, if the effect were due to a time lag in the Faraday rotation, it seems that it would be impossible to observe "minima" with the Nicols uncrossed, as they are actually ob-

(8) Abraham and Lemoine, *Compt. rend.*, **130**, 499 (1900).

served, for the following reason: the rotation which takes place, if any, when the position of a "minimum" is passed must be very small indeed, since the effect is so difficult to observe. Mr. Wingard[9] suspects that a rotation of the plane of polarization of about ten minutes may be detected when an Allison "minimum" is passed, although this has not been established definitely. Now if the analyzer were set ten minutes off the position of extinction, a rotation of ten minutes toward the position of extinction might possibly be detected, since one would be observing the difference between an intensity of $I_0 \cos^2 (90° - 10')$, or $I_0 \sin^2 10'$, and an intensity of zero. (I_0 equals the intensity of light with Nicols parallel.) However, in the case in which the Nicols were parallel, as one moved past the position of a "minimum," he would have to detect a difference between I_0 and $I_0 \cos^2 10'$; that is, a difference of $I_0 (1 - \cos^2 10')$. But $(1 - \cos^2 10')$ is equal to 4.1×10^{-6}, so that a change in relative intensity of about 4.1×10^{-4} per cent. would be expected and this could hardly be detected. The fact is, of course, that an effect is observed under these conditions.

On the other hand, it can be shown in a similar manner that if the Allison phenomenon were caused by a rotation large enough to produce a perceptible effect with the Nicols uncrossed, then the effect obtained with the Nicols crossed should be extremely easy to detect, whereas the fact is that it is very difficult to detect.

There is still another objection to the theory that the Allison effect is caused by a Faraday time lag. If the phenomenon were caused by such a lag in rotation, then for a certain angular setting of the analyzer, near the angle of extinction, it would be expected that no effect would be observed, while at angles to one side of this position "minima" should be observed and at angles on the other side of this position "maxima" should be seen. However, experimentally it has been found possible to observe effects, indistinguishable from one another, with the analyzer set at the angle of most complete extinction or at any position on either side of this angle, within certain limits.

It is possible that a rotation of the plane of polarization takes place in the Allison apparatus when the trolley is moved past the position of a "minimum." It is even possible that this rotation, if it does occur, which is doubtful, is caused by a lag in the Faraday effect, but it seems that such a rotation cannot explain the Allison phenomenon.

A possible explanation of the Allison effect will now be submitted which is based upon the following assumptions:

1. The rapidly changing magnetic field present in the solenoids in the Allison apparatus is accompanied by an electric field. The presence of this electric field in the liquid inside the solenoid causes the beam of plane-polarized light to become elliptically polarized, because of the Kerr electric double refraction effect.

2. Under the influence of the magnetic field the molecules of the liquid are, to a certain degree, distorted and oriented. Likewise, under the influence of the electric field the molecules undergo a distortion and an orientation which are, in general, not the same, in magnitude and direction, as the distortion and orientation caused by the magnetic field. It may be supposed that the time which is measured with the Allison apparatus is the time required for the molecules of the liquid to change from the configuration which they have when the magnetic field is at maximum to the configuration which they have when the electric field is at a maximum.

According to the theory of electro-magnetism, a changing magnetic field is always accompanied by an electric field. This fact is expressed mathematically by the vector equation[10]

$$\nabla \times \overline{E} = -\frac{\mu}{c}\dot{\overline{H}} \tag{1}$$

where $\overline{E}$ is the electric vector, μ is the magnetic permeability, c the velocity of light and $\dot{\overline{H}}$ the time rate of change of the magnetic vector. In cylindrical coördinates $\nabla \times \overline{E}$ may be written[11]

$$\begin{aligned} \nabla \times \overline{E} = \frac{\bar{\rho}}{\rho}\left[\frac{\partial E_z}{\partial \theta} - \frac{\partial(\rho E_\theta)}{\partial z}\right] \\ + \bar{\theta}\left[\frac{\partial E_\rho}{\partial z} - \frac{\partial E_z}{\partial \rho}\right] \\ + \frac{1}{\rho}\bar{z}\left[\frac{\partial(PE_\theta)}{\partial \rho} - \frac{\partial E_\rho}{\partial \theta}\right] \end{aligned} \tag{2}$$

where $\bar{\rho}$, $\bar{\theta}$ and $\bar{z}$ are unit vectors along the ρ, θ and z axes, respectively, and E_ρ, E_θ and E_z are the components of the electric intensity, $\overline{E}$, along the ρ, θ and z axes, respectively.

In the Allison apparatus let the z-vector be

(11) Max Mason and Warren Weaver, "Electromagnetic Field," University of Chicago Press, Chicago, 1929, pp. 118 and 366.

along the axis of the solenoid and let the ρ and θ vectors lie in a plane perpendicular to the axis. From reasons of symmetry, the electric field cannot be a function of θ or of z, so

$$\frac{\partial E_z}{\partial \theta} = \frac{\partial(\rho E_\theta)}{\partial z} = \frac{\partial E_\rho}{\partial z} = \frac{\partial E_\rho}{\partial \theta} = 0 \qquad (3)$$

Equation (2) then reduces to

$$\nabla \times \overline{E} = -\bar{\theta}\frac{\partial E_z}{\partial \rho} + \bar{z}\left[\frac{\partial(\rho E_\theta)}{\partial \rho}\right] \qquad (4)$$

Combining with (1), we obtain

$$\nabla \times \overline{E} = -\bar{\theta}\frac{\partial E_z}{\partial \rho} + \frac{\bar{z}}{\rho}\left[\frac{\partial(\rho E_\theta)}{\partial \rho}\right] = -\frac{\mu}{c}\dot{H} \qquad (5)$$

Now $\overline{H}$ is along the z-axis and has no component along the θ-direction, so, therefore, $\frac{\partial E_z}{\partial \rho}$ equals zero and we have the result

$$\frac{1}{\rho}\frac{\partial(\rho E_\theta)}{\partial \rho} = -\frac{\mu}{c}\left|\dot{\overline{H}}\right| \qquad (6)$$

This equation shows that there is a component of the electric vector along the θ-direction, that is, perpendicular to the radius line at any point, and that the magnitude of this component depends upon ρ and the rate of change of the magnetic field. In addition, of course, it may be a function of the time. Furthermore, it is obvious from reasons of symmetry that there can be no component of the electric vector along the ρ or the z direction.

It is reasonable to assume that this tangential electric field causes a Kerr electric double refraction to take place. That is, the liquid in the solenoid acts like a peculiar kind of doubly-refracting crystal in which the optic axis is at all points perpendicular to the radius line. This is illustrated in Fig. 1, where the circle represents the cross section of the cell and the arrows represent the optic axis at various points. Regardless of the question of whether there is an Allison effect, or, if so, what its cause may be, it seems that the double refraction described above should occur in the Allison apparatus.

According to assumption number two made above, the Allison effect is a measure of the time required for the molecules of the liquid to change from the configuration which they have in a magnetic field to that which they have in an electric field. Let this time be t_{CS_2} and t_{HCl} for carbon disulfide and hydrogen chloride, respectively. Further, let the time required for the light to pass from the carbon disulfide to the hydrogen chloride cell be t_0. Then suppose that at zero time one half of one of the divided pulses reaches the solenoid around the carbon disulfide, so that at a time, t_{CS_2}, a Kerr double refraction takes place in the carbon disulfide. This would cause a certain amount of light to pass the crossed Nicols. Suppose that the wire path lengths are such that the other half of the same pulse reaches the hydrogen chloride cell at a time, $t_0 + (t_{\mathrm{HCl}} - t_{\mathrm{CS}_2})$. Then the Kerr double refraction in the hydrogen chloride would act on the same light which was elliptically polarized in the carbon disulfide by the other half of the pulse.

If the magnetic fields were assisting and the Nicols crossed, this would cause an increase in the light intensity, since the double refraction would be increased, so that maxima should be observed at this scale reading. If the magnetic fields were opposing, the effect would be the same, for the direction of the optic axis in the doubly-refracting liquid would be unchanged. Further, these same results should be obtained whether the analyzing Nicols were set at extinction or on either side of the angle of extinction.

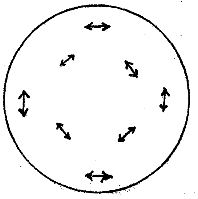

Fig. 1.

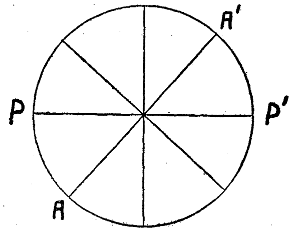

Fig. 2.

If the Nicols were parallel, or approximately so, an increase in double refraction would decrease the intensity of the light passing the analyzer. It is easily seen that in this case minima of light intensity should be observed with the magnetic fields either opposed or in the same direction, for in either case the double refraction of the hydrogen chloride would reinforce that of the carbon disulfide.

Now the effect of the double refraction would be zero in those parts of the field of vision for which the axis of the polarizer was either parallel or perpendicular to the optic axis in the carbon disulfide cell. Likewise, no elliptically polarized light would be produced in those parts of the field for which the axis of the analyzer was either parallel or perpendicular to the optic axis in the carbon disulfide. Thus, if the axis of the analyzer made an angle of 45° with that of the polarizer, the conditions would be represented by Fig. 2, where the circle is the field of view, and PP′ and AA′ are the optical axes of the polarizer and analyzer, respectively. The areas between the lines represent areas in which elliptically polarized light would be expected. It is obvious that under such conditions the double refraction would have its smallest value and it might be so small that it could not be observed. This is in agreement with the fact,[12] which is inexplicable according to the hypothesis of a Faraday lag, that the "minima" have been observed to disappear when the analyzing Nicol is rotated from the position for which it is parallel to the polarizer.

Allison, Christensen and Waldo[7] have described some experiments with the magneto-optic apparatus in which solutions possessing zero magnetic rotation were used. According to their interpretation the results indicated the presence of a Faraday time lag, but it is obvious that they may also be explained by assuming that double refraction takes place in the Allison apparatus.

Acknowledgment.—This work was suggested by Dr. Herman Schlundt and was carried out under his direction. His intense interest in the problem and his many years of careful investigation have been a continual source of inspiration.

The members of the Physics Department of the University of Missouri, particularly Dr. H. M. Reese, have constantly contributed advice, encouragement and criticism. The extent of their aid has been so great that it may be said that this is a joint production of the Physics Department and the Chemistry Department, although the Physics Department reserves judgment as to the reality of the Allison effect.

Sincere thanks are due to Mr. Perry L. Bidstrup for making many of the observations and aiding in the performance of some of the experiments.

The author also wishes to thank Dr. T. R. Ball and R. E. Wingard of the Chemistry Department of Washington University for extending the use of their laboratory and for giving so freely of their valuable information and advice.

Summary

Definite evidence has been presented for the existence of an objective effect in the Allison apparatus. Results have been obtained which indicate that this effect is caused by the presence of a particular compound, vanishing when the concentration of the compound is reduced to a very small value. However, the latter has not been proved conclusively.

Certain experiments have been described which give some information about the properties of the magneto-optic apparatus.

A partial theoretical explanation for the Allison effect has been presented.

Atomic Radii from Parachor Data and from Electron Diffraction Data

By N. S. Bayliss

Introduction

Although the parachor[1] is the most nearly additive of all "additive" properties of liquids, it has always suffered from the lack of a clear physical interpretation. Sugden, the discoverer of the function, considers it to be a measure of molecular volume, but this interpretation has been disputed by others.[2] Attempts at a theoretical treatment[3] of the parachor have not succeeded in supplying an interpretation, and without a considerable advance in our knowledge of the theory of the liquid state, it would seem impossible to obtain one on purely theoretical grounds.

By making use of the available data on atomic and molecular dimensions, it is now possible to show that Sugden's original interpretation may be applied with marked success. It will be shown in this paper that by assuming that atomic parachor constants are a direct measure of atomic volumes, it is possible to calculate atomic radii that are in good agreement with the values obtained by the electron diffraction and X-ray methods.

For the present, the discussion will be confined to molecules whose structure is simple, and that contain only quadrivalent and univalent atoms.

Atomic Parachor Constants.—From the point of view of the present problem, it is unfortunate that the literature contains several sets of atomic parachor constants,[2b,4] which differ seriously, however, only in the values assigned to carbon and hydrogen. In any derivation of atomic parachors, the fundamental constant is that of CH_2, which is found from the observed parachors of members of various homologous series. Some of the previous authors seem to have committed the error of taking the arithmetic mean of $P(CH_2)$ differences over a homologous series, a procedure that automatically cancels all the measurements except those for the lowest and highest members of the series.

It was therefore thought advisable to recalculate the fundamental constants, and it will be seen that the resulting set agrees best with the set proposed by Mumford and Phillips.[4] The linear expression $P(C_nH_{2n+2}) = nP(CH_2) + 2P(H)$ was fitted by least squares to the data on the n-paraffins,[5] with the result that $P(CH_2) = 39.92 \pm 0.04$, $P(H) = 15.4 \pm 0.1$, $P(C) = 9.1 \pm 0.2$. The other fundamental parachors that were necessary for the purpose of this paper were those of the halogens, which were calculated from the data on the n-alkyl halides[6] by the relation $P(X) = P(C_nH_{2n+1}X) - nP(CH_2) - P(H)$. The recalculated atomic constants are compared with previously recorded values in Table I, where it is seen that the only significant differences are in the values for carbon and hydrogen.

Atomic Dimensions of Quadrivalent Atoms.—The closeness of approach of two atoms is governed by their bond radii (denoted hereafter by r) if they are chemically bound, and by the vaguer "packing" radii (r') if they are not. The comparison of atomic parachors with atomic volumes will begin with the case of quadrivalent atoms that occupy the central position in a tetrahedral molecule. Such atoms touch only those atoms to which they are chemically bound, and since the space that they occupy is determined by their bond radii only, it will be assumed that their volume is that of a sphere whose radius is r. Adopting the well established value of $r = 0.77$ Å. for the carbon atom,[7] and assuming that the atomic parachor of carbon is a measure of its atomic volume, one obtains the relation that *one parachor unit* = 0.210 Å.[3] This relation may then be used to calculate the bond radii of other quadrivalent atoms whose atomic parachors are known, the result being shown in Table II, which includes the Pauling and Huggins[7] bond radii for comparison. The atomic parachors of the elements in question have been recalculated to conform with Table I; but the differences from the Sugden values are insignificant, except in the case of carbon.

TABLE II

The agreement between the two sets of bond radii is good, but becomes better when some individual cases are considered in detail. It has been shown recently that in the chlorides and fluorides of certain quadrivalent atoms, the observed bond distances are less than those calculated from the Pauling and Huggins bond radii,[8] whereas the corresponding tetraalkyl compounds have been found to behave normally.[9] This behavior is reflected in the parachors, since the atomic parachors of silicon, germanium and tin are lower in their tetra-

halides than in their tetraethyls. Bond radii calculated for these elements from the parachors of their tetrachlorides and their tetraethyls are given in Table III, and are compared with the bond radii obtained from similar compounds by the electron diffraction method.[8,9] A simplification has been made in making the central atom of the tetrahedral molecule wholly responsible for the changes in both the parachor and the bond distance. The case of lead has also been included in Table III, since the bond radius calculated from the parachor is in better agreement with the value observed in lead tetramethyl[9] than with the Pauling and Huggins radius.

[a] Values obtained from tetramethyls.

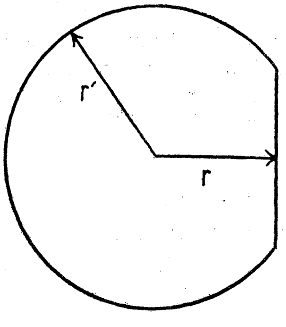

Fig. 1.—Atomic radii from parachor data and from electron diffraction data.

Atomic Dimensions of Univalent Atoms.—The volume of a univalent atom is determined largely by its packing radius, which is less easily defined than its bond radius. This case may be treated by adopting the rather naïve atomic model of a segment of a sphere (see Fig. 1) of radius r', and with the plane surface at a distance r from the center. Values of r and r' cannot both be derived from parachor data alone; but by using the relation *one parachor unit* = 0.210 Å.,[3] and by assuming the Pauling and Huggins values of r, it is possible to determine values of the packing radii of hydrogen and the halogens from their atomic parachors, as shown in Table IV. The value 1.03 Å. for hydrogen is in good agreement with those of 1.1 and 1.0 Å. quoted by Stuart,[10] and with that of 1.07 Å. observed by Pauling and Carpenter.[11] The values of the packing radii calculated for fluorine and chlorine may be compared with the following experimental values obtained by the electron diffraction method:[12] $^1/_2$(F–F) in carbon tetrafluoride = 1.12 Å., $^1/_2$(Cl–Cl) in carbon tetrachloride = 1.44 Å. and in chloroform = 1.47 Å. The results of Dornte[13] give values rather greater than the calculated packing radii of bromine and iodine, the experimental results being: $^1/_2$(Br–Br) in bromoform = 1.73 Å. and in methylene dibromide = 1.81 Å., $^1/_2$(I–I) in methylene diiodide = 2.03 Å. There is some evidence, however, that the values of Dornte are high, since Brockway and Jenkins[9] find the bond distance C–Br = 1.91 Å., which, assuming the tetrahedral angle, gives $^1/_2$(Br–Br) = 1.56 Å., and the Pauling and Huggins radii predict that C–I = 2.10 Å., which gives $^1/_2$(I–I) = 1.71 Å., in good agreement with the values in Table IV.

TABLE IV

Atom	H	F	Cl	Br	I
Packing radius, Å.	1.03	1.16	1.44	1.54	1.67

Conclusion

Although the approach to the subject has been empirical, the examples quoted above provide strong evidence that atomic parachors must be interpreted as atomic volumes. Divalent and trivalent atoms have not been included in the discussion, because of the lack of packing radius data with which to compare the atomic parachors. It is probable that many of the anomalies encountered in the study of the parachor could be explained on the basis of the above interpretation; Parachor anomalies *must* be expected in cases where there is a tendency to ionic binding or resonance, since both phenomena are accompanied by changes in molecular dimensions. It is in just such cases, unfortunately, that attempts have been made to use the parachor to determine the structure. Parachor increments due to such features as double and triple bonds find at least a qualitative explanation in the suggestion of Noyes and Singh[14] that the shorter distance between such atoms is more than compensated by their greater packing radius.

Summary

1. Revised atomic parachor constants have been calculated from existing parachor data.

2. On the assumption that atomic parachors

The Specific Heats of Aqueous Sucrose Solutions at 20 and 25° and the Apparent Molal Heat Capacity of Non-electrolytes[1]

BY FRANK T. GUCKER, JR., AND FRED D. AYRES

Introduction

The specific heats of aqueous solutions of electrolytes have been studied recently by a number of investigators. The behavior of such solutions is summarized conveniently in terms of the apparent molal heat capacity. Randall and Rossini[2] first showed that over a wide range the apparent molal heat capacity is a linear function of the square root of the concentration and that the slopes of the curves increase with the valence type of the electrolyte, in qualitative agreement with the Debye–Hückel limiting law. The extrapolated value of the apparent molal heat capacity at infinite dilution is usually negative for strong electrolytes, and increasingly more negative for electrolytes of higher valence type.[3]

The apparent molal heat capacity of non-electrolytes is usually assumed to be a constant independent of concentration and nearly equal to the heat capacity of the pure solute in the liquid state. The present investigation is the beginning of a systematic study of the thermochemistry of non-electrolytic aqueous solutions, undertaken to find out how ideal these solutions are and what light they may throw on the general properties of solutions. Sucrose was chosen as the first solute because it could be obtained pure and because other thermodynamic properties of its solutions already had been investigated carefully.

Preparation of the Sucrose Solutions.—The sucrose used in these experiments was the best material obtainable, purified by the Bureau of Standards as a standard for polarimetry[4] and supplied to us through the courtesy of Dr. F. D. Rossini and Dr. F. J. Bates. Following the procedure recommended by the Bureau of Standards, the sucrose was pulverized in an agate mortar and dried for four hours at 65–70° in a vacuum of about 0.01 mm. This procedure is found to reduce the moisture content to less than 0.01%. The solutions were made up determinate, with distilled water freshly boiled to remove air. In the concentrated solutions, the sucrose and water were weighed successively into the same flask in which the solution was made up. In the dilute solutions, the smaller amounts of sucrose were determined with sufficient accuracy by weighing from a weighing bottle. All weights were reduced to the vacuum basis. In order to conserve material, the most concentrated solution (Expt. 4, Table I) was diluted quantitatively in two successive steps (Expts. $4a_1$, $4a_2$) while solution 3 was divided into two portions, each of which was diluted quantitatively to form solutions 3a and 3b.

Experimental Results.—The specific heats were determined by means of the differential twin calorimeter apparatus previously described.[5] Each value represents the average of at least two experiments with heating ratios on either side of the exact balancing ratio. The dilute sucrose solutions were handled as easily as the salt solutions, and their specific heats are probably accurate to ±0.01% as in our previous work. The great viscosity of the concentrated solutions introduced two complications which seem unavoidable in any calorimetric apparatus. First, the heat of stirring was increased enormously (amounting to about 0.001° per minute in the 5.8 m solution). This large temperature trend increased the uncertainty in determining the balancing resistance ratio to about 0.02% error in the specific heat. A second effect of the high viscosity of the solution was a lag in the distribution of heat from the coil in the working calorimeter. Heat may be lost from the working calorimeter by increased conduction up the heater lead wires, if the temperature of the heater in this calorimeter is greater than that in the tare. On the other hand, heat may be gained by the working calorimeter, because the temperature of the rest of its surface is lower than that of the tare. Fortunately these errors tend to

cancel each other, but we have no method of measuring or calculating the resultant systematic error.

The experimental results are collected in Table I, from which no experiments are omitted. The specific heat of the 0.1 *m* solution (Expt. 6) was not determined at 25° because one of the heaters was burned out after the experiment at 20°. The experiments are numbered chronologically. Each number refers to a solution made up from weighed quantities of sucrose and water, while the letters and subscripts refer to those made by quantitative dilution in the manner already described. We have listed the weight % and molality, *m* (moles of sucrose per 1000 g. of water) taking the molecular weight of sucrose as $M_2 = 342.18$. The molarity *c* (moles of sucrose per liter of solution) at 20° was calculated with the aid of the accurate density data of the "International Critical Tables."[6] The specific heat, *s*, is relative to water at the temperature of the experiment. The values of the apparent molal heat capacity, $\Phi(C_{p2})$, calculated by means of the usual equation

$$\Phi(C_{p2}) = \left[\frac{1000}{m} + M_2\right] s - \frac{1000}{m}$$

are also expressed in calories at the temperature of the experiment. The calculated values of Φ were obtained from equations which will be described subsequently. Δ*s* is the difference, in 0.01%, between the observed values of *s* and those corresponding to the calculated values of Φ.

These results show that the apparent molal heat capacity of sucrose is not constant, but changes appreciably with concentration, although the change from 0 to 1 *m* is only about a third as great as in the case of hydrochloric acid, which has the least change of any uni-univalent electrolyte. A plot of the apparent molal heat capacity against $c^{1/2}$ shows, however, no linear relationship over any appreciable concentration range, such as that which characterizes electrolytic solutions. Instead, the apparent molal heat capacity is much more nearly a linear function of the *first* power of the concentration, although appreciable curvature appears above 1.6 molar. Figure 1 is a plot of all the values of Φ at 20°, above a concentration of 0.1 molar, comparing the two abscissas. The values at 25° are similar.

These results are almost exactly like those which Redlich and Klinger[7] found when they calculated

(7) Redlich and Klinger, *Sitzb. Akad. Wiss. Wien.*, Abt. IIb, **143**, 489 (1934); *Monatsh.*, **65**, 137 (1934).

the apparent molal volume of this same solute. Using the best density data available, they showed that the apparent molal volume is much more nearly a linear function of the first power than of the square root of the concentration, but that there is a slight concavity upward such as we find for the apparent molal heat capacity. If this functional relationship is general, it would show a clear-cut difference between the behavior of electrolytes and of non-electrolytes in solution. Very little attention has been devoted to the theory of non-electrolytic solutes, but recently Fuoss[8] has published a brief article in which he derives certain thermodynamic properties of solute molecules which may be regarded as spheres with point dipoles at the center. He finds that, in very dilute solutions, the partial molal heat capacity of such a solute should be a linear function of the first power of the concentration.

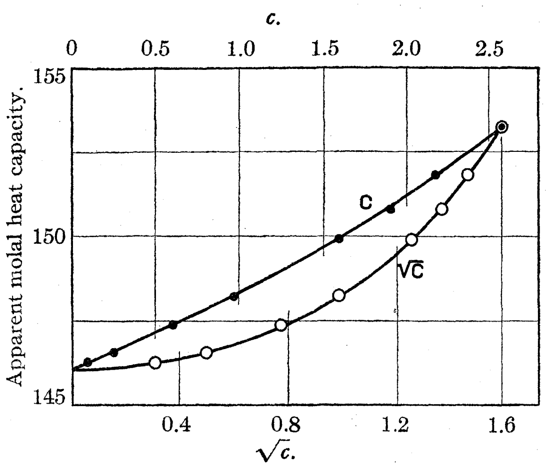

Fig. 1.—A comparison of square root and first power of concentration.

In order to obtain a convenient analytical expression for apparent molal heat capacity, which could be used to calculate values of the specific heat and partial molal heat capacities at various concentrations, we investigated plots of Φ against the molality, m, and also against ($1000\ N_2/M_1$) where M_1 is the molecular weight of the solvent and N_2 is the mole fraction of solute. N_2 is multiplied by the factor ($1000/M_1$) in order to make it equal to m in the dilute range and comparable at all concentrations. Figure 2, from which the results at concentrations below 0.1 m have been omitted to avoid confusion, shows that there is little difference between kN_2 and m, although the molarity, c, differs greatly from them both. The plot against m exhibits a curvature opposite to that against c, and about 50% greater.[9] Since the molality is a more convenient abscissa than the molarity, we employed it in subsequent calculations. A power series of the type

$$\Phi = \Phi^\circ + am + bm^2 \qquad (1)$$

proved adequate to reproduce the data over the whole range of concentration. We evaluated the coefficients by the method of least squares. Since the same error in the heat capacity makes a large change in the apparent molal heat capacity in dilute solutions and only a small change in concentrated ones, we weighted the values of Φ suitably in carrying out the calculations. The results were

$$(20^\circ) \quad \Phi = 145.87 + 1.950m - 0.1182m^2$$
$$(25^\circ) \quad \Phi = 151.20 + 1.325m - 0.0704m^2$$

From these equations we obtained the calculated values of Φ which are compared with the observed in Table I. As this tabulation shows, the agreement is quite satisfactory, with an average deviation in the specific heat of ±0.006% and a maximum deviation of 0.016%.

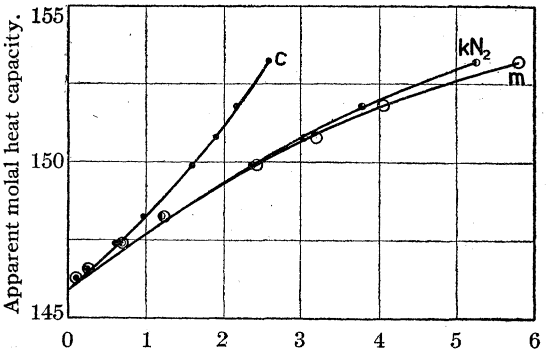

Fig. 2.—A comparison of volume and weight concentration (abscissas).

The partial molal heat capacities of solute and solvent may be calculated from equation (1) by means of the equations

$$\bar{C}_{p2} = \Phi^\circ + 2am + 3bm^2 \qquad (2)$$
$$\bar{C}^\circ_{p1} - \bar{C}_{p1} = 10^{-3}M_1(am^2 + 2bm^3) \qquad (3)$$

which are analogous to those derived by Randall and Rossini[2] when Φ is a linear function of $m^{1/2}$. For sucrose the equations are

---

[8] FUOSS, THIS JOURNAL, **58**, 982 (1936).

[9] The graph of Φ against $m^{1/2}$ was also plotted. It is like an elongated S. In the dilute region it shows a curvature about midway between that of the graphs against $c^{1/2}$ and c. It nearly coincides with the latter in solutions more concentrated than 1.5 molar, although it exhibits a slight concavity downward. This curve was omitted from Fig. 1 to avoid confusion.

$$\text{(at 20° in cal}_{20}\text{/deg.)}\begin{cases}\overline{C}_{p2} = 145.87 + 3.900m - 0.3546m^2\\ \overline{C}^{\circ}_{p1} - \overline{C}_{p1} = 0.018016\,(1.950m^2 - 0.2364m^3)\end{cases}$$

$$\text{(at 25° in cal}_{25}\text{/deg.)}\begin{cases}\overline{C}_{p2} = 151.20 + 2.650m - 0.2112m^2\\ \overline{C}^{\circ}_{p1} - \overline{C}_{p1} = 0.018016\,(1.325m^2 - 0.1408m^3)\end{cases}$$

In Fig. 3 we have plotted the values of the apparent and partial molal heat capacities of sucrose at 20 and 25°. The experimental values of Φ at 20° are designated by open circles; those at 25° by dots. The values at every point agree within the limits of 0.016% in the specific heat, as we mentioned above. In the very dilute region (below 0.04 *m*) seven of the eight points lie *below* their respective lines. Although the differences appear large on the graph, only two of them actually correspond to more than 0.01% difference in *s*, as Table I shows. We hesitate to attribute any particular significance to this trend, although we hope that a study of heats of dilution of very dilute solutions, now under way in this Laboratory, may settle this question unequivocally.

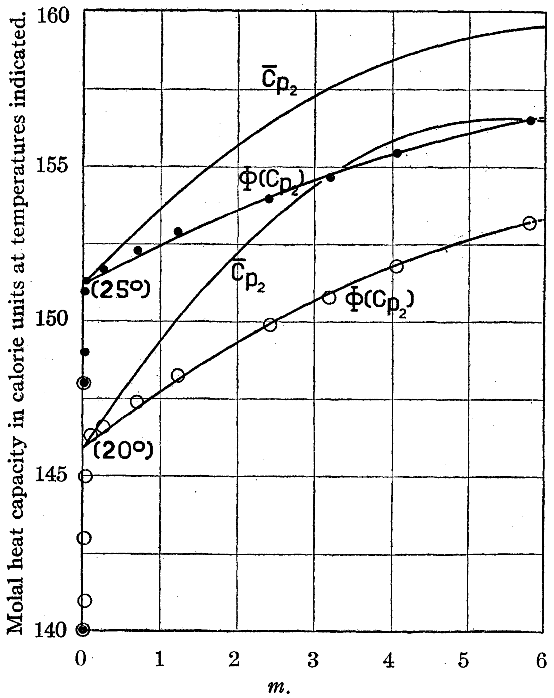

Fig. 3.—Apparent and partial molal heat capacities of sucrose at 20 and 25°.

In comparing the results at 20 and at 25°, the large change of the apparent molal heat capacity with temperature is a striking fact. The value of Φ° changes by 5.3 calorie units—over 1 unit per degree. This is much larger than the change[10] of a 1–1 electrolyte, which averages only about 0.3, and even a 2–1 electrolyte, which averages about 0.8. The initial slope of the curve is appreciably larger at 20 than at 25°. If the slope decreased at the same rate it would be 0 at about 40°—and at this temperature we might have a solute with a nearly constant apparent molal heat capacity, such as has usually been postulated for all orthodox non-electrolytes.

Comparison with Previous Results.—There are two recent series of measurements of the heat capacities of sucrose solutions. Frenzel, Burian and Haas[11] determined the heat capacities by measuring with a Beckmann thermometer the rise of temperature in the solution contained in a Dewar flask, in which a known amount of electrical energy was dissipated. They record in 15°-calories their results for solutions from 0.1 to 1 *m* at 16, 24, 32 and 39°. We have calculated the corresponding values at 20 and 25° by graphical interpolation and have converted them into 20- and 25°-calories by multiplying by the factors 1.0010 and 1.0017. These factors are obtained from Jaeger and von Steinwehr's[12] equation for the heat capacity of water at different temperatures, which Frenzel, Burian and Haas employed in their calculations. The results at 20° are given in column 3 of Table III, while the corresponding values calculated from our equation are given in the final column. Their values at 20° agree with ours to about ±0.06%, which is within their es-

timated uncertainty of ±0.1%. Their values at 25°, on the other hand, are all *higher* than ours, on an average about 0.3%. We have no explanation for this discrepancy.

Yanovski and Archangelski[13] measured the heat capacities of solutions at approximately even weight percentages up to 65%, and at temperatures of 20.6, 51.2 and 80.8°. We have made the slight changes necessary to interpolate their results to even weight percentages at 20°, and have changed them from 15- to 20°-calories and tabulated them in column 4 of Table III. These results differ from ours on an average by ±0.4%, which is slightly more than their estimated error of 0.2 or 0.3%. Their experiments were not precise enough to detect the change of the apparent molal heat capacity with concentration and they concluded it was constant at any temperature. However, they noted its linear increase with temperature from an average value of 148.2 at 20° to 185.9 at 80°. This change is in qualitative agreement with the change in $\Phi°$ from 20 to 25°, which we have observed. The change in the *average* value is smaller because the change of the apparent molal heat capacity with temperature is less at higher concentrations.

In the fifth column of Table III we have tabulated the values of the specific heats calculated from the heat capacities given in the "International Critical Tables."[14] These represent a weighted mean of the early results. They differ from our results by ±1.5%, and are *lower* for every concentration except the last.

Other Non-electrolytes.—Unfortunately we have not been able to find in the literature any values of the heat capacities of non-electrolytes which allow us to draw further conclusions as to the functional relationship between the apparent molal heat capacity and the concentration. Such data must be accurate and they must include a series of results extending over a wide concentration range and including dilute solutions. The recent excellent study of the heat capacities of solutions of urea and mannite, made by C. M. White,[15] unfortunately does not extend above 1 *m*. White finds that "The apparent molal heat capacities seem to follow a linear equation when plotted against the $\sqrt{m}$." However, even his results, precise to ±0.01%, are not adequate to decide unequivocally between the square root and first power of the concentration over so short a range, when the change with concentration is so small.

Among the older determinations there are several series of results for liquids miscible with water, covering the whole range of concentration. We have taken the specific heat values from the "International Critical Tables" and calculated the corresponding apparent molal heat capacities of the solutes. This may introduce some errors, depending upon the way the original data were smoothed in tabulation, but it does not affect our discussion. In this case, so as to minimize the confusion of intersecting curves, we have taken the mole per cent. as abscissa and have plotted as ordinate the difference between the apparent molal heat capacity of the solute and the molal heat capacity of the pure solute (C_{p_2}). The results are shown in Fig. 4, and several interesting conclusions can be drawn. In the first place, acetone alone shows an appreciable deviation in the very concentrated solution. Most of the others lie within 10 calorie units until the solution contains 70 or more mole % water. The large deviations occur beyond this dilution, in a region which is still, how-

ever, considered concentrated—8 or 10 molar. In contradiction to the behavior of all electrolytes and of sucrose, urea and mannite the apparent molal heat capacities of all these solutes except *n*-propyl alcohol *decrease* with increasing concentration. The highest value in the dilute region and the steepest slope occurs at low temperature. In other words, in almost every case when the temperature is raised, the solute shows a closer approximation to the behavior of an ideal non-electrolyte, where the apparent molal heat capacity is constant.

Acknowledgments.—It is a pleasure to express our thanks to Dr. Rossini and Dr. Bates of the Bureau of Standards for supplying us with the sucrose used in these experiments.

Summary

We have determined the specific heats of solutions of sucrose at 20 and 25° by means of a differential apparatus employing adjustable heaters.

The apparent molal heat capacity of sucrose is not constant, although it increases with concentration considerably less than a uni-univalent strong electrolyte. It is much more nearly a linear function of the first power than of the square root of the concentration. Its change with concentration decreases with rising temperature. Its limiting value at low concentration increases more rapidly with temperature than the same property of most electrolytes. The apparent molal heat capacity can be expressed satisfactorily as a second degree power series in the molality, and values of the apparent and partial molal heat capacities and the specific heats calculated by these equations are tabulated.

A review of other available specific heat data for non-electrolytes shows a general *decrease* of apparent molal heat capacity with concentration. with greater deviations at *low* temperatures.

The Reactivity of Zinc Amalgams

BY HERMAN A. LIEBHAFSKY

The stability of zinc amalgams, and perhaps of most amalgams, depends in a curious way upon their concentrations. The great inertness of the concentrated (say, 1%) amalgams has been observed by all investigators who have tried to make them react with hydrochloric acid: hydrogen evolution, even when fairly strong acid is employed, does not proceed rapidly with a cold amalgam although the reaction mixture is shaken; this inertness has usually been attributed, in part at least, to the overvoltage of these amalgams for hydrogen gas. On the other hand, dilute (say, 0.001%) amalgams become increasingly unstable as their concentrations decrease, so that the electromotive forces of cells containing these amalgams vary with time and cannot be measured accurately even when the amalgams are in contact with oxygen-free zinc salt solutions.[1] That these two sets of experimental facts constitute a paradox well worth investigating appears to have escaped previous notice.

Accordingly, exploratory experiments were undertaken and the following experimental method was adopted. (1) With oxidizing agents in aqueous solution, approximately 25 cc. of amalgam and 40 cc. of solution were shaken vigorously by hand at a constant rate (240 times a minute) in a 125-cc. separatory funnel. From time to time 3-cc. samples of amalgam were withdrawn into one side of a cell containing a similar portion of the original amalgam as reference electrode in the other. The electromotive force of this concentration cell was then measured, a 1 *M* zinc sulfate–0.05 *M* sulfuric acid solution serving as electrolyte. (The acid was added in order to prevent the formation of an oxidized film on the amalgam surface; concentrations as high as 0.1 *M* have been employed without sensibly disturbing the measurements except in the case of amalgams containing less than about 10^{-4} % zinc, which are so unstable anyhow that an accurate measurement is impossible.) Beyond stirring the amalgams several times during the measurements, which were made as rapidly as possible and without excluding air, no precautions were taken. The electromo-

---

[1] (a) Liebhafsky, THIS JOURNAL, **57**, 2657 (1935), recently has correlated and re-interpreted the accurate electromotive force data for zinc amalgams. See also (b) Crenshaw, *J. Phys. Chem.*, **14**, 158 (1910), and the other work cited in Ref. 1a.

tive forces were read to 0.1 mv. although this accuracy was not generally necessary. For reaction times shorter than five seconds, time was estimated from the number of times the separatory funnel was shaken. (These estimates obviously become less accurate as the reaction time decreases; perhaps the maximum inaccuracy approximates ±20%.) (2) For the experiments in Fig. 1 with oxygen as the oxidizing agent, the gas was bubbled at moderate rate through a column, initially 7 cm. high, of the amalgam contained in a test-tube; samples for the electromotive force measurements were withdrawn from its bottom by means of a pipet; the original amalgam again served as reference electrode. Under these experimental conditions the measured electromotive force shows the extent to which the amalgam being oxidized has lost zinc; and the rapidity with which the electromotive force increases with the time of reaction for an amalgam of given concentration measures the reactivity of that amalgam.

15	1.0	50	1.4	0.898	20[b]

[a] Exhaustion of the zinc made a higher rate impossible. [b] This high value is probably inaccurate; the least reliable rates are those calculated from the smallest electromotive forces. When 1% amalgam was shaken for 100 sec. with 1 *N* sodium hydroxide, the average rate in the above units was $6(10^{-4})$. [c] This rate is the decrease per second in the percentage of zinc in 25 cc. of amalgam, calculated independently for each "short interval," Δt.

Figure 1 shows some of the experimental results obtained with amalgams containing 1.0 and 0.001% zinc. (Because the ordinate scale for the 1% amalgams is the larger by tenfold, the difference in reactivities is correspondingly larger than the curves alone would appear to indicate.) The oxygen gas curves are not strictly comparable with the others because of the difference in experimental method, which has been mentioned above. The curves for the dilute amalgams terminate near 1100 mv., which (as Crenshaw[1b] has discovered previously) is the electromotive force of a cell like ours when the one half-cell contains pure mercury, the other a zinc amalgam of appreciable concentration. When the electromotive force has reached this value, therefore, the complete removal of zinc from the experimental amalgam has been accomplished.

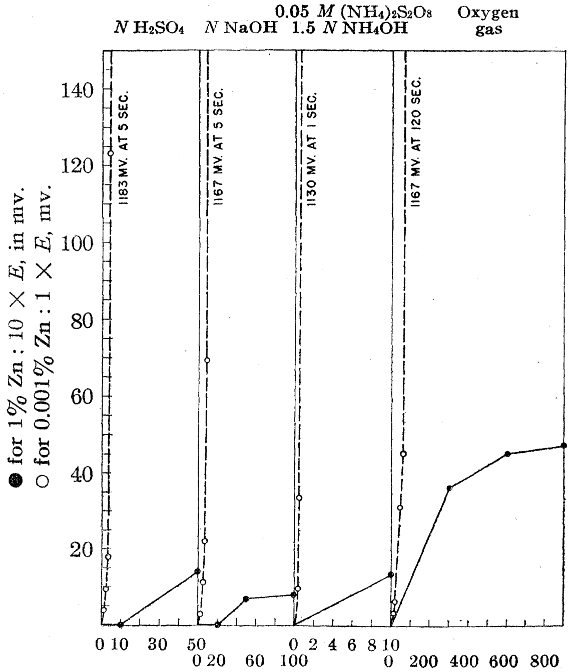

Fig. 1.

Reactivity and Concentration.—All the detailed results for amalgams of intermediate concentrations need not be reported since the curves for these concentrations fall at regular intervals between those of Fig. 1. The most important results for 1 *N* sulfuric acid are given in Table I; the rates are "short interval" values.

The conclusion to be drawn from the last column of Table I is that the rate at which zinc disappears from an amalgam shaken in air with 1 *N* sulfuric acid is virtually independent of the concentration of zinc. This conclusion is supported most strongly by the data for dilute amalgams, where the relative concentration changes are most pronounced; it shows that concentrated zinc amalgams appear to be "inert" because their absolute rate of reaction is proportionately so small as to escape detection. The results with 1 *N* sodium hydroxide closely parallel those given in Table I, and those with oxygen gas do not differ greatly. The persulfate results are the most unreproducible, because the reaction is so extremely rapid and attended by complications (temperature rise in the reaction mixture, cloudiness, scum formation); but here also the rate increases relatively little with increasing concentration of zinc; 0.001 (representing complete removal), 0.009, 0.006, 0.012%/sec./25 cc. were obtained for 0.001, 0.01 and 1% amalgams, respectively. These exploratory experiments lead to the conclusion that the absolute rate of oxidation of zinc amalgams increases only slightly with the concentration of zinc.

Air as the Oxidizing Agent.—The close parallelism of the results with 1 *N* sulfuric acid and 1 *N* sodium hydroxide suggested the investigation of intermediate acid concentrations. This investigation was restricted to the 0.001% amalgams, which were studied by the shaking method already described. The estimated times required at room temperature for the electromotive forces to reach 100 mv. (which represents almost complete removal of the zinc) in these experiments were

Solution	1 *N* NaOH	1.5 *N* NH_4OH	0.001 *N* H_2SO_4

Time, sec.	7	8	4 and 5

[a] Zinc hydroxide precipitated in these experiments.

These data suggest that the principal oxidizing agent for the experiments is neither hydrogen nor hydroxide ion, and probably not water. That this oxidizing agent is the oxygen of the air appears from the following results

Solution	1 *N* NaOH	H_2O	1 *N* H_2SO_4
Atmosphere	Hydrogen	Hydrogen	Hydrogen
Time, sec.	60	60	60
E. m. f., mv.	2.5	1.2	0.9

Solution	1 *N* H_2SO_4	1 *N* H_2SO_4	None (Dry)
Atmosphere	Air	Oxygen	Oxygen
Time, sec.	4	1	10
E. m. f., mv.	123	108	39

Within the accuracy of the experiments, the rate of oxidation is proportional to the partial pressure of oxygen,[2] and the reaction is less rapid when no solution is present.

Hydrogen Peroxide Formation.—Although the status of hydrogen peroxide as an intermediate step in the reduction of oxygen is so well established as to make specific reference unnecessary, the interesting work of Furman and Murray[3] deserves mention, because the reducing agent in their case was metallic mercury. To prove that hydrogen peroxide was formed also when zinc amalgam was the reducing agent, several experiments were performed with 0.01% zinc amalgam, air and 1 *N* sulfuric acid; hydrogen peroxide was identified by the formation of peroxytitanic acid and determined iodimetrically. The number of moles of hydrogen peroxide formed in these experiments was about $^1/_{15}$ to $^1/_{20}$ of the number of moles of zinc initially present, pointing either to catalytic decomposition or, more plausibly, to reduction of hydrogen peroxide by zinc. That the latter reaction occurred was proved by shaking 25 cc. of 0.01% amalgam for twenty seconds with 40 cc. of 1 *N* sulfuric acid containing 0.01 *M* hydrogen peroxide: here the zinc was completely removed, as compared with half-removal under similar conditions with the peroxide absent. $4.5(10^{-4})$ mole of zinc was oxidized, but only $3.1(10^{-4})$ of $4.0(10^{-4})$ mole of the peroxide was reduced, indicating that oxygen oxidizes some of the zinc even when hydrogen peroxide is present. These results agree with the fact that hydrogen peroxide was found at relatively low concentration when none had been added initially; in other words, hydrogen peroxide is an intermediate step in the reduction of oxygen by zinc amalgams and, under our experimental conditions, is comparable in reactivity with oxygen itself. Comparison with the work of Furman and Murray shows that

---

(2) There is a chance that the results in Table I for the 1% amalgam are somewhat low because of a decrease in the partial pressure of oxygen, although the separatory funnel was opened each time a sample was withdrawn. The results with the more dilute amalgams escape this criticism since only 0.13 cc. of oxygen is required to lower the concentration of 25 cc. of amalgam by 0.001% if the oxygen is reduced to hydrogen peroxide, and nearly one hundred times that much oxygen was normally present.

Whether or not significant amounts of hydrogen gas were evolved when oxygen was reduced in the experiments with aqueous solutions is not certain. There is always the remote possibility that the reaction producing hydrogen is accelerated by the reaction between zinc amalgam and oxygen; but in the absence of concrete evidence this possibility will not be considered further. Zinc amalgams that had stood overnight in contact with the 0.05 *M* sulfuric acid electrolyte solution often showed a bubble of gas (presumably hydrogen) the next morning.

(3) Furman and Murray, THIS JOURNAL, **58**, 429 (1936).

hydrogen peroxide is far more inert than oxygen when mercury alone is the reducing agent. A complete investigation of the kinetics of these reactions must include a measurement of the concentration of hydrogen peroxide under various experimental conditions—at different temperatures, for example.

Temperature Coefficient.—For 0.1% amalgams, the following results were obtained after shaking for 120 sec.

Temperature	Near 0°	Near 30°	Near 55°
E. m. f., mv.	2.0[a]	2.1	2.1

[a] Estimated; actual results: 0.2 mv. at 80 sec.; 2.3 mv. at 160 sec.; 2.6 mv. at 240 sec.

For 0.001% amalgams, the times required at these temperatures to reach an e. m. f. of 100 mv. were estimated from the data for amalgam samples withdrawn after different times of shaking. The results were

Temperature	Near 0°	Near 30°	Near 55°
Time, sec.	6 and 7	5	5

In these measurements, the temperature was not controlled accurately; during the 0° work it rose, and during the 55° work it fell, several degrees. Nevertheless, these data show that the temperature coefficient of the reaction is near unity, and the energy barrier involved must consequently be small—perhaps three or four thousand calories.[4]

Other Oxidizing Agents.—It has been mentioned above that 40 cc. of ammoniacal 0.05 *M* (or 0.1 *N*) ammonium persulfate solution oxidized 25 cc. of zinc amalgam at a rate near 0.01%/sec.; Table I shows that the average rate for 40 cc. of 1 *N* sulfuric acid saturated with air is $3(10^{-4})$%/sec. To a first approximation, both rates are independent of the zinc concentration; with oxygen, the rate was roughly proportional to its partial pressure, hence to its concentration in solution. The concentration of oxygen in 1 *N* sulfuric acid in equilibrium with air near room temperature is about $2.2(10^{-4})M$,[5] or $9(10^{-4})N$, if the oxygen is reduced to water. The specific rate, assuming this equilibrium to be maintained under our experimental conditions, for the oxidation of zinc amalgams by dissolved oxygen will be taken as $k = 3(10^{-4})$%/sec./25 cc. amalgam/$9(10^{-4}) = 0.3$. The corresponding specific rate for ammoniacal persulfate is $0.01/0.1 = 0.1$. That two such dissimilar oxidizing agents should have virtually identical specific rates, leads to the conclusion that the reaction under investigation is essentially simple.

The results with other oxidizing agents confirm this conclusion. The experiments in Table II were carried out by the experimental method previously described, but 50, not 40, cc. of aqueous solution was usually employed. The specific rates were calculated as in the case of dissolved oxygen; an arithmetical average of the normality of the oxidizing agent was substituted for the normality of the dissolved oxygen. The results indicate that persulfate in acid solution reacts somewhat more rapidly than in ammoniacal; no great significance can be attached to this difference, however, because experimental conditions were not identical. The concentration of zinc ion in the latter solution is presumably much the lower because of the formation of the zinc-ammonia complex ion; perhaps this indicates that the rate of removing zinc ions from the amalgam, like the zinc concentration itself, has no influence on the rate of reaction. In the peroxide and permanganate experiments, a decrease in hydrogen ion concentration accompanies the oxidation of zinc; this circumstance probably complicates the permanganate results, but permanganate reactions are generally so complex anyhow that the point was not investigated further. The small and nearly constant rate observed in the experiments where persulfate and peroxide were completely consumed may be the rate at which hydrogen ion oxidizes zinc amalgam; this oxidizing agent is certainly far less reactive than the others in this group. The copper ion results are complicated by the formation of copper amalgam (the solubility of copper in mercury is about 0.002% at these temperatures).[6] The behavior of zinc amalgams toward these oxidizing agents under our experimental conditions may be summarized as follows. (1) Dissolved oxygen, hydrogen peroxide, persulfate ion, permanganate ion and copper ion oxidize zinc amalgams at about the

---

[4] Since the solubility of oxygen in water decreases about 2.5-fold between 0 and 55°, there should be a corresponding decrease of rate with temperature if the heat of activation were zero. No decrease was observed, and the results of the above experiments indicate that the heat of activation is approximately large enough to counteract the decrease in solubility as the temperature is changed. On this basis, the heat of activation is about 3600 cal.

[5] Bohr, *Z. physik. Chem.*, **71**, 47 (1910). His data correspond to $10^3\alpha = 25$ for oxygen in equilibrium with sulfuric acid near 25°. The manner in which these data are cited (under "Air") in "I. C. T.," Vol. III, p. 272 ("Values of cm.^{3} of N_2 and O_2 at S. T. P. dissolved by 1 liter of soln. in equilibrium with the normal dry atmosphere") makes them liable to misinterpretation.

[6] Unpublished results from this Laboratory have confirmed published values of this datum.

same rate. (No great accuracy is claimed although the measurements are fairly reproducible.) (2) Hydrogen ion is comparatively inert, perhaps because of the difficulty of forming monatomic hydrogen.

0	0.0108	140	0.078	0.2
0.25	.0073[f]		.067	

[a] (Ox) denotes the normality of the oxidizing agent. [b] Values in parentheses may be low because of exhaustion of zinc. [c] Sulfuric acid initially 0.1 *N*. [d] Sulfuric acid initially 0.2 *N*. [e] Concentration uncertain because of oxidation of appreciable mercury. [f] This percentage was computed from the decrease, determined colorimetrically, of the copper ion concentration in the 45 cc. of solution employed. It was found that the formation of a zinc–copper amalgam made e. m. f. values unreliable for the computation of the remaining % Zn. The e. m. f. in experiments like these never reached 1100 mv., which is characteristic of pure mercury, but seemed to approach a limit near 70 mv. For the experiment above, the e. m. f. corresponded to 0.0011% zinc at 0.25 sec.

In the experiments with air as oxidizing agent, the final concentration of hydrogen peroxide was near $6(10^{-4})N$. The normality of dissolved oxygen in equilibrium with air is about $9(10^{-4})N$. The specific rate for dissolved oxygen is about 0.3; that for peroxide, about 0.2. These data agree well enough to indicate that the peroxide exists at a steady-state concentration near $6(10^{-4})N$.

The experimental data, crude though they are, permit an interesting calculation bearing on the collision number in aqueous solution. The usual calculation, in which it is assumed that the Arrhenius constant A is identical with or simply related to the collision number Z, applies to collisions within aqueous solutions; one of the underlying assumptions, which is by no means always valid, is that $k = Ae^{-Q/RT}$, where Q is the empirically determined heat of activation. We shall make a similar assumption and attempt to identify A with the number of collisions between the oxidizing agent and the amalgam surface. The calculation will be carried out for dissolved oxygen; since all the oxidizing agents investigated show comparable specific rates, the conclusions presumably are of general application. The concentration of dissolved oxygen is about $2.2(10^{-4})$ M, corresponding to a pressure of $5.5(10^3)$ dynes/sq. cm. How large will be the amalgam surface struck per second by $2.5(10^{-4})$ g. of oxygen (assumed to be unhydrated), which corresponds to removing zinc at the average rate of $3(10^{-4})\%$/sec. from 25 cc. of amalgam?

The calculation was carried out according to one equation given by Langmuir[7] and according to another given by Hinshelwood[8] with the identical result: area = 0.0032 sq. cm. The area of contact between the amalgam and aqueous solution at rest was near 15 sq. cm.; during the shaking, it was of course larger—say, 40 sq. cm. The ratio of the actual rate to the kinetic theory rate is therefore 1/12,500; if this factor is equal to $e^{-Q/RT}$, $Q = 5600$ cal., approximately. The agreement between this result and the estimate[4] $Q = 3600$ cal. is good enough to encourage confidence in the calculation; if the assumption $k = Ae^{-Q/RT}$ is valid, the sign of the discrepancy indicates either that the number of collisions is smaller than kinetic theory calls for or that the requirement of minimum energy is not alone mandatory

---

(8) Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Oxford Univ. Press, Oxford, 1933, p. 4.

for the occurrence of reaction on collision. The agreement indicates further (as do the facts that all oxidizing agents show nearly the same specific rate and that the rate of oxidation increases somewhat with the amalgam concentration) that the reaction does not involve diffusion through a stationary layer near the amalgam–solution interface. (Presumably a zinc amalgam at rest reacts so slowly because diffusion of reactants or resultants through a film near this interface helps limit the rate.)

Mechanism.—Any mechanism for the oxidation of zinc amalgams by oxygen (and, through legitimate inference, by other oxidizing agents) must explain the following facts: (1) the rate of oxidation is limited by the rate at which new amalgam surface is produced, other factors remaining constant; (2) the rate increases only slightly with the concentration of the amalgam; (3) it is proportional to the concentration of the oxidizing agent; (4) it is little affected by temperature changes; (5) when oxygen is reduced, hydrogen peroxide appears as a reactive intermediate compound; (6) a dry amalgam oxidizes less rapidly than one in contact with an aqueous solution.

These results are far simpler than those previously obtained in investigations of similar reactions.(9) They support the idea that we are actually studying the transfer of electrons from the amalgam to the oxidizing agent with all the usual complicating factors of a heterogeneous reaction stripped away. An attempt will now be made to formulate a mechanism describing this process, with the understanding that other mechanisms may prove acceptable provided they explain the experimental results.

The transfer of electrons to oxygen in acid solution may be visualized as follows

Rapid equilibrium: $\text{Amalgam} \rightleftharpoons \text{Amalgam surface}^{n+} + n \text{ electrons} \quad (1)$

Rate-determining: $O_2 + 2 \text{ electrons} + 2H^+ \longrightarrow H_2O_2 \quad (2)$

Rapid follow reaction: $\text{Amalgam surface}^{(n+2)+} = \text{Amalgam surface}^{n+} + Zn^{++} \quad (3)$

When the solution is not acid, it may be necessary to substitute water for hydrogen ion in reaction 2 with corresponding changes in the products. The substitution of hydrogen peroxide or of other oxidizing agents for oxygen presents no difficulty.

This mechanism, which should be applicable to many similar cases, has two necessary features: (1) the electrons transferred in reaction 2 need not originate with the zinc, but are furnished by the entire amalgam. The "electron concentration" at the amalgam surface appears to be nearly independent of the concentration of zinc; this explains why the rate does not increase more rapidly with the concentration and is in accord with the data on the electrical conductivity of zinc amalgams.(10) (2) The base-metal characteristics of zinc are responsible for the readiness with which reaction 3 proceeds. Shaking speeds up the oxidation because it continuously exposes a fresh surface, thus preventing the accumulation of reaction products, and because it provides a fresh supply of reactants. Several reasons suggest themselves for the accelerating effect of water; for example, water might make gaseous oxygen more reactive by activating it or by combining with it. The small energy barrier involved in the oxidation suggests, among other things, that the transfer of electrons to an oxidizing agent requires little or no activation when conditions are favorable.

This mechanism is conservative in that it is no more detailed than the experimental facts appear to warrant. The highly reactive substances H and HO_2, postulated by Furman and Murray, which have long been used in explaining photochemical and chain reactions(11) have not been assumed as intermediate for the following reasons. (1) It has not been proved that the reduction of oxygen by mercury or an amalgam involves a chain reaction (further experimental work bearing on this point would be welcome). (2) The assumption that H exists on a mercury or amalgam surface in contact with an aqueous solution containing an excess of reactive oxidizing agents appears implausible. (3) Intermediate products (like HO_2), to form which oxygen must accept an odd number of electrons, could scarcely have an appreciable life on a zinc amalgam surface, provided no chain or photochemical reaction is occurring. The evidence from many inorganic oxidation reactions in aqueous solutions favors the idea that oxygen is reduced to oxide in two steps (peroxide first and oxide afterward), whenever

---

(9) See, for example, Fraenkel, Wengel and Cahn, *Z. anorg. Chem.*, **171**, 82 (1928).

(10) In this connection, *cf.* Schulze, *Z. Metallkunde*, **17**, 170 (1925), where data are given showing that the addition of 1% zinc to mercury increases its electrical conductivity by about 15%.

(11) See, for example, Marshall, (a) *J. Phys. Chem.*, **30**, 34 (1926); (b) THIS JOURNAL, **49**, 276 (1927); (c) Haber and Weiss, *Proc. Roy. Soc.* (London), **147A**, 332 (1934).

this is possible; in each of these steps two electrons are transferred.

There is no reason, *a priori*, why the oxidation of other amalgams—at least of amalgams baser than mercury—should not be closely analogous to the reaction under discussion. Indeed, examination of the literature reveals that the amalgams of cadmium, lead, copper, tin, thallium, sodium, potassium, lithium, calcium and barium[12] all show peculiarities of behavior indicating that their dilute amalgams are much more unstable than the concentrated.

Other Explanations.—Polymerization of zinc amalgams[1a] might serve as a qualitative explanation of the inertness of concentrated zinc amalgams, but it falls so far short of being quantitative that it must be rejected. A preferential accumulation (analogous to a Gibbs adsorption) of zinc in the surface layer of the amalgams so that the surface concentration of a very dilute amalgam is not much smaller than that of one more concentrated is another possible explanation; but it seems quantitatively unsatisfactory and conflicts with the fact that the amalgams obey the Nernst equation quite well in the concentration range $10^{-6} - 2(10^{-3})\%$.[1b] Overvoltage as a possible explanation provides little more than a restatement of the problem. The suggested explanation of Erdy-Grúz and Vázsonyi-Zilahy for the electromotive forces of cells with dilute amalgams involves several implausible features and will be examined elsewhere.

I am indebted to Dr. A. L. Marshall of this Laboratory for many valuable discussions bearing on the foregoing material.

Conclusions and Summary

The reactivity of zinc amalgams toward several oxidizing agents has been studied under experimental conditions that lead to extremely simple results. With violent agitation, the rate of oxidation for a given oxidizing agent appears to be limited mainly by the rate at which a fresh surface can be exposed; when this is constant, the rate of oxidation increases only slightly with the concentration of the amalgam, is proportional to the concentration of oxidizing agent and almost unaffected by a change in temperature. The conclusion has been drawn that the reaction being studied involves the capture of electrons by the oxidizing agent at the amalgam surface, followed by the expulsion of a zinc ion.

Work on other amalgams is required to test the generality of this conclusion. Meanwhile, the experimental facts for zinc amalgams are interesting because they show that concentrated zinc amalgams appear to be inert (although they react somewhat more rapidly than those more dilute) only because the amount of zinc disappearing from them is proportionally small enough to escape detection. Results like these have a number of applications. In the cleaning of mercury, for example, they indicate that the removal by oxidation of a metal like zinc becomes progressively easier as the concentration of zinc decreases, a situation highly unusual in purification processes.

A Study of the Products Obtained by the Reducing Action of Metals upon Salts in Liquid Ammonia Solution. IV. The Action of Potassium and Sodium upon Silver Salts

BY WAYLAND M. BURGESS AND FRANCIS R. HOLDEN[1]

Introduction

In investigating the reducing action of the alkali metals on liquid ammonia solutions of inorganic salts, but little attention has been given to potassium as the reducing agent. Weyl,[2] in the first recorded reaction ever carried out in liquid ammonia, condensed ammonia on both potassium and a salt, using salts of zinc, copper, mercury and silver. But in later work of this kind, sodium has been employed, and a detailed description of the reactions with salts of zinc, silver and manganese has been given in previous articles of this series.[3-5] From the concept of the alkali metal solutions, as developed by Kraus,[6] one would expect the reducing action of potassium to parallel that of sodium. However, with potassium the rate of reaction with ammonia, in which the amide and hydrogen are formed, is greater. Thus, an increased tendency for the concurrent reaction between the metal and the solvent, as was observed in the reduction of manganous iodide with sodium,[5] is to be expected.

In order to compare directly the reducing action of potassium and sodium, several silver salts have been reduced by each of these metals. The reactions are found to be similar in that the silver salt is reduced to free silver; but with potassium, there is always a concurrent reaction with ammonia, catalyzed by the freshly reduced silver. The effectiveness of the reduced silver as a catalyst is greater when potassium is the reducing agent, and also varies with different silver salts, silver cyanide in particular furnishing an active catalyst. The metallic precipitate from most reactions is inert in air, but in the reduction of silver cyanide with potassium a pyrophoric precipitate is obtained. Furthermore, the reduction may extend to the anion of the salt and, in the case of silver thiocyanate, the thiocyanate radical is reduced. The cyanate group, however, is stable in the presence of sodium and potassium in liquid ammonia solution.

The Reduction of Silver Iodide and Silver Chloride

In a previous paper[4] the reduction of silver iodide and silver chloride by sodium was shown to proceed smoothly with the formation of free silver and the corresponding sodium salt. The free silver so formed was non-reactive toward air and did not catalyze the reaction between sodium and ammonia. The ratio between the gram atoms of sodium and gram moles of silver salt reacting (called reaction ratio), was determined accurately and found to be close to 1.00.

Using the same experimental method, with Merck potassium (shown by analysis to be 99.85% potassium) as the reducing agent, higher values for the reaction ratio were obtained and a slight gas formation observed. The method was then modified to permit the collection of the gas. Upon analysis, this proved to be hydrogen. From the hydrogen volume so obtained, the amount of potassium reacting with ammonia was determined and the reaction ratio corrected for this loss of potassium. This was also checked by treating the product of the reaction, after evaporation of the ammonia, with distilled water, which reacted with the potassium amide, and titrating this basic solution, previously boiled, with tenth normal hydrochloric acid. From the acid used, the amount of potassium amide present was calculated, and the reaction ratio corrected for the loss of potassium as determined in this way.

The results of the reduction of silver chloride and silver iodide are given in Table I, in which reaction ratio of column 5 refers to the ratio between gram atoms of potassium and gram moles of silver salt employed; corrected ratios (1) and (2) are the values obtained when the potassium that reacted with ammonia, as determined by the collection of hydrogen and by the amide analysis, respectively, has been subtracted from the total potassium used.

TABLE I

REDUCTION OF SILVER CHLORIDE WITH POTASSIUM

Expt.	K, g.	Ag salt, g.	H_2, cc. N. T. P.	Ratio K/AgCl (I)	Corr. ratio (1) K/AgCl (I)	Corr. ratio (2) K/AgCl (I)
22	0.9674	3.3412	[a]	1.06	..	..
112	.4021	1.4358	[a]	1.03	..	1.01
115	.3106	1.1235	2.6	1.01	0.99	1.00
116	.4535	1.5928	5.1	1.04	1.00	1.01
REDUCTION OF SILVER IODIDE						
36	0.4656	2.6785	3.6	1.04	1.02	1.01
41	.3895	2.2636	1.5	1.03	1.02	1.01
45	.3565	2.0614	0.8	1.04	1.03	1.00

[a] Hydrogen not collected.

The reaction ratio is slightly higher than 1.00 as obtained in the sodium reaction but this difference is, without doubt, due to the experimental error in determining the amount of potassium that reacted with the ammonia. Thus, potassium reduces silver chloride and iodide to free silver, with a small amount of concurrent reaction between potassium and ammonia.

The precipitated silver was found to be nonreactive toward air. An analysis of the precipitate from a reaction using silver iodide and potassium, where the precipitate had been washed carefully by a method described in an earlier paper,[3] gave a silver content of 98.5%. This purity is almost the same as found using sodium as the reducing metal and shows that all soluble impurities cannot be removed by washing with liquid ammonia.

Since the reaction with ammonia requires that there always be an excess of reducing metal used, a method was tried by which a large excess of potassium was added to a liquid ammonia solution of the silver salt. Then, after reduction was complete, the excess metal was destroyed by the addition of ammonium bromide. From the gas collected, the excess potassium was calculated. The results are given in Table II.

TABLE II

REDUCTION OF SILVER IODIDE WITH EXCESS POTASSIUM

Expt.	K, g.	AgI, g.	H_2, cc. N. T. P.	Ratio K/AgI	Corr. ratio K/AgI
209	0.3639	1.0428	53.8	2.10	1.01
210	.3344	1.0240	46.4	1.96	1.01

The corrected reaction ratio is 1.01, and shows that this procedure is a satisfactory method for study of these reduction reactions.

The Reduction of Silver Cyanide

The reduction of silver cyanide by sodium was investigated by Kraus and Kurtz,[7] who found that more sodium was necessary for the reaction than would be required for the simple reduction to metallic silver—a reaction ratio of the order of 1.1 being obtained. Preliminary work with sodium, in which the salt was added to the metal solution, gave a high ratio, averaging 1.03. This indicated that the silver might catalyze the reaction between sodium and ammonia. However, the formation of appreciable hydrogen was not detected. But when the silver cyanide was reduced with potassium, the precipitated silver was found to be a catalyst for the reaction between potassium and the solvent, much better than the reduced silver from the iodide or chloride. An accurate determination of the reaction ratio for both sodium and potassium was made by adding an excess of metal to a liquid ammonia solution of the salt and, in the case of sodium, destroying the excess metal with ammonium chloride. Ammonium chloride was not needed with the potassium reaction. The results are shown in Table III.

TABLE III

REDUCTION OF SILVER CYANIDE WITH SODIUM

Expt.	Na (or K), g.	AgCN, g.	H_2, cc. N. T. P.	Ratio Na(K)/AgCN	Corr. ratio Na(K)/AgCN
205	0.2502	0.9780	39.9	1.49	1.00
206	.2432	1.0118	33.1	1.40	1.01
REDUCTION OF SILVER CYANIDE WITH POTASSIUM					
199	0.4708,	0.9967	50.4	1.62	1.01
200	.4420	.9837	41.8	1.54	1.03
203	.3905	1.0185	25.2	1.31	1.02

The corrected reaction ratio approaches 1.00 for sodium, but is slightly higher for potassium. In each case, the reaction parallels that with the other silver salts, except that the precipitated silver is very finely divided and distinctly more reactive. This was especially marked by the fact that the precipitate from experiments numbered 199 and 200 was pyrophoric, bursting into flame when exposed to air. That the activity of the precipitated metal may vary with the salt employed, has not been observed before. In run 203, ammonium chloride was added after the completion of the reaction and this reduced silver was not pyrophoric. Neither was the precipitate pyrophoric in those runs where an excess of silver cyanide was always present or where sodium was the reducing agent.

In some reduction reactions using nickel salts,[8] it has been shown definitely that a high reaction

---

(7) Kraus and Kurtz, THIS JOURNAL, 47, 43 (1925).

(8) Eastes, Ph.D. Thesis, University of Cincinnati, 1936.

ratio may be obtained due to hydrogen being adsorbed by the precipitated nickel. It is probable that the slightly higher ratio with potassium in all cases of silver salt reduction is due to a small loss of hydrogen through adsorption by the silver. It is also possible that the reduced silver owes its pyrophoric property to adsorbed hydrogen. In all cases in which the reduced metal was pyrophoric, the formation of hydrogen also occurred. In the work with nickel, it was shown that the addition of ammonium chloride released hydrogen adsorbed by the precipitated nickel. The effect of ammonium chloride in destroying the pyrophoric property of the reduced silver precipitate may be explained in a similar manner. A further study is being made of the nature and properties of pyrophoric precipitates formed by reduction in liquid ammonia.

The Reduction of Silver Thiocyanate and Cyanate

Because of solubility relations, there are relatively few salts that may be used for the reduction reaction in liquid ammonia. Some of the generally soluble salts, in particular the thiocyanates, cyanates and nitrates, have an anion that may not be stable in the presence of such a strong reducing reagent as the alkali metals. Having established a simple reduction in the case of several silver salts, a study was made of the reduction of silver thiocyanate and silver cyanate to determine the stability of these anions. With silver cyanate, excess metal was added to a solution of the salt, while with silver thiocyanate, the salt was added to a solution of the metal. The results are given in Table IV.

TABLE IV

REDUCTION OF SILVER THIOCYANATE WITH SODIUM

202	.4288	1.0023	47.6	1.64	1.00

The average ratio for the reduction of silver thiocyanate is 1.08. This definitely points to another reaction, the most probable being the reduction of the thiocyanate anion. Evidently, the reduction is far from complete. The ratio for the reduction of the silver cyanate approaches 1.00 in each case, thereby proving that silver cyanate is reduced to silver and alkali cyanate, the cyanate radical not being attacked.

To confirm the reduction of the thiocyanate radical, qualitative tests, which were made on the product of the reduction after evaporation of the ammonia, showed the presence of cyanide. Furthermore, potassium was found to react slowly with potassium thiocyanate to form both sulfide and cyanide.

A preliminary study of the reduction of silver nitrate showed that the nitrate radical was readily reduced by both sodium and potassium in liquid ammonia solutions. Silver nitrate diammoniate, $AgNO_3 \cdot 2NH_3$, prepared by evaporating the ammonia from a liquid ammonia solution of silver nitrate, was found to be stable in air at room temperatures, but lost ammonia at 60°. The ratio for the reaction where this salt was added to a solution of the alkali metal, was 5.4 gram atoms of sodium per mole of salt, and 4.6 gram atoms of potassium per mole of salt. The reaction product when sodium was used was black and pyrophoric, and a good catalyst for the reaction between sodium and ammonia, this being the only case where the product of the sodium reduction showed these properties. Some work was done on the reduction of other nitrates with the following results. Using sodium nitrate and sodium, the reaction ratio was 3.5 gram atoms of sodium per mole of salt, and the reaction product was yellow and explosive in air. With potassium nitrate and potassium the ratio was 3.1 and the reaction product was yellow but not explosive. Using ammonium nitrate and potassium, practically no hydrogen was obtained, and the reaction ratio was 3.1 gram atoms of potassium per mole of ammonium nitrate. All of this work shows definitely that the nitrate anion is unstable in the presence of metal solution in liquid ammonia, but further study is necessary to determine the nature of the reduction products.

Summary

Silver salts are reduced by both sodium and potassium in liquid ammonia solution to free silver. This reduced silver may catalyze the reac-

tion between the alkali metal and ammonia. Its efficiency as a catalyst is greater when potassium is the reducing agent and it also varies with the silver salt. With silver thiocyanate, the thiocyanate radical is partially reduced, but with silver cyanate the cyanate group is stable in the presence of either sodium or potassium solutions.

A Study of the Products Obtained by the Reducing Action of Metals upon Salts in Liquid Ammonia Solution. V. The Action of Calcium upon Silver Salts

BY WAYLAND M. BURGESS AND FRANCIS R. HOLDEN[1]

Introduction

In a previous paper,[2] the reducing action of the two alkali metals, sodium and potassium, upon a number of silver salts was compared. The reactions were similar, forming free silver and the corresponding alkali metal salt, except that the precipitate from the potassium reactions was reactive in air and a better catalyst for the concurrent reaction between the metal and ammonia. A similar study, in which calcium has been used as the reducing metal, has led to the remarkable results that, with calcium, the reduction reactions are decidedly more vigorous, the precipitated silver is also reactive toward air, and is superior, as a catalyst, to that obtained with potassium. No reference to a previous investigation has been found that would indicate calcium solutions to be a better reducing medium than solutions of the alkali metals.

The Reduction of Silver Iodide and Silver Cyanide

To a solution of silver iodide in liquid ammonia, using an apparatus and procedure described in earlier papers,[2,3] was added an excess of Kahlbaum calcium, found by analysis to be 99.1% calcium. The reaction was rapid and the resulting black precipitate so fine that it settled very slowly. It was such an excellent catalyst for the reaction between calcium and ammonia that the excess metal was converted rapidly into calcium amide and hydrogen. The experimental results showing the amounts of the reacting substances and the volume of hydrogen collected are given in Table I.

TABLE I

REDUCTION OF SILVER IODIDE

Expt.	Ca, g.	Ag salt, g.	H_2, cc. N. T. P.	Ratio 1/2Ca/ AgI(CN)	Corr. ratio 1/2Ca/ AgI(CN)
182	0.2224	1.2903	62.7	2.02	1.00
183	.2709	1.3623	88.3	2.33	0.97
184	.2126	1.1741	62.5	2.12	1.01
REDUCTION OF SILVER CYANIDE					
178	0.2716	1.1993	48.4	1.51	1.03
179	.3254	1.0306	96.6	2.11	0.99
180	.2934	0.7564	100.4	2.59	1.01

Corrected reaction ratio, column 6, has been corrected by subtracting from the total calcium used, the amount of calcium that reacted with ammonia, as determined by the hydrogen collected. This is a true measure of the amount of calcium and silver salt that reacted. This value being 1.0, shows that the silver salt is reduced to free silver. Two concurrent reactions occur as presented by the equations

$$\mathrm{Ca} + 2\mathrm{AgI}\ (\text{or AgCN}) \longrightarrow \mathrm{CaI_2}\ (\text{or } \mathrm{Ca(CN)_2}) + 2\mathrm{Ag}$$

$$\mathrm{Ca} + 2\mathrm{NH_3} \longrightarrow \mathrm{Ca(NH_2)_2} + \mathrm{H_2}$$

In a study of the reaction between silver cyanide and calcium by Kraus and Kurtz,[4] it was postulated that a compound CaAg was formed. The average reaction ratio obtained by them was 2.12, but no attempt was made to determine the amount of hydrogen formed. The present work shows that their high ratio was due to the reaction of calcium and ammonia and that no compound of calcium and silver is prepared in this way.

The precipitated silver from the silver cyanide was pyrophoric and more reactive than that from the silver iodide reaction. In each case, the reduced silver from the calcium reaction was a better catalyst than that obtained by the reduction of the same salt with potassium or sodium. After the completion of one experiment, using calcium and silver cyanide, 0.06 g. of sodium was added to

(3) Burgess and Rose, *ibid.*, **51**, 2127 (1929).

(4) Kraus and Kurtz, *ibid.*, **47**, 43 (1925).

the solution and it was converted to sodium amide in less than fifteen minutes. Silver cyanide reduced by sodium gives silver whose catalytic power is negligible.

The Reduction of Silver Thiocyanate and Silver Cyanate

It has been shown previously[2] that in the reduction of silver thiocyanate to free silver using potassium and sodium, a small amount of the alkali metal was used in the concurrent reduction of the thiocyanate group to sulfide and cyanide. With silver cyanate, the cyanate radical appeared to be stable in the presence of the alkali metal solutions. In view of the more vigorous reduction of the silver iodide and cyanide with calcium, the reaction between silver thiocyanate and calcium offers another opportunity to compare the reducing powers of calcium and the alkali metals. The results obtained by adding an excess of calcium to solutions of sodium thiocyanate are shown in Table II.

TABLE II

REDUCTION OF SILVER THIOCYANATE

Expt.	Ca, g.	AgCNS, g.	H_2, cc. N. T. P.	Ratio 1/2Ca/ AgCNS	Corr. ratio 1/2Ca/ AgCNS
175	0.3949	0.9960	15.2	3.28	3.06
176	.5054	.9979	79.6	4.20	3.01
177	.4705	1.0061	58.4	3.88	3.01

The corrected ratio should be 1.0, if the silver thiocyanate were reduced to silver and no other reaction occurred. The value is close to 3.0, indicating that the reduction of the thiocyanate group to cyanide and sulfide, which requires two additional equivalents of calcium per mole of silver thiocyanate, does occur and goes to completion. The reduction of silver thiocyanate then may be represented by three equations

$$2AgSCN + Ca \longrightarrow 2Ag + Ca(SCN)_2$$
$$Ca(SCN)_2 + Ca \longrightarrow 2CaS + Ca(CN)_2$$
$$Ca + 2NH_3 \longrightarrow Ca(NH_2)_2 + H_2$$

In the reduction of silver cyanate with calcium, it was found that when approximately equivalent amounts of the calcium and silver cyanate were employed, the only reaction to occur was the reduction of the salt to free silver; but with an excess of calcium, a partial reduction of the cyanate radical did occur. These results are shown in Table III, where the first three experiments are with nearly equivalent amounts, and the last three with an appreciable excess of calcium.

TABLE III

REDUCTION OF SILVER CYANATE

Expt.	Ca, g.	AgCNO, g.	H_2, cc. N. T. P.	Ratio 1/2Ca/ AgCNO	Corr. ratio 1/2Ca/ AgCNO
169	0.0213	0.1514	0.5	1.05	1.01
170	.0320	.2275	.5	1.05	1.02
171	.0319	.2148	.8	1.11	1.06
174	.2752	1.0000	62.9	2.06	1.22
166	.3498	1.0020	102.4	2.61	1.24
167	.4367	1.1983	131.7	2.73	1.26

In those experiments where but a very small excess of calcium was used, the corrected ratio shows that little, if any, reduction of the cyanate radical occurred. However, with an excess of calcium, an appreciable reduction of the cyanate group took place. This was also confirmed by the analysis of the products of experiment 174 after evaporation of the ammonia. Strong positive tests for the presence of cyanides were obtained. Thus, we have further evidence that a solution of calcium in liquid ammonia is a stronger reducing agent than solutions of the alkali metals.

Summary

Silver salts are reduced by calcium in liquid ammonia solution to free silver. The reduced silver is pyrophoric and a good catalyst for the reaction between calcium and ammonia. The thiocyanate group of silver thiocyanate is reduced completely to sulfide and cyanide, and the cyanate group of silver cyanate is partially reduced to cyanide when an excess calcium is present.

The Infrared Absorption Spectra of Certain Liquid Mixtures

BY WALTER GORDY[1]

Numerous investigations of liquid mixtures[2] have been made recently by means of the Raman spectra. With few exceptions, however, in all of these studies the spectra obtained were the sum of the spectra of the individual components for the lines which were observed. Infrared studies of alcohol–water mixtures[3] and of acetone–water mixtures[4] have revealed bands not characteristic of either of the components. It was suggested that these were associational bands indicating some type of linkage between the two liquids. Associational bands had been reported previously for aqueous solutions[5] of some inorganic acids, hydroxides and salts, and for alcoholic solutions of some hydroxides.[6] More recently[7] a study of alcohol–acetone mixtures has revealed changes in the spectrum of both components indicating association of the two liquids through dipole interaction.

The present work was undertaken as an attempt to determine whether there is association between aniline and certain other liquids, and, if possible, to determine the nature of the linkage. We may anticipate a linkage of aniline with liquids like acetone through the formation of hydrogen bonds, the hydrogen of the NH aniline group forming a bond between the nitrogen of the NH aniline group and the oxygen of the CO acetone group. The hydrogen bond theory[8] has received considerable attention recently.

Experimental

A Hilger infrared spectrometer with a fluorite prism was used throughout the investigation. Cell windows were of fluorite and were sealed with paraffin. The absorbing layer was maintained at a constant thickness of 0.002 cm. by means of mica washers. The chemicals were Baker certified products.

Results

Studies were made of 50% mixtures of aniline with acetone, ethyl acetate, ethyl formate, methyl cyanide, isopropyl ether and carbon tetrachloride. Figure 1 shows the results obtained in the region 2.5 to 3.1 μ. The band appearing at 2.85 μ in pure aniline arises from changes in the vibrational energy of the NH group. For mixtures of aniline with acetone, ethyl acetate, ethyl formate, isopropyl ether and methyl cyanide, this band is shifted to the shorter wave lengths by about 0.05 μ, and its intensity is definitely increased.

These changes are more apparent when the experimental transmission curves for the mixtures are compared with the theoretical transmission curves for a purely mechanical mixture in which no interaction occurs. The theoretical curves are represented by the broken lines in the figure. Here the transmission of the mechanical mixture for a given frequency is represented by

$$T = e^{-f_1 m_1 - f_2 m_2}$$

where f_1 and f_2 are the fractional parts of aniline and the liquid with which it is mixed, respectively, and where m_1 and m_2 are defined by

$$T_1 = e^{-m_1}, \quad T_2 = e^{-m_2}$$

T_1 being the transmission of pure aniline for the given frequency, and T_2 that of the second liquid. It should be remembered that the cell thickness was the same in all cases.

In contrast to the pronounced shifts and changes in intensity observed in the NH band for other mixtures, no measurable changes were observed in the case of mixtures of aniline with carbon tetrachloride, Fig. 1, F.

Figure 2 shows the effects of aniline on the vibrational band of the CO group of acetone, ethyl acetate and ethyl formate. In each of these mixtures the CO band is shifted to the longer wave lengths by approximately 0.05 μ, and in each mixture the intensity of the band is slightly increased. The experimental curves for the mix-

tures should be noted especially in comparison with the theoretical curves for the same mixtures.

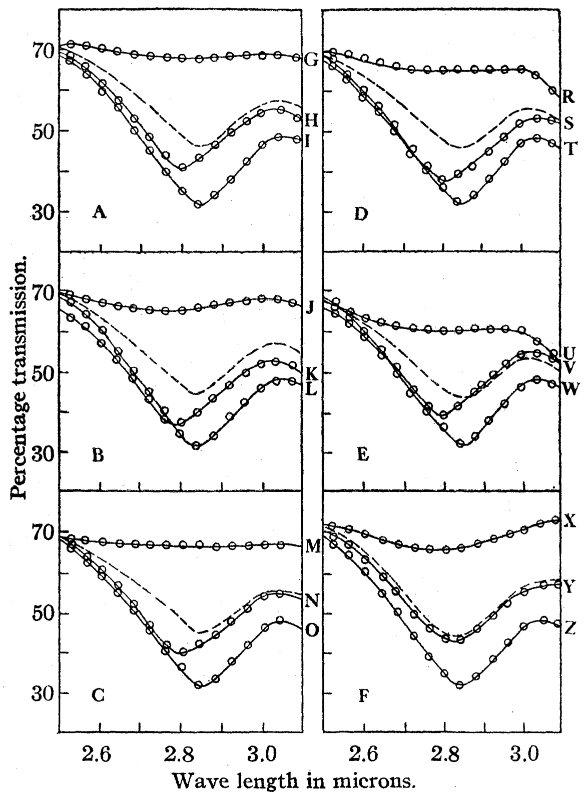

Fig. 1.—Transmission curves in the region 2.5 to 3.1 μ: ----, theoretical for 1:1 mixtures; ——, observed. A, Curve (G) pure isopropyl ether, (H) 1:1 volume mixture with aniline, (I) pure aniline. B, Curve (J) pure acetone, (K) 1:1 volume mixture with aniline, (L) pure aniline. C, Curve (M) pure methyl cyanide, (N) 1:1 volume mixture with aniline, (O) pure aniline. D, Curve (R) pure ethyl formate, (S) 1:1 volume mixture with aniline, (T) pure aniline. E, Curve (U) pure ethyl acetate, (V) 1:1 mixture with aniline, (W) pure aniline. F, Curve (X) pure carbon tetrachloride, (Y) 1:1 mixture with aniline, (Z) pure aniline.

A study was made of aniline bands appearing in the regions of 6.15 μ and 6.65 μ. Transmission curves obtained for these regions are not given. No shifts could be detected in either of the bands for any of the mixtures. Because of overlapping of bands it was not found practicable to study the mixtures in other regions below 8.5 μ.

Discussion

The pronounced changes in the dipole moments of the NH group of aniline and the CO group of acetone, ethyl acetate and ethyl formate, as revealed by changes in the vibrational infrared bands of these groups, in contrast to the approximate constancy of the moments of other groups, indicate association of the liquids through the dipole interaction of these groups. A pos-

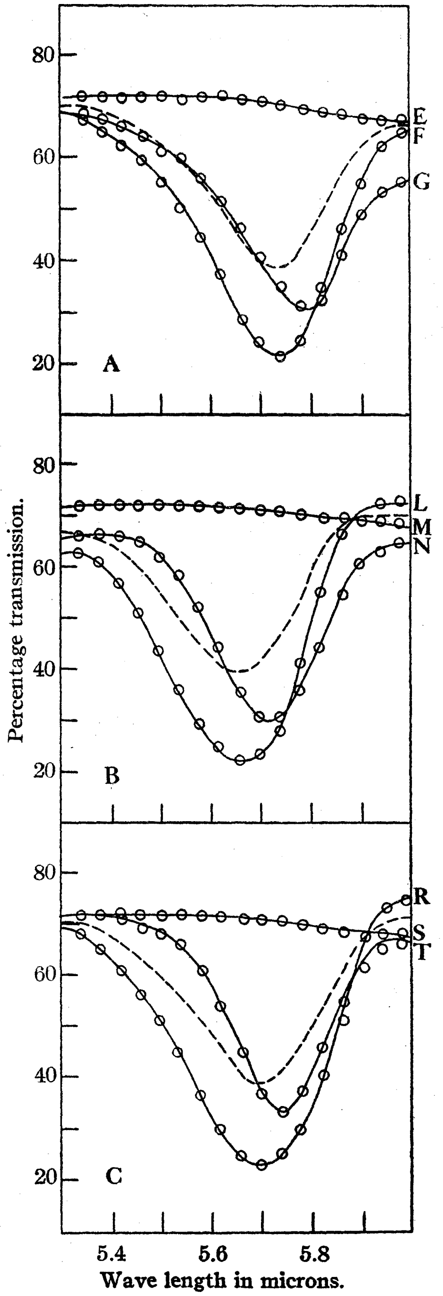

Fig. 2.—Transmission curves in the region 5.3 to 6.0 μ: ----, theoretical for 1:1 mixtures; ——, observed. A, Curve (E) pure aniline, (F) pure acetone, (G) 1:1 volume mixture. B, Curve (L) pure ethyl acetate, (M) pure aniline, (N) 1:1 volume mixture. C, Curve (R) pure ethyl formate, (S) pure aniline, (T) 1:1 volume mixture.

sible explanation of this interaction would be the formation of hydrogen bonds, the hydrogen of the NH aniline group forming a bond between the nitrogen of this group and the oxygen of the CO group. Likewise, the pronounced changes in the NH aniline band in the aniline–isopropyl ether mixtures and the aniline–methyl cyanide mixtures suggest the association of these liquids through the formation of hydrogen bonds. There seems to be no interaction between the NH aniline group and carbon tetrachloride.

The apparent changes in the polarization of molecules in liquid mixtures as determined by dielectric constant measurements are no doubt in many cases due to changes in the electric moments of certain groups resulting from association of the liquids through the interaction of the dipoles of these groups. It should be possible through infra-red absorption measurements to ascertain in many of these mixtures which dipoles undergo pronounced changes and thereby to determine something of the nature of the linkage. The work is being continued on other mixtures in which the formation of hydrogen bonds may be anticipated. Preliminary results,[9] similar to those given above for aniline mixtures, indicate that water and also alcohols associate with certain other liquids through the formation of hydrogen bonds.

The writer wishes to thank Dr. E. K. Plyler for the use of his instrument and Dr. B. G. Carson, of Carson-Newman College, for his helpful discussions.

Summary

In mixtures of aniline with acetone, ethyl acetate, ethyl formate, methyl cyanide and isopropyl ether, the NH vibrational band of aniline is shifted to shorter wave lengths and its intensity is increased. In mixtures of aniline with carbon tetrachloride this band appears to remain constant. Other aniline bands remain approximately constant for all the mixtures. The CO band of acetone, ethyl acetate and ethyl formate is shifted to longer wave lengths, and its intensity increased in mixtures of these liquids with aniline.

It is suggested that the observed changes in the spectrum indicate association of the liquids through dipole interaction. The formation of hydrogen bonds is proposed as a possible interpretation of the results.

Kinetics of Condensation Polymerization; the Reaction of Ethylene Glycol with Succinic Acid

BY PAUL J. FLORY

Bifunctional condensation polymerizations, such as the formation of polyesters either from hydroxy acids or from glycols and dibasic acids,[1] proceed through the intermolecular reaction of the functional groups attached to bifunctional reactants. The reaction involved is fundamentally no different than the reaction between monofunctional reactants bearing the same functional groups; *e. g.*, in polyester formation the reaction is simply esterification, as Kienle and Hovey[2,3] have shown. Unless the reaction of one functional group of a bifunctional reactant changes the reactivity of the other group, all functional groups may be assumed to be equally reactive. When this is true, the reaction should be of the same kinetic character as the analogous monofunctional reaction. Unpublished experiments carried out in this Laboratory verify this deduction.

Recently Dostal and Raff[4,5] have examined the course of the reaction of ethylene glycol with succinic acid. They combined equimolar quantities either in dioxane solution or in the absence of solvent, and in two sets of experiments the succinic acid was dissolved in a large excess of glycol. The progress of the reaction was followed by titration of the unreacted acid in samples heated for various lengths of time at constant temperatures.

[1] Carothers, *Chem. Rev.*, **8**, 359 (1931).

[2] Kienle and Hovey, THIS JOURNAL, **52**, 3636 (1930).

[3] Kienle and Hovey, *ibid.*, **51**, 509 (1929).

[4] Dostal and Raff, *Monatsh.*, **68**, 188 (1936).

[5] Dostal and Raff, *ibid.*, **68**, 117 (1936).

Inasmuch as the reaction takes place between two functional groups, Dostal and Raff assume that it is second order. As proof of this they cite the observation that the rate, expressed as the fraction reacting per unit time, increases as the square of the initial concentration when equivalents of the reactants are used. But this observation is actually indicative of a third order mechanism.

In the estimation of approximate activation energies Dostal and Raff use the quantity nE for the critical energy increment in the Arrhenius equation[6] where n is a factor (> 1) depending upon the average degree of polymerization, $\bar{x}$, of the polymer molecules. However, the polymer molecules are not formed through the *simultaneous* formation of several linkages between segments as this expression for activation energy implies, but through the *stepwise* formation of $\bar{x} - 1$ linkages between the $\bar{x}$ segments. The temperature coefficient is simply dependent upon the activation energy E required for one elementary reaction, and so n must equal unity regardless of $\bar{x}$. In view of the confusion in Dostal and Raff's discussion of their results, a re-interpretation seemed desirable.

To this end, for each temperature and concentration at which Dostal and Raff have furnished adequate data, their results have been compared by conventional graphical methods with both bimolecular and trimolecular kinetic equations. When equivalents of the reactants are used the bimolecular equation may be written in the form

$$C_0k_2t = 1/(1 - p) - 1 \qquad (1)$$

where C_0 is the initial concentration in *equivalents* of OH or of COOH groups per liter (Dostal and Raff use *moles* of reactant per liter), k_2 is the velocity constant in liters per equivalent per hour, t is the time in hours, and p is the extent of reaction, *i. e.*, the fraction of the COOH groups which has reacted at time t. For the trimolecular equation

$$2C_0^2k_3t = 1/(1 - p)^2 - 1 \qquad (2)$$

where k_3 is in (liters per equivalent)^2 per hour. When succinic acid was dissolved in a large excess of ethylene glycol, the concentration of the latter remained practically unchanged during the reaction. If the rate is dependent upon the first power of the acid concentration

$$C_gk_2t = -\ln(1 - p) \qquad (3)$$

where C_g is the concentration of glycol. If the rate is proportional to the second power of the acid concentration

$$C_gC_0k_3t = 1/(1 - p) - 1 \qquad (4)$$

where C_0 is the initial concentration of succinic acid.

Although the experimental error in Dostal and Raff's results is rather large, in most cases the reaction was carried far enough to justify a significant choice between the bimolecular (equations (1) or (3)) and trimolecular equations ((2) or (4)). For the reaction of equivalents of acid and glycol, plots of $1/(1 - p)^2$ *vs.* t are invariably more nearly linear than plots of $1/(1 - p)$ *vs.* t. For the reaction of succinic acid dissolved in a large excess of glycol $1/(1 - p)$, but not $\ln(1 - p)$, is approximately linear with t. To illustrate the accordance of the results with equation (2), the bimolecular and trimolecular velocity constants, calculated from equations (1) and (2), respectively, for the reaction of equivalents in the absence of solvent at 123° are given in Table I. It is apparent that k_3 is approximately constant, whereas k_2 decreases as the reaction progresses. Similarly in Table II, k_3 calculated from (4) for the reaction of succinic acid in an excess of glycol is more nearly constant than k_2 calculated from (3).

4	8	140	1.00 acid in glycol[c]	2.70
		1,4-Butylene glycol + succinic acid		
4	9	140	1.00	1.02

[a] Dostal and Raff give concentrations in moles/liter. Unless otherwise stated the solvent was dioxane. [b] Based on the densities of the reactants and assuming no contraction on mixing we take $C_0 = 13$ equiv./liter. [c] Similarly, $C_g = 30$ equiv./liter.

stants obtained over a wide range of concentrations reveals that at a given temperature k_3 is almost independent of the concentration, thus substantiating the choice of kinetic order. It is especially significant that k_3 at 120° at 1.00 equiv./liter is nearly the same as k_3 at 123° in the absence of solvent. It is true, however, that the velocity constants for the reaction of equivalents tend to increase slightly with dilution (*e. g.*, note the 150° k's at $C_0 = 0.20$ and at 0.50), and the velocity constants for the reaction in glycol are greater than those obtained using equivalents. This suggests that a small part of the reaction may be bimolecular. The rates of reaction of 1,4-butylene glycol and of ethylene glycol are comparable at $C_0 = 1.00$ and $T = 140°$.

This analysis shows, therefore, that the reaction of ethylene glycol with succinic acid cannot be bimolecular as Dostal and Raff have supposed; it is approximately trimolecular, the rate being proportional to the first power of the concentration of hydroxyl groups and to the square of the concentration of carboxyl groups.

These results are in harmony with the conclusions reached by Goldschmidt[7,8] from his extensive studies of esterifications, and confirmed by the more recent work of Hinshelwood and coworkers.[9,10] According to these conclusions the esterification reaction requires a hydrion catalyst in addition to a molecule of the alcohol and one of the acid. In the case of esterifications catalyzed by an added acid[7,10] (to which Goldschmidt devoted most of his attention) the hydrion is furnished by this acid. In the "uncatalyzed" reaction the hydrion is furnished by another molecule of the acid undergoing esterification,[8,9] and hence the reaction is trimolecular since two molecules of acid and one of alcohol are required in the formation of the reaction complex. Rolfe and Hinshelwood's observation that the esterification reaction is catalyzed by traces of substances yielding hydrions may explain the irreproducibility in Dostal and Raff's results.

The three energies of activation calculated from the velocity constants in Table III for the polyesterification in the absence of solvent, in dioxane, and in an excess of glycol, respectively, are all within 2 kcal. of 25 kcal. Rolfe and Hinshelwood[9] find a much lower value, 13 kcal., for the reaction of methanol with acetic acid. For the second stage of the reaction of ethylene glycol with phthalic anhydride, *i. e.*, the reaction

$$\text{—O—C}_2\text{H}_4\text{—O—CO—C}_6\text{H}_4\text{—COOH} + \text{HO—C}_2\text{H}_4\text{—O—} \longrightarrow \text{—O—C}_2\text{H}_4\text{—O—CO—C}_6\text{H}_4\text{—CO—O—C}_2\text{H}_4\text{—O—} + \text{H}_2\text{O}$$

Kienle and Hovey[3] have obtained 22.6 kcal. for the activation energy, a value more nearly in agreement with the one for the reaction of glycol with succinic acid.

Polymerization Kinetics and Size Distributions

In a recent paper the author[11] has presented molecular size distribution equations for polymers formed by bifunctional condensations in which it is permissible to assume equal reactivity of all functional groups. By means of these equations the weight-fraction, mole-fraction, or number of any individual molecular species or group of mo-

lecular species may be calculated. For polymers prepared from equivalents of the reactants the functions are entirely determined by the extent of reaction, p. When an excess of one reactant is used, the distribution functions are expressed as functions of both p and r, where r is the ratio of the initial concentration of the deficient group to the initial concentration of the group present in excess. No application of the equations to the kinetic problem of the relation of the amount of a particular species, or a particular group of species, to time of reaction was discussed. If the kinetic order of the reaction of the functional groups is known, such relationships can be derived by the following procedure. Considering, for example, the number of x-mer molecules N_x

$$\mathrm{d}N_x/\mathrm{d}t = (\partial N_x/\partial p)(\mathrm{d}p/\mathrm{d}t) \qquad (5)$$

since $\mathrm{d}r/\mathrm{d}t = 0$. When $r \neq 1$ the form of the function N_x depends upon whether x is an even or an odd integer; when $r = 1$, $N_x = N_0p^{x-1}(1 - p)^2$ where N_0 is the initial concentration in numbers of molecules. $(\partial N_x/\partial p)$ will be a function of r and p when $r \neq 1$ and of p alone when $r = 1$. From the known kinetics of the process p and $\mathrm{d}p/\mathrm{d}t$ can be expressed as functions of t. Hence, $\mathrm{d}N_x/\mathrm{d}t$ can be expressed in terms of t, and integration will yield N_x as a function of t. In a similar way it is possible to relate the number of molecules within a particular group of sizes $y \leqq x \leqq z$ to time by replacing N_x by $\sum_{x=y}^{x=z} N_x$ in the above equations.

Dostal and Raff have attempted to utilize the size distribution equations in the interpretation of the kinetics of the glycol–succinic acid reaction.[12] Since the size distribution theory is based upon the assumption that the reaction consists of straightforward intermolecular reaction of functional groups, all of equal reactivity, it is obviously useless in an analysis of the kinetics of the reaction of the functional groups. Using the procedure outlined in the preceding paragraph and assuming that the reaction is second order, they have derived an equation for the relation of monomer concentration to time. They attempt to fit this equation in one case (Fig. 9 of ref. 4) to their experimental results which consist of measurements of concentration of COOH groups and not of monomer concentration. There is no foundation for this comparison.

Not having had access to the derivations of the size distribution equations at the time they carried out their work, Dostal and Raff presented the following arguments as proof that these equations are only approximate. First they compared the second order rate of disappearance of monomer given by $\mathrm{d}N_1/\mathrm{d}t = (\partial N_1/\partial p)(\mathrm{d}p/\mathrm{d}t)$ with the rate of disappearance of monomer given by the summation of the second order rates of reaction of monomer with each *other* molecular species, *i. e.*, with the summation $2k\sum_2^\infty N_1N_x$. $\partial N_1/\partial p$ and the concentrations, N_x, of each species were obtained from the distribution equations and substituted in each expression. The two expressions were compared and found to be somewhat different. In the above summation, however, they have omitted the term $2kN_1^2$, which arises from reaction of monomer with monomer. If this term is included, as it obviously should be, the two expressions are found to be identical. In a second similar attempt they have compared the second order rate of change in x-mer concentration given by $\mathrm{d}N_x/\mathrm{d}t = (\partial N_x/\partial p)(\mathrm{d}p/\mathrm{d}t)$ with the rate given by

$$k\sum_{y=1}^{y=x-1} N_yN_{x-y} - 2k\sum_{z\neq x} N_zN_x$$

In the second summation above the term $2kN_x^2$ should not have been excluded, for this term expresses the rate of disappearance of x-mer through reaction with another x-mer. The omission of this term caused Dostal and Raff to obtain nonidentical expressions.

As a result of these errors in setting up the summations, Dostal and Raff were led to the fallacious conclusion that the distribution equations are approximate in character. The distribution equations have been derived without introducing approximations beyond the basic assumption of equal reactivity of all functional groups.

Summary

Using the data of Dostal and Raff, it has been shown that the ethylene glycol–succinic acid polymerization is predominantly a trimolecular process. The rate of the reaction, which is simply an esterification, is proportional to the first power of the concentration of hydroxyl groups and to the square of the carboxyl group concentration. The activation energy for the reaction is about 25 kcal.

---

(12) Dostal and Raff at the time they published their paper did not have at their disposal the complete account of the work on size distributions, but only a brief preliminary account included in a paper presented by Carothers [*Trans. Faraday Soc.*, **32**, 39 (1936)] before the Faraday Society, September, 1935.

A number of erroneous conclusions in Dostal and Raff's paper have been pointed out. The relation of the previously published molecular size distribution equations to kinetic problems has been discussed.

Organic Reactions with Boron Fluoride.[1] XIII. The Alkylation of Benzene with Alcohols

BY JAMES F. McKENNA AND FRANK J. SOWA

Sulfuric acid[2] and aluminum chloride[3,4] have been used to accomplish the condensation of alcohols with benzene.

It was the purpose of this investigation to treat benzene with various alcohols in the presence of boron fluoride. An attempt was also made to determine the course of the reaction by subjecting primary, secondary and tertiary alcohols to the same treatment.

The reaction of alcohols with benzene might proceed by the direct elimination of water from the hydroxyl group of the alcohol and the hydrogen of the aromatic ring (see equation I below) or by first dehydrating the alcohol to an unsaturated compound with subsequent condensation into the aromatic nucleus (equations II and III).

$$CH_3(CH_2)_3\boxed{OH + H}C_6H_5 \longrightarrow CH_3(CH_2)_3C_6H_5 + H_2O \quad \text{I}$$

$$CH_3CH_2CH_2CH_2OH \longrightarrow CH_3CH_2CH{=}CH_2 + H_2O \quad \text{II}$$

$$CH_3CH_2CH{=}CH_2 + C_6H_6 \longrightarrow CH_3CH_2CH(CH_3)C_6H_5 \quad \text{III}$$

Both *n*-propyl and isopropyl alcohols reacted with benzene to give identical alkylation products, namely: mono-, di-, and tri-isopropylbenzenes. Likewise *n*-butyl and *s*-butyl alcohol both yielded *s*-butylbenzene derivatives. Both isobutyl and *t*-butyl alcohols gave *t*-butylbenzene derivatives.

Since neither *n*-propyl, *n*-butyl nor isobutylbenzenes were isolated from the corresponding primary alcohols, the reaction did not take place to any appreciable extent according to equation (I). The direct elimination of water from the hydroxyl of the alcohol and the hydrogen of the aromatic nucleus therefore does not suggest itself as a plausible mechanism. On the other hand, however, the products of alkylation of benzene with alcohols all indicated that an unsaturated compound was first formed with subsequent condensation into the aromatic nucleus. It is, therefore, proposed that the mechanism of the reaction of benzene with an alcohol is first by dehydration to an unsaturated compound with subsequent condensation of the olefin with benzene according to equations (II) and (III).

Other alcohols besides the *n*-propyl, isopropyl, *n*-butyl, *s*-butyl and *t*-butyl were treated with benzene in the presence of boron fluoride. Cyclohexanol gave mono- and dicyclohexylbenzene; benzyl alcohol yielded mono- and dibenzylbenzene; allyl alcohol gave a small quantity of allylbenzene with a much larger quantity of light brown, high boiling material.

The disubstituted benzenes were the para derivatives with very small quantities of the ortho compounds. The positions were determined by oxidation. Sulfuric acid and boron fluoride both gave the para-substituted dialkylbenzene as the main product with a little ortho and no meta dialkylbenzene. When aluminum chloride is used, as an alkylation agent, in the Friedel–Crafts reaction, however, the main product is most often the meta dialkylbenzene.

The *t*-butyl, benzyl, cyclohexyl, allyl, *s*-butyl and isobutyl alcohols reacted very readily with benzene in the presence of boron fluoride while *n*-propyl and *n*-butyl reacted with more difficulty. Ethylene chlorohydrin reacted only very slightly to give a halogenated compound the structure of which was not determined. Phenol, as would be expected, did not react with benzene. Methyl and ethyl alcohols did not react under the conditions used in this investigation.

Experimental Part

Since the procedure was quite uniform for all of the reactions, only a general one will be described.

One mole of either *n*-propyl, isopropyl, *n*-butyl, *s*-butyl, isobutyl, *t*-butyl, benzyl, cyclohexyl or allyl alcohol and one mole of benzene were weighed into a 500-cc. Erlenmeyer flask which was fitted with an inlet tube that extended to within 2 cm. of the bottom and an outlet tube. Boron fluoride was then added, the quantity varied from 20 to 65 g. depending upon the alcohol used. For *t*-butyl alcohol only 20 g. of boron fluoride was necessary and two layers appeared during the addition while *n*-butyl alcohol required 63 g. of boron fluoride and was heated at 60° for a period of nine hours in a closed Pyrex bottle. The most common quantity was 47 g. of boron fluoride; if two layers had not separated after standing overnight it was warmed.

After the reaction mixture was cooled the lower layer was separated and proved to be water, hydroxyfluoboric acid (b. p. 160°) and hydrofluoric acid. The upper layer was washed several times with 75-cc. portions of a 10% solution of sodium hydroxide, then water, dried over calcium chloride, and carefully fractionated through a Widmer column.

TABLE I

ALKYLBENZENES FROM ALCOHOL AND BENZENE

Alcohols used	Nature of alkyl group in benzene	Yield of alkylbenzenes, g. Mono	Di	Poly
n-Propyl	Isopropyl	23.5	14.2	17.6
i-Propyl	Isopropyl	24.4	13.0	10.0
n-Butyl	*s*-Butyl	42.5	21.0	20.0
s-Butyl	*s*-Butyl	35.9	16.9	14.6
i-Butyl	*t*-Butyl	16.2	8.9	21.2
t-Butyl	*t*-Butyl	32.0	21.8	10.1
Cyclohexyl	Cyclohexyl	56.2	27.4	6.4
Benzyl	Benzyl	23.2	15.1	34.0 (Above 250° at 15 mm.)
Allyl	Allyl	8.7	31.1 (Above 165°)	

TABLE II

PHYSICAL PROPERTIES OF ALKYLBENZENES

Alkylbenzene	B. p., °C.	n_D^{25}	Sp. gr., 25°
n-Propylbenzene	157	1.4925	0.8656
i-Propylbenzene	151	1.4885	.8581
Diisopropylbenzene	204	1.4892	.8550
s-Butylbenzene	171	1.4880	.8577
s-Dibutylbenzene	237	1.4880	.8548
t-Butylbenzene	167	1.4905	.8623
t-Dibutylbenzene	M. p. 77°		
Cyclohexylbenzene	235	1.5190	.9338
Dicyclohexylbenzene	M. p. 100–102°		
Benzylbenzene	261	1.5697	1.0043
Dibenzylbenzene	M. p. 84–85°		
Allylbenzene	156–159	1.5042	0.8812

The results of several runs are given in Table I and the physical properties are tabulated in Table II.

Oxidation of Dialkylbenzenes.—In order to determine the position of the alkyl group in the dialkylbenzenes, oxidation of the side chains to well-known benzene derivatives was used. The phthalic acids or their methyl esters differ widely in melting points.

Several methods of oxidation of diisopropylbenzene were tried but the only successful method was by the use of dilute nitric acid.

Two grams of diisopropylbenzene was refluxed with 300 cc. of 25% nitric acid for twenty hours. An 85% yield of a phthalic acid was obtained. After recrystallization from hot water and drying the acid sublimed without melting above 300°, indicating terephthalic acid. This acid was heated with absolute methyl alcohol in the presence of hydrogen chloride. On cooling a mass of white crystals separated in the form of thin plates. The crystals melted at 140°, which checks with the dimethyl ester of terephthalic acid. No metaphthalic ester could be detected. A separate sample of the acid was tested for ortho phthalic acid by conversion to fluorescein. The test indicated the presence of the ortho isomer but in very small quantity.

The structure of *p*-*s*-dibutylbenzene and of *p*-*t*-dibutylbenzene was best determined by oxidation with chromic acid in acetic acid solution.

The structures of most of the other para dialkylbenzenes have been determined previously and the physical properties of the compounds in this investigation checked well with them.

Summary

Benzene has been alkylated by normal and iso as well as secondary and tertiary alcohols in the presence of boron fluoride.

Normal and secondary alcohols give identical products; iso- and *t*-alcohols also give identical alkylation products.

A mechanism for the alkylation of benzene with alcohols has been proposed.

Boron fluoride, in general, gives different dialkylbenzenes than aluminum chloride, as the main product, when used as an alkylating agent.

The ease of reaction has been found to be dependent upon the ease of dehydration of the alcohol.

The Kinetics of the Thermal Isomerization of Cinnamic Acid Catalyzed by Iodine

BY ROSCOE G. DICKINSON AND H. LOTZKAR

It is well known that *cis–trans* isomerizations at ethylenic linkages can be catalyzed by various substances including iodine,[1] but the kinetics of this iodine catalysis have received comparatively little attention. The kinetics of the iodine-sensitized photochemical conversion of *cis*- into *trans*-cinnamic acid have been examined in benzene solution by Berthoud and Urech,[2] whose results are interpretable in terms of an iodine-atom catalysis. The results of the present thermal experiments likewise carried out in benzene solution indicate a close relation between the photochemical and thermal reactions.

Materials.—*cis*-Cinnamic acid was prepared by the reduction of phenylpropiolic acid by hydrogen using colloidal palladium as a catalyst; the method was essentially that of Paal and Hartmann.[3] The phenylpropiolic acid was prepared through the bromination of ethyl cinnamate and subsequent treatment with alcoholic potash; the procedures were those described in "Organic Syntheses,"[4] and the yields reported there were obtained. The colloidal palladium used in the reduction of the phenylpropiolic acid was prepared by the reduction of palladous chloride by hydrogen in aqueous solution in the presence of sodium protalbinate.[5] To effect the reduction of phenylpropiolic acid, the colloidal palladium protected by protalbinate was added to sodium phenylpropionate in somewhat alkaline solution. The solution was placed in a 200-cc. flask connected with a gas buret; the flask was evacuated and one mol of hydrogen added for each mol of phenylpropionate taken. After reduction, the solution was acidified, whereupon the *cis*-cinnamic acid separated as an oil. This was extracted with ether, treated with sodium carbonate and reprecipitated as oil with acid. In one preparation the oil was converted to the aniline salt and crystallized from a ligroin and benzene mixture.[6] The *cis*-cinnamic acid was then liberated with hydrochloric acid and recrystallized from water. In a second preparation, the formation of an aniline salt was omitted. The oil was frozen repeatedly using solid carbon dioxide, whereupon the oil crystallized. It was then twice recrystallized from water. The melting point of the first preparation was from 48 to 53°; that of the second was from 58 to 65°. Both preparations were evidently mixtures of *cis*-cinnamic acids for both gave the same equivalent conductance, 73.3, in 0.003 M solution at 25°. Values obtained by other observers are: Bjerrum, 72.5;[7] Vaidya, 74;[8] Olson and Hudson, 72.8.[9]

The *trans*-cinnamic acid was an Eastman product recrystallized from hot water.

The water was commercial distilled water redistilled from alkaline permanganate. The specific conductance of the water at 25° was 1.0×10^{-6} mho cm.$^{-1}$.

Thiophene-free benzene was used.

The iodine was a Merck product.

Analytical Method.—Conductance measurements were employed to determine the fraction of *cis*-cinnamic acid in mixtures of *cis*-cinnamic acid with *trans*-cinnamic acid. For this purpose the specific conductances of a series of known mixtures of the two acids were measured in 0.003 volume molal solution at 25°. The results are given in Table I.

TABLE I

SPECIFIC CONDUCTANCES AT 25° OF MIXTURES OF *cis*- AND *trans*-CINNAMIC ACIDS AT 0.003 M

% *cis*-acid	100	90.0	80.0	70.0	60.0	50.0	40.0	30.0	20.0	10.0	0
$\bar{L} \times 10^4$	2.200	2.108	2.025	1.934	1.838	1.743	1.641	1.537	1.421	1.307	1.188

These conductivities were plotted on a large scale and a smooth curve drawn. The cell constant used in these measurements was obtained from measurements on 0.001 N potassium chloride solution using Shedlovsky's value, 146.93, for the equivalent conductance at 25°.[10]

Experimental Procedure.—Stock solutions with appropriate known concentrations of *cis*-cinnamic acid and of iodine in benzene were prepared. In carrying out an experiment, 5.00 cc. of cinnamic acid solution and 5.00 cc. of iodine solution were pipetted into a 15-cc. ampoule and sealed off with the exclusion of light. The ampoule was then placed for a measured period of time in a light-tight chamber surrounded by the vapor of a boiling liquid (water was used in some experiments and methylcellosolve in others); in any one experiment the temperature range was less than 0.1°. The ampoule was then removed, cooled with water, opened and the contents transferred to a flask. The benzene and iodine were then pumped off at room temperature. These manipulations were carried out in red light or in the dark. The colorless residue of cinnamic acids (whose weight was presumed to be that of the *cis*-cinnamic acid taken) was dissolved in such a quantity of water as to give a 0.00300 M solution. The conductivity of the solution was then measured in a thermostat at 25°.

12	.03	.024	122.6	6.5	1.602	63.8	1.011	1.003
13	.09	.0015	122.7	8	1.964	26.7	1.002	0.988
14	.09	.006	122.8	10	1.716	52.5	0.960	.935
15	.09	.024	122.4	6.5	1.639	60.1	.910	.920

When a blank experiment was made by evaporating 20 cc. of benzene alone and any residue dissolved in 100 cc. of water, the specific conductance of the water changed from 1.0 × 10^{-6} to 1.3 × 10^{-6} mho cm.$^{-1}$. The analytical conductivity measurements were corrected for this change. Blank experiments in which iodine was heated with benzene in the absence of cinnamic acid, gave no more conductivity change than the benzene above. A blank experiment was made in which a benzene solution 0.03 *M* (volume molal) in cinnamic acid and 0.0015 *M* in iodine was prepared and immediately analyzed without heating; the conductivity of the resulting 0.003 *M* aqueous solution was 0.0002191 (corrected) in satisfactory agreement with the value 0.0002200 expected for pure *cis*-cinnamic acid.

A series of experiments was made starting with *trans*-cinnamic acid. In one of these a benzene solution 0.03 *M* in *trans*-cinnamic acid and 0.0015 *M* in iodine was heated for ninety-one hours at 99.4°. In no case did the measured conductivity differ significantly from that expected for pure *trans*-cinnamic acid; accordingly, in interpreting measurements of the *cis–trans* conversion, reverse reaction has been regarded as negligible.

Experimental Results.—The kinetic measurements are given in Table II. The initial concentrations given are in moles per 1000 cc. at 22°; the *k*'s given in the table are calculated in terms of these concentrations from the equation:

$$k = \frac{1}{t(\mathrm{I_2})^{1/2}} \ln \frac{(C)_0}{(C)}$$

where (C) is the concentration of *cis*-cinnamic acid. This equation arises from integration of the equation $-\mathrm{d}(C)/\mathrm{d}t = k(C)\ (\mathrm{I_2})^{1/2}$. Since the temperatures obtained with methylcellosolve varied somewhat from one experiment to another, the rate constants measured using it have been reduced to the temperature 122.5° by means of the Arrhenius equation.

In the tabulated experiments, the initial concentration of *cis*-cinnamic acid has been varied three-fold, and the iodine concentration sixteen-fold; at the upper temperature the ratio of *trans*- to *cis*-acid present at the end of an experiment varied from 0.37 in expt. 13 to 3.0 in expt. 6. In all of these experiments except those (nos. 4, 14, 15) where the concentrations of both acid and iodine were comparatively high, constancy of *k* within probable experimental error was found. The somewhat lower values of *k* found at the highest concentrations are possibly attributable to addition of I_2 to the double bond of cinnamic acid. Dissociation constants of the order of 0.5 mole/liter for the assumed di-iodo compounds would suffice to account for this apparent trend.

The mean values of the constants obtained with the lower cinnamic acid concentration (0.03 *M*) are 0.150 at 99.4° and 1.013 at 122.5° the units being moles, liters at 22° and hours. When the units used are moles, cc. at the temperature of the reaction and seconds, these constants become 1.39 × 10^{-3} at 99.4°, and 9.59 × 10^{-3} mole$^{-1/2}$ cc.$^{1/2}$ sec.$^{-1}$ at 122.5°. Between these temperatures, the ten-degree multiplication of the constant is accordingly 2.28.

Discussion.—The fact that the thermal reaction is of one-half order with respect to I_2 suggests that the catalytic agent is atomic iodine just as in the photochemical reaction.[2] A reaction scheme which then leads to the type of rate expression found experimentally is the following

$$\begin{array}{rll} I_2 \rightleftharpoons 2I & (1) \text{ and } (1') \\ I + C \rightleftharpoons AI & (2) \text{ and } (2') \\ AI \rightleftharpoons BI & (3) \text{ and } (3') \\ BI \rightleftharpoons T + I & (4) \text{ and } (4') \end{array}$$

Here C and T represent *cis*- and *trans*-cinnamic acid; AI and BI represent the molecules resulting from the addition of an iodine atom to these two respective acids. The reversal of all steps has been included in order explicitly to avoid possible conflict with the principle of microscopic reversibility. In order for a conversion of one isomer into the other to occur, in effect a rotation about the ethylenic bond is necessary; this presumably occurs after the addition of the iodine atom. Furthermore, an odd number of inversions of carbon tetrahedra is necessary if a tetrahedral character be attributed to both the ethylenic carbons in the iodine atom addition compound. Whether such inversions occur in the acts of addition and removal of the iodine atom as well as in reactions (3) and (3′), or whether inversion occurs only in reactions (3) and (3′), cannot be decided from the present experiments; nor can these possibilities be distinguished from the case where tetrahedral character is not ascribed to both carbons of the compounds AI and BI so that inversion becomes unnecessary. This latter case is covered in the rate expression given below if k_3 be placed equal to $k_{3'}$ and made very large. The usual treatment of the reaction scheme given above leads, on the assumption that I, AI and BI remain at low concentration, to the following rate expression

$$-\frac{d(C)}{dt} = \sqrt{\frac{k_1}{k_{1'}}(I_2)}\;\frac{k_2k_3k_4\,(C) - k_{2'}k_{3'}k_{4'}\,(T)}{k_{2'}k_{3'} + k_{2'}k_4 + k_3k_4}$$

Evidently k_1/k_1' is the dissociation constant of iodine into atoms, and $k_2k_3k_4/k_{2'}k_{3'}k_{4'}$ is the equilibrium constant for the transformation of *cis*- into *trans*-cinnamic acid. Since, in experiments starting with *trans*-cinnamic acid, any isomerization was small, the term in (T) may, for purposes of the experiments of Table II, be dropped. This leaves a rate expression of the form of that found empirically, *viz.*, $-d(C)/dt = k(C)(I_2)^{1/2}$ with $k = \sqrt{\frac{k_1}{k_{1'}}}\,\frac{k_2k_3k_4}{k_{2'}k_{3'} + k_{2'}k_4 + k_3k_4}$.

The local rate (thin layer) of the photochemical conversion is reported to be given by the[2] expression $-d(C)/dt = k_{Ph}I_0^{1/2}(I_2)^{1/2}(C)$ where I_0 is the radiation incident per unit area per unit time. Assuming the photochemical reaction to proceed by the same mechanism as the thermal except for replacement of step (1) by $I_2 + h\nu \longrightarrow 2I$, it is readily seen that $k/k_{Ph} = \sqrt{k_1/\alpha}$, where α is the molal absorption coefficient of iodine for the wave length used. On the assumption that α varies relatively little with temperature it follows that at a given temperature $d \ln k/dT - d \ln k_{Ph}/dT = {}^1/_2 d \ln k_1/dT$. The multiplication of the photochemical rate between 25 and 35° at constant concentrations and intensity is given as 1.3. From this the over-all activation energy of the photochemical reaction may be calculated from the Arrhenius equation $d \ln k_{Ph}/dT = Q_{Ph}/RT^2$ treating Q_{Ph} as constant with temperature; the value obtained is 4800 cal. Similarly, for the thermal reaction the Q obtained is 24,200 cal. Hence, for reaction (1), $Q_1 = 2(24{,}200 - 4800) = 38{,}800$ cal. There is evidence[11] that reaction (1′) goes at every kinetic theory collision and accordingly requires no activation energy. If this be the case, Q_1 should equal ΔH for the dissociation of molecular iodine in benzene solution. The value of ΔH for the dissociation of gaseous iodine at 18° obtained with the aid of spectroscopic data[12] is 36,270 cal./mole. Since heats of solution of gases in non-polar solvents often amount to several thousand calories[13] extremely close agreement between the dissociation energies in solution and gas is not to be expected. The reasonably close agreement found in the present case lends independent support to the supposition that the iodine catalysis is brought about by iodine atoms.

Summary

Rates of isomerization of *cis*- into *trans*-cinnamic acid as catalyzed by iodine have been measured in benzene solution at 99.4 and 122.5°. The rates have been found to be substantially of first order with respect to *cis*-cinnamic acid and half-order with respect to iodine. This result has been interpreted as indicating an iodine atom catalysis such as has been supposed to occur in the

[12] F. R. Bichowsky and F. D. Rossini, "The Thermochemistry of Chemical Substances," Reinhold Publishing Corp., New York, 1936, p. 189.

[13] For example, from the tabulations of Bichowsky and Rossini,[12] the following values for the heat content increase, ΔH, per mole on vaporization from various solutions at 18° may be obtained: I_2 from C_6H_6, 8910 cal.; Br_2 from CCl_4, 7150; Cl_2 from CCl_4, 4500; HCl from CCl_4, 3620; O_2 from H_2O, 3850; H_2 from H_2O, 1420. The value of ΔH for the vaporization of atomic iodine from benzene solution calculated from that for molecular iodine together with Q_1 and ΔH for the gaseous dissociation, is 3200 calories per atomic weight.

photochemical iodine-sensitized reaction. Comparison of the temperature coefficients of the thermal and photochemical reactions leads to a calculation of the energy of dissociation of iodine into atoms in benzene solution and gives further evidence in favor of the supposition of an iodine atom catalysis.

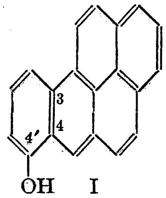
Hydroxy Derivatives of 3,4-Benzpyrene[1] and 1,2-Benzanthracene

BY L. F. FIESER, E. B. HERSHBERG,[2] L. LONG, JR., AND M. S. NEWMAN[3]

The study of hydroxy derivatives of carcinogenically active hydrocarbons was undertaken partly because it is of interest to determine the influence of hydroxyl and modified hydroxyl substituents on the cancer-producing properties of the hydrocarbons, and partly in the hope of broadening the field of biological experimentation. If suitable functional groups can be introduced without complete loss of carcinogenic activity, it should be possible to attach to the carcinogens side chains of such a character as to vary the solubility relations in different directions. Hydroxy compounds would be of further interest, as Cook and his associates[4] have observed, because polynuclear aromatic compounds arising in the body as products of the metabolism of steroids might be expected to appear in an hydroxylated form comparable with oestrone and equilenin.

From the information now available, the most potent of the known carcinogenic hydrocarbons can be classified as either 10-alkyl-1,2-benzanthracenes or as compounds containing the 1,2-benzanthracene ring system with a carbon substituent in the alternate meso position 9.[5] Methylcholanthrene, cholanthrene, 9,10-dimethyl-1,2-benzanthracene and 10-methyl-1,2-benzanthracene are the most powerful agents of the first type, while 3,4-benzpyrene is the most active representative of the second type of hydrocarbon. On the basis of this provisional classification, a systematic investigation has been undertaken to determine the influence of hydroxyl, amino and other groups at various positions on the carcinogenic properties of these hydrocarbons. The results presented in this paper are incidental observations which constitute a start in the direction indicated.

The synthesis of 4′-hydroxy-3,4-benzpyrene (I) was reported in a preliminary communication,[6]



I

and further details of the preparation of the compound and of various derivatives are given in this paper. The hydroxyl group of this compound occupies position 5 in the 1,2-benzanthracene ring system present in the molecule. Dr. M. J. Shear injected the crystalline hydroxy compound into mice and obtained no tumors at the site of injection after sixteen months. Negative results were obtained also with 4′-ketotetrahydro-3,4-benzpyrene, from which I is prepared by dehydrogenation. The action of 4′-methoxy-3,4-benzpyrene suggested that it may prove to be weakly carcinogenic, although it is too early to make a definite decision. Experiments with the acetate, benzoate, *p*-aminobenzoate, and carboxymethyl derivative are in progress.

Although 1,2-benzanthracene itself is almost completely devoid of cancer-producing properties,[7] the fact that some of the simple alkyl derivatives of the hydrocarbon are potent carcinogenic agents suggested the idea of testing samples of the 3-hydroxy and 3-methoxy compounds which were available from an earlier research

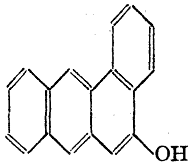
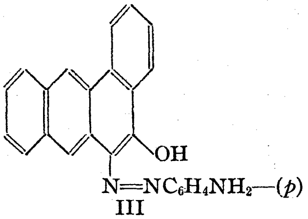
of one of us with Dietz.[8] As the preliminary tests of Dr. Shear gave interesting results, the experiments were repeated with fresh samples of the compounds and a few additional derivatives were prepared. 3-Hydroxy-1,2-benzanthracene (II) gave entirely negative results in one experiment with eleven mice, but in another experiment tumors were obtained at the site of injection in two of ten mice after eight months. These mice were males and the tumors were in immediate contact with injected material still present. 3-Methoxy-1,2-benzanthracene has given tumors at the site of injection in several animals and the tumors have been found to be transplantable. Both the hydroxy compound and the ether appear to have carcinogenic properties, although the action in each case is slow and irregular. No tumors have been obtained as yet with the benzoate (eight months) or stearate (six months). It is of interest that 9-methoxy-1,2,5,6-dibenzanthracene has been found to possess carcinogenic activity.[7]



II

In view of the discovery by Yoshida[9] that *o*-aminoazotoluene has carcinogenic properties, it seemed of interest to investigate the *p*-aminobenzeneazo derivative of 3-hydroxy-1,2-benzanthracene, III. A product presumably containing this compound was obtained in an amorphous condition by the alkaline hydrolysis of the crystalline acetate resulting from the coupling of the hydroxy compound with diazotized N-acetyl-*p*-phenylenediamine. Nitrogen-containing compounds are of further interest because of carcinogenic properties of 2-(*p*-aminostyryl)-6-(*p*-acetylaminobenzoylamino) - quinoline methoacetate,[10] because of the biological changes produced by 3,4,5,6-dibenzcarbazole,[4] and because of the indications that aromatic amines may be responsible for cases of bladder-cancer among workers engaged in the manufacture of dyestuff intermediates.[4] For this reason, 3-hydroxy-1,2-benzanthracene was converted into 3-amino- and 3-methylamino-1,2-benzanthracene by the Bucherer reaction, and tests with the compounds are now in progress.



III

Experimental Part[11]

4′ - Keto - 1′,2′,3′,4′ - tetrahydrobenzpyrene.—Sannié and Poremski[12] have pointed out that in preparing this ketone by the method very briefly described by Fieser and Fieser[13] it is advisable to employ carefully purified γ-3-pyrenylbutyric acid and to remove the excess thionyl chloride as completely as possible. These specifications were included in the original directions but they are properly emphasized. Although the acid should be of good quality (from xylene[13]), purification through the ester[14] is not necessary. The importance of carefully eliminating the excess thionyl chloride was established by adding some of the reagent to one of two portions of a satisfactory sample of the acid chloride in carbon bisulfide solution. On subsequently adding stannic chloride, a copious black precipitate separated at once and the final product was of an inferior grade. In the parallel test there was very little immediate precipitation of black material and the bright purple-red complex slowly formed. It is important to avoid overheating the acid chloride during the preparation. The reaction of the acid with thionyl chloride can be hastened safely by warming the mixture in a water-bath maintained at 40°, and in removing the ether at reduced pressure this bath temperature should not be exceeded or the material may be spoiled. The first evaporation leaves a yellow oil which largely solidifies on adding fresh ether. On removing the solvent again and distributing the product over the walls of the flask, the acid chloride forms a hard, nearly colorless cake streaked in places with yellow. After evaporating fresh portions of ether and of carbon bisulfide, the yellow streaks disappear and the product is obtained as a light gray solid, m. p. 76–77°. The cyclization can be conducted satisfactorily at 25°, followed by refluxing. On using four times the amount of stannic chloride specified, the yield of ketone dropped to 46–49%. Water may be used at the end of the reaction in place of ice and, as the red complex is unusually stable, steaming should be continued for some time. The crude ketone, which has been obtained repeatedly in a good condition in 80–85% yield, can be purified by distillation in vacuum or, very satisfactorily, by crystallization from dioxane. The purest sample obtained melted at 174–174.5°.

4′-Hydroxy-3,4-benzpyrene.—The best results were obtained by heating a mixture of 2 g. of the pure ketone (from dioxane) and 0.24 g. of sulfur at 210–215° for seventy to

eighty minutes, distilling the product at reduced pressure, and crystallizing the distillate from xylene; yield, 0.6 g. (30%), m. p. 216–218°. Recrystallized from xylene, the substance formed yellow needles with a bronze luster, m. p. 218–219°.

The **acetate**, prepared by refluxing the hydroxy compound with acetic anhydride and sodium acetate for two hours, was crystallized from acetic acid and then from absolute alcohol. It formed small, yellow needles, m. p. 194–195°.

Anal. Calcd. for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55. Found: C, 84.75; H, 4.77.

The **benzoate** was obtained with the use of benzoyl chloride and pyridine (two hours on the steam bath) and crystallized from benzene–absolute alcohol; flat yellow needles, m. p. 191–192°.

Anal. Calcd. for $C_{27}H_{16}O_2$: C, 87.07; H, 4.33. Found: C, 86.74; H, 4.71.

For the preparation of the **methyl ether,** 0.3 g. of the hydroxy compound was dissolved in a solution of 1 g. of potassium hydroxide in 20 cc. of 50% alcohol and treated in the cold with 2 cc. of dimethyl sulfate. After adding more alkali and more reagent, the ether (0.28 g.) was precipitated with water and crystallized from benzene–absolute alcohol. It formed pale yellow-orange, flat prisms, m. p. 183–184°.

Anal. Calcd. for $C_{21}H_{14}O$: C, 89.33; H, 5.00. Found: C, 89.38; H, 5.14.

The **carboxymethyl derivative** was obtained by the action of excess chloroacetic acid on hydroxybenzpyrene dissolved in aqueous potassium hydroxide and dioxane under varying conditions, but the yield at best was only about 30%. The crude material obtained on acidification of the solution was dried and dissolved in acetone. Benzene was added, and after removing most of the acetone by distillation the product separated as rosets of fine, yellow needles, m. p. 243–244°.

Anal. Calcd. for $C_{21}H_{14}O_3$: C, 80.23; H, 4.52. Found: C, 79.97; H, 4.12.

The ***p*-nitrobenzoate,** prepared as above, crystallized from benzene–ligroin as shiny brown needles, m. p. 252–253°.

Anal. Calcd. for $C_{27}H_{15}O_4N$: C, 77.68; H, 3.62. Found: C, 77.85; H, 3.57.

The ***p*-aminobenzoate** was obtained in excellent yield by the hydrogenation of the nitro compound in warm dioxane solution using Adams catalyst. When the color of the solution had changed from yellow-orange to pale yellow-green, the filtered solution was diluted with water and the crystalline precipitate was crystallized from dioxane–alcohol. The amine formed pale yellow needles, m. p. 268–269°.

3-Methoxy-1,2-benzanthracene.—The reduction of crude 3-methoxy-1,2-benz-10-anthrone with aluminum amalgam and alcoholic ammonia was reported by Fieser and Dietz[8] to give somewhat irregular results, the yields varying from 25 to 65%. The reaction seems to be particularly sensitive to the nature of the aluminum metal, and in the present work we had little success using the aluminum turnings on hand and only slightly better results with aluminum foil. A more reliable method of reduction was found in the use of activated zinc dust, sodium hydroxide, and toluene.[15]

Fifty grams of zinc dust was shaken with a solution of 2.5 g. of copper sulfate in 100 cc. of water and the supernatant liquor was decanted. The crude anthrone from 20 g. of 4-methoxy-1-naphthylphenylmethane-2′-carboxylic acid was added, together with 800 cc. of 1 *N* sodium hydroxide solution and 300 cc. of toluene. In some experiments the anthrone was employed in the moist condition originally obtained;[8] in others the moist material was suspended in water, the acid present was neutralized with ammonia and the product was collected and dried before use in the reduction. The reaction mixture was boiled under reflux for eight hours, during which time the aqueous layer changed in color from dark brown to red to red-brown while the toluene layer remained yellow. The liquor was filtered hot into a separatory funnel and a separation was made at once. The toluene solution deposited nearly colorless needles of 3-methoxy-1,2-benzanthracene, and additional material was obtained from the mother liquor, which was combined with benzene extracts of the aqueous layer and of the zinc residue. The total yield of material of average melting point 160–161°, uncorr., was 11 g. (63%). Repeated crystallization from glacial acetic acid gave colorless needles, m. p. 167–168°.

3-Hydroxy-1,2-benzanthracene Benzoate.—The hydroxy compound, prepared according to Fieser and Dietz,[8] was heated with benzoyl chloride in pyridine solution at the boiling point for a few minutes. On dilution with water and cooling, the benzoate separated as long, pale yellow needles. Recrystallization from alcohol gave long, colorless needles, m. p. 174–174.5°; it is readily soluble in dioxane, moderately so in benzene, sparingly soluble in alcohol.

Anal. Calcd. for $C_{25}H_{16}O_2$: C, 86.24; H, 4.63. Found: C, 85.82; H, 4.94.

3-Hydroxy-1,2-benzanthracene Stearate.—A solution of 0.5 g. of hydroxybenzanthracene and 0.8 g. of stearyl chloride (from the acid with thionyl chloride, b. p. 179–182° at 4 mm.) in 5 cc. of dry pyridine was heated for two hours on the steam bath and cooled. On adding 5–6 drops of 0.5 *N* potassium hydroxide solution, an amorphous white precipitate separated. Washed with 50% pyridine solution and dried, the crude material (1.2 g.) melted at 72–78°. After digestion with small portions of methanol, in which the substance is only moderately soluble, the bulk of the material was crystallized from this solvent and obtained as small, colorless needles, m. p. 87–89° (0.5 g.). The melting point was not changed on further crystallization.

Anal. Calcd. for $C_{36}H_{46}O_2$: C, 84.65; H, 9.09. Found: C, 84.33; H, 8.84.

Carboxymethyl Derivative of 3-Hydroxy-1,2-benzanthracene.—A mixture of 0.5 g. of hydroxybenzanthracene, 1.8 cc. of 33% aqueous sodium hydroxide solution, 2 cc. of dioxane, and 2 cc. of water was warmed until solution was complete, cooled (two layers), treated with 1.3 cc. of 50% aqueous chloroacetic acid solution and heated at 100° for three hours. The solution was diluted with water,

---

(15) Martin, THIS JOURNAL, 58, 1438 (1936).

made acid to Congo red paper and the product was extracted with ether, taken into dilute soda solution and precipitated by acidification. Crystallization from toluene, using decolorizing carbon, gave colorless needles, m. p. 216–217°.

Anal. Calcd. for $C_{20}H_{14}O_3$: C, 79.20; H, 4.99. Found: C, 78.93; H, 4.89.

4 - *p* - Acetaminobenzeneazo - 3 - hydroxy - 1,2 - benzanthracene.—A solution of 0.615 g. of N-acetyl-*p*-phenylenediamine, prepared according to Nietzki,[16] and purified by vacuum distillation and crystallization from water, in 5.1 cc. of glacial acetic acid was treated with 0.4 cc. of concentrated sulfuric acid, which precipitated the sulfate, cooled to 17°, and treated slowly with 1.2 cc. of ice-cold isopropyl nitrite. To the resulting red solution 20 cc. of absolute ether was added, which precipitated the diazonium salt as an oil. After decanting the cloudy liquid, the oil was dissolved in 5 cc. of glacial acetic acid and on adding ether the diazonium salt was precipitated in a crystalline, somewhat pink, condition. The salt, suspended in 10 cc. of glacial acetic acid (in which the crystalline material is sparingly soluble) was added to a mechanically stirred solution of 0.5 g. of 3-hydroxy-1,2-benzanthracene in 47 cc. of glacial acetic acid at 17°. A deep red suspension of the azo compound was soon obtained, and after stirring for one and one-half hours the mixture was diluted with 50 cc. of water, stirred for fifteen minutes, and the product was collected. The crude azo compound melted at 275–279°, uncorr.; yield 0.72 g. (95%). Crystallized from a large volume of benzene, the substance formed small, lustrous red needles, m. p. 278–279°, uncorr. It is sparingly soluble in all ordinary solvents.

Anal. Calcd. for $C_{26}H_{19}O_2N_3$: C, 77.00; H, 4.73. Found: C, 77.10; H, 4.50.

4 - *p* - Aminobenzeneazo - 3 - hydroxy - 1,2 - benzanthracene.—The hydrolysis of the acetate presented difficulties and the amine was not obtained in a completely pure condition. Of a number of methods of hydrolysis with acids and alkalies investigated, the following was the most satisfactory. The acetate (1.4 g.) was refluxed with 420 cc. of a 10% solution of potassium hydroxide in absolute alcohol for nineteen hours and the hot solution was filtered from a small amount of brown residue and diluted with 300 cc. of hot water. The material which separated on cooling was washed with 50% alcohol, and then washed with water until free from alkali. The amine was obtained in this way as an amorphous, deep brownish-purple powder melting at 211–213°, uncorr.; yield 0.54 g. (43%). It is practically insoluble in all solvents tried except pyridine, and it did not crystallize from the solvent. Analyses of the amorphous material indicated the presence of impurities (Calcd. for $C_{24}H_{17}ON_3$: C, 79.3; H, 4.7; N, 11.6. Found: C, 80.5; H, 5.2; N, 9.2).

3-Amino-1,2-benzanthracene.—A mixture of 1 g. of 3-hydroxy-1,2-benzanthracene, 5 g. of sodium bisulfite in 10 cc. of water, 10 cc. of concentrated ammonia solution, and 5 cc. of dioxane was heated in a sealed tube at 180–190° for ten hours. After dilution with water, the crystalline product was collected, dried and crystallized from absolute alcohol; yield 0.65 g. (65%), m. p. 209–210°. After further crystallizations the substance formed fan-shaped clusters of yellow needles, m. p. 211.5–212.5°. The amine is very slightly soluble in hot, dilute hydrochloric acid.

Anal. Calcd. for $C_{18}H_{13}N$: N, 5.76. Found: N, 5.86.

3 - Methylamino - 1,2 - benzanthracene.—This derivative was prepared exactly as described above except that 33% aqueous methylamine solution was substituted for the ammonia solution; the yield of pure material was 38%. Crystallized from alcohol, in which it is much more soluble than the primary amine, the compound formed rosets of short, flat, yellow needles, m. p. 115.5–116.5°.

Anal. Calcd. for $C_{19}H_{15}N$: N, 5.45. Found: N, 5.73.

Summary

The preparation of various functional derivatives of 4′-hydroxy-3,4-benzpyrene and of 3-hydroxy-1,2-benzanthracene is described and it is reported that 3-hydroxy- and 3-methoxy-1,2-benzanthracene have weak carcinogenic properties.

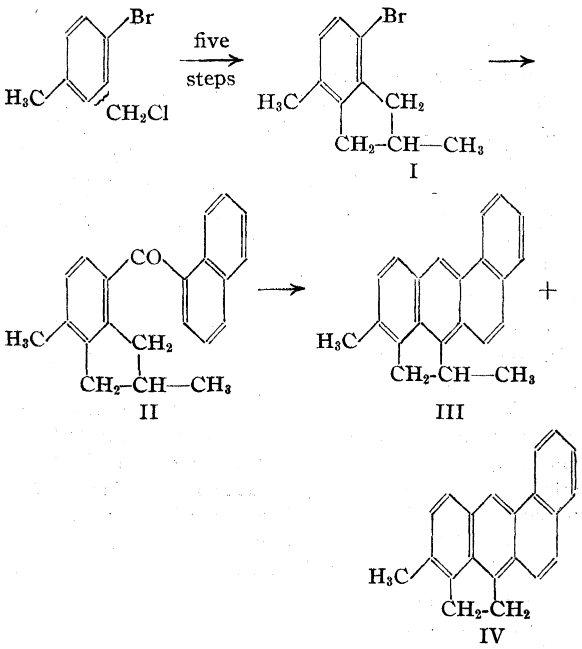
Carcinogenic Hydrocarbons. I. 15,20-Dimethylcholanthrene[1]

BY W. F. BRUCE WITH L. F. FIESER

In order to study the effect of optical isomerism on carcinogenic potency, hydrocarbons related to the active carcinogenic agents cholanthrene and methylcholanthrene and possessing also a center of asymmetry are being synthesized and tested biologically. The synthesis of 16,20-dimethylcholanthrene was accomplished by Fieser and Seligman,[2] but Shear has found[3] that the average time of the appearance of tumors following the injection of the hydrocarbon into mice is about seven and one-half months, as compared with about two and one-half months for 20-methylcholanthrene. In view of this surprising increase in the time required for the appearance of tumors as a result of the added methyl group at C_{16}, it seemed desirable to investigate the effect of a methyl group in the alternate position of the five-membered ring, and consequently the synthesis of 15,20-dimethylcholanthrene (III) was undertaken.

The synthesis was accomplished using the general method of the methylcholanthrene synthesis[4] and utilizing in the initial steps a process which has been described by Bachmann, Cook, Hewett and Iball[5] in a paper published since the completion of this part of the present work. The mixture of isomers resulting from the chloromethylation of *p*-bromotoluene[4] was condensed with ethyl methylmalonate and the product was hydrolyzed, decarboxylated, and cyclized to a mixture of dimethylbromohydrindones. On Clemmensen reduction the mixture yielded pure 2,7-dimethyl-4-bromohydrindene (I). From the Grignard reagent of I with α-naphthoyl chloride, the ketone II was obtained, and on pyrolysis it yielded a mixture from which the desired hydrocarbon (III) was separated in an apparently pure condition.

After three crystallizations from propyl alcohol the substance melted at 134–136°, a value which was not changed by another crystallization.



This material was secured in very small yield; the principal part of the hydrocarbon from the pyrolysis was methylcholanthrene (IV), the formation of which involved loss of the methyl group on the carbon adjacent to the point of ring closure. This series of reactions is unsuitable for the production in quantity of either methylcholanthrene or 15,20-dimethylcholanthrene.

Experimental Part[6]

2,7-Dimethyl-4-bromohydrindone.—Since our preparation of 2,7-dimethyl-4-bromohydrindone was anticipated by Bachmann, Cook, Hewett and Iball, the steps leading to this substance may be summarized briefly. From a mixture of 2- and 3-chloromethyl-4-bromotoluenes[3] a mixture of the corresponding diethyl methylbromobenzylmethylmalonic esters was prepared (yield 83.6%, b. p. 168–170° at 1.6 mm.) and from it by hydrolysis with potassium hydroxide and acidification the malonic acid mixture (yield 95%, m. p. 163–165°, dec.) was obtained. The malonic acid mixture was decarboxylated at 170°, giving the propionic acid mixture (yield 98%, m. p. 74–76°) which was converted through the acid chloride to a mixture of hydrindones boiling at 121–142° at 1.5 mm. (yield 95%). The mixture (d^{30}_{30} 1.27) on distillation was separated rather sharply into two fractions of which one, comprising 20% of the total, boiled at 125° (1.5 mm.) and the other at 145° (1.5 mm.). The lower boiling portion ap-

(6) Semimicroanalyses by E. L. Martin and R. G. Larsen; microanalyses by W. F. Bruce.

pears to be the 2,7-dimethyl-4-bromohydrindone (b. p. 115–117° at 0.15 mm.) of Bachmann, Cook, Hewett and Iball, for like theirs it failed to crystallize. The higher boiling portion solidified and after four crystallizations from petroleum ether the 2,4-dimethyl-7-bromohydrindone melted at 81°.

Anal. Calcd. for $C_{11}H_{11}OBr$: C, 55.23; H, 4.64. Found: C, 55.25; H, 4.76.

2,7-Dimethyl-4-bromohydrindene (I).—The mixture of hydrindones was reduced by the Clemmensen method according to the technique of Fieser and Seligman. From 27 g. of hydrindone mixture 22 g. (87%) of 2,7-dimethyl-4-bromohydrindene was obtained. The substance is a colorless mobile liquid with a kerosene-like odor boiling at 104–106° (2.5 mm.).

Anal. Calcd. for $C_{11}H_{13}Br$: C, 58.66; H, 5.82. Found: C, 58.77; H, 6.14.

4-(α-Naphthoyl)-2,7-dimethylhydrindene (II).—The ketone was prepared by allowing the Grignard reagent prepared from the hydrindene to react with α-naphthoyl chloride according to the procedure of Fieser and Seligman.[8] It was advantageous in the preparation of the Grignard reagent to add a few drops of ethyl bromide to the ethereal solution of the hydrindene rather than to the initial portion only. From 10 g. of the hydrindene 4.3 g. (48%) of a light yellow oil boiling at 200° (1 mm.) was secured. Upon four crystallizations from petroleum ether rosets melting at 80–81° separated.

Anal. Calcd. for $C_{22}H_{20}O$: C, 87.9; H, 6.7. Found: C, 87.4; H, 6.6.

In addition 3.0 g. of a hydrocarbon, presumably **2,4-dimethylhydrindene,** boiling at 105–106° (25 mm.) was isolated.

Anal. Calcd. for $C_{11}H_{14}$: C, 90.35; H, 9.64. Found: C, 89.8; H, 9.7.

15,20-Dimethylcholanthrene.—For pyrolysis 2.5 g. of the ketone was heated for one-half hour at 405–410°. A light yellow fraction boiling at 200–210° (0.5 mm.) and weighing 0.6 g. (23.5%) was secured. This material readily formed a dark purple picrate which after three crystallizations from benzene melted at 179–180° and weighed 0.4 g. This material was washed with warm dilute ammonia to remove picric acid, leaving 0.3 g. of a pale yellow solid. This was crystallized from benzene and petroleum ether and yielded 0.25 g. of yellow solid melting at 163–165°. This was dissolved in anhydrous benzene and passed twice through a tower containing activated alumina, by which a considerable amount of dark colored material was removed. The product melting at 169–171° was sublimed in a small molecular still, by which more dark colored material was left behind, and was again crystallized from benzene and petroleum ether. The solution deposited 0.06 g. of light yellow silky needles melting sharply at 174–175° (177.5–178.5°, corr.). A mixed melting point with methylcholanthrene (177–178°, corr.) showed no depression.

Anal. Calcd. for $C_{22}H_{18}$: C, 93.6; H, 6.4. Calcd. for $C_{21}H_{16}$: C, 93.98; H, 6.02. Found: C, 93.9; H, 6.4.

From the Elbs condensation there was obtained, in addition to this fraction, 1.1 g. of a dark red very viscous oil boiling from 240–250° at 0.5 mm. This portion formed very little picrate and failed to crystallize from petroleum ether.

From the mother liquor after the first crystallization of the picrate a second crop of crystals (0.15 g.) was secured. After three recrystallizations, the substance melted fairly sharply at 173–174°. The picric acid was removed by warm alcoholic ammonia, and the residue was purified by microsublimation. The product melted at 120–122°, and the mixed melting point with methylcholanthrene was 117–120°. After three crystallizations from propyl alcohol, the substance melted at 134–136°, mixed melting point with methylcholanthrene 120–126°. Purification involved a large loss of material since the product was more soluble than the impurity, methylcholanthrene.

Anal. Calcd. for $C_{22}H_{18}$: C, 93.58; H, 6.43. Found: C, 93.49; H, 6.42.

Summary

The synthesis of 15,20-dimethylcholanthrene has been accomplished by the method of Fieser and Seligman, but the yield is very low because the pyrolysis results in loss of the methyl group adjacent to the point of ring closure, giving 20-methylcholanthrene as the chief product, and 15,20-dimethylcholanthrene in smaller amount.

The Infrared Absorption of Liquid and Gaseous 1,4-Dioxane between 1.4 and 14.0 μ

BY D. S. MCKINNEY, C. E. LEBERKNIGHT AND J. C. WARNER

The infrared absorption of liquid and gaseous dioxane has been investigated between 1.4 and 14.0 μ using a rock salt spectrometer. The region from 2.27 to 3.72 μ also has been studied using a prism-grating spectrometer. The 1,4-dioxane was purified by refluxing over metallic sodium using a 24-inch (61-cm.) fractionating column packed with short pieces of glass tubing. The fraction used boiled at 99.3–99.4° at 738 mm.

The rock salt spectrometer consists of an equilateral prism 8.5 cm. on an edge so arranged as to pass the energy through the prism twice, thus securing a high resolving power without the necessity of using extremely narrow slits. Effective slit widths for various spectral regions are as follows

Region (μ)	4	7	12	14
Effective slit (μ)	0.01	0.01	0.02	0.06

Effective slit widths, in wave numbers, are given in Figs. 1 and 2. The existing data on the dispersion of rock salt were not considered accurate enough for the calibration of the instrument. It was therefore necessary to select suitable materials for calibration. The following established bands and lines were used:

Sodium D lines (mean)	0.5893 μ		
Benzene band at	2.464 μ		
Q branches of ethylene bands at	5.292 μ	6.925 μ	10.53 μ

The data of Cross[1] were used to interpolate between the calibration points. It has been found possible to resolve the above ethylene bands practically as well as done by Levin and Meyer[2] using grating instruments. The spectrometer is enclosed in a steel case. The thermocouple, its leads and the galvanometer, are also shielded in steel pipe. The shielding and spectrometer are grounded. The steel spectrometer case is covered with a Masonite case to prevent local changes in temperature.

The grating instrument consisted of an echelette grating with a resolving power of 15,000 in the first order and a small angle rock salt prism which was used to eliminate lower order energy. The energy was measured by means of compensating single-junction vacuum thermocouples connected to a Leeds and Northrup high voltage sensitivity galvanometer. The deflections of this galvanometer were amplified by means of an optical relay. The calculations of Firestone[3] concerning the relation between the speed of response and resistance of the thermocouple were confirmed. Due to external disturbances, extreme care had to be taken to ensure stability in the receiving system. The unique features of the rock salt spectrometer and the receiving system will be published elsewhere. This report will describe in detail the means of ensuring stability even when operating near the limit of sensitivity fixed by the Brownian motion of the first galvanometer.

A survey of the spectrum of liquid dioxane from 1.4 to 14.0 μ (Fig. 1, top) using a 0.2-mm. cell showed four regions of intense absorption at 880, 1100, 1350 and 2800 cm.$^{-1}$, and regions of moderate absorption at 1720, 1950, 3550 and 4200 cm.$^{-1}$. The regions of intense absorption were first studied using 0.02-mm. cells (marked C, Fig. 1). The correct thickness in these cells was obtained by rolling lead sheet to the desired thickness and cutting washers from the lead ribbon which were used as spacers between the rock salt windows. In the regions around 880, 1100, 1350 and 2800 cm.$^{-1}$ absorption was still intense with the 0.02-mm. cell. These regions were therefore investigated using a cell in which the windows were pressed together with only a capillary film of dioxane between (curves marked B, Fig. 1). With this cell there was still almost complete absorption in the regions of 880 and 1100 cm.$^{-1}$. These regions were finally studied using a cell made up of carefully polished flat rock salt windows, held together by small spring clips (curves marked A, Fig. 1). Since the wave number resolving power of the prism instrument is rather poor at shorter wave lengths than 4 μ, the regions of wave number 2800 cm.$^{-1}$ and greater were studied in detail on the prism grating spectrometer. The effective slit widths, in wave numbers, for the various spectral regions, are marked in Figs. 1 and 2. The regions 880,

[3] Firestone, *Rev. Sci. Instruments*, **1**, 630 (1930).

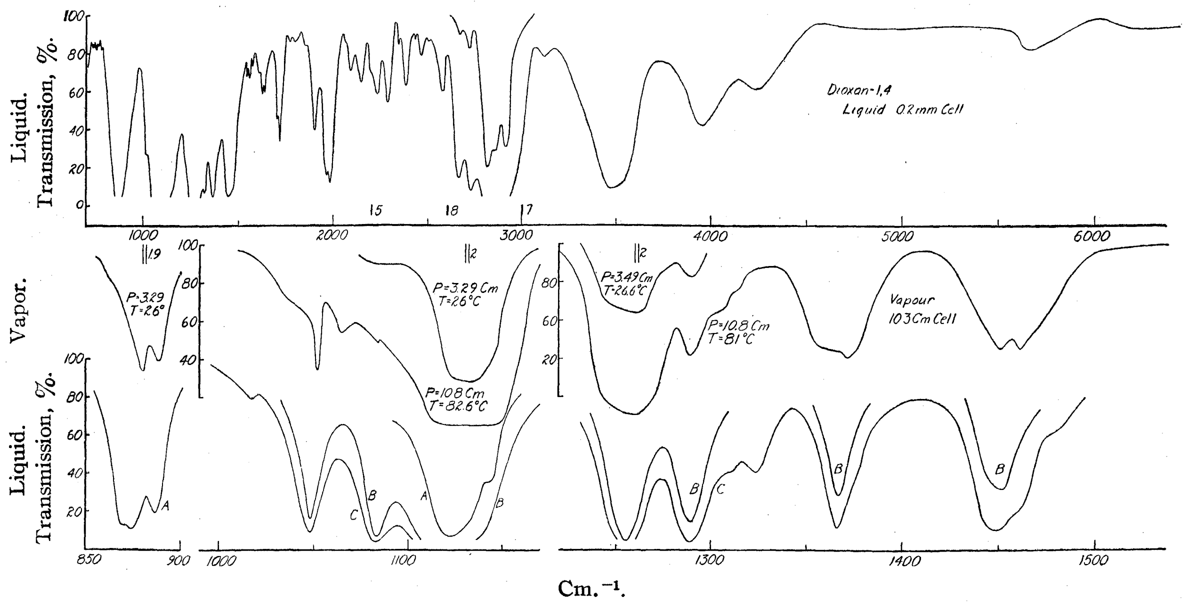

Fig. 1.—Liquid: A, very thin cell; B, moderately thin cell; C, 0.02-mm. cell.

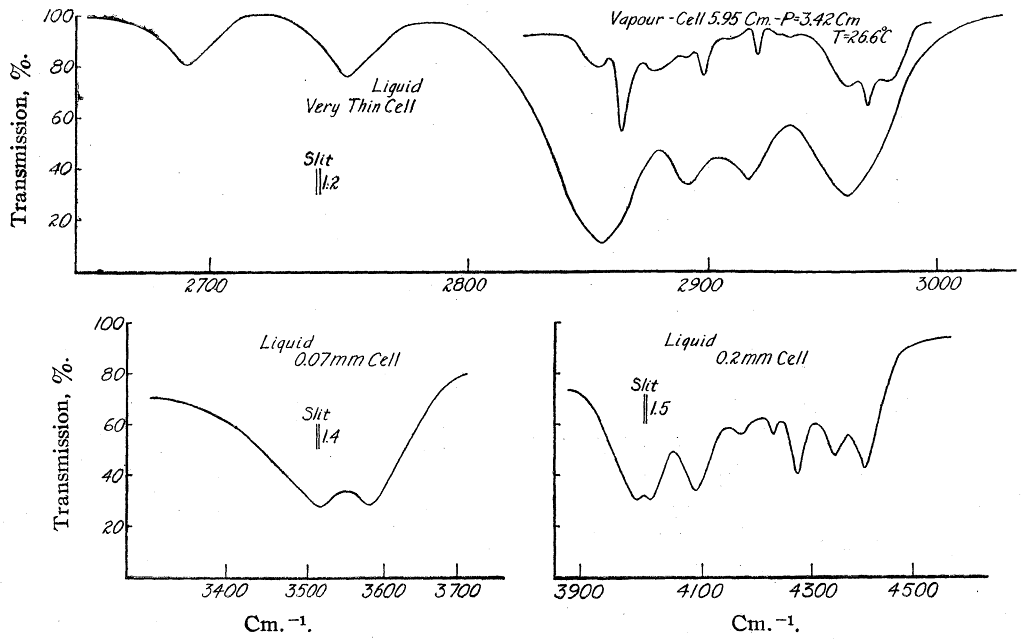

Fig. 2.

1100 and 1350 cm.$^{-1}$, using thin liquid cells, are shown to a larger scale in the lower part of Fig. 1. Each region is seen to be composed of a number of bands (3 in 880, 5 in 1100 and at least 5 in 1350 cm.$^{-1}$ region).

The absorption of gaseous dioxane was next investigated in a 10.3-cm. cell with rock salt windows containing dioxane vapor. To guard against the condensation of liquid dioxane on the windows, the cell was filled with a mixture of 20% dry air and 80% dry air saturated with dioxane vapor. With this concentration of dioxane only the more intense bands were observed. To secure higher concentration without increasing the cell length, a cell was made with a small bulb sealed to one side containing liquid dioxane. This cell and side bulb were heated electrically, always maintaining the cell at a higher temperature than the side bulb. The temperature of the bulb determines the vapor pressure of dioxane in the cell, while the higher temperature of the cell prevents condensation on the windows. The dioxane pressures (in cm.) and the cell temperatures are recorded on Figs. 1 and 2.

Comparison with the vapor shows that the bands are not markedly different from the liquid, the shift in the location of the bands is toward higher frequencies in the vapor and is not constant for the various components. The vapor band at 1050 cm.$^{-1}$ shows evidence of rotation (envelope of vibration–rotation band).

The regions at 2880, 3550 and 4200, cm.$^{-1}$ were studied with the grating spectrometer (Fig. 2). At 2880, 6 bands were found in the liquid. Of these the four most intense were studied in the vapor, where again the envelope of the vibration–rotation bands is clear. The shifts for these bands are again unequal:

$\bar{\nu}$ in Liquid	Shift in vapor
2854.9	+8.5
2891.0	+7.1
2916.6	+4.4
2960.8	+8.9

Furthermore, the breadths of the two bands 2855 and 2961 are not the same, the latter being 24 wave numbers (which is the same as that at 1050 cm.$^{-1}$) and the former 34 wave numbers. The bands at 3550 and 4200 wave numbers were studied only in the liquid state. That at 3550 was resolved into a doublet. The 4200 bands show a more complicated structure. Table I shows the positions of the bands studied in detail on the prism spectrometer and comparison with the Raman spectra.[4–6] Table II shows the positions of the bands studied on the grating, and comparison with the Raman Spectra.[4–6] In all 55 bands were found. The comparison with

(4) Villars, THIS JOURNAL, **52**, 4612 (1930).

(5) Wolkenstein and Syrkin, *J. Chem. Phys.*, **3**, 594 (1935).

(6) Kohlrausch and Stockmair, *Z. physik. Chem.*, **B31**, 382 (1936).

Raman spectra shows good agreement, especially with the results of Kohlrausch and Stockmair. The superior resolving power of the prism spectrometer used in this work is illustrated by comparison with the work of Gordy[7] on dioxane–water mixtures using a fluorite prism spectrometer. In the region 5.9 to $6.5\,\mu$ (1695 to 1538 cm.$^{-1}$) Gordy used too thin a cell (0.02 mm.) to detect the six weak bands found by us. In the region from 4.4 to $5.2\,\mu$ (2273 to 1923 cm.$^{-1}$) Gordy finds one band at $5.05\,\mu$ (1980 cm.$^{-1}$). Our instrument resolves this band into two at 1964 and 1982 cm.$^{-1}$. The single band found by Gordy at $3.38\,\mu$ (2959 cm.$^{-1}$) was resolved by our prism instrument into three bands as shown in the curve inserted in Fig. 1 (top). Subsequent examination on the grating spectrometer showed four bands at 2855, 2891, 2917 and 2961 cm.$^{-1}$ (Fig. 1, bottom).

The authors acknowledge with thanks a grant-in-aid from the National Research Council to one of us (J. C. W.), which made possible the construction of the rock salt prism spectrometer.

Summary

The infrared absorption of liquid and gaseous 1,4-dioxane has been investigated between 1.4 and 14.0 μ using a rock salt spectrometer of unusually high resolving power. The region from 2.27 to 3.72 μ has also been investigated using a prism - grating spectrometer. The absorption in the gas is not much different than that observed in the liquid. In passing from the liquid to the gas there is a slight shift to higher frequencies: For example, the liquid bands in the 3.45 μ region are shifted 4 to 9 wave numbers, and the vapor band shape is characteristic of the envelope of vibration–rotation lines.

The Viscosity of Aqueous Solutions of Electrolytes as a Function of the Concentration. V. Sodium Chloride

BY GRINNELL JONES AND SCHUYLER M. CHRISTIAN

This paper gives data on the viscosity of aqueous solutions of sodium chloride at both 25 and 0° from 0.002 up to 2 *N*. The earlier papers[1] of this series should be consulted for a discussion of the historical background and theoretical interest of the problem.

The best measurements at 25° appear to be those of Ruby Kawai;[2] at 18° those of Grüneisen;[3] and at 0° those of Lyle and Hosking.[4] The only measurements at extreme dilution known to us are those of Bousfield[5] at 18° which extend down to 0.0017 *N*.

The best sodium chloride available by purchase was dissolved, filtered through a sintered glass filter, then precipitated in a silica dish by passing hydrochloric acid gas into the solution and dried in a centrifuge. The process, except the filtration, was then repeated and the salt finally dried by ignition to a red heat in a platinum dish. The solutions were made up by weight and the period of flow determined in an Ostwald viscometer, the same instrument used by Jones and Stauffer. The timing was done by the automatic photoelectric cell method developed by Jones and Talley. The results are shown in Tables I and II. The figures for the density are the averages of two or three independent determinations which rarely differed by more than 0.001%, obtained with different pycnometers of approximately 60-ml. capacity.

Unfortunately the density determinations on the 2 *N* solutions were omitted through an oversight, but this figure has been estimated with sufficient precision for the purpose from the data of Baxter and Wallace.[6] The fourth column gives the values of d_ct_c/d_0t_0, which is the average of results obtained with at least two fillings of the viscometer and of several runs on each filling.

The relative viscosity, η, given in Column 4 is obtained from these figures by the application of a small kinetic energy correction.

In a few cases a correction of 0.001 or 0.002% has been applied to the data as given to bring them to the round concentration given in the first column. For the 2 *N* solution at 25° and for the three strongest solutions at 0° this correction is so large that it seemed best to publish the data as actually determined. The corrected figures at the round concentration are given in parentheses.

Interpretation of the Data

The experimental data given above on the density of sodium chloride up to 1 *N* may be expressed with an average deviation of only 0.001% by the equations having the form suggested by Root.[7]

$$d^{25}_4 = 0.997074 + 0.041882c - 0.001878c^{3/2}$$
$$d^{0}_4 = 0.99987 + 0.04605c - 0.00307c^{3/2}$$

The fifth column shows that the "Grüneisen Effect" is shown by sodium chloride although it is not so pronounced as has been observed with salts of a higher valence type.

The results for the viscosity at 25° can be expressed by the equation $\eta = 1 + 0.00670\sqrt{c} + 0.07866\ c$ up to 0.2 N with an average deviation of only 0.003%. By adding a term proportional to the square of the concentration the equation which is shown at the bottom of Table I may be obtained which fits the data with an average deviation of 0.005% up to 1 N. If the results are expressed in terms of fluidity, φ, instead of viscosity there is a slight improvement in that the simple two-parameter equation holds up to 0.5 N and the extended three-parameter equation holds up to 2 N.

At 0° we find that as usual the relative viscosity is less than at 25°. Here there is little to choose between the equations expressed in terms of viscosity or of fluidity. The average deviations are slightly greater than at 25°, probably because of the greater difficulty in maintaining temperature control during the hot summer weather when this work was done.

The coefficient of the square root term (A) computed by the Falkenhagen and Vernon[8] equation is 0.0060 at 25° and 0.0056 at 0°, whereas the experimentally determined values are 0.0067 and 0.0045, respectively. The agreement is not quite as good as has been found in several other cases, especially at 0°.

Summary

1. The absolute density and relative viscosity of many aqueous solutions of sodium chloride have been determined at 0 and 25°, covering the range of concentration from 0.002 to 2 N.

2. The density of these solutions as a function of the concentration can be expressed by the Root equation, and the viscosity by the Jones and Dole equation.

The Heat Capacities of Molybdenite and Pyrite at Low Temperatures[1]

BY C. TRAVIS ANDERSON[2]

In previous papers[3] the writer has presented low temperature thermal data on manganese sulfide, ferrous sulfide, calcium sulfide and the sulfides of copper and lead. The present paper deals with the heat capacities of molybdenite and pyrite.

The methods, apparatus and accuracy have been described previously.[4]

Materials

Both samples used in this investigation were naturally occurring minerals. The pyrite used was taken from one large specimen. It was broken, and samples that did not show particles of quartz or discoloration were selected. The material was then crushed and screened, the fines being discarded. Analysis of the sample for iron content indicated a purity of 99.24% FeS_2. The only detectable impurity was 0.02% SiO_2. A 301.4-g. sample with a density of 4.951 at 22.4° was studied.

The sample of molybdenite consisted of laminated flakes about 5 mm. in diameter. Since they could not be crushed, the sample was put through a food chopper and screened to size. The only impurities found in the sample were 0.31% FeS_2 and 0.53% SiO_2, which were corrected for in the specific heat measurements. The calorimeter was filled with 166.4 g., with a density of 4.991 at 20.0°.

The Specific Heats

Specific heat measurements have been made on pyrite from 21.7 to 84°K. by Eucken and Schwers,[5] and three points have been measured by

Ewald.[6] No previous low temperature measurements have been reported on molybdenite. The results obtained in this Laboratory on these two sulfides, expressed in gram calories (15°) per gram formula weight, as well as a number of Eucken and Schwers' and Ewald's determinations, are shown graphically in Fig. 1. The experimental values for the heat capacities are given in Tables I and II. The calculations were made on the basis of Fe = 55.84, Mo = 96.0 and S = 32.06.

TABLE I

HEAT CAPACITY PER GRAM FORMULA WEIGHT OF PYRITE (FeS_2)

80.6	3.944	161.3	10.57	292.3	15.08
		189.5	11.78		

Calculation of Entropies

The conventional method was used in calculating the entropy. The heat capacity curves were extrapolated from the lower points and coincided with Debye functions having the parameters (Θ) for FeS_2, 421, and MoS_2, 280. The following combinations of Debye and Einstein functions were found to fit the specific heat curves per formula weight of these sulfides.

$$C_{FeS_2} = D\left(\frac{421}{T}\right) + 2E\left(\frac{532}{T}\right)$$

$$C_{MoS_2} = D\left(\frac{280}{T}\right) + 2E\left(\frac{528}{T}\right)$$

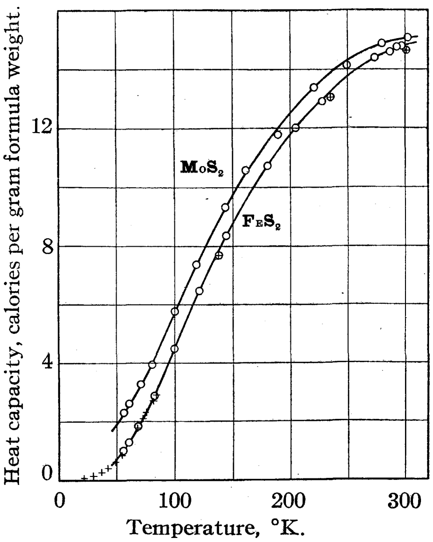

Fig. 1.—The heat capacities of pyrite and molybdenite, in calories per gram formula weight: ○, Anderson; +, Eucken and Schwers; ⊕, Ewald.

The results of the entropy calculations from the experimental heat capacity data and the function sums are given in Table III.

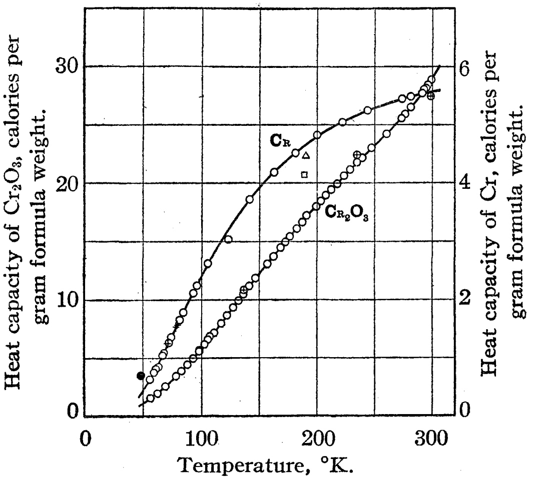
The Heat Capacities of Chromium, Chromic Oxide, Chromous Chloride and Chromic Chloride at Low Temperatures[1]

BY C. TRAVIS ANDERSON[2]

The work presented in this paper is a part of the program for a systematic thermodynamic study of chromium and some of its compounds that the U. S. Bureau of Mines has been conducting for a number of years. This report deals with the heat capacities and entropies of chromium, chromic oxide, chromous chloride and chromic chloride. A manuscript, the "Chemistry of the Anhydrous Chlorides of Chromium," is in course of publication as a Bureau bulletin.

The methods, apparatus and accuracy have been described previously.[3]



○, Anderson; ●, Dewar; □, Richards and Jackson; △, Nordmeyer and Bernoulli; +, Simon and Ruhemann; ⊕, Russell.

Fig. 1.—The heat capacities of chromium and chromic oxide, in calories per gram formula weight.

Materials

The sample of chromium metal, which was prepared electrolytically, was obtained for this Laboratory through the courtesy of Dr. John Chipman, who obtained it from Mr. Marsh of the Hoskins Manufacturing Company. It was carefully hand-picked to obtain particles of uniform color without a coating of chromic oxide. The selected particles were placed in a silica flask, evacuated and heated to 1100° to remove any hydrogen that might have been present. An analysis of the sample, after this treatment, by Dr. Chipman showed it to contain 0.65% oxygen and no nitrogen. This oxygen was assumed to be present in the form of chromic oxide and was corrected for in the heat capacity of the chromium. The calorimeter was filled with 401.6 g.

The chromic oxide was Kahlbaum highest quality, containing no detectable impurity. It was compressed into pellets, placed in a silica flask, evacuated and heated. Measurements were made on a 145.6-g. sample.

The author is indebted to H. A. Doerner and W. C. McGavock for the preparation of the anhydrous chlorides of chromium. The chromic chloride was prepared by passing chlorine gas through a mixture of chromic oxide and carbon at about 800°. The resulting vapor was condensed, removed from the condenser and redistilled in an atmosphere of dry chlorine containing small amounts of carbon tetrachloride vapor. The product consisted of brilliant violet, flat, thin flakes about 2 mm. in diameter. It was compressed into pellets, broken to size and dried by passing dry chlorine containing a little carbon tetrachloride through the chromic chloride at about 300°. It was finally evacuated to remove any excess chlorine, after which a 113.6-g. sample was transferred to the calorimeter out of contact with air.

The chromous chloride used in this investigation was prepared from a portion of the pure chromic chloride described above by reduction with hydrogen containing a small amount of hydrogen chloride to prevent reduction of the chloride to metal. The resulting chloride was grayish-white and extremely hygroscopic. The material was transferred from the reaction flask to the calorimeter out of contact with air; 111.8 g. of this sample was used in the specific heat measurements.

The Specific Heats

A number of investigators[4] have made specific heat measurements on chromium metal. With the exception of those of Simon and Ruhemann, these determinations are mean specific heats. The various values obtained by these investigators on chromium are shown in Fig. 1.

Russell[5] has made measurements on the specific heat of chromic oxide ranging from 137 to 299°K. These values are also shown in Fig. 1.

Trapeznikowa, Schubnikow and Miljutin[6] have recently measured the specific heat of chromic chloride from 12 to 130°K. Their results are definitely higher than those of the present work.

Over the range of 56 to 112°K. they average 0.82 cal./deg. higher. These values are represented graphically in Fig. 2. From the description of their apparatus it appears that their measurements have been sufficiently accurate and their temperature scale should not be in error. However, the sample they used might have contained water, as the apparently insoluble chromic chloride is capable of absorbing up to 3% water in sixty minutes of contact with laboratory air as shown by Crespi.[7] It appears probable, since the difference between these two curves is constant over the range of 56 to 112°K., that some systematic error is the cause of the discrepancy.

Fig. 2.—The heat capacities of chromous chloride and chromic chloride, in calories per gram formula weight.

No previous low temperature measurements have been reported on chromous chloride. The results obtained in this Laboratory on the heat capacities of chromium and chromic oxide expressed in gram calories (15°) per gram formula weight are shown graphically in Fig. 1 and the values for chromous and chromic chlorides are represented graphically in Fig. 2. The experimental determinations of the heat capacities for chromium are given in Table I, the values for chromic oxide up to about 270°K. are given in Table II, while Table III shows the values for the heat capacities from about 270° to 340°K. with the temperature rise (ΔT) of the determinations. This table is represented graphically in the upper figure in Fig. 3. The experimental values for the chromous and chromic chlorides are given in Tables IV and V. The calculations were made on the basis of Cr = 52.01, O = 16.00 and Cl = 35.457.

After calculating and plotting the heat capacity curve for chromic oxide it was noted that the points above the ice point appeared to deviate from the smooth curve which was drawn through the lower points. Further measurements were made which showed this deviation was due to an anomaly. The peak of the curve appears at about 305°K. No measurements were made on the energy necessary to heat the chromic

oxide through this transition. Honda and Sone[8] measured the magnetic susceptibility of chromic oxide over a wide temperature range. A graphical representation of a portion of their results is shown in the lower figure of Fig. 3. The magnetic susceptibility is plotted against the logarithm of the absolute temperature. The temperature of the break in their curve approximates very closely the peak in the specific heat curve which is drawn in for comparison.

The calorimeter was cooled to below 300°K. five times, after which measurements were made both below and above the transition temperature. The curve was found to be perfectly reproducible.

Calculation of Entropies

The entropies were calculated by the usual graphical method of plotting the heat capacity against the logarithm of the temperature. In the case of the chromic chloride the results of Trapeznikowa, Schubnikow and Miljutin were used on the lower portion of the curve. Since there appeared to be a constant difference of 0.82 cal. over the range of 56 to 112°K. between their measurements and those presented in this report, it was assumed that this difference would exist below 56°K. Accordingly, their results were used on the lower end of the curve to attempt to obtain a more reliable value for the entropy than if they had not been used. If their data are extrapolated to room temperature from their highest point, assuming a 1.0 calorie difference between the two curves over this region, an entropy value of 31.2 units is obtained.

The experimental heat capacity curves coincided at low temperature with Debye functions having the following parameters (Θ): for chromium, 488; chromic oxide, 362; chromous chloride, 82; and chromic chloride, 100. Simon and Ruhemann gave a value for $\Theta = 486 \pm 8$, after correcting the 92% chromium they used for the impurities it contained. This is in excellent accord with the value of 488 obtained in this work.

Obviously, no combination of Debye and Einstein functions can be made to fit the experimental curve for the heat capacity of chromic chloride. Similarly, the function sum cannot be expected to fit the chromic oxide near room temperature as the transition begins to have an influence on the heat capacity even as low as

---

(8) Honda and Sone, *Science Rep. Tôhoku Imp. Univ.*, **3**, 223 (1914).

200°. For this reason one may expect the function sum in this case to give a considerably lower entropy value than that obtained by the more accurate graphical method.

The following combinations were found to fit the experimental data on chromic oxide and chromous chloride to above 100°.

$$C_{Cr_2O_3} = D\left(\frac{362}{T}\right) + 2E\left(\frac{470}{T}\right) + 2E\left(\frac{780}{T}\right)$$

$$C_{CrCl_2} = D\left(\frac{82}{T}\right) + E\left(\frac{226}{T}\right) + E\left(\frac{444}{T}\right)$$

The Ternary Systems $KClO_3$–K_2SO_4–H_2O and $NaClO_3$–Na_2SO_4–H_2O[1]

BY JOHN E. RICCI AND NICHOLAS S. YANICK

Introduction

This study is part of a systematic investigation of ternary systems involving sodium and potassium chlorates, a series of systems of which several examples are already to be found in the literature. No double salts containing sodium chlorate have yet been reported, the only ternary systems studied being $NaClO_3$–Na_2CO_3–H_2O, $NaClO_3$–$NaCl$–H_2O and $NaClO_3$–$KClO_3$–H_2O.[2] Similarly, in the systems involving potassium chlorate that have been investigated, no compounds are found (–H_2O + KCl, K_2CO_3, $NaClO_3$[2]; also +KBr and KI[3]); potassium chlorate however is found to form solid solutions in the systems $KClO_3$–KNO_3–H_2O and $KClO_3$–$TlClO_3$–H_2O.[2]

As for the sulfates in the present systems, while sodium sulfate is known to form both various double compounds and solid solutions with other sodium salts, potassium sulfate, in systems so far studied, forms no double salts with other potassium salts, but does form solid solutions with potassium chromate and potassium molybdate.[2]

In the present investigation potassium chlorate and potassium sulfate show no complex formation, while the sodium salt system forms one double salt, $NaClO_3 \cdot 3Na_2SO_4$. As for the other sodium halogenates, sodium sulfate forms similar compounds with sodium iodate, namely, $NaIO_3 \cdot 3Na_2SO_4$ and $NaIO_3 \cdot 4Na_2SO_4$,[4] while with sodium bromate it forms no definite compound but a solid solution.[5]

Experimental Methods

The experimental procedure was that usually described for similar investigations. Weighed complexes of known composition were brought to equilibrium by stirring in a

large water-bath in which the temperature was maintained constant to ±0.02°. The time required for attainment of equilibrium was determined by analysis, and varied from a few days in the case of the potassium salts, to several weeks in some cases of the sodium salt system. The order of mixing of the components, and the process of "seeding" or inoculation for required phases, had to be varied in accordance with the phase sought. All the solid phases involving sodium sulfate show a considerable tendency to persist in metastable equilibrium, and these metastable phases sometimes change only very slowly to the stable form even with repeated seeding. The densities reported for some of the isotherms were obtained by means of volumetric pipets calibrated for delivery.

The method of analysis of the saturated solution was the same in both systems. In one sample of the solution the chlorate was determined by a volumetric method; in another sample the total solid was determined by evaporation to dryness at 100° followed by 250°; and the sulfate was then calculated by difference. For the chlorate determination, the method of Peters and Deutschländer[6] was used: to the chlorate sample (containing about 0.11 g. of ClO_3^-) is added a definite volume (50 cc.) of 0.05 *M* arsenious oxide solution (previously standardized against pure sodium chlorate by the same procedure); after the addition of a trace of potassium bromide, the solution is acidified strongly with hydrochloric acid and boiled for ten minutes. The excess arsenious oxide is then titrated by Györy's method,[7] by means of 0.033 *M* potassium bromate solution (previously compared with the arsenite solution) using indigo sulfonic acid as indicator.

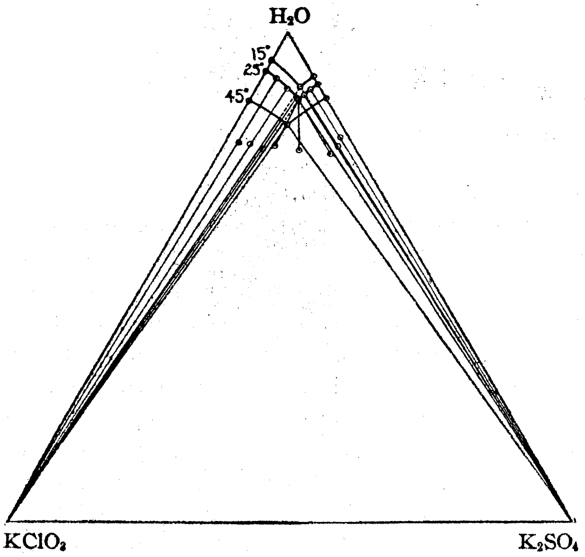

Fig. 1.—System $KClO_3$–K_2SO_4–H_2O.

For the identification of known solid phases, microscopic examination and algebraic extrapolation of tie-lines sufficed. The determination of the formula of the new double salt however was more difficult. Direct analysis of the crystals was not successful; the salt is always incongruently soluble; the crystals were very small, always contaminated with a mother liquor highly concentrated with respect to sodium chlorate, and readily decomposed by washing; even centrifuged residues contained large amounts of mother liquor or of its crystallized salts. Dehydration of residues over various drying agents showed no break in the drying–time curve, so that the solid appeared to be anhydrous. This however is also very clearly seen from the definite convergence of all the tie-lines for complexes giving the double salt as single solid phase, on a point on the $NaClO_3$–Na_2SO_4 side of the triangle. Considering the wide spread of the solubility curve of the double compound at the various temperatures employed, and the fact that the compound is anhydrous, these extrapolations constitute a sufficiently accurate determination of the formula of the double salt. Extrapolating 38 such tie-lines, covering the three different temperatures at which the double salt was obtained, to the point on the base of the triangle representing the formula $NaClO_3 \cdot 3Na_2SO_4$ (containing 80.01% Na_2SO_4), the average absolute error of the extrapolations was 0.63% and the average algebraic error only +0.06%, in sodium sulfate. A further check on the formula was made by means of a method due to Bijlert;[8] two different complexes, of definite compositions, calculated to give the double salt (in metastable equilibrium) were made up, with the addition of a definite amount of a fourth component, sodium chloride, to each. By means of a complete analysis, when equilibrium had been reached, both of the saturated solution and of a wet residue, the amount of mother liquor contained in the wet residue was calculated through the sodium chloride content, thus making possible quite an accurate determination of the composition of the double salt. The results again gave an anhydrous compound, with 80.45 and 80.24% Na_2SO_4 in the two different runs, as compared with 80.01% calculated from the formula $NaClO_3 \cdot 3Na_2SO_4$.

Results

System $KClO_3$–K_2SO_4–H_2O.—The results on this system are given in Table I, and the curves for the three temperatures are shown in condensed form in Fig. 1. No complex formation is observed, the only solid phases being potassium chlorate and potassium sulfate.

System $NaClO_3$–Na_2SO_4–H_2O.—The experimental data for the four temperatures studied (75, 45, 25 and 15°) are presented in Tables II–V, the isotherms being shown graphically in Figs. 2–5. (In these tables, the abbreviation "D.S." stands for "double salt," while (m) indicates metastable phases.)

75° Isotherm.—The solid phases at this temperature are Na_2SO_4 for the curve a-b, $NaClO_3 \cdot 3Na_2SO_4$ for b-c, and $NaClO_3$ for c-d. As may be seen from the diagram, the double salt exists as a stable phase over a short range of variation of

only 5% in respect to sodium chlorate, but its solubility curve has been followed as a metastable equilibrium as far as 41% $NaClO_3$ (a total range of 15% on the diagram). The same behavior is observed at the other temperatures (45 and 25°), where the range of stability is even smaller (3.4

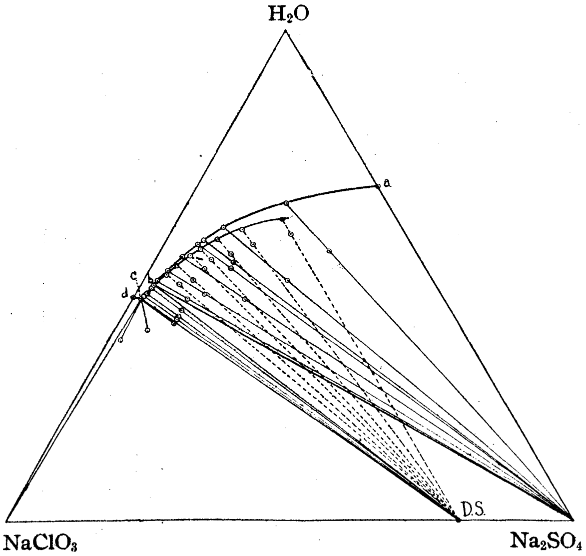

Fig. 3.—45° Isotherm: $NaClO_3$–Na_2SO_4–H_2O.

and 0.3%, respectively); at 45° the total range recorded is 33%, and at 25°, 22%. Possibly these curves could be followed even further, but a point of congruent saturation was not reached in the present work. Another peculiarity of this double compound to be pointed out is the extreme slowness with which the phase, when present in a metastable state (fine, lustrous, needle-shaped crystals) yields, on seeding, to the formation of the stable sodium sulfate. In fact mere seeding never gave a complete change from the metastable to the stable curve. The stable curve for sodium sulfate is obtained only by taking care to prevent seeding with the double salt; otherwise crystals of the latter forming temporarily or accidentally persist in an extraordinary manner.

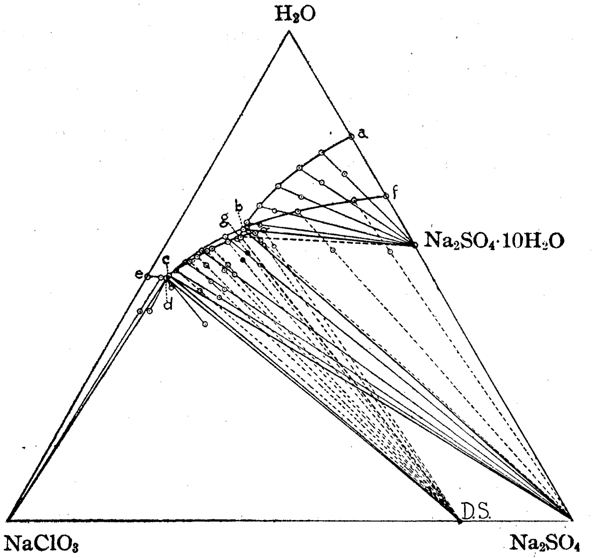

Fig. 4.—25° Isotherm: $NaClO_3$–Na_2SO_4–H_2O.

45° Isotherm.—Phases and general relations just as at 75°.

25° Isotherm.—The stable phases and their solubility curves are as follows: $Na_2SO_4 \cdot 10H_2O$, for a-b; Na_2SO_4 for b-c; $NaClO_3 \cdot 3Na_2SO_4$ for c-d; and $NaClO_3$ for d-e. The curve b-f is the metastable extension of the sodium sulfate solubility curve, point f being the metastable solubility of sodium sulfate at 25°. The double salt curve extends for a considerable distance beside the stable sodium sulfate curve, and meets a metastable extension of a-b at the point g, which is therefore an isothermally invariant solution in metastable equilibrium with $Na_2SO_4 \cdot 10H_2O$ and the double salt.

As already stated the stable range for the double salt at this temperature appears to be extremely short. Because of the close similarity of the slopes of the sodium sulfate and double salt curves, the narrowness of the isothermally invariant area for the ocurrence of both phases together, the slowness with which transformations take place, and the tendency for solutions to remain in metastable equilibrium with either sodium sulfate or double salt separately, the isothermally invariant point for the two solid phases sodium sulfate + double salt is very difficult to obtain at all three temperatures, especially at 25°. At 25° seven complexes gave a solution with the composition 46.62% $NaClO_3$ and 3.87% Na_2SO_4, with sodium chlorate and double salt as solid phases. Two complexes, with sodium chlorate and sodium sulfate apparently as solid phases, gave the same composition, 46.64% $NaClO_3$ and 3.86% Na_2SO_4. The former are probably stable, the latter metastable. Probably the most that can be said with certainty from the data is that the quintuple point representing the disappearance of the double salt as a stable phase (with lowering temperature) must occur at a temperature close to and probably slightly below 25°.

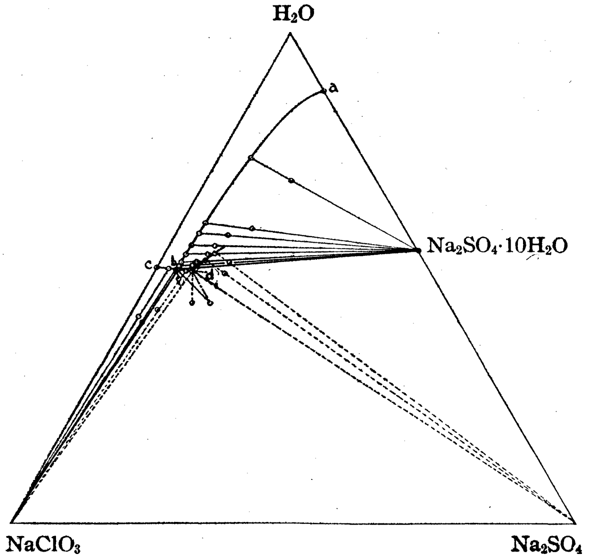

Fig. 5.—15° Isotherm: $NaClO_3$–Na_2SO_4–H_2O.

15° Isotherm.—The only stable solid phases at this temperature are $Na_2SO_4 \cdot 10H_2O$ for the curve a-b, and $NaClO_3$ for b-c. The point d is an isothermally invariant solution in metastable equilibrium with sodium chlorate and anhydrous sodium sulfate; the curve for the solubility of the latter could be followed for only a short distance, being extremely unstable. At this temperature, finally, the double salt is not stable at all; it formed only as a temporary metastable phase a few times, but was too labile in respect to the decahydrate to allow any part of its solubility curve to be determined.

Summary

1. Solubility measurements are given for the system $KClO_3$–K_2SO_4–H_2O at 15, 25 and 45°; no double salt formation is found in this system.

2. The system $NaClO_3$–Na_2SO_4–H_2O has been studied at 15, 25, 45 and 75°. A double salt with the formula $NaClO_3 \cdot 3Na_2SO_4$ is formed at 25° and above, having always a very short range of stable existence, but persisting in metastable equilibrium over a very considerable range of concentration.

The Thermodynamics of Aqueous Potassium Hydroxide Solutions from Electromotive Force Measurements

BY HERBERT S. HARNED AND MELVIN A. COOK[1]

The electromotive forces of the cell

$$H_2 \mid KOH(m_2) \mid K_xHg \mid KOH(m_1) \mid H_2 \quad (1)$$

have been measured at 25° by Knobel.[2] Following the procedure which Harned and Hecker[3] employed with sodium hydroxide solutions, a thorough investigation of these cells has been made. Measurements have been obtained from 0 to 35° at 5° intervals and at concentrations from 0.1 to 4 *M*. For purposes of theoretical computations, these measurements have been supplemented with density determinations over the above ranges of temperature and concentration. From these data, the activity coefficient, the relative partial molal heat content and the relative partial molal heat capacity of this hydroxide have been computed.

Experimental Results

The method of measurement and cell technique was with slight modification the same as described by Harned,[4] and Harned and Hecker.[3] The hydrogen electrodes were of the usual platinized platinum foil type. The potassium amalgam was prepared as described by Harned and was approximately 0.02% potassium. The temperature control was ±0.02°. A stock solution of 5 *M* potassium hydroxide was made from the highest grade analyzed chemical. The carbonate present was removed by addition of a slight excess of a barium hydroxide solution. The solution was then boiled under vacuum, and kept under an atmosphere of hydrogen. From this solution a reference solution of 0.05 *M* hydroxide was made. The solutions of varying concentrations were made from the 5 *M* stock solution by weight dilution with water. Potassium hydroxide solutions were analyzed by titration with a gravimetrically standardized hydrochloric acid solution. The concentrations were all known to within ±0.05%.

The densities of the solutions were obtained by means of dilatometers in the manner described by Harned, Keston and Donelson.[5]

The measurements of the electromotive forces were made with a Leeds and Northrup Type K potentiometer. Results were obtained at 25 different potassium hydroxide concentrations and at 5° intervals from 0 to 35°. Duplicate or triplicate results were obtained at each concentration and temperature. The results, all of which were reproducible to within ± 0.08 mv., were smoothed to round concentrations by plotting the function $(E - 2k \log m/0.05)$, where k is $2.303\, RT/F$, against the molality. 8.315, $t + 273.1$ and 96,500 were employed for R, T and F, respectively. Since a table of all these results is voluminous, we have resorted to the expediency of expressing the electromotive forces at a given concentration by means of the equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \quad (2)$$

The constants of this equation were determined by the graphical method used by Harned and Nims.[6] The values of E_{25}, a and b are given in

The density data have been expressed by an equation of the form

$$d = d_0 + a'm + b'm^{3/2} \qquad (3)^7$$

where d_0 is the density of water at the temperature in question and a' and b' are constants. The latter were evaluated from the observed densities by the method of least squares. Values of the constants of equation (3) are listed in Table II.

TABLE II

25	.9970	.0526	.0047
30	.9957	.0514	.0043
35	.9940	.0516	.0045

Activity Coefficients

Upon rearranging the usual expression for the electromotive force for cells of the type used here, we obtain

$$\log \frac{\gamma}{\gamma_{0.05}} = \frac{E}{2k} - \log \frac{m}{0.05} - {}^1/_2 \log \frac{p_{0.05}}{p} \qquad (4)$$

Here γ is the activity coefficient of the hydroxide, $\sqrt{\gamma_K \gamma_{OH}}$, at a concentration m, $\gamma_{0.05}$ the value of this quantity at the reference concentration, 0.05 M, $p_{0.05}$ the vapor pressure of the reference solution and p the vapor pressure of the solution of hydroxide at the concentration m.

The Gibbs–Duhem equation may be converted to the form

$$-\mathrm{d} \log p = \frac{2}{55.51 \times 2.303}\, \mathrm{d}m + \frac{2}{55.51}\, m\, \mathrm{d} \log \gamma \qquad (5)$$

since $\log \gamma_{0.05}$ is a constant, $\mathrm{d} \log \gamma$ in the last term may be written $\mathrm{d} \log \gamma/\gamma_{0.05}$. Making this substitution in equation (5) and integrating, we obtain

$${}^1/_2 \log \frac{p_{0.05}}{p} = \frac{1}{55.51} \int_{0.05}^{m} m\, \mathrm{d} \log \frac{\gamma}{\gamma_{0.05}} + \frac{m - 0.05}{55.51 \times 2.303} \qquad (6)^8$$

To evaluate the first term on the right of equation (6), values of $\log \gamma/\gamma_{0.05}$, obtained from equation (4) (omitting the last term), are plotted against m, and the area under the curve evaluated. Upon substituting this result in equation (6), 1/2 $\log p_{0.05}/p$ is obtained. This result is substituted in equation (4) and a more exact value of $\log \gamma/\gamma_{0.05}$ is obtained. This result is employed to reëvaluate the first term on the right of equation (6). This method of arithmetical approximation is repeated until both equations (4) and (6) are satisfied. In Table III, values of 1/2 $\log p_{0.05}/p$ are given. This quantity changes at the most only about 3 units in the fourth decimal place between the limits 0 and 35°. Since 1 in this decimal place corresponds to a difference of 0.01 mv. in the electromotive force, an assumption of constancy is within the error of the experiment.

TABLE III

VALUES OF THE VAPOR PRESSURE TERM

m	0.1	0.15	0.25	0.35	0.5	0.75	
${}^1/_2 \log p_{0.05}/p$	.0004	.0008	.0015	.0022	.0033	.0053	
m	1.0	1.5	2.0	2.5	3.0	3.5	4.0
${}^1/_2 \log p_{0.05}/p$	0.0072	0.0106	0.0154	0.0210	0.0278	0.0344	0.0412

By substitution of these values for the vapor pressure correction in equation (4), values of $\log \gamma/\gamma_{0.05}$ were obtained. For purposes of extrapolation, we have employed the equation of Debye and Hückel which for a 1–1 electrolyte is

$$\log \gamma = -uc^{1/2}/(1 + A(2c)^{1/2}) + Bc - \log(1 + 0.036m) \qquad (7)$$

For the activity coefficient ratio, this equation becomes

$$\log \gamma/\gamma_{0.05} = -u[c^{1/2}/(1 + A(2c)^{1/2}) - (0.05)^{1/2}/(1 + A(0.1)^{1/2})] + B(c - 0.05) - \log(1 + 0.036m)/(1 + 0.0018) \qquad (8)$$

---

(1). $a = 3.7$ Ångström units.

(2). The number in ( ) is the difference in the third decimal place between the observed γ and the value calculated by equation (7), it being positive when the calculated value is greater than the observed.

which is suitable for evaluating A and B. By using values of c computed from the equation

$$c = [1000m/(1000 + 56.1m)](d_0 + a'm + b'm^{3/2}) \quad (9)$$

the constants A and B may be determined by means of equation (8) from two values of the activity coefficient ratio. Firstly, the 0.1 and 1 M results were employed, and secondly, the 0.25 and 0.5 M were used at each temperature. Both computations gave consistent results.

The apparent ionic diameter, a, in Ångström units was obtained from D by means of the equation derived from theory

$$A = K'a \quad (10)$$

by using values of K' computed by Harned and Ehlers.[9] No indication of a variation of this quantity with temperature was found. The results of the calculation indicated a constant value of 3.7 Å.

The values of the constant B may be expressed within narrow limits by the equation

$$B = 0.118 + 0.00072t - 1.06 \times 10^{-5}t^2 \quad (11)$$

The observed activity coefficients at some of the temperatures are given in Table IV. The differences between these values and those computed by equation (7) are designated in the table. Values of the parameters of equation (7) necessary for this computation are given in the bottom rows of the table. The range of validity of equation (7) is from 0 to 1 M.

The Relative Partial Molal Heat Content

$\overline{L}_2$ was evaluated at concentrations from 0.05 to 1 M by the differentiated form of equation (7). If the value of ln γ given by equation (7) be substituted in the equation for $\overline{L}_2$, namely

$$\overline{L}_2 = -\nu RT^2\, \partial \ln \gamma/\partial T \quad (12)$$

and the differentiation performed, we obtain

$$\overline{L}_2 = U'c^{1/2}/(1 + A(2c)^{1/2}) - V'/(1 + A(2c)^{1/2})^2 (c\mathrm{d}A/\mathrm{d}T + A\ \mathrm{d}c/2\mathrm{d}T) + W'(B\mathrm{d}c/\mathrm{d}T + c\mathrm{d}B/\mathrm{d}T) \quad (13)$$

where U', V' and W' are isothermal constants[5] (eq. 11, Table VI) derived from theory. $\mathrm{d}B/\mathrm{d}T$ was obtained by differentiating equation (11). $\mathrm{d}A/\mathrm{d}T = a\ \mathrm{d}K'/\mathrm{d}T$ was obtained graphically from the values of K' in Table IV. Since equation (9) may be written $c = A'm + B'm^2 + C'm^{5/2}$, we have that

$$\mathrm{d}c/\mathrm{d}T = m\mathrm{d}A'/\mathrm{d}T + m^2\mathrm{d}B'/\mathrm{d}T + m^{5/2}\mathrm{d}C'/\mathrm{d}T \quad (14)$$

The values of these differential coefficients were determined graphically at each temperature and then used to determine $\mathrm{d}c/\mathrm{d}T$. All the required quantities were then substituted in equation (13) and values of $\overline{L}_2$ at concentrations up to 1 M were obtained.

In addition to this calculation, the partial molal heat content relative to the 0.05 M solution was computed by the Gibbs–Helmholtz equation

$$\overline{H}_m - \overline{H}_{0.05} = NE'F - NF\mathrm{d}E'/\mathrm{d}T \quad (15)$$

in which E' is the electromotive force corrected for the vapor pressure term. Since we have

---

[9] Harned and Ehlers, THIS JOURNAL, **55**, 2179 (1933). The values of u used were also taken from this paper.

shown that this term does not vary sufficiently with the temperature to affect our results, the equation for E' is according to equation (2) simply

$$E' = E'_{25} + a(t - 25) + b(t - 25)^2 \qquad (16)$$

whence

$$\overline{H}_m - \overline{H}_{0.05} = NE'F - NFT[a + 2b(t - 25)] \qquad (17)$$

The values of this quantity obtained by this method were within 20 calories of those computed by equation (13) except in the range of concentration of 0.1 to 0.25 M at temperatures below 15° where a discrepancy of the order of 50 calories sometimes occurred. We consider that in these cases the computation by equation (13) is the more reliable. At concentrations from 1.5 to 4 M, inclusive, equation (17) was employed. These results are given within 10 cal., which is less than the error in their determination, by the equation

$$\overline{L}_2 = \overline{L}_2^0 + \alpha t + \beta t^2 \qquad (18)$$

where $\overline{L}_2^0$ is the value of $\overline{L}_2$ at 0°, and α and β are constants. Table V contains the values of these constants at the designated hydroxide concentrations. A plot of these results is shown in Fig. 1.

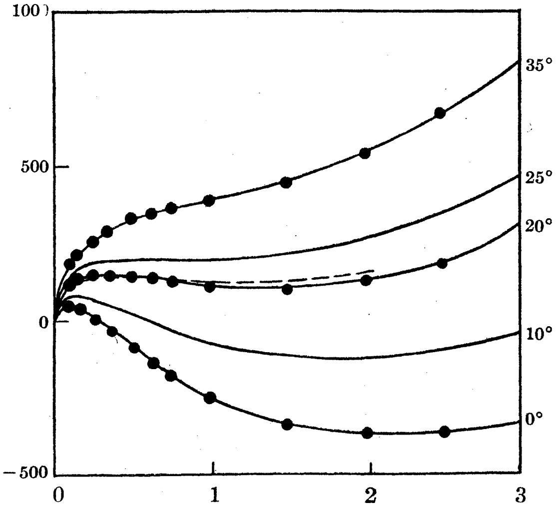

Fig. 1.—The relative partial molal heat content (Rossini's values at 18° are represented by the dotted line).

Rossini[10] has computed $\overline{L}_2$ for potassium hydroxide in aqueous solution at 18° from heat of dilution data. These values are also plotted in the figure whence it is apparent that excellent agreement is obtained in the concentration range from 0.05 to 1 M. At concentrations from 1 to 2 M, the agreement is not so good.

TABLE V

The Relative Partial Molal Heat Capacity

By differentiation of $\overline{L}_2$ with respect to the temperature, $(\overline{C}_{p_2} - \overline{C}_{p_2}^0)$ is found to be expressed by

$$(\overline{C}_{p_2} - \overline{C}_{p_2}^0) = \alpha + 2\beta t \qquad (19)$$

Values of this quantity at 25° are given in the last column of Table V. In Fig. 2, these results have been plotted against $m^{1/2}$ and are designated by circles. The two solid straight lines represent the equations which Gucker and Schminke[11] and Rossini[12] proposed to express the results obtained from calorimetric data. The limiting slope of the Debye and Hückel theory is also represented. The maximum difference between our results and those of Gucker and Sch-

minke is two calories. This is good agreement considering all the difficulties encountered in this determination. Our results indicate a slight curvature.

Summary

Measurements of the electromotive forces of the cell $H_2 \mid KOH(m) \mid K_xHg \mid KOH(0.05) \mid H_2$ have been made from 0 to 35° inclusive at 5° intervals and m was varied from 0.1 to 4 M.

2. From these data, the activity coefficient, relative partial molal heat content, and the relative partial molal heat capacity have been computed. Satisfactory agreement with similar results derived from calorimetric data has been obtained.

The Heat Capacity of Carbon Disulfide from 15 to 300°K. The Entropy and Heat of Fusion of Carbon Disulfide

BY OLIVER L. I. BROWN[1] AND GEORGE G. MANOV

The heat capacity of solid and liquid carbon disulfide, and the heat of fusion have been determined in order to complete the data necessary for the calculation of the entropy of carbon disulfide.

Material.—The carbon disulfide was fractionally distilled several times after drying with calcium chloride. About two liters of material obtained in this way was fractionally distilled using a special column about 60 cm. high, packed with brass shoe eyelets. The distilling flask contained phosphorus pentoxide to remove the last traces of water, and the distillation was carried out in an atmosphere of helium gas to avoid possible oxidation of the carbon disulfide. About half the distillate was collected as a middle fraction, which served as the starting material for a new fractionation. This procedure was repeated a third time before the product was placed in the calorimeter. The calorimeter, which was copper, was filled in such a manner that the carbon disulfide came in contact with only helium, copper, glass and the solder used for sealing the top. A small amount of helium was admitted to ensure heat conduction in the sample before the calorimeter was sealed. From the change in melting point with percentage

(1) Present address, University of Michigan, Ann Arbor, Michigan.

melted and the absence of appreciable premelting, it was estimated that the solid-insoluble liquid-soluble impurity was less than 0.001 mole per cent. Measurements were made on a sample of 145.987 g. (weight *in vacuo*).

Heat Capacity Measurements.—The method used for the heat capacity measurements has been described previously.[2] One calorie was taken equal to 4.1833 international joules, and the molecular weight of carbon disulfide was taken as 76.12. The heat capacities are tabulated in Table I, and plotted as a function of temperature in Fig. 1. The values of the heat capacities are listed in the order of increasing temperature, but are numbered in the order in which they were determined. No previous values for the heat capacity of solid carbon disulfide have been reported in the literature. Previous measurements on the liquid have been made by Koref,[3] Hartung[4] and Battelli.[5] Koref made seven determinations, all of which agree with our results to within 0.2%. Hartung reported only one value, which agrees with our results to within 0.16%. Our results are not in agreement with those of Battelli, whose values differ in some cases by as much as 17% from those reported here.

Melting Point and Heat of Fusion.—The melting point and heat of fusion were obtained by the method described by Johnston and Giauque.[6] The melting point determination is summarized in Table II. The resistance thermometer had a temperature coefficient of one ohm per degree in this range. The values of the resistance are included in the table because of the greater accuracy of the resistance thermometer for small temperature changes, although the actual temperatures were obtained from the thermocouple readings. The thermocouple was calibrated in terms of the laboratory standard No. 17, and is believed to be accurate to 0.05 °K. After the completion of these measurements the thermocouple was compared directly with the boiling point of hydrogen and found to correspond to within 0.02 °K.

Previous values for the melting point have been reported by Henning[7] (−112.00°C.), Timmermans, van der Horst and Onnes[8] (−111.6°C.), Timmermans[9] (−111.8°C.), Keyes, Townshend and Young[10] (−112.97°C.), and Skau[11] (−111.88°C.).

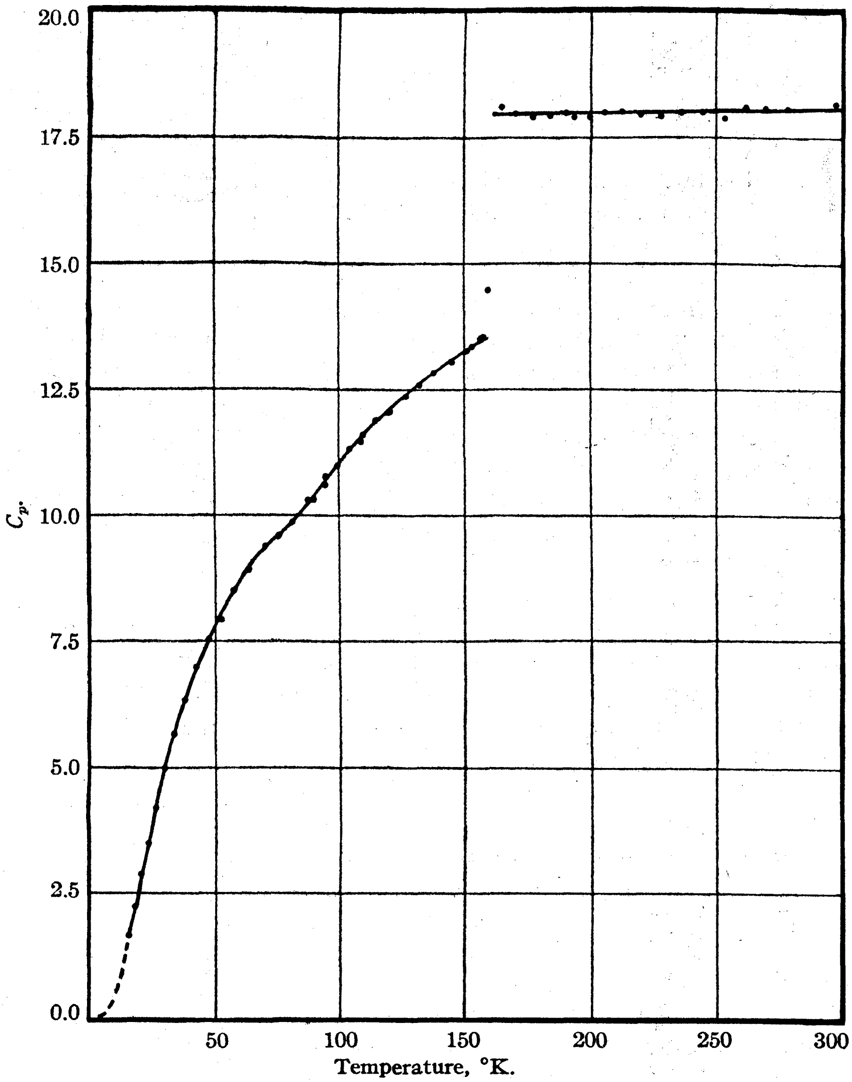

Fig. 1.—Molal heat capacity of carbon disulfide.

The heat of fusion of carbon disulfide was found to be 1049.0 cal. per mole. We were able to make only one heat of fusion measurement, as the calorimeter unfortunately split open after the completion of run No. 54, and while the calorimeter was being heated up to the melting point in order to make a second determina-

Average melting point 161.11 ± 0.05°K. (−111.99°C.).

tion of the heat of fusion. Since circumstances have arisen which make it unlikely that we will repeat these measurements, we have considered it best to offer our results even though the lack of a second heat of fusion makes it difficult to estimate the total probable error. We have no reason to suspect the accuracy of our single measurement, and in similar measurements made in this Laboratory by other workers the error has not usually exceeded 0.3% or about 3 cal. per mole. We have assigned the total probable error in the entropy as 0.5 E. U., which we believe to be a very conservative figure.

The heat of fusion of carbon disulfide has been determined indirectly by Timmermans,[12] and Mitsukuri and Aoki,[13] who measured the change in freezing point when organic solutes were dissolved in carbon disulfide. The former gives 1350 cal. per mole with an uncertainty of 10 to 20%, and the latter give 660 cal. per mole for the heat of fusion.

Entropy of Carbon Disulfide.—The entropy calculations are summarized in Table III. The graphical portion of the entropy was obtained from an integration of C_p *vs.* log T, and also as an arithmetical check, from an integration of C_p/T *vs.* T. The entropy of vaporization was taken from the work of Mathews,[14] who found by direct vaporization using electrical energy that the heat of vaporization of carbon disulfide at 45.29° was 84.07 ± 0.03 cal. per gram. The vapor pressure, heat capacity of the vapor, critical temperature and critical pressure used in calculating the last three items in Table III were taken from the "International Critical Tables."[15]

TABLE III

CALORIMETRIC ENTROPY OF CARBON DISULFIDE

0–15.05°K., Debye extrapolation	0.629 E. U.

Entropy of ideal gas at 319.35°K., 57.48 ± 0.5

The entropy of gaseous carbon disulfide may be calculated from spectroscopic data using the moment of inertia of Cross,[16] which was checked by Sanderson,[17] the vibration frequencies of Dennison and Wright[18] and the methods of Giauque.[19] The result of this calculation at the temperature of the normal boiling point, 319.35°K., is summarized in Table IV.

TABLE IV

ENTROPY OF CARBON DISULFIDE FROM SPECTROSCOPIC DATA

$S°$ Rotation		15.725 E.U.
$S°$ Translation		39.255
$S°$ Vibration	v_1 = 655.5 cm.$^{-1}$	0.441
	v_2 = 396.8 (double wt.)	2.167
	v_3 = 1532	0.016
$S_{319.35}$; CS_2 (gas)		57.60

The calorimetric value (57.48 E. U.) agrees with the spectroscopic value (57.60 E. U.) well within the estimated experimental error.

Summary

The heat capacity and heat of fusion of carbon disulfide have been measured. The entropy calculated from calorimetric data agrees with the spectroscopic value within the experimental error. The entropy of liquid carbon disulfide at 298.1°K. was found to be 36.10 E. U.

The Determination of Activity Coefficients from the Potentials of Concentration Cells with Transference. III. Potassium Chloride. IV. Calcium Chloride

BY THEODORE SHEDLOVSKY AND DUNCAN A. MACINNES

In the two previous papers in this series[1,2] it was shown that accurate activity coefficients can be obtained from the results of potential measurements on concentration cells with transference of the form

$$\text{Ag; AgCl, MCl}\,(C_1)\text{:MCl}(C_2)\text{, AgCl; Ag} \qquad \text{(A)}$$

in which M represents a positive ion constituent. The computations involved the use of the equation

$$-E = \frac{2RT}{F}\int_{C_1}^{C_2} t \,\mathrm{d}\log Cf \qquad (1)$$

in which E is the potential of a cell of type A, t is the transference number of the positive ion, C is the concentration in gram moles per liter of solution and f the activity coefficient. The papers mentioned describe the determination of the activity coefficients of sodium chloride and of hydrochloric acid, respectively, up to concentrations of 0.1 normal, the upper limit being determined by the available accurate transference data. We have continued the measurements to include solutions of potassium chloride and calcium chloride. The first of these was chosen because it is a commonly used type and reference salt, and also because precise determinations of the transference numbers of potassium chloride have been made over a wide range of concentrations. Longsworth[3] has obtained transference data for that substance over the concentration range 0.001 to 1.0 N, by the moving boundary method, and MacInnes and Dole[4] have used the Hittorf method over the range 0.2 to 3.0 N. The two methods gave closely agreeing values, the greater precision, however, being obtained with the moving boundary method.

Calcium chloride has been added to the series because it is an example of a salt of a higher valence type. For a bi-univalent electrolyte equation (1) must be modified to

$$-E = \frac{3RT}{2F}\int_{C_1}^{C_2} t \,\mathrm{d}\log Cf \qquad (2)$$

The value of the coefficient 3/2 may be explained readily by the fact that the passage of 2 faradays of current through a calcium chloride concentration cell "without transference" is accompanied by the transport of three gram moles of ions, *i. e.*, one of calcium and two of chloride. Accurate transference numbers for calcium chloride have been obtained recently by Longsworth[5] in the concentration range C = 0.005 to 0.1 N.

The experimental procedure employed in determining the potentials of the concentration cells followed closely that described for cells containing hydrochloric acid.[2] The potassium chloride was of the best obtainable grade, and was given a further purification by precipitation with hydrogen chloride gas, and repeated crystallization from conductivity water. The calcium chloride was from the same sample as was used by Shedlovsky and Brown[6] in their conductance measurements. The solutions were made up by weight dilution from known stock solutions and their concentrations confirmed by accurate conductance determinations.[6,7] The two silver–silver chloride electrodes in the concentration cell never differed from each other by more than 0.02 mv. and the effect of this small difference of potential was eliminated, within a few microvolts, by duplicate measurements with the positions of the two solutions in the cell reversed. From the experimental data values of activity coefficient ratios have been computed by the method described in the first paper of this series.[8]

Activity coefficients may be stated in terms of concentrations, C (moles per liter), m (moles per 1000 g. of solvent), mole fractions, n and other concentration scales which will not concern us here. They are connected by the relation

$$a_c : a_m : a_n = fC : \gamma m : f_r n \qquad (3)$$

in which a_c, a_m and a_n are activities on the scale represented by the subscripts, and f, γ and f_r

[8] In that paper,[1] equation (11) should read

$$-\Delta\log f = -\frac{E}{118.29\,t_1} - (\log C_2 - \log C_1) - \frac{1}{t_1}\int^{2} \Delta t \,\mathrm{d}\log C + \frac{1}{t_1}\int_{1}^{2} \Delta t \,\mathrm{d}(\Delta\log f)$$

are the corresponding activity coefficients. Since it is assumed that these activity coefficients approach unity at infinite dilution they are measures of deviations from ideal solutions defined in three different ways. The activity coefficient f_r has been called "rational" because it measures departures from Raoult's law.[9] The relations between f, γ and f_r are the following

$$f_r = f(d - 0.001MC + 0.018\nu C)/d_0 = \gamma(1 + 0.018\nu m) \quad (4)$$

in which ν is the number of ions into which the solute dissociates, M is the molecular weight of the solute and d and d_0 are the densities of the solution and solvent.

To obtain the activity coefficients, f, from values of $-\Delta\log f$ computed directly from the data it was necessary to evaluate the activity coefficient of the reference solution. To this end use was made of the Debye–Hückel equation in the form

$$-\log f = \Delta\log f - A = \alpha\sqrt{C}/(1 + \beta\sqrt{C}) + \log\frac{(d - 0.001MC + 0.018\nu C)}{d_0} \quad (5)$$

in which α is 0.5056 for a uni-univalent and 1.7515 for a bi-univalent electrolyte, respectively, at 25° and β involves the distance of closest approach of the ions. The last term of this equation is of negligible magnitude in dilute solutions.[10] To obtain a value of A a plot was made of $(\Delta\log f - \alpha\sqrt{C})$ against $(A - \Delta\log f)\sqrt{C}$, and the value of A adjusted until it agreed with the intercept of the plot, as described in more detail in the previous papers. With this value of A, $\log f$ values may be obtained directly from $\Delta\log f$, as indicated in equation (5).

Results and Discussion

(a) Potassium Chloride.—The results of the series of measurements on the potentials of potassium chloride concentration cells are given in Table I. The first column of the table contains the concentrations C_2 in moles per liter at 25°. The reference solution C_1 was 0.1 mole per liter. The second and third columns contain the corresponding potentials, E, in millivolts, and the transference numbers, t. The fourth column lists values of $-\Delta\log f$. From these figures the activity coefficients f, given in the next column, were obtained with the aid of the value of A determined as described above. The value of β in equation (5) was found to be 1.350, corresponding to a distance of closest approach of 4.13 Å.[11] Using this constant and equation (5), the activity coefficients "f computed" in column 6 were calculated. It will be seen that the agreement between the experimental and computed activity coefficients extends to about $C = 0.2$. This concentration is considerably higher than the usual upper limit of validity of this equation. In the cases of sodium chloride and hydrochloric acid it is about $C = 0.04$.

For higher concentrations Hückel[9] has proposed the equation

$$-\log f_r = \alpha\sqrt{C}/(1 + \beta\sqrt{C}) - DC \quad (6)$$

in which D is a constant. A careful analysis, to be published elsewhere, has proved that an equation of this type will not fit our data above $C = 0.5$. However, the equation

$$-\log f = \alpha\sqrt{C}/(1 + \beta\sqrt{C}) - DC\log C + \log[(d - 0.0386C)/d_0] \quad (7)$$

was found to agree surprisingly closely with the experimental results throughout the concentration range studied, *i. e.*, $C = 0.005$ to 3.0, as can be seen by comparing the figures in columns 5 and 7 of Table I. The values of β and D in this equation were found to be 1.50 and 0.0365, respectively.

It has, however, been usual to express activity coefficients in terms of γ values, *i. e.*, a_m/m, in which m represents moles per 1000 g. of water. The relation between f and γ is given in equation (4). Thus, equation (7), which was obtained from the data in Table I, can also be put in the form

$$-\log\gamma = \frac{0.5056\sqrt{C}}{1 + 1.50\sqrt{C}} - 0.0365C\log C + \log(1 + 0.036m) \quad (7a)$$

For reference, values of γ at round concentrations for potassium chloride at 25° are given in Table II.

(b) Calcium Chloride.—The results of measurements and computations on solutions of calcium chloride are given in Table III, which is

---

(9) Hückel, *Physik. Z.*, **26**, 93 (1925).

(10) In the previous papers of this series this term was not included. For sodium chloride and hydrochloric acid it is negligible, within the experimental error, up to $C = 0.1$, the upper limit of the measurements.

(11) The last term in equation (5) was computed with the aid of the relation

$$d = 0.99707 + 0.04805C - 0.00230C^{3/2}$$

for the density, d, at 25°, of potassium chloride solutions, from the data given in the "International Critical Tables." For the density, d, at 25°, of calcium chloride solutions the corresponding equation is

$$d = 0.99707 + 0.0924C - 0.0042C^{3/2}$$

from the measurements of Shedlovsky and Brown.[6]

.096540	− 8.607	.3958	− .0438	.5275	.5198	.5276

mostly self-explanatory. For this salt the reference concentration was C_1 = 0.05 mole per liter and the computation yielded the value for β of 2.98. This value for β corresponds to a distance of closest approach of 5.27 Å. The sixth column of the table gives values of f computed, using these constants and the appropriate value of α in equation (5). It will be seen that the observed and computed values of the activity coefficient f agree to C = 0.03. It is of great interest to find that the Debye–Hückel theory in its simple form holds for this "unsymmetrical" type of electrolyte. The distance of closest approach is large enough so that the higher terms of the theory[12] are negligible. Agreement between the observed and computed values is observed throughout the range of the measurements with the equation

$$-\log f = \frac{1.7515\sqrt{C}}{1 + 2.814\sqrt{C}} - 0.147C + \log(1.0029d - 0.057C) \quad (8)$$

as can be seen by comparing the fifth and seventh columns of Table III. Values of γ for solutions of calcium chloride at 25° can be obtained from the equation

$$-\log \gamma = \frac{1.7515\sqrt{C}}{1 + 2.814\sqrt{C}} - 0.147C + \log(1 + 0.054m) \quad (8a)$$

---

[12] La Mer, Gronwall and Greiff, *J. Phys. Chem.*, **35**, 2245 (1931).

Summary

The activity coefficients in aqueous solution at 25° of potassium chloride from $C = 0.005$ to 3.00 moles per liter, and of calcium chloride from $C = 0.002$ to 0.1 have been determined from measurements of potentials of concentration cells with transference, and accurate transference numbers.

It has been found that the simple Debye–Hückel equation $-\log f_r = \alpha \sqrt{C}/(1 + \beta \sqrt{C})$ fits the data, with high precision to $C = 0.2$ for potassium chloride and to $C = 0.03$ for calcium chloride, with distances of closest approach of 4.1 and 5.2Å., respectively.

The equation

$$-\log f_r = \frac{0.5056 \sqrt{C}}{1 + 1.50 \sqrt{C}} - 0.0365C \log C$$

holds for potassium chloride up to $C = 3.00$, and the expression

$$-\log f_r = \frac{1.7515 \sqrt{C}}{1 + 2.814 \sqrt{C}} - 0.147C$$

fits the data for calcium chloride up to $C = 0.1$.

A Revision of the Atomic Weight of Carbon. II

BY GREGORY P. BAXTER AND ARTHUR H. HALE

Quantitative combustion of hydrocarbons has been continued during the past year and the results confirm the conclusion already reported[1] that the atomic weight of carbon is not far from 12.010.

Only minor changes were made in the combustion apparatus and analytical technique. The ring seal of the second bulb in the water absorption system was eliminated in order that complete equalization of pressure might be more easily secured during weighing. Furthermore, the air in this system was saturated with water during the first weighing, so that no correction was necessary on this score. In some of the analyses (71, 74, 78, 79, 80), a somewhat smaller but similar system was used for absorbing the carbon dioxide, in order to increase the accuracy of weighing.

During the earlier work preliminary experiments had shown that the "blank" corrections were very small. These and later experiments, carried out by passing air and oxygen through the empty combustion tube while it was heated as in the combustions, produced the changes in weight (positive) given in the following tables.

AIR

	Duration of run, hours	H_2O, mg.	CO_2, mg.
	44	0.26	0.38
	64	.52	.62
Total	108	.78	1.00
Gain per hour		.0072	0.0093

OXYGEN

At the close of each run the tubes were swept out with air, and a correction made for the period during which air was used.

	Duration of run, hours	H_2O, mg.	CO_2, mg.
	44	0.76	0.01
	71	.68	1.17

On the basis of these results in each of the new experiments as well as in those already reported a negative correction based on these blanks has been applied. This correction usually amounted to about 0.1 mg. each for both water and carbon dioxide.

Purification of Hydrocarbons

Pyrene.—Although our earlier attempts to purify pyrene had apparently been unsuccessful, further efforts were made as follows. One specimen after crystallization from pure benzene was first melted in vacuum with freshly fused potassium hydroxide and then distilled from the potassium hydroxide. After another crystallization the sample was melted in nitrogen at low pressure in contact with metallic sodium, and then distilled from the sodium. Crystallization from benzene, distillation at low pressure and another crystallization followed.

Another sample was kept melted, in nitrogen at low pressure, over metallic mercury for twenty hours. This was followed by crystallization from benzene, treatment with sodium as described above, another crystallization, distillation at low pressure and a final crystallization.

The benzene used in these experiments and in the puri-

fications described below had been treated with concentrated sulfuric acid, distilled and three times fractionally frozen.

The two samples of pyrene, when quantitatively burned, yielded 12.023 (Analysis 78) and 12.019 (Analysis 79) for the atomic weight of carbon, results essentially like those previously obtained with pyrene. Apparently these efforts at purification were as unsuccessful as the earlier ones. Actually Dr. E. B. Hershberg was able to detect sulfur in both these samples.

Chrysene.—A portion of the chrysene used in Analyses 39, 40, 45 and 47 of the previous work was further purified by distillation in nitrogen at low pressure and by crystallization from pure benzene (Sample II). The melting point was kindly determined by Dr. Hershberg to be 254.1–254.4°, corr.[2] Before this purification the melting point was 254.5–255.0°, although the composition before the treatment described above was identical with that of this sample.

Through the kindness of Professor L. F. Fieser we received a synthetic sample of chrysene[3] built upon naphthalene as a nucleus. We subjected this sample to three crystallizations from benzene with intermediate distillations at low pressure; m. p. 254.1–254.4° (corr.), Sample III.

Triphenylbenzene.—A portion of Sample II (previous paper, m. p. 174.3–174.5°, corr.) was slowly distilled at very low pressure with rejection of about a gram of slightly yellow residue. The product was once crystallized from pure benzene; m. p. 174.3–174.5° (corr.), Sample III.

A new sample was prepared for us by Dr. M. S. Newman under the direction of Professor Fieser. Benzaldehyde

---

(2) All other melting points given in this paper were determined by Dr. Hershberg.

(3) Fieser, Fieser and Hershberg, THIS JOURNAL, **57**, 1851 (1935); **58**, 1463 (1936).

from amygdalin was converted to secondary phenylethyl alcohol with methylmagnesium chloride. Oxidation with dichromate and sulfuric acid yielded acetophenone, and condensation of acetophenone in a sealed tube with hydrochloric acid at 200° yielded triphenylbenzene. The latter was crystallized from acetic acid, distilled at low pressure and crystallized four times from dioxane. We purified the sample further by two crystallizations from benzene, low pressure distillation and a final crystallization from benzene; m. p. 174.2–174.5° (corr.), Sample IV. The sample previously used melted at 174.3–174.5° (corr.).

Anthracene.—A new sample of anthracene was purified as described in our earlier paper, Sample II.

Still a third sample was prepared from phthalic acid and benzene. Phthalic acid, after crystallization from water, was dehydrated to the anhydride. From phthalic anhydride and benzene with aluminum chloride *o*-benzoylbenzoic acid was prepared, and crystallized from benzene. Treatment of the product with concentrated sulfuric acid yielded anthraquinone which was recrystallized from glacial acetic acid. Reduction of anthraquinone to anthrone was effected with tin and hydrochloric acid. After recrystallization from a mixture of benzene and petroleum ether the anthrone was reduced to anthracene with zinc dust, sodium hydroxide and ammonia, and the anthracene was three times recrystallized from benzene. To purify the anthracene further it was melted in contact with potassium hydroxide in nitrogen at low pressure, distilled from the mixture, and crystallized from benzene. These processes were then repeated. Finally the product was melted in nitrogen, distilled at low pressure and recrystallized from pure benzene; m. p. of distilled material, 216.2–216.4° (corr.). The sample previously prepared melted at 216.4–216.7° (corr.), Sample III.

In Table I the weights of hydrocarbon have been corrected to vacuum. The weights of water have been corrected to vacuum, for dissolved air (see preceding paper), and for the blank (see page 506). The weights of carbon dioxide have been corrected to vacuum, and for the blank (see page 506).

A restandardization of the weights brought to light an error in the correction of one of the weights used in the earlier experiments. Because of this, and because "blank" corrections are now available the recalculated results of the earlier experiments are included with the new ones. No experiments are omitted from the table except those abandoned because of some accident.

In most of the analyses about 3 g. of hydrocarbon was burned. This quantity seemed to ensure sufficient accuracy and since seven to nine hours were required for combustion alone of this amount the experiment was as prolonged as it could be without too much tax on the analyst. In four experiments about 6 g. was burned, Nos. 61, 76, 77 and 81. The average result of these four experiments is 12.0111, that is, slightly less carbon dioxide was recovered than in the others. But of these four, Analysis 61 yielded more than the average and the atomic weight 12.0102. In Analyses 56, 70 and 74 only 1.5–2.0 g. was burned. The average of these three is 12.0099, but the average of Analyses 70 and 74 is 12.0103.

In four experiments, Analyses 55, 60, 68 and 77 the rate of burning was less than normal, about twelve hours for 3 g., and the average result 12.0108, while in Analysis 61 6 g. was burned in ten hours, yet Analysis 61 yielded slightly more carbon dioxide than the normal.

It seems unlikely that variations in quantity of hydrocarbon burned or minor variations in speed of combustion had any important effect on the result.

The average atomic weight of carbon (excluding results with pyrene), 12.010, is 0.001 unit higher than that reported in our earlier paper, partly because of the new corrections, partly because the effect of experiments 39 and 56 is distributed over a larger number.

As we have already pointed out, because of the low percentage of hydrogen in our hydrocarbons the method is comparatively insensitive to the present uncertainty in the atomic weight of hydrogen. Aston's[4] recent value, corrected to the chemical scale and for H^2, is 1.0081. With this value for hydrogen, that of carbon is lowered only 0.00026. It seems unlikely that natural variations in isotopic proportions (H, O, C) will be observed large enough to affect present chemical accuracy.

Although in this method it is unnecessary that the hydrocarbons should be pure, but only necessary that they should be free from impurities other than hydrocarbons, the composition of each hydrocarbon seems to correspond very closely with the formula in every case except that of pyrene. In the following table calculations of the percentages of hydrogen and carbon are made from the weights of water and carbon dioxide, with the use of the values 1.0078 and 12.010, for hydrogen and carbon, respectively. For the twenty-seven analyses (those with pyrene excluded) the average net deficiency from the theoretical in hydrogen is 0.0001%, that in carbon 0.002%. This apparent deficiency in carbon necessarily disappears entirely if our average atomic weight, 12.0104, is employed.

Aston's[4] most recent value for C^{12}, converted to the chemical scale with the factor 1.00025, is

12.0005. This is 1/10,000 lower than the value reported by him a year earlier, 12.0018.[5] Bainbridge (private communication) finds 12.0012, corrected to the chemical scale. With the value 12.0012 for C^{12} and our atomic weight the calculated abundance ratio of C^{13} is 1/109. This value is lower than that computed from our earlier results. Jenkins and Ornstein[6] find 1/106; Vaughan, Williams and Tait[7] 1/92 and Aston[8] 1/138.

Summary

It seems unlikely that our final value would be altered materially by continuance of the experiments. Of the four hydrocarbons investigated, one, pyrene, proved incapable of being purified by any method we could devise. The other three yielded identical results for carbon, whether they had been initially separated from coal tar, or synthesized, from a simple coal tar product in two cases (chrysene and anthracene), from a natural product in the third (triphenylbenzene).

The average atomic weight of carbon obtained by combustion of chrysene, triphenylbenzene and anthracene, 12.010, may therefore be taken as a fair outcome of this method of attack.

Studies in the Physical Chemistry of the Proteins. XIV. The Amphoteric Properties of Hemoglobin*

BY EDWIN J. COHN, ARDA A. GREEN AND MURIEL H. BLANCHARD

The behavior of proteins is determined largely by the number and distribution of their electrically charged groups. An accurate knowledge of the number of dissociable groups is therefore an essential requisite for the study of their distribution by such means as dielectric constant measurements and measurements of change in activity coefficient with change in ionic strength. In extending to proteins relationships developed by the study of amino acids and peptides, we shall first consider those that can be obtained as pure chemical individuals.

From certain points of view the hemoglobin of the horse may be considered the best known of the proteins. It is readily crystallizable by a number of procedures. It contains 0.335% iron[1] and

---

* For supplementary tables of data obtained in this work, order Document 1007 from Science Service, 2101 Constitution Ave., Washington, D. C., remitting 25¢ for microfilm form, or 50¢ for photocopies readable without optical aid.

[1] Zinoffsky, *Z. physiol. Chem.*, **10**, 16 (1886).

0.390% sulfur. The minimal molecular weight of hemoglobin estimated from its sulfur content is 8223, and that from its iron content is double this value, or 16,669. Svedberg and Nichols have studied "the influence of *p*H on the diffusion constant, molecular weight and specific sedimentation velocity of carbon monoxide hemoglobin. . . over a *p*H range of 5.4 to 10.2. The diffusion constant and the specific sedimentation velocity are normal. . . over the range of *p*H 6.0 to 7.56, and the molecular weight is normal, 68,000, at least from a *p*H of 6.0 to 9.05."[2] Osmotic pressure measurements upon aqueous hemoglobin solutions yield the same molecular weight,[3] though it has been suggested that this weight is halved in urea solutions[4] and perhaps under other conditions.

The solubility of horse hemoglobin also has been investigated under a wide variety of conditions, and has been demonstrated to be essentially independent of the amount of saturating body.[5,6,7] Hemoglobin is therefore not only monodisperse, but a chemical individual.

The isoelectric point of hemoglobin has been estimated to be near *p*H 6.8.[8] Its acid properties are increased to the same extent by combination with either oxygen or carbon monoxide, but this effect, important over the physiological range, does not extend to extremely acid or alkaline reactions.

The basic properties of globin depend upon the large amounts of arginine, histidine and lysine in the molecule. Isolation methods have yielded nearly the same values for histidine[9,10] as the nitrogen distribution method[11] (Table I).

The latter method, however, yielded slightly higher estimates for arginine and lysine, suggesting the difficulties of quantitative isolation of these most basic amino acids. The nitrogen distribution method often yields too high values, however. Horse hemoglobin may therefore be assumed to contain between 83 and 93 free basic groups derived from histidine, arginine and lysine.

[a] Values by Hunter and Borsook recalculated by Vickery and Leavenworth.[10]

Estimates of the dicarboxylic amino acids in hemoglobin are unfortunately incomplete, or unsatisfactory, but tyrosine has been analyzed by Folin and Marenzi[12] and found to be present to 3.15%. This analysis as well as those of Vickery and Leavenworth[10] were carried out on hemoglobin isolated and recrystallized in this Laboratory by the same methods as the preparations employed in the physical chemical studies.

Materials and Methods.—The method employed in the preparation of hemoglobin has been described repeatedly[6,13] and essentially consists in recrystallization at the isoelectric point. Experiments I to III were carried out with preparations made in 1930, and preparations IV to VIII in 1936.[14]

The repeatedly recrystallized and washed carboxyhemoglobin generally had a *p*H near 6.5. At this reaction, however, horse hemoglobin is relatively insoluble. It was dissolved by the addition of just sufficient sodium hydroxide of known concentration. The *p*H of these stock solutions was generally between 7.4 and 7.8. They were saturated with carbon monoxide and analyzed

The varying amounts of standard acid or alkali were added to aliquot parts of the stock carboxyhemoglobin solutions and brought to constant volume shortly before they were transferred to hydrogen electrodes. Clark hydrogen electrode vessels, 0.1 *N* calomel electrodes and a saturated potassium chloride salt bridge were employed, no correction being made for the liquid junction potential. The electrodes were always standardized with 0.1 *N* hydrochloric acid, the *p*H of which was considered to be 1.075.[15] Four different electrodes were used, measurements generally being made in duplicate.

Calculation of Results.—Acid and base combined by protein is calculated as the difference between the total and the free acid, C_{H^+}, or base C_{OH^-}, present. This calculation involves the activity coefficients of the hydrogen and hydroxyl ions, which were estimated by Lewis and Randall[16] from mean activity coefficients on the assumption that γ_{H^+} is equal to γ_{OH^-} in solutions more dilute than 0.01 *N*. They estimate $-\log \gamma_{H^+}$ in 0.1 *N* hydrochloric acid as 0.076. Scatchard's[15] subsequent revision yields slightly higher values for $-\log \gamma_{H^+}$ at low concentrations, but his result, 0.075, is in good agreement at 0.1 *N*. The standardization of our electrodes with 0.1 *N* hydrochloric acid has always given a value close to this for the hydrogen potential.[17]

"Although Lewis and Randall's . . . value 1.005 × 10^{-14} . . . is now the most probable value for the dissociation constant of water, its use in the calculation of our data leads to different values for p_{OH^-} in alkaline solution than those calculated from Lewis and Randall's coefficients for the activity of the hydroxyl ion. In all probability this de-

pends not upon the value of K_w, but upon diffusion potentials, for which we have not corrected. If, however, we employ the Sørensen–Michaelis values for K_w at different temperatures, our p_{OH}-values conform approximately to those calculated from the activity of the hydroxyl ion"[17] (p. 53). Without making any assumption whatever as to the correct value for K_w we have adopted tentatively the latter.[18] The temperature variation of pH is also ascribed to K_w, and not to p_{OH}-(pK_w − pH$^+$).

The activity coefficients of the hydrogen and hydroxyl ions depend not only on their concentrations, but on those of all other ions in solution and decrease as the valency of the latter increases. Thus the higher valencies of protein anions and cations might be expected to have a large effect on the activity coefficients of the hydrogen and hydroxyl ion. In an attempt to evaluate the kind of correction that should be employed in studies of amino acids and proteins, we studied some years since the activity coefficients of the hydroxyl ion in sodium hydroxide solutions containing other sodium compounds, including "four bivalent acids, sulfuric, oxalic, glutamic, and aspartic, the two latter amino acids. . . . The results with these acids. . . suggest that anions of higher valence have greater effects upon the activity of the hydroxyl ion. This effect might be expected to increase with the ionic strength, but the effect on the amino acids studied at this concentration was not so great as that of other divalent salts. . . . Because of their high valence, protein anions may, of course, further depress the activity of the hydroxyl ion. Uncertainty regarding the valence type to be ascribed to proteins makes it difficult, however, to apply a correction for this factor, and their very low concentration may make it unnecessary. Accordingly we have tentatively used the values of γ deduced from measurements of sodium hydroxide solutions in the calculation of our data"[17] (p. 57).

There is no doubt that activity coefficients, calculated on the basis of inorganic ions, are too low. There is also no doubt that those calculated on the basis of the valence of protein salts are far too high. Recent studies on the effect of the sodium salts of proteins, including hemoglobin, on the solubility of thallous chloride have been reported by Stone and Failey. Their results confirm the above conclusion, for the activity coefficients of the thallous chloride are far smaller than would be expected on the basis of ionic strengths calculated in terms of the molecular weights and the number of free groups of proteins. They calculated base combining capacity by assuming the mean activity coefficient of the thallous chloride, as determined by these solubility measurements, to yield the activity coefficient of the hydroxyl ion.[19]

In all of these methods, the activity coefficient of the hydroxyl ion varies with the sodium hydroxide concentration, and with the protein concentration. In order to minimize the influence of these factors we have carried out measurements in systems normal with respect to sodium chloride

from acidities at which the hemoglobin chloride is precipitated by the neutral salt, to reactions at which the hemoglobin is completely bound by base.

Under these conditions the effect on the activity coefficient, due to the influence of the neutral salt on the hydroxyl ion, is sufficiently large to mask the changes due to variation with sodium hydroxide and presumably with protein concentration. "It has been shown that the Nernst formula for electromotive force, the solubility product and mass action law in the case of a complicated ionic equilibrium are applicable in their classical form to such concentrated salt solutions, the reason for this simplicity being the practical constancy of the activity coefficients in the practically constant medium. Utilization of these results would mean in many cases a great simplification in problems pertaining to electrolytic solutions"[20] (p. 431). Measurements upon 0.01 and 0.1 N sodium hydroxide in N sodium chloride, calculated by means of the Michaelis values of K_w, yield values of $-\log\gamma_{OH}$ which vary less than 0.01 and may be taken as 0.23 at 25° for all the systems containing salt that are reported.

Maximal Acid and Base Combining Capacity of Hemoglobin.—Several studies of the combination of hemoglobin with acid and base have been reported. One of these is the titration with the quinhydrone electrode by Lewis[21] of the carboxyhemoglobin of the ox with sulfuric acid in the presence of ammonium sulfate. His results yield an acid combining capacity of 145×10^{-5} equivalent per gram of hemoglobin. Pauli and Schwarzacher[22] report that hemoglobin combines 159×10^{-5} mole hydrochloric acid per gram and 124.5×10^{-5} mole lithium hydroxide per gram. The results of Stone and Failey[19] yield a base combining capacity of slightly over 100×10^{-5} mole per gram calculated on the basis of the activity coefficient of thallous chloride and the value 14 for pK_w. Recalculation by the methods we have employed yields essentially the same result.

In several experiments we have titrated carboxyhemoglobin to saturation with hydrochloric acid (Table II). No appreciable increase in acid combining capacity was detected at reactions acid to pH 2.2. From pH 2.2 to 1.5 the free hydrochloric acid increased more than sixfold, with a change in combined hydrochloric acid only from 144.6 to 150.4×10^{-5} mole per gram. These results, as calculated, yield a maximal acid combining capacity of 148×10^{-5} mole per gram. The influence of protein in increasing the activity coefficients employed would result in a lower estimate of the combining capacity. The measurements in Table II are subject to correction at such a time as data are available for the activity coefficients of the hydrogen ion in the presence of hemoglobin hydrochloride.

The base combining capacity of hemoglobin has been calculated in Table III. The base bound by hemoglobin increased until the reaction was more alkaline than pH 12.2. At this reaction the concentration of free and combined base was approximately equal. At pH 12.68 the free base was three times that bound, and no appreciable increase in combining capacity was observed, provided the measurements were made soon after the hemoglobin was exposed to such extremely alkaline reactions. In either strongly acid or basic solutions, the hemoglobin changed from its characteristic red color to a deep brown. At either longer times or more alkaline reactions, greater apparent base combining capacities were noted and ascribed to hydrolysis. This was the case with many of the earlier experiments, which yielded satisfactorily constant acid combining capacities, but apparent base combining capacities which varied from experiment to experiment and were always greater than those reported.

The use either of higher activity coefficients, such as those employed by Stone and Failey, or of a larger value for pK_w, would result in lower estimates of base combining capacity than the value which results from the mode of calculation we have always employed (Table III). It was largely to test this point that measurements were undertaken in the presence of normal sodium chloride (Table IV).

Hemoglobin preparations V to VIII were studied in molal sodium chloride. Although the hemoglobin in these experiments varied from 16.37 to 48.08 g. per liter, the results with all but preparation V (which yielded a normal titration curve, but a maximal combining capacity of 148×10^{-5} mole sodium hydroxide per gram, and is not reported in detail since unconfirmed by any subsequent experiment) yield the same or slightly lower maximal combining capacity in the pres-

ence of N sodium chloride as had the earlier experiments on systems to which no salt was added. The base combining capacity in the systems containing normal sodium chloride appears to pass through a minimum near pH 12.3. The apparent decrease in combined base at more alkaline reactions suggests that the activity coefficients employed may have been too large. The curve in Fig. 1 is constructed as though hemoglobin dissociated 261 × 10^{-4} mole of hydrogen ions between pH 1.5 and 13.

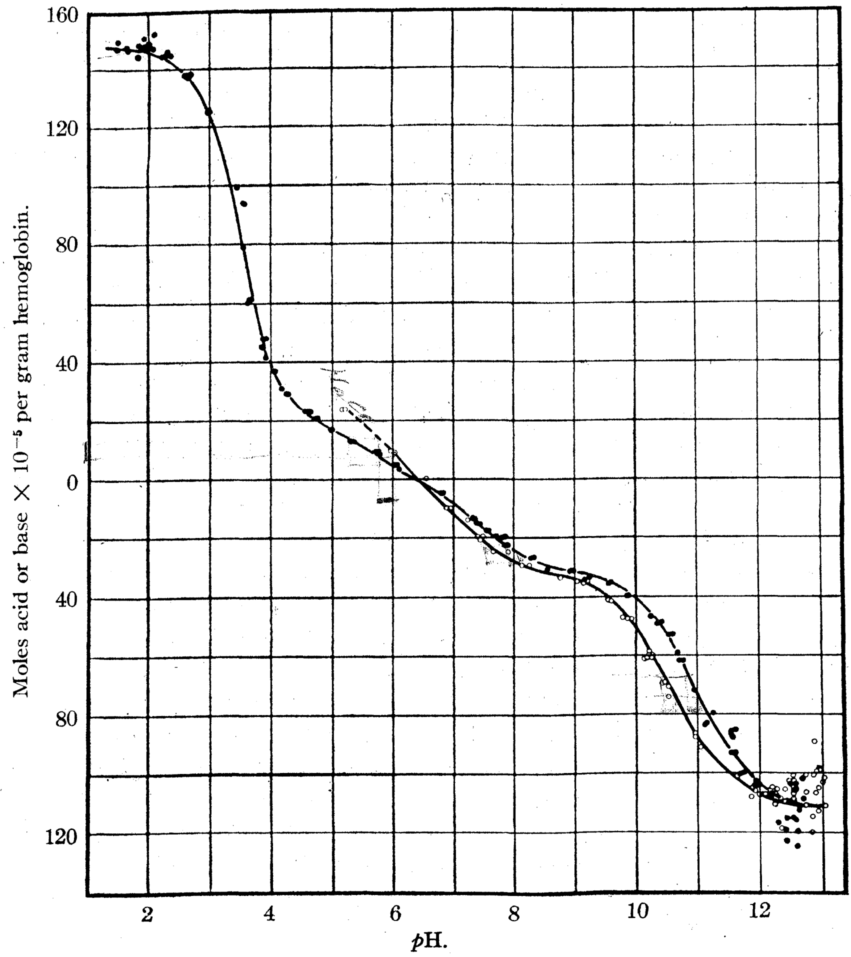

Fig. 1.—The titration curve of carboxyhemoglobin of the horse in the absence of added salt ● and in the presence of 1 M NaCl ⊙.

TABLE V

Protein	Acid combining capacity, moles × 10^5	Base combining capacity, moles × 10^5	Total combining capacity, moles × 10^5
Ox-oxyhemoglobin (21)	145		
Horse—carboxyhemoglobin (19)	159	105 124.5	283.5
(22)	148	113	261

These results are compared with those previously reported in Table V. The final column gives the total acid and base combining capacity of hemoglobin.

Titration Curve of Hemoglobin and its Apparent Dissociation Constants.—Although the acid combining capacity of a protein depends on the histidine, arginine and lysine in the molecule, these basic amino acids dissociate at alkaline reactions. The titration curve of hemoglobin,[23] given in Fig. 1, is readily divisible into at least three well-defined sigmoid curves, one extending from saturation with acid roughly to pH 5, the second from pH 5 to 9 and the third from pH 9 to saturation with base. Although analyzable into a larger number of component parts, we have preferred describing this curve—and that in the presence of N sodium chloride—in terms of the smallest possible number of dissociation constants. The curve in the absence of salt in Fig. 1 is constructed on the basis of the following groups.

Taking the molecular weight of hemoglobin as 67,000, each free reactive group combines with 1.5 × 10^{-5} mole of acid or base per gram. On this basis one may assume 12 tyrosine, from 13 to 16 arginine and from 37 to 44 lysine

[23] The large number of measurements at neutral reactions, on which the titration curve is constructed, are not reported in detail for lack of space, but have been filed as a Science Service Document.

molecules per hemoglobin molecule on the basis of the analyses in Table I.

The solid curve in Fig. 1 is constructed on the assumption that 60×10^{-5} mole dissociate with a *p*K of 10.8 and 21×10^{-4} mole with a *p*K of 11.6. In the free condition the *p*K of the ε-amino group of lysine is 10.53 and of the guanidine nucleus 12.48.[24]

The hydroxyl group of tyrosine dissociates at *pK* 10.28[25] and analytical data suggest 12 molecules of tyrosine in the hemoglobin molecule. The titration curve does not reveal a sufficient number of dissociable groups in the range alkaline to *p*H 9 to account for arginine, lysine and tyrosine,[26] but enough to account for lysine and either tyrosine or arginine. Groups dissociating beyond *p*H 13 would not, it is true, be described by our measurements. The experimental errors at more alkaline reactions are, however, formidable.

The unusual feature of the titration curve of hemoglobin is the extremely well-defined sigmoid curve in the neutral range. This part of the curve has previously been investigated by Hastings,[27] and Sörensen,[7] and is now being reinvestigated by German and Wyman[28] by means of the glass electrode, over the region in which it is shifted to more acid reaction as a result of combination with oxygen or carbon monoxide.

Hemoglobin combines with almost exactly 50×10^{-5} mole per gram between *p*H 5 and 9. That is to say, over this range 33 groups dissociate on the hemoglobin molecule, or exactly the number of histidine molecules revealed by analysis. The difference in dissociation of reduced and carboxyhemoglobin does not involve as many as 33 groups. The free group of histidine has a *pK* of 6.04.[24] In histidyl-histidine the comparable groups have dissociation constants of *p*K 5.6 and 6.8.[29] The titration curve in Fig. 1 is constructed by assuming 12 groups dissociating with *pK* 5.6 and 21 groups with *pK* 7.4. The latter groups, or a portion of them, may be considered as combining less acid in the oxygenated than in the reduced state, and as arranged with some sort of symmetry with respect to the four hematin groups of the hemoglobin molecule.[30]

The basic amino acids revealed by analysis suffice to account for the groups dissociating from *p*H 5 to saturation with base. Over this range 87 groups per molecule dissociate. From this reaction to saturation with acid (Table II) roughly the same number of groups would appear to dissociate.

Since phenolic hydroxyl groups do not generally dissociate in a range more acid than *p*H 5, all of the rest of the groups have been assumed to be carboxyl groups. The curve, acid to *p*H 5, is a sigmoid curve with a point of inflection near *p*H 3.6. Amino acid and protein titration curves are generally analyzed by assuming the independence and additivity of the groups dissociating.[31] The most acid segment of the hemoglobin curve appears to be too steep to be accounted for in this manner, suggesting that the acid groups are not independent of each other. Larger activity coefficients, and therefore a smaller acid combining capacity and estimate of dissociable carboxyl groups, might yield a simpler form of sigmoid curve. The curve tentatively has been described in terms of an equation of the type previously suggested, having the form[32]

$$\frac{A^{-n}}{(\mathrm{H}_nA)} = \frac{K_1}{(\mathrm{H}^+)\gamma_1} + \frac{2K_1K_2}{(\mathrm{H}^+)^2\gamma_2} + \frac{3K_1K_2K_3}{(\mathrm{H}^+)^3\gamma_3} + \cdots \\ \frac{nK_1K_2K_3 \ldots K_n}{(\mathrm{H}^+)^n\gamma_n}$$

The first two right-hand terms suffice, *pK*$_1$ being taken as 3.7, and *pK*$_2$ as 4.0. The total curve fits somewhat better if a small number of groups—possibly representing four of the groups of hematin—is assumed to dissociate in the neighborhood of *p*H 4.9.

Influence of Sodium Chloride upon the Titration Curve.—Apparent dissociation constants are not independent of hemoglobin or of salt concentration. In the systems reported salt concentration was maintained below 0.01 *N*, and hemoglobin concentration varied from 10.8 to 88 g. per liter. Over this range, no large effect of protein concentration was observed, but the largest effect of hemoglobin upon its dissociation occurs at very low concentrations, at which it is not practicable to work in strongly acid or alkaline solutions. The influence of sodium chloride concentration on *p*H in systems differing from each other only in re-

spect to concentration of electrolyte is given in Fig. 2. The smallest effect of salt on the *p*H of protein solutions is near the isoelectric point, as pointed out by Sörensen, and is opposite in direction on either side of the isoelectric point.[5,33,34]

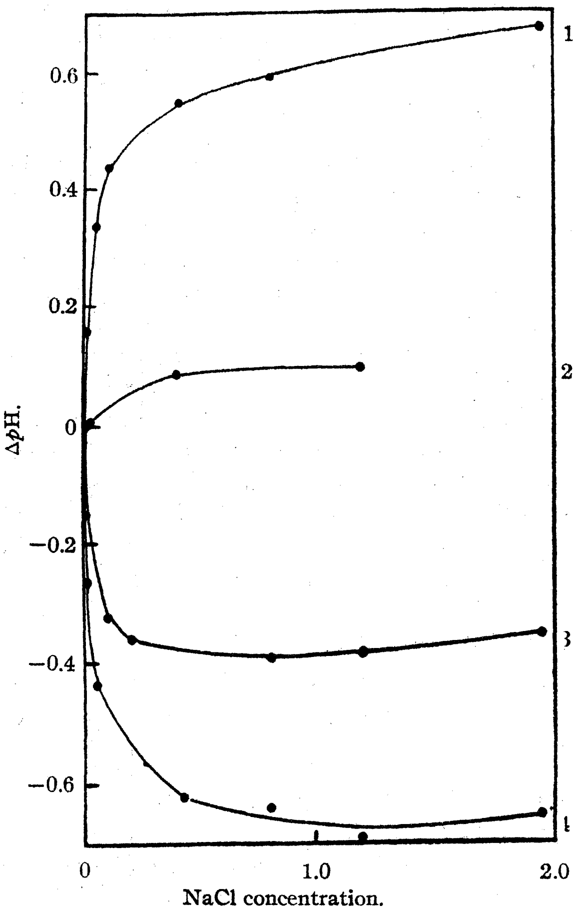

Fig. 2. *Influence of NaCl on the pH of Hemoglobin Solutions.*—Change in *p*H with increasing salt concentration, Δ*p*H, measured at 37° with glass electrode standardized with 0.1 *M* phosphate buffers. The *p*H of the hemoglobin solutions to which no salt was added were: (1) 4.90; (2) 6.60; (3) 7.73; (4) 8.7.

The titration curve in the presence of 1 *M* sodium chloride (Fig. 1) is constructed using the values of 5.2, 6.1, 7.1, 10.4 and 11.2 for pK_3', pK_4', pK_5', pK_6' and pK_7', respectively. pK_3' and pK_4' are thus 0.4 greater and pK_5', pK_6' and pK_7' are 0.4 less than the values in Table IV. Although apparent dissociation constants vary with temperature, salt and protein concentration, total base combining capacity we calculate to be independent of the presence or absence of salt.

Relation between Acid and Basic Dissociation and the Isoelectric Point.—The method of calculation that has been employed may be expected to yield a maximal estimate of dissociable groups.[35] The number of these derived from the histidine may be considered well known. It follows that basic groups dissociate on both sides of the isoelectric point, which bears no simple relation to the reaction, near *p*H 5, on the one side of which acid and on the other side basic groups are presumably dissociating. That certain of the free groups of basic amino acids dissociate in the protein at acid reactions previously has been noted.[36]

The dipolar ion structure of amino acids and proteins demanded reinterpretation of the reactions at which the various groups dissociate. Such analyses of titration curves have been reported,[36–38] but it has often been assumed that the apparent dissociation constants of protein groups bear simple relation to the true dissociation constants of the groups of the free amino acids, a conclusion which by no means follows. The apparent dissociation constants of proteins, as of amino acids and peptides, vary with the number and distribution of the dissociable groups on the molecule.[31–32] The basic strength of an amino group is diminished by carboxyl groups and this is true whether the latter are dissociated or in the non-dissociated condition. Conversely, carboxyl dissociation is increased by juxtaposition of amino and carboxyl groups, and most other substituents. The result is that the closer amino and carboxyl groups are to each other, the more acid the molecule. On the basis of analytical data, casein has half again as many free carboxyl as basic groups, and gelatin twice as many basic as carboxyl groups. In egg albumin the numbers of free acid and basic groups are nearly equal. None the less, all of these proteins have very nearly the same isoelectric point.

Relation between Basic Groups and Acid Combining Capacity, and between Acid Groups and Base Combining Capacity.—In earlier investigations the relation between the number of basic groups and acid combining capacity and between the number of acid groups and base combining

(34) Sörensen, Linderstrøm-Lang and Lund, *J. Gen. Physiol.*, **8**, 543 (1927).

(35) If larger activity coefficients were assumed, not only the base combining but the acid combining capacity would be smaller. The possibility of measuring these activity coefficients by the simultaneous use of cells without liquid junction remains to be accomplished. See Harned and Åkerlöf, *Physik. Z.*, **27**, 411 (1926), and Joseph, *J. Biol. Chem.*, **111**, 479, 489 (1935).

capacity has been stressed.[17,32] Reinterpretation of the regions in which the free groups of proteins dissociate in no way alters this relation. Indeed new analyses of the amino acids[39] in proteins have on the whole confirmed the estimates of the number of free groups derived from physical chemical measurements.[40]

Our measurements yield an acid combining capacity of 148 × 10^{-5} and a base combining capacity of 113 × 10^{-5} mole per gram of carboxyhemoglobin. The total combining capacity of 261 × 10^{-5} mole per gram thus represents 174 ± 2 dissociable groups on the hemoglobin molecule, of which 75 would be acid and 99 basic groups. On this basis not more than 75 dipole pairs can be considered dissociated at the isoelectric point.

There remains a discrepancy between these results and those derived from analytical data, for whereas no more than 85 basic amino acids have been isolated from hydrolysates, or 93 estimated by the nitrogen distribution method (Table I), the acid combining capacity suggests the presence of 99 trivalent basic amino acid groups in the hemoglobin molecule.[41] Some of these might conceivably titrate only after partial splitting of the molecule in acid solution, where heme is liberated from globin and the latter yields molecules of smaller molecular size.

Summary

1. Electromotive measurements have been made with the hydrogen electrode on systems containing carboxyhemoglobin and sodium hydroxide and hydrochloric acid.

2. The methods of calculating the combining capacity of a protein from such measurements is discussed, and the acid combining capacity estimated to be 148 × 10^{-5}; the base combining capacity 113 × 10^{-5} mole per gram.

3. On the basis of a molecular weight of 66,700 hemoglobin thus has 174 dissociable groups. Of these not more than 75 dipole pairs can exist at the isoelectric point.

4. Since various analyses reveal between 83 and 93 trivalent basic amino acids per mole of hemoglobin, approximately half the dissociable groups in hemoglobin are derived from the imino group of histidine, the guanidine nucleus of arginine and the ε-amino group of lysine.

5. The free groups of arginine and lysine dissociate at very alkaline reaction, but those of histidine near neutrality. There are 33 histidine molecules in hemoglobin. The free groups of approximately 13 of these appear to dissociate at reactions acid to the isoelectric point. Not more than the remaining 20 dissociate at physiological reactions, in the regions affected in dissociation by oxygenation and reduction of the hemoglobin.

6. The titration curve reported is described in terms of the following pK' values: 3.7, 4.0, 4.8, 5.7, 7.5, 10.8, 11.6. Of these the first three are considered to represent acid groups, the next two histidine groups, and the most alkaline lysine and tyrosine or arginine groups.

7. Although the titration curve is very sensitive to ionic strength, the maximal base combining capacity is demonstrated to be the same in solutions to which no salt was added and in N sodium chloride.

BOSTON, MASS. RECEIVED NOVEMBER 13, 1936

(39) Among them investigations of the dicarboxylic amino acids of edestin [Jones and Moeller, *J. Biol. Chem.*, **74**, Proc. liv (1927)] and of egg albumin [Calvery, *J. Biol. Chem.*, **94**, 613 (1932)] and of the basic amino acids of the latter protein [Calvery, *ibid.*, and Vickery and Shore, *Biochem. J.*, **26**, 1101 (1932)].

(40) The acid combining capacity of zein, not detected in aqueous systems in which the protein is insoluble [Cohn, Berggren, Hendry, *J. Gen. Physiol.*, **7**, 81 (1924)] has been investigated in the dry state with gaseous hydrogen chloride [Czarnetzky and Schmidt, *J. Biol. Chem.*, **105**, 301 (1934)], and in ethanol–water mixtures [Cohn, Edsall and Blanchard, *ibid.*, **105**, 319 (1934)], and reveals approximately the number of basic groups previously estimated to be present from the results of analyses. See also Neuberger, *Biochem. J.*, **28**, 1982 (1934).

(41) Note added to proof: This discrepancy suggested that part of the acid combining capacity might be ascribable to the heme. Accordingly a study of the acid combining capacity of globin was undertaken and the first preparation investigated combined 138 × 10^{-5} mole per gram, representing 92 free basic groups, or almost exactly those expected from the analyses of basic amino groups in globin and hemoglobin. Other differences between the titration curves of globin and hemoglobin will be reported subsequently.

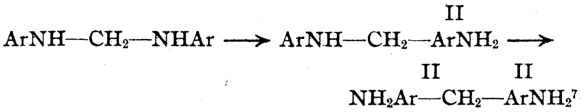
Condensations of Aromatic Amines with Formaldehyde in Media Containing Acid. IV. The Conversion of Diarylaminomethanes to Substituted Dihydro- and Tetrahydroquinazolines in Non-Aqueous Media

BY J. K. SIMONS[1]

Interaction of aromatic amines with formaldehyde in media containing acid generally has been assumed to proceed with the primary formation of diarylaminomethane (diimine), $(ArNH)_2CH_2$ or Schiff base, $ArN{=}CH_2$ $\left(\text{or } \left(\begin{matrix}\text{ArN—CH}_2\\ |\quad\;\; |\end{matrix}\right)_n\right)$.[2] The end-products of the condensation, however, appear to be the results of further reactions induced by the instability in an acid medium of the grouping $>N{-}CH_2{-}N<$[2]. Among these secondary reactions is the isomerization of the diimine (or Schiff base) to the aminobenzylaniline or diphenylmethane bases.[3]

The aminobenzylaniline base may be obtained as major product from a mixture of the diimine or Schiff base with the corresponding amine and amine salt under mild conditions and in the absence of water.[4] At higher temperatures essentially the same reaction mixture yields the diphenylmethane base,[4,5] and as this is formed also if the aminobenzylaniline base is used instead of the diimine (or Schiff base)[6] it is obvious and is generally accepted that the entire transformation involves two well defined steps



$$\text{ArNH—CH}_2\text{—NHAr} \longrightarrow \text{ArNH—CH}_2\text{—}\overset{\text{II}}{\text{ArNH}_2} \longrightarrow \overset{\text{II}}{\text{NH}_2\text{Ar}}\text{—CH}_2\text{—}\overset{\text{II}}{\text{ArNH}_2}{}^{7}$$

These behaviors appear to be general for aromatic primary amines and secondary amines of the type ArNHR, whether or not the para hydrogen is substituted. It has been shown, however, that in the case of *p*-toluidine the second stage of the reaction occurs less readily than with amines without para substituents.[3] It was therefore thought that the first step, *e. g.*, conversion of di-*p*-toluidinomethane or of methylene-*p*-toluidine to *o*-amino-*m*-xylyl-*p*-toluidine, could be studied separately under a variety of conditions with a view to the positive elucidation of the mechanism of the change. Accordingly di-*p*-toluidinomethane was allowed to react at 80–90° with toluidine and toluidine hydrochloride with the unexpected result that the products of the reaction were 3-*p*-tolyl-6-methyl-3,4-dihydroquinazoline, 3-*p*-tolyl-6-methyl-1,2,3,4-tetrahydroquinazoline, *o*-amino-*m*-xylyl-*p*-toluidine, *p*-toluidine and methyl-*p*-toluidine.

This paper presents the results of experiments in which di-*p*-toluidinomethane, methylene-*p*-toluidine and di-*p*-phenetidinomethane were treated in varying proportions and under various conditions with the corresponding amine and amine salt. Fifty to ninety per cent. of the starting materials were accounted for by the formation of di- and tetrahydroquinazolines, aminobenzylaniline bases, amines (toluidine or phenetidine) and methylated amines (methyltoluidine or methylphenetidine).

The formation of quinazolines and the occurrence of methylation during interaction of para substituted primary aromatic amines and formaldehyde in wholly or partially aqueous media containing acid has been reported by Maffei,[8] by Eisner and Wagner,[9] by Wagner,[10] and by Cairncross and Bogert.[11] Several of these investigators have discussed the mechanism of heterocycle formation and of methylation.[8c,9,10] The initial product is the diimine (or Schiff base) which rearranges to the aminobenzylaniline base. From this the several obtainable heterocyclic compounds are formed owing to the reactivity of the system

whose two amino groups are suitably disposed to permit ring closure with formic acid or formaldehyde. In these reactions the formaldehyde and formic acid needed to effect ring closure are demonstrably present so that formation of quinazolines is readily explicable. In the experiments recorded below, however, no such agents are present, the conditions being in fact those previously considered suitable for the formation of aminobenzylaniline and diphenylmethane bases. It was therefore necessary to determine the manner in which the diimine or Schiff base, by the action of amine hydrochloride and amine, yields (through the aminobenzylaniline base) the tetrahydroquinazoline, the dihydroquinazoline and methylated amine.

The probable course of the formation of such compounds from *o*-amino-*m*-xylyl-*p*-toluidine is indicated in Fig. 1.

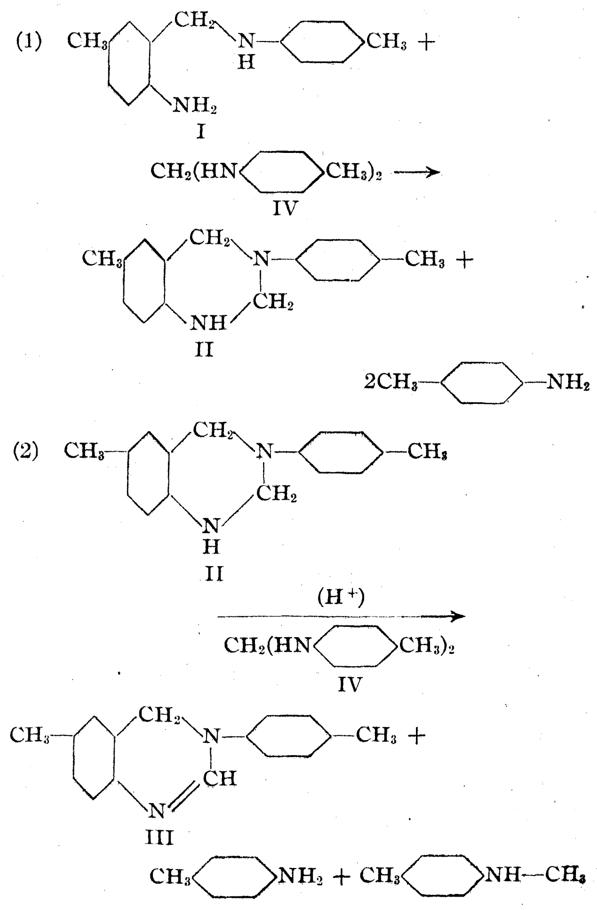

Fig. 1.

Reaction 1 has been realized independently in the present study. It is the counterpart of the formation of II from I and formaldehyde,[12] both reactions occurring in the absence of acids. The fact that II can also be formed by the action of formaldehyde in the presence of free acid in the cold as shown by Wagner[13] removes any doubt that the same compound may result by reaction 1, in the presence of amine salt. It is to be considered probable, however (see below), that under such conditions the reaction may be reversible.

Evidence for reaction 2, the conversion of II to III, is less direct but is circumstantially convincing. The data from experiments in which quinazolines are formed from IV show that conditions which lead to an increased yield of II bring about an approximately corresponding decrease in the yield of III and *vice versa*. This seems to indicate that the tetrahydro is a precursor of the dihydroquinazoline. The formation of III would accordingly require the dehydrogenation of II by some suitable hydrogen acceptor. Removal by conventional means of the two hydrogens involved was effected by mild oxidation with permanganate in acetone solution.[14] It is suggested that in the conversions of diimine reported in this paper the tetrahydro compound is "oxidized" by the diimine in the presence of amine salt or the fragment . As a result of such a reaction methyl-*p*-toluidine is formed. This is supported by the experimental fact that only when III was formed was there any secondary amine among the reaction products. It appears impossible to devise an experiment to test the "oxidation" of II by diimine because the diimine can only produce the fragment  in the presence of an amine salt (or acid) which was found independently to bring about a conversion of II to III.

Thus heating together II and *p*-toluidine hydrochloride produced III, methyl-*p*-toluidine and 2,2′-diamino-5,5′-dimethyldiphenylmethane. These results serve to (1) illustrate the unusual properties of the tetrahydroquinazoline and (2) support the idea of its "oxidation" by the diimine. The appearance of the diphenylmethane base suggests the intermediate formation of I by a cleavage of the tetrahydroquinazoline ring by the action of amine salt

A similar cleavage of tetrahydroquinazolines in aqueous acids produces aminobenzylamines and aldehydes.[15] Benzoyl chloride in pyridine also brings about fission,[16] compound II yielding the benzoyl derivative of I. Toluidine hydrochloride, however, produces IV in addition to I so that the cleavage is actually reaction 1 reversed by the presence of amine salt. The diimine in the presence of the hydrochloride cleaves to toluidine and the fragment  Aminoxylyltoluidine by the action of toluidine and toluidine hydrochloride is converted to the diphenylmethane base.[3] The fragment  now "oxidizes" uncleaved II, being itself reduced to methyltoluidine. In this respect the reaction would be analogous to the Doebner reaction in which secondary amine is produced from a dihydrocinchoninic acid and a methylene amine ArCH=NAr.[17] The quantities of toluidine and methyltoluidine formed during the conversions of IV to III and II were observed experimentally to be in roughly quantitative agreement with the requirements of the reactions in Fig. 1. From these considerations it seems certain that in the conversion of IV to III methylation occurs during the conversion of the intermediately formed tetrahydroquinazoline to the dihydroquinazoline and that formation of the latter involves the "oxidation" of the tetrahydroquinazoline by di-*p*-toluidinomethane or the fragment 

A similar series of reactions explains the conversion of di-*p*-phenetidinomethane to 3-*p*-phenetyl-6-ethoxy-3,4-dihydroquinazoline and methyl-*p*-phenetidine.

Experimental Part

Preparation of Materials.—Di-*p*-toluidinomethane, m. p. 95.5–96.0° corr., was prepared according to Eberhardt and Welter;[18] di-*p*-phenetidinomethane, m. p. 80.3–81.0° corr. by the directions of Bischoff.[19] *p*-Toluidine and *p*-phenetidine hydrochlorides were crystallized from aqueous solutions by addition of strong hydrochloric acid. 3-*p*-Tolyl-6-methyl-3,4-dihydroquinazoline hydrochloride was prepared by chilling the hot solution of the base in 1:1 hydrochloric acid. It was crystallized from dilute acid, m. p. 219.5° obsd. (226.3° corr.). *p*-Toluidine was Eastman best grade; *p*-phenetidine was vacuum distilled before use. All melting points are corrected.

Rearrangements of Di-*p*-toluidinomethane (IV); General Procedure.—Compound IV (0.01 mole) was mixed with the desired quantities of amine and amine hydrochloride, heated for one-half to four hours at the required temperature, made alkaline and steam distilled.

The steam distillate, in experiments recorded in Table II, was then treated with benzene sulfonyl chloride by the Hinsberg–Kessler procedure to estimate quantities of primary and secondary amines.[20] No tertiary amine was found in these distillates. In some experiments (Nos. 34, 34R, 35, 36, 39) in which small quantities of base hydrochloride were used, preceding the Hinsberg separation the steam distillate was titrated with 0.5 *N* hydrochloric acid using Congo paper as indicator. This served not only as a check on the Hinsberg analysis but to separate primary and secondary amine from unreacted IV which under these conditions was not titratable and could be filtered from the solution of base hydrochloride. A test titration of 1.60 g. of *p*-toluidine in the presence of 0.8 g. of IV indicated 1.62 g. of *p*-toluidine.

Yields of I and III in the non-steam-volatile residue were estimated as follows.

The residue, separated from the alkaline solution by ether extraction or filtration, was dissolved in boiling alcohol (25–50 cc.) and benzaldehyde (1.5–2.0 cc.) added to the hot solution which was kept hot for two to three minutes. On cooling, the benzal derivative of I crystallized. The melting point of this material was usually 127°.[21] The filtrate was then heated to boiling and a solution of picric acid (0.2–0.8 g.) in alcohol (10–15 cc.) added. The picrate of III crystallized on chilling. It melted usually at 210°.[22] A test of this separation of I and III was made with 1.0 g. of I and 0.5 g. of III. The benzal compound weighed 1.24 g., 89.6%; the picrate, 1.07 g., 108%.

An over-all test of the steam distillation, ether extraction and separation using known quantities of I, III, *p*-toluidine and *p*-toluidine hydrochloride and correcting for an 89.6% recovery of I indicated 102% of I and 122% of III.

(22) Eisner and Wagner, Ref. 9, p. 1940.

To estimate II this procedure had to be modified by extracting I and III from the ether solution of the residue with 0.5 *N* acid. The ether soluble portion on crystallization from ligroin (b. p. 70–90°) yielded II, m. p. 140°.[23]

The identity of III was shown by mixed melting point tests of base and/or picrate with authentic specimens. Compound I was identified by the recovery as its benzal derivative. No derivatives of II were available and its identification consisted in satisfactory mixed melting point determinations. Results are collected in Tables I, II, III.

Rearrangement of Di-*p*-phenetidinomethane.—The diarylaminomethane (5.8 g., 0.02 mole) was heated for four hours on the boiling water-bath with 1.73 g. (0.01 mole) of *p*-phenetidine hydrochloride. The mixture was then made alkaline, steam distilled and the solid, non-volatile residue crystallized once from alcohol yielding 1.17 g. of a slightly yellow product, m. p. 141–142°.[24] The mother liquors gave no precipitate with benzaldehyde showing the absence of aminobenzylaniline base. The benzaldehyde was then removed by steam distillation and the residue converted to an impure picrate, m. p. 140–60°. This on recrystallization from alcohol yielded 0.58 g., m. p. 160–70°. Total yield of 3-*p*-phenetyl-6-ethoxy-3,4-dihydroquinazoline was 1.5 g. (76%).

The steam distillate yielded the benzene sulfonyl derivatives of methyl-*p*-phenetidine, m. p. 65°, and of *p*-phenetidine, m. p. 142–143°.

A second trial of the same procedure with 20 g. (0.07 mole) of the diimine and 3.0 g. (0.01 mole) of the hydrochloride yielded 3.57 g. (52%) of the dihydroquinazoline (2.49 g. of free base, m. p. 140–141°; 1.9 g. of the picrate, m. p. 180–183°).

The following derivatives of phenetylethoxydihydroquinazoline were prepared.

Hydrochloride, by dissolving the base in hot dilute (1:1) acid containing a little alcohol and chilling. The product after recrystallization from dilute acid containing alcohol melted at 195.3°. The reported m. p. is 193°.[24b]

Tetrahydroquinazoline.—Reduction of the dihydro base in alcohol with 9 times the theoretical amount of sodium gave a crude product, m. p. 131–135°. One crystallization from alcohol raised the m. p. to 143–143.5°. (Mixed with the dihydro compound melting at 141–142° the m. p. was 134–135.5°.) Another crystallization yielded pure tetrahydroquinazoline, m. p. 144–144.5°. The reported m. p. is 144°.[24a]

3-*p*-Tolyl-6-methyl-3,4-dihydroquinazoline from Methylene-*p*-toluidine.—Six grams of methylene-*p*-toluidine, 5.8 g. of *p*-toluidine, and 2.9 g. of *p*-toluidine hydrochloride were heated together at 90° for five hours. The non-steam volatile residue was crystallized twice from ligroin (b. p. 90–120°) to give 0.7 g. of III m. p. 163°. From the mother liquors there was isolated a little more of III and some I, m. p. 82°.

3-*p*-Tolyl-6-methyl-1,2,3,4-tetrahydroquinazoline: Interaction of *o*-Amino-*m*-xylyl-*p*-toluidine and Di-*p*-toluidinomethane.[25]—A solution of IV (2.1 g.) and I (2.1 g.) in 90 cc. of alcohol was refluxed for one hour. Eighty cc. of alcohol was then distilled off and the residue allowed to crystallize. The mother liquors were diluted with water, ether was added followed by dilute hydrochloric acid (1:20) to separate toluidine and II. The solute in the ether layer was combined with the first crop of solid and crystallized from ligroin (90–120°) yielding II, m. p. 141°; yield 1.90 g., 86.3%.

The toluidine in the acid layer was recovered as the benzoyl derivative, m. p. 156°; yield 2.1 g., 60.5%.

Oxidation to the Dihydroquinazoline

Action of *p*-Toluidine Hydrochloride.—Compound II (1.19 g., 0.005 mole) and *p*-toluidine hydrochloride (1.6 g., 0.011 mole) in 50 cc. of alcohol were refluxed four hours. The products were isolated by the usual procedure. The benzal derivative weighed 0.12 g., melted at 182–184.5° and proved to be 2,2-dibenzalamino-5,5′-dimethyldiphenylmethane by mixed melting point of 183.5° with a specimen prepared as described below and melting at 186°. The yields of other products were: III, 0.40 g.; methyl-*p*-toluidine, 0.11 g.; *p*-toluidine, 0.83 g.

A duplicate experiment run at 110° for two hours without alcohol and worked up in the same way gave essentially the same yields of the same products.

Permanganate Oxidation.—Seventy-five cc. of acetone containing 0.63 g. of potassium permanganate was added in portions to II (1.19 g.), dissolved in 75 cc. of acetone. The reaction took place immediately and was allowed to proceed at room temperature. The precipitated manganese dioxide was filtered off and the product in the filtrate converted to the picrate as usual. The yield was 28.8% of picrate which after crystallization from alcohol melted at 208–209°.

Action of Di-*p*-toluidinomethane and *p*-Toluidine Hydrochloride.—A mixture of IV and II (1.2 g. each) was heated with 1.6 g. of *p*-toluidine hydrochloride in 50 cc. of alcohol for three hours at 61 ± 1°. The yields were: I, 0.36 g.; III, 0.40 g.; methyl-*p*-toluidine, 0.26 g.; *p*-toluidine, 1.44 g. These data indicate that 0.84 g. of IV was available to take part in reactions forming 0.40 g. of III. The ratio of 3 diimine to 1 of III indicates, however, that only 0.29 g. of III could be formed from this quantity of available IV. It may be concluded that 0.11 g. of III was formed from II.

Cleavage by Benzoyl Chloride.—One gram of II was treated in benzene solution with 2 cc. of pyridine and 1.0 cc. of benzoyl chloride. Recovery of the benzoylation product in the ordinary manner[26] yielded, after one crystallization, 0.45 g. of white crystalline material melting at 186–190°. Recrystallization from dilute alcohol gave a product melting at 190.2–190.5°. This material was identical with a sample melting at 188.5–189° prepared from II by the usual Schotten–Baumann procedure as shown by a mixed m. p. of 189°. Benzoylation of I in aqueous alkali gave the same compound, m. p. 189.6°, mixed m. p. 190°, shown by analysis to be the dibenzoyl derivative of I and not the monobenzoyl derivative.

2,2'-Dibenzalamino-5,5'-dimethyldiphenylmethane.—The diphenylmethane base (0.24 g., 0.01 mole) in 5 cc. of alcohol was treated in the hot with 0.22 g. (0.02 mole) freshly distilled benzaldehyde. The solution was boiled for a few minutes and then chilled to give 0.38 g. of a product melting at 182–184°. One crystallization from alcohol gave the pure derivative with m. p. 186°. Analysis showed it to be a dibenzal derivative.

Anal. Calcd. for $C_{29}H_{26}N_2$: N, 6.97. Found: N, 6.98.

Discussion of Results

Formation of *o*-Amino-*m*-xylyl-*p*-toluidine.—The data of a number of experiments performed to ascertain the effect of conditions on the production of this base from di-*p*-toluidinomethane are tabulated in Table I. The largest yield was 82.5% obtained by using a molar ratio of diimine: toluidine hydrochloride: toluidine of 1:1:25. The data showed that (1) the time required for reaction was not more than one-half hour, longer periods of heating had no beneficial effect; (2) the temperature at which the reaction proceeded within the limits of 60 and 100° had no effect on the yields; (3) the effect of solvent (alcohol) was to lower the yield of I and increase the quantity of III; (4) the amount of toluidine hydrochloride had to be greater than 0.01 g. (0.0001 mole) for 2.26 g. (0.01 mole) of diimine in order for any transformation to take place; (5) the best conversions were observed when there was used 0.005–0.01 mole of hydrochloride per 0.01 mole of diimine; 0.001 mole of hydrochloride resulted in smaller yields of I, larger yields of III and the formation of II.

Formation of Quinazolines.—A number of experiments were made to find out under what conditions these compounds became the major products of the transformation of IV. The data are recorded in Table II. In the absence of a solvent the greatest amount of III obtained was 0.00144 mole from 0.01 mole of diimine (43.2%). This quantity resulted when only diimine and toluidine hydrochloride reacted and was essentially the same as long as the molar ratio of hydrochloride:diimine remained larger than 0.5. When less hydrochloride was used the yield of III decreased and II was found among the products. Compound I was found under practically all conditions (up to 0.0023 mole). When alcohol was used as a solvent the quantity of III was raised to 0.0021–0.0025 mole (62–75%) while the amount of I was lowered to 0.0005 mole or less. In all of these experiments both methyl-*p*-toluidine and *p*-toluidine were produced.

In Table III are recorded the yields of III obtained from the diimine by the action of a number

Summary

1. Di-*p*-toluidinomethane by the action of *p*-toluidine and *p*-toluidine hydrochloride has been shown to yield *o*-amino-*m*-xylyl-*p*-toluidine, 3-*p*-tolyl-6-methyl-1,2,3,4-tetrahydroquinazoline, 3-*p*-tolyl-6-methyl-3,4-dihydroquinazoline, *p*-toluidine and methyl-*p*-toluidine.

2. This conversion has been studied using varying proportions of reactants and under a variety of conditions essentially those previously thought suitable for converting di-*p*-toluidinomethane to *o*-amino-*m*-xylyl-*p*-toluidine or 2,2′-diamino-5,5′-dimethyldiphenylmethane.

3. Di-*p*-phenetidinomethane similarly yielded 3-*p*-phenetyl-6-ethoxy-3,5-dihydroquinazoline and methyl-*p*-phenetidine.

4. The probable course of the formation of quinazolines under these conditions has been shown to consist in the intermediate production of a tetrahydroquinazoline from the aminobenzylaniline base followed by "oxidation" to a dihydroquinazoline effected by the diarylaminomethane in an acid medium.

5. The interaction of di-*p*-toluidinomethane and *o*-amino-*m*-xylyl-*p*-toluidine to yield 3-*p*-tolyl-6-methyl-1,2,3,4-tetrahydroquinazoline and its behavior toward a number of reagents has been described.

Condensation Reactions of Quinoline Aldehydes

BY CHARLES E. KWARTLER[1] AND H. G. LINDWALL

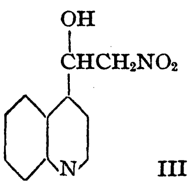
It has been found that lepidine and 6-methoxylepidine yield the corresponding quinoline-4-aldehydes when subjected to oxidation through the action of selenium dioxide. Their behavior with that oxidizing agent is analogous to that of quinaldine, which, as has been reported, is converted to quinoline-2-aldehyde.[2]

Quinoline-4-aldehyde (I) was isolated from its reaction mixture by steam distillation as the hydrate, which loses water upon being recrystallized from absolute toluene, or after long standing in a vacuum desiccator over sulfuric acid. Compound I reduces Tollens' reagent, and forms a sodium bisulfite addition product slowly; it has been characterized by oxime formation and by the preparation of its *p*-nitrophenylhydrazone.

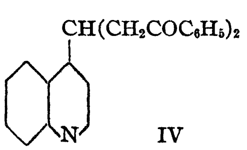
It was found that 6-methoxyquinoline-4-aldehyde (II) does not steam distil; it was isolated directly from the reaction mixture as the free aldehyde. Even after crystallization from water no hydrate was obtained. Compound II reduces Tollens' reagent, and forms an oxime. The corresponding cinchoninic acid is a by-product in the preparation of both I and II.

Quinoline-4-aldehyde hydrate melts at 84–84.5°, and the free aldehyde (I) at 51–53°. Neither of these melting points agrees with that (101–102°) reported by Koenigs[3] for the oxidation product of apocinchene, for which he suggested the quinoline-4-aldehyde structure.

Quinoline-4-aldehyde hydrate (I) condenses with nitromethane, yielding β-hydroxy-β-(quinolyl-4)-α-nitroethane (III). This reaction is catalyzed by diethylamine. Condensation of acetophenone with I takes place in the presence of sodium hydroxide; the product is diacetophenonyl-lepidine (IV). Compound IV forms a dioxime with hydroxylamine.

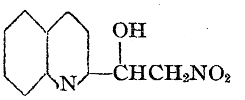


III

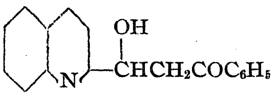


IV

Quinoline-2-aldehyde hydrate reacts with "active-methylene" compounds somewhat more readily than does I. Nitromethane, in the presence of diethylamine, condenses to yield β-hydroxy-β-(quinolyl-2)-α-nitroethane (V). Acetophenone likewise yields an aldol-like product, (VI) β-hydroxy-β-(quinolyl-2)-ethyl phenyl ketone, when either diethylamine or sodium hydroxide is used as the catalyst.

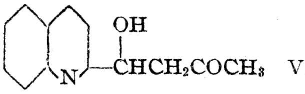


V

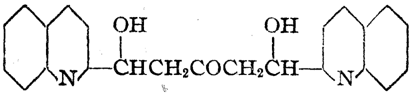


VI

The action of acetone with quinoline-2-aldehyde hydrate also has been studied. Two products result, depending upon the conditions (described in the Experimental part) under which the reactions are carried out. These condensation products are of the aldol type, 4-hydroxy-4-(quinolyl-2)-butanone-2 (VII) and 1,5-dihydroxy-1,5-bis-(quinolyl-2)-pentanone-3 (VIII).



VII



VIII

This research is being continued with the study of further condensation reactions, and their products, especially in the case of quinoline-4-aldehyde and its 6-methoxy derivative.

Experimental Part

Hydrate of Quinoline-4-aldehyde (I).—4-Methylquinoline (4 g.) was dissolved in 60 cc. of xylene, and the solution was held at 135° with constant stirring. Selenium dioxide (4.5 g.) was added in small portions over the period of one-half hour, after which the mixture was held at 135° for one hour. As selenium formed the mixture gradually became dark red. Upon cooling, crystals of cinchoninic acid separated; this and selenium were removed by filtration. The filtrate was steam distilled and the aldehyde collected separately after the xylene had distilled. The hydrate of I was filtered from the distillate after standing overnight, and more was obtained from the ether extract of the dis-

tillate; yield, 61%, of small plates, m. p. 84–84.5°, soluble in water, toluene, xylene, ether, ethyl alcohol.

Anal. Calcd. for $C_{10}H_9NO_2$: C, 68.57; H, 5.15; N, 8.00; mol. wt., 175. Found: C, 68.77, 68.89; H, 5.02, 5.03; N, 7.86, 7.71; mol. wt., 174, 174.

Quinoline-4-aldehyde (I).—The hydrate of I formed I after three weeks in a vacuum desiccator, or upon recrystallization from absolute toluene as colorless needles, m. p. 51–53°; these are soluble in ether, butyl alcohol, toluene, xylene. Compound I gives a positive reaction with Tollens' reagent, and forms a sodium bisulfite addition product slowly.

Anal. Calcd. for $C_{10}H_7NO$: N, 8.92. Found: N, 8.93.

Cinchoninic Acid.—4-Methylquinoline with larger amounts of selenium dioxide, and with longer heating of the mixture than described above for the preparation of I, is oxidized to cinchoninic acid in excellent yields.

***p*-Nitrophenylhydrazone of I.**—Yellow rectangular prisms from ethyl alcohol, m. p. 261–262°. Slightly soluble in warm carbon tetrachloride.

Anal. Calcd. for $C_{16}H_{12}O_2N_4$: N, 19.18. Found: N, 19.16.

Oxime of I.—White needles from methyl alcohol, m. p. 181–182°; yield, 88%.

Anal. Calcd. for $C_{10}H_8ON_2$: N, 16.28. Found: N, 16.33, 16.41.

6-Methoxyquinoline-4-aldehyde (II).—Compound II was prepared by the oxidation of 6-methoxy-4-methylquinoline in a manner identical with that employed for the preparation of the hydrate of I. Upon attempted steam distillation of the reaction mixture it was found that none of II would distil, and it was isolated from the residual material after steam distillation of the xylene. No hydrate was obtained even after crystallization from water: needles, m. p. 96–98°, from toluene; soluble in water, ethyl alcohol, xylene; reduces Tollens' reagent; yield, 52%.

Anal. Calcd. for $C_{11}H_9NO_2$: N, 7.49. Found: N, 7.49.

Oxime of II. Needles from ethyl alcohol; m. p. 214–216°; soluble in toluene.

Anal. Calcd. for $C_{11}H_{10}N_2O_2$: N, 13.86. Found: N, 13.81.

Oxime of Quinoline-2-aldehyde.—Fine white needles from 80% ethyl alcohol. The melting point of this compound, 188–190°, prepared by the action of hydroxylamine with quinoline-2-aldehyde, is in agreement with that reported by Pfitzinger,[4] who prepared this oxime by another method.

2′,4′ - Dinitrophenylhydrazone of Quinoline - 2 - aldehyde.—Yellow needles were obtained by diluting the ethyl alcohol solution of the crude product with water to incipient crystallization and allowing the mixture to stand, m. p. 251–253°.

Anal. Calcd. for $C_{16}H_{11}O_4N_5$: N, 20.59. Found: N, 20.77.

β - Hydroxy - β - (quinolyl - 4) - α - nitroethane (III).—A mixture of 0.3 g. of nitromethane, 0.5 cc. of absolute alcohol and 2 drops of diethylamine was cooled in ice and to it was added 0.32 g. of the hydrate of I. The reaction mixture was held at room temperature for one day, and then the alcohol was allowed to evaporate partially. Compound III separated as small plates, soluble in toluene, acetic acid and ethyl alcohol; recrystallized from ethyl alcohol, m. p. 133–136°; yield 78%.

Anal. Calcd. for $C_{11}H_{10}O_3N_2$: N, 12.84. Found: N, 12.50.

β - Hydroxy - β - (quinolyl - 2) - α - nitroethane (V).—A mixture was prepared of quinoline-2-aldehyde hydrate (0.43 g.) and 2 drops of diethylamine; to this was added 0.34 g. of nitromethane and 0.5 cc. of absolute ethyl alcohol. The reaction mixture became warm. Upon cooling, V separated as long white needles from ethyl alcohol; m. p. 110–113°; soluble in ethyl alcohol, isopropyl alcohol and acetic acid; yield 81%.

Anal. Calcd. for $C_{11}H_{10}O_3N_2$: N, 12.84. Found: N, 12.54.

Diacetophenonyl-lepidine (IV).—To a mixture of 6 cc. of 10% sodium hydroxide and 15 cc. of 95% ethyl alcohol were added 0.35 g. of acetophenone, 0.25 g. of the hydrate of I, and some small chips of ice. The temperature of the reaction mixture was allowed to rise to that of the room, and after one-half hour IV began to separate as white needles. Recrystallized by the slow dilution of the ethyl alcohol solution with water; yield 87%; m. p. 144–146°. Slight variations in the conditions for condensation resulted in other products which have not been studied.

Anal. Calcd. for $C_{26}H_{21}O_2N$: N, 3.69. Found: N, 3.52, 3.74.

Dioxime of IV.—Colorless needles from a methyl alcohol and dioxane mixture; m. p. 204–205°.

Anal. Calcd. for $C_{26}H_{23}O_2N_3$: N, 10.27. Found: N, 10.39.

β-Hydroxy-β-(quinolyl-2)-ethyl Phenyl Ketone (VI). Method A.—To a 10% solution of sodium hydroxide (15 cc.) were added 8 cc. of 95% ethyl alcohol, 0.2 g. of acetophenone, 0.2 g. of quinoline-2-aldehyde hydrate and a few chips of ice. Soon a light yellow solid (VI) separated and was recrystallized by the careful addition of water to its alcohol solution as pale yellow needles, m. p. 114–116°; yield 78%. **Method B.**—A solution of 0.12 g. of quinoline-2-aldehyde hydrate and 0.12 g. of acetophenone in 8 cc. of absolute ethyl alcohol was cooled in ice, and to it was added 2 drops of diethylamine. After four days water was added, and VI precipitated; purified as above in method A; yield 77%.

Anal. Calcd. for $C_{18}H_{15}O_2N$: N, 5.05. Found: N, 4.94, 4.99, 5.04.

4 - Hydroxy - 4 - (quinolyl - 2) - butanone - 2 (VII).—To a solution consisting of 12 cc. of 10% aqueous sodium hydroxide and 10 cc. of 95% ethyl alcohol were added 0.11 g. of quinoline-2-aldehyde hydrate, 0.15 g. of acetone and a few small chips of ice. Turbidity resulted after a few minutes of shaking, and soon VII separated in 68% yield. It was recrystallized from ethyl alcohol; m. p. 164–167°.

Anal. Calcd. for $C_{13}H_{13}O_2N$: N, 6.51. Found: N, 6.64.

1,5-Dihydroxy-1,5-bis-(quinolyl-2)-pentanone-3 (VIII).—A mixture was prepared consisting of 0.4 cc. of ace-

---

[4] Pfitzinger, *J. prakt. Chem.*, **66**, 264 (1902).

tone, 0.9 cc. of 95% ethyl alcohol and 4 drops of diethylamine; to this was added 0.31 g. of quinoline-2-aldehyde hydrate. The reaction mixture was allowed to remain at room temperature for two days, and at the end of that time crystals of VIII had separated: soluble in benzene, xylene, butyl alcohol; recrystallized from xylene; m. p. 208–210°; yield 32%.

Anal. Calcd. for $C_{23}H_{20}O_3N_2$: N, 7.53. Found: N, 7.60.

Summary

Lepidine and 6-methoxylepidine are oxidized by selenium dioxide to quinoline-4-aldehyde and 6-methoxyquinoline-4-aldehyde, respectively. Quinoline-4-aldehyde condenses with nitromethane to give a product of the aldol type, while acetophenone yields diacetophenonyl-lepidine. Quinoline-2-aldehyde, previously described, forms aldol-like products with acetone, acetophenone and nitromethane.

Studies of Crystalline Vitamin B_1. XV. C-Methylated 6-Amino- and 6-Oxypyrimidines

BY ROBERT R. WILLIAMS, A. E. RUEHLE AND JACOB FINKELSTEIN

For purposes of comparison with the pyrimidine cleavage products of vitamin B_1 (Aneurin), we have prepared 6-amino- and 6-oxypyrimidine and all of the possible mono- and di-C-methyl derivatives and have observed the ultraviolet absorption of each. 5-ethyl-6-aminopyrimidine is also included. The literature references indicate the methods of preparation of certain known compounds.[1] Some known compounds were obtained by new methods: *e. g.*, 4-methyl-6-oxy- and 5-methyl-6-oxypyrimidines were obtained by oxidizing the 2-thio derivatives with hydrogen peroxide.[2] 2,5-Dimethyl-6-oxypyrimidine resulted from condensing sodioformylpropionic ester with acetamidine and the oxy derivative was converted in the conventional way to the amino. The preparative operations were not carried out repeatedly so the reported yields in general are probably not optimal.

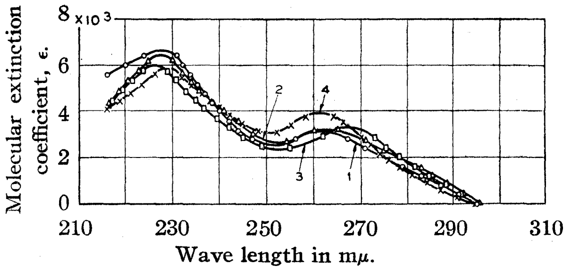

Fig. 1.—1. 6-Oxypyrimidine. 2. 4-Methyl-6-oxypyrimidine. 3. 2-Methyl-6-oxypyrimidine. 4. 5-Methyl-6-oxypyrimidine.

Discussion of Results

Curves of ultraviolet absorption in water solution for the series of 6-oxypyrimidines are shown in Figs. 1, 2 and 3. A great similarity of character is observed throughout, all the compounds exhibiting absorption in two bands which vary somewhat in frequency and slightly in intensity according to the number and position of substituent alkyls. Curves of this character are observed also in other oxy compounds in which one hydrogen of a substituent methyl group is replaced by ethoxy, halogen or sulfonic group as will develop in later papers.

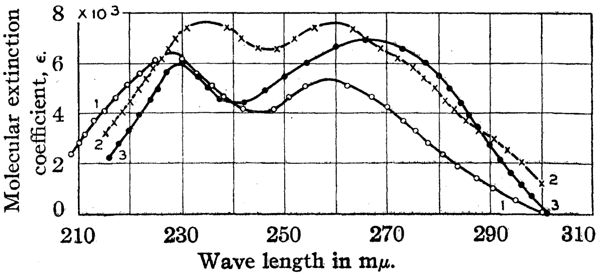

Fig. 2.—1. 2,4-Dimethyl-6-oxypyrimidine. 2. 4,5-Dimethyl-6-oxypyrimidine. 3. 2,5-Dimethyl-6-oxypyrimidine.

The 6-amino series shows a kindred absorption in water solution (Figs. 4 and 5), but the curves are less homogeneous in type than in the oxy series. The amino compounds show a striking

Chem.*, **3**, 287 (1907); (b) 6-aminopyrimidine—Buttner, *Ber.*, **36**, 2232 (1903); (c) 2-methyl-6-oxy- and 2-methyl-6-aminopyrimidine—Gabriel, *ibid.*, **37**, 3638 (1904); (d) 5-ethyl-6-aminopyrimidine—v. Merkatz, *ibid.*, **52**, 871 (1919); (e) 2,4-dimethyl-6-oxypyrimidine—Wollner, *J. prakt. Chem.*, [2] **29**, 132 (1884); (f) 2,4-dimethyl-6-aminopyrimidine—v. Meyer, *ibid.*, [2] **27**, 152 (1883).

(2) Wheeler and McFarland, *Am. Chem. J.*, **42**, 105 (1909).

influence of added acid and alkali as well as a lesser influence of the number and position of substituent alkyl groups. Comparison of each amino derivative with the corresponding oxy compound reveals that the marked acid–alkali contrasts are associated with the presence of the basic amino group (*cf.* Fig. 3 with Figs. 4 and 5).

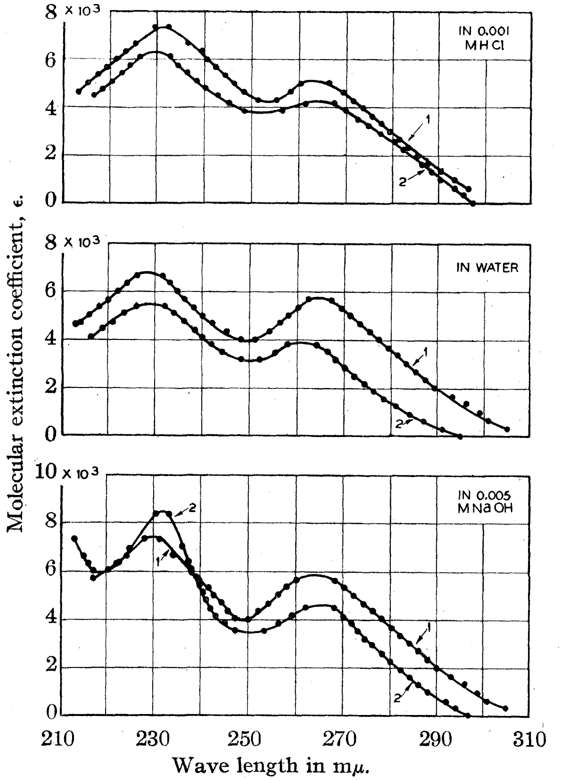

Fig. 3.—(a) In 0.001 *M* HCl, (b) in water, (c) in 0.005 *M* NaOH. 1. 2,5-Dimethyl-6-oxypyrimidine. 2. 5-Methyl-6-oxypyrimidine.

It will be noted that in the absence of added acid or alkali the 6-amino series shows a considerable range in respect to the relative prominence of the two absorption bands and that the addition of alkali in each case tends in the direction of equal prominence of the bands, that of acid toward submerging both bands under a more intense one at about 250 mμ. This fact suggested that the variation exhibited by the series in the absence of added base or acid might be a reflection of the basic strength of the several members of the series. Colorimetric determinations of the *p*H of concentrated water solutions of the compounds (see Table I), however, do not bear out this view in a quantitative sense.

The phenomenon which we have observed may well be intimately related in some fashion to the effect of acid and alkali on guanine,[3] as well as to the effect of acid on the vitamin itself.[4]

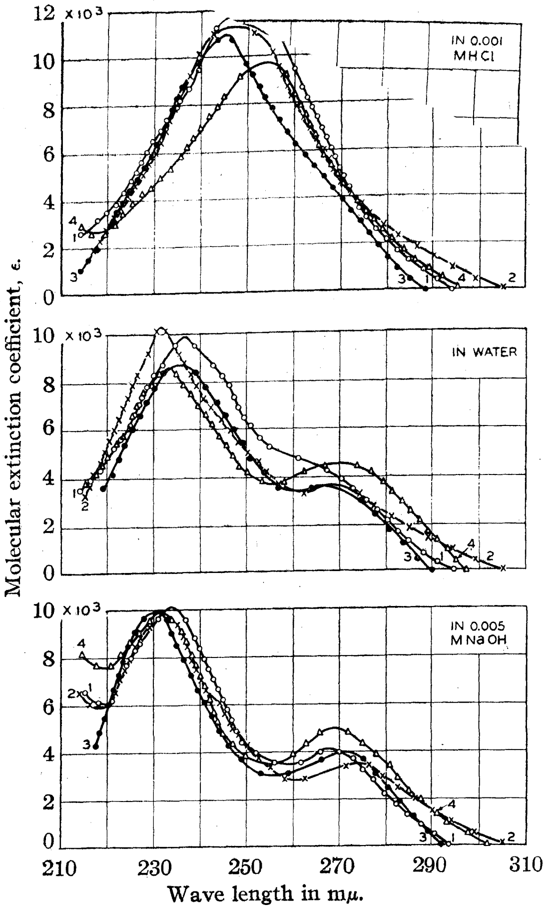

Fig. 4.—(a) In 0.001 *M* HCl, (b) in water, (c) in 0.005 *M* NaOH. 1. 4-Methyl-6-aminopyrimidine. 2. 6-Aminopyrimidine. 3. 2-Methyl-6-aminopyrimidine. 4. 5-Methyl-6-aminopyrimidine.

In the amino as in the oxy series, there is evidence which will be presented at a later time that substituents in side chains do not in general affect absorption profoundly.

It is of interest to note that the amino sulfonic acid, derived from the vitamin, exhibits only an inconspicuous band at 268 mμ in water solution (Fig. 6) which, however, becomes prominent in alkali and then more resembles that of the oxysulfonic acid. This behavior appears quite consistent with that of the 6-aminopyrimidines when one reflects that the acidic character of the sulfonic group would be expected to modify the absorption in the direction of submerging the band at the longer wave length. The weight

---

(3) F. F. Heyroth and J. R. Loofbourow, This Journal, **56**, 1728 (1934); Holiday, *Biochem. J.*, **24**, 619 (1930).

(4) Holiday, *ibid.*, **29**, 718 (1935).

of the sulfonic group on the other hand presumably tends to shift this band toward longer wave lengths.

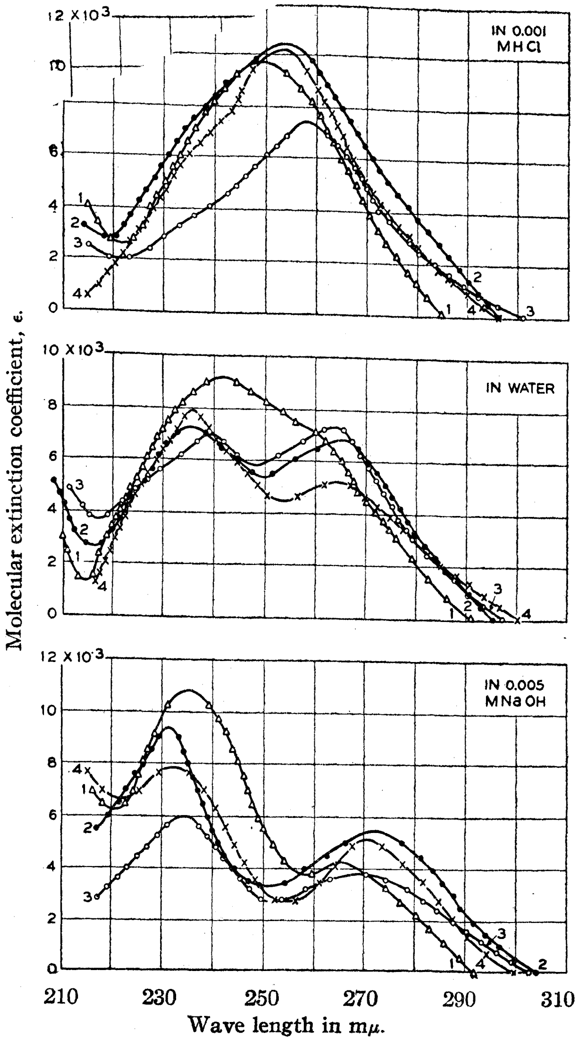

Fig. 5.—(a) In 0.001 M HCl, (b) in water, (c) in 0.005 M NaOH. 1. 2,4-Dimethyl-6-aminopyrimidine. 2. 2,5-Dimethyl-6-aminopyrimidine. 3. 4,5-Dimethyl-6-aminopyrimidine. 4. 5-Ethyl-6-aminopyrimidine.

Neither in the oxy nor the amino series is the effect of the number and position of substituent alkyls upon absorption sufficiently well differentiated to justify a broad generalization, although a considerable degree of consistency can be observed.

Experimental

4-Methyl-6-oxypyrimidine.—Two hundred and sixty-five cc. of 12% hydrogen peroxide was warmed to 70° to start reaction and 20 g. of 4-methyl-2-thio uracil[2] was added with stirring in small portions to avoid rise of temperature above 90°. The solution was evaporated to small volume, made alkaline with sodium carbonate and brought to dryness on the steam-bath. The residue was extracted with benzene, the benzene evaporated and the residue sublimed in high vacuum at 100–110°. Sublimate was recrystallized from ethyl acetate, m. p. 148–149°; yield 8 g.

Anal. Calcd. for $C_5H_6N_2O$: C, 54.54; H, 5.45; N, 25.45. Found: C, 54.93, 54.98; H, 5.28, 5.39; N, 25.71.

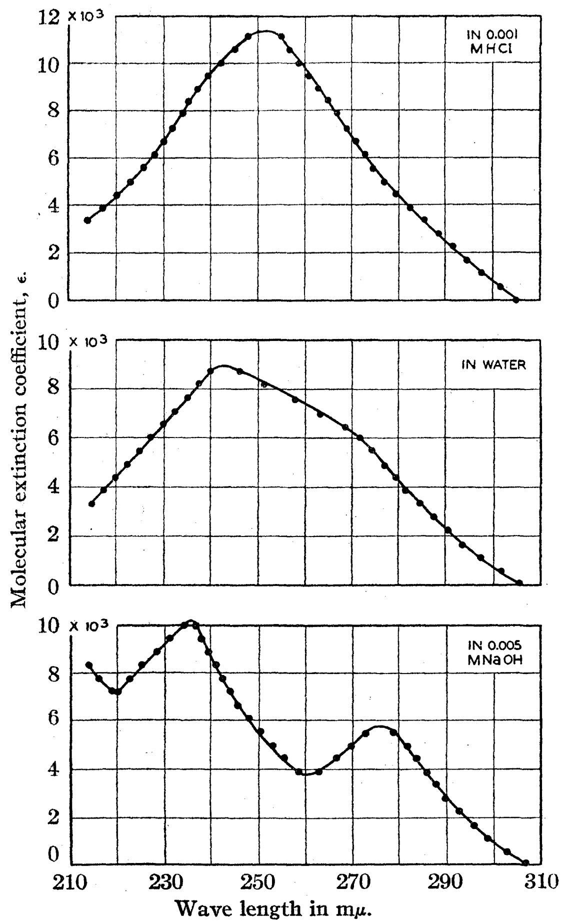

Fig. 6.—(a) In 0.001 M HCl, (b) in water, (c) in 0.005 M NaOH. Amino sulfonic acid.

This compound was prepared by Gabriel and Colman[5] from 4-methyl-2,6-dichloropyrimidine who found the m. p. 149–150°.

4-Methyl-6-aminopyrimidine.—One gram of 4-methyl-6-chloropyrimidine was heated with alcoholic ammonia at 110° for ten hours, the solution evaporated to dryness, the residue taken up in a minimum amount of water, potassium hydroxide added while cooling with ice and the crystalline product filtered off, recrystallized from hot water and sublimed in high vacuum at 85–90°; yield 0.4 g.; m. p. 194–195°.

Anal. Calcd. for $C_5H_7N_3$: N, 38.53. Found: N, 38.52, 38.52.

The same substance, prepared by Gabriel and Colman[5] from 2-chloro-4-methyl-6-aminopyrimidine, melted at 194–195°.

---

[5] Gabriel and Colman, *Ber.*, **32**, 2929 (1899).

5-Methyl-6-oxypyrimidine.—Seven and one-half grams of thiothymine[6] was oxidized with hydrogen peroxide as described above for methyl thiouracil. The solution was made alkaline with ammonia and evaporated to dryness. The residue was extracted with chloroform, the chloroform solution dried and evaporated and the residue sublimed in high vacuum at 110°, yielding 4.14 g. of a compound melting at 153–154°.

Anal. Calcd. for $C_5H_6N_2O$: C, 54.54; H, 5.45; N, 25.45. Found: C, 54.90, 54.81; H, 5.10, 5.32; N, 25.05, 25.17.

5-Methyl-6-aminopyrimidine.—One gram of the above compound was warmed gently in a water-bath with 4 cc. of phosphorus oxychloride until completely in solution. The solution was evaporated *in vacuo* to one-half volume and added to crushed ice, made alkaline with sodium hydroxide and extracted with chloroform. The extract was dried and evaporated *in vacuo* at 20° leaving an oil which did not crystallize. This was heated at 120° for eight hours with excess alcoholic ammonia. The product was isolated as in the case of 4-methyl-6-aminopyrimidine and sublimed in high vacuum at 110°, yielding a white sublimate of m. p. 175–176°.

Anal. Calcd. for $C_5H_7N_3$: C, 55.05; H, 6.42; N, 38.53. Found: C, 55.48, 55.71; H, 6.47, 6.46; N, 38.88, 38.60.

This compound was prepared from 4-iodo-5-methyl-6-aminopyrimidine by Gerngross[7] who recorded its melting point as 176°.

2-Thio-4,5-dimethyl-6-oxypyrimidine.—Seventy-two grams of thiourea and 132 g. of ethyl α-methylacetoacetate were refluxed with stirring on a steam-bath with 21 g. of sodium dissolved in 500 cc. of absolute alcohol for three hours. The reaction mixture was evaporated on the steam-bath nearly to dryness, cooled and acidified with acetic acid. After standing in an ice-box overnight the crystalline precipitate was collected and recrystallized first from 95% alcohol and then from absolute. The substance does not melt up to 255°; yield 88 g.

Anal. Calcd. for $C_6H_8N_2OS$: C, 46.15; H, 5.13; N, 17.95. Found: C, 46.17; H, 5.20; N, 18.19.

4,5-Dimethyl-6-oxypyrimidine.—Ten grams of the above thiopyrimidine was oxidized with hydrogen peroxide and the product was isolated as in the case of 5-methyl-6-oxypyrimidine. Instead of subliming it was recrystallized from hot ethyl acetate in which it is sparingly soluble; m. p. 202–203°; yield 4.22 g.

Anal. Calcd. for $C_6H_8N_2O$: C, 58.06; H, 6.45; N, 22.58. Found: C, 58.23, 58.13; H, 6.42, 6.37.

Schlenker[8] prepared this substance, m. p. 204°, by reducing the 2,6-dichloro-4,5-dimethylpyrimidine.

4,5-Dimethyl-6-chloropyrimidine.—2.2 grams of the 6-oxy compound was converted to the 6-chloro derivative as in the case of the 5-methyl-6-oxy analog. The solid product was sublimed in high vacuum at 50°; m. p. 52°; yield 1.57 g.

Anal. Calcd. for $C_6H_7N_2Cl$: C, 50.53; H, 4.91; N, 19.65. Found: C, 50.93, 50.79; H, 4.93, 4.82; N, 19.55, 19.46.

Schlenker[8] has reported this compound melting at 51°.

4,5-Dimethyl-6-aminopyrimidine.—One gram of the above chloro derivative was converted to the corresponding amino by heating for fifteen hours at 110° with alcoholic ammonia. Isolation was effected as in the case of the previous aminopyrimidines; purification by recrystallization first from hot water and then from benzene; m. p. 229–231°; yield 0.35 g.

Anal. Calcd. for $C_6H_9N_3$: C, 58.54; H, 7.32; N, 34.15. Found: C, 58.32; H, 7.39; N, 34.37.

Schlenker[8] prepared this compound from 2-chloro-4,5-dimethyl-6-aminopyrimidine and recorded the m. p. as 230°.

2,5-Dimethyl-6-oxypyrimidine.—Forty-two grams of ethyl sodioformylpropionate[6] and 26 g. of acetamidine hydrochloride were dissolved in 200 cc. of water and allowed to stand for two days. The solution was evaporated on the steam-bath until crystallization started, made alkaline with ammonia and repeatedly extracted with chloroform. The extract was dried over sodium sulfate and evaporated to dryness *in vacuo.* The residue was sublimed in high vacuum at 125°, and the sublimate was recrystallized twice from acetone; m. p. 174°; yield, approximately 6 g.

Anal. Calcd. for $C_6H_8N_2O$: C, 58.06; H, 6.45; N, 22.58. Found: C, 58.22, 57.96; H, 6.36, 6.30; N, 23.23, 23.29.

2,5-Dimethyl-6-chloropyrimidine.—2.58 grams of 2,5-dimethyl-6-oxypyrimidine was converted to the chloro derivative in the usual way. The crude product was distilled at 40 mm. yielding a colorless oil which, due to its volatility, could not be weighed readily for satisfactory micro-analyses.

2,5-Dimethyl-6-aminopyrimidine.—One gram of the above 2,5-dimethyl-6-chloro pyrimidine was heated with excess alcoholic ammonia in a sealed tube at 125° for seven hours. Isolation of the product proceeded as in the case of other 6-aminopyrimidines. The product was purified by sublimation at 80°; m. p. 201–202°; yield 0.35 g.

Anal. Calcd. for $C_6H_9N_3$: C, 58.54; H, 7.31; N, 34.15. Found: C, 58.95, 59.02; H, 6.94, 7.20; N, 33.74, 33.63.

Picrate from water solution with aqueous picric acid, m. p. 222°.

Anal. Calcd. for $C_{12}H_{12}N_6O_7$: N, 23.87. Found: N, 24.10.

Approximate colorimetric determinations of the *p*H of water solutions of each of the aminopyrimidines were made using meta cresol purple and thymol blue as indicators. The solutions were approximately 0.01 *M* except in the case of 5-ethyl-6-amino which was insufficiently soluble and was, therefore, tested as a saturated solution.

TABLE I

ALKALINITY OF 6-AMINOPYRIMIDINE SOLUTIONS

Base	Solubility	*p*H
6-Amino	Moderate	8.3
2-Methyl-6-amino	Free	8.6–8.7
4-Methyl-6-amino	Moderate	8.3
5-Methyl-6-amino	Moderate	8.3
5-Ethyl-6-amino	Very sparing	7.9–8.0
2,4-Dimethyl-6-amino	Free	8.6–8.7
2,5-Dimethyl-6-amino	Sparing	8.5–8.6
4,5-Dimethyl-6-amino	Sparing	8.2–8.3

(7) Gerngross, *Ber.*, **38**, 3403 (1905).

(8) Schlenker, *ibid.*, **34**, 2823 (1901).

The ultraviolet absorption of all of the compounds was measured with a Hilger "Spekker" Photometer in conjunction with a Hilger E316 spectrograph. The source was a tungsten steel spark in some cases and a wide aperture hydrogen discharge tube in others. Either source was satisfactory. The Spekker photometer gave much more satisfactory results than the rotating sector used for earlier work.[9] Eastman d. c. Ortho and Cramer Contrast plates were both used with success. Solutions were in distilled water unless otherwise indicated.

We wish to express our gratitude to Mr. D. F. Hayman and Mr. S. Adler for the micro-analyses, to Dr. Joseph K. Cline for the preparation of 2-methyl-6-oxy- and 2-methyl-6-aminopyrimidines, to Mr. R. E. Waterman for the *p*H determinations and to Dr. H. T. Clarke for the use of facilities in preparing some of the spectrograms.

Summary

1. Methods of preparation are given for all of the previously unknown mono- and di-C-methyl derivatives of 6-oxy and 6-aminopyrimidine.

2. The ultraviolet absorption is given of both complete series including the non-alkylated members.

3. Addition of acid modifies the absorption of the 6-amino pyrimidines by reducing the prominence of the longer wave length band; alkali tends to equalize the prominence of the two bands.

4. The absorption of aminosulfonic acid from the vitamin reveals the influence of the acidity of the sulfonic group and is affected by alkali in a similar manner as non-sulfonated 6-aminopyrimidines.

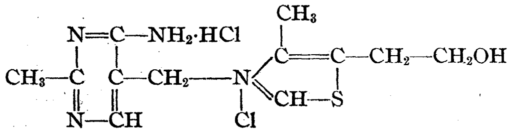
Studies of Crystalline Vitamin B_1. XVI. Identification of the Pyrimidine Portion

By Joseph K. Cline, Robert R. Williams, A. E. Ruehle and Robert E. Waterman

In a recent communication[1] the structure



was assigned to vitamin B_1 (aneurin) upon the basis of evidence which was indicated briefly at that time. Since then this structure has been confirmed by our synthesis[2] of the vitamin, by Grewe's synthesis[3] of two cleavage products, $C_6H_{10}N_4$, obtained from the vitamin by Windaus and collaborators,[4] and the amino sulfonic acid described previously[5] by our own group of associates, and finally by Bergel and Todd's synthesis of thiochrome.[6] Except for some questions which have not yet been fully resolved about possible stereoisomerism of the vitamin, the structure of the substance is established. The purpose of this paper is therefore merely to relate in greater detail the experimental evidence upon which our conclusions were based.

The earliest clear evidence of a bridge between the two nuclei in the vitamin came to us through the discovery that the vitamin is split at room temperature in liquid ammonia solution yielding a base, $C_6H_{10}N_4$, whose picrate melts at 225° and is evidently identical with the picrate of Windaus.[4] The base exhibits absorption in the ultraviolet characteristic of a C-alkylated 6-aminopyrimidine rather than a diaminopyrimidine. In Fig. 1 the absorption curve of this base is compared with those of 2,5-dimethyl-6-aminopyrimidine,[7] 4-methyl-5,6-diaminopyrimidine,[8] 4,5-dimethyl-2,6-diaminopyrimidine[9] and 5-ethyl-4,6-diaminopyrimidine.[10] These curves for diaminopyrimidines representing the several possible positions on the ring of the second amino group all differ radically from that for the base obtained from the vitamin. The latter substance, however, resembles in absorption the mono- and dialkylated 6-aminopyrimidines as displayed in the preceding paper[7] as well as the sodium salt of the amino sulfonic acid and the free oxysulfonic acid previously de-

rived from the vitamin. The resemblance to 2,5-dimethyl-6-aminopyrimidine is particularly close. Bearing in mind the influence of alkali upon the absorption of 6-aminopyrimidines and upon that of the aminosulfonic acid, the added basicity of the second amino group in the base $C_6H_{10}N_4$ would be expected to operate in the same direction. Since the absorption of the diamino base closely resembles those of the monoaminopyrimidines when the latter are observed in alkaline solution, we concluded that the second amino group is in a side chain. This side chain is common also to the aminosulfonic acid and therefore to the vitamin itself. This conclusion was fortified by the observation that groups other than amino in side chains influence the absorption only to a minor degree. Thus as we shall show in a later paper, ethoxymethyl, bromomethyl, carbethoxymethyl, or sulfomethyl groups on the pyrimidine ring behave in general somewhat as unsubstituted methyl groups in their influence on ultraviolet absorption of 6-amino and 6-oxy derivatives.

While the attachment of the second amino group to a side chain was clear, one could not be certain of the position of the side chain from absorption evidence alone. Now that the position of this side chain has been fixed by other independent evidence, the better correlation in absorption of the base $C_6H_{10}N_4$ with 2,5-dimethyl-6-amino-pyrimidine than with the other dimethylated 6-amino compounds is seen to be significant.

Satisfactory comparison of absorption curves cannot be made in the form of the picrates on account of the strong absorption of picric acid. Hydrochlorides are also unsatisfactory, as these on account of their acidity display only single banded and therefore less distinctive absorption.

In the light of this evidence, the aminosulfonic acid was reduced with metallic sodium in liquid ammonia solution. The larger part of the pyrimidine appeared as unidentifiable amorphous, insoluble and unsublimable products, possibly resulting from coupling of two rings.[11] We were, however, able to isolate a small yield of a base, m. p. 202°, which formed a picrate, m. p. 221–222°, identical by mixed melting point with that of 2,5-dimethyl-6-aminopyrimidine.[7] This provided the first unequivocal evidence of the positions of alkylation as well as final confirmation of the presence of the 6-aminopyrimidine nucleus in the vitamin.

Accepting the above evidence for 2,5-methylation, it was still necessary to determine whether the thiazole of the vitamin was located on the 2- or the 5-side chain. Consideration of the evidence as to the structure of thiochrome[4,12] led us to prefer the 5-position, our process of reasoning following the general lines upon which Makino and Imai[13] based their suggestion of the possibility of a methylene bridge. We had prepared synthetically, as will appear in a later paper, several 6-oxypyrimidines[1] with an ethoxymethyl group in various other positions. By treating 2-methyl-6-oxy-5-ethoxymethylpyrimidine with sodium sulfite, we were able to reproduce the oxy-sulfonic acid[5] previously derived from the vitamin and thus fixed the final detail of the structure of the latter.

Experimental Part

Liquid Ammonia Cleavage of Vitamin.—212 mg. of vitamin hydrochloride was dried for two hours at 80° *in vacuo* in a fragile glass bulb which was sealed off at the end of the drying period and transferred to a heavy-walled bomb tube. The latter was then connected to a system consisting of liquid ammonia cylinder, soda lime tube and a bomb tube with side-arm containing metallic sodium. The glass system was then evacuated and dried, liquid ammonia was admitted and condensed upon the sodium by packing the appropriate tube in solid carbon dioxide. Thence the ammonia was distilled off into the bomb tube containing the vitamin within the small tube. This bomb tube was sealed off and the bulb within was broken by shaking. The vitamin dissolved with a light brown color

which, as the ammonia approached room temperature, turned to a deep green which grew in intensity for a half hour then slowly faded over a period of forty-two hours at room temperature. The tube was then cooled and opened and the ammonia distilled off under anhydrous conditions and finally *in vacuo*. A light colored gummy mass containing much crystalline matter remained. This was extracted successively with 8-, 5- and 3-cc. portions of chloroform. On evaporation of the chloroform, 129.8 mg. of oil remained which on analysis contained 3% sulfur.

This oil after standing for a week was no longer fully soluble in chloroform. On extracting successively with 3-, 2- and 2-cc. portions of chloroform, the combined extracts left a partly crystalline residue of 88.3 mg. This was treated with 4 drops of water and the insoluble residue washed successively with 2, 2 and 1 drops of water. The aqueous solution was evaporated to dryness leaving a yellow crystalline mass which was washed with 0.5 cc. of an equal volume mixture of chloroform–alcohol and finally recrystallized three times from hot absolute alcohol; yield 13.9 mg. of dense colorless columnar crystals growing in rosets; m. p. 211–215°. The ultraviolet absorption in water solution is shown in Fig. 1.

Anal. Calcd. for $C_6H_{10}N_4$: C, 52.17; H, 7.25; N, 40.58. Found: C, 51.35; H, 6.35; N, 38.53.[14]

Dumas nitrogen determinations in these pyrimidines are troublesome.[15] The method here used was one devised by Hayman[16] and previously tested on a series of synthetic pyrimidines of similar structure.

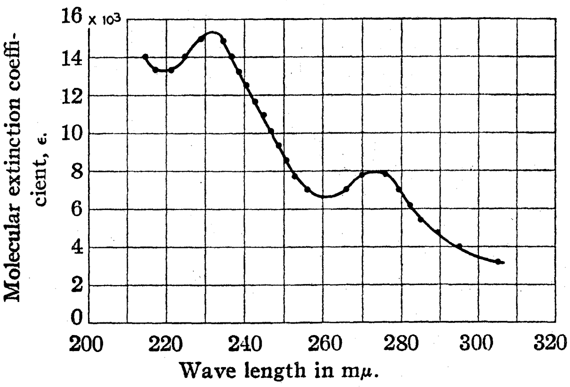

Fig. 2.—4-Methyl-5-formylamino-6-aminopyrimidine.

A portion of the base was converted to the hydrochloride and treated in aqueous solution with picric acid to incipient precipitation. On standing overnight rosets of yellow needles appeared; m. p. 225°.

Anal. Calcd. for $C_6H_{10}N_4[C_6H_2OH(NO_2)_3]_2$: C, 36.24; H, 2.68; N, 23.49. Found: C, 36.94; H, 2.56; N, 23.80.

The fate of the thiazole portion of the molecule was not determined. Considerable evolution of hydrogen sulfide was noted on distilling one of the by-products *in vacuo* and it seems probable that an extensive degradation occurs. The thiazole by itself does not give the green color in liquid ammonia.

Preparation of Diaminopyrimidines.—The preparation of 4-methyl-5,6-diaminopyrimidine,[8] 4,5-dimethyl-2,6-diaminopyrimidine[9] and 5-ethyl-4,6-diaminopyrimidine[10] followed the literature. It should be added that in preparing the last named from 4-iodo-5-ethyl-6-aminopyrimidine it was necessary to heat with saturated alcoholic ammonia at 220° for fifteen hours. The product melted at 235–237° compared with the literature figure of 233–235° but on further purification by sublimation or recrystallization from ethyl acetate, melted at 245°. It formed a dipicrate, m. p. 165–167°.

Anal. Calcd. for $C_6H_{10}N_4[C_6H_2OH(NO_2)_3]_2$: N, 23.49. Found: N, 23.68.

4-Ethyl-5,6-diaminopyrimidine[17] was also prepared by Dr. E. R. Buchman in a manner analogous to that of the cited literature[8] for 4-methyl-5,6-diamino. Dr. Buchman kindly supplied a sample for ultraviolet examination. Its absorption is almost identical with that of the 4-methyl analog. The formyl derivatives of the 5,6-diamino compounds show a striking modification of absorption (see Fig. 2).

Reduction of Amino Sulfonic Acid with Sodium.—27 mg. of the aminosulfonic acid was suspended in 5 cc. of anhydrous liquid ammonia (distilled from sodium) and 10 mg. of metallic sodium was added in portions with shaking. After standing a half hour, the ammonia was evaporated by passing in a stream of dry air. A few drops of alcohol were added to destroy any excess of sodium and the residue sublimed *in vacuo* at about 120° at 0.1 mm., and then at atmospheric pressure at 180–200°. The final sublimate melted sharply at 202°.

Anal. Calcd. for $C_6H_9N_3$: C, 58.54; H, 7.32; N, 34.15. Found: C, 58.34; H, 7.40; N, 33.67.

An aqueous solution of the sublimate was treated with aqueous picric acid solution to faint opalescence. Upon standing overnight needle crystals of a picrate separated which melted at 221–222°. When mixed with the picrate of 2,5-dimethyl-6-aminopyrimidine, the melting point was not depressed.

Anal. Calcd. for $C_6H_9N_3C_6H_2OH(NO_2)_3$: N, 23.86. Found: N, 23.41.

Synthesis of Oxysulfonic Acid.—300 mg. of 2-methyl-5-ethoxymethyl-6-oxypyrimidine prepared according to a method to be described in a later paper was dissolved in 5 cc. of water containing 1 g. of sodium sulfite. The mixture was saturated with sulfur dioxide and heated for eighteen hours at 144° in a sealed tube. To the pale yellow solution concentrated hydrochloric acid was added and the solution was saturated with dry hydrogen chloride to precipitate sodium chloride. The filtrate from the sodium chloride was concentrated to a small volume, again saturated with hydrochloric acid to remove further sodium chloride. After removing sodium chloride as completely as possible, the oily residue was dissolved in 3 cc. of water and 8 cc. of alcohol was added. On standing white crystals separated. These were purified by dissolving in 3 cc. of concentrated hydrochloric acid, centrifuging off a trace

---

(14) This analysis was made after heating *in vacuo* to 100° for one hour during which a small loss of weight occurred. Previous to this heating values for C and H of 50.66 and 5.98%, respectively, were obtained. The results suggested that the base absorbs carbon dioxide from the air.

(16) D. F. Hayman and S. Adler, *ibid.*, in press.

(17) Robinson and Tomlinson, *J. Chem. Soc.*, II, 1283 (1935).

of insoluble matter, evaporating to dryness and recrystallizing from water and alcohol as before. The crystals did not melt up to 360°.

Anal. Calcd. for $C_6H_8N_2SO_4$: C, 35.27; H, 3.95; N, 13.73; S, 15.69. Found: C, 35.23, 35.53; H, 3.78, 3.89; N, 14.06, 13.78; S, 15.30, 15.33.

Through the kindness of Mr. H. W. Hermance the crystals were compared crystallographically with the natural oxysulfonic acid obtained from the vitamin. He reported: "The bulk of the crystals of the synthetic sulfonic acid occurred in the form of slightly tapering rods, 50–100 microns in length, with a sharp terminal angle (not measured because of the smallness of the crystal). Some twinning was observed but individually developed crystals were more general. The extinction angle, measured from the long edge, was fairly constant through about twenty observations. It was found to be 59 ± 0.5°. The crystals appeared to belong either to the monoclinic or triclinic system. As oriented on the slide, two indices of refraction were evident. The higher, observed at the extinction position, was slightly greater than 1.632, the lower, slightly less than 1.623.

"The natural oxysulfonic acid corresponded in the above crystallographic constants with the synthetic within the limits of experimental error. It showed a somewhat greater tendency to twinning which, however, cannot be regarded as evidence of a difference in molecular structure."

The synthetic sulfonic acid was also compared with the natural with respect to ultraviolet absorption. Close agreement was observed (Fig. 3). Since no melting point was available as a criterion of identity, and since experience with alkylated oxypyrimidines[7] had indicated that ultraviolet absorption is not a definitive index of the position of alkyl substituents, it still appeared possible that the synthetic oxysulfonic acid was merely isomeric and not identical with the natural. This was especially true since all such sulfonic acids might be expected also to resemble one another in other physical properties, such as solubilities. Under these circumstances resort was had to a special form of solubility comparison. Portions of absolute ethyl alcohol were saturated with (a) the natural sulfonic acid, (b) the synthetic and (c) both synthetic and natural. The intensities of ultraviolet absorption of these three solutions were then compared and found to be identical throughout the range of frequency. If the substances were not identical, solution (c) should have absorbed with an intensity approximating that of (a) + (b). In making such comparisons, it was found essential to clarify the solutions thoroughly. This was done by centrifuging in a horizontal position in the optical cells in which solution had been effected so that any sediment deposited on the cylindrical walls. It was of course necessary to check carefully the equality of intensity of illumination produced by the two parallel beams of light.

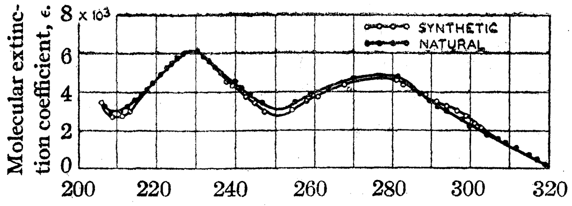

Fig. 3.—2-Methyl-6-oxy-5-methylsulfonic acid.

We gratefully acknowledge our indebtedness to Mr. D. F. Hayman and Mr. S. Adler for the microanalyses, to Mr. J. Finkelstein for the synthesis of 2,5-dimethyl-6-amino- and several diaminopyrimidines, as well as to Dr. E. R. Buchman and Mr. H. W. Hermance for the courtesies noted in the text. Thanks are also due to Dr. R. T. Major for advice and for facilities put at our disposal.

Summary

1. The vitamin undergoes cleavage with liquid ammonia producing a base, $C_6H_{10}N_4$, which exhibits ultraviolet absorption akin to that of C-methylated-6-aminopyrimidines but unlike that of 6-aminopyrimidines having another amino group elsewhere on the ring.

2. Reduction by means of sodium in liquid ammonia of the aminosulfonic acid obtained by sulfite cleavage of the vitamin yields 2,5-dimethyl-6-aminopyrimidine.

3. Reaction of sulfite with 2-methyl-5-ethoxymethyl-6-oxypyrimidine yields 2-methyl-6-oxypyrimidine-5-methylsulfonic acid which is identical with the oxy-sulfonic acid previously derived from the vitamin.

4. The structure of the vitamin is thereby established.

Arsinic Acids[1]

By F. F. Blicke and G. L. Webster[2]

The object of this paper is to describe the preparation and properties of a number of arsinic acids and their derivatives which were prepared in connection with our study of diarsyls.

By means of an unusual process, namely, treatment of diazotized 2-aminophenylarsonic acid with sulfur dioxide, Kalb[3] obtained a substance which he claimed to be an anhydride of the dihydroxy form of 2-hydroxyphenylarsine oxide, $C_6H_4(OH)As(OH)_2$, but the only experimental evidence offered in support of his structure was an arsenic analysis.

We prepared Kalb's product by means of a more orthodox procedure, that is, hydrolysis of 2-hydroxyphenyldichloroarsine. Both an arsenic analysis and a molecular weight determination offer strong support for the anhydride formula and it seems that this oxide does not exist in the ordinary form $C_6H_4(OH)As{=}O$.

Experimental Part

2- and 3-Aminodiphenylarsinic Acid.—Reduction of 25 g. of the required nitro acid, dissolved in 20 g. of sodium hydroxide and 250 cc. of water, was effected with ferrous hydroxide obtained by addition of 61 g. of sodium hydroxide in 235 cc. of water to 195 g. of ferrous sulfate dissolved in 400 cc. of water. After twenty-four hours the mixture was filtered and the filtrate carefully acidified; yield 15 g. of the 2-amino acid and 16 g. of the 3-amino compound.

2-Hydroxydiphenylarsinic Acid.—A solution, prepared from 27.7 g. of 2-aminodiphenylarsinic acid, 160 cc. of water and 20 cc. of concd. sulfuric acid, was poured onto 400 g. of ice and diazotized with 15.2 g. of sodium nitrite, whereupon a slow evolution of nitrogen began almost immediately. After twenty-four hours the dark brown precipitate of hydroxy acid was filtered; yield 25 g. or 90% of the calcd. amount.

2-Methoxydiphenylarsinic Acid.—A mixture, composed of 5.5 g. of 2-hydroxydiphenylarsinic acid, 20 cc. of water, 5.0 g. of sodium hydroxide and 3.6 cc. of dimethyl sulfate, was shaken until the sulfate had disappeared; the methylation process was repeated four times. The mixture was heated on a steam-bath for one-half hour, partially neutralized with 20 cc. of hydrochloric acid, treated with charcoal and filtered. The cold filtrate was acidified to congo red; yield 5.2 g.

3-Nitrodiphenylarsinic Acid.—A solution, prepared from 27.6 g. of technical 3-nitroaniline, 50 cc. of hydrochloric acid and 100 cc. of water, was diazotized with 13.8 g. of sodium nitrite, dissolved in 400 cc. of water, the mixture then diluted with 1000 cc. of water and treated with 5 *N* sodium hydroxide until no longer acid toward congo red.

To the stirred diazonium solution, maintained at 15°, there was added, slowly, 33.6 g. of phenylarsine oxide, dissolved in a mixture of 40 cc. of 10 *N* sodium hydroxide and 180 cc. of water. The mixture was stirred for two hours, made slightly acid with acetic acid, filtered and the filtrate acidified with hydrochloric acid until acid to congo red; the precipitated arsinic acid weighed 16.5 g. The filtrate was neutralized with sodium hydroxide and evaporated to a volume of 300 cc., cooled, made slightly acid with acetic acid, filtered and the filtrate acidified to congo red; 16 g. more of the arsinic acid precipitated; total yield 51% of the calcd. amount.

4-Bromodiphenylarsinic Acid.—A solution of 172 g. of 4-bromoaniline in 350 cc. of hydrochloric acid and 400 cc. of water was poured onto 1000 g. of ice, 1000 cc. of water added and more ice, if necessary to keep the temperature at 0°. The amine was diazotized with 70 g. of sodium nitrite, dissolved in 500 cc. of water.

A solution, prepared from 170 g. of phenylarsine oxide, 160 g. of flake sodium hydroxide and 3000 cc. of water, was added to the diazonium solution during the course of one hour and the mixture was stirred vigorously for three hours. After twelve hours it was filtered. The tarry residue contained 4-chlorobromobenzene. The filtrate was shaken with charcoal, filtered and acidified to congo red with hydrochloric acid; yield 137 g.

3,4′-Dinitrodiphenylarsinic Acid.—The solution, obtained by sifting 30.7 g. of 4-nitrodiphenylarsinic acid[4] onto 100 cc. of concd. sulfuric acid, was cooled to 0°, stirred, and treated, dropwise, with a mixture of 6.4 cc. of nitric acid (sp. gr. 1.42) and 6.4 cc. of sulfuric acid while the temperature was maintained at 0–3°. After twelve hours the mixture was poured onto 700 g. of ice, the yellow, crystalline nitro acid filtered and washed with water; yield 35.0 g.; calcd. yield 35.2 g.

3,4′-Dihydroxydiphenylarsinic Acid.—A solution, prepared from 3.6 g. of 3,4′-diaminodiphenylarsinic acid, 5 cc. of sulfuric acid and 50 cc. of water, was diazotized at 0–5° with 2.0 g. of sodium nitrite dissolved in 10 cc. of water. The mixture was heated for two hours at 55–65°, the liquid decanted from a small amount of red by-product, cooled with ice and stirred. The red gum which separated was discarded. After some time the dihydroxy acid separated from the clear solution in a colorless, crystalline form.

3,3′-Dinitro-4-hydroxydiphenylarsinic Acid.—Twenty-one grams of 4-hydroxydiphenylarsinic acid,[4,5] dissolved in

[5] If the solution of diazotized 4-aminophenylarsonic acid is heated to 65–70° for one hour, instead of at the boiling point, the yield of 4-hydroxydiphenylarsinic acid is increased to 75% of the calcd. amount.

TABLE I

ARSINIC ACIDS

Compounds 3, 10, 13 and 14 were recrystallized from water, 1, 4 and 11 from 15% acetic acid, 2 and 9 from 40% acetic acid, 5 from 20% alcohol, 6 and 7 from 50% alcohol and 8 and 12 from 85% alcohol. All of the acids are soluble in acetic acid and insoluble in benzene.

		M. p., °C.	Formula	As, % Calcd.	As, % Found

[a] Kalb [*Ann.*, **423**, 60 (1921)] reported the same melting point. [b] For preparative method see corresponding 2-hydroxy compound. [c] For preparative method see corresponding 2-methoxy compound. [d] For preparative method see corresponding 3,3′-diamino compound [Blicke, Oakdale and Oneto, THIS JOURNAL, **56**, 142 (1934)]. [e] Bertheim [*Ber.*, **48**, 358 (1915)] reported 206–207°.

105 cc. of concd. sulfuric acid, was nitrated very slowly with 9.6 cc. of nitric acid (sp. gr. 1.42) and an equal volume of concd. sulfuric acid while the temperature was maintained below 0°. After eight hours the mixture was poured onto 1000 g. of ice and the precipitated acid washed with water; yield 26.5 g. or 95% of the calcd. amount.

Methyl-3-amino-4-hydroxyphenylarsinic Acid.—To 185 g. of technical ferrous sulfate, dissolved in 650 cc. of water, and 200 g. of flake sodium hydroxide, dissolved in 300 cc. of water, there was added 26.1 g. of methyl-3-nitro-4-hydroxyphenylarsinic acid[6] dissolved in a mixture of 100 cc. of water and 10 g. of sodium hydroxide. The mixture was shaken vigorously in a stoppered flask for thirty minutes. After twenty-four hours the material was filtered and the filtrate made acid to congo red by the addition of approximately 280 cc. of concd. hydrochloric acid. The solution was then evaporated to a volume of about 600 cc., filtered, cooled and neutralized to congo red by the addition of sodium hydroxide solution. The amino acid precipitated when the sides of the container were scratched. The product was filtered and a further amount of acid obtained by concentration of the filtrate; yield 16.5 g. or 71% of the calcd. amount.

Methyl-3-nitro-4-methoxyphenylarsinic Acid.—A mixture of 12.2 g. of 3-nitro-4-methoxyphenylarsine oxide, 80 cc. of methyl alcohol, 6 g. of sodium hydroxide (70%) and 45 cc. of water was cooled and shaken with 4 cc. of methyl iodide in a stoppered flask. After twenty-four hours the mixture was filtered and then heated in an evaporating dish until a crust began to form on the surface of the liquid. The material was cooled, diluted with 25 cc. of water and 17 cc. of acetic acid added. The precipitated, crystalline arsinic acid weighed 13.5 g. which is 97% of the calcd. amount; m. p. 216–217° after recrystallization from water.

4-Bromophenylarsonic Acid.[7]—A solution of 172 g. of 4-bromoaniline, 300 cc. of hydrochloric acid and 400 cc. of water was poured onto 800 g. of ice, the mixture stirred and diazotized at 0° with 70 g. of sodium nitrite dissolved in 200 cc. of water. During this process the temperature should remain below 5°.

A mixture of 5 g. of copper sulfate, 50 cc. of water and 10 cc. of ammonia water was added to a solution of 210 g. of sodium arsenite and 250 g. of sodium carbonate in 2000 cc. of water. The mixture was cooled to 15°, stirred vigorously and the solution of the diazotized amine added slowly during the course of one hour. The material was stirred for two hours and after twelve hours was filtered; the filtrate was acidified to congo red with hydrochloric acid; yield 193 g.

4-Nitrophenyldichloroarsine.—One drop of hydriodic acid was added to 10 g. of 4-nitrophenylarsonic acid,[8] dissolved in 25 cc. of hydrochloric acid, the mixture treated with sulfur dioxide and the oily precipitate obtained extracted with benzene. Since the dichloroarsine would not solidify, a crystalline derivative was obtained in the following manner. One-half of the original benzene solution of the dichloroarsine was dried with calcium chloride and treated with the piperidine salt of N-pentamethylene dithiocarbamate.[9] After twenty-four hours the solvent was allowed to evaporate, the crystalline residue washed thoroughly with water and the dried material (8.9 g.) recrystallized from ethyl acetate; m. p. 177–178°. This product was 4-nitrophenylarsylene-N-pentamethylenedithiocarbamate, $(NO_2)C_6H_4As[S—C(S)—NC_5H_{10}]_2$.

[a] Obtained when 5 g. of 2,2″-diacetyldiaminotetraphenylarsyl oxide was warmed with 20 cc. of hydriodic acid for a few minutes. [b] Prepared from 2 g. of 2-methoxydiphenylarsinic acid and 10 cc. of hydriodic acid. [c] Prepared in the same manner as the corresponding 2-amino compound. [d] The compound obtained by acetylation of 3.6 g. of 3,3″-diaminotetraphenylarsyl oxide was rubbed under 35 cc. of hydriodic acid, the acid decanted and 5 cc. of acetic acid added, whereupon the oily iodide became crystalline. [e] Prepared by shaking 5 g. of 4-methoxyphenylarsine oxide with 25 cc. of hydrochloric acid. [f] Michaelis and Weitz [*Ber.*, **20**, 51 (1887)] reported 48°.

Anal. Calcd. for $C_{18}H_{24}O_2N_3S_4As$: As, 14.49; S, 24.79. Found: As, 14.83; S, 24.72.

2-Nitrodiphenyliodoarsine.—Five grams of 2-nitrodiphenylarsinic acid was heated with 20 cc. of hydrochloric acid until the arsinic acid dissolved. A crystalline material, undoubtedly an addition product of the two acids, often begins to precipitate at this stage. After the addition of 5 cc. of water and several drops of hydriodic acid the mixture was saturated with sulfur dioxide. The chloroarsine, which precipitated as a gum, was washed with water. The gum was covered with ether, treated with ammonia water and the arsyl oxide produced dissolved in the ether. The ether solution was separated and the solvent allowed to evaporate. The yellow, crystalline residue (3.6 g.) of the arsyl oxide was pulverized and triturated with excess hydriodic acid. After some time the iodoarsine was filtered on a Jena filter.

2-Aminodiphenylchloroarsine Hydrochloride and 2,2″-Diaminotetraphenylarsyl Oxide.—A mixture of 2 g. of 2-aminodiphenylarsinic acid, 75 cc. of hydrochloric acid and two drops of hydriodic acid was saturated with sulfur dioxide, the precipitated chloroarsine hydrochloride filtered, dissolved in the least possible amount of water and precipitated by the addition of fuming hydrochloric acid.

To obtain the oxide the chloroarsine hydrochloride was dissolved in water, the solution shaken with charcoal, filtered and the filtrate treated with ammonia water, drop by drop, until no more oxide precipitated. The latter was extracted with ether, the solution dried and the solvent removed. The oxide was obtained as a semi-solid mass.

A mixture of 10 g. of the semi-crystalline 2,2″-diaminotetraphenylarsyl oxide and 25 cc. of acetic anhydride was heated until all of the oxide dissolved. White, glistening crystals separated when the mixture was cooled. The product is soluble in alcohol, hot acetone, benzene and acetic acid; m. p. 180–181° after recrystallization from acetic acid.

According to the analyses the acetylated oxide contains acetic acid of crystallization. The three analyses recorded below were made with material prepared at different times.

Anal. Calcd. for $C_{28}H_{26}ON_2As_2 + 1.5CH_3COOH$: As, 22.10. Found: As, 21.97, 22.09, 22.00.

Methyl-3-amino-4-hydroxyphenylchloroarsine Hydrochloride.—A mixture of 5 g. of methyl-3-amino-4-hydroxyphenylarsinic acid, 25 cc. of hydrochloric acid, 15 cc. of water and a drop of hydriodic acid was saturated with sulfur dioxide, the crystalline precipitate dissolved in 25 cc. of warm water, shaken with charcoal, filtered and the chloride hydrochloride precipitated with 25 cc. of hydrochloric acid.

Methyl-3-amino-4-hydroxyphenyliodoarsine Hydriodide.—A solution of 2.6 g. of methyl-3-amino-4-hydroxyphenylchloroarsine hydrochloride in 10 cc. of water was treated with 1.7 g. of sodium bicarbonate, dissolved in 15 cc. of water. The gummy precipitate was triturated with 10 cc. of hydriodic acid (sp. gr. 1.7), the crystalline iodide hydriodide dissolved in 5 cc. of water and precipitated by the addition of 10 cc. of hydriodic acid.

Anhydride of 2-Hydroxyphenylarsine Oxide.—The solution of 2-hydroxyphenylarsonic acid, obtained by coupling 9.3 g. of diazotized 2-aminophenol with sodium arsenite,[10] was made neutral to litmus with hydrochloric acid, filtered, boiled with charcoal, filtered again and acidified to congo red with hydrochloric acid. After several extractions with ether to remove phenol, 1 cc. of hydriodic acid was added and the solution treated with sulfur dioxide. The precipitated, oily dichloroarsine was stirred with 10 g. of sodium carbonate dissolved in water. The thick gum which formed became crystalline when the mixture was heated. After recrystallization from acetone the compound melted at 181–182°.[11]

Anal. Calcd. for $C_6H_4(OH)As{=}O$: As, 40.73; mol. wt., 184. Calcd. for anhydride, $C_{12}H_8O_3As_2$: As, 42.83; mol. wt., 350. Found: As, 42.86; mol. wt., 341.[12]

3-Nitro-4-methoxyphenylarsine Oxide.—Twenty grams of 3-nitro-4-methoxyphenylarsonic acid[13] was dissolved in 1800 cc. of hot water, the solution cooled to 55° and a mixture of 10 cc. of sulfuric acid and 50 cc. of water added. After the addition of 4 cc. of hydriodic acid, sulfur dioxide was led into the hot solution for two hours. After

twelve hours the precipitated oxide was filtered; yield 16.5 g. or 94% of the calcd. amount.

The oxide is insoluble in all of the common organic solvents but dissolves in sodium hydroxide solution and precipitates upon the addition of acid. For analysis the crude oxide was washed with hot 10% sodium carbonate solution and then with water until free from sodium carbonate and halides; m. p. 247–248° with decomposition.

Anal. Calcd. for $C_7H_6O_4NAs$: As, 30.84. Found: As, 30.94.

Summary

The preparation of fifteen arsonic and arsinic acids, ten haloarsines and three arsine oxides has been described.

ANN ARBOR, MICH. RECEIVED SEPTEMBER 18, 1936

Diarsyls. VIII. Amino and Hydroxydiarsyls[1]

BY F. F. BLICKE AND G. L. WEBSTER[2]

It was to be expected that water-soluble tetraaryldiarsyls could be obtained by the preparation of salts of tetraaryldiarsyls which contained nuclear amino or hydroxyl groups. It has been found that 3,3′,3′′,3′′′-tetra-(aminophenyl)-diarsyl[3] forms a water-soluble hydrochloride and that the sodium salts of 4,4″-dihydroxytetraphenyldiarsyl[4] and 3,3′,3′′,3′′′-tetra-(hydroxyphenyl)-diarsyl[4] are soluble in water.

A study of 2,2″-diaminotetraphenyldiarsyl has shown that this substance, dissolved in benzene, separates from the solution when the latter is shaken with concentrated hydrochloric acid in the form of a crystalline, benzene-insoluble compound. When water is added to the mixture the crystalline product dissolves and the diarsyl is found to be present in the benzene layer. This behavior indicates that the hydrochloride of this diarsyl is hydrolyzed extensively by water.

2,2″-Diaminotetraphenyldiarsyl was prepared by two methods: (a) interaction of 2,2″-diaminotetraphenylarsyl oxide with diphenylarsine, a reaction which yields both 2,2″-diaminotetraphenyldiarsyl and tetraphenyldiarsyl; (b) reaction between 2,2″-diaminotetraphenylarsyl oxide and 2-aminodiphenylarsine.

When diphenylarsine was added to 2,2″-dihydroxytetraphenylarsyl oxide, dissolved in benzene, tetraphenyldiarsyl began to precipitate at once but we were not able to isolate the alkali-soluble 2,2″-dihydroxytetraphenyldiarsyl in crystalline form.

2-Methoxydiphenyliodoarsine, dissolved in benzene, reacted rapidly with molecular silver. Although the reaction product could be obtained only in the form of an oil, the halogen-free material seemed to be 2,2″-dihydroxytetraphenyldiarsyl since it decolorized iodine instantly to yield 2-methoxydiphenyliodoarsine.

3,3″-Dihydroxytetraphenyldiarsyl was formed when 3,3′-dihydroxydiphenylarsinic acid was reduced with hypophosphorous acid. The compound is soluble in alkali and reacts rapidly with oxygen when dissolved in an organic solvent.

When 3,3″-dihydroxytetraphenyldiarsyl was methylated with dimethyl sulfate the corresponding 3,3″-dimethoxydiarsyl was produced. This compound also reacts rapidly with oxygen.

A very limited chemical study of dimethyl-di-(3-amino-4-hydroxyphenyl)-diarsyl was made by Bertheim.[5] He treated methyl-3-amino-4-hydroxyphenylarsinic acid with hypophosphorous acid, whereupon the crystalline dihypophosphite of the diarsyl precipitated. He analyzed this compound and stated that it irritates the mucous membrane. Upon treatment of the dihypophosphite with hydrochloric acid a water-soluble dihydrochloride was produced. Bertheim concluded his study of this diarsyl with the analysis of this salt.

We prepared the dihypophosphite of dimethyl-di-(3-amino-4-hydroxyphenyl)-diarsyl in the manner described above, treated the material with sodium hydroxide solution until a clear solution was obtained, acidified the latter with acetic acid and isolated the precipitated diarsyl. The dihydrochloride was prepared from the free base. It was found that this salt, as well as an aqueous, alkaline solution of the diarsyl, absorbed oxygen.

Experimental Part

The apparatus shown in the accompanying drawing was found to be very useful for the preparation of amino and hydroxy diarsyls. When an aminodiarsyl is precipitated from an acid solution or a hydroxydiarsyl from an alkaline solution the diarsyls tend to separate in a somewhat flocculent state, hence are difficult to wash by decantation. By the use of the modified free radical bulb the product can be filtered by means of the glass filter (Jena filter). A slight pressure from a tank of nitrogen is applied through the side arm attached to the bulb. After filtration the diarsyl is dissolved from the filter plate by a suitable solvent and the solution decanted into the usual type of radical bulb.

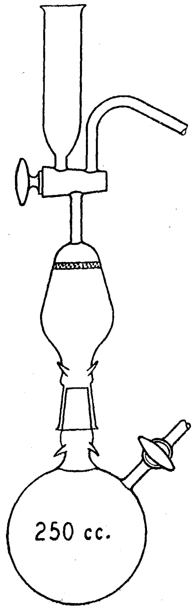

Fig. 1.

2,2″ - Diaminotetraphenyldiarsyl. (a) **From 2,2″-Diaminotetraphenylarsyl Oxide and Diphenylarsine.**—To 3.6 cc. (0.02 mole) of diphenylarsine, washed into a radical bulb filled with nitrogen with 10 cc. of absolute alcohol, there was added 5.0 g. (0.01 mole) of 2,2″-diaminotetraphenylarsyl oxide, dissolved in 10 cc. of alcohol. After twelve hours the alcoholic mother liquor was decanted from the precipitated diarsyls and discarded and the latter washed several times with small amounts of alcohol. The material was dried under diminished pressure, dissolved in 35 cc. of benzene, the solution transferred to a modified radical apparatus (see illustration) and shaken with 25 cc. of hydrochloric acid. The white, crystalline precipitate, the dihydrochloride of the diaminodiarsyl, was filtered, the crystals washed three times with 20 cc. of benzene and the benzene added to the original benzene filtrate which had been collected in a second radical bulb (this solution contained tetraphenyldiarsyl).

The white, crystalline material was shaken with a mixture of 50 cc. of water and 20 cc. of benzene, whereupon the product dissolved in the benzene layer. The aqueous layer was removed, the solvent distilled from the benzene layer under diminished pressure and the crystalline residue dissolved in 10 cc. of hot alcohol. 2,2″-Diaminotetraphenyldiarsyl separated from the cold solution and was then recrystallized from 20 cc. of alcohol; yield 2.3 g.

The diarsyl is very soluble in benzene, acetone and ether and the solutions rapidly turn dark red when exposed to air.

Dissolved in bromobenzene 0.860 g. of the diarsyl absorbed 30 cc. (N. T. P.) of oxygen in one minute.

In order to isolate the tetraphenyldiarsyl the solvent was removed from the benzene solution in the second radical bulb, the crystalline residue washed with alcohol and then recrystallized from 200 cc. of this solvent; yield 2.6 g.; m. p. 129–131° in a sealed tube filled with nitrogen.[6]

The rather peculiar behavior of the hydrochloride of the diaminodiarsyl was studied again after the diarsyl had been isolated. A sample of the diarsyl, dissolved in benzene, was shaken with hydrochloric acid, whereupon a white, crystalline precipitate appeared. After the addition of water the precipitate disappeared and the diarsyl was recovered from the benzene layer. Apparently the hydrochloride is hydrolyzed very extensively by water.

When 0.57 g. of the diaminodiarsyl was dissolved in 1 cc. of acetic anhydride, heated for thirty minutes, cooled and treated with water the gummy diacetyl derivative was obtained. This material was dissolved in 2 cc. of acetic acid and treated with 0.3 g. of iodine, dissolved in benzene. The iodine was decolorized instantly and after removal of the solvents 1 g. of crude 2-acetylaminodiphenyliodoarsine[7] was obtained; m. p. 147–148° after recrystallization from acetic acid.

(b) **From 2,2″-Diaminotetraphenylarsyl Oxide and 2-Aminodiphenylarsine.**—From a mixture of 2.3 g. of 2-aminodiphenylarsine, dissolved in 20 cc. of alcohol, and 2.5 g. of 2,2″-diaminotetraphenylarsyl oxide, dissolved in 30 cc. of the same solvent, there had precipitated, at the end of twenty-four hours, 2.1 g. of the diaminodiarsyl; m. p. 133–135° after recrystallization from 50 cc. of alcohol.

3,3″-Diaminotetraphenyldiarsyl.—Ammonia water was added to 4.5 g. of 3-aminodiphenylchloroarsine hydrochloride,[7] dissolved in water, the gummy precipitate extracted with ether, the ether solution poured into a radical bulb and the solvent removed. The colorless, oily 3,3″-diaminotetraphenylarsyl oxide was dissolved in 20 cc. of 50% hypophosphorous acid which contained four drops of hydriodic acid. The mixture was heated at 70° for three hours and after twelve hours made alkaline with 10% sodium hydroxide solution, the precipitate washed with water, dissolved in 100 cc. of alcohol and filtered into a second radical bulb. After distillation of about 75 cc. of alcohol the diarsyl separated in crystalline condition.

Dissolved in acetophenone 1.1550 g. of the diarsyl absorbed 47 cc. (N. T. P.) of oxygen in thirty seconds; calcd. amount 53 cc.

A mixture of 1.2 g. of the diarsyl, 15 cc. of acetone and 3 cc. of acetic anhydride was heated for one hour and the solvents removed. Since the residue would not crystallize the acetylated diarsyl was treated with 0.66 g. of iodine, dissolved in 10 cc. of alcohol. The iodine color disappeared instantly. The alcohol was removed and the residue rubbed under 3 cc. of acetic acid whereupon the product crystallized; this compound, 3-acetylaminodiphenyliodoarsine,[7] melted at 146–147° after recrystallization from acetic acid; mixed m. p. 146–147°.

3,3″-Dihydroxytetraphenyldiarsyl.—A mixture of 5.8 g. of 3-hydroxydiphenylarsinic acid, 10 cc. of alcohol, two drops of hydriodic acid and 20 cc. of 50% hypophosphorous acid in a modified radical bulb was heated in a bath at 70° for three hours. To the cold solution, 200 cc. of water was added slowly. The diarsyl precipitated as a liquid which soon became crystalline. The liquid was decanted, the diarsyl washed thoroughly with water, dried under reduced pressure, dissolved in hot benzene, the solution filtered, cooled, and the diarsyl precipitated by the addition of 150 cc. of petroleum ether (90–100°); yield 3.6 g.

The hydroxydiarsyl is soluble in alkali: 0.417 g. of the

---

[6] Blicke, Weinkauff and Hargreaves [THIS JOURNAL, **52**, 782 (1930)] reported 129–130°.

[7] Blicke and Webster, *ibid.*, **59**, 536 (1937).

material dissolved in a mixture of 0.14 g. of sodium hydroxide and 10 cc. of water. Upon the addition of hydrochloric acid the diarsyl was recovered unchanged. It is also soluble in benzene and very soluble in alcohol and acetone. Dissolved in acetophenone the diarsyl absorbed oxygen rapidly.

3,3″-Dimethoxytetraphenyldiarsyl.—The 3,3″-dihydroxytetraphenyldiarsyl, obtained from 5.8 g. of 3-hydroxydiphenylarsinic acid, was dissolved in a mixture of 10 cc. of 40% sodium hydroxide solution and 25 cc. of water and shaken with 3 cc. of dimethyl sulfate. The methylation process was repeated with 20 cc. of 40% sodium hydroxide solution and 6 cc. of dimethyl sulfate. The mixture, from which the methoxy derivative had settled as a gum, was heated for some time; when cooled, the product crystallized. It was washed with alkali and water, dissolved in 35 cc. of benzene and the solution filtered into a second radical bulb. The benzene was removed and the diarsyl recrystallized from 20 cc. of alcohol; yield 3.8 g.

A solution obtained from 1.28 g. of the diarsyl and 20 cc. of acetophenone absorbed 52 cc. (N. T. P.) of oxygen in thirty seconds; calcd. 55 cc.

Dimethyl-di-(3-amino-4-hydroxyphenyl)-diarsyl.—A solution prepared from 4.6 g. of methyl-3-amino-4-hydroxyphenylarsinic acid and 30 cc. of 50% hypophosphorous acid was introduced into the modified radical bulb and a mixture of 0.5 cc. of hydriodic acid and 20 cc. of hypophosphorous acid added. After about thirty minutes the precipitated diarsyl hypophosphite[5] (p. 358) was filtered and the material washed three times with 50-cc. portions of water. It was then dissolved in a hot alkaline solution, prepared from 15 g. of sodium hydroxide (70%) and 50 cc. of water, and the hot solution acidified to phenolphthalein with 25% acetic acid. The pure white mat of crystalline product was filtered, washed free from acid with water and then washed with 50 cc. of acetone. The product was washed from the filter plate into the bulb of the apparatus with the aid of a small amount of acetone, the acetone removed by distillation under reduced pressure and the crystalline diarsyl dried at 80–85° for four hours under reduced pressure.

In order to obtain the diarsyl dihydrochloride 2.5 g. of the diarsyl was dissolved in a mixture of 27 cc. of 0.5 *N* hydrochloric acid and 75 cc. of methyl alcohol and the solvents removed at 35° under reduced pressure. The residue was dried at 85–90° under reduced pressure for six hours and isolated in a carbon dioxide atmosphere; m. p. 168–170° in a sealed tube filled with nitrogen.

Anal. Calcd. for $C_{14}H_{20}O_2N_2Cl_2As$: As, 31.95; Cl, 15.12. Found: As, 31.44; Cl, 14.81.

TABLE I

DIARSYLS

	M. p., °C.[a]	Formula	As, % Calcd.	As, % Found
2,2″-Diamino-tetraphenyl	133–134	$C_{24}H_{22}N_2As_2$	30.71	30.76
3,3″-Diamino-tetraphenyl	146–148	$C_{24}H_{22}N_2As_2$	30.71	30.39
3,3″-Dihydroxy-tetraphenyl	134–136	$C_{24}H_{20}O_2As_2$	30.59	30.24
3,3″-Dimethoxy-tetraphenyl	98–99	$C_{26}H_{24}O_2As_2$	28.92	28.86
Dimethyl-di-(3-amino-4-hydroxyphenyl)	184–185	$C_{14}H_{18}O_2N_2As_2$	37.84	37.59

[a] Determined in a sealed tube filled with nitrogen.

2-Aminodiphenylarsine.—A solution of 46 g. of 2-aminodiphenylarsinic acid[8] in 280 cc. of hydrochloric acid was placed in a three-liter, three-necked flask the necks of which were fitted with a mercury trap, through which hydrogen could escape, a mechanical stirrer and a wide-stemmed funnel. The stem of the funnel was connected to the flask by means of a short piece of rubber tubing which could be opened and closed with the aid of a pinch clamp. The mixture was stirred and 90 g. of dry, amalgamated zinc dust was added during the course of two hours. A dark colored, sandy precipitate formed. After five hours 100 cc. of hydrochloric acid was added and the mixture stirred for twelve hours longer; 500 cc. of 40% sodium hydroxide solution and 400 cc. of ether, previously saturated with nitrogen, were then added. The ether layer was siphoned into a nitrogen-filled separatory funnel which contained soda-lime. The dry ether solution was allowed to flow, very slowly, into a small Claisen distillation flask heated on a steam-bath. After removal of the ether the arsine was distilled; b. p. 218–220° under 35 mm. pressure. The arsine absorbs oxygen extremely rapidly and becomes deep red-brown in color.

When 5.81 g. of the arsine, dissolved in benzene, was allowed to oxidize in air there were obtained 1.43 g. of 2-aminodiphenylarsinic acid and 4.53 g. of 2,2″-diaminotetraphenylarsyl oxide.

Summary

The preparation and properties of 2,2″-diamino-, 3,3″-diamino-, 3,3″-dihydroxy- and 3,3″-dimethoxytetraphenyldiarsyl as well as of dimethyl-di-(3-amino-4-hydroxyphenyl)-diarsyl and 2-aminodiphenylarsine have been described.

Keto Ethers. II. α-1,3-Dichloroisopropoxyethyl Alkyl Ketones[1]

BY BRUCE B. ALLEN WITH HENRY R. HENZE

Continuing the investigation in this Laboratory on aliphatic compounds of bifunctional type,[2] we have now studied the utilization of glycerol 1,3-dichlorohydrin in the preparation of chlorinated keto ethers. With but very few exceptions, only the simpler, monohydric alcohols have been condensed with the unsubstituted aliphatic aldehydes of low molecular weight, or with trichloroacetaldehyde, according to Henry's[3] method for synthesizing α-chloro ethers. The first successful utilization of a substituted alcohol in this chloro ether synthesis was that of Stappers,[4] in 1905, who effected the condensation of propylene chlorohydrin with formaldehyde, even though aqueous formalin solution was used as a source of the aldehyde. Somewhat later, Grignard and Purdy,[5] using ethylene chlorohydrin and paraldehyde, were able to produce α-chloroethyl β'-chloroethyl ether. However, the attempts of Farren, Fife, Clark and Garland[6] to cause trioxymethylene to interact with glycol and glycerol, respectively, led to no satisfactory results. Although these investigators were convinced that condensation had occurred, they were unable to isolate any pure products from the reaction mixtures. Finally, Blanchard[7] has reported the only other attempt at reaction of an aldehyde with a chlorohydrin, he having obtained 1,3-dichloroisopropyl chloromethyl ether by the action of hydrogen chloride on a mixture of trioxymethylene and glycerol 1,3-dichlorohydrin.

Following the work of Gauthier,[8] by which it was possible to convert α-chloro ethers into the corresponding alkoxy nitriles by heating the former with either cuprous or mercuric cyanides, there have been, from time to time, numerous references made to the preparation and characterization of compounds of this type. Apparently, however, no attempts have been made to apply this reaction to the synthesis of substituted alkoxy nitriles, *e. g.*, chloroalkoxy nitriles from polyhalogenated ethers. Likewise, since chloroalkoxy nitriles were unknown prior to this investigation, there necessarily have been no chloroalkoxy ketones obtained by the procedure of Béhal and Sommelet,[9] in which they found it possible to adapt Blaise's[10] modification of the Grignard reaction in the formation of keto ethers from alkoxy nitriles.

Glycerol 1,3-dichlorohydrin has now been caused to react with paraldehyde to form 1,3-dichloroisopropyl α-chloroethyl ether. This new trichloro ether has been converted into α-1,3-dichloroisopropoxypropionitrile, the latter representing the first example of a chloroalkoxy nitrile to be prepared. From this nitrile there has been obtained, by means of the Grignard reaction, a series of dichloroalkoxy alkyl ketones.

The Hoesch[11] test, as modified by Howells and Little,[12] has been proposed as a micro method for the identification of alkyl nitriles. The condensation of α-1,3-dichloroisopropoxypropionitrile with phloroglucinol has been investigated, with the result that the proposed test appears to be of no value for the recognition of chloroalkoxy nitriles.

Experimental

1,3-Dichloroisopropyl α-Chloroethyl Ether.—Dry hydrogen chloride was passed into a well-stirred mixture of 973 g. (7.55 moles) of glycerol 1,3-dichlorohydrin, prepared by the method of Conant and Quayle,[13] and 502 g. (3.8 moles) of paraldehyde contained in a flask cooled by an ice–salt bath. Saturation was attained in five hours, the mixture separating into two layers. The crude chloro ether layer, weighing 1646 g., was dried over calcium chloride and distilled under diminished pressure. Redistillation at 18 mm. pressure yielded 1142 g. (79.2% of the theoretical) of 1,3-dichloroisopropyl α-chloroethyl ether boiling at 89–90° (corr.). The colorless, oily liquid has a pleasant odor and in contact with air undergoes rather rapid decomposition with the evolution of hydrogen chloride and the deposition of a black, gummy mass: d^{20}_4 1.2864; n^{20}_D 1.4711; M_R calcd., 41.53; M_R found, 41.60; γ^{20} 34.44 dynes/cm.; P calcd., (Sugden's atomic constants) 360.8;

P found, 360.5. *Anal.* Calcd. for $C_5H_9Cl_3O$: Total Cl, 55.56. Found: Cl, 55.51, 55.07 (by Carius method). α-Cl content calcd., 18.52. Found: Cl, 18.15, 18.29 (by direct determination with aqueous silver nitrate solution).

α-1,3-Dichloroisopropoxypropionitrile.—The method of Gauthier[8] was adapted: 500 g. (2.61 moles) of 1,3-dichloroisopropyl α-chloroethyl ether, diluted with 125 cc. of anhydrous benzene, was added dropwise over a period of one hour to 250 g. of dry cuprous cyanide. Reaction was evidenced by the evolution of sufficient heat to occasion refluxing of the benzene. The mixture was stirred and heated on a steam-bath for three hours. After removal of the mixed cuprous salts by filtration, the benzene was distilled and the residual liquid fractionated under diminished pressure; yield, 232 g. (48.8%); b. p. 99° (corr.)/4 mm.; d^{20}_4 1.2259; $n^{20}D$ 1.4643; M_R calcd., 41.10; M_R found, 40.99; γ^{20} 37.77 dynes/cm.; P calcd., 370.4; P found, 368.0.

Preparation of α-1,3-Dichloroisopropoxyethyl Alkyl Ketones.—Sommelet's[14] method for preparing alkoxy ketones from alkoxy nitriles was applied successfully to the synthesis of dichloroalkoxy ketones, except in the case of the first member of the series. In general, the appropriate alkylmagnesium halide was prepared under anhydrous conditions and treated with the α-1,3-dichloroisopropoxypropionitrile. The reaction product, after standing overnight, was decomposed by addition of ice-cold, dilute hydrochloric acid, and the yellow colored ether solution was separated,

---

[14] Sommelet, *Ann. chim. phys.*, [8] 9, 484 (1906).

dried over calcium chloride, and fractionated under a pressure of 5 mm. until sufficiently purified. The keto ethers were obtained as colorless oils having faint, slightly rancid odors which became more intense with age; unless highly purified the compounds darkened to a deep yellow color upon standing in contact with air. All of these oils were found to be insoluble in water, but readily miscible with organic solvents such as alcohol, ether, acetone, chloroform, benzene and petroleum ether.

An attempt to prepare the simplest member of the series by interaction of α-1,3-dichloroisopropoxypropionitrile and methylmagnesium iodide resulted in the formation of a reddish-brown oil which decomposed on distillation below 5 mm. pressure. From this oil there was formed a semicarbazone which melted with decomposition at 123–124° (corr.) after recrystallization from a benzene–petroleum ether mixture. Analysis of the semicarbazone indicated there had been partial replacement of chlorine by iodine during the Grignard reaction, with production of α-1-chloro-3-iodoisopropoxyethyl methyl ketone. Effort was made to regenerate this ketone from its semicarbazone, but the resulting liquid decomposed on attempted distillation under diminished pressure. For this semicarbazone the following data were obtained. *Anal.* Calcd. for $C_8H_{15}ClIN_3O_2$: Cl, 10.20; I, 36.52; N, 12.09. Found: Cl, 9.99; I, 36.30; N, 11.96.

The desired dichloro ketone was secured by utilizing methylmagnesium bromide instead of the iodide. Difficulty was also encountered in endeavors to synthesize the *t*-butyl member of the series. Initial trials were made using *t*-butylmagnesium bromide, but very nearly all of the chloroalkoxy nitrile was recovered unchanged. Following the suggestion of Gilman and Zoellner,[15] that better yields of Grignard reagent are obtained by using *t*-butyl chloride rather than the bromide, renewed attempts were made using the alkylmagnesium chloride, but here, too, no keto ether was obtained.

Semicarbazones, easily prepared and readily purified, useful as a further means of identifying the keto ethers, were formed from all the ketones containing the normal alkyl structure and, also, from α-1,3-dichloroisopropoxyethyl isoamyl ketone. Since these ketones which formed solid semicarbazones did so with such rapidity and in such good yields, failure to obtain such solids in the instances of the isobutyl, *s*-butyl and *s*-propyl α-1,3-dichloroisopropoxyethyl ketones must be attributed to steric hindrance resulting from alkyl substitution in the positions alpha or beta to the carbonyl group.

The Hoesch[11] test, as proposed by Howells and Little[12] as a micro method for identifying alkyl cyanides, was employed in the formation of a new dichloroalkoxyalkyl trihydroxyphenyl ketone. Although the amounts of materials used (0.04 mole) were considerably larger than those deemed adequate by Howells and Little, the yield of purified ketone was scarcely more than enough for simple characterization and analysis.

Boiling points were taken with calibrated thermometers and the properly corrected values are reported for the liquid keto ethers. Likewise, the melting points of the trihydroxyphenyl ketone and of the seven semicarbazones prepared are corrected values. Surface tensions were measured by means of Cassel's[16] precision capillarimeter at 20°. Densities were determined by means of a Sprengel tube weighing 1.2734 g. and calibrated to contain 2.1316 g. of distilled water at 4°. The data resulting from the determination of physical constants, the values derived from these data by calculation, and such information as was obtained through analysis of these keto ethers have been tabulated in Table I. Table II is devoted to the data resulting from the study of the semicarbazones of the dichloroalkoxy ketones.

Summary

1. The series of β',β''-dichloro-α-chloroalkyl ethers has been extended by the synthesis of 1,3-dichloroisopropyl α-chloroethyl ether. The latter has been converted into α-1,3-dichloroisopropoxypropionitrile, the first chloroalkoxy nitrile yet prepared.

2. Nine examples of a new type of chlorinated keto ether have been obtained. In this series of dichloroisopropoxyethyl alkyl ketones, the normal, iso- and secondary alkyl types are represented; the tertiary alkyl type could not be synthesized by means of the Grignard reaction from the nitrile.

In an attempted preparation of α-1,3-dichloroisopropoxyethyl methyl ketone from methylmagnesium iodide, replacement of chlorine was observed, and the iodochloroalkoxy ketone formed was subsequently identified by means of its semicarbazone.

3. Semicarbazones, useful in the identification of the keto ethers, were obtained from each of the normal alkyl homologs and, as well, from the isoamyl member of the series. Failure of the secondary propyl, secondary butyl, and isobutyl ketones to form solid semicarbazones may be attributed to steric hindrance.

4. The Hoesch test, as modified by Howells and Little, apparently is valueless as a micro method for the identification and recognition of chloroalkoxy nitriles.

5. For the series of compounds included in this investigation, the parachor was found to be less sensitive than the molecular refraction as an index to purity.

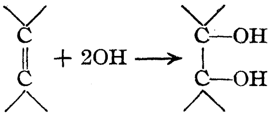
The Photochemical Addition of Hydrogen Peroxide to the Double Bond

BY NICHOLAS A. MILAS, PHILIP F. KURZ[1] AND WILLIAM P. ANSLOW, JR.[2]

Considerable spectroscopic evidence[3] has recently accumulated to show that light in the region of about 3000 Å. causes the dissociation of hydrogen peroxide into two hydroxyl radicals. However, very little direct chemical evidence exists in favor of the formation of these radicals. Our interest in the hydroxylation of unsaturated substances[4] led us to devise experiments whereby free hydroxyl radicals, produced either by the photochemical dissociation of hydrogen peroxide or by the dissociation of water or hydrogen peroxide in the field of an electrodeless discharge,[5] could be made to react with unsaturated substances to form hydroxylated products in which the hydroxyl groups retain their identity. Essentially, the reactions may be illustrated as follows

$$\mathrm{HOOH} + h\nu \longrightarrow 2\mathrm{OH} \qquad (1)$$



(2)

Since the life of these radicals is of short duration, the unsaturated substances were either mixed directly with their precursor, hydrogen peroxide, and the mixture exposed to ultraviolet radiation, as in the case of the present experiments, or allowed to meet the hydroxyl radicals in the immediate vicinity of, but not within, the field of the electrodeless discharge. Using the first method, we succeeded in producing glycerol from allyl alcohol, dihydroxybutyric acid from crotonic acid, mesotartaric acid from maleic acid, and diethyl mesotartrate from diethyl maleate. It was not possible to produce these dihydroxy substances when the mixtures were allowed to stand in the dark, and their production therefore is attributed to the presence of hydroxyl radicals in the photochemical reaction. That free hydroxyl radicals react in this fashion was also shown by the second method in which ethylene glycol was produced from ethylene.[5]

Experimental Part

A Cooper–Hewitt mercury vapor lamp was used in all of our experiments at a distance of 50 cm. from the quartz vessel containing the reaction mixtures. The latter was surrounded with an aluminum reflector in such a way that maximum utilization of the necessary light was effected. To ensure a greater surface, shaking of the reaction vessel during radiation was found beneficial in some experiments. An electric fan was allowed to play on the reaction vessel, thereby preventing a rise of temperature above that of the room.

The hydrogen peroxide used in many of the experiments was prepared either by the method of Rice, Reiff and Kilpatrick,[6] or that of Hurd and Puterbaugh,[7] and appropriate dilutions were made from this. Parallel experiments of the same concentration of the reactants were conducted in the presence and absence of ultraviolet light and the rate of the disappearance of hydrogen peroxide was determined in each case. Preliminary experiments were first made in 70 and 30% solutions of hydrogen peroxide, respectively, with maleic and crotonic acids, but the oxidation was much too destructive to permit isolation of the hydroxy compounds. Best results were finally obtained in a solution of about 10% hydrogen peroxide. In the dark, the reactions were not only slow, but in no case were we able to isolate the dihydroxy compounds. The 70% solution of hydrogen peroxide oxidized maleic acid rapidly in the dark, but attempts to isolate mesotartaric acid were not successful.

Glycerol from Allyl Alcohol.—Ten grams of allyl alcohol was mixed in a quartz flask with a solution of 10% hydrogen peroxide in the molal ratio of 1:1.05, and the mixture exposed to ultraviolet light under shaking at about 100 strokes per minute. At the end of one hundred and sixty-eight hours, the mixture had lost 89% of its peroxide content while the sample in the dark remained the same. To separate the glycerol formed, the mixture was subjected to fractional distillation and the fraction (6.8 g.) boiling at 287–289° collected. This corresponds to a yield of 43% based on the amount of alcohol used. Since there was no carbon dioxide evolved during the reaction and most of the unreacted allyl alcohol recovered, the yield of glycerol was actually considerably higher. It may also be seen that for every mole of hydrogen peroxide reacted there was approximately one mole of peroxide decomposed to oxygen and water.

Dihydroxybutyric Acid from Crotonic Acid.—Ten grams of crotonic acid (Eastman Kodak Company) was mixed in a quartz flask with 70 cc. of 5.8% solution of hydrogen peroxide and the mixture exposed to ultraviolet light while

shaking at about 100 strokes per minute. At the end of one hundred and seventy hours, the mixture had lost 77% of its peroxide content while the mixture in the dark remained the same. The products were separated following the method of Braun.[8] The unreacted crotonic acid was separated by extraction with chloroform and the residual solution concentrated at room temperature under reduced pressure. The viscous sirup thus obtained was further dried for twenty-four hours in a vacuum oven at 40° and at a pressure of 2 mm. The highly viscous sirup (4.2 g.) thus obtained corresponded to a 30% yield of dihydroxybutyric acid based on the total amount of crotonic acid used. Two samples of this were then titrated against a standard alkali and gave an average neutralization equivalent of 119 which is in close agreement with the calculated value of 120 for dihydroxybutyric acid.

A small amount of destructive oxidation also took place since both carbon dioxide and acetaldehyde were detected in the reaction mixture.

Mesotartaric Acid from Maleic Acid.—Several experiments were carried out with maleic acid using concentrated hydrogen peroxide solutions, but in all cases the oxidation was too destructive, yielding copious quantities of carbon dioxide and products not easily identifiable. Finally, 10 g. of maleic acid was dissolved in 53 cc. of 5.8% hydrogen peroxide solution and the latter exposed to ultraviolet light under similar conditions as in the previous cases. After one hundred and twenty-two hours, the solution had lost about 88% of its original strength of hydrogen peroxide while the dark reaction lost only 12% of its strength. When the products of the photochemical reaction were worked up following the method of Milas and Sussman,[4] a yield of 4.65% of mesotartaric acid was obtained. In another experiment in which the reaction was allowed to proceed only for thirty hours, the yield of mesotartaric acid was 9% of the total maleic acid used. The calcium salt of the mesotartaric acid obtained was purified by reprecipitation and dried in an oven for twenty-four hours at 105°.

Anal. Calcd. for $C_4H_4O_6Ca$: Ca, 21.28. Found: Ca, 21.05, 21.09, 21.52.

The dark reaction yielded no mesotartaric acid. This observation is in accordance with the findings of Hatcher and Mueller.[9]

Mesotartaric Acid from Diethyl Maleate.—The diethyl maleate was prepared by refluxing for four hours a mixture of 100 g. of maleic acid, 250 cc. of absolute ethyl alcohol and 20 g. of sulfuric acid (sp. gr. 1.84), then cooling and pouring the mixture into cold water. The ester was separated, washed with five successive 40-cc. portions of saturated sodium bicarbonate solution and fractionated; the fraction boiling from 219 to 220° (uncorr.) was collected and used in our experiments. The b. p. of this ester is given in the literature[10] as 225° (corr.). Inasmuch as this ester is insoluble in water, anhydrous solutions of hydrogen peroxide in ether or tertiary butyl alcohol were mixed with it in such proportions that the molal ratio of the ester to hydrogen peroxide was 1:1.05. The solvents were then removed under reduced pressure and the residual mixture irradiated as before. At the end of one hundred and twenty-two hours, the reaction mixture was hydrolyzed by refluxing with a solution of 10% alcoholic potash. The alcohol was then removed by distillation, the residue neutralized with dilute hydrochloric acid and the resulting solution made ammoniacal. From this, the mesotartaric acid was precipitated as calcium mesotartrate. A yield of 21.7% calculated as diethyl mesotartrate was obtained. The amount of destructive oxidation, as judged by the amount of carbon dioxide produced, was considerably less than in the case of maleic acid.

Summary

1. It has been shown that hydrogen peroxide, under the influence of ultraviolet light, reacts with double bonded compounds to form the corresponding glycols.

2. Glycerol, dihydroxybutyric acid, mesotartaric acid and diethyl mesotartrate have been obtained from allyl alcohol, crotonic acid, maleic acid and diethyl maleate, respectively.

3. The formation of glycols, in the present case, is assumed to take place through the addition to the double bond of free hydroxyl radicals which are formed by the dissociation of hydrogen peroxide under the influence of ultraviolet light.

Lactic Acid Production by Species of Rhizopus[1]

BY SELMAN A. WAKSMAN AND I. J. HUTCHINGS

Although the capacity of forming lactic acid is not widespread among the fungi, it seems to be definitely established that various species belonging to the genus *Rhizopus* are capable of producing this acid from a variety of carbohydrates, including glucose, maltose, sucrose, dextrin and starch. According to Saito,[2] inulin, lactose and sucrose cannot be used as a source of acid; Kanel[3] found, however, that the last carbohydrate is readily utilized. The presence of calcium carbonate is essential for the formation of appreciable quantities of the acid. Ammonium salts or compounds which produce ammonia, such as urea, are preferable to nitrates.

The nature and yield of the lactic acid vary considerably, depending largely upon the specific nature of the organism, including strain specificity, and upon the conditions of cultivation. Saito obtained only a low yield of the levo-rotatory form of the acid; Kanel, however, reported a yield, both from sugar and from starch, of 40% of the *d*-form; the period of incubation was twenty days. Ward, *et al.*,[4] also found that 32 to 62% of sugar was transformed into *d*-lactic acid in sixteen days.

Practically all the fungi capable of producing lactic acid from carbohydrates have been found among the *Mucorales*, chiefly in the genus *Rhizopus*. The only other exception so far reported was found to be a species of *Monilia*.[5] Saito employed in his investigations *Rh. chinensis*. According to Ehrlich,[6] *Rh. nigricans* and *R. tritici* are capable of bringing about the formation of lactic acid. Takahashi[7] used four different strains of *Mucor*. The organism employed by Kanel was *Rh. japonicus*, or a closely related form; Ward, *et al.*, worked with *Rh. oryzae* and *Rh. arrhizus*. When the incubation period is prolonged more than twenty days, the concentration of the lactic acid was shown[3] to be gradually reduced, and other acids, notably fumaric, are formed.

Experimental

In the study of decomposition of plant materials in composts and in soil, a culture of *Rhizopus*, designated as MX, was isolated, which had the capacity of producing, from various carbohydrates large quantities of lactic acid. A comparison was later made of several strains of *Rhizopus* kept in the culture collection, and another organism, No. 36, was selected. The two organisms varied in cultural appearance, especially in the rapidity of spore formation and in the yields of lactic acid. MX was closely related to *Rh. nodosus* or *Rh. arrhizus*. The No. 36 was morphologically very similar to MX.

Several preliminary experiments, using glucose as a source of carbon, were carried out in order to determine the nature of the acid produced. It was soon found that, during the early stages of the growth of the organism, namely, between three and fifteen days, the acid is almost exclusively lactic acid. This was demonstrated by the precipitation of the calcium salt of the acid with alcohol and analysis of the salt. However, after fifteen to twenty days' growth, the lactic acid was transformed slowly to lower acids (fumaric?), as shown by the increase in the calcium content of the salt. It was felt, therefore, that when the determinations were made in cultures only ten to eighteen days old, the calculation of the lactic acid equivalent of the calcium in the salt did not involve any large error. This checked well with the organic matter content of the culture solution, which, after all the sugar had been consumed, was due almost entirely to the acid produced.

Once the nature of the acid was established, a series of experiments was carried out to determine the nutrient requirements of the organisms and especially the acid production from different carbohydrates, under different conditions of culture.

In a preliminary experiment it was found that during the growth of the organism MX in a 5% glucose solution, with ammonium sulfate as a source of nitrogen, the reaction was usually changed, within three days' growth at 28°, from *p*H 7.4 to 4.0 or 4.1. Little lactic acid was formed, unless calcium carbonate was added. When a 10% glucose solution was introduced into flasks containing the fully grown fungus pad, rapid acid production began, especially when the pad was obtained in a medium containing calcium carbonate.

The following culture medium was at first employed

Glucose	100 g.
NH_4NO_3	2.0 g.
K_2HPO_4	1.0 g.
$MgSO_4 \cdot 7H_2O$	0.5 g.
$FeCl_3$	0.02 g.
Tap water	1000 cc.

In order to illustrate the balance of carbon and nitrogen in the growth of the organism, the results of a typical experiment are reported here. Three hundred-cc. portions of the medium were placed in 1000-cc. Erlenmeyer flasks,

sterilized by means of flowing steam, on three consecutive days, inoculated with the spores of the fungus, and incubated at 28°. After forty-eight hours of undisturbed growth, 5-g. portions of sterile calcium carbonate were added to the flasks. Some of these were shaken daily by hand, for one or two minutes, and some were left undisturbed. Analyses were made after five and nine days.

The results (Table I) show that *Rhizopus* consumed the ammonium ion in preference to the nitrate ion, and that the above medium contained a considerable excess of nitrogen above the nutrient requirements. The cell synthesis was not very extensive, since only about 13% of the glucose consumed was utilized to cover this requirement.[8] The preference of the organism for the ammonium ion is also brought out in another experiment. Three media were prepared containing glucose, minerals and calcium carbonate in the above proportions. Different forms of nitrogen were used, namely, ammonium sulfate, 5 g. per liter, ammonium nitrate, 2.5 g. and ammonium phosphate 2.5 g. per liter. The cultures were incubated for ten and seventeen days at 28° (Table II). All the three salts were utilized readily as sources of nitrogen, the sulfate being somewhat more efficient than the others.

[a] Calculated from calcium equivalent.

In order to bring about the proper neutralization of the acid, it was sufficient to shake the flasks once or twice daily, for two or three minutes by hand, so as to bring the calcium carbonate, which was usually added in excess, in intimate contact with the acid. The results presented in Table III show that proper stirring of the culture, after a pellicle has been formed, which usually required forty-eight hours, is essential for maximum acid production.

TABLE III

INFLUENCE OF SHAKING UPON GLUCOSE DECOMPOSITION BY *Rhizopus* MX[a]

Shaken	10.9	73.3	30.9	..	...	..

[a] Thirteen days' incubation.

The medium was now modified, by reducing the concentration of the ammonium sulfate to 1.25 g. and the dipotassium phosphate to 0.5 g. per liter. The results of an experiment on prolonged incubation show (Table IV) that the most efficient production of the acid took place in eighteen days, at which time over 60% of the glucose was converted into acid; after twenty-eight days, the conversion was only 43%. When the acid was recovered by crystallization and alcohol precipitation, it was found to increase in calcium content with the age of the culture; the calcium oxide content of the younger cultures was 27.5% or close to the theoretical requirement for lactic acid, while in the older cultures it increased to 33 and even 35%. These results tend to confirm those of other investigators concerning the gradual transformation, in the older cultures of *Rhizopus*, of some of the lactic acid into lower acids.

TABLE IV

INFLUENCE OF PROLONGED INCUBATION ON ACID PRODUCTION BY *Rhizopus* FROM GLUCOSE

Organism	Incubation, days	Glucose consumed, g.	Acid produced, g.
MX	18	50.5	31.9
MX	25	75.2	..
MX	28	81.4	34.8
No. 36	18	36.8	22.3
No. 36	25	58.5	..

A large quantity of the calcium salt of the acid was now collected by concentrating the medium, crystallizing, dissolving the salt in hot water and reprecipitating with alcohol. The calcium salt was then acidified with phosphoric acid, extracted with ether and the zinc salt prepared. Both salts gave, by chemical analysis and rotation, the dextrorotatory form of the lactic acid.

When starch was substituted for glucose as a source of energy, active lactic acid production was also found to take place. Potato starch was used in the form of a paste, 50 g. per liter. The raw starch contained 86% of pure starch, by chemical analysis. Ammonium sulfate, as a source of nitrogen, and the above minerals were added to the medium. Five hundred-cc. portions were placed in 1000-cc. flasks and sterilized in flowing steam. The flasks were inoculated and incubated in an undisturbed condition for forty-eight hours at 28°; an excess of calcium carbonate was then added; the flasks were shaken twice daily. After seventeen days' incubation, the starch completely disappeared and 26.4 g. of lactic acid, calculated from the calcium salt, was produced per liter of medium. This is equivalent to a yield of over 60%.

---

(8) On the basis of carbon content, this would be equivalent to over 15%.

The results of two other experiments, using culture MX, show (Table V) that the starch is at first transformed into reducing sugar, and the latter is gradually changed to lactic acid. The yield of the acid was as high with starch as a source of energy as with glucose, namely, 74.2% in the first experiment, and 50% in the second. Considerable sugar was left in the cultures in the last experiment, even after fourteen days.

TABLE V

PRODUCTION OF ACID BY *Rhizopus* FROM STARCH

On basis of 50 g. of raw potato starch[a]

Experiment 1			Experiment 2		
Period of incubation, days	Sugar as glucose, g.	Acid produced, g.	Period of incubation, days	Sugar as glucose, g.	Acid produced, g.
4	19.3	9.0	5[b]	23.2	8.4
6[b]	10.8	21.5	9	14.5	17.1
8	1.8	27.6	14	6.5	21.3
11	0.6	31.9			

[a] Equivalent to 43 g. of dry starch. [b] Starch completely disappeared.

A more detailed study was now made of the utilization of starch as a source of carbon for the production of lactic acid (Table VI). In the absence of calcium carbonate, no lactic acid accumulated; a large part of the starch was converted, however, into sugar, and remained as such; the growth of the organism was considerably less, and some of the starch remained unhydrolyzed even after eleven days. In the presence of calcium carbonate (1 g. per 2 g. of starch), the starch was also converted to sugar, but the latter was transformed rapidly to lactic acid. Nearly 60% of the starch was changed to the acid within eight days of incubation, and over 65%, in eleven days. After that period, the acid was gradually destroyed and became transformed to lower acids as shown by the increasing ash content. The nature of these acids was not determined.

TABLE VI

TRANSFORMATION OF STARCH TO SUGAR AND TO LACTIC ACID BY *Rhizopus*

On basis of 50 g. of raw potato starch[a]

11	14.40	0	0	28.08	10.20
18	...	...	0	16.50	7.54

[a] Equivalent to 43 g. of dry starch.

A study of the influence of temperature on the lactic acid production revealed the fact that 28–37° was the optimum, the rate of the process being reduced rapidly above and below that temperature. A decrease in lactic acid production was accompanied, in starch media, to a certain point, by an increase in sugar accumulation, emphasizing the fact that two distinct enzyme mechanisms are responsible for the two processes.

Inulin was also utilized as a source of carbon by the organism, at a much slower rate, however, than either glucose or starch. Raw artichoke juice or cooked artichoke extract were used as sources of this carbohydrate. When the inulin was first hydrolyzed by means of a dilute mineral acid, lactic acid production took place more rapidly. No sugar accumulated in the inulin medium. These facts point to limited formation of the enzyme inulase by species of *Rhizopus*.

Summary

Two species of *Rhizopus*, isolated from composts of decomposing organic matter and from soil, were found capable of producing lactic acid from glucose, starch and inulin. As much as 60 to 70% of the first two carbohydrates was converted to the *d*-lactic acid in ten to eighteen days at 28°.

The starch was at first converted to sugar, and the latter gradually changed to lactic acid. When conditions were not favorable to the formation of the acid, as a lack of neutralizing agent or at an unfavorable temperature, the sugar accumulated.

Inulin was only slowly converted to lactic acid, due to insufficient production of inulase by the organisms.

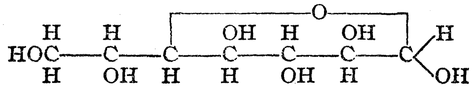
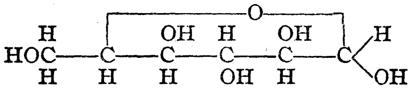
d-Beta-Galaheptose and Some of its Derivatives[1]

BY RAYMOND M. HANN AND C. S. HUDSON

In a recent publication[2] experimental details of the preparation and properties of *d*-alpha-galaheptose and of some of its derivatives were recorded. Attention was called to the close similarity of the configuration of this newly crystallized sugar to that of *l*-mannose, and the resulting similarity of the physical and chemical properties of these related sugars and of their compounds. In the present communication the properties of the epimeric *d*-beta-galaheptose, configurationally related to *l*-glucose, and of some of its derivatives, will be described.



α-Form of *d*-β-galaheptose (−19°)



β-Form of *l*-glucose (−19°)

This heptose was obtained in crystalline condition by Fischer,[3] but only cursory study of its behavior has been recorded. The sugar has an initial rotation[3a] of about −19° and mutarotates to an equilibrium value of −54°, comparable in magnitude with the recorded value for *d*-glucose, +19° (β-form) to +52°, and opposite in sign because the heptose is configurationally related to *l*-glucose, though it belongs in the *d*-series by Fischer's nomenclature. We name the heptose form of rotation −19° the alpha modification because its rotation is more toward the positive than the equilibrium rotation of the sugar (−54°), in accordance with generally accepted conventions; thus α-*d*-β-galaheptose and β-*l*-glucose are configurationally similar. This correspondence in rotation extends to several pairs of glucose and β-galaheptose derivatives and is sufficient for supplying an indication, though not a proof, of the structures and configurations in the β-galaheptose series. Because of the paucity of data in the *l*-glucose series the comparisons will refer to substances in the *d*-glucose series, which are opposite in sign of rotation.

TABLE I

COMPARISON OF SPECIFIC ROTATIONS [$[\alpha]^{20}\text{D}$] OF SUBSTANCES IN THE GLUCOSE AND β-GALAHEPTOSE SERIES

		d-Glucose series		*d*-β-Galaheptose series
Sugar (initial)	(β)	+ 19	(α)	−19
(final)		+ 52		−54
Aldonic acid phenylhydrazide		+ 12[4]		− 7.8
Aldonic acid amide		+ 31[5]		−20
Methyl glycoside	(β)	− 34.2[6]	(α)	+36
Ethyl mercaptal		− 29.8[7]		+37.8[8]
Benzyl mercaptal		− 98.4[9]		+73.8
Hexose pentaacetate	(α)	+101.6	(β)	−55.8
or				
Heptose hexaacetate	(β)	+ 3.8	(α)	+30.2
Methyl glycoside acetate	(β)	− 18.3	(α)	+51.8
Ethyl mercaptal acetate		+ 11.3[10]		+26.6[8]
Benzyl mercaptal acetate		+ 28.4[11]		+ 9.1

The parallelism noted in these rotations is evident also in the chemical behavior of the structurally related pairs of derivatives. Thus, *d*-glucose upon acetylation with sodium acetate and acetic anhydride yields largely the β-form of glucose pentaacetate which may be rearranged readily to the α-acetate by acid acetylating catalysts (zinc chloride or sulfuric acid). The heptose under the same conditions of acetylation yields a configurationally similar hexaacetate, which, because of conventions of nomenclature, is to be named the α-form, it being the more dextrorotatory member of a pair of isomers in the *d*-series. This acetate under the same experimental rearranging conditions yields the β-form, a result which may be anticipated due to the similarity in structure of the parent sugars. By application of the Koenigs and Knorr synthesis to β-*d*-glucose pentaacetate one obtains tetraacetyl-β-methyl glucoside while the same procedure with α-*d*-(β-galaheptose) hexaacetate yields pentaacetyl-α-methyl-*d*-β-galaheptoside. These results are

in complete agreement with those obtained in earlier studies in the mannose and α-galaheptose series and support the hypothesis that the physical and chemical properties of the heptose sugars may be in first measure predicted from the space configurations of carbons one to five inclusive, which show that aldohexose to which the heptose is similar.

The isorotation rules allow the calculation of the expected values of the rotations of some of these compounds; Table II summarizes these data.

TABLE II

OBSERVED AND CALCULATED SPECIFIC ROTATIONS $[\alpha]^{20}\mathrm{D}$ IN THE *d*-β-GALAHEPTOSE SERIES

Substance	Obsd.	Calcd.
Sugar (α-form)	−19°	− 10°
(β-form)	. .	− 91°
α-Methyl glycoside	+36°	. . .
α-Methyl glycoside acetate	+52°	. . .
β-Methyl glycoside	. .	−131°
β-Methyl glycoside acetate	. .	− 72°
α-Acetate	+30°	+ 35°
β-Acetate	−56°	− 54°

From well-known considerations of isorotation, the molecular rotation (30,830) of α-methylglucoside may be written as $A_{\mathrm{CH}_3} + B$, where A_{CH_3} is the contribution of the aldehydic carbon atom and B that of the basal chain, to the total rotation. The same considerations allow the expression $-A_{\mathrm{CH}_3} + B$ to signify the molecular rotation (−6630) of β-methylglucoside. By subtracting these equations one can evaluate the quantity A_{CH_3} as +18,730.[12] From α- and β-glucose, similarly, a value of A_{OH} of +8460 is obtained. Upon the assumption that A_{CH_3} will not differ widely in value in configurationally similar sugars, the molecular rotation of α-methyl-*d*-β-galaheptoside (8060) may be expressed as $18{,}730 + B' = 8060$, whence B' in the galaheptose series becomes −10,670 and the calculated molecular rotation of the α-form of *d*-β-galaheptose becomes $A_{\mathrm{OH}} + B' = -2210$, corresponding to a specific rotation of about −10°. The unknown β-form would be $-A_{\mathrm{OH}} + B'$, or −19,130 in molecular rotation and −91° in specific rotation. The calculated molecular rotation of the unknown β-methyl-*d*-β-galaheptoside is $-A_{\mathrm{CH}_3} + B'$, −29,400, corresponding to −131° in specific rotation.

By introducing the value of A'_{CH_3} (26,950) derived from the acetylated methyl glucosides[12] into the equation expressing the molecular rotation of pentaacetyl-α-methyl-*d*-galaheptoside, $A'_{\mathrm{CH}_3} + B_{\mathrm{Ac}} = +22{,}600$, one obtains the value of B_{Ac} in the β-galaheptose series as −4350 and this substituted in the expression $-A'_{\mathrm{CH}_3} + B_{\mathrm{Ac}}$ yields a molecular rotation of −31,300, indicating that the now unknown pentaacetyl-β-methyl-*d*-β-galaheptoside will have a specific rotation near −72°. Similar considerations using the value of A_{Ac} (20,700) of the glucose series and B_{Ac} (−4350) give calculated values of +35 and −54° for the specific rotations of α- and β-*d*-β-galaheptose hexaacetate, respectively, in good agreement with the observed values of +30 and −56°.

In the preparation of β-galaheptonic amide use was made of the excellent method of Glattfeld and Macmillan;[5] sirupy β-galaheptonic lactone when dissolved in liquid ammonia readily yielded the desired crystalline amide. This substance rotated in the levo direction in accordance with the amide rule. The previously described phenylhydrazide also shows a negative rotation as would be expected from the phenylhydrazide rule. The mercaptals in pyridine agree in sign of rotation with those of the *l*-glucose series, but their acetates, measured in chloroform, do not; evidently no generalization regarding rotation may now be made of these open chain mercaptal derivatives.

Experimental

d-(β-Galaheptonic) Phenylhydrazide from d-Galactose.—Hydrocyanic acid was added to 500 g. of *d*-galactose as described previously.[2] The filtrate from the separation of the α-galaheptonic amide was transferred to a 3-liter Erlenmeyer flask and boiled with 400 g. of barium hydroxide octahydrate until ammonia was no longer evolved (twelve to fifteen hours), the volume being maintained at about 1500 cc. by occasional addition of water. The barium was precipitated by addition of 385 to 400 cc. of 6 *N* sulfuric acid, the barium sulfate was removed and the solution was balanced until free of sulfate and barium ions. It was adjusted to a volume of 1500 cc., 140 cc. of phenylhydrazine and 40 cc. of acetic acid were added and the solution was heated for five hours on the steam-bath. After cooling, the phenylhydrazide of α-galaheptonic acid was removed (fraction I), the filtrate was concentrated to 750 cc. and an equal volume of 95% alcohol was added. The next day the separated solid was filtered off (fraction II), the filtrate concentrated to 500 cc., an equal volume of alcohol added and after standing overnight the third fraction was removed. The filtrate was concentrated to 200 cc. and 200 cc. of 95% alcohol was added to obtain the final fraction. From seven preparations the average yields and specific rotations of the fractions were as follows:

---

(12) Dale and Hudson, THIS JOURNAL, **52**, 2535 (1930).

fraction I, 133 g., +8.00°; fraction II, 96 g., −7.21°; fraction III, 12.5 g., +7.35°; fraction IV, 30.2 g., −5.80°.

Pure β-galaheptonic phenylhydrazide of specific rotation −7.8° and melting at 189–190° (corr.) was obtained by combining fractions II and IV, dissolving in 15 parts of water and allowing the solution to stand for twenty-four hours at 20° when the major portion of the α-phenylhydrazide separates. The β-isomer was recovered by concentrating the solution to one-half its volume and adding an equal volume of 95% alcohol. Fischer reports a melting point of 185° (uncorr.) and a specific rotation of −6.32°. Kiliani[13] reports 185° (uncorr.).

***d*-(β-Galaheptonic) Amide from *d*-(β-Galaheptonic) Phenylhydrazide.**—A solution of 100 g. of pure phenylhydrazide and 80 g. of copper sulfate pentahydrate in 1000 cc. of water was refluxed for five hours and filtered from the separated solid. The solution, freed of copper by hydrogen sulfide, was treated with a warm solution of 500 g. of barium hydroxide octahydrate in 500 cc. of water, the barium sulfate was filtered off and the filtrate was balanced until free of barium and sulfate ions. The yield of β-galaheptonic acid, as shown by titration, was 65.8 g. (92%). A portion of the galaheptonic acid sirup, which had been lactonized in part by heating for twenty-four hours on the steam-bath, upon standing for several weeks dried to a hard vitreous non-crystalline solid. A solution of 5.9 g. of this material in 150 cc. of liquid ammonia was allowed to evaporate to a sirup spontaneously at room temperature, then transferred to a vacuum desiccator over sulfuric acid and the residual ammonia removed, crystallization occurring during the process. The dark brown solid was dissolved in 20 cc. of water, 40 cc. of 95% alcohol added and the solution decolorized by carboraffin. Upon seeding, the amide crystallized in a yield of 3 g. It was recrystallized to constant properties by solution in one part of warm water and addition of one part of 95% alcohol, separating in colorless needles, melting at 170–171° (corr.) and having a specific rotation of −20° in water. (0.1940 g. in 25 cc. in a 4-dm. tube rotated 0.62° to the left.)

Anal. Calcd. for $C_7H_{15}O_7N$: N, 6.2. Found: N, 6.2.

***α-d*-(β-Galaheptose).**—The acid solution from 100 g. of pure *d*-(β-galaheptonic) phenylhydrazide was concentrated *in vacuo* to a thin sirup, transferred to a 3-liter beaker and heated on the steam-bath for eighteen hours. The heavy sirup was dissolved in 200 cc. of cold water and reduced in the usual manner with 2000 g. of 2.5% sodium amalgam. Following removal of the sodium sulfate by alcohol, the reduced solution was concentrated to a thin sirup which became a crystalline magma after several days. The crystals were separated by thinning the magma with a small amount of 50% alcohol, filtering and drying. The average yield of 13 experiments was 23.2 g. (38% based on the acid concentration). The sugar was recrystallized conveniently by solution in 2 parts of warm water and addition of 10 parts of warm 95% alcohol, separating in prisms, melting at 196–197° (corr.) with decomposition, and showing an equilibrium specific rotation in water of −54°. Fischer reports the corrected melting point as 195–199° and the rotation at equilibrium as −54.4°. The course of its mutarotation is recorded in Table III. It is designated the alpha form of *d*-(β-galaheptose) because the course of mutarotation indicates it to be the less levorotatory form of a sugar of the *d*-series. The mutarotation follows the unimolecular formula and the extrapolated initial rotation is about −19°.

***α-d*-(β-Galaheptose) Hexaacetate.**—A suspension of 20.4 g. of oven-dried β-galaheptose and 5 g. of fused sodium acetate in 80 cc. of redistilled acetic anhydride was heated gently to incipient reaction, when the heat of reaction was sufficient to bring about a rise in temperature to the boiling point of the anhydride. Following subsidence of the reaction the solution was refluxed for fifteen minutes, cooled and poured into crushed ice, the crystalline acetate separating as the excess anhydride decomposed; yield 36 g. (80%). α-*d*-(β-Galaheptose) hexaacetate crystallizes from 10 parts of methyl alcohol in groups of colorless needles, 5 to 6 mm. long, giving the appearance of a silky mat upon filtration. The substance melts at 151–152° (corr.) to a clear colorless oil and when recrystallized to constant specific rotation gives a value of +30.2° (0.5002 g. in 25 cc. of chloroform in a 2-dm. tube rotated 1.21° to the right).

Anal. Acetyl: 0.2179 g. consumed 28.4 cc. of 0.1 *N* NaOH. Calcd. for six acetyl groups, 28.3 cc. Calcd. for $C_{19}H_{26}O_{13}$: C, 49.33; H, 5.67. Found: C, 49.34; H, 5.68.

***β-d*-(β-Galaheptose) Hexaacetate.**—A solution of 5.0 g. of α-*d*-β-galaheptose hexaacetate in 25 cc. of a rearranging solution, prepared by adding 2.3 cc. of concd. sulfuric acid dropwise to an ice-cold mixture of 68 cc. of acetic anhydride and 29 cc. of glacial acetic acid, showed a progressive change in specific rotation from +18.7 to −68.9° in forty-eight hours at 20°. The solution was poured upon cracked ice and the gum which separated was crystallized by repeated trituration with cold water; yield 3.3 g.

---

(13) Kiliani, *Ber.*, **55**, 99 (1922).

(66%). *β*-*d*-(*β*-Galaheptose) hexaacetate crystallizes from 5 parts of 50% ethyl alcohol in small needles melting at 100–101° (corr.) and when recrystallized to constant specific rotation showed a value of −55.8° (0.5150 g. in 25 cc. of chloroform in a 2-dm. tube rotated 2.3° to the left).

Anal. Calcd. for $C_{19}H_{26}O_{13}$: C, 49.33; H, 5.67. Found: C, 49.25; H, 5.68.

α - Methyl - *d* - (*β* - Galaheptoside) Pentaacetate.—A solution of 10 g. of *α*-*d*-(*β*-galaheptose) hexaacetate in 50 cc. of acetic acid saturated with gaseous hydrobromic acid was allowed to stand for one hour, concentrated *in vacuo* (bath 40°) to remove the major part of the acid and twice treated with 100 cc. of toluene and concentrated to a sirup, to remove the residual acid. The dry sirup was dissolved in 100 cc. of methyl alcohol and 10 g. of silver carbonate was added. Following completion of the reaction, which proceeded with local generation of heat, the hot solution was filtered to remove silver halide, the glycoside acetate crystallizing from the filtrate as it cooled; yield 6.9 g. (73%). *α*-Methyl-*β*-galaheptoside pentaacetate crystallizes from 5 parts of 50% acetic acid in colorless elongated plates, melting at 122–123° (corr.) and exhibits a specific rotation of +51.8° in chloroform (0.5717 g. in 25 cc. in a 2-dm. tube rotated 2.37° to the right), these properties remaining unchanged upon recrystallization.

Anal. Calcd. for $C_{18}H_{26}O_{12}$: C, 49.74; H, 6.04; OCH_3, 7.1. Found: C, 49.56; H, 6.02; OCH_3, 7.1.

α - Methyl - *d* - (*β* - Galaheptoside).—A solution of 4.8 g. of pentaacetyl-*α*-methyl-*d*-*β*-galaheptoside in 25 cc. of methyl alcohol was saturated with gaseous ammonia, allowed to stand overnight and concentrated *in vacuo* to dryness, crystallization occurring during the process. The dry solid was taken up in methyl alcohol, the solution filtered through carboraffin, and upon cooling the filtrate yielded the glycoside in a yield of 2.0 g. (80%). *α*-Methyl-*d*-*β*-galaheptoside crystallizes from methyl alcohol in small clear prisms, melting at 182–183° (corr.) without decomposition. Its specific rotation in water when pure is +36.0° (0.4096 g. in 25 cc. in a 2-dm. tube rotates 1.18° to the right).

Anal. Calcd. for $C_8H_{16}O_7$: C, 42.83; H, 7.20; OCH_3, 13.8. Found: C, 42.95; H, 7.28; OCH_3, 13.8.

***d*-(*β*-Galaheptose) Benzyl Mercaptal.**—A solution of 5 g. of powdered *d*-*β*-galaheptose in 10 cc. of concentrated hydrochloric acid was shaken with 10 cc. of benzyl mercaptan, crystallization occurring at the end of one and one-half hours. After a further half hour, 50 cc. of ice water and 25 cc. of 95% alcohol were added and the mercaptal filtered off; yield 3.3 g. (31%). The mercaptal crystallizes from 10 parts of 95% alcohol in a cottony mass of minute needles, which melt at 146–147° (corr.) and give a specific rotation of +73.8° in pyridine (0.2303 g. in 10 cc. in a 1-dm. tube rotated 1.70° to the right).

Anal. Calcd. for $C_{21}H_{28}O_6S_2$: S, 14.56. Found: S, 14.51.

Hexaacetyl-*d*-(*β*-galaheptose) Benzyl Mercaptal.—To a solution of 2.6 g. of *d*-*β*-galaheptose benzyl mercaptal in 20 cc. of pyridine, 20 cc. of acetic anhydride was added and the reaction mixture allowed to stand overnight. Upon pouring the solution into crushed ice and stirring, crystallization readily took place; yield 4.1 g. (quantitative). The mercaptal acetate was purified by recrystallization from 5 parts of 95% alcohol, separating in well formed prisms. The substance, recrystallized to constant physical properties, melts at 82–83° (corr.) and gives a specific rotation of +9.2° (0.3047 g. in 10 cc. of chloroform in a 1-dm. tube rotated 0.28° to the right).

Anal. Calcd. for $C_{33}H_{40}O_{12}S_2$: S, 9.26. Found: S, 9.10.

Summary

A number of crystalline derivatives of *d*-(*β*-galaheptose) have been prepared and described. Attention has been called to the parallelism in rotational behavior of certain derivatives of *d*-*β*-galaheptose with those of the configurationally related *l*-glucose. This similarity extends also to the chemical behavior of these sugars and would indicate that such properties are conditioned by the spacial arrangement of carbons one to five in the sugar molecule.

Permonosulfuric Acid in Organic Media*

BY GERRIT TOENNIES

Permonosulfuric acid as an oxidizing agent in organic synthetical work has been employed almost exclusively in the form of aqueous solutions.[1] It is the purpose of this paper to record some data on the behavior of permonosulfuric acid in various alcohols and in a nitrile.

Permonosulfuric Acid, Preparation and Analytical.—The peracid was prepared either from potassium persulfate and sulfuric acid (method A)[2a] or from hydrogen peroxide[2b] and chlorosulfonic acid (method B).[3] Permonosulfuric acid was determined iodometrically by thiosulfate (about 0.025 *N*) titration. When the excess of iodide is kept small (about 0.005 *M*), the first end-point obtained on *rapid* titration, *immediately* after adding the peracid to a solution containing starch, potassium iodide and, if necessary (for securing an excess of acid over the iodide consumed), some sulfuric acid, corresponds to permonosulfuric acid (as established by comparison with the more generally specific method of Müller and Holder[4]). The accuracy of the initial reading can be improved by subtracting a correction equal to the small additional amount of iodine liberated on waiting again as long as was required to reach the first end-point. A subsequent end-point obtained after addition of molybdate yields the sum of permonosulfuric acid and hydrogen peroxide as long as persulfuric acid ($H_2S_2O_8$) is present in minor amounts. The total peroxygen was determined according to Lubarski and Dikowa.[5] Free acidity, including one acid group of H_2SO_5,[6] is obtained at the methyl red end-point, while five to ten minutes of boiling with excess (about 0.01 *N*) sodium hydroxide was found necessary[7] for the determination of total acidity ($H_2SO_5 \longrightarrow H_2SO_4 + O$, $H_2S_2O_8 + H_2O \longrightarrow 2H_2SO_4 + O$). In the concentrated peracid solutions prepared according to method B (*vide infra*) water was calculated by the difference between the sum of the directly determined constituents and the total.

Permonosulfuric Acid in Organic Media. General.—The relative stability of permonosulfuric acid solutions in 75% methanol has been mentioned.[8] Solutions containing about 10% water were made with 92% ethanol, and others of 3 to 5% water content, with isopropyl alcohol (98–99%, "petrohol"), isoamyl alcohol (Merck Reagent) and acetonitrile (Merck Reagent). Reaction mixtures obtained by method A[9] were stirred by portions into the solvent, which was kept below −15° by addition of solid carbon dioxide. In the case of isoamyl alcohol it was found preferable to grind the alcohol (of −15°) in portions into the almost solid reaction mass contained in a mortar imbedded in freezing mixture (thus dispensing with the need for carbon dioxide). In the cases of the lower alcohols or acetonitrile the insoluble salt is filtered by suction, while an amyl alcohol solution is better separated by centrifuging. Other solutions, of low $H_2SO_4{:}H_2SO_5$ ratios, were made by carefully adding concentrated peracid, prepared according to method B, to alcohol of less than −10° (*vide infra* on explosions).

Yields.—Table I gives a summary of the solutions prepared on the basis of method A. The fact (not shown in the table) that the total peroxygen recovery, *i. e.*, including the amount found in the solid residue, was 96–100% of that contained in the starting material, indicates that the yield of permonosulfuric acid in solution is limited by incompleteness of the reaction between sulfuric acid and persulfate and by incomplete separation from the solid residue (in order to maintain the concentration of the filtrate as high as possible no washings were added) rather than by loss of oxygen. Variations in the time the sulfuric acid–persulfate reaction mixture was allowed to stand (one to eighteen hours at 0° or two hours at room temperature) showed no definite effect on the yield. The solid residue appears to be chiefly $KHSO_4 + H_2O$ and additional H_2SO_4, approaching $2KHSO_4 + H_2SO_4$ in the case of isoamyl alcohol. In the ethanol experiment the washed and dried (at 125°) residue weighed 128 g. which, calculated as $KHSO_4 + H_2O$ (acid equivalent found 149, calculated 154), is equal to 98.5% of the potassium used. Three preparations according to method B, from 140, 160 and 250 mml. of chlorosulfonic acid and the equivalent amounts of hydrogen peroxide (85, 81 and 91%, respectively[2b]), gave permonosulfuric acid yields of 77 ± 1%. The resulting oily solutions (they did not crystallize at −15°) contained per gram, 6.2 ± 0.3 mml. of H_2SO_5, 1.9 ± 0.1 mml. of H_2SO_4, 0.8 ± 0.3 mml. of H_2O_2, 3.4 ± 0.6 mml. of H_2O, 0.0–0.2 mml. of $H_2S_2O_8$ and less than 0.02 mml. of Cl_2. These solutions keep well at low temperatures. At −12° the determined molarities of H_2SO_5 and H_2O_2 had changed from 6.01 and 0.80 to 6.19 and 0.65 after fourteen days and to 6.09 and 0.57 after fifty-nine days. However, care must be exercised in handling since contact with such organic matter as textiles, wood, paper causes immediate ignition.

(9) *Cf.* footnote 2a. The chief difficulty in maintaining low temperature and achieving intimate mixing of the components—both essential—appears at a stage when an appreciable part of the persulfate has been added and when rather suddenly the reaction spreads through the mixture as evidenced by rising temperature and stiffening of the whole mass. Previous reports do not appear to have mentioned this phenomenon.

[a] The sulfuric acid used was of 92.5% concentration in preparations 1–7, and of 96% in number 8. [b] *I. e.*, including that from $K_2S_2O_8 + H_2O \longrightarrow K_2SO_4 + O + H_2SO_4$. [c] The amount used was equal in cc. to the mml. $K_2S_2O_8$ used, *e. g.*, 230 cc. for 230 mml. of $K_2S_2O_8$.

Stability and Reactions. (a) **in Alcohols.**—In order to obtain some initial information on the factors of stability of, and the nature of the reactions involved in, alcoholic solutions of the peracid, the ethanol solution described above and two ethanolic dilutions, one of one-half and one of one-quarter the original concentration, were each divided into three portions, and of these one was kept at room temperature (about 26°), one in a refrigerator (about 2°) and one in the low temperature compartment of the refrigerator (about −12°). On each of these nine portions periodical determinations were made of permonosulfuric acid, total peroxygen, free acidity and total acidity. The results are given in Fig. 1. A comparison of plots 1, 2 and 3 indicates that the rate of decomposition of permonosulfuric acid is higher in presence of higher acid concentration. Since in none of the solutions formation of free oxygen ($2H_2SO_5 \longrightarrow 2H_2SO_4 + O_2$, $H_2SO_5 + H_2O_2 \longrightarrow H_2SO_4 + H_2O + O_2$ or $2H_2O_2 \longrightarrow H_2O + O_2$)—the cause of decreasing strength in pure aqueous solutions—was perceptible, and since the characteristic odor of ethyl acetate became very noticeable as the peracid disappeared from the alcoholic solutions, the decrease in total peroxygen may be attributed to formation of acetic acid which in the presence of the prevailing high concentrations of acid and

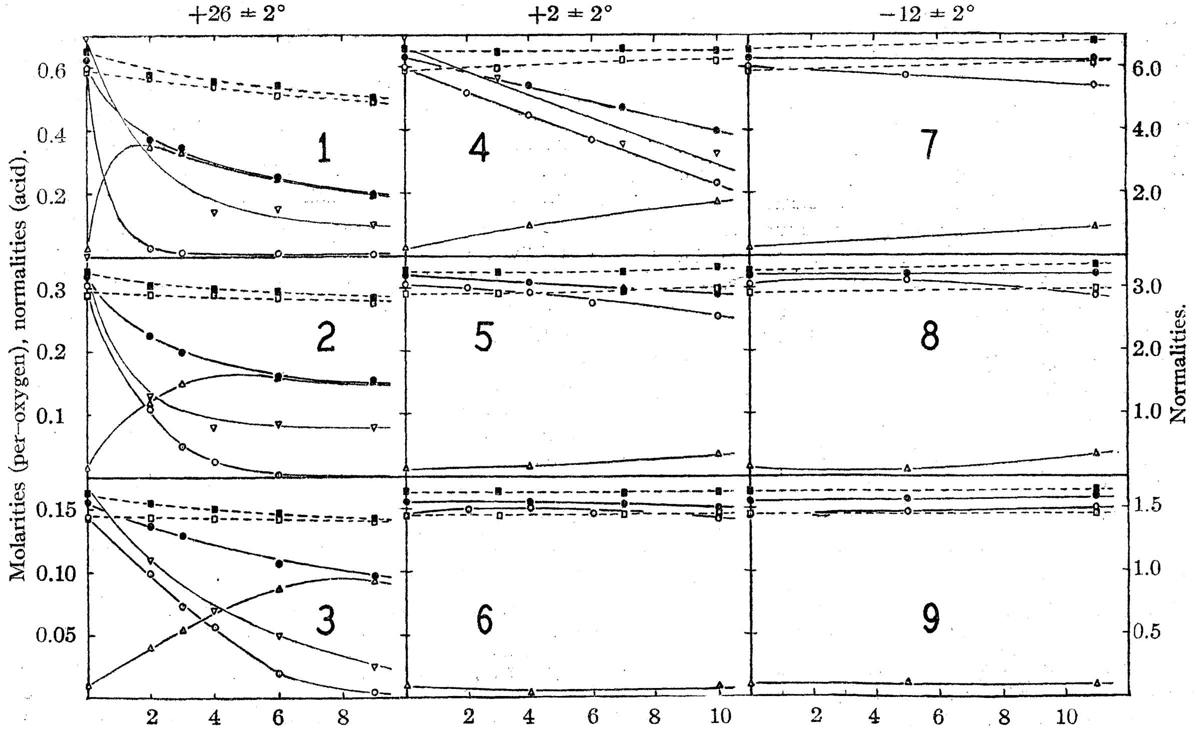

Fig. 1.—The behavior of ethanolic solutions of permonosulfuric acid. Full lines refer to the left ordinate scale, broken lines to the right ordinate scale. "Molarity (peroxygen)" is used to signify number of g.-atoms of active oxygen per 1000 cc. ■, total acid; □, free acid; ▽, acid formed by alkaline boiling (total minus free acid); ●, total peroxygen; ○, permonosulfuric acid; △, peroxygen other than H_2SO_5 ("non-SO_5," *i. e.*, total peroxygen minus permonosulfuric acid). The plots of the nine individual experiments are numbered 1 to 9.

alcohol would be expected to esterify to a large extent. On account of attending difficulties[10] quantitative determination of the ester was not attempted in this exploratory work. Assuming that the reaction $H_2S_2O_8 + H_2O \longrightarrow H_2SO_4 + H_2SO_5$ is substantially irreversible as it is in aqueous solution[11] the "non-SO_5 peroxygen" would consist of one or several of the possible neutral peroxides (hydrogen peroxide, mono- or diethyl peroxide). The oxidation to acetic acid (as measured by the decrease in total peroxygen) is effected by permonosulfuric acid as well as by the "non-SO_5" fraction (although at a lower rate by the latter) as evidenced in plots 1, 2 and 3 by the continued decrease in total peroxygen after the permonosulfuric acid has become nearly zero. The decrease in total acidity which is evident at room temperature is presumably due to formation of ethylsulfuric acid, which is highly resistant to alkaline hydrolysis (Beilstein), while an increase in free acidity, visible in plot 4, may be attributed to hydrolysis of residual persulfuric acid. The main practical result expressed in Fig. 1 is the observation that at about −10° temperatures are approached at which all other reactions become negligible compared with the transfer of oxygen atoms from H_2SO_5 to "non-SO_5" combinations, while even the speed of this reaction drops below one per cent. per day.

Results quite similar to those shown for the ethanol solution were obtained with regard to the stability of the isopropyl alcohol solution (Table I). The concentrated solution showed at −12°, over a period of nine days, a decrease in permonosulfuric acid of 1.1% per day, while all other changes were negligible. In an isopropyl alcohol dilution to one-quarter the original strength the corresponding rate of decrease was 0.5% per day. The stability of the peracid in similar isoamyl alcohol solutions was somewhat less; solutions nos. 4–7 (Table I) showed rates of decrease of 2.5–3.9% per day. However, the effect of acidity on the stability is also marked here. Table II shows results obtained on a solution made by adding 4.7 cc. of a concentrated permonosulfuric acid solution, prepared according to method B, to isoamyl alcohol of −12° and making up to 100 cc. The average rate of decrease of the peracid is about 0.8% per day, while the sum of $H_2SO_5 + H_2O_2$ decreased only by 4.7% over the whole ninety day period, indicating that the main reaction occurring is a shift of oxygen between permonosulfuric acid and hydrogen peroxide.

TABLE II

STABILITY OF PERMONOSULFURIC ACID IN ISOAMYL ALCOHOL at −12°

Days	−4[a]	0	5	13	34	90
H_2SO_5, M	0.502	0.534	0.514	0.482	0.397	0.258
H_2O_2, M	.102	.042	.060	.087	.166	.291
H_2SO_4, M	.167	.116				
H_2O, M	.243					

[a] This column shows the values calculated from the analytical data and the weighed amount used, of the concentrated H_2SO_5 solution which was made and analyzed four days prior to the amyl alcoholic solution.

(b) **In Acetonitrile.**—In the acetonitrile preparation (solution no. 8, Table I) the total recovery of the peroxygen used (including that contained in the solid residue) was 98%. The stability of the resulting solution is apparent from the data of Table III. In contrast to the rapid decomposition at room temperature[12] the solution is of useful stability at −13°.

TABLE III

STABILITY OF PERMONOSULFURIC ACID IN ACETONITRILE

[a] Due to heat of reaction temperature of flask has risen to about 40°. [b] Orange color and odor of acetic acid present. [c] Also odor of sulfur dioxide present. [d] On further standing gradually a heavy brown oil settles out, leaving a colorless supernatant liquid of pure acetonitrile odor.

(c) **Explosions.**—In studying the effect of the medium it became desirable to use at least one secondary and one tertiary alcohol for comparison with the primary ones. An advantage expected from these alcohols was slower esterification with sulfuric acid and concomitantly slower formation of water the presence of which is undesirable for some purposes. The alcohols chosen were *s*-methylisobutylcarbinol (Eastman, practical) and *t*-ethyldimethylcarbinol (Eastman).[13] Especially with regard to the tertiary one there was the additional expectation of greater resistance against oxidation by permonosulfuric acid, based on determinations of oxidation velocities by alkaline permanganate, of Tronov, Lukanin and Pavlinov[14] who for the tertiary amyl alcohol reported a velocity constant of about $^1/_{500}$ of that of isoamyl alcohol, while they found the oxidation velocity of secondary alcohols generally a little higher than that of the primary ones. Addition of concentrated peracid (made by method B) to 9.5 cc. of 1.1 M H_2SO_4 (using 99% H_2SO_4) in methylisobutylcarbinol at −10°, to make a 0.50 M H_2SO_5 solution, was done without difficulty, while in the corresponding operation using ethyl-

---

(10) Indications were obtained that the acid which is liberated by alkaline boiling and which results from decomposition of H_2SO_5 and $H_2S_2O_8$ as well as from saponification of ethyl acetate, may be further increased by oxidation of alcohol to acid, occurring during the alkaline boiling.

(11) Palme, *Z. anorg. allgem. Chem.*, **112**, 47 (1920).

(12) It seems probable that the rapid decomposition is linked to the acid catalyzed hydrolysis of acetonitrile [*cf.* Lavine and Toennies, *J. Biol. Chem.*, **101**, 727 (1933)].

(13) Their relative speeds of esterification were determined by measuring the change in acidity at room temperature of small samples containing anhydrous sulfuric acid at a concentration of approximately twice molar. After four days the free acidity of the solution of the primary alcohol had diminished 32%, that of the secondary 15%, while that of the tertiary was substantially unchanged, although after three days an initial drop of about 5% had taken place. We can suggest no reason for this subsequent increase in free acidity.

(14) Tronov, Lukanin and Pavlinov, *J. Russ. Phys.-Chem. Soc.* **59**, 1173 (1927); *cf. C. A.*, **22**, 3336 (1928).

dimethylcarbinol an explosive reaction occurred on addition of few drops of the concentrated peracid, in spite of careful cooling. After thorough purification—by twice allowing to stand overnight with an excess of concentrated permanganate solution, washing, drying with barium oxide and fractionating (collected between 101.6° and 102.5°)—this tertiary alcohol still showed the same explosive tendencies, indicating that impurities can hardly be considered responsible for this behavior. A more dramatic demonstration of potential dangers occurred when a repetition, with fourfold amounts, of the above methylisobutylcarbinol experiment resulted in a violent detonation. Local overheating leading to a cumulative reaction evidently represents a real danger, at least in this particular alcohol. The following experiments throw some additional light on the danger factors. 0.30 cc. of concentrated peracid (11.7 M H_2SO_5, 3.3 M H_2SO_4, 0.6 M H_2O_2, 5.3 M H_2O) was added to 4 cc. of each of the following, cooled in freezing mixture: (a) isoamyl alcohol, (b) 4 M H_2SO_4 (99.4%) in isoamyl alcohol, (c) methylisobutylcarbinol, (d) 4 M H_2SO_4 in methylisobutylcarbinol. Of the resulting solutions (c) exploded after about one minute and (d) a little later, both while remaining in the freezing mixture. (a) and (b) were taken to room temperature after fifteen minutes, and now (a) exploded after several minutes while (b) did not explode. Obviously the primary $C_5H_{11}OH$ is less reactive than the secondary $C_6H_{13}OH$ and the latter in turn is more stable than the tertiary $C_5H_{11}OH$. The apparent reduction of explosibility by the presence of considerable sulfuric acid (about 37.5%) may be caused by the dilution of the organic component. It should be noted that the permonosulfuric acid concentration used (about 0.8 M) as well as the sulfuric acid concentration are considerably higher than those encountered in the solutions described in the earlier part of this paper, and in which no explosive tendencies were ever observed, even though considerable quantities were handled.

The writer wishes to express his appreciation of the assistance rendered by Dr. Mary A. Bennett in some phases of the experimental work.

Summary

Methods for obtaining solutions of permonosulfuric acid in some of the lower alcohols, including isoamyl alcohol, and in acetonitrile have been described. Examples illustrating the nature of the slow decompositions taking place in such solutions have been given and it has been shown that at −12° solutions containing as much as 0.6 M H_2SO_5 are of convenient stability. Attention is called to the possibility of explosive reactions with secondary and tertiary alcohols, and generally in cases of too high concentrations of the peracid.

A New Method for the Preparation of Permonophosphoric Acid[1]

BY GERRIT TOENNIES

Permonophosphoric acid since its discovery in 1910 by Schmidlin and Massini[2] has received little attention although it is distinguished by a remarkable oxidizing power (lower manganese salts are oxidized, in the cold, to permanganate). The method of Schmidlin and Massini, consisting in gradually combining phosphoric anhydride and concentrated hydrogen peroxide in very small portions, is difficult on account of the violence of the interaction, and uncertain as to result in spite of its tediousness. The only other method proposed by Fichter and associates,[3] produces by anodic oxidation mixtures of alkali salts of H_3PO_5 and $H_4P_2O_8$ in solutions of potassium fluoride and therefore is of limited usefulness. The present experiments were undertaken with a view of simplifying the production of this interesting compound by moderating the reaction between phosphoric anhydride and hydrogen peroxide through the use of suitable inert diluents for the latter.

Of three solvents studied, ether, isoamyl alcohol and acetonitrile, only the last one gave satisfactory results. Acetonitrile is completely inert against phosphoric anhydride and it can be used to make solutions of hydrogen peroxide of high concentration and high stability.[4] In two parallel experiments, in which the components were used in ratios approximately corresponding to the assumed reaction

$$P_2O_5 + 2H_2O_2 + H_2O \longrightarrow 2H_3PO_5 \qquad (I)$$

phosphoric anhydride (5.55 and 5.18 mml., respectively,) was suspended in 1.5 cc. of acetonitrile (Merck reagent) and at low temperature (freezing mixture) an acetonitrile solution (1.10 and 1.05 cc.) containing hydrogen peroxide[5] (12.94 and 12.35 mml.) and water (4.03 and 3.84 mml.) was added slowly. Besides, 0.30 cc. of acetonitrile was

(5) Hydrogen peroxide of 80 to 90% concentration was prepared according to Hurd and Puterbaugh, THIS JOURNAL, **52**, 950 (1930).

added in the first case, and 0.30 cc. of acetonitrile containing 0.023 mml. of 2,4-dinitrobenzenesulfonic acid[6] in the other case. The purpose of this modification was to examine the possibility that the reaction between phosphoric anhydride and hydrogen peroxide might be catalyzed by strong acids, as it has been found that the reaction between aliphatic anhydrides and hydrogen peroxide in non-aqueous systems is highly susceptible to acid catalysis.[4] The phosphoric anhydride was in both instances energetically attacked and cooling was necessary for some time to keep the reaction mixture from exceeding room temperature. Some escape of gas was visible and the odor of ozone appeared, to which after a while the characteristic "peracid" odor (known from perbenzoic and permonosulfuric acid) was added. Analysis—by the methods previously (*cf.* preceding paper) used by the author for solutions of permonosulfuric acid—after twenty hours gave for the two solutions, respectively: peracid 56 and 57%, hydrogen peroxide 20 and 18.5%, total peroxygen 76.5 and 76.5%, all in terms of the hydrogen peroxide used. In terms of phosphoric anhydride the result is that 65.3 and 68.0%, respectively, have been converted into permonophosphoric acid. The agreement between the two experiments, surprisingly close for a heterogeneous reaction of this character, indicates the absence of acid catalysis as a rate determining factor, and the data further show that the desired reaction takes place to a satisfactory extent in acetonitrile and that no peroxide other than permonophosphoric acid, such as perphosphoric acid $H_4P_2O_8$,[2,3] is formed. It should be stated here that the conclusion that the peroxide (previously referred to as "peracid") formed is permonophosphoric acid, is based on the following considerations: (1) the evidence of Schmidlin and Massini[2] indicating that the compound resulting from interaction of phosphoric anhydride and hydrogen peroxide is permonophosphoric acid, (2) observations[4] that solutions of hydrogen peroxide in acetonitrile are extremely stable and show no evidence of formation of a peroxide which reacts rapidly with iodide in the manner observed here and which is indistinguishable from the analogous action of permonosulfuric acid, (3) acidimetric evidence (described in connection with the next experiment, *vide infra*) that the acid left after removal of the peroxygen is H_3PO_4 and not HPO_3 which should result if the peracid present had the formula HPO_4, and (4) the qualitative observation that these acetonitrile solutions cause oxidation of Mn^{++} to MnO_4^- in the cold, a reaction which, according to the discoverers,[2] distinguishes permonophosphoric acid from other peroxides.

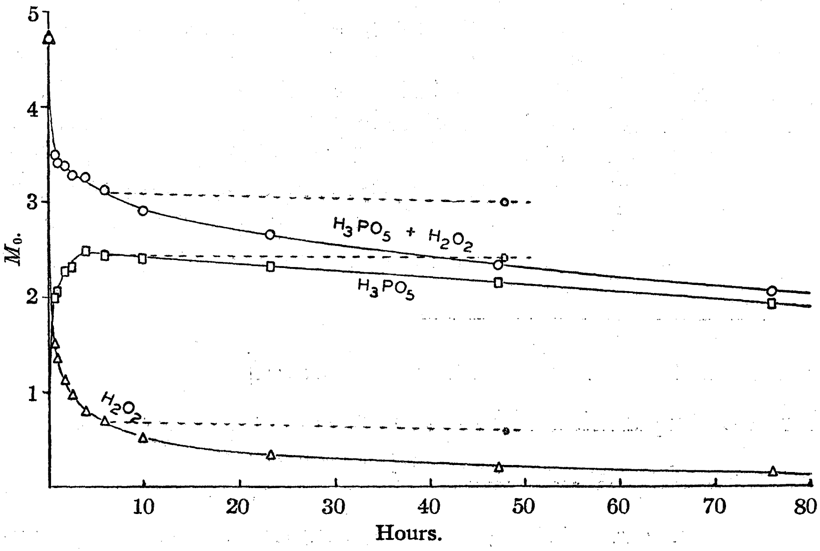

Fig. 1.—The reaction between phosphoric anhydride and hydrogen peroxide at room temperature (about 25°). M_0 indicates molarity in peroxygen, *e. g.*, 1 M H_3PO_5 or 1 M H_2O_2 = 1 M_0. The moment when the hydrogen peroxide was completely added has been taken as zero time. The dotted lines show the stabilizing effect of low temperature, obtained by keeping a part of the solution at about −12°.

The next experiment was designed to throw some light on the rate of formation of the peracid. To a suspension of 15.55 mml. of phosphoric anhydride in 4 cc. of acetonitrile, cooled in freezing mixture, 3.05 cc. of an acetonitrile solution containing 35.87 mml. of hydrogen peroxide and 11.34 mml. of water were added slowly during about five minutes. After three additional minutes the mixture was brought to room temperature and after forty-five minutes of standing, with occasional shaking, very little phosphoric anhydride remained undissolved. From this point on, 0.1-cc. samples were withdrawn periodically (by means of a Folin micro blood sugar pipet; the average deviation in the size of the sample obtained was ±0.15%) and analyzed. The data obtained are plotted in Fig. 1. They show that the bulk of the peracid is formed within the first hour, during the dissolving of phosphoric anhydride, that most of the loss of peroxide occurs during this period, and that even after the phosphoric anhydride has completely dissolved (about 100 minutes) additional peracid is formed. The yield of peracid at the maximum (four hours) is 60.5% in terms of phosphoric anhydride. Further work is planned to study the mechanism of the reaction and the factors influencing it. To determine if metaphosphoric acid, or its hypothetical per-derivative (HPO_4) might be present in the solution, acidimetric titrations were carried out as follows: about two hours after the beginning of the reaction 0.1-cc. samples were added to 0.8 cc. of 0.6 M dibenzyl sulfide in acetonitrile. This causes the transfer of the active peroxygen to dibenzyl sulfide, thus eliminating it as a disturbing factor in acidimetry since the resulting dibenzyl sulfoxide is relatively inert as an oxidizing agent. Titration with 0.05 N NaOH to the turning point of (a) methyl orange (pH 4) and (b) thymolphthalein (pH 10) gave the following results: (a) 4.07, 4.16 N, (b) 8.36, 8.58 N. The 1:1 ratio is in agreement with H_3PO_4 (and possibly

---

[6] *Cf.* G. Toennies and M. Elliott, This Journal, **57**, 2136 (1935).

$H_4P_2O_7$) and suggests absence of appreciable amounts of a monobasic acid (HPO_3).

The relative stability at room temperature of this peracid in acetonitrile is remarkable in comparison with that of solutions of permonosulfuric acid in acetonitrile (*cf.* preceding paper). Since the peroxygen of H_3PO_5 is more active than that of H_2SO_5 it appears likely that the difference in stability is due to catalytic effects of the accompanying acids, inasmuch as H_3PO_4 is a weak acid compared with H_2SO_4. Just as permonosulfuric acid (*cf.* preceding paper), so also permonophosphoric acid can be kept in isoamyl alcoholic solution, the stability being of a similar order. Dilutions of the first two acetonitrile solutions described here with 10 volumes of isoamyl alcohol showed, in terms of the yields reported above, after three days at $-11°$, the presence of 51 and 50.5% (instead of initially 56 and 57%) of peracid and of 71.5% of peroxygen (instead of 76.5%) in both cases.

When instead of acetonitrile, ether or isoamyl alcohol was used as the medium for the interaction between hydrogen peroxide and phosphoric anhydride, the results were as follows. An ether solution, about 2.8 *M* in hydrogen peroxide and 0.85 *M* in water, left in contact, for twenty-four hours at room temperature, with an amount of phosphoric anhydride corresponding to the hypothetical reaction

$$P_2O_5 + H_2O_2 \longrightarrow HPO_3 + HPO_4 \qquad \text{(II)}$$

showed little action upon the solid phase. Analysis of the whole reaction mixture showed 2.5% of the hydrogen peroxide as such, 17% as peracid and a total peroxygen recovery of 26%. When the components were used in ratios corresponding to reaction (I) (2.5 *M* H_2O_2, 1.2 *M* H_2O) the phosphoric anhydride went into solution within two hours, forming an oily layer. Analysis showed a total recovery of 9.4% as peracid and 68% as hydrogen peroxide. After twenty hours the corresponding figures were 14 and 44% showing that formation of additional peracid proceeds much slower than loss of hydrogen peroxide. In similar experiments using isoamyl alcohol as the medium less than 2% of the hydrogen peroxide was converted into peracid.

Summary

A convenient method for the preparation of solutions of permonophosphoric acid, based on the heterogeneous interaction between phosphoric anhydride and hydrogen peroxide in acetonitrile, has been described and it has been shown that such solutions, even at room temperature, are relatively stable. When instead of acetonitrile, ether or isoamyl alcohol is used as the medium, the reaction between hydrogen peroxide and phosphoric anhydride is of negligible extent.

A Comparison of Hydrogen, Quinhydrone and Glass Electrodes in Magnesium Sulfate Solutions

BY E. S. AMIS AND J. L. GABBARD

The error of the glass electrode compared with that of the hydrogen electrode in solutions of various ions has received much attention,[1-8] and the rapid increase in its use in various *p*H studies and industrial processes justifies further investigation. Therefore, the authors have made a direct comparison of the hydrogen, quinhydrone and glass electrodes in buffered and unbuffered, except for small quantities of hydrochloric acid, magnesium sulfate solutions.

Apparatus and Materials

The glass electrodes having a resistance of the order of 10^7 ohms were blown of Corning 015 glass in the form of a thin bulb[1,9] on the end of a tube of ordinary soft glass and aged for at least twenty-four hours before using. The silver–silver chloride electrode of the reduced oxide type[10] was placed in the 0.1 *N* hydrochloric acid inside the glass electrode and served as the reference electrode. The hydrogen electrodes were made in the usual manner and the quinhydrone electrodes were made and cleaned as recommended by Morgan, Lammert and Campbell.[11] The hydrogen electrodes were also cleaned in this manner before being platinized. This cleaning process was repeated and the hydrogen electrodes were newly platinized before each series of measurements. The platinum black was removed from the hydrogen electrodes by the use of hot aqua regia. Two hydrogen and two quinhydrone electrodes were used in making the measurements. If the difference in potential between the two respective electrodes was not less than 0.2 mv., a new pair of electrodes was selected. The calomel electrode was prepared from the Leeds and Northrup chemicals especially purified for the purpose. Commercial tank hydrogen was purified as described by Dole.[4] Since

only comparative results were being sought, the solutions were made of commercial C. P. salts without further purification by accurately weighing the salts on an analytical balance, dissolving and diluting in a calibrated flask. The weaker solutions were made by diluting the stronger ones. The buffered solutions were made according to the directions given by Clark,[12] and standardized with the hydrogen electrodes. The quinhydrone was prepared by the Eastman Kodak Company.

The electrode vessel for the buffered solutions was similar to that used by Hovorka and Dearing,[13] consisting of four cylindrical separatory funnels of 80-ml. capacity sealed together and holding, respectively, the hydrogen, the glass and the quinhydrone electrodes and the connecting arm of the calomel electrode. The vessel for the unbuffered solutions was a 250-ml. Pyrex beaker containing the glass and the quinhydrone electrodes and the connecting arm of the calomel electrode.

The circuit used in the construction of the vacuum tube potentiometer was that described by DuBridge and Brown[14] modified to measure small potentials and to meet other requirements. The sensitivity of the potentiometer was 0.05 mv. and since there was no perceptible drift during the time required to make a measurement and neither body capacity nor external electrostatic fields had any effect upon its operation, the measurements could be repeated easily with a precision of 0.2 mv.

Experimental Procedure

The experiments consist of a direct comparison of the glass, hydrogen and quinhydrone electrodes in buffered magnesium sulfate solutions of various concentrations and slightly differing *p*H values, and also a comparison of glass and quinhydrone electrodes in unbuffered, except for very small quantities of dilute hydrochloric acid, magnesium sulfate solutions of various concentrations but of constant *p*H values. However, in the latter, different series at different *p*H values were studied, providing a means of observing the effect upon the electrode potentials caused by changing both the concentration and the *p*H values of the solutions.

With the glass, hydrogen, calomel and quinhydrone electrodes immersed in the same solutions connected by stopcocks as in the case of the buffered solutions, the following cells could be formulated

(A) Hydrogen–Quinhydrone Pt, H_2/soln., H^+ (a), Quinhydrone/Au

(B) Hydrogen–Glass Pt, H_2/soln./glass/0.1 *N* HCl/AgCl/Ag

(C) Glass–Quinhydrone Ag/AgCl/0.1 *N* HCl/glass/soln., H^+ (a), Quinhydrone/Au

(D) Hydrogen–Calomel Pt, H_2/soln.//sat. KCl/HgCl/Hg

(E) Calomel–Quinhydrone Hg/HgCl/sat. KCl//soln., H^+ (a), Quinhydrone/Au

(F) Glass–Calomel Ag/AgCl/0.1 *N* HCl/glass/soln.//sat. KCl/HgCl/Hg

The values for all these cells were obtained where possible for each solution and the values of D, E and F used to check the direct readings of A, B and C. The procedure followed in the actual measurement of the cells in the buffered solutions was similar to that used by Hovorka and Dearing,[13] with the exception that in this work the vacuum tube potentiometer was used for measuring all potentials. The quinhydrone electrodes were very unstable in the solutions of *p*H 7 or above.

In the solutions where a constant *p*H based on the readings of the quinhydrone electrodes was maintained, the quinhydrone electrodes were allowed to come to equilibrium in the unbuffered solutions and the e. m. f. of cell E noted. Then dilute (0.0101 *N*) hydrochloric acid was added dropwise, with stirring after each addition, until the e. m. f. corresponding to the desired *p*H was obtained, the glass electrodes were placed in the solution and the readings made. The hydrogen electrodes were unstable in these solutions, particularly those of higher *p*H values.

Results and Discussion

It is noted by observing cells A, B and C that as long as the quinhydrone and glass electrodes act as perfect hydrogen electrodes the values of the respective cells will remain constant and independent of the *p*H of the solutions. The potential of cell A is

$$(1)\quad E = E_h + E_q = -RT/F \ln aH^+ + E_0 - RT/2F \ln ah/aq + RT/F \ln aH^+$$

$$(2)\quad = E_0 - RT/2F \ln ah/aq$$

where ah, aq and aH^+ are the activities of the hydroquinone, quinone and hydrogen ions, respectively. E_0 is the normal potential of the quinhydrone electrode (0.69938 v. at 25°).[13] Since the presence of dissolved substances may cause the value of the second term of equation (2) to vary due to the alteration of the activity ratio of the hydroquinone to the quinone, it is expected that the constant value of cell A should be slightly different from 0.69938 v., the actual value depending upon the kind of salts present and their con-

centrations. However, as long as the value remains constant with change of magnesium sulfate concentration, it is evident that the *a*h/*a*q ratio is remaining constant and the quinhydrone electrode is functioning as a perfect hydrogen electrode.

The value of cell B has been discussed by Dole[4] (p. 4064). The value of cell C should be the value of cell A minus the value of cell B (0.6994 − 0.3524 = 0.3470 v. at 25°). Therefore, the constant value of this cell varies with each particular series of experiments. The constant values for cells A, B and C were obtained for each series of experiments by taking the values of the cells in the solutions of increasing concentration, plotting these values against the concentration, and extrapolating for the value of the cell at zero concentration. Any deviation of the cells from their constant values in each series of experiments is termed, respectively, the "quinhydrone electrode error," the "glass electrode error" and the "glass–quinhydrone error" and shown in Tables I and II. From Table I it is observed that neither the glass nor the quinhydrone electrodes show an appreciable error in 1 *M* concentration or less of buffered magnesium sulfate solutions below *p*H 4.15, but in the 2 *M* concentrations it is seen that each electrode has an appreciable error. The "glass–quinhydrone error" is, as would be expected, in close agreement with the numerical sum of the errors, disregarding sign, of the two electrodes.

The error of the glass electrode is negative, which means that the error is not a function of the positive magnesium ions. If the positive magnesium ions were entering or being adsorbed by the glass membrane of the glass electrode, it is easily seen by observing cell B that the error would be positive, in agreement with the observations of other investigators upon other positive ions.[3,4,6] If the equation (3) $\Delta E = S\,RT/F \ln a\mathrm{H_2O} = RT/F \ln \frac{p\,\mathrm{H_2O\ in\ MgSO_4}}{p\,\mathrm{H_2O}}$ derived by Dole[5] for the glass electrode functioning as a water electrode is used, letting $S = 1$, and using the vapor pressure of water and of water in magnesium sulfate solution at 50° as given in the "International Critical Tables," −1.2 mv. is obtained for the error in 2 *M* solution and −0.5 mv. in 1 *M* solution. The temperature interval of 21° (50 to 29°) would cause little change in the calculated error since Carpenter and Jette[15] have shown that the

---

(15) C. D. Carpenter and E. R. Jette, THIS JOURNAL, **45**, 578 (1923).

p H_2O in $MgSO_4/p$ H_2O ratio for a saturated solution of magnesium sulfate is practically constant with change of temperature. In a trial calculation ΔE changed less than 0.2 mv. in going from 50 to 70° where the greatest change in the ratio as influenced by temperature is observed. Assuming that the concentration of the buffers in the solutions would have very little effect upon the total water vapor pressure, -1.2 mv. is in excellent agreement with the observed values except the value for the glass electrode No. 2. Therefore, it is felt that the observed error of the glass electrodes is due to the water error of the glass electrode.

The "quinhydrone error" is due to the "salt error"[13,16–18] of the quinhydrone electrode. From equation (2) it is seen that $E_s = -RT/2F \ln a\text{h}/a\text{q}$ where E_s is the "salt error" or the deviation of potential produced by the change of the activity coefficient ratio of the hydroquinone to quinone. Kiss and Urmanczy[18] showed that this error in salt concentrations above 1 N could be expressed by the linear relation (4) $E_s = C\mu + D$ where μ is the ionic strength of the solution and C and D are constants characteristic of the salt ($C = 0.300$ and $D = 1.3$ for magnesium sulfate). Hovorka and Dearing[13] have more recently shown that the error can be expressed by the more simple linear relation (5) $E_s = AN$ with A being a constant characteristic of the salt (0.00122 for magnesium sulfate) and N the normality of the solution. The data reported by these investigators were obtained by dissolving magnesium sulfate in 0.01 N hydrochloric acid. Table III contains a comparison of the data taken with the magnesium sulfate solutions at pH 4.30 in this investigation with theirs. When corrections are made for the water error of the glass electrodes in the higher concentrations it is seen that the data agree closely.

Table III

The "Salt Error" of the Quinhydrone Electrode in Magnesium Sulfate Solutions of Various Concentrations from Different Investigations

	Kiss and Urmanczy $MgSO_4$ in 0.01 N HCl		Hovorka and Dearing $MgSO_4$ in 0.01 N HCl		This investigation Pure $MgSO_4$ brought to pH 4.30 by use of dilute HCl Glass No. 5		Glass No. 6	
M	E_m, mv.	E_c, mv.	E_m, mv.	E_c, mv.	E_m, mv.	$E_{corr.}$	E_m, mv.	$E_{corr.}$
0.25	1.0	1.6	0.68	0.61	0.1		0.1	
.5	1.7	1.9	1.32	1.22	1.0		1.0	
1.0	2.4	2.5	2.40	2.44	2.4		2.2	
1.25	2.8	2.8						
1.5	3.1	3.1			3.4	2.6	3.8	3.0
2.0	4.0	3.7			4.7	3.5	5.1	3.9

E_m = measured errors; E_c = calculated errors and $E_{corr.}$ = corrected errors.

The data in Table II show that the "glass–quinhydrone errors" in the unbuffered solutions of higher pH, particularly in the higher concentrations, are much larger than in the solutions of lower pH. They are also much larger than those calculated by equations (4) and (5), even after corrections are made for the water error of the glass electrode. This is to be expected when it is considered that the pH of quinhydrone in pure water is about 5.85[19,20] which means that in the solutions of higher pH considerable ionization of the hydroquinone is taking place. This may affect the electrode potential as shown by La Mer and Parsons[21] by changing the electrode reaction from

$$C_6H_4O_2 + 2H^+ + 2e \rightleftharpoons C_6H_4(OH)_2 \text{ to } C_6H_4O_2 + 2e \rightleftharpoons C_6H_4O_2^{--}$$

or it may affect the actual pH of the solution by taking part in the acid base equilibrium by removing OH^- ions.

Kolthoff and Bosch[20] found close agreement between the quinhydrone and hydrogen electrodes in weakly buffered solutions ranging in pH from 3.6 to 7.2, which would indicate that the buffered solutions not only hold the activity coefficients of the hydrogen ion constant, but also tend to hold the ratio of the activity coefficients of the hydroquinone to the quinone constant thus preventing the "salt error." This would explain the absence of any appreciable "salt error" for the quinhydrone electrodes in the buffered solutions below one molar concentrations.

Acknowledgments.—To Dr. Malcolm Dole of the Department of Chemistry, Northwestern University, the authors wish to give sincere thanks for his many helpful suggestions during this investigation and for his constructive criticisms of the data. To Dr. F. E. Tuttle, Professor *Emeritus*, of the Chemistry Department, University of Kentucky, they wish to express their appreciation for interest and suggestions during this investigation and in the preparation of the manuscript.

Summary

1. It has been shown that the presence of magnesium ions to the extent of two moles per liter does not affect the potential of the glass electrode.

2. The water error of the glass electrode in magnesium sulfate solutions has been found to conform well with the equation $\Delta E = S\,RT/F \ln a'H_2O$ as derived by Dole.

3. It has been shown that the glass electrode is suitable for measuring the "salt error" of the quinhydrone electrode in solutions buffered with only traces of hydrochloric acid, and that this error depends upon the pH of the solution.

The Entropy of Water from the Third Law of Thermodynamics. The Dissociation Pressure and Calorimetric Heat of the Reaction $Mg(OH)_2 = MgO + H_2O$. The Heat Capacities of $Mg(OH)_2$ and MgO from 20 to 300°K.

BY W. F. GIAUQUE AND R. C. ARCHIBALD

The thermodynamic properties of water are sufficiently important and interesting to invite the fullest possible investigation. The present work was undertaken because it had been shown[1] that the experimental $\int_0^T C_p \, d \ln T$ for water does not give the correct entropy. This quantity is accurately known from the band spectrum data.

It seemed desirable to perform at least one experiment in which the third law of thermodynamics would give the entropy of water accurately and in a straightforward manner. The reaction $Mg(OH)_2 = MgO + H_2O$ was selected for this purpose for several reasons. First, a measurable dissociation occurs at a rather low temperature, although not at as low a temperature as we were led to expect from the erroneous available data. Second, the identity of the water molecule should be very completely lost in magnesium hydroxide and such difficulties as are present in ice, or conceivably in water of crystallization, should not be present. Third, the reaction is one which is well adapted to an accurate calorimetric investigation of the heat of reaction. Fourth, the atoms in the substances concerned are all of low atomic weight, which makes the measured and extrapolated quantities of entropy low, with a corresponding increase in the accuracy of the entropy of water derived from the experimental data.

The entropy of water was obtained from the thermodynamic relation

$$S_T(H_2O) = S_T(Mg(OH)_2) - S_T(MgO) + (\Delta H_T/T) + R \ln P_T \quad (1)$$

where ΔH_T and P_T are the heat and pressure of dissociation, respectively, at temperature T. It safely may be assumed that the fugacity is equal to the pressure at the low pressures and high temperatures of the experiment. We may state at once that complete agreement was found between the entropy value obtained as above and that derived from the molecular spectrum of water.

Since this research was undertaken the heat capacity of ice has been reinvestigated accurately by Giauque and Stout.[2] They have shown that the entropy discrepancy is in very exact agreement with the quantitative predictions of Pauling,[3] who bases his calculation on false equilibrium at low temperatures with respect to the random orientation of hydrogen bonds in ice.

More recently Long and Kemp[4] have made similar measurements on deuterium oxide. They have shown that a similar discrepancy exists in this case and find that it also is in quantitative agreement with the calculated discrepancy of Pauling.[3]

While there is no reason to doubt the reliability of the entropy of water as deduced from the accurately known band spectrum, and although this value is strongly supported by the above investigations, we believe that it is very desirable to have one or more third law checks on this important quantity.

Preparation and Purity of Magnesium Hydroxide and Magnesium Oxide.—Crystalline magnesium hydroxide was prepared by the method of de Shulten.[5] A wide-mouthed platinum bottle of one liter capacity was used. This fitted closely inside a well-insulated vertical tubular

electric oven. A typical charge for the bottle was: 1375 g. of potassium hydroxide, 48.5 g. of $MgCl_2 \cdot 6H_2O$ and 243 cc. of water. The charge was heated in the oven to 210°C. and held at this temperature until the solution became clear. This required about thirty minutes from the time heating was started. It was then allowed to cool to room temperature in the oven. This required about eighteen hours. The solid mass was dissolved out of the platinum bottle with water and filtered through a sintered glass filter. The crystals of magnesium hydroxide remaining on the filter were washed several times with distilled water. When a sufficient quantity of the crystals had been made they were given a final washing with water and dried for two hours in an oven at 100°C.

The crystals were well formed and of an average diameter of about 0.2 mm. A photograph of a representative sample of the crystals is shown in Fig. 1.

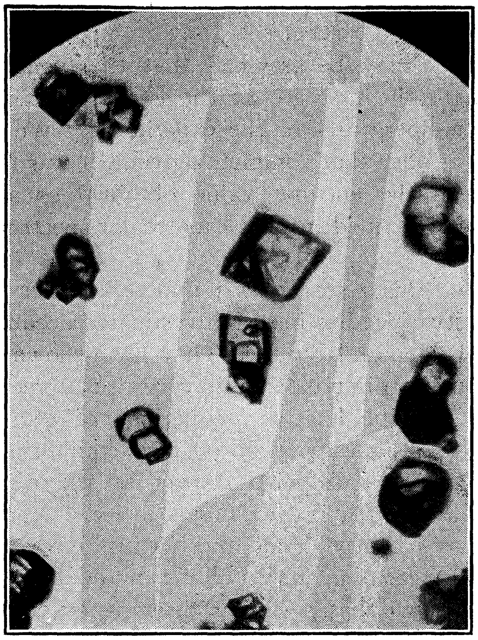

Fig. 1.—Photograph of representative sample of magnesium hydroxide crystals. The average diameter was about 0.2 millimeter.

Since the main impurities possible in the magnesium hydroxide are potassium and phosphate from the potassium hydroxide, analyses were made for these substances. These analyses gave potassium as K, 0.15%, and phosphate as PO_4, less than 0.005% of the magnesium hydroxide. The material was protected carefully from carbon dioxide and a test showed that carbonate was not present.

In order to obtain magnesium oxide as it exists in equilibrium with the magnesium hydroxide used, the hydroxide was decomposed under vacuum at 300°C., and the temperature raised to 350°C. toward the end of the decomposition. The decomposition was attempted at 200°C. but was very slow. At 300°, however, it was about 95% complete in ten days. All of the measurements on magnesium oxide were made with this material and the results corrected for the amount of magnesium hydroxide present. The small amount of potassium hydroxide impurity was assumed to have the same heat capacity as magnesium hydroxide. Such error as is involved by this assumption could hardly have an appreciable effect on the heat capacity results. The effect of impurity on the heat of solution measurements will be discussed in that connection.

The Heat Capacities of Magnesium Hydroxide and Oxide.—The heat capacities were measured in a manner and calorimeter similar to that described by Giauque and Wiebe,[6] but, the weight of the heavy, hollow, lead-copper, thermally isolated cylinder that served as an enclosure for the calorimeter was about 50% greater. The electrical leads were carried through the protective cylinder by insulated wire sealed in, for a length of about 7 cm., with a low melting alloy.

The calorimeter was of copper 10.8 cm. in length and 3.8 cm. in diameter and with twelve radial vanes. The gold resistance thermometer-heater was wound on the outside of the calorimeter and brought into good thermal contact by Bakelite lacquer. A short German silver tube, through which the calorimeter was filled, was attached to the bottom of the calorimeter. This tube was provided with a soldered cap containing a pin hole through which the air was pumped out and helium admitted, after which the hole was closed with solder. The helium was necessary to ensure good thermal conductivity. The German silver tube permitted soldering without appreciable heating of the calorimeter.

The resistance thermometer was calibrated by means of standard thermocouple No. 16[7] which was attached to the bottom of the calorimeter. A small correction to the original calibration was applied on the basis of a recent comparison with the oxygen and hydrogen vapor pressure thermometers and the melting point, 54.39°K., and higher transition point, 43.76°K., of oxygen.

The thermocouple was brought through the protective cylinder in a paraffin filled tube. The resistance thermometer, which gave high precision and accuracy over short intervals of temperature, was calibrated at about five-degree intervals over the entire range of investigation. The calibrating was done concurrently with the heat capacity measurements.

All low temperatures were produced by means of liquid air or liquid hydrogen, transferred from laboratory supply dewars. In calculating energy, 1.0004 absolute joules were taken equal to 1 international joule and 4.185 absolute joules were taken equal to 1 calorie.

The heat capacity data are summarized in Tables I and II and are shown graphically in Figs. 2 and 3. 173.203 g. of magnesium hydroxide and 118.671 g. of magnesium oxide were used in the measurements.

In Table III the data have been presented in the form of values taken from smooth curves through the experimental values. Since the equilibrium measurements had to be extended to higher temperatures than had been indicated by the erroneous available data a considerable extrapolation was necessary in the case of mag-

nesium hydroxide. The extrapolated values used in the later calculations are included for this reason. A discussion of the probable error introduced by their extrapolation is given later.

The heat capacity of magnesium oxide has been measured at ordinary or higher temperatures by Regnault,[8] Russell,[9] Magnus,[10] McDowell and Howe,[11] Parks and Kelley,[12] and Wilkes.[13]

We have adopted the smoothed values given in the "I. C. T."[14] The curve through these values connects well with the curve through our data below 300°K.

The heat capacity of magnesium oxide has been measured at low temperatures by Günther[15] and by Parks and Kelley.[12] The measurements of Günther are not self-consistent and deviations from the present data range from 70 to 13% low over the interval 40 to 85°K.

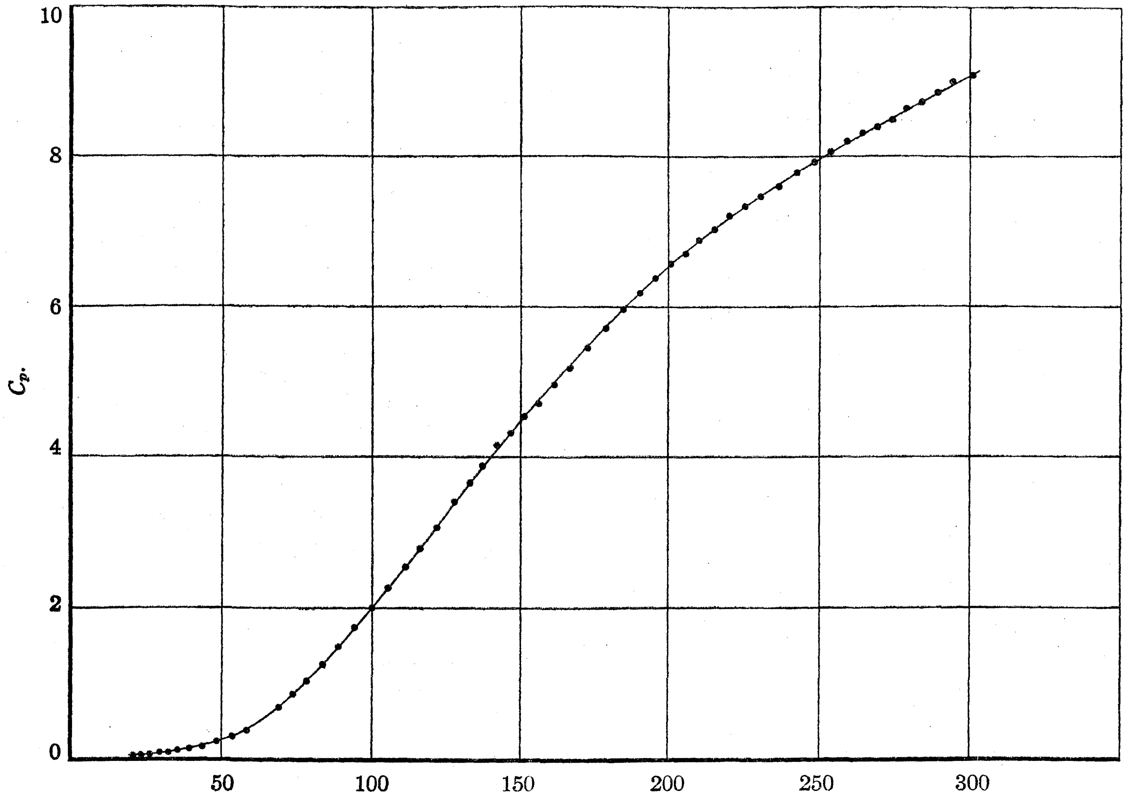

Fig. 2.—Molal heat capacity of magnesium oxide in calories per degree.

The measurements of Parks and Kelley over the range 90–290°K. fall on a smooth curve which lies about 1% below the present observations at ordinary temperatures with the difference increasing by systematically greater amounts at lower temperatures. At 90°K. the deviation has increased to −6%.

We do not question the accuracy of the measurements of Parks and Kelley, since some of their other measurements with the same calorimeter have been substantiated by the work of other observers. Thus the probable cause of the deviation deserves some comment.

The magnesium oxide used by Parks and Kelley had been crystallized from the fused oxide by the Norton Company. It was shown to be pure by analysis. We have learned in a personal communication from Dr. Kelley that cleavage planes of the crystal indicated it to be cubic and rather perfect in character. Also an x-ray investigation on some of the same material had shown typical Laue spot patterns.

As has been mentioned above, the magnesium oxide used in the present investigation was prepared by decomposing the hydroxide in a vacuum at 300–350°. This was considered desirable in order that we might have material in the same state as that in which it was present during the decomposition equilibrium. The material obtained in this manner was of course a powder and it appears that the difference in the results obtained by Parks and Kelley and in this research is due to the difference in the physical state of the material. The low temperature heat capacity results on the very poorly conducting finely divided magnesium oxide are not as accurate as those on the crystalline magnesium hydroxide but it seems probable that the present results on the oxide are too low rather than too high. The fact that the measurements are 6% higher than those of Parks and Kelley on large crystals of magnesium oxide at 90°K. is not so surprising when one considers that the actual difference is a little less than a tenth of a calorie per mole and that some of the molecular restraints must have been weakened on and near the very large amount of surface formed when the magnesium hydroxide was dehydrated.

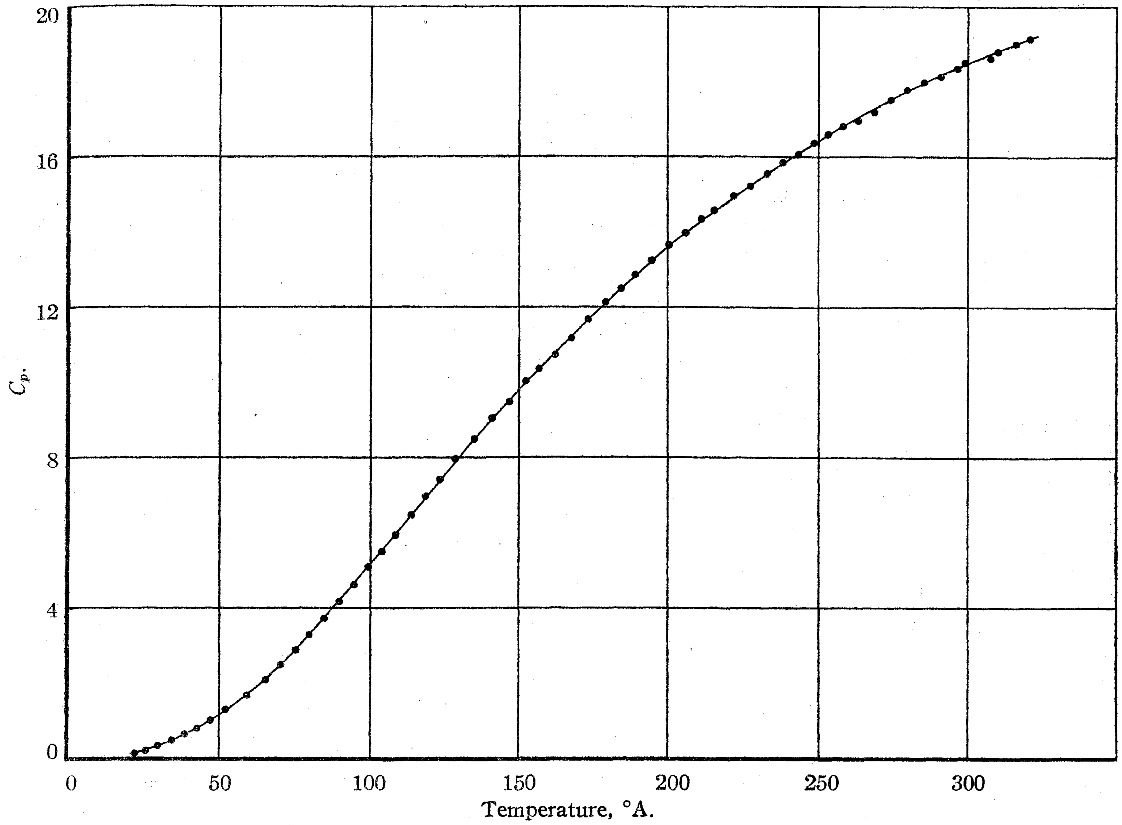

Fig. 3.—Molal heat capacity of magnesium hydroxide in calories per degree.

The Heat of Decomposition of Magnesium Hydroxide.—The heat of the reaction $Mg(OH)_2 = MgO + H_2O(l)$ was determined by measuring the heats of solution of magnesium hydroxide and magnesium oxide in dilute hydrochloric acid.

Figure 4 shows a cross-sectional diagram of the calorimeter used for the measurements of the heats of solution of magnesium oxide and magnesium hydroxide in hydrochloric acid. The apparatus consisted essentially of a dewar vessel equipped with a stirrer, a resistance thermometer and heater combined, and a means of admitting the sample. The one-liter silvered dewar vessel was specially made, without spacing plugs, to minimize heat leak. The resistance thermometer-heater, A, was wound on a platinum tube 2 cm. in diameter and 7 cm. long. It consisted of about 45 ohms of number 40 B. and S. gage double silk-covered copper wire insulated and kept in good thermal contact with the tube by Bakelite lacquer. A thin platinum sheath was put over this and welded around the ends. The leads of number 24 copper wire came through a small platinum tube welded to the inside tube of the thermometer-heater. Potential leads were attached at a point somewhat above the surface of the liquid in the dewar vessel, thus minimizing the effect of the heat generated in the leads. The thermometer-heater was supported by the small platinum tube.

Two different stirrers, B, were used at different times during the work. One was a 10-blade platinum stirrer, the other a 3-blade glass stirrer. These were fastened with deKhotinsky cement into the stirrer shaft well above the liquid level in the dewar vessel. The stirrer shaft was made from thin German silver tubing to minimize heat conduction. Bearing surfaces were provided only near the ends.

The upper framework of this calorimeter was a heavy support with a series of tubes leading down to the mouth of the dewar vessel. The joint between the support and the dewar was made water tight with adhesive tape and paraffin while the dewar flask was held snugly in place by a metal ring underneath attached to the upper metal part by three cords and a spring. The tubes were used as follows: one for the stirrer shaft; one for the thermometer-heater, E (this tube was filled with paraffin to keep the wires in thermal contact with the tube), and two for the sample tube. These tubes were made long to make sure that all heat leaking into the calorimeter through the various shafts and wires would be from the temperature of the outside bath.

The device for admitting the sample was constructed as follows: A glass tube, C, 5 cm. long and 1.5 cm. outside diameter was ground flat on both ends. A piece of thin gold foil was fastened over one end with paraffin. The sample was then weighed into the tube, after which the other end was sealed with gold foil. This tube was then fastened with adhesive tape and paraffin to one end of a glass rod which passes through one of the tubes in the upper framework of the calorimeter. In placing the dewar flask on the apparatus, the sample tube could be turned under the stirrer to pass the neck of the flask, then turned out and drawn up to its place beside the resistance thermometer. A pointed glass rod, D, passed through the other tube in the upper part of the apparatus and was held so that its point was about a millimeter directly above the sample tube. When it was desired to dissolve the sample, this glass rod was pushed through both pieces of gold foil, then pulled back to its original position.

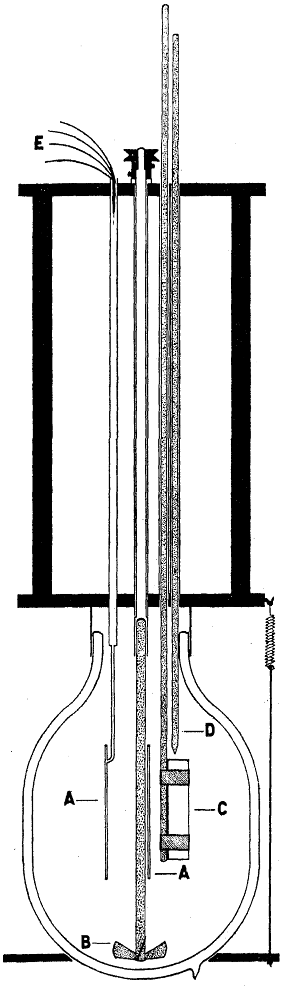

Fig. 4.—Calorimeter used for heat of solution measurements.

Resistance thermometer measurements were made with a Müller type Wheatstone bridge with a galvanometer of high sensitivity. When the bridge was in balance the current through the resistance thermometer was about 3 m. a. The small amount of heat resulting from the thermometer current was included in the "heat of stirring" correction. The stirrer was driven at constant speed to ensure constancy of this correction factor. The energy used for determining the heat capacity of the calorimeter was supplied by storage cells. The energy measurements were made with a Leeds and Northrup type K potentiometer.

The heat of solution measurements were arranged so that the various concentrations and amounts were the same in the final solution of every experiment. This solution was obtained by adding 5.0000 g. of magnesium hydroxide to 900 cc. of 1.0000 *N* hydrochloric acid. 1.461 g. of water was added to the acid solution before the magnesium oxide measurements.

The thermostat surrounding the calorimeter was kept at about 25°C. and the temperature was recorded to 0.001°. The experiments were arranged so that the bath temperature was midway between the initial and final calorimeter temperatures. Perhaps it would have been preferable to keep the calorimeter temperature always below that of the thermostat to eliminate any possibility of distillation heat effects. However, it may be shown that there was practically no tendency for distillation to occur in the present case. The affinity of water for hydrogen chloride is so great that it approximates the properties of a non-volatile solute in dilute solution. The vapor pressure of water over 1 *M* hydrochloric acid is sufficiently below that of pure water so that the solution must be about 0.7° above the thermostat temperature before a practicable mechanism for distillation becomes possible.

The correction for heat interchange with the surroundings was made graphically and it was assumed that the thermal leakage was at every instant proportional to the temperature difference between the bath and the calorimeter. The validity of this assumption for the present apparatus and conditions was carefully checked experimentally. Temperature readings were taken at minute intervals during the reaction period and the reaction was considered complete only when the observed rate of temperature change agreed with the value calculated from the known thermal head and the "heat of stirring." The oxide dissolved much more readily than the hydroxide and consequently the runs were shorter. The magnitude of the total heat corrections was about 1% of the heat of solution.

Several heat capacity determinations were made after each heat of solution experiment. These measurements were made with approximately the same temperature increase as that during solution and were made both at lower and higher temperatures so a good interpolated value could be obtained.

The 0.15% (0.22 mole %) potassium impurity is sufficient to require some consideration concerning its possible effect on the results. It may safely be assumed that it was present as potassium hydroxide and it would remain as potassium hydroxide when magnesium oxide was formed from the hydroxide. By coincidence, not only are the molecular weights of potassium and magnesium hydroxides nearly the same but their molal heats of solution are the same within a fraction of a per cent. Thus no appreciable error would have been introduced by ignoring the presence of the potassium hydroxide in the pure magnesium hydroxide, or by counting it as magnesium hydroxide in the magnesium oxide. The heat of solution of magnesium hydroxide to be given later was obtained by making the above assumption. However, in determining the heat of dehydration of magnesium hydroxide we made the better assumption that the heat of solution of the potassium hydroxide would cancel in obtaining the difference of the two experimental values. The experimental values are given in Table IV.

TABLE IV

HEATS OF SOLUTION OF "$Mg(OH)_2$" AND "MgO" IN *M* HCl AT 25°C.

5.0000 g. "$Mg(OH)_2$" = 0.085526 mole $Mg(OH)_2$ + 0.000192 mole KOH. 3.5386 g. "MgO" = 0.081119 mole MgO + 0.004407 mole $Mg(OH)_2$ + 0.000192 mole KOH. Molecular weights: $Mg(OH)_2$ = 58.336, MgO = 40.32.

Experiment	"$Mg(OH)_2$"	"MgO"
1	2294.2	3084.1
2	2293.5	3082.4
3	2294.7	3085.5
Mean	2294.1	3083.8

From Table IV it is found that the dehydration of 0.081119 mole of magnesium hydroxide requires 3083.8 − 2294.1 = 789.7 cal. The corresponding value is 9735 cal./mole of magnesium hydroxide. From the data of Rossini[16] we estimate that the

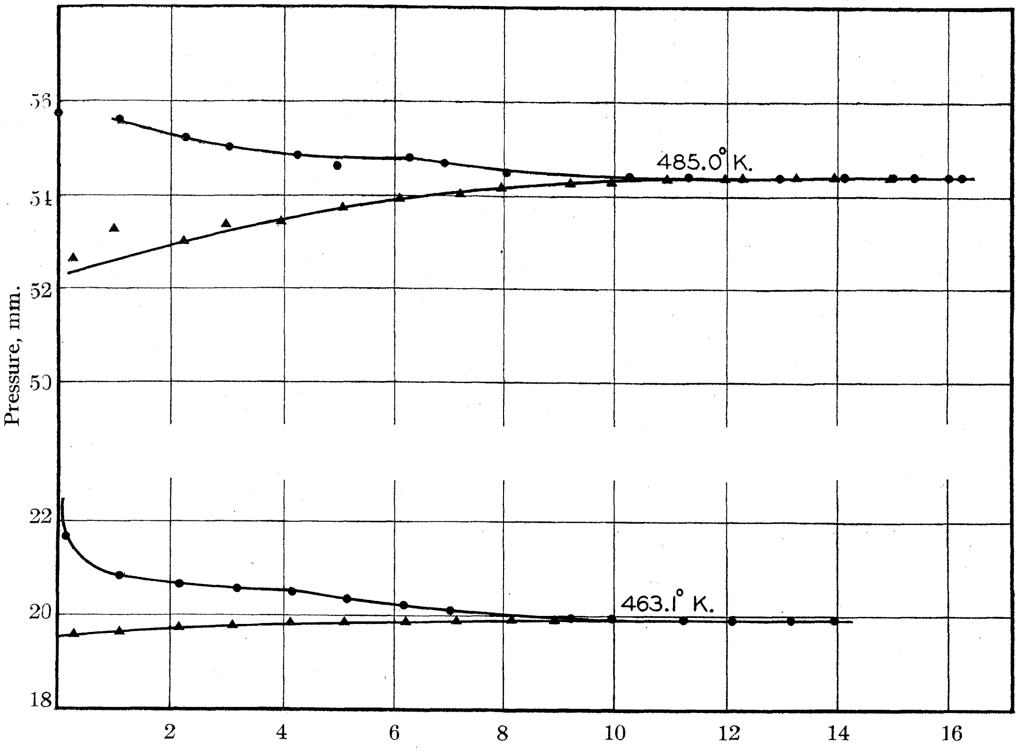

Fig. 5.—The dissociation pressure, showing the approach to equilibrium.

partial molal heat content of water in the final calorimetric solution is 4 cal. less than that of pure water. Applying this correction

$$Mg(OH)_2 = MgO + H_2O(l) \quad \Delta H_{298.1} = 9739 \text{ cal.}$$

Also

$$Mg(OH)_2 + 10{,}500 \text{ cc. } M \text{ HCl} = \text{Solution} + 26{,}763 \text{ cal.}$$
$$MgO + 1 \text{ mole } H_2O \text{ in } 10{,}500 \text{ cc. } M \text{ HCl} = \text{Solution} + 36{,}498 \text{ cal.}$$

The Dissociation Pressure of Magnesium Hydroxide.—The apparatus used to measure the dissociation pressure of magnesium hydroxide was a manometer, of 1.5-cm. inside diameter glass tubing, with a bulb on one side containing a mixture of magnesium hydroxide and magnesium oxide. The other side of the manometer was connected through a mercury U-trap to a high vacuum system. The manometer, sample bulb and U-trap were kept in a stirred air thermostat which could be kept constant to 0.1° at any temperature up to 220°C.

Both sides of the manometer and the sample were pumped, by means of a mercury diffusion pump with a liquid air trap in the line. The sample and line were at a temperature of about 200°C. during the evacuation. The sample bulb side was then sealed off. The mercury could be run up in the U-trap thus allowing the vapor pressure of mercury on the vacuum side of the manometer to balance that on the bulb side. The U-trap also served to prevent distillation of the mercury from the manometer to the vacuum line outside the thermostat. This is an important consideration in cases such as the present one where the rate of change of pressure due to volume change on the bulb side, because of loss of mercury, would have been of the same order as the rate of change during approach to equilibrium. The difference in height of the mercury menisci was read through a plate glass window by means of a cathetometer accurate to a few hundredths of a mm.

Equilibrium pressures were obtained at 463.1 and 485.0°K. In each case the equilibrium was approached from both higher and lower temperatures. Table V gives the pressures measured during the approach to equilibrium. Each observation given is an average of several measurements. The individual readings did not vary more than 0.1 mm. from the average. The pressures are given in international cm. of mercury. In correcting the observations the density of mercury was taken from the "I. C. T."[17] The standard acceleration of gravity was taken as 980.665 cm./sec.^{2}. The gravitational acceleration at this location has been determined by Sternwarte[18] as 979.973 cm./sec.^{2}. The data are represented graphically in Fig. 5.

The first flat portion in the curves approaching equilibrium from high pressures is attributable to adsorption. That this might easily have been mistaken for true equilibrium is shown by the following experiment. During some preliminary measurements the apparatus was cooled while the approach to equilibrium was in the adsorption stage. On return to the original temperature there was a return to the false equilibrium value and later a decrease to

the true equilibrium pressure. It is quite evident that approach to the same pressure from each side of an equilibrium is not a sufficient criterion of true equilibrium. The effect is so insidious that we have little doubt that many such errors have occurred in the study of equilibria. A case in point are the previous data[19] on the dissociation pressure of magnesium hydroxide. These measurements are so badly in error that we were led to believe that the dissociation pressure could be measured conveniently at temperatures obtainable with a water thermostat and we set up such an apparatus. It soon became clear that the dissociation pressure measurements of Johnston over the system magnesium hydroxide and magnesium oxide were in reality adsorption pressures and calculation of the heat of reaction from the data showed a value of the same order as the heat of vaporization of water.

Thermodynamic Treatment of the Data.—Various thermodynamics quantities of interest to the experiment are tabulated in Table VI. They were obtained from data relating to the reactions

$$Mg(OH)_2 = MgO + H_2O(l) \qquad (2)$$

$$H_2O(l) = H_2O(g) \qquad (3)$$

$$Mg(OH)_2 = MgO + H_2O(g) \qquad (4)$$

$\Delta F^\circ = -RT \ln K$ where K is the vapor pressure (in atm.) of water in equation 3 and the dissociation pressure (in atm.) in equation 4.

$$\Delta H_T = \Delta H_{298.1} + \int_{298.1}^{T} \Delta C_p \, dT$$

$$\Delta S_T = (\Delta H - \Delta F)/T$$

$$\Delta S_{298.1} = \Delta S_T - \int_{298.1}^{T} \Delta C_p \, d \ln T$$

The heat of vaporization of water at 298.1°K., ΔH of equation 3, has been estimated as 10,499 ± 3 cal. per mole by Giauque and Stout[2] after a consideration of the very accurate available data which have been reviewed by Fiock.[20]

Thermodynamic quantities including the heat content and entropy of gaseous water have been calculated from spectroscopic data by Gordon[21] and these values were used where necessary. However, corrections for the rotational deformation of the water molecule were applied to Gordon's values in accordance with the calculations of Wilson.[22]

The entropies of magnesium hydroxide and oxide were obtained from the third law of thermodynamics by graphical integration of the heat capacity data

$$S = \int_0^T C_p \, d \ln T$$

Since the heat capacity of magnesium hydroxide was extrapolated for about 150° above the last measurement, at 320°K., the probable error due to this assumption requires comment. While we believe the extrapolation is reliable, we wish to point out that considerable error in the assumed values would produce little effect in the final result. For example let us consider the effect of an error of one calorie per degree in the assumed heat capacity at 475°K. The curve at 320°K. gives direction as well as value to the curve above that temperature, thus a reasonable type of deviation would be given by a proportionality to the square of the temperature difference above 320°K. Since the same heat capacity values are used for calculating differences in heat content and in entropy the effect of an error in the assumed heat capacity values largely cancels. It may be shown that a deviation of the above type will increase the derived entropy of water by approximately 0.01 cal./deg. per mole for each increase of one calorie per degree in the

heat capacity of magnesium hydroxide at 475°K. Thus error introduced by the extrapolation can be estimated at not more than a few hundredths of an entropy unit.

The experimental entropy value given for 298.1°K. was calculated from an average of the measurements at 463.1 and 485.0°K.

As may be seen from the comparisons in the last two columns of Table VI the third law values of the entropy of water are in excellent agreement with those calculated from the band spectrum data.

We thank Dr. Roy Overstreet for analyzing the magnesium hydroxide used in the above experiments.

Summary

The heat capacities of magnesium oxide and magnesium hydroxide have been measured from 20 to 300°K. and 20 to 320°K., respectively.

Evidence has been presented to show that the low temperature heat capacity of magnesium oxide prepared by the decomposition of magnesium hydroxide at 300–350°C. is definitely greater than the heat capacity of crystalline material prepared from the fused oxide.

The dissociation pressure of the system $Mg(OH)_2$, MgO has been measured accurately at 463.1 and 485.0°K. The pressures found were 1.991 and 5.439 international cm., respectively.

During the dissociation measurements it was found that an approach to the equilibrium from the high temperature side was at first accompanied by a slowly obtained false equilibrium pressure due to surface adsorption of the water. If the substance was cooled at this stage it was possible to approach the same false equilibrium from the low temperature side. It is evident that this usual experimental criterion for true equilibrium in such cases is by no means a safe one.

It is suggested that dissociation equilibria should be first approached from the low temperature side. Subsequent attainment of the same value from the high temperature direction may be taken as substantial evidence of true equilibrium.

The heat of solution of one mole of magnesium hydroxide in 10,500 cc. of molal hydrochloric acid was found to be 26,763 calories at 25°C.

The heat of solution of one mole of magnesium oxide in 10,500 cc. of molal hydrochloric acid +1 mole of water was found to be 36,498 calories at 25°C.

These measurements when corrected for the partial molal heat content of water in the solution lead to a value of $\Delta H_{298.1°\text{K.}} = 9738$ cal. for the dissociation of one mole of magnesium hydroxide to give magnesium oxide and pure liquid water.

The above data have been used with the third law of thermodynamics to calculate the molal entropy of gaseous water at 485.0, 463.1 and 298.1°K. The values obtained are 49.11, 48.65 and 45.10 cal./deg., respectively.

These may be compared with values obtained with the assistance of the band spectrum data for water. The values for corresponding temperatures are 49.10, 48.72 and 45.13 cal./deg., respectively.

The excellent agreement constitutes one of the best pieces of evidence in support of the third law of thermodynamics and of the results of quantum statistics.

The free energy for the dissociation of magnesium hydroxide is

$$Mg(OH)_2 = MgO + H_2O(g) \quad \Delta F_{298.1°\text{K.}} = 9297 \text{ cal./mole.}$$

Double Compounds of Urea with Magnesium Nitrate and Magnesium Sulfate

BY J. Y. YEE, R. O. E. DAVIS AND S. B. HENDRICKS

In the course of an investigation of new fertilizer materials several new double compounds of urea with magnesium salts were obtained. Urea is quite hygroscopic at high humidities and also has the tendency to form double compounds. This tendency is sometimes a disadvantage in fertilizer mixtures, when urea displaces water of crystallization in forming a double compound with other constituents in the mixtures. Such a reaction has been attributed by Whittaker, Lundstrom and Hendricks[1] as the cause of stickiness encountered sometimes in fertilizer mixtures containing urea. The possibility was suggested that double compounds suitable for fertilizers might be obtained, which would be less hygroscopic than urea and also would not react further in mixtures to release free water from hydrated salts. A number of double compounds of urea are known, such as $Ca(NO_3)_2 \cdot 4CO(NH_2)_2$, $CaSO_4 \cdot 4CO(NH_2)_2$;[1] $SrBr_2 \cdot CO(NH_2)_2$,[2] etc.; and in some cases these render the urea in combination less hygroscopic.

The compound $MgSO_4 \cdot CO(NH_2)_2 \cdot 3H_2O$ has been reported recently by Whittaker, Lundstrom and Shimp[3] of this Laboratory, in their study of the system magnesium sulfate–urea–water at 30°. This was formed from water solution while the sulfate compounds reported here were formed from alcoholic solution. In treating magnesium salts with urea in this manner three new double compounds were prepared and because of their high urea content, they were considered a potential source of nitrogen in fertilizers.

Preparation of New Double Compounds

The chemical compositions and the crystal properties of the new double compounds have been studied, but their physical condition and behavior in mixed fertilizer are still under investigation. One of these double compounds is a combination of urea and magnesium nitrate and the other two are of urea and sulfate in different proportions. They are represented by the formulas:

$$Mg(NO_3)_2 \cdot 4CO(NH_2)_2 \cdot 2H_2O$$
$$MgSO_4 \cdot 5CO(NH_2)_2 \cdot 2H_2O$$
$$MgSO_4 \cdot 6CO(NH_2)_2 \cdot 2H_2O$$

Double Compound, $Mg(NO_3)_2 \cdot 4CO(NH_2)_2 \cdot 2H_2O$.—The nitrate double compound was prepared from equal parts (100 g. each) of the solids magnesium nitrate hexahydrate and urea by the following procedure. At first the crystalline nitrate and urea were mixed in small amounts in ratio of about 8 to 1 in a tube maintained at about 55°. After the appearance of a liquid phase, further amounts of the two salts were added slowly with gentle stirring in about the same proportion. When all the magnesium nitrate had been added, the resulting liquid was quite clear. The remainder of the urea was then introduced gradually. After removal of the tube from the bath, fine crystals came down with stirring and were separated from the mother liquor at room temperature. About 100 g. of the product was obtained from 100 g. each of magnesium nitrate hexahydrate and urea.

Larger individual crystals of this double compound for x-ray diffraction photographs were obtained by dissolving 30 g. of magnesium nitrate hexahydrate and 40 g. of urea in 30 cc. of ethyl alcohol at 40°. On standing at 20° well-formed crystals of $Mg(NO_3)_2 \cdot 4CO(NH_2)_2 \cdot 2H_2O$ were obtained.

Double Compound, $MgSO_4 \cdot 5CO(NH_2)_2 \cdot 2H_2O$.—This compound was obtained as individual orthorhombic crystals from methyl alcohol solution. One gram of powdered magnesium sulfate heptahydrate was dissolved in 20 cc. of methyl alcohol in a crystallizing dish (9 cm. in diameter). To this solution, 2.5 g. of finely powdered urea was added. On gently stirring the solution, or by slowly rotating the dish, the urea was dissolved completely. With the dish tightly covered to prevent evaporation of the alcohol, clear crystals of the compound formed on standing at 30°.

Double Compound, $MgSO_4 \cdot 6CO(NH_2)_2 \cdot 2H_2O$.—This compound, when prepared from absolute methyl alcohol solution, formed polycrystalline masses with clear clusters of crystals. Clear, individual crystals, however, were prepared from 95% methyl alcohol solution. Two grams of powdered magnesium sulfate heptahydrate was dissolved in 25 cc. of 95% methyl alcohol in a crystallizing dish (9 cm. in diameter). To this was added 4 g. of powdered urea. On gently stirring the solution, or rotating the dish, the urea was dissolved completely. With the dish tightly covered, individual crystals formed on standing at room temperature, about 25°.

The similarity of conditions for formation of the two magnesium sulfate–urea compounds is quite striking, but the concentrations of solutions are different in the two cases. At the particular ratio of the salts used in preparing the six urea compound, individual crystals were obtained from 95% methyl alcohol, while polycrystalline masses only were obtained from absolute methyl alcohol.

Examination of the Compounds.—Chemical analyses were made and x-ray and optical properties were determined for the three compounds. The molecular weights of all three compounds, derived from the x-ray diffraction data, are in positive agreement with the values calculated from the chemical analyses. It is of interest to note that

the densities obtained for $Mg(NO_3)_2{\cdot}4CO(NH_2)_2{\cdot}2H_2O$ and $MgSO_4{\cdot}5CO(NH_2)_2{\cdot}2H_2O$ are identical within the limits of experimental error. Analyses for urea by the Yee and Davis urease method[4] and for magnesium by the magnesium ammonium phosphate method gave results checking consistently with calculated values for the three compounds. Some of the results are shown in Table I.

TABLE I

	β	1.539	1.533	1.508
	γ	1.595	1.551	1.520
Density		1.596	1.596	1.458

Refractive indices were measured by the immersion method. x-Ray powder diffraction photographs, rotating crystal and equatorial zone Weissenberg photographs, about the crystallographic axes, were obtained for the three compounds; CuK radiation being used. Densities were determined by the Retger suspension method. None of the compounds is piezoelectric.

Since there are only two $Mg(NO_3)_2{\cdot}4CO(NH_2)_2{\cdot}2H_2O$ in the monoclinic prismatic unit of structure, it follows that the magnesium atoms must be in unique positions. In the space group $P2_1/n$ they are at symmetry centers about which the urea and water molecules are repeated. It thus is probable that the four oxygen ends of the urea molecules and the two water molecules are grouped around magnesium at the corners of an octahedron, giving magnesium a coördination number of six. The plane of the optic axes is (010) with the acute bisectrix 50° from the a axis and the low value of α suggests that the direction of vibration is approximately normal both to the planes of the nitrate and urea group, which planes would thus be parallel.

The space group of $MgSO_4{\cdot}5CO(NH_2)_2{\cdot}2H_2O$ requires the sulfate groups to be on symmetry planes which also contain one and possibly three urea molecules. It cannot be said whether $5CO(NH_2)_2$ and $2H_2O$ have their oxygen ends toward Mg or whether only $4CO(NH_2)_2{\cdot}2H_2O$ are so arranged. The birefringence of this compound is very low compared with that of the nitrate. This is also true of $MgSO_4{\cdot}6CO(NH_2)_2{\cdot}2H_2O$, which in addition must have a very complex structure as indicated by the large number of formula weights in the unit.

The authors wish to express their thanks to M. E. Jefferson of this Laboratory for making the refractive index measurements.

Summary

Three new double compounds of urea with magnesium salts have been prepared, and the methods of preparation described.

Two of the compounds are with magnesium sulfate and one with magnesium nitrate. Their compositions are represented by the formulas $MgSO_4{\cdot}5CO(NH_2)_2{\cdot}2H_2O$, $MgSO_4{\cdot}6CO(NH_2)_2{\cdot}2H_2O$ and $Mg(NO_3)_2{\cdot}4CO(NH_2)_2{\cdot}2H_2O$; and they contain 65.7, 69.7 and 56.5% of urea, respectively. The first two contain more urea than any of the previously known double salts.

x-Ray and optical examinations have been made of the compounds and the properties have been given. From x-ray diffraction data the molecular weights of the compounds have been calculated and found to agree closely with those derived from the chemical analyses.

Their physical properties and behavior when mixed in fertilizers have not yet been determined.

Relative Acid Strengths in Normal Butyl Alcohol[1]

BY R. BURGESS MASON AND MARTIN KILPATRICK

The study of acid strengths in non-aqueous solvents has necessitated a more critical use of the colorimetric method. This paper is a report of the use of a photoelectric colorimeter in the determination of acid strengths in the basic solvent *n*-butyl alcohol. A recent report of relative strengths of acids in this solvent by an electrometric method affords a basis for comparison of the two methods.[2]

Indicators behave just as do other acids and bases and the protolysis constant for the transfer of a proton from the acid A to the basic form of the indicator I_B to give the acid form of the indicator I_A and the base B is written

$$K_{A_1I_B} = C_{B_1}C_{I_A}/C_{A_1}C_{I_B} \qquad (1)$$

For the reverse reaction we would have $K_{I_AB_1}$ as the acid is written first.

The concentration of the acid or basic form of the indicator can be determined colorimetrically and $K_{A_1I_B}$ computed from the stoichiometric concentrations. From the protolytic constants with indicators the classical dissociation constants or the protolytic constants of a series of acids referred to a common base (in this case the solvent) can be obtained.

Upon addition of hydrogen chloride to the weak base normal butyl alcohol the reaction

$$\mathrm{HCl} + \mathrm{ROH} \longrightarrow \mathrm{ROH{\cdot}H^+} + \mathrm{Cl^-} \qquad (2)$$

probably goes practically to completion and we can take the concentration of $\mathrm{ROH{\cdot}H^+}$ as equal to the stoichiometric concentration of the hydrochloric acid. This assumption is in agreement with the results of catalytic studies by Brönsted and Vance[3] who show that both hydrochloric and hydrobromic acids are probably practically completely dissociated in isoamyl alcohol. The reaction with the indicator base is

$$\mathrm{ROH{\cdot}H^+} + \mathrm{I_B} \rightleftarrows \mathrm{ROH} + \mathrm{I_A} \qquad (3)$$

for which the protolysis constant is

$$K'_{(\mathrm{ROH\cdot H^+})\mathrm{I_B}} = C_{\mathrm{ROH}}C_{\mathrm{I_A}}/C_{(\mathrm{ROH\cdot H^+})}C_{\mathrm{I_B}} \qquad (4)$$

Now, since the concentration of the solvent is practically constant, this equation becomes

$$K_{(\mathrm{ROH\cdot H^+})\mathrm{I_B}} = C_{\mathrm{I_A}}C_{\mathrm{I_B}}C_{\mathrm{ROH\cdot H^+}} \qquad (5)$$

It follows from (1) and (5) that the protolysis constant of any acid and the solvent *n*-butyl alcohol may be expressed by the equation

$$K_{\mathrm{A(ROH)}} = \frac{K_{\mathrm{AI_B}}}{K_{(\mathrm{ROH\cdot H^+})\mathrm{I_B}}} = \frac{C_{\mathrm{B}}C_{\mathrm{I_A}}}{C_{\mathrm{A}}C_{\mathrm{I_B}}}\,\frac{C_{\mathrm{I_B}}C_{\mathrm{ROH\cdot H^+}}}{C_{\mathrm{I_A}}} = \frac{C_{\mathrm{B}}C_{\mathrm{ROH\cdot H^+}}}{C_{\mathrm{A}}} \qquad (6)$$

If an indicator is very sensitive to acids it is impossible to determine $K_{(\mathrm{ROH\cdot H^+})\mathrm{I_B}}$ with accuracy, and if the indicator is not very sensitive to acids it is equally impossible to determine $K_{\mathrm{AI_B}}$ with precision if the acid is weak. This difficulty is overcome by a stepwise procedure. $K_{\mathrm{A(ROH)}}$ can be determined for an acid with an indicator which is fairly insensitive to acids. With this value another indicator more sensitive toward acids is used and $K_{(\mathrm{ROH\cdot H^+})\mathrm{I_B}}$ for this second indicator is found, and now with another acid, A_1, and this same indicator, $K_{\mathrm{A_1(ROH)}}$ is computed from the experimentally determined $K_{\mathrm{A_1I_B}}$. A continuation of this stepwise procedure makes possible the evaluation of acidity constants that could not be reached by direct measurement.

Experimental Procedure

All colorimetric determinations of acid strength were carried out by measuring the concentration of a colored form of the indicator and then by substitution in equation (1), $K_{\mathrm{AI_B}}$ was found. With $K_{(\mathrm{ROH\cdot H^+})\mathrm{I_B}}$ determined by means of previous measurements, $K_{\mathrm{A(ROH)}}$ was evaluated.

The colorimetric determinations were based directly upon Beer's law, which states that the light transmitted by a solution is an exponential function of the thickness of the solution and of the concentration of the light-absorbing molecules. This expressed mathematically is

$$I_{\mathrm{T}} = I_0e^{-kcx} \qquad (7)$$

where I_{T} is the transmitted light, I_0 the incident light, e the natural base of logarithms, k a constant, c the concentration of the light-absorbing molecules and x the thickness of the solution through which the light traveled. Here it should be emphasized that this equation is applicable for light of one and only one wave length. The extinction coefficient k has a definite value for each particular wave length and if any agreement with Beer's law is to be expected, which in turn means great accuracy for the determinations, only monochromatic light should be used.

In order to have the readings free from personal error a photoelectric colorimeter was constructed. Approximately monochromatic light was obtained by passing light from an automobile head lamp, operated by a six-volt

storage battery, through a Hilger constant deviation spectroscope. This source was used in preference to a lamp operating on the a. c. line because its intensity was more constant, since Partridge[4] has shown that one of the greatest limitations of the photoelectric cell is the variable voltage of the light source. He states that the intensity of a tungsten filament lamp is

$$I = kv^{3.6}$$

where I is the intensity, k a constant and v the voltage across the lamp. This equation shows that a large change in light intensity results from a small change in voltage, which means a large variation in the photoelectric current also.

The prism was on a turntable and by turning a calibrated drum a beam of light of any wave length could be obtained. The prism was first adjusted at 5890 and 6705 Å. by means of sodium and lithium flames. The light obtained from the incandescent bulb was approximately monochromatic (covering a range of 30 Å. units) after resolution by the prism.

The light from the spectrometer passed through the solution cell to the photoelectric cell, and as shown in Fig. 1 photoelectric currents were amplified by means of the amplifier of Razek and Mulder.[5] The solution cell was a quartz cell with clear quartz end-plates which were not sealed to the cylindrical part of the cell but were ground to fit. By means of an outer metal jacket the end-plates were held in place making a liquid-tight container. It was possible to have varying lengths of cell simply by removing an end-plate and attaching an extension to a 2-cm. tube. The extension had a concave grind at one end, a convex at the other and the concave grind fitted into the convex grind at the end-plate, the convex into the concave grind of the 2-cm. cell. With extensions it was possible to obtain cell lengths of 2, 4, 6, 8 and 10 cm. Most of the work, however, was carried out in the 2-cm. section.

Two types of photoelectric cells were used, a potassium hydride which is sensitive in the blue portion of the spectrum, and a cesium cell which has its maximum sensitivity in the longer wave lengths of the spectrum. These cells were housed in a copper box and were so arranged that the cesium cell could be used for yellow or red light and the potassium hydride cell for blue light. Neither of these cells shows much response to green light.

The apparatus was balanced by adjusting P_1 and P_2 so that the milliammeters would read the same (5 or 6 m. a.), and with the galvanometer fully protected by the galvanometer shunt R_G the switch was closed. Now by gradually increasing R_G more current flowed through the galvanometer causing a deflection. When this took place the plate currents of the two tubes were not the same but were brought into better adjustment by the variable resistance R′, and for very fine balance the variable resistance R was employed. The apparatus balanced by this means did not remain so unless the filament voltages of the two tubes were compensated, which was brought about by fixing the settings of the resistors at P_7 and P_8 and by finding the points where a small change in the setting of P_9 would result in no change of the galvanometer reading. With the apparatus thus balanced and adjusted it was ready for use. When the photoelectric voltage was superimposed on the grid of one tube, the galvanometer showed a deflection which was proportional to the photoelectric current which in turn was proportional to the intensity of the light striking the photoelectric cell. Although the galvanometer readings were only relative and not absolute measurements of the light intensity, nevertheless these deflections could be used to obtain the concentrations of the colored forms of the indicators, as will now be shown. Equation (7) may be put into the form

$$\log I_T = \log I_0 - (kcx/2.3) \qquad (8)$$

If Beer's law is obeyed the logarithm of the intensity of the transmitted light will be found to be a linear function of c, the concentration of the light-absorbing substance. The slope of the line is $-kx/2.3$. Since the galvanometer readings are proportional to the intensity of the light striking the photoelectric cell, galvanometer readings may be plotted as ordinates in place of I_T.

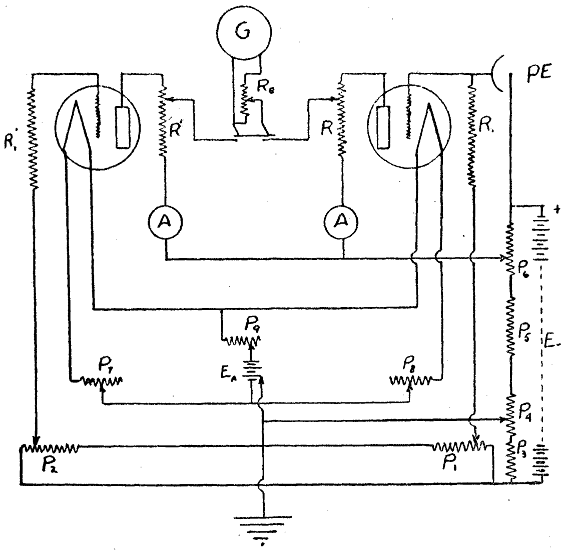

Fig. 1.—Electric circuit, meaning of symbols: A, milliammeters (10-m. a. range); G, Leeds and Northrup type R galvanometer No. 2500e; R_G, variable resistor, 1500 ohms; R_1, resistor, 100 megohms; R_1', resistor, 100 megohms; R, resistor, total of 1030 ohms (1000 ohms with variable portion of 30 ohms); R′, resistor, total of 1100 ohms (850 ohms with variable portion of 250 ohms); P_1 and P_2, potentiometers, 3000 ohms each; P_3, potential divider, 1500 ohms; P_4, potential divider, 1500 ohms; P_5, potential divider, 7000 ohms; P_6, potential divider, 3000 ohms; P_7 and P_8, variable resistors, 6 ohms each; P_9, variable resistor, 1 ohm; E_A, filament battery (6-volt storage); E_T, six 45-volt B batteries connected with two series of three in parallel; Cunningham 112A vacuum tubes were used.

The experimental procedure consisted of making one form of the indicator at various concentrations, which was done by preparing indicator solutions of the desired concentration and then adding a sufficient quantity of acid or base to produce the completely acidic or basic form of the

indicator. The necessary amount of acid or base was determined experimentally, that is, acid or base was added to the indicator solution until an additional amount caused no change in the galvanometer reading. The basic forms of brom phenol blue and brom cresol green were solutions of their lithium salts, while the basic form of picric acid was prepared by the addition of lithium butylate until an increase of one drop caused no color change in the solution. The basic forms of brom cresol green, brom phenol blue and picric acid were used and the acidic forms of dimethyl yellow and benzene-azodiphenylamine. Different amounts of the colored form of each of these indicators were put into the solution cell, light passed through and the galvanometer read. The logarithms of these readings plotted against the concentration, lay on a straight line as required by Beer's law. From such curves the concentration of the colored form of the indicator in an unknown solution, corresponding to a given galvanometer deflection, could be read off. Owing, however, to the fact that it was difficult to keep the amplifier balanced over a long period of time, our practice was to construct a calibration curve of two points only at the time of the colorimetric analysis of the unknown solution. With experience it was possible to locate one of these points on each side of the unknown solution.

Beer's law as expressed in equation (7) is applicable only when the light-absorbing molecules are identical. For indicators presenting one color there are no obstacles to be met because the light-absorbing molecules are all the same and colored light which is preferentially absorbed may be used. For example, the fact that picric acid solutions are yellow means that the light absorption is greater in the violet range of the spectrum. In this work a blue light of 4600 Å. was employed for picric acid solutions because of the deficiency of violet light in the source. Although with a two-color indicator there are two kinds of light-absorbing molecules, it is sometimes possible to find a wave length at which only one form of the indicator absorbs light. The yellow forms of dimethyl yellow and benzene-azodiphenylamine absorb negligible amounts of light at 5900 Å. wave length while their red forms absorb a fair amount. By using light of 5900 Å. wave length, it was possible to treat these indicators like one-color indicators. The use of light of 5750 Å. made the same procedure possible in the case of brom phenol blue (yellow-blue).

With brom cresol green it was not possible to find a wave length at which one form of the indicator absorbed no light. While there was a minimum absorption at 5800 Å. by the yellow form, it was nevertheless appreciable. In this case Beer's law has the form

$$I_{\mathrm{T}} = I_0 e^{-k_{\mathrm{A}} c_{\mathrm{A}} x} e^{-k_{\mathrm{B}} c_{\mathrm{B}} x} \qquad (9)$$

where k_{A} is the extinction coefficient and c_{A} the concentration of the acid form and k_{B} and c_{B} the extinction coefficient and concentration, respectively, of the basic form.

The procedure with brom cresol green was as follows. The extinction coefficient of the indicator wholly in its acid form, k_{A}, was obtained by measurement of the intensity of the light transmitted by solutions of concentrations c_1 and c_2. From (8) it follows that

$$k_{\mathrm{A}} = \frac{2.3}{(c_2 - c_1)x} \log \frac{I_{\mathrm{T}_1}}{I_{\mathrm{T}_2}} \qquad (10)$$

Table I shows the extinction coefficient of the acid form of brom cresol green at 5800 Å.

Table I

Extinction Coefficient of Yellow Form of Brom Cresol Green at 5800 Å.

Cell length = 10 cm.

2.918	17.0	630
5.836	14.5	600
14.59	8.5	610
	Mean k =	617

An approximate value of the concentration of the basic form in the unknown solution was found in the customary manner. The corresponding approximate concentration of the acid form was then obtained by difference and $e^{-k_{\mathrm{A}} c_{\mathrm{A}} x}$ was computed. Dividing the galvanometer reading by $e^{-k_{\mathrm{A}} c_{\mathrm{A}} x}$ gave a corrected intensity, I'_{T}, from which a more reliable value of c_{B} was computed.

Tables II, III and IV illustrate how the calculations for *o*-toluic acid with brom cresol green were carried out.

Table II

Galvanometer Readings for *o*-Toluic Acid

Unknowns		Comparison standards		
Flask	I_{T}	Flask	I_{T}	$c_{\mathrm{IB}} \times 10^5$

$c_{\mathrm{IA}} \times 10^5$	1.18	1.20	1.19

The concentration of the indicator was comparable to that of the buffered solution of the acid, so in calculating the acid strength constants a correction had to be made for the acid that was used to convert the indicator. That is to say, the acid was added to the basic form of the indicator and the concentration of the undissociated acid became the original acid concentration minus the concentration of the acid form of the indicator, while the concentration of the *o*-toluate ion increased the concentration of the acid form of the indicator. The values of the protolysis constant for *o*-toluic acid and the basic form of brom cresol green are given in Table IV.

Mean K_{AI_B}			.520

Brom cresol green was the only indicator with which it was necessary to make a correction because of absorption of light by both acid and basic forms. With the other two-color indicators it was possible to find a wave length at which absorption by one form was negligible.

As was previously mentioned, the method of determining the protolysis of the indicators least sensitive to acids was to add a definite amount of hydrochloric acid and then measure the change in color of the indicator. This procedure was followed with dimethyl yellow, but since benzeneazodiphenylamine hydrochloride could be prepared pure, the hydrochloride was added to the solution in this case.

Preparation of Materials.—The *n*-butyl alcohol was purified by treating a commercial grade of the alcohol with sulfuric acid, distilling and refluxing over sodium hydroxide. This treatment was followed by refluxing over lime and subsequent distillation in a 17-ball Snyder column.

Lithium butylate was prepared by dissolving lithium in the pure *n*-butyl alcohol in an inert atmosphere. The solution was standardized against Bureau of Standards benzoic acid.

Lithium Chloride.—Our original plan included the study of the effect of ionic strength on the acid strength constants and a few measurements were carried out using fused lithium chloride. Difficulties with the alkalinity of the salt led us to defer that part of the work.

Acids.—Acetic acid was purified by the method of Bousfield and Lowry.[6] Monochloroacetic acid was twice crystallized from benzene, dichloroacetic acid was fractionally distilled. Picric acid was recrystallized from an aqueous solution of hydrochloric acid. The *o*-chlorobenzoic acid was purified in connection with solubility studies of Osol and Kilpatrick.[7] The other acids were Kahlbaum products which upon drying were found, by titration with standard base, to be sufficiently pure.

Bases.—The hydrochlorides of ethylamine, piperidine and aniline were dried *in vacuo* over sulfuric acid for a period of four weeks and used without further purification. Each of these was a Kahlbaum product.

Indicators.—The indicators brom cresol green and brom phenol blue were purified samples used in connection with other studies.[8] The lithium salts were prepared by adding two equivalents of lithium ethoxide to the acid dissolved in ethyl alcohol and evaporating to dryness.

The dimethylaminoazobenzene was purified by recrystallization from an alcoholic solution. The purified product melted at 117°. The benzeneazodiphenylamine was recrystallized from alcohol until the product had a melting point of 82°. The hydrochloride was prepared by the method of Witt, that is, the free base was dissolved in benzene and the hydrochloride precipitated by passing dry hydrogen chloride into the solution.[9]

Experimental Results

The experimental results are given in Tables V, VI, VII, VIII and IX, and summarized in Table

The accuracy of the results obtained depends upon the accuracy of the composition of the solutions, upon the validity of Beer's law, and upon the constant amplification of the photoelectric current. It will be noted that with the corresponding lithium salt, no deviations greater than ±2% were obtained. In other cases the deviations ran as high as 6%. To ensure constant amplification of the photoelectric current, a new calibration curve was made at the time each unknown solution was analyzed. By means of equation (6) the values of the dissociation constants were found. With dimethyl yellow as indicator K_{AI_B} was determined for four acids including the solvated hydrogen ion. From these data $K_{A(ROH)}$ was obtained for each of these acids. With $K_{A(ROH)}$ for dichloroacetic acid $K_{(ROH)I_B}$ was found from brom phenol blue and continuing in this manner $K_{A(ROH)}$ for each acid in the table was found. It is to be noted that $K_{A(ROH)}$ for an indicator is $K_{I_A(ROH)}$ which is the reciprocal of $K_{(\mathrm{ROH \cdot H^+})\mathrm{I_B}}$. The values of $K_{\mathrm{A(ROH)}}$ are summarized in Table XI; their logarithms and the logarithms of the corresponding dissociation constants in aqueous solution are also given.

[k] Hammett and Paul, THIS JOURNAL, **56,** 827 (1934).

The data of Table XI are summarized graphically in Fig. 2 in which log $K_{\mathrm{A(ROH)}}$ is plotted against log $K_{\mathrm{A(H_2O)}}$. Both lines in Fig. 2 are drawn with unit slope. In general we believe that these slopes may vary from unity.

For both types of acid, the logarithm of the dissociation constant in *n*-butyl alcohol is proportional to the logarithm of the dissociation constant in water. As in other cases the change in strength with change[10] in dielectric constant is in qualitative agreement with the theory.

Brönsted in a consideration of the effect of charge and medium on[11] the equilibrium constants of protolytic reactions arrives at the equation

$$\ln K_{\mathrm{A_1B_2}} = \ln K_{\mathrm{a_1}} + \ln K_{\mathrm{b_2}} + \frac{\epsilon^2}{2kTD}\left[\frac{2Z_{\mathrm{A_1}} - 1}{r_1} - \frac{2Z_{\mathrm{A_2}} - 1}{r_2}\right]$$

where $K_{\mathrm{A_1B_2}} = C_{\mathrm{B_1}}C_{\mathrm{A_2}}/C_{\mathrm{A_1}}C_{\mathrm{B_2}}$ is the equilibrium constant for the transfer of a proton from $\mathrm{A_1}$ to $\mathrm{B_2}$, $K_{\mathrm{a_1}}$ and $K_{\mathrm{b_2}}$ the constants $a_{\mathrm{H^+}}\,(a_{\mathrm{B_1}}/a_{\mathrm{A_1}})$ and $\frac{1}{a_{\mathrm{H^+}}}\frac{a_{\mathrm{A_2}}}{a_{\mathrm{B_2}}}$, respectively, ϵ the electronic charge, k the Boltzmann constant, T the absolute temperature, D the dielectric constant, Z the valence and r_1 and r_2 the effective radii of the first and second protolytes. If $\mathrm{A_2}$ is taken as the standard acid, $K_{\mathrm{A_1B_2}}$ becomes K_r in the symbols of Wynne-Jones.[12]

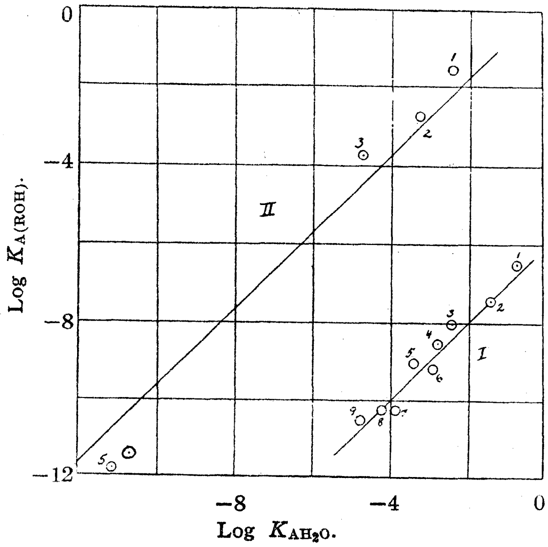

Fig. 2.—Log $K_{\mathrm{A(ROH)}}$ plotted against log $K_{\mathrm{AH_2O}}$. I. Carboxylic acids: 1, trichloroacetic acid; 2, dichloroacetic acid; 3, cyanoacetic acid; 4, monochloroacetic acid; 5, *m*-nitrobenzoic acid; 6, *o*-chlorobenzoic acid; 7, *o*-toluic acid; 8, benzoic acid; 9, acetic acid. II. Ammonium ion type acids: 1, benzene-azodiphenylammonium ion; 2, azobenzene-dimethylammonium ion; 3, anilinium ion; 4, ethylammonium ion; 5, piperidinium ion.

This author finds that if one plots the logarithm of K_r against $1/D$ for the three solvents ethyl alcohol, methyl alcohol and water the linear relationship permits an extrapolation to $D = \infty$, and an evaluation of $K_{r\infty}$ or the intrinsic acid strength. The results in the present paper are at sufficiently low ionic strengths to afford a test of the validity of this relationship.

Table XII

Log K_r for Carboxylic Acids in Various Solvents

Solvent	Water	Acetonitrile	Methyl alcohol	Ethyl alcohol	*n*-Butyl alcohol (a)	*n*-Butyl alcohol (b)	*m*-Cresol
Dielectric constant	80	37	33	25	17	17	13
Benzoic acid	0.0	0.0	0.0	0.0	0.0	0.0	0.0
Acetic acid	− .56	− .69	− .1	.0	− .19	− .05	.20
o-Toluic acid	.30	.19	...	...	.04	.02	..
m-Nitrobenzoic acid	.74	..	...	1.1	1.22	1.09	.78
o-Chlorobenzoic acid	1.28	1.09	...	1.0	1.11	1.00	..
Monochloroacetic acid	1.34	1.48	...	...	1.75	1.71	1.63
Cyanoacetic acid	1.77	..	...	...	2.23	..	2.15
Dichloroacetic acid	2.9	2.73	3.0	3.1	2.79	3.1	2.96
Trichloroacetic acid	3.50	3.88	4.3	4.4	3.77	4.1	3.88

In Table XII are listed the values of log K_r (K_r is the ratio of the dissociation constant in question to that of a benzoic acid) for a number of carboxylic acids in various solvents.

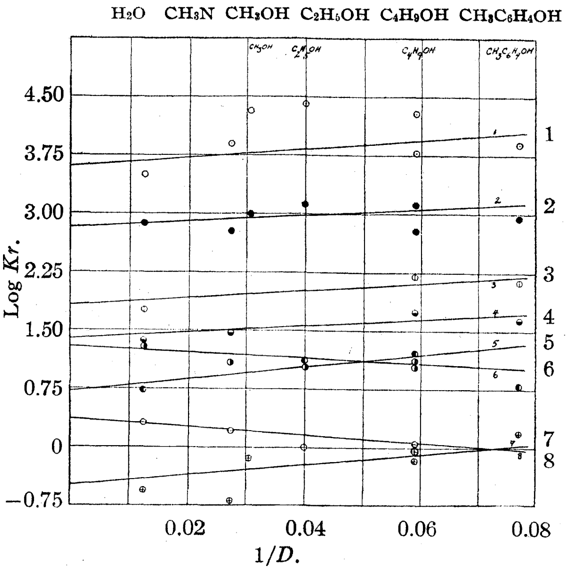

Fig. 3.—Graphic presentation of the Wynne-Jones relationship: 1, trichloroacetic acid; 2, dichloroacetic acid; 3, cyanoacetic acid; 4, monochloroacetic acid; 5, *m*-nitrobenzoic acid; 6, *o*-chlorobenzoic acid; 7, acetic acid; 8, *o*-toluic acid.

A negative value for log K_r means that the acid is weaker than benzoic acid. For aqueous solutions the K_r's were computed from the dissociation constants given in Table XI.

The values for K_r in *m*-cresol were calculated from the results of Brönsted, Delbanco and Tovborg-Jensen.[10] The source of the data for methyl and ethyl alcohol is given by Wynne-Jones. The results in acetonitrile are from the unpublished data of M. and M. L. Kilpatrick. For comparison with the results of the present study the column marked (b) under *n*-butyl alcohol gives the values from the data of Wooten and Hammett.[2] These data were obtained in the presence of 0.05 molar lithium chloride and are not strictly comparable with our data obtained at low ionic strengths. These differences are not greater than those which might be attributed to specific salt effects.

An inspection of Table XII and the graphic presentation in Fig. 3 indicates at best a qualitative agreement with the relationship of Wynne-Jones. The slopes of the lines for *o*-toluic and *o*-chlorobenzoic acid are in accord with his observations on ortho substituted acids. No correlation with the relationship was found for the ammonium type acids. Wooten and Hammett have given a different interpretation of the variation in relative strength of the carboxylic acids.

The authors would like to make due acknowledgment of a research grant made to one of us (M. K.) by the Faculty Research Committee of the University.

Summary

1. A photoelectric colorimeter has been constructed.

2. The dissociation constants of seventeen acids in *n*-butyl alcohol have been determined.

3. The results have been compared with other results in the same solvent and the acid strengths relative to benzoic acid have been compared in different solvents.

The Apparent Volumes and Thermal Expansions of Certain Salts in Glycol and Methanol

BY R. E. GIBSON AND JOHN F. KINCAID

Simple theoretical considerations which give at least a rough account of many of the thermodynamic properties of electrolytes in aqueous solutions become quite inadequate when applied to describe the magnitude or the dependence on concentration of the thermal expansions of these solutions. For example, in the vicinity of 25° it is possible to obtain moderately good values of the apparent volumes or apparent compressions of salts in water at infinite dilution merely by extrapolation of data at moderate concentrations with a formula, linear in the square root of the concentration, but it seems certain that such a procedure leads to erroneous results when applied to apparent expansions. Furthermore, different salts show large individual differences even in solutions as dilute as 0.5 molal. The results of an investigation of the apparent expansions of aqueous salt solutions[1] convinced us that the peculiar properties of water play a dominant role in determining the apparent expansions of salts in this solvent and, as a step toward elucidating this behavior, we have determined the apparent volumes and apparent thermal expansions of sodium iodide, sodium bromide and lithium bromide in glycol, of lithium bromide in methanol, and the apparent volumes of potassium iodide in glycol and of sodium iodide in methanol, with the object of comparing the results with those for the same salts in aqueous solution. Water, glycol and methanol are similar chemically, all being rich in oxygen, but their compressibilities and thermal expansions are quite different. Their specific compressions to 1000 bars are 0.03940, 0.02814 and 0.10180, respectively, at 25°. The dielectric constants at 20° of water, glycol and methanol[2] are 80.37, 38.66 and 32.35, respectively.

Experimental

Measurements of the specific volumes of the solutions at 25° and of the expansions corresponding to temperature changes of 2.50° between 20 and 32.5° were made with the same apparatus[1] that was used in a study of the aqueous solutions. The temperature of the dilatometer could be held constant and measured to 0.01° and a volume change of 10^{-4} ml. could be determined readily. The specific volumes at the different temperatures were known, therefore, with a relative accuracy of approximately 2 parts in 10^6. The preparation of samples of sodium iodide,[1] sodium bromide[3] and lithium bromide[1] also has been outlined. Although our purified sample of lithium bromide gave perfectly clear solutions in water and in glycol, it produced a slightly cloudy solution in methanol. As this was eliminated by evaporating the aqueous solution from which the salt was recrystallized in a platinum rather than a Pyrex glass dish we concluded that the cloudiness was due to siliceous matter. Checks of the specific volumes of the aqueous solutions indicated that these impurities were insignificant.

An account of the preparation of *methanol* has already been given.[4] *Glycol* obtained from the Eastman Kodak Company was redistilled twice in a vacuum. The different fractions varied slightly in density, but all immediately developed a yellow color when sodium iodide was added. This color was quite intense in dilute solution but died out completely when sodium iodide sufficient to make a solution stronger than 20% was added. If the concentrated solutions were diluted, the color reappeared. When the last traces of glycolaldehyde were removed from the glycol, no coloration was produced with sodium iodide and we conclude that the peroxide of glycolaldehyde was probably responsible for the oxidation of the iodide. The reason for the disappearance of the yellow coloration in the presence of large amounts of sodium iodide is still to be investigated. It may be noted that even after standing for months in air, solutions of sodium iodide in pure glycol do not develop a yellow color. In order to obtain as accurate an estimate of the specific volume of pure glycol as possible we purified it in two different ways. The addition compound of sodium iodide with glycol was crystallized from anhydrous solution and filtered by suction from the supernatant liquor. From this solid, glycol was distilled off in a high vacuum and then redistilled. The specific volume of this sample at 25.00° was 0.90101. The commercially obtained glycol was also mixed with sodium hydroxide, distilled *in vacuo* and redistilled. This procedure freed it completely from glycolaldehyde and the specific volume of the sample was 0.90102. Three different samples treated by the same method had specific volumes of 0.90102 ml. per gram. The specific volumes of samples distilled once or twice from Eastman glycol without chemical treatment varied between 0.90095 and 0.90098. A small amount of the denser glycolaldehyde seemed to account for the discrepancies.

Results

Table I summarizes the results of the specific volume measurements. At the head of each sec-

tion is written the empirical equation which best represents the data. It will be noticed that several concentration functions have been used as arguments in these equations. The choice of such functions was determined solely by which argument gave the best fit in the simplest type of equation. The last column of the table demonstrates the adequacy of the equation used.

The thermal expansion data were converted to values of $\Delta_T v$,[5] the finite changes in specific volumes for a given rise of temperature, which were expressed as quadratic functions of the temperature by a least square method.[6] Table II gives the coefficients of these equations and the deviation diagrams in Fig. 1 show how well the equations represent the observations. From the equations given in Table II the specific expansibility $(\mathrm{d}v/\mathrm{d}T)_P$ was calculated readily. The ap-

(5) The symbols used are as follows. The subscripts 1 and 2 refer to the liquid solvent and the salt in solution, respectively; the subscripts w and s stand for pure solvent and pure solid salt, respectively. The symbol Δ_T indicates the increase with temperature of the quantity to which it is prefixed. The weight fraction is represented by x, the grams per ml. by c, the moles per liter by C, the specific volume in ml. by v, the apparent volume by ϕ, the temperature in °C. by t, the molecular weight by M. The apparent volume is defined by the relation $v = x_2\phi_2 + x_1v_w$ and the apparent expansibility at any temperature $\phi_T \equiv (\mathrm{d}\phi_2/\mathrm{d}T)_P$.

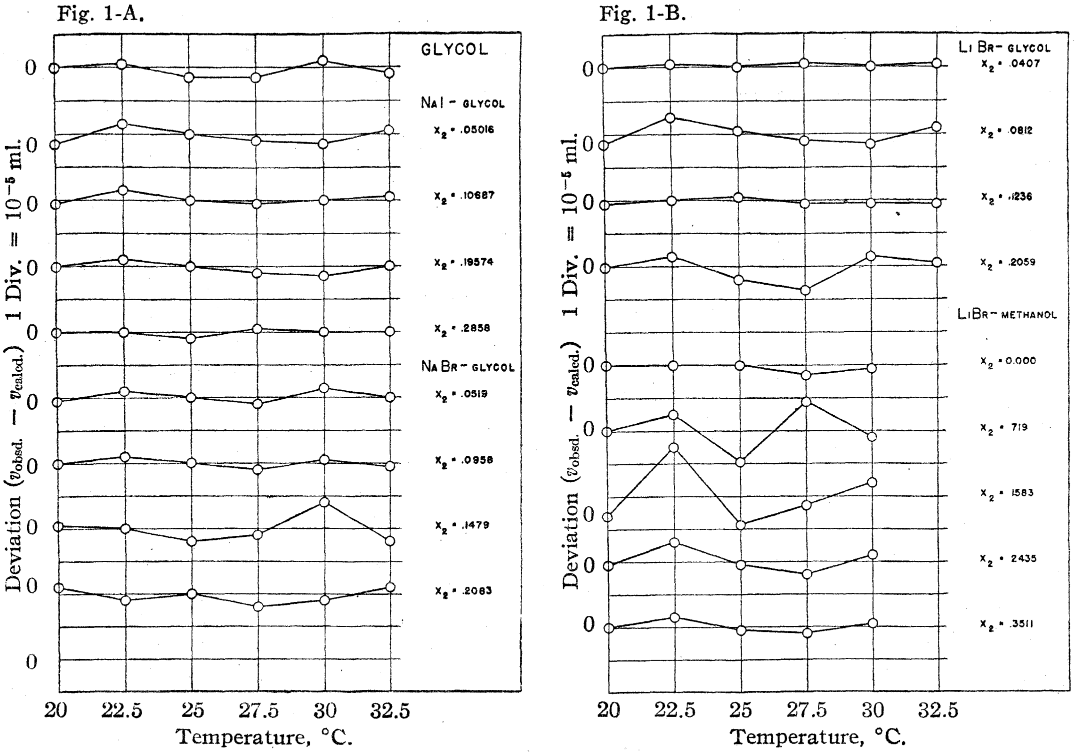

Fig. 1-A.

Fig. 1-B.

Fig. 1.—Differences between the observed specific expansions of non-aqueous solutions and those calculated by the equations in Table II.

parent expansibility was computed from the obvious relation

$$\phi_T = \frac{1}{x_2}\left[\frac{\mathrm{d}v}{\mathrm{d}T} - x_1\frac{\mathrm{d}v_w}{\mathrm{d}T}\right]$$

Discussion of Results

In Fig. 2 we have plotted $(\phi_2 - v_s)$,[7] the apparent expansion which occurs when 1 g. of salt mixes with sufficient solvent to give a solution of a given concentration, against $C_2^{1/2}$ for some of the salts in glycol, in methanol and, for purposes of comparison, in water.[1] Vosburgh, Connell and Butler[8] found that the apparent volumes of salts in dilute solutions in alcohols were linear functions of $C_2^{1/2}$ and for sodium iodide in methanol we find that this result holds in concentrated solution, but in the other cases the linear function is not adequate. It may be noted that when our results for sodium iodide solutions in methanol are extrapolated by the equation in Table I to the low concentrations investigated by Vosburgh, Connell and Butler, our specific volumes agree with theirs to within 3×10^{-5} cc.

Simple considerations lead to the conclusion that $(\phi_2 - v_s)$ should decrease algebraically with rising compressibility of the solvent for solutions of the same salt in chemically related solvents, where the forces between the solvent and the solute are roughly the same. The relative positions of the various curves in Fig. 2 are all in accord with this conclusion with one exception, namely, the curve of $(\phi_2 - v_s)$ for lithium bromide in water which lies above that of the same salt in glycol, whereas the reverse would be expected from the compressibilities of the two solvents. This phenomenon is accounted for on the now well-known hypothesis of the structure of liquid water.[9] The lithium ion in virtue of its small radius can approach close enough to a water molecule to polarize the molecule, thereby causing a strengthening of the electrostatic bonds which hold the water molecules in the less random open liquid structure (the "quartz-like" structure of Bernal and Fowler with all inference as to its exact nature removed). The effect is to cause an expansion of the water and hence to produce a smaller net contraction than if structural effects were absent. This also

---

[7] Values of v_s were taken from the data of Baxter and Wallace, THIS JOURNAL, **38**, 70 (1916).

[8] W. C. Vosburgh, L. C. Connell and J. A. V. Butler, *J. Chem. Soc.*, 933 (1933).

[9] J. D. Bernal and R. H. Fowler, *J. Chem. Phys.*, **1**, 540 (1933); S. Katzoff, *ibid.*, **2**, 841 (1934).

accounts for the fact that the compressions of lithium salt solutions are abnormally high.[3] Such an effect is either absent or much less significant in glycol, as will be evident from the following discussion of apparent expansibilities. A reasonable extrapolation shows that in solutions of high concentration, where effects due to structural changes become less, the curve for the glycol solutions of lithium bromide should cross that for the aqueous solutions. This is seen without extrapolation in the differential effects. In Fig. 3 the partial volumes[10] of lithium bromide in glycol and in water are plotted against $C_2^{1/2}$; at low concentrations the partial volumes of lithium bromide are greater in the aqueous solutions, but when the concentration exceeds 4 moles per liter the partial volumes are greater in the glycol solutions. The apparent volumes of lithium bromide in glycol solutions also throw light on the puzzling phenomenon that, whereas the negative departures from Raoult's law in aqueous solutions indicate strong attractive forces between lithium salts and the water, the contraction on solution as measured by $(\phi_2 - v_s)$ is very small and even becomes an expansion in highly concentrated solutions. The quantity $(\phi_2 - v_l)$, where v_l is the volume of the pure liquefied solute at the temperature and pressure of the solution, should be taken as a measure of the electrostriction rather than $(\phi_2 - v_s)$ and the glycol solutions show that $(v_l - v_s)$ must be quite large for lithium bromide in comparison with other salts. A lower limit for v_l is given by the partial volume of the salt in the most concentrated glycol solution. This is at least 0.315 cc. per gram (see Fig. 3), indicating that the salt expands more than 9.1 per cent. on melting.

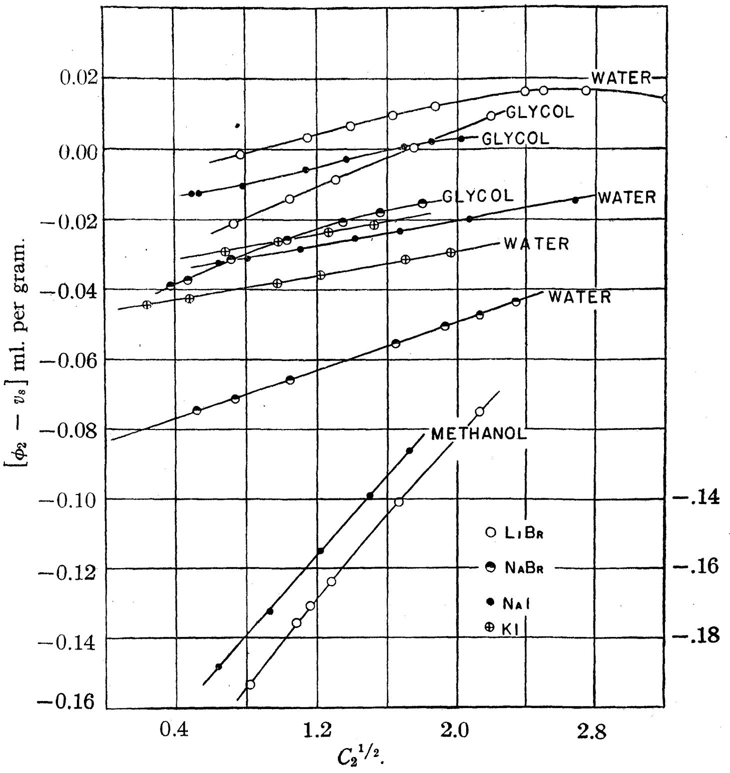

Fig. 2.—The volume changes per gram of salt accompanying the solution of salts in different solvents. The scale of ordinates on the right refers to lithium bromide in methanol.

The Apparent Thermal Expansions and Expansibilities.—In Fig. 4 the apparent molal expansibilities, $M_2\phi_T$, of the salts in different solvents are plotted against $C_2^{1/2}$. It will be seen at once that the magnitude, sign and concentration-variation of $M_2\phi_T$ for the salts in glycol and methanol are quite different from what they are in aqueous solutions. These curves for the non-aqueous solutions run in what may be regarded as a fairly normal way and by contrast bring out the abnormal behavior of similar curves for aqueous

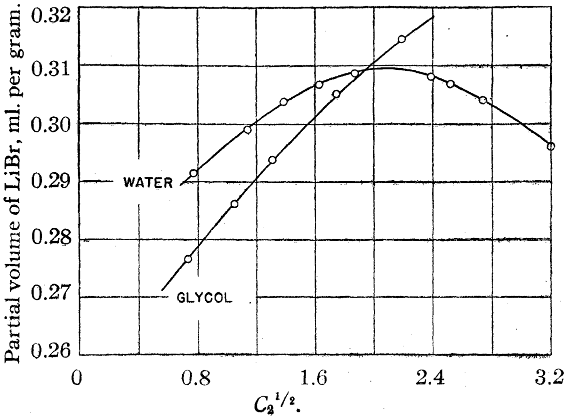

Fig. 3.—The partial volumes of lithium bromide in water and in glycol solutions as functions of the square root of the number of moles of salt per liter of solution at 25°.

---

(10) The partial volumes were calculated from the apparent volumes by the formula of Adams and Gibson, This Journal, **54**, 4523 (1932). For glycol solutions $d\phi_2/dx_2$ was obtained from the equation in Table II and for aqueous solutions it was determined from tabular differences.

solutions. In general $M_2\phi_T$ is negative except in the most concentrated solutions of sodium iodide, and the slopes of the curves are positive, as would be expected from the interionic attraction theory[11] and a reasonable assumption about the effect of pressure and temperature on the dielectric constant. Data necessary for calculating the magnitudes of these slopes from the theory unfortunately are lacking.

On comparing the effect of the three salts on the expansibility of glycol we note that $M_2\phi_T$ decreases algebraically as we pass from salt to salt by an amount roughly proportional to the increase in the effective pressure of the solution, P_e,[12] as determined by compression measurements.[13] Indeed, it seems possible that, when the necessary data are at hand, ϕ_T may actually be calculated quantitatively from P_e and a knowledge of the effect of pressure on the expansion coefficient of the solvent, a thing which seems quite impossible with aqueous solutions. Furthermore, the expansion coefficient of methanol changes much more rapidly with pressure than that of glycol and it will be seen that ϕ_T for lithium bromide is much greater numerically in methanol than in glycol solutions. This again suggests that P_e may be the predominant factor in determining the expansion coefficient of these non-aqueous salt solutions.

The effective pressure hypothesis does not by any means explain the thermal expansibilities of aqueous solutions. The values of $M_2\phi_T$ are too large and, moreover, when we compare aqueous solutions of different salts we see that there is not even a qualitative relationship between the effective pressures and the thermal expansibilities. The large positive values of $M_2\phi_T$ may be explained by the assumption that salts increase the randomness of the water structure and by considering the purely mechanical effect of the volume of the dissolved ions. A detailed discussion of this cannot be given here, but it is necessary to show that the assumption made in the foregoing that lithium bromide promotes the tetrahedral arrangement of the water molecules is not incompatible with the observation that although $M_2\phi_T$ for lithium bromide in water is quite small it is, nevertheless, positive.

The observed thermal expansion of water may be regarded as the resultant of (a) an expansion due to the ordinary increase of the kinetic energy of the system as a whole, and (b) a contraction resulting from the increase in randomness as produced by a loosening up of the tetrahedral arrangement of the water molecules which is well pictured by Katzoff[9] as a departure of the O–H–O angles from 180°. The magnitude of contraction (b) depends on the amount of randomness introduced by a given rise of temperature and on the amount of excess volume which the tetrahedral structure introduces into the system.

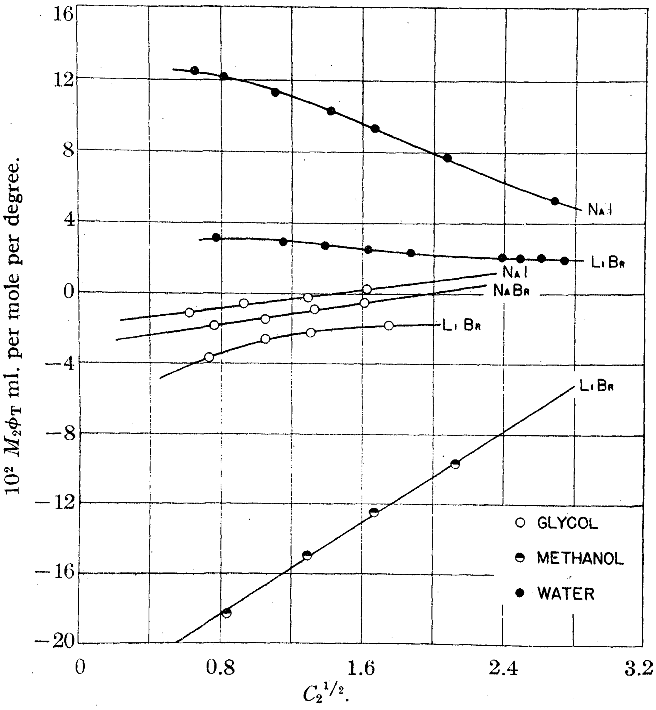

Fig. 4.—The apparent molal expansibilities at 25° of salts in different solvents as functions of the square root of the number of moles of salt per liter of solution.

Because of its polarizing power, the lithium ion, we have supposed, increases the strength of those bonds which hold the water molecules in the tetrahedral arrangement. We should, therefore, expect that a given rise of temperature would introduce less randomness into water in lithium bromide solution than in pure water and hence that contraction (b) would be diminished. This would lead to an apparent expansibility of the water in the solution larger than that of pure water and hence a positive value of $M_2\phi_T$, as is observed.

The specific volume of water is 84% greater than if the molecules of radius 1.4 Å. were packed

[13] Unpublished results obtained in this Laboratory.

closely together.[9] The excess volume introduced by the tetrahedral arrangement is therefore approximately 45% of the total volume. The expansion coefficient of water at 25° is 25.7×10^{-5} ml. per gram per degree. If it behaved as a normal liquid it would have an expansion coefficient of approximately 85×10^{-5} ml. per gram per degree. This difference may be accounted for if we assume that a rise of one degree introduces a randomness which corresponds to a loss of about 0.1% of the excess volume, a very reasonable amount.

Summary

We have measured the specific volumes at 25° and the expansion coefficients in the neighborhood of this temperature of solutions of some salts in methanol and glycol. A comparison of the apparent and partial volumes of lithium bromide in water, glycol and methanol gives strong evidence that this salt influences the structure of water by promoting the tetrahedral arrangement of the molecules.

Unlike the same quantities for salts in aqueous solution, the apparent molal expansibilities of the salts in glycol and methanol are negative and increase with the concentration of salt, thereby agreeing qualitatively with the predictions of the interionic attraction theory and the effective pressure hypothesis. A comparison of the behavior of the salts in water on the one hand and in glycol and methanol on the other indicates that the structural changes in water play a predominant role in determining the thermal expansions of aqueous solutions.

The Rate of Reaction of Magnesium with Acids in Ethyl Alcohol[1,2]

BY MARTIN SCLAR[3] AND MARTIN KILPATRICK

The rate of reaction of metals with acids in aqueous solution has been the subject of many investigations. A summary of the work up to 1929 has been given by Centnerszwer.[4] In non-aqueous solvents two quantitative studies have appeared. Zecchini[5] measured the rates of reaction of zinc with hydrogen chloride in water, ethyl alcohol, methyl alcohol and acetone. Brönsted and Kane[6] sought to show that sodium amalgam reacted with molecules of carboxylic acids in benzene, and that the rate of the reaction increased with the ease with which the acid gave up its proton. In addition, several partially quantitative observations have been made, especially by Kahlenberg and his co-workers in connection with their criticism of the Arrhenius theory of electrolytic dissociation. Smith[7] gives a summary of this work. Additional investigations are desirable because comparison of the results in aqueous and non-aqueous solutions may lead to a better understanding of the problem.

In the present work ethyl alcohol was selected as the solvent and magnesium as the metal for the general study. After describing the procedure and some orientating experiments, we shall proceed to demonstrate that magnesium can displace hydrogen from the molecules of ethyl alcohol without the intermediate formation of solvated proton. We shall also show that this reaction predominates when magnesium dissolves in alcoholic solutions of acids. It will be seen that the observed rate of this reaction shows great variations. Experiments with solutions of acids containing chloride ion, organic chlorine compounds and small amounts of water, respectively, will be described, which indicate that the variations in the observed rates probably are due to differences in the amount of metal surface available for reaction. The results of experiments to determine the effect of temperature and the rate at which the magnesium cylinder is rotated will then be presented. Finally some miscellaneous experiments will be described.

Experimental

1.—The experimental procedure is essentially a modification and improvement of that of Kilpatrick and Rushton.[8] Figure 1 is a diagram of the apparatus. The reaction vessel was located in an air thermostat regulated at 30 ± 0.05°. The cylinder of magnesium was rotated at 980 r. p. m. by a small synchronous motor. Other speeds were obtained by the use of gears. A piece of Bakelite was inserted between the steel shaft and the magnesium, and the latter was completely immersed. The solution was added from a fast delivering 50-cc. pipet to the reaction vessel through the side-arm extending through the top of the thermostat. The gas evolved was collected over anhydrous ethyl alcohol in a water-jacketed double-armed buret.

The ethyl alcohol was dried by the method of Bjerrum and Lund.[9] Density measurements on various batches showed that the water content did not exceed 0.025%. Dried nitrogen was bubbled through the alcohol to remove oxygen.

The solutions of hydrogen chloride were freshly prepared, and precautions were taken to exclude moisture. The carboxylic acids were purified where necessary. All acid solutions were diluted to the desired concentration and standardized against 0.1 *M* sodium hydroxide one-half hour before use. Solutions of lithium chloride were prepared from Kahlbaum fused lithium chloride, which was found to contain a negligibly small amount of alkali.

Kahlbaum magnesium was used in the form of cylinders about 0.9 cm. in diameter and 5.5 cm. in length. Zinc cylinders of the same dimensions were cast in vacuum from a supply of very pure zinc.[10] Before use a skin was removed from each cylinder by turning on a lathe. Then the metal was washed with carbon tetrachloride and ethyl alcohol, polished with emery paper and wiped with a dry cloth.

Each experiment was carried out in duplicate, and at least 3 runs were made when the reproducibility was unsatisfactory. The reproducibility varied with the acid used, hydrochloric and the chloro acids yielding much better results than acetic acid. Different batches of alcohol gave the same results. It made no difference whether or not the magnesium was polished with emery paper. Table I shows the reproducibility of the results with hydrochloric and chloroacetic acids.

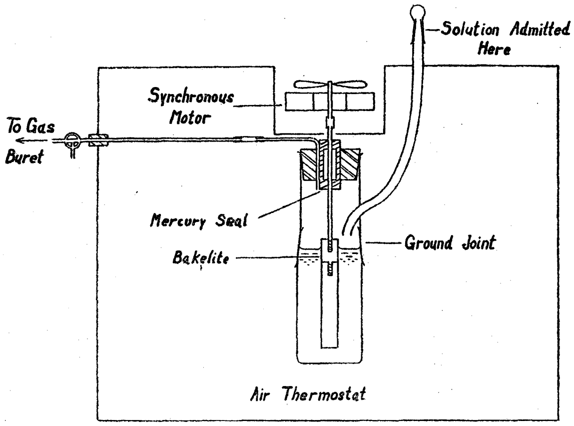

Fig. 1.—Apparatus.

2.—Whitby[11] and Kilpatrick and Rushton[8] found that no oxygen was consumed when magnesium dissolved in aqueous solutions of sodium chloride and acids, respectively. When ethyl alcohol is the solvent, however, considerable quantities of hydrogen are lost as a result of its combination with oxygen. This can be seen from the data in the last three rows of Table II. The difference in the results in water and in alcohol may be due to the fact that oxygen is 8.6 times more soluble in alcohol than in water[12] at 76 cm. of oxygen. However, when oxygen is removed from both the alcohol and the reaction vessel, the hydrogen evolved, the magnesium dissolved and the acid consumed are equivalent to within a few per cent. The results of some of the experiments which were carried out to determine this are given in Table II. Therefore, unless otherwise noted, oxygen was excluded in the experiments. Additional reasons for excluding oxygen were: first, in some cases oxygen increases the rate of the reaction in the initial stages, and, second, the formation of water inhibits the reaction.

slightly reduced. Lund[13] heated 1 g. of magnesium with 30 cc. of alcohol containing 1 cc. of carbon tetrachloride until the metal dissolved completely, and found that the amount of chloride ion in the resultant solution corresponded to only 8% of the total. In that experiment the volume of hydrogen evolved was about 1000 cc. or 10 times the volume evolved in our experiments. In the latter, therefore, where the maximum concentration of chlorine compound was about one-half of that used by Lund and the maximum temperature 50°, the amount of reduction was probably slight. Kilpatrick and Rushton[8] working with aqueous solutions found that the chloro acids used by them were not reduced. However, Tarle,[14] Bodforss and Kajmer[15] and Dunning and Fletcher,[16] the latter working with sodium and lithium amalgams, observed reduction.

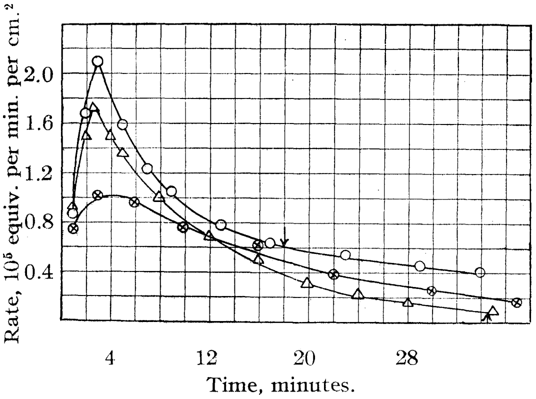

Fig. 2.—Effect of water on the reaction of magnesium with 0.064 *M* hydrochloric acid. The arrow indicates when all the acid has been consumed. The circles, triangles and crossed circles show the rates obtained with solutions which were 0.011, 0.050 and 0.102 *M* in water, respectively.

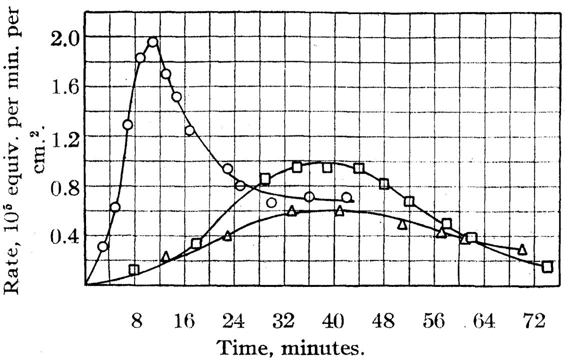

Fig. 3.—Effect of water on the reaction of magnesium with 0.12 *M* chloroacetic acid. The circles, squares and triangles show the rates obtained with solutions which were 0.011, 0.024 and 0.05 *M* in water, respectively.

3.—Data for some typical experiments are presented graphically in Figs. 2, 3 and 4. From them it may be observed that, in contrast to the behavior in aqueous solutions of acids, induction periods are observed in alcohol. After the induction period the reaction rate decreases, and the magnesium continues to liberate hydrogen from the alcohol after a volume of hydrogen equivalent to the acid originally present has been evolved, despite the fact that magnesium does not react with pure boiling ethyl alcohol. We have been

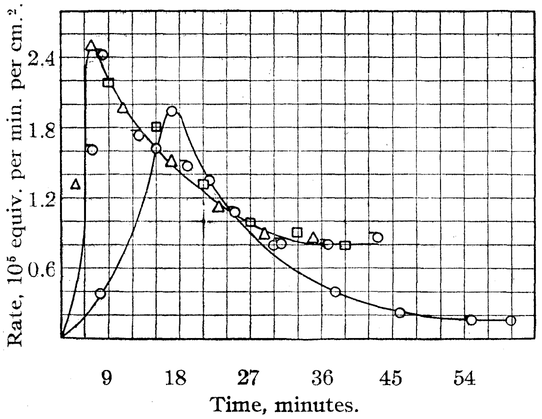

Fig. 4.—The effect of lithium chloride on the solution of magnesium in 0.12 *M* acetic acid. The circles, triangles, squares and tailed-circles show the rates for solutions which were 0.0, 0.025, 0.05 and 0.10 *M* in lithium chloride, respectively.

unable to fit a reaction rate equation to any portion of the reaction for experiments of this type. Since the "alcohol reaction" after the "equivalence point" is not complicated by the presence of acid, we shall deal with it first.

The velocity of this reaction is too great to be accounted for on the basis of the number of collisions of hydrogen ion, $C_2H_5OH_2^+$, with the surface of the metal. Therefore, alcohol molecules must react with magnesium. A simple calculation will demonstrate this.

From Table X, in which some data on the effects of stirring are presented, it can be seen that at 30° a reaction velocity as high as 0.705×10^{-5} equivalent per min. per sq. cm. has been observed in 0.05 *M* magnesium ethylate. This rate would require $0.705 \times 10^{-5} \times 6.06 \times 10^{23} = 4.27 \times 10^{18}$ collisions of hydrogen ion per minute with one sq. cm. of the magnesium cylinder, if every colliding ion gave up its proton. Now, the ionic product of ethyl alcohol is[17] about 10^{-20}, so that the concentration of solvated proton in 0.05 *M* ethylate is 10^{-22} mole per cc. For this concentration of solvated proton, the number[18] of collisions of the protons per minute with one sq. cm. of the magnesium cylinder is 3.36×10^7. Therefore, the ratio of the number of collisions which occur to the minimum number required is 7.87×10^{-12}, or collisions of hydrogen ion with the surface of the metal could account for only $7.87 \times 10^{-10}\%$ of the observed reaction. The answer for a similar calculation, which was made for an observed reaction velocity of 2.72×10^{-5} equivalent per min. per sq. cm. at the equivalence point, is 0.20%. These calculations constitute a definite proof that metals can displace hydrogen from the molecules of acids without the intermediate formation of solvated proton.

4.—We shall now try to determine what portion of the reaction rates which are observed when acid is present is due to the reaction of the alcohol molecules with magnesium. In order to do this it will be necessary to compare the reaction rates obtained with magnesium and zinc, respectively, with hydrochloric acid.

TABLE III

EXPERIMENTS AT 30° WITH MAGNESIUM AND HYDROCHLORIC ACID

N_i = initial molarity of acid. N_m = molarity of acid at point of maximum rate. *M* = maximum rate of reaction. *R* = equivalents per sq. cm. reacted during induction period. *T* = minutes elapsed during induction period. *F* = equivalents of magnesium dissolved per min. per sq. cm. at the equivalence point.

N_i, mole/l.	N_m, mole/l.	*M*, 10^5 equiv./min./cm.^{2}	*R*, 10^5 equiv. per cm.^{2}	*T*, min.	*F*, 10^5 equiv./min./cm.^{2}
0.0285	0.0191	0.960	2.75	4.5	0.371
.0407	.0288	1.25	3.20	3.8	.312
.0654	.0534	2.21	3.68	2.5	.598

.101	.0828	3.22	5.35	2.3	.625
.112	.0975	3.78	4.31	1.8	.705

Detailed data for the experiments with magnesium are to be found in Table III. As previously stated we have been unable to fit a reaction rate law to individual experiments of this type. However, we have found that a fairly straight line is obtained on plotting the maximum rate of reaction, that is, the rate at the end of the induction period, *versus* the concentration of acid at the time of maximum rate. The plots for hydrochloric and the other acids are given in Fig. 5. From these plots we can find the maximum rate of reaction for any corresponding concentration of acid.

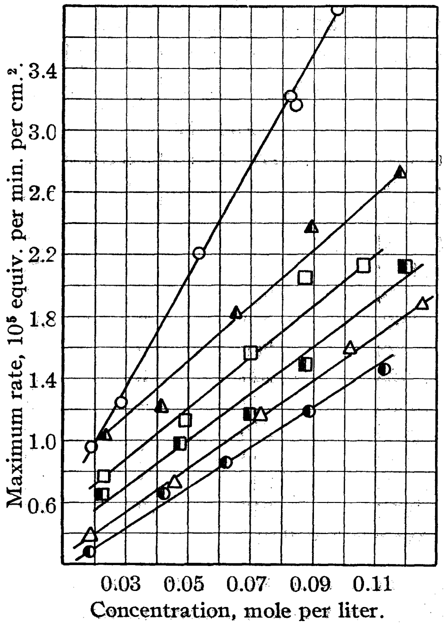

Fig. 5.—Maximum rate of reaction *versus* the concentration of acid at the time of maximum rate. Circles, hydrochloric acid. Shaded triangles, chloroacetic (up 0.4). Squares, acetic (up 0.4). Shaded squares, dichloroacetic (down 0.1). Triangles, *o*-chlorobenzoic (down 0.1). Shaded circles, α-chloropropionic (down 0.5). In parentheses is given the number of units the line is displaced. A point has been omitted for acetic acid at concentration = 0.074, rate = 1.04.

(18) Moelwyn-Hughes, "Kinetics of Reactions in Solution," Oxford University Press, Oxford, 1933, p. 281.

The results of the experiments with zinc and alcoholic hydrochloric acid are summarized in Table IV. We have found that zinc dissolves in alcoholic hydrochloric acid in accordance with the unimolecular reaction rate law. The zinc reacts only with hydrogen ion, $C_2H_5OH_2^+$. The average unimolecular velocity constant, $k = (2.3\ V/St) \log a/(a - x)$, is 0.217 cm. per min. V is the volume of the solution in cc., S the area of the metal cylinder in sq. cm. and t the minutes elapsed since the start of the experiment. a is the concentration of acid at the start of the experiment and $a - x$ the concentration at the time t.

Sometimes a short induction period was observed, and the reaction velocity decreased too rapidly at the end of the experiment for the reaction rate law to be obeyed. The extent of these deviations is also given in Table IV. The addition of lithium nitrate as a depolarizer did not speed up the reaction. When lithium nitrate was present very little hydrogen was evolved, which shows that it was an efficient depolarizer.

TABLE IV

EXPERIMENTS AT 30° WITH ZINC AND HYDROCHLORIC ACID

Molarity of acid, mole/l.	k, cm./min.	Induction period, min.	% law obeyed

.1123	.200	0	81
.1128	.224	6	88
.0635	.157	4	78
.0636	.210	1	75
.0615	.214	1	46
.0288	.245	4	94
.0296	.213	10	37
Average k = 0.217			

King and his co-workers[19,20] have found that magnesium and zinc dissolve in aqueous hydrochloric acid with very nearly the same velocity. If the reaction of the magnesium were with the $C_2H_5OH_2^+$ alone, we should expect the same result for the two metals with alcoholic hydrochloric acid. When different solids dissolve in identical solutions with the same velocity, it is generally conceded that the rates of the reactions are governed by the speed with which the dissolved reactant is transported to the surface of the solid. Therefore, a comparison of the results obtained with magnesium and zinc, respectively, and hydrochloric acid should enable us to determine what portion of the maximum reaction rate is due to the reaction of the magnesium with alcohol.

Using the velocity constant $k = 0.217$ cm. per min. for the dissolution of zinc in alcoholic hydrochloric acid, reaction rates have been calculated for three concentrations of acid, which would also be correct for magnesium if it reacted only with the acid. These rates are compared in Table V with those taken from the plots of maximum rate of reaction *versus* the concentration of acid at the time of maximum rate in Fig. 5. From the data in the table it would appear that ethylate ion was being generated at the surface of the metal about as fast as hydrogen ion was scheduled to arrive. On this basis most of the acid would be neutralized before it reached the magnesium. Then to account for the observed rates we would have to raise the estimate of the portion of the reaction due to the reaction of the metal with the alcohol molecules considerably. The ethylate would then be produced much more rapidly than the hydrogen ion was scheduled to arrive. This would mean that practically no hydrogen ion reaches the surface, so that the observed reaction rate must be almost entirely an alcohol reaction and the region immediately adjacent to the surface of the metal must be alkaline. The same picture applies to the carboxylic acids. In brief, the alcohol reaction predominates, and the rapid production of ethylate ion prevents any reaction with acids other than the solvent.

TABLE V

COMPARISON OF THE RATES OF SOLUTION OF MAGNESIUM AND ZINC IN HYDROCHLORIC ACID AT 30°

N_m, mole/liter	M (for Mg) 10^5 equiv./min./cm.^{2}	Rate for Zn (Z) 10^5 equiv./min./cm.^{2}	M − Z, 10^5 equiv./min./cm.^{2}	(M − Z)/M
0.03	1.35	0.65	0.70	0.52
.06	2.44	1.30	1.14	.47
.09	3.52	1.95	1.57	.45

5.—It is apparent from the tables and graphs that the observed rate of the reaction after the induction period varies considerably. Now if the reaction is always one of magnesium with alcohol, the concentration of which is practically constant, some explanation must be found for this variation. The results of experiments with solutions of acids containing chloride ion and small amounts of water, respectively, indicate that the variation is due to differences in the amount of metal surface available for reaction. Small traces of water retard the reaction and chloride ion speeds it up.

The water content of the dehydrated alcohol

---

(19) King and Braverman, THIS JOURNAL, **54**, 4774 (1932).

(20) King, *ibid.*, **57**, 828 (1935).

was 0.025%, corresponding to a molarity of 0.011. The effect of adding small amounts of water to solutions of hydrochloric and chloroacetic acids made from the dehydrated alcohol can be seen from Figs. 2 and 3, respectively. From the plots of rate *versus* time we note that the addition of water depresses the rate. Seligman and Williams[21] and Zecchini[5] observed a similar result for the solution of aluminum in phenol and glacial acetic acid and zinc in alcoholic hydrochloric acid, respectively. The inhibitory effect of water is usually attributed to the formation of a difficultly soluble coating of hydroxide on the surface of the metal. This coating is supposed to result from the reaction of the metal with the water. That we can vary the rate of reaction by causing a portion of the surface of the metal to become covered with a coating during the course of an experiment indicates that the original variations in rate are due to differences in the amount of surface available for reaction. It also shows that the amount of clean surface varies in the same experiment.

It should be pointed out that the addition of water to the dehydrated alcohol did not destroy the reproducibility of the experiments with hydrochloric acid, but did destroy it for the experiments with chloroacetic acid. In the latter case, therefore, the faster of two duplicate experiments was used for comparison.

6.—From Fig. 4 it may be seen that the addition of lithium chloride to acetic acid solutions speeds up the reaction during the induction period and at the equivalence point. The fact that chloride ion hastens corrosion has been observed by many investigators, and the effect is generally ascribed to the ability of that ion to penetrate coatings. The results of these experiments, in conjunction with the fact that induction periods were observed, are evidence, therefore, that the magnesium cylinders contain an invisible coating before being placed in the acid solutions. This coating must be removed before the alcohol can react with the metal, and the magnitude of the observed reaction depends on the extent to which the coating is removed. From Fig. 4 it also may be seen that the effects due to chloride ion were independent of its concentration between 0.025 and 0.1 M.

7.—With certain organic chlorine compounds results were obtained which were similar to those observed with chloride ion. Thus from Table VI it may be seen that solutions of acetic acid which are 0.12 M in ethyl dichloroacetate, chloroform or carbon tetrachloride dissolve magnesium more rapidly than solutions of acetic acid alone. This happens despite the fact that magnesium does not dissolve in 0.12 M solutions of these substances in alcohol at 30°. From the data it is also seen that the compound with the greatest number of chlorine atoms in the molecule speeds up the reaction most. The effects were found to decrease with the concentration of chlorine compound, but in no regular manner. Similar results were observed in a few experiments with *o*-toluic and phenylacetic acids. They could not be used alone to any considerable extent, because with them the metal bore scattered deep pits at the conclusion of an experiment, and because the reproducibility was exceedingly poor. This pitting and poor reproducibility, which were observed with acetic acid alone to a smaller extent, are further evidence that the surface of the metal is not entirely available for reaction.

TABLE VI

THE EFFECT OF CHLORINE COMPOUNDS ON THE RATE OF SOLUTION OF MAGNESIUM IN 0.125 M ACETIC ACID

Concentration of chlorine compound = 0.12 M

Chlorine compd.	N_m, mole/liter	M, 10^5 equiv./min./cm.^{2}	M/N_m	F, 10^5 equiv./min./cm.^{2}	Induction, pd., min.
None	0.0699	1.11	15.9	0.15	29.0
Ethyl dichloroacetate	.1107	3.21	29.0	1.35	2.5
Chloroform	.0947	3.26	34.4	1.55	5.5
Carbon tetrachloride	.101	4.30	42.6	1.69	3.5

TABLE VII

EXPERIMENTS AT 30° WITH MAGNESIUM AND CHLOROACETIC ACID

N_i, mole/liter	N_m, mole/liter	M, 10^5 equiv./min./cm.^{2}	R, 10^5 equiv. per cm.^{2}	T, min.	F, 10^5 equiv./min./cm.^{2}
0.0297	0.0232	0.635	2.00	5.5	0.368
.0588	.0419	.823	5.14	12.5	.594
.0909	.0654	1.42	7.75	9.5	.776
.121	.0894	1.97	9.25	9.5	.629
.150	.118	2.32	9.55	9.3	.689

From the similarity of the results with chloride ion and the chlorine compounds it appears that the latter also clean the surface of the metal. We cannot say how they do this. However, it is not probable that the similarity is due either to the formation of chloride ion resulting from the reduction of the chlorine compounds or to those compounds acting as depolarizers. We have al-

---

ready shown that the amount of reduction is very small.

TABLE VIII

COMPARISON OF THE MAXIMUM RATES OF SOLUTION AT 30° OF MAGNESIUM IN DIFFERENT ACIDS[a]

N_m, mole/liter	Maximum rates (M) in 10^5 equivalents per min. per cm.^{2} Acetic	Chloro-acetic	α-Chloro-propionic	*o*-Chloro-benzoic	Dichloro-acetic
0.03	0.50	0.74	0.94	0.62	0.78
.06	1.00	1.28	1.34	1.06	1.24
.09	1.49	1.82	1.73	1.50	1.71

[a] For hydrochloric acid see Table V.

The curves in Fig. 5 enable one to obtain the maximum rates of reaction for the same concentration of different acids. (The data used to construct the curve for chloroacetic acid are contained in Table VII.) Maximum rates obtained in this manner are compared in Table VIII. With the exception of *o*-chlorobenzoic acid, the rates for the chloro acids are greater than those for acetic acid. While we should have predicted this from the results of the experiments with acetic acid and the chlorine compounds, we should also have expected greater rates with dichloroacetic acid than with monochloroacetic and α-chloropropionic acids. However, the rates at 30° of the alcohol reaction at the equivalence point, which were obtained with 0.12 M solutions of the five carboxylic acids, may be divided into three distinct groups, according to the number of chlorine atoms to the molecule. For the acids in the order in which they are given in Table VIII the rates are 0.145, 0.660, 0.885, 0.715 and 1.13×10^{-5} equivalents per min. per sq. cm., respectively.

8.—The rate at which the magnesium cylinder rotates and the temperature also affect the maximum rates of reaction and the alcohol reaction. The results of experiments to determine the extent of these influences are presented in Tables IX to XII.

TABLE IX

INFLUENCE OF STIRRING AT 30° ON THE MAXIMUM RATES OF SOLUTION OF MAGNESIUM IN ACIDS

[a] Approximate solubility of magnesium ethylate = 0.1 M at 30°.

The maximum rates were taken from plots of maximum rate *versus* concentration of acid at the time of maximum rate. They are given for only two concentrations of acid because the fractional changes did not differ to any considerable extent for the other concentrations. The stirring effects are not sufficiently[20,22] great and the temperature effects not sufficiently small to indicate that the observed rates of reaction are controlled solely by diffusion processes. However, the diffusion of solutes must be a contributing factor. Because the reproducibility of the experiments at 40 and 50° was not good, and it was difficult to draw a curve through the points obtained on plotting maximum rate *versus* concentration of acid at the time of maximum rate, too much weight should not be given to the negative temperature coefficients for hydrochloric acid in Table XI. Moreover, at 40 and 50° it was difficult to select the points of maximum reaction for the higher concentrations of acid, because the induction periods were exceedingly short and the reaction velocities inconveniently rapid.

---

(22) Roller, *J. Phys. Chem.*, **39**, 221 (1935).

In connection with the results for the alcohol reaction, we have found that the solubility of magnesium ethylate is approximately 0.1 *M* at 30°. Consequently the progressive decrease in the reaction rate after the equivalence point could not be due to the insolubility of that substance.

9.—A description of some miscellaneous experiments concludes the presentation of the experimental results.

The presence of oxygen in the alcohol and reaction vessel was found to affect the rates of solution of magnesium in acid solutions. In experiments in which oxygen was not excluded, the progress of the reaction was followed by determining the loss in weight of different cylinders of metal after they had dissolved in solutions of the same initial composition for successively longer periods of time.

In Table XIII the results of such experiments with acetic and chloroacetic acids are compared with those obtained in the absence of oxygen. In the initial stages of the experiment the reaction rates were more rapid when oxygen was not excluded. But as the reaction proceeded it slowed down more rapidly due to the formation of water. The greater initial velocity was probably due to depolarization on the surface of the metal. This is the first time depolarization has been observed for magnesium.

TABLE XIII

EFFECT OF OXYGEN ON THE DISSOLUTION OF MAGNESIUM IN ACIDS AT 30°

Atmosphere, and gas in alcohol	10^5 equiv. per min. per sq. cm. Metal dissolved			
	Minutes 5	12	19	27
	0.12 *M* Acetic Acid			
Nitrogen	1.17	8.07	19.8	28.6
Air	4.25	12.8	17.0	23.0
	Minutes 5	12	18	25
	0.059 *M* Chloroacetic Acid			
Nitrogen	1.29	6.28	11.1	15.8
Air	1.48	8.69	10.1	15.0

Experiments were also carried out with mixtures of hydrochloric acid and lithium chloride, in which oxygen was not excluded. The results of these experiments are summarized in Table XIV. Most of the acid was consumed in accordance with the unimolecular reaction rate law. The unimolecular velocity constant is 0.242 cm. per min. The straight lines in Fig. 6, which were obtained by plotting log *a* − *x versus* time, illustrate how well the law was obeyed. In these experiments the amount of acid consumed always was found to be equivalent to the weight of metal which had been dissolved.

TABLE XIV

EXPERIMENTS AT 30° WITH MAGNESIUM AND HYDROCHLORIC ACID WITH OXYGEN NOT EXCLUDED

Concn. of acid, mole/l.	Concn. of lithium chloride, mole/l.	Slope of log $a-x$ *vs.* time	% Acid consd. via law

.0679	.0000	.0430	82
.0926	.0000	.0524	82

Average slope = 0.0459.
k = 0.242 cm. per min.

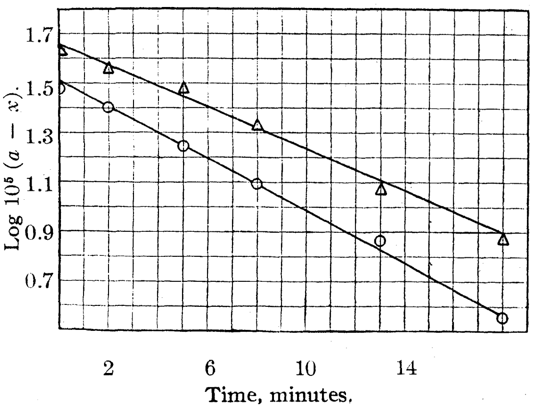

Fig. 6.—Relationship between log *a* − *x* and time for the solution of magnesium in hydrochloric acid when oxygen is not excluded. The circles and triangles show the points obtained with 0.0626 and 0.0679 *M* acid, respectively. The line for the latter solution is displaced upward 0.1 unit.

Short induction periods were expected here as in the experiments in which oxygen was excluded. That they were not detected was probably due to the method which had to be used to follow the progress of the reaction. After most of the acid had been consumed, the reaction velocity decreased too rapidly to obey the rate law, and no reaction with the solvent was detected. The apparent absence of this reaction is peculiar, when we consider that it occurred when magnesium dissolved in a solution of acetic acid containing lithium chloride in the presence of oxygen. However, the velocity constant is very similar to that for the solution of zinc in alcoholic hydrochloric acid, which is 0.217. And as we explained previously, this is exactly what we should expect if magnesium reacted only with the hydrochloric acid and if the observed reaction rate was governed by the rate at which the acid was transported to the surface of the metal.

We have already described how a very pure sample of zinc dissolved readily in alcoholic hydrochloric acid without the aid of a depolarizer. In contrast to this, it is commonly known that pure zinc scarcely dissolves in aqueous acids unless a depolarizer such as potassium nitrate is present.[23] From these results it appears that the discharge potential of hydrogen on zinc is smaller in alcohol than in water. For magnesium the reverse seems to be true, since we have already shown that oxygen hastens the solution of magnesium in alcoholic solutions, whereas depolarizers,[8,19] do not increase the velocities of solution of magnesium in aqueous acids.

In connection with these experiments, it might well be pointed out that one should be careful in the use of depolarizers, when measuring the rates of solution of metals in acids. Thus the data in Table XV show that lithium nitrate lowers the rates of solution of magnesium and zinc in aqueous acetic acid. In order to show this for zinc it was necessary to determine the effect of increasing the duration of different experiments with solutions of the same initial composition since the reaction scarcely proceeded in the absence of nitrate.

A more striking example of the effect may be observed in the behavior of zinc with alcoholic dichloroacetic acid solutions. Although zinc scarcely dissolved in solutions of acetic and chloroacetic acids, it did dissolve readily in 0.1 *M* dichloroacetic acid. No hydrogen was evolved, no titratable acid was consumed and considerable chloride ion was formed. This reaction, which seems to be similar to the Wurtz reaction, did not occur when the solution was 0.05 *M* in lithium nitrate. We consider these results evidence that nitrate ion can oxidize the surfaces of magnesium and zinc.

Data for similar experiments with aqueous mixtures of hydrochloric acid and lithium nitrate are also reported in Table XV. From this it is plainly seen that with hydrochloric acid a considerable side reaction occurs.

TABLE XV

EXPERIMENTS AT 30° WITH AQUEOUS MIXTURES OF ACIDS AND LITHIUM NITRATE

Concn. of acid, mole/liter	Concn. of nitrate, mole/liter	Length of expt., min.	Vel. const., *k*, cm./min.

.0312	.10	12	.544
.103	.10	3	.592
.103	.10	12	.459

Although experiments of this type with alcoholic solutions are not reported in detail, because water was formed, we did find that lithium nitrate retarded the solution of magnesium in alcoholic hydrochloric and acetic acids.

Discussion

The following description of what occurs when a cylinder of magnesium is rotated in a solution of an acid in ethyl alcohol is based on the preceding experimental results.

The induction period probably starts with acid reacting and removing a coating from the surface of the metal. The acid is aided by chloride ion or chlorine compound if present. Chloroacetate ion (and like ions) aids also, when produced in the reaction. On those areas which have been cleaned the alcohol reacts. Ethylate ion is formed faster than acid approaches the surface of the metal. As a result the acid is neutralized before it reaches the metal, and the region adjacent to the metal is alkaline. The clean portions of the metal tend to become covered again with a coating of magnesium hydroxide, due to the water present, more rapidly than they can be cleaned by chloride ion, etc., as we have seen from the fact that the reaction rate decreases after the acid has been con-

---

(23) This opportunity is taken to correct a statement by Kilpatrick and Rushton,[8] that potassium nitrate causes zinc to dissolve in aqueous acids more rapidly than magnesium. Our results agree more nearly, though not completely, with those of King and Braverman,[19] who found that the addition of nitrate raised the rates of solution of zinc to those of magnesium.

sumed. Since the region adjacent to the surface of the metal is alkaline, the acid cannot aid in this cleaning. Meanwhile, the rate of cleaning of surface with which alcohol is not reacting decreases, due to the decrease in the concentration of acid. When equal areas of the metal are being cleaned and covered in the same period of time, the clean area will have reached a maximum, and the maximum rate of reaction will be observed. The higher the initial concentration of an acid, the larger will be the quantity of acid consumed during the induction period and consequently the area of clean surface. This is what happens, as can be seen from the data in Tables III and VII. From the point of maximum reaction onward surface is covered more rapidly than cleaned.

The observed rate of reaction at any time depends on the area of clean surface. This, in turn, appears to be related to the concentration of ethylate ion adjacent to it. We should expect this to be so, since the concentration of ethylate ion next to the surface should be an important factor in determining the amount of magnesium hydroxide which forms on the metal due to the reaction with water. From the results of the experiments to determine the influence of temperature and the rate of stirring we should conclude as was pointed out previously, that the rate of disappearance of ethylate ion from the surface by transport of acid and ethylate ion only partially determines the concentration of ethylate at the reaction interface. It also depends on the actual rate of the chemical reaction between the magnesium and the alcohol molecules. That is, the two rates do not differ sufficiently in magnitude for one to be the sole rate-determining factor.

The authors wish to make due acknowledgment of a research grant made to one of us (M. K.) by the Faculty Research Committee of the University and of a fellowship granted to the other (M. S.) for the year 1934–1935 by the George Leib Harrison Foundation of the University of Pennsylvania.

Summary

1. It was found that magnesium can displace hydrogen from the molecules of ethyl alcohol without the intermediate formation of solvated proton.

2. When magnesium dissolves in solutions of acids in ethyl alcohol the predominant reaction is between the metal and the alcohol. The production of ethylate ion is sufficiently rapid to prevent other acids from reaching the metal.

3. The observed rate of reaction depends directly on what portion of the measured surface of the metal is available for reaction. This is related to the concentration of ethylate ion at the reaction interface, which is determined by two processes whose velocities do not differ sufficiently for either of them to be the sole rate-controlling factor. They are the actual rate of the chemical reaction between the metal and alcohol and the rate of removal of ethylate ion from the reaction interface by neutralization and transport.

NOTES

Ultramicroscopic Examination of Mixed Films

BY FREDERICK M. FOWKES, ROBERT J. MYERS AND WILLIAM D. HARKINS

The presence of a paraffin oil, such as nujol, in an expanded film formed by a fatty acid, such as myristic or pentadecylic acid, has a surprisingly great effect upon the pressure–area relations, as found by Myers and Harkins [R. J. Myers and W. D. Harkins, *J. Phys. Chem.*, **40,** 959 (1936); W. D. Harkins and R. J. Myers, THIS JOURNAL, **58,** 1817 (1936)]. This fact suggests that even if some of the paraffin oil is present in the form of lenses, a part remains mixed with the monomolecular film of acid. Myers and Harkins were unable to find any lenses visible to the naked eye in most of the mixed films investigated by them. In order to determine whether microscopic lenses are present, somewhat similar work has been done in which the pressure–area relations were determined by the Wilhelmy method and simultaneous observations of the structure of the film were made by the use of a dark field condenser and a microscope, as in the work of Zocher and Stiebel [*Z. physik. Chem.*, **147A,** 40 (1930)].

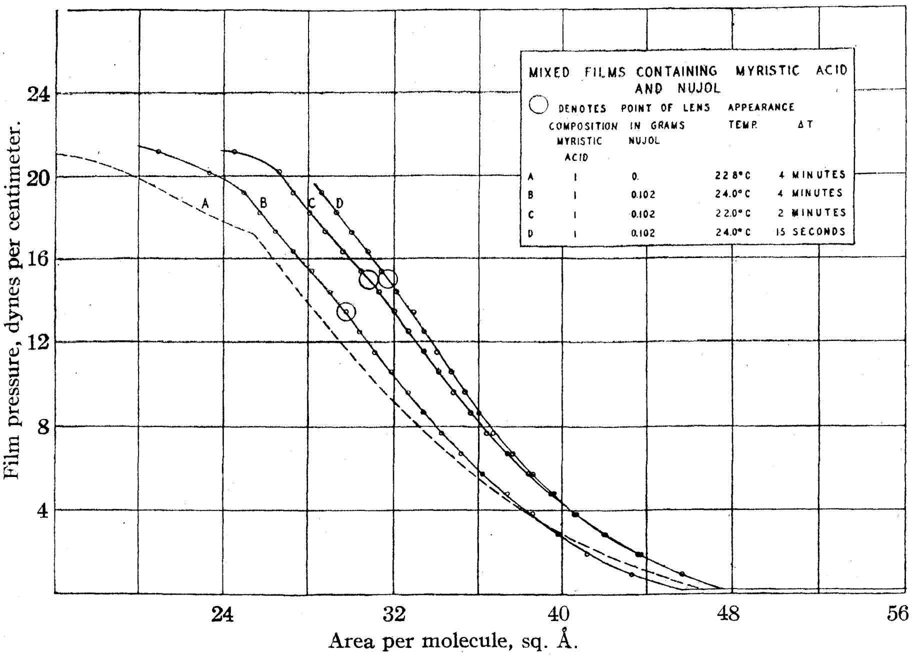

Fig. 1.

Mixtures of one part by weight of nujol to two parts of stearic, myristic, pentadecylic or oleic acids exhibit many oil lenses from gaseous film pressures up through collapse pressures. The average lens diameter in these films is about 1–2 μ and the lens concentration on an expanded film is of the order of 2000 lenses per sq. mm.

All films which contain a larger ratio of the paraffin oil to fatty acid give oil lenses, the lenses increasing in size as the relative concentration of the oil increases.

However, when mixtures which contain 0.3 or less parts of the paraffin oil to one part of fatty acid are examined, no lenses appear until the film is compressed to a certain critical pressure. At these points the lenses appear suddenly, their diameters seem to be less than 1 μ, and their concentration is of the order of 2500 lenses per sq. mm. If the pressure is decreased one or two dynes per cm. the lenses disappear, but reappear as before upon recompression. The force–area curves with nujol–myristic acid mixtures on 0.01 *m* hydrochloric acid show the dependence of the appearance of the lenses on film composition, film pressure and rate of compression. It probably depends also on the nature of the substrate.

The apparent compressibility of the film increases as the time of compression is increased (Fig. 1), but lenses first appear at areas which are largest for the most rapid compression. In both figures the line of dashes represents pure myristic

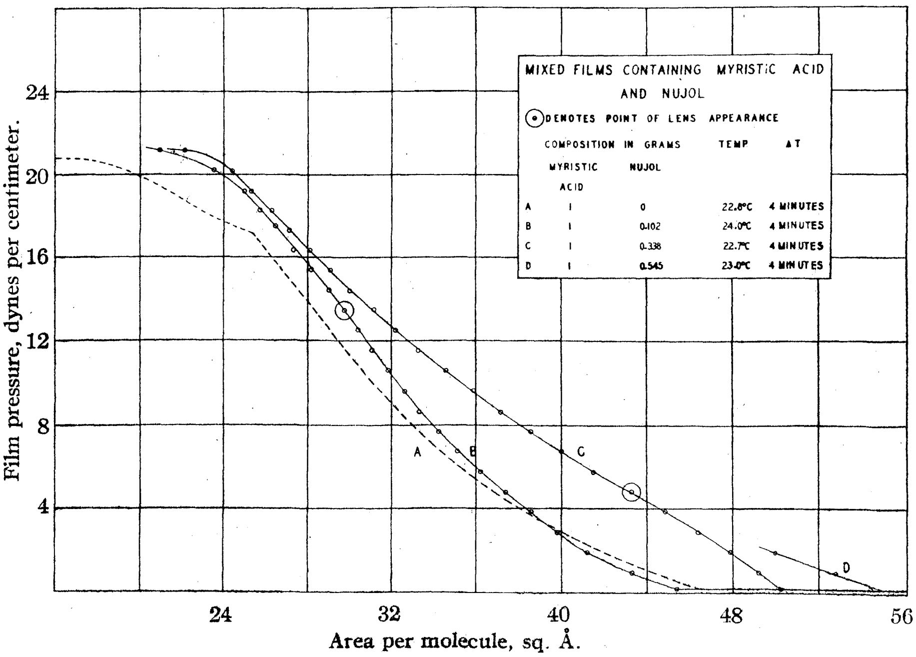

Fig. 2.

acid. All areas for the mixtures refer to the area per molecule of the acid, without reference to the amount of paraffin oil present.

From Fig. 2 it is obvious that at areas at which no lenses are visible, if the molecules of acid were to be oriented as in a condensed film, the total area would be more than sufficient to allow every molecule of the paraffin oil to be in contact with the water, but it is not suggested that the orientation is of this type. The presence of the oil causes these films to occupy larger areas, and Myers and Harkins have shown that larger amounts of oil expand the film at low pressures, but more greatly condense it at high pressures.

Thus it appears that uniform mixed films composed of fatty acids and liquid hydrocarbons may exist but these films are transformed at definite film pressures to composite films with lenses of hydrocarbon oil.

An investigation of these phenomena is in progress. An important feature revealed in this work is that the appearance of the lenses does not give rise to a discontinuity in the pressure–area curves.

Protein Content of the Bark of Black Locust, *Robinia Pseudacacia*

BY D. BREESE JONES AND SAMMIE PHILLIPS

The observations here recorded relate to the surprisingly large quantity of protein in the bark of the common black locust tree. Protein is a well-recognized constituent of most plants and animal tissues, but as far as known the black locust is the only tree from the bark of which protein has been isolated and studied.

In 1899, Power and Cambier[1] demonstrated that the protein of the black locust tree was responsible for the poisoning of horses which had gnawed the bark of this tree. Later, other investigators[2–4] found that hypodermic injections of a solution of this same crude protein preparation produced an alteration of the kidneys producing a nephritis, and that even in great dilutions it agglutinated the red corpuscles of the blood of many different animals. Several instances are recorded[5] where both people and animals have been poisoned by the bark of the locust tree.

In the work of the authors referred to only the crude protein coagulum was used. No attempt was made to study the chemical and physical properties of the bark proteins or to determine the amount of protein in the bark. In 1925, Jones and Gersdorff[5] found that the dried inner bark collected from two locust trees in Maryland contained 17.5% crude protein. This protein was found to consist chiefly of a globulin, albumin and a proteose. The physical properties and composition of the proteins isolated were similar to those of most vegetable and animal proteins. They contained practically the same assortment and proportions of amino acids as found in most proteins.

Occasion was recently had to examine the bark from a number of black locust trees grown in different localities. This bark was collected[6] in Ohio and Indiana from trees ranging in age from seven to ten years. The outer brown, suberous portion of the bark was carefully removed. Only the inner, light colored portion was employed. The latter was allowed to dry by exposure to the air, and then was ground to a coarse powder in a mill. Moisture in the ground bark was determined by heating for twenty-four hours at 110°. Nitrogen in the samples was determined by the Kjeldahl method, and the crude protein calculated by multiplying the percentage of nitrogen by the conventional factor 6.25. The percentages given in Table I are based on moisture-free material.

The quantity of protein found covers a rather wide range. The average, 21.5%, is, however, considerably higher than that previously found in this Laboratory when working with the bark from the trees grown in Maryland. This difference may be due to the fact that the barks were collected at different seasons of the year. The bark from the Maryland trees was collected about the middle of August, while that from the

(6) The samples were collected under the supervision of Dr. Ralph C. Hall of the Bureau of Entomology and Plant Quarantine, to whom grateful acknowledgment is made. Some locust trees are seriously damaged by the locust borer. Other trees seem to be resistant to the attacks of this insect. Determinations of protein in the bark of resistant and susceptible trees were made with the idea that there might be a correlation between immunity to borer attack and the quantity of protein in the bark. No such correlation was found, however.

The Existence of a Maximum in the Gas Solubility–Pressure Curve

BY I. R. KRICHEVSKY

Basset and Dodé[1] have measured the nitrogen solubility in water at 18° and under pressure up to 4500 kg./sq. cm. They detected an excessively interesting phenomenon, that at pressures about 3000 kg./sq. cm. the nitrogen solubility passes through a maximum. Though their determinations are not particularly exact, nevertheless the existence of a maximum is a reality and can be predicted theoretically.

For a case of slightly soluble gases in solvents with small vapor pressure we[2] have deduced a thermodynamical equation

$$\log f_2/N_2 = \log K + \overline{V}_2P/2303RT \qquad (1)$$

where f_2 is the fugacity of the gas, N_2 its mole fraction in the solution, K Henry's coefficient, $\overline{V}_2$ partial molal volume of the dissolved gas and P total pressure.

The solubility maximum corresponds to that pressure at which

$$\partial \ln N_2/\partial P = 0 \qquad (2)$$

Differentiating the equation (1) with respect to pressure and substituting V_2/RT for $\partial \ln f_2/\partial p$, where V_2 is gas volume, we can readily find that at the maximum solubility

$$V_2 = \overline{V}_2 \qquad (3)$$

The partial molal volume of the water-dissolved nitrogen at 18° is 32.7 cc.[2] For lack of data we shall accept that the partial molal volume of nitrogen does not depend upon pressure. Extrapolating data of Amagat[3] for nitrogen compressibility we found that at 18° the pressure of 3600 kg./sq. cm. corresponds to the volume of 32.7 cc., which is in a fairly good agreement with measurements of Basset and Dodé.

Mechanism of the Reduction of Unsaturated Compounds with Alkali Metals and Water

BY CHARLES BUSHNELL WOOSTER AND KENNETH L. GODFREY

A number of valuable methods for reducing unsaturated organic compounds involve the use of a combination of an alkali metal or its amalgam with water or some other hydrolytic solvent, and the various interpretations which have been offered for these reactions are based on one, or the other, of two rival hypotheses. The earlier of these hypotheses attributes the reduction to "nascent" hydrogen liberated by the reaction between the alkali metal (or its amalgam) and the hydrolytic solvent.[1] In more general terms, this hypothesis requires that the actual reduction is effected by the *combination* and not by the metal alone. The more recent hypothesis attributes the

actual reduction to the alkali metal alone; that is, the primary reduction process is assumed to be addition of the alkali metal to the unsaturated compound. It is considered that the function of the solvent is merely to replace the metal in the addition compound with hydrogen by a hydrolytic process and that direct reaction between the solvent and the free alkali metal (or its amalgam) is a side reaction.[2] It has been shown definitely that certain specific reduction processes actually follow the course prescribed by the second hypothesis.[3]

We have now discovered another specific reduction reaction which appears definitely to follow the course prescribed by the *first* hypothesis. This reaction is the reduction of toluene with sodium (or potassium) and water in liquid ammonia. Toluene is not attacked by solutions of these alkali metals in liquid ammonia in the absence of water for the blue color of the alkali metal solutions is not discharged by addition of a large excess of toluene even when the mixture is allowed to stand for several hours. Furthermore, the presence of the total amount of metal in the free state may be demonstrated by the addition of ethyl bromide, ammonium chloride or a catalyst (iron rust) which initiates reaction between the metal and the solvent ammonia. Under these conditions the theoretical amount of ethane or hydrogen is always evolved and the toluene may be recovered. On the other hand, when water is added to the mixture much less than the theoretical amount of hydrogen is evolved and there is obtained a highly unsaturated liquid product which boils over the range 110–115°, chars with fuming sulfuric acid, reacts vigorously with liquid bromine and rapidly decolorizes a solution of bromine in carbon disulfide.

It is evident that although toluene does not react with liquid ammonia solutions of these alkali metals, it is immediately attacked (doubtless reduced) when water also is added. These facts are especially significant because under such conditions a very appreciable concentration of toluene is always present in the same phase with the ammonia and the alkali metal so the action of water cannot be ascribed to any purely surface phenomenon. It is also noteworthy that the effective combination is relatively specific, thus the hydrogen produced by reactions between the alkali metals and ammonia or ammonium chloride does not attack the toluene.

Finally, these observations have an important bearing on the technique of studying reactions in liquid ammonia, because two common practices are the use of toluene as a diluent to facilitate the reaction of organic substances sparingly soluble in ammonia, and the measurement of the hydrogen evolved on addition of water to determine the amount of excess free alkali metal remaining at the end of a reaction. It is now clear that a combination of these two practices will give misleading results, and that ammonium chloride (or an ammonolysis catalyst) should be used instead of water under such circumstances.

These studies are being continued in the hope of obtaining further significant information regarding the mechanism of such reduction processes.

COMMUNICATIONS TO THE EDITOR

OCCURRENCE OF ACETOVANILLONE IN WASTE SULFITE LIQUOR FROM CONIFEROUS WOODS

Sir:

Investigation of the products of alkaline degradation of waste sulfite liquor from the pulping of coniferous woods (mixture of spruce and balsam) on a large laboratory scale has disclosed the presence therein of acetovanillone (3-methoxy-4-hydroxyacetophenone) identical in every way with the synthetic product made from guaiacol acetate. *Anal.* OCH_3, 18.65; calcd. 18.68; m. p. 114.5°. Synthetic acetovanillone: m. p. 115°; mixed m. p. 114–115°. Semicarbazone: m. p. 165.5–166°; mixed m. p. 164.5–165.5°.

OCCURRENCE OF ACETONE AND SYRINGIC ALDEHYDE AS DEGRADATION PRODUCTS OF LIGNIN SUBSTANCES

Sir:

We wish to report two degradation products obtained from lignin substances. The first, acetone, has been obtained by a stepwise oxidation as well as by ozonization of formic acid spruce lignin and identified as acetone superoxide, dibenzalacetone, and acetone 2,4-dinitrophenylhydrazone, melting points 132.5°, 112°, and 128°, respectively. No lowering of melting point was found after admixture with authentic synthetic samples. The second product, syringic aldehyde, was isolated by the alkaline scission of sulfite liquor obtained from yellow birch wood and identified as follows. *Anal.* (1) Calcd. for $C_9H_{10}O_4$: C, 59.3; H, 5.5; OCH_3, 34.1; mol. wt., 183. Found: C, 59.1; H, 5.6; OCH_3, 33.8; mol. wt. (Rast method), 175.6. (2) M. p. 111.5–112° (corr.). (3) Semicarbazone, m. p. 185–186° (corr.). (4) Deep green coloration with ferric chloride. (5) Crystalline derivative with dimedone. All these properties are in entire agreement with those recorded by McCord, THIS JOURNAL, **53**, 4181 (1931).

NEW BOOKS

An Introduction to the Preparation and Identification of Organic Compounds. By ROBERT D. COGHILL, Assistant Professor of Chemistry, and JULIAN M. STURTEVANT, Instructor in Chemistry, Yale University. McGraw-Hill Book Company, Inc., 330 West 42nd Street, New York, N. Y., 1936. xiii + 226 pp. 14 × 21 cm. Price, $1.75.

The use of typical preparations as a means of introducing students to the theory and practice of laboratory technique in elementary organic chemistry has been recognized as the most feasible approach for the past hundred years. The corresponding employment of systematic methods of organic qualitative analysis as a means of instruction is much more recent, and may perhaps be said to have been initiated about 1900 through the efforts of the late Professor Samuel P. Mulliken at the Massachusetts Institute of Technology. Since the publication of his monumental work, appreciation of the value of this aspect of the subject as a means of instruction has been growing, as evidenced by the appearance of elementary books such as those of Clarke, Kamm, Shriner and Fuson, and others. No institution of learning can claim a first rank course in elementary organic chemical laboratory unless adequate attention is given to the identification as well as to the preparation of simple organic compounds.

Despite the present recognition of the equal importance of the study of both the synthetic and analytical aspects of organic laboratory instruction, there has been a surprising delay in the appearance of a laboratory manual placing both on an equal footing in the same volume. The present book is intended to fill this recognized need.

Apart from the necessary indices, appendices, etc., the 207 actual text pages of the volume are divided among three types of treatment: manipulative operations (both from synthetic and analytical viewpoint), 48 pages; synthetic preparations, 67 pages; and identification of organic compounds, 92 pages.

The synthetic section includes 42 experiments about equally divided between solids and liquids. In addition to many standard preparations included in all laboratory manuals several new selections are offered, including benzene from sodium benzoate, mandelic acid from benzaldehyde, *m*-chloronitrobenzene from *m*-nitroaniline, anthranilic acid from phthalimide, ethyl resorcinol from resorcinol *via* resacetophenone and subsequent Clemmensen reduction, *p*-nitrobenzoyl chloride from the acid and thionyl chloride, *p*-bromophenacyl bromide from bromobenzene *via p*-bromoacetophenone, and indigo from benzaldehyde *via o*-nitrobenzaldehyde. Each procedure is preceded by a short discussion and followed by questions. Both the manipulative and preparative sections are well written and fully illustrated with diagrams.

The analytical section is based upon a selected list of between three and four hundred of the most common and easily available organic compounds arranged to be identified by a set of tests according to a given key. After a short introductory chapter, the subject is discussed in three chapters entitled, respectively, analytical methods, 21 pages; classified list of compounds, 14 pages; and preparation of derivatives, 49 pages. In the list of compounds it is very unfortunate that the order and group headings reiterating the distinctive characteristics of each part were not carried along in the text, as the present arrangement requires an inconvenient amount of cross references to preceding pages for interpretation of the key. Selections of group tests are generally good, but the experienced analyst will miss some of the most useful methods, such as the use of the Duclaux number in the characterization of volatile fatty acids, the characterization of phenols by formation of aryloxyacetic acids, etc. The long chapter on derivatives is apparently intended to acquaint the student with a very large number of possible procedures rather than with their several advantages or disadvantages in the rigorous identification of a particular individual compound. Despite the breadth of treatment of this aspect, the text contains only three specific references to the periodical literature: the authors could well have afforded to be a little more helpful in extending the horizon of the better students.

A little knowledge is a dangerous thing. The difficulties of selection for a short treatment of the methods of identification of organic compounds are so severe that the educational world must be not too critical. The authors deserve congratulation on this somewhat daring experiment. It is sincerely to be hoped that the accessibility of this manual will result in immediate attention to the subject in all courses of organic instruction where the analytical aspect is not yet included.

Ernest H. Huntress

Cours de Chimie Industrielle. Tome III. **Metallurgie.** (Industrial Chemistry. Vol. III. Metallurgy.) By G. Dupont, Professor in the Faculty of Sciences of the University of Paris. Gauthier-Villars, Éditeur, 55 Quai des Grands-Augustins, Paris, France, 1936. iii + 357 pp. Illustrated. 16 × 25 cm. Price, 65 francs.

This third volume of Dupont's "Cours de Chimie Industrielle" is a brief (355 pages) and elementary French textbook of metallurgy, including smelting and refining, the laboratory technique of preparation and testing of metals and alloys, and some discussion of the uses of metals and a little statistical information. The elementary character of the discussion is illustrated by the fact that the whole subject of special alloy steels requires only one page with a mention of only nickel, chromium, copper and tungsten as elements which may be added to steel with advantage. In another part of the book the metallurgy of vanadium is disposed of in one-half page which includes the statement "The ferrovanadium is used, in small proportions, for the refining of iron and steel, which results in an appreciable improvement in the mechanical qualities." The cobalt steels are not merely ignored but their industrial significance is denied: "Cobalt has no applications as the metal; its properties are not, from this point of view, very different from those of nickel, and it is much more rare than the latter. On the other hand, cobalt has in its combinations two industrial uses: (1) the manufacture of smalt, silicate of cobalt, a very beautiful blue glass, used as a pigment; (2) the manufacture of various salts of cobalt, used especially as an oxidation catalyst in the drying of oils." The entire invention and development of the cryolite method of making aluminum is ascribed to Héroult, without even a mention of the name of Charles M. Hall.

It seems clear that an experienced metallurgist will have no need to consult this book and that an American student or beginner can find better books in English unless he is primarily interested in improving his knowledge of the French language.

Grinnell Jones

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. Meyer. Eighth Edition. System-Number 23, **Ammonium,** Parts 1–2. Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1936. 602 pp. 17 × 25 cm. Price, RM. 28.00 + 42.25.

The ammonium radical is the only non-elementary ingredient of matter which has been allotted a separate "System-Number" in Gmelin's Handbook. This fact and the 602 pages devoted to this subject reflect the importance of ammonium in inorganic chemistry.

The major part of this volume, as would be expected, is occupied with the physical properties of ammonium salts and their solutions, and is replete with tables and diagrams, so that a wealth of information is presented in small compass and in easily accessible form. The literature has been covered for the first half of the volume to the end of February, and for the second half to the beginning of July, 1936.

It is indeed a great advantage to students of inorganic chemistry to have this mass of information on an important subject so completely and conveniently presented.

Arthur B. Lamb

Synthetic Inorganic Chemistry. A Course of Laboratory and Classroom Study for First Year College Students. By Arthur A. Blanchard, Ph.D., Professor of Inorganic Chemistry, Joseph W. Phelan, S.B., Late Professor of Inorganic Chemistry, and Arthur R. Davis, Ph.D., Assistant Professor of Chemistry, at the Massachusetts Institute of Technology. Fifth edition. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1936. xii + 379 pp. 25 figs. 15 × 24 cm. Price, $3.00.

The fact that this book is now in its fifth edition would indicate that it fulfills the purpose stated in its preface, namely, "to meet satisfactorily the problem of first-year college students in chemistry." The present edition differs from the previous ones in that "a very considerable portion of the text has been wholly rewritten and the entire text has been subjected to a revision and rearrangement. Specific new exercises and discussions which have been introduced include such topics as the determinations of vapor density and molecular weight, the standardization of acids and the titration of acids and bases, Faraday's law and the use of the p_H scale of hydrogen-ion concentration. Several new preparations have been introduced and a few of the old ones have been discontinued."

Chapter I includes a number of quantitative experiments such as the determination of the "Weight of a Liter of Oxygen" and the "Volume of Hydrogen Displaced by Zinc." One chapter is devoted entirely to the theory of ionization. The remaining chapters are divided into two parts: the first includes directions for preparing typical compounds of the different groups of elements, while the second describes various experiments to be carried out with these compounds. A rather extended appendix covers the preparation of reagents, a discussion of the electromotive series, and the periodic classification of the elements.

The authors state that "all students entering the Massachusetts Institute of Technology should have met an entrance requirement in chemistry. It is very discouraging to such students to be set at once to reviewing what they have already had, however much they may need the review. The nature, and the considerable freedom in the choice, of laboratory work solves this situation in a very satisfactory manner. A review of preparatory school work is of course necessary, but by bringing this in incidentally the sting of it is removed."

Undoubtedly the student who successfully performs the experiments outlined in this text and is able to deduce correct conclusions from his findings will have gained a thorough knowledge of the fundamental principles of chemistry so far as may be expected of first-year college students.

2,3,6-Trimethylglucose Diethyl Mercaptal and its Use in the Preparation of 2,3,6-Trimethylglucose

BY M. L. WOLFROM AND LOUIS W. GEORGES[1]

2,3,6-Trimethylglucose has been synthesized from *d*-glucose by Irvine and Rutherford,[2] but the procedure employed is rather laborious for preparative purposes. The trimethylglucose can also be obtained as a hydrolytic product of methylated cellulose, methylated starch and a number of methylated disaccharides. The free sugar is very sensitive and is difficult to isolate in good yield. We have found that it forms a well-crystallized and easily isolable diethyl mercaptal, from which the free sugar can be regenerated under mild conditions and can thus be prepared readily in good purity.

In the work herein reported, methylated cellulose has been used as a source of 2,3,6-trimethylglucose. Irvine and Hirst[3] prepared this trimethylglucose by the treatment of methylated cellulose under pressure with methanol containing hydrogen chloride, and subsequent hydrolysis of the glycosidic methyl group. Denham and Woodhouse,[4] who first obtained crystalline 2,3,6-trimethylglucose, prepared it from methylated cellulose by direct hydrolysis with fuming hydrochloric acid. Hess and Neumann[5] likewise prepared this trimethylglucose by the hydrolysis of methylated cellulose with fuming hydrochloric acid, purifying the product through its methylglycoside.

In our experiments, methylated cellulose was hydrolyzed with fuming hydrochloric acid at low temperatures and the diethyl mercaptal of 2,3,6-trimethylglucose was isolated directly from the acid solution. This was an extension of the work previously reported from this Laboratory[6] on the hydrolysis of cellulose with fuming hydrochloric acid and mercaptalation at various stages of the hydrolysis. The free sugar was then regenerated from its diethyl mercaptal by treatment with mercuric chloride in moist acetone in the presence of cadmium carbonate.[7]

2,3,6-Trimethylglucose diethyl mercaptal is a readily crystallizable substance and forms a crystalline dibenzoate. There are thus added two crystalline derivatives to the rather small number recorded for this sugar. The diethyl mercaptal offers promise as a characterizing derivative for 2,3,6-trimethylglucose. The diethyl mercaptal of tetramethylglucopyranose was also obtained. This was an oil which formed a crystalline monobenzoate.

[8] We wish to acknowledge the assistance rendered by Messrs. M. E. Bernstein and R. D. Koons in the preparation of the methylated cellulose used in this work.

[9] Furnished through the courtesy of the du Pont Rayon Co., Waynesboro, Va. The viscosity of this material in 7% solution in acetone was 16.8 on the basis of an assigned viscosity of 100 for pure glycerol.

was methylated in one step to an approximate trimethyl cellulose according to the procedure employed by Haworth, Hirst and Thomas.[10] This method gave an average yield of 15 g. of the crude methylated product with a methoxyl content varying from 42 to 44%. This material was used without further purification in the subsequent hydrolytic experiments.

2,3,6-Trimethyl-*d*-glucose Diethyl Mercaptal.—Methyl cellulose (13.5 g.; OCH_3, 42–44%) was placed in a glass-stoppered pressure bottle and 200 cc. of fuming hydrochloric acid (d_4^{15} 1.202) added. Complete solution was effected by cooling to 0° and shaking. The solution, colored a pale amber, was allowed to stand at 4° for thirteen days. The solution had then acquired a dark-brown color which was removed by two treatments with Carboraffin, filtering each time through a layer of asbestos, previously treated with fuming hydrochloric acid. The final volume of the solution was adjusted with water to approximately 220 cc. and the solution divided into two 110-cc. portions for mercaptalation. Each portion was shaken mechanically for fifteen minutes at 0° with 14 cc. of purified ethyl mercaptan and was neutralized by pouring into a suspension of 107 g. of sodium bicarbonate in 170 cc. of water. During the neutralization a curdy precipitate formed. The mixture was kept overnight at ice-box temperature, filtered and dried in a vacuum desiccator over sodium hydroxide. The crude products from the two mercaptalations were combined and extracted with anhydrous ether. The ethereal extract was decolorized with Carboraffin, dried and the solvent removed; yield 10.5 g. of crystalline material. Pure material was obtained on recrystallization from petroleum ether (b. p. 65–110°); m. p. 71–72°; $[\alpha]^{29}$ $-15°$ (*c*, 3.8; $CHCl_3$).[11] The compound crystallizes in fine needles and is soluble in water, alcohol and the usual organic solvents.

Anal. Calcd. for $C_6H_9O_2(OCH_3)_3(SC_2H_5)_2$: S, 19.5; OCH_3, 28.3. Found: S (Carius), 19.3; OCH_3 (Kirpal and Bühn[12] method), 27.8.

Preparation of 2,3,6-Trimethyl-*d*-glucose from 2,3,6-Trimethyl-*d*-glucose Diethyl Mercaptal.—2,3,6-Trimethylglucose diethyl mercaptal (5.0 g.) was dissolved in acetone (30 cc.) containing water (0.8 cc.) and finely ground cadmium carbonate (4 g.) was added. A solution of mercuric chloride (16.0 g.) in acetone (30 cc.) was added gradually with mechanical stirring. The reaction was allowed to run at room temperature for twenty-four hours with occasional additions of fresh cadmium carbonate and acetone. The reaction mixture was then heated with stirring on a water-bath (40°) for fifteen minutes, filtered and the residue washed with acetone. The filtrate was concentrated in the presence of cadmium carbonate under reduced pressure at 35° to a viscous residue. This residue was extracted several times with warm chloroform until only a powder remained. The chloroform solution was filtered and then concentrated under reduced pressure at 35° to a sirup. The latter was dissolved in warm water and hydrogen sulfide passed into the cooled solution. The mercuric sulfide was removed by filtration, the filtrate aerated and the acid neutralized with solid sodium bicarbonate. The aqueous solution was then concentrated under reduced pressure at 40° to about one-third of the original volume. At this point inorganic salts began to separate and were removed by the addition of acetone to the solution and filtration. The filtrate was concentrated to a crystalline mass and the latter taken up in chloroform and the chloroform solution evaporated in a vacuum desiccator. The last traces of solvent were removed by stirring dry ether into the mass and evaporating under reduced pressure; yield, 2.6 g. The crystals so obtained were contaminated with a small amount of sirup, which was removed by two extractions with warm anhydrous ether; yield 2.0 g.; m. p. 104–108°. After one recrystallization from ordinary ether the melting point was 116–117°. Digestion of this material with cold, ordinary ether raised the melting point to 118–119°. The compound shows a downward mutarotation in aqueous solution and gave a final value after three and one-half hours of $[\alpha]^{26}$ $+68°$ (*c*, 1.7). The initial value after extrapolation to zero time was found to be $[\alpha]^{26}$ $+102°$. These constants identify the substance as 2,3,6-trimethylglucose of good purity.[13]

2,3,6-Trimethyl-*d*-glucose Diethyl Mercaptal 4,5-Dibenzoate.—2,3,6-Trimethylglucose diethyl mercaptal (1.0 g.) was benzoylated with pyridine (2 cc.) and benzoyl chloride (1 cc.) by standing at room temperature for twenty-four hours. Chloroform was added and the solution washed successively with 10% hydrochloric acid, aqueous sodium bicarbonate and water. The dried chloroform solution was concentrated under reduced pressure to a crystalline mass. Ether was added and the last traces of solvent removed under reduced pressure; yield 1.3 g. of crystalline material. The substance was obtained pure on recrystallization from ethanol; m. p. 115–116°; $[\alpha]^{23}$ $+61°$ (*c*, 4; $CHCl_3$). The compound crystallizes in glittering, elongated prisms and is soluble in ether, chloroform, acetone and benzene; is moderately soluble in alcohol; and is practically insoluble in water and petroleum ether.

Anal. Calcd. for $C_6H_7O_2(OCH_3)_3(COC_6H_5)_2(SC_2H_5)_2$: S, 11.9; C_6H_5CO, 39.1. Found: S, 11.6; C_6H_5CO,[14] 38.8.

2,3,4,6 - Tetramethyl - *d* - glucose Diethyl Mercaptal 5 - Benzoate.—Tetramethylglucopyranose[15] (3.0 g.) was dissolved in 30 cc. of concentrated hydrochloric acid (d^{15}_4 1.185) and the solution cooled to 0°. Ethyl mercaptan (6 cc.) was added and the mixture shaken at 0° for fifteen minutes, whereupon it was poured with stirring into a suspension of 30 g. of sodium bicarbonate in 75 cc. of water. The oily layer that separated was dissolved in chloroform and the mother liquor was extracted with chloroform. The combined extracts were dried, decolorized with Carboraffin and concentrated under reduced pressure to a thin sirup. Anhydrous ether was added and the solvent again removed under reduced pressure; yield 2.5 g. The sirup did not crystallize on standing for several weeks.

An amount of 2.5 g. of the sirupy tetramethylglucose diethyl mercaptal was benzoylated with pyridine (3 cc.) and benzoyl chloride (1.5 cc.) as described for the synthesis of

Summary

1. 2,3,6-Trimethyl-*d*-glucose diethyl mercaptal, its dibenzoate and the monobenzoate of 2,3,4,6-tetramethyl-*d*-glucose diethyl mercaptal have been synthesized in crystalline condition.

2. 2,3,6-Trimethyl-*d*-glucose may be prepared readily by the hydrolysis of methylated cellulose with fuming hydrochloric acid, isolation of the sugar as its diethyl mercaptal and subsequent removal of the ethylmercapto groups.

The Cleavage of Diphenyl Ethers by Sodium in Liquid Ammonia. I. Ortho and Para Substituted Diphenyl Ethers

BY PAUL A. SARTORETTO AND FRANK J. SOWA

It has been found that a solution of sodium in liquid ammonia reacts vigorously and quantitatively with diphenyl ether. The reaction is complete when two atom equivalents of sodium is added to one mole equivalent of the ether. The products are mole equivalents of sodium phenate and benzene.

Conductivity experiments by Kraus[1] have shown that sodium is ionized in the medium of liquid ammonia, the metal being in equilibrium with sodium cations and electron anions. If reactivity involves sodium cations, a compound such as sodamide which is also ionized in liquid ammonia should cleave diphenyl ether; but it does not. Cleavage, therefore, involves either atomic sodium or the electron anions. Although there is no experimental proof favoring either, in a reduction of this type the electron anions are commonly thought of[2] as being the effective reagent. The mechanism of the reaction may be expressed as

$$\begin{gathered} ROR + 2Na^+ + 2e^- \longrightarrow Re^- + ROe^- + 2Na^+ \\ Re^- + NH_3 + Na^+ \longrightarrow RH + NH_2^- + Na^+ \end{gathered}$$

where (R) represents a phenyl group, and (e^-) an electron anion.

The purpose of this investigation was to use the above quantitative method to evaluate the effect of various substituents in the ortho and para positions. It was also employed to evaluate the effect of the ortho against the para position using the same substituent.

Experimental

For the preparation and physical properties of the substituted diphenyl ethers listed in Table I and used in this work the authors are indebted to John J. Verbanc for his assistance.

[2] Franklin, "The Nitrogen System of Compounds," Am. Chem. Soc. Monograph, 1935, p. 50.

(9) and (10) the procedure was the same as described under method (5) using the reagents phenol and *o*-bromotoluene for (8), phenol and *p*-bromotoluene for (9) and *o*-cresol and *p*-bromotoluene for (10). (11) Described by Brewster and Strain, THIS JOURNAL, **56**, 117 (1934). (12) *p*-Carboxydiphenyl ether was prepared from the *p*-methyldiphenyl ether by oxidation. Twenty-five grams of *p*-methyldiphenyl ether was stirred with 1300 cc. of water and 60 g. of potassium permanganate was added in 20-g. portions. The mixture was refluxed and stirred for eight hours. After treatment with dilute potassium hydroxide solution and extraction with ether, the mixture was acidified by adding sulfur dioxide. The *p*-carboxydiphenyl ether separated as white fluffy crystals. The compounds *p*-methoxydiphenyl ether, *o,p'*-dimethyldiphenyl ether were new compounds. The carbon and hydrogen analyses checked well with the calculated values.

A standard method of cleavage, described below, was followed throughout this work.

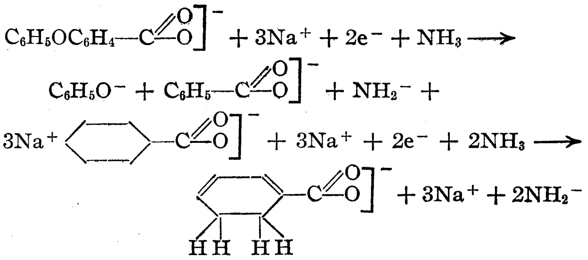
Cleavage of Diphenyl Ethers.—A 2-liter 3-necked flask was fitted with a mercury-sealed mechanical stirrer, liquid ammonia reflux condenser and a large spout dropping funnel. About 200 cc. of liquid ammonia was added to the flask and a solution of 0.25 mole of the diphenyl ether in 25 cc. of dry ethyl ether was introduced slowly. About 200 cc. of dry liquid ammonia was added to the dropping funnel, and to this was added 0.25 gram atomic weight of sodium. After a sufficient time was allowed for the sodium to dissolve, the solution was introduced into the reaction flask with constant stirring. Another 0.25 gram atomic weight of sodium was made to react in a similar manner. Completion of the reaction was indicated by the appearance of a permanent blue sodium–liquid ammonia coloration. The mixture was evaporated to dryness with the aid of a cold water-bath, hydrolyzed with water and acidified with dilute hydrochloric acid, substituting an ice-bath for the last two processes. The cleavage products were extracted with ether and analyzed, each according to a method thought most suitable.

In Table II the cleavage products and methods of analysis are listed for each cleavage. For brevity, the groups attached to oxygen of the ether are designated as (R) and (R'). In every case the yield was based upon the phenolic products, for it was found that products such as benzene and toluene were short of theoretical recovery, due to loss in entrainment with ammonia gas evolving from heat of reaction.

Discussion of Experimental Results

The cleavage of the above diphenyl ethers requires two atom equivalents of sodium with the exception of the carboxydiphenyl ethers.

4-Carboxydiphenyl ether reacts with approximately 5 atom equivalents of sodium, the last two atom equivalents reacting slowly. The mechanism for the reaction, based on the supposition that sodium reacts slowly with sodium benzoate in liquid ammonia,[3] and also that the sodium salt of the carboxydiphenyl ether reacts with 4 atom equivalents of sodium to form hydrogenated benzoic acid and phenol, is as follows



The second reaction is to be investigated further.

The cleavage of 2-carboxydiphenyl ether required approximately 4 atom equivalents of sodium, with incomplete hydrogenation of sodium benzoate.

In mono-substituted diphenyl ethers the linkage between the oxygen and the substituted phenyl group is strengthened against cleavage by sodium in liquid ammonia by the introduction of the following substituents, listed according to their increasing effectiveness: *o*-CH_3, *p*-CH_3, *p*-OCH_3, *o*-NH_2, *p*-NH_2; and the linkage is weakened toward cleavage by the following substituents, similarily listed: *o*-OCH_3, *o*-COONa, *p*-COONa. The results of cleavage of 2,4'-disubstituted diphenyl ethers, using the same substituent in each phenyl group, are in accord with those results expected from the knowledge of cleavage of mono-substituted diphenyl ethers.

In all the cleavages studied that are comparative, it has been indicated that a substituent, either hindering or facilitating cleavage of the linkage between oxygen and the substituted phenyl group, is more effective in para position than in ortho position.

Theoretical Discussion

Unequal amount of cleavage on each side of the oxygen to carbon linkage in substituted diphenyl ethers indicates that the electronic configuration of the carbon atoms directly linked to oxygen has been disturbed by the effects of the substituents. Since the electron (or sodium atom) may be considered as a nucleus seeking reagent, it will attach itself more readily to the carbon atom, linked to oxygen, which has the lowest electron density. In the mono-substituted diphenyl ethers, containing a substituent of the first series mentioned above, the electron attaches itself more readily to the phenyl group

that does not contain the substituent. It is reasonable to assume that the electronic configuration of the carbon atom, to which the electron attaches itself more readily, has not been disturbed appreciably by the substituent in the opposite phenyl group. Therefore, the electron density of the carbon atom (of the substituted phenyl group), which is attached to oxygen, has increased by the introduction of a substituent of the first series. On the other hand, the second series of substituents decrease the electron density of the carbon atom (of the substituted phenyl group) attached to oxygen.

Interpreting the experimental data in the light of electronic theories of Ingold,[4] Robinson,[5] etc., the influence of various substituents upon the carbon atoms in a phenyl group consists of two factors: an inductive effect, and a tautomeric effect. The effects observed in the case of the first series of substituents are in agreement with the application of these theories to such cleavage reactions and indicate that the tautomeric effect is the more dominating effect, and more pronounced in para than in ortho position; while the effect of the ortho substitution of OCH_3 group can be explained only by assuming that the inductive effect of the OCH_3 dominates the tautomeric effect, in this particular instance. This assumption is further substantiated by the cleavage of 2,4′-dimethoxydiphenyl ether. It is not in accord with the usual views, although it is to be expected that the inductive effect would be more pronounced in ortho than in para position.

The authors wish to express their appreciation to Dr. Andrew J. Boyle for his helpful suggestions.

Summary

Sodium in liquid ammonia cleaves diphenyl ethers rapidly and quantitatively at the carbon–oxygen linkage.

In mono-substituted diphenyl ethers, the tendency for the linkage between oxygen and the substituted phenyl group to cleave is decreased by the introduction of the following substituents, listed according to their increasing effectiveness: *o*-CH_3, *p*-CH_3, *p*-OCH_3, *o*-NH_2, *p*-NH_2. The tendency for the linkage between oxygen and the substituted phenyl group to cleave is increased by the introduction of the following substituents, similarly listed: *o*-OCH_3, *o*-COONa, *p*-COONa. The results of cleavage of 2,4′-disubstituted diphenyl ethers, using the same substituent in each phenyl group, are in accord with those results expected from the knowledge of cleavage of mono-substituted diphenyl ethers.

In all the cleavages studied that are compara-

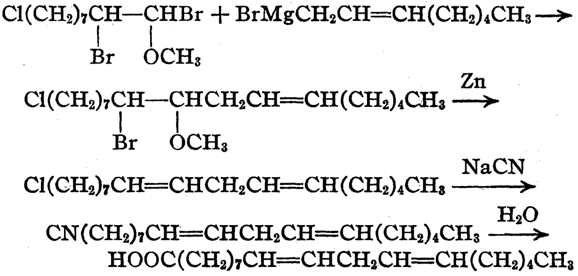
The Synthesis of Unsaturated Fatty Acids. II. Linoleic and 11-*n*-Amyl-9,12-tridecadienoic Acids

BY C. R. NOLLER AND M. D. GIRVIN

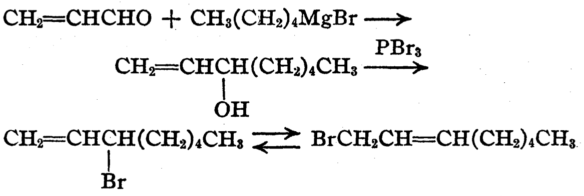
The synthesis of linoleic acid (9,12-octadecadienoic acid) is desirable not only because the commonly accepted structure is periodically questioned[1] but also because linoleic acid is apparently one of the accessory food factors, designated by Evans and his co-workers[2] as vitamin F, which is necessary for the growth and fertility of both male and female rats.

Using the following series of reactions which is similar to that previously used for the synthesis of oleic and elaidic acids[3] we have succeeded in synthesizing a product which contains α-linoleic acid.



$$\underset{\text{Br}}{\text{Cl(CH}_2\text{)}_7\text{CH}}\text{—}\underset{\text{OCH}_3}{\text{CHBr}} + \text{BrMgCH}_2\text{CH=CH(CH}_2\text{)}_4\text{CH}_3 \longrightarrow$$
$$\underset{\text{Br}}{\text{Cl(CH}_2\text{)}_7\text{CH}}\text{—}\underset{\text{OCH}_3}{\text{CH}}\text{CH}_2\text{CH=CH(CH}_2\text{)}_4\text{CH}_3 \xrightarrow{\text{Zn}}$$
$$\text{Cl(CH}_2\text{)}_7\text{CH=CHCH}_2\text{CH=CH(CH}_2\text{)}_4\text{CH}_3 \xrightarrow{\text{NaCN}}$$
$$\text{CN(CH}_2\text{)}_7\text{CH=CHCH}_2\text{CH=CH(CH}_2\text{)}_4\text{CH}_3 \xrightarrow{\text{H}_2\text{O}}$$
$$\text{HOOC(CH}_2\text{)}_7\text{CH=CHCH}_2\text{CH=CH(CH}_2\text{)}_4\text{CH}_3$$

The 1-bromooctadecene-2 from which the Grignard reagent was prepared was obtained by the series of reactions



$$\text{CH}_2\text{=CHCHO} + \text{CH}_3\text{(CH}_2\text{)}_4\text{MgBr} \longrightarrow$$
$$\text{CH}_2\text{=CH}\underset{\text{OH}}{\text{CH}}\text{(CH}_2\text{)}_4\text{CH}_3 \xrightarrow{\text{PBr}_3}$$
$$\text{CH}_2\text{=CH}\underset{\text{Br}}{\text{CH}}\text{(CH}_2\text{)}_4\text{CH}_3 \rightleftarrows \text{BrCH}_2\text{CH=CH(CH}_2\text{)}_4\text{CH}_3$$

It was realized at the outset that a mixture of 1-bromooctadecene-2 and 3-bromooctadecene-1 would result but the work of Winstein and Young[4] on analogous compounds indicated that the primary bromide would be formed in larger amount. Moreover, it was expected that the products arising from the secondary bromide would be the lower boiling and would be partially removed during the purification of the intermediate products of the synthesis.

The final product of the synthesis had the correct neutralization equivalent, iodine value, and molecular refraction for linoleic acid. Bromination of the product, however, gave none of the solid tetrabromide characteristic of α-linoleic acid. Since in the synthesis of oleic and elaidic acids[3] the equilibrium mixture of the two stereoisomers was obtained, it seemed unlikely that a mixture now had been obtained in which the geometrical isomer corresponding to α-linoleic acid was missing. Nevertheless a quantity of the synthetic material was elaidinized with Poutet's reagent[5] and the product again treated with bromine. Again no solid tetrabromide was obtained.

A portion of elaidinized product was next oxidized with permanganate according to the modified Hazura procedure used by Green and Hilditch[6] when a quantity of tetrahydroxystearic acids was obtained from which both α- and β-sativic acids were isolated. This proves definitely that α-linoleic acid was present. The amount of crude tetrahydroxy acids was about seven-tenths of that obtained from a sample of elaidinized natural α-linoleic acid and this would indicate that the amount of α-linoleic acid present in the synthetic mixture was of the order of 70%. The crude hydroxy acids from the synthetic product, however, were quite gummy and the total amount of once recrystallized product was only about 28% of that obtained from the natural product.

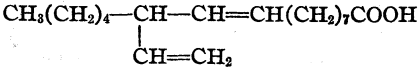
The other constituent of the synthetic mixture is undoubtedly 11-*n*-amyl-9,12-tridecadienoic acid



$$CH_3(CH_2)_4\text{—}\underset{\displaystyle CH{=}CH_2}{\underset{|}{CH}}\text{—}CH{=}CH(CH_2)_7COOH$$

arising from the 3-bromooctadecene-1. Ozonation gave an amount of formaldehyde corresponding to 16% of the calculated amount for this compound. Pure undecylenic acid, however, under the same conditions gave only 44% of the calculated amount of formaldehyde so that as high as 30% of the second isomer is indicated. It was noted that the synthetic product did not become viscous when exposed to air as readily as did α-linoleic acid and it is likely that a large amount of α-linoleic acid in the synthetic product was lost during the course of the numerous fractional distillations by which it was hoped to remove the lower boiling isomer.

The amount of synthetic material obtained during the course of this work was not sufficient for feeding experiments. Because of the numerous steps, poor yields and uncertainty concerning the exact composition of the product, it would seem desirable to develop a more satisfactory method of synthesis rather than attempt to produce synthetic linoleic acid in quantity by this method.

Experimental

***n*-Amylvinylcarbinol** was prepared from *n*-amylmagnesium bromide and acrolein in 47–49% yields observing the precautions recommended by Bouis.[7] After two fractionations the main product boiled at 78–81° at 20 mm. This alcohol has been prepared previously by Levene and Walti[8] who give the boiling point as 81–82° at 20 mm. but give no details concerning the preparation.

1-Bromooctadecene-2 and 3-Bromooctadecene-1.—A mixture of these bromides was prepared from the above alcohol and phosphorus tribromide according to the procedure of Bouis.[7] The yield of product, b. p. 87–89° at 20 mm., was 79%; $n^{23}\text{D}$ 1.4768; d^{23}_4 1.1314.

Anal. Calcd. for $C_8H_{15}Br$: Br, 41.88. Found: Br, 41.70, 41.85.

Because of the high boiling point and the ease with which rearrangement takes place,[4] no attempt was made to separate the mixture into pure isomers. On rapid redistillation at 20 mm. the first 5 cc. of distillate showed $n^{23}\text{D}$ 1.451 and the last 5 cc. $n^{23}\text{D}$ 1.477. After long standing the equilibrium value was $n^{23}\text{D}$ 1.472. Assuming the first and last fractions to be pure secondary and primary bromides, respectively, the equilibrium mixture would contain about 80% of the primary bromide.

1-Chloroheptadecadiene-8,11 and 1-Chloro-10-*n*-amyldodecadiene-8,11.—The mixed bromides were converted into the Grignard reagent in 75% yields, condensed with 8,9-dibromo-9-methoxynonyl chloride, and the bromine and methoxyl groups removed according to the procedure previously used for the synthesis of 1-chloroheptadecene-8.[3] None of the intermediate product was isolated in a pure state and the over-all yield based on the ω-chlorononylaldehyde was 12–15% boiling at 165–171° at 6 mm. after three fractional distillations; $n^{24}\text{D}$ 1.4604; d^{24}_4 0.8912; mol. ref. calcd., 84.6; found, 83.4.

Anal. Calcd. for $C_{17}H_{31}Cl$: Cl, 13.1; iodine no., 187.6. Found: Cl, 13.0; iodine no., 185.8.

A large amount of low boiling material was obtained which was not investigated.

1-Cyanoheptadecadiene-8,11 and 1-Cyano-10-*n*-amyldodecadiene-8,11.—To 12 g. of the mixed chlorodienes in 90 cc. of 95% alcohol was added 3 g. of sodium cyanide and the mixture refluxed for ninety-six hours. The sodium chloride was filtered from the solution and washed with alcohol, the alcohol distilled from the filtrates, and the residue fractionated under reduced pressure. There was obtained 7 g. (60.5%) b. p. 160–170° at 6 mm. Refractionation gave 5 g. (43%) of b. p. 165–170° at 6 mm.

Anal. Calcd. for $C_{18}H_{31}N$: N, 5.36; iodine no., 194.3. Found: N, 5.21; iodine no., 194.8.

9,12-Octadecadienoic and 11-*n*-Amyl-9,12-tridecadienoic Acids.—A solution of 7 g. of nitrile, 2 g. of sodium hydroxide in 10 cc. of water, and 90 cc. of 95% alcohol was refluxed for one hundred and twenty hours. The alcohol was distilled, the residue taken up in 200 cc. of water and extracted three times with petroleum ether. The aqueous solution was acidified and the acids extracted. The solvent was removed and the residue fractionated under reduced pressure. There was obtained 3 g. (40%); b. p. 200–205° at 6 mm. or 185–187° at 3 mm.; $n^{27}\text{D}$ 1.4640; d^{27}_4 0.8948; mol. ref. calcd. 85.9; found: 86.4.

Anal. Calcd. for $C_{17}H_{31}COOH$: neut. equiv., 280.2; iodine no., 180.8. Found: neut. equiv., 281.4; iodine no., 179.2.

The synthetic product after standing for several days at 10° deposited a small amount of solid which after filtration and recrystallization from petroleum ether melted at 59–61° and was saturated to bromine. It was thought that the prolonged heating with alkali may have converted some of the linoleic acid into palmitic or myristic acids, but mixed melting point determinations showed that the solid compound was not either. It was not investigated further.

Chemical Investigation of the Synthetic Product.—Bromination in petroleum ether under conditions that readily yielded the characteristic tetrabromide from natural α-linoleic acid[9] gave no solid bromide. The same results were obtained on samples of the synthetic and natural acids after isomerization with Poutet's reagent.[5]

Oxidation of 1.0 g. of isomerized natural α-linoleic acid by potassium permanganate according to the modified

---

(7) Bouis, *Ann. chim.*, [10] **9**, 407 (1928).

(8) Levene and Walti, *J. Biol. Chem.*, **94**, 593 (1931).

(9) Natural α-linoleic acid used for comparison purposes was prepared from cottonseed oil through the tetrabromide (m. p. 114.5–115°) and the methyl ester by Rollett's procedure [*Z. physiol. Chem.*, **62**, 414 (1909)]. It was noted in another run where debromination of the tetrabromide was carried out in the absence of acid and without going through the methyl ester that the product solidified in the cold room at 10°. The highest melting point previously recorded for pure α-linoleic acid is −7° [Holde and Gentner, *Ber.*, **58**, 1067 (1925)] and we hope to investigate this product further.

Hazura procedure recommended by Hilditch[6] gave 0.57 g. of solid tetrahydroxystearic acids. Hilditch states that the tetrahydroxy acids were "separated by fractional crystallization from ethyl acetate." We used absolute ethyl acetate and found that the lower melting acid could be extracted and recrystallized from this solvent but that the higher melting acid was too insoluble to be recrystallized from it. After extraction of the lower melting acid with absolute ethyl acetate, the higher melting acid was recrystallized from 95% alcohol. There was obtained in this way 0.28 g. of tetrahydroxystearic acid, m. p. 156–157° and 0.07 g., m. p. 172–175°. When 1.0 g. of the synthetic acid was treated in exactly the same way there was obtained 0.40 g. of a sticky product from which was isolated only 0.08 g. of m. p. 151–154° and 0.02 g., m. p. 174–175°. Mixed melting points with the corresponding acids from natural α-linoleic acid were 152–155° and 173–175°.

A solution of 1.536 g. (0.00548 mole) of synthetic acids in 20 cc. of absolute ethyl acetate was ozonized and the solution decomposed with zinc dust and water according to the procedure of Whitmore and Church[10] without removal of the solvent. After distillation and extraction of the aqueous layer with ethyl acetate the formaldehyde was estimated iodimetrically.[11] A blank run was made in which 20 cc. of ethyl acetate was ozonized for the same length of time and decomposed in the same manner as the sample. The amount of formaldehyde from the sample, corrected by the blank, was 0.000883 mole, indicating the presence of 16% of 11-*n*-amyl-9,12-tridecadienoic acid. Pure undecylenic acid, however, gave only 44% of the calculated amount of formaldehyde under the same conditions. The water–zinc dust decomposition of the ozonides does not seem to be very satisfactory for compounds giving water insoluble products since the latter tend to coat the zinc dust and cause it to agglomerate.

The formaldehyde was identified positively by conversion into the 2,4-dinitrophenylhydrazone which after four crystallizations from methyl alcohol melted at 158–162°. The mixed melting point with pure formaldehyde-2,4-dinitrophenylhydrazone (m. p. 166–167°) was 159–163°.

An attempt to isolate the *n*-hexoic and *n*-heptoic acids which also should be formed on ozonation of the synthetic product gave a small amount of mixed acids distilling at 200–260° but conversion to the anilides gave an oil which could not be made to crystallize.

Summary

A series of reactions has been carried out which led to the synthesis of a mixture of linoleic acid and 11-*n*-amyl-9,12-tridecadienoic acid.

Studies of Absorption Spectra. I. Crotonaldehyde and Acrolein

BY FRANCIS E. BLACET, WILLIAM G. YOUNG AND JACK G. ROOF

In connection with problems in photochemistry and in the synthesis of pure stereoisomeric compounds, a quantitative study of the absorption spectra of crotonaldehyde and acrolein in the vapor phase has been made. The object of this investigation was (1) to determine the types of absorption in different regions of the spectrum, (2) to compare the absorption of these two closely related compounds, and (3) in the case of crotonaldehyde, to test by spectroscopic means for the presence of *cis*-crotonaldehyde in the purified commercial product.

Although a number of investigators have studied these compounds,[1] the work for the most part was done with solutions in which the band structure of absorption, as shown by the vapors, was not observed. However, two exceptions to this generalization should be mentioned. Lüthy[1c] reported the fine structure but did not attempt to calculate extinction coefficients from studies of the vapor phase. Eastwood and Snow[1h] also have done nothing with extinction coefficients, but by means of a 21-foot (6.3 meter) grating have shown that some of the prominent maxima of acrolein may be resolved into very narrow bands which they attribute to rotational levels in the molecule.

Experimental Part

Purification and Treatment of Samples.—In an attempt to detect the presence of *cis*-crotonaldehyde in the purified commercial product, samples were prepared in two different ways and their absorption spectra studied. The first of these, which is hereafter called the "original" sample, was made in such a way that any mixture of the *cis* and *trans* forms would be preserved. The second or "irradiated" sample was treated with hydrochloric acid and sunlight by a procedure which is known to cause similar compounds to be converted into the *trans* form.[2]

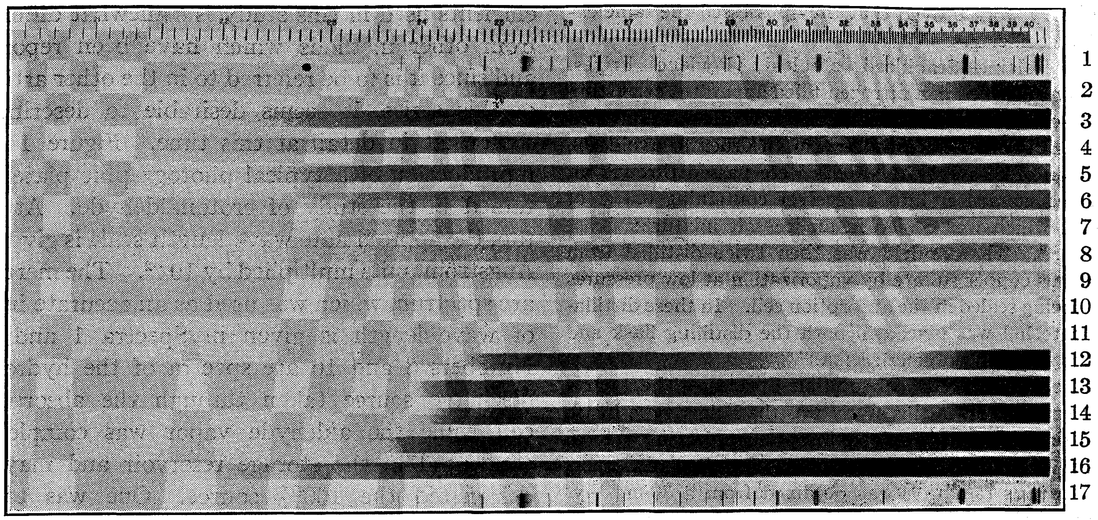

Fig. 1.—Reproduction of a typical spectrogram obtained in the study of crotonaldehyde.

(a) **Crotonaldehyde (Original).**—The crotonaldehyde obtained from the Niacet Chemical Corporation was purified by distillation through a 90-cm. Claisen-head column full of cut glass rings and equipped with a Hopkins condenser. The fraction boiling between 101–102° (750 mm.) was dried over anhydrous copper sulfate and redistilled in an atmosphere of nitrogen through a 30-cm. Vigreux column, b. p. 102.6–102.8°; d^{25}_4 0.8495; $n^{20}\text{D}$ 1.4356. Other drying agents such as calcium chloride and magnesium perchlorate caused more or less polymerization of the aldehyde.

(b) **Crotonaldehyde (Irradiated).**—One hundred cc. of the freshly distilled commercial crotonaldehyde, b. p. 101–102°, was placed in a Pyrex flask with 4 cc. of 6 *N* hydrochloric acid and exposed to strong sunlight for five hours. In some experiments the irradiated mixture was then treated with sodium bicarbonate and distilled through a 30-cm. Vigreux column. The water together with a small amount of aldehyde distilled between 90–95°. The temperature then rose rapidly and a chloride-free fraction was collected between 101.5–102.5°. This product was dried over anhydrous copper sulfate and distilled, b. p. 102.6–102.8°, $n^{20}\text{D}$ 1.4358. In other experiments the irradiated mixture was distilled at once; the large portion of the hydrochloric acid coming over in the first fraction, b. p. 90–101.5°. The main distillate, b. p. 101.5–102.5°, $n^{20}\text{D}$ 1.4356, was essentially chloride free. It was likewise dried and fractionated, b. p. 102.6–102.8°, $n^{20}\text{D}$ 1.4356. The crotonaldehyde samples prepared by both of these procedures are referred to as the "irradiated" sample since

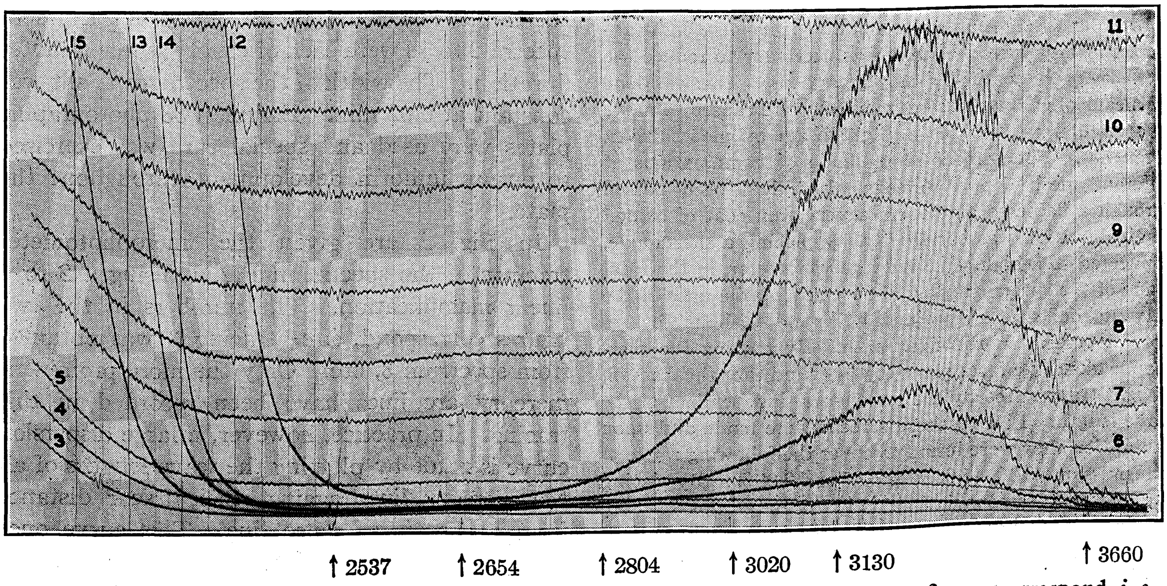

Fig. 2.—Microphotometer tracings of the spectra shown in Fig. 1. The numbers in the two figures correspond, *i. e.*, tracing 3 was obtained from spectrum 3, etc. The positions of the more prominent mercury arc lines are indicated.

preliminary work proved that they possessed the same extinction coefficients.

(c) **Acrolein.**—Stabilized acrolein (Poulenc Frères, Paris) was distilled in a nitrogen-filled apparatus consisting of a 90-cm. column, containing glass rings and equipped with a Hopkins reflux condenser. In order to avoid the formation of disacryl the vapors were passed through an ice-cooled condenser into a receiver containing 0.5 g. of catechol which was cooled in an ice–salt mixture; b. p. 53.0–53.2°. The acrolein was then twice distilled from anhydrous copper sulfate by vaporization at low pressures before being sealed in the absorption cell. In these distillations catechol was placed in both the distilling flask and receiver to avoid polymerization.

Method of Study of Absorption Spectra.—The quartz spectrograph used in this study was the Hilger type E316. It is primarily an ultraviolet instrument, having a focal plane of 18 cm. in length between λ 2000 and 4000 Å.

Continuous radiation was obtained from a 30-cm. hydrogen discharge between water-cooled iron electrodes. Purified hydrogen was pumped through the discharge tube at a constant rate during the exposures. The pressure in the tube was regulated by observing the structure of the discharge. A blue double herring bone structure was used since it is very sensitive to pressure change and also gives a source with the minimum number of lines due to atomic hydrogen.

The aldehyde vapors were studied in a fused silica absorption cell 40 cm. in length, 3 cm. in diameter and having plane parallel windows. A mercury manometer of 8 mm. inside diameter and a small reservoir for storing the liquid to be studied were connected to the tube by silica-to-Pyrex graded seals. The aldehyde was introduced into the reservoir in the following manner: the system was first flushed out with nitrogen and then about 3 cc. of the aldehyde was distilled at low pressure into the reservoir which contained 0.1 g. of catechol. While the reservoir was still cooled by means of solid carbon dioxide the system was evacuated, and sealed off.

In order to determine the amount of incident light absorbed at any wave length it was necessary to reduce the intensity of the source by known fractions. This was done by means of calibrated screens which were caused to move in a circular manner in the light beam by motor-driven eccentrics. The screens were made of combinations of different mesh copper screens which had been passed through a flame to give them a very thin coat of oxide.[3] The calibration was carried out by placing a thermopile, connected to a high sensitivity galvanometer, in the focal plane of the spectrograph and determining the ratio of the galvanic deflections obtained with and without the revolving screens in the light path. By moving the thermopile along the focal plane it was found that the fraction of light transmitted by the screens was independent of the wave length. Five of these screens were made and upon calibration they were found to cover the following range of transmission: 67.0, 45.0, 22.2, 5.85 and 2.90%. By placing the different screens individually or in groups of two, moving out of phase with one another, in the light path, a large variation in transmission could be obtained.

Since the method of obtaining extinction coefficients used in this study is somewhat different from other methods which have been reported and since it is to be referred to in the other articles of this series, it seems desirable to describe it somewhat in detail at this time. Figure 1 is a reproduction of a typical photographic plate obtained in the study of crotonaldehyde. At the top, the approximate wave length scale is given in Ångström units multiplied by 10^{-2}. The mercury arc spectrum which was used as an accurate index of wave length is given in Spectra 1 and 17. Numbers 3 and 16 are spectra of the hydrogen discharge source taken through the absorption cell while the aldehyde vapor was completely condensed in the storage reservoir and may be designated the 100% source. One was taken before and the other after all of the other spectra were taken in order to afford a check on the constancy of the source. If in any case it was found that the 100% source had changed in intensity during the time exposures were being made, the entire plate was discarded. Numbers 4, 5, 6, 7, 8, 9, 10 and 11 were taken in like manner except that rotating screens were placed in the path of light so that the intensity of the source was diminished, respectively, to 67, 45, 22.2, 14.9, 10.0, 5.85, 3.92 and 2.90% of the original intensity. Numbers 2, 12, 13, 14 and 15 are absorption spectra of crotonaldehyde taken with pressures in the cell of 42.5, 42.5, 12.0, 23.0 and 5.0 mm., respectively. These pressures were maintained by controlling the temperature of the liquid in the reservoir. Exposure times of spectra 2 to 16 were each of exactly three minutes duration. The width of the spectrograph slit was constant at 0.02 mm. Eastman 33 photographic plates were used and special care was exercised to ensure uniform development throughout the plate.

In Fig. 2 are given the microphotometer tracings of the spectra in Fig. 1, using a 2 to 1 linear magnification. The numbers in the two figures correspond, *i. e.*, tracing 3 was obtained from spectrum 3, etc. Only the more prominent mercury arc lines have been recorded in this tracing. In practice, however, a large dispersion curve is made by plotting the wave lengths of all the mercury lines against their linear distance from a chosen reference line. This curve once made may be used to determine the wave length of all points on any tracing having this 2 to 1 ratio to an original spectrogram. By placing the

---

(3) G. R. Harrison, *J. Opt. Soc. Am.*, **18**, 492 (1929).

tracings on thin millimeter cross-section paper over a ground glass illuminating table, the linear distance of any point from the reference line may be obtained with sufficient accuracy to give the wave length in the ultraviolet to within one or two Ångström units.

In calculating ε, the molecular extinction coefficient, Lambert–Beer's law

$$\epsilon = \frac{l}{cl} \log \frac{I_0}{I} \tag{1}$$

is used in the form

$$\epsilon = \frac{RT}{pl}\left(2 - \log \frac{100\,I}{I_0}\right) \tag{2}$$

R is the gas constant in liter-atmospheres per mole per degree, T the absolute temperature, p the pressure of the gas in atmospheres, l the length in centimeters of the light beam in the absorbing medium, I_0 the intensity of the incident beam and I the intensity of the transmitted light. Since for a given spectrum T, p and l are measurable constants, it is obvious that wherever the ratio I/I_0 can be determined, ε may be calculated. In Fig. 2, tracings 3 to 11 inclusive are lines of known values of I/I_0. Hence wherever a tracing of an absorption spectrum crosses one of these lines the extinction coefficient may be determined. In regions of continuous absorption these points may be sufficient in number to give a satisfactory curve of extinction coefficients.

However, in regions of discontinuous absorption it is not always easy to estimate the point of intersection; furthermore, there are maxima and minima which do not strike any of the source tracings. To eliminate this difficulty an interpolation curve for a given wave length may be made by plotting log 100 I/I_0 against the perpendicular distance from an arbitrary base line. This gives a smooth curve and by measuring from this line the height of an absorption tracing at the wave length in question, log 100 I/I_0 may be obtained from the graph. For convenience a tracing representing zero transmission of the plate was used as the base line. In regions in which the source tracings are approximately horizontal, the same interpolation curve may be used for a considerable range of wave lengths. When this is not the case, a new curve must be plotted for each wave length at which extinction coefficients are desired. However, this is not a very tedious process since all curves have the same source values for log 100 I/I_0 and it is only necessary to read off the heights of the tracings and record them on the graph. The microphotometer used in this study has been described elsewhere and has been shown to have constant sensitivity and to give reproducible results.[4]

It may be recognized that because of overexposure between wave lengths 2450 and 2900 Å. and above 3600 Å., Figs. 1 and 2 are of no value in calculating extinction coefficients. In order to bring out these regions, some spectrograms were taken with the time of exposure reduced to sixty seconds, while still others had the spectrograph slit width reduced from 0.02 mm. to 0.01 mm. as well. As far as it could be ascertained, by studying overlapping regions, these variations had no effect upon the value of the extinction coefficients.

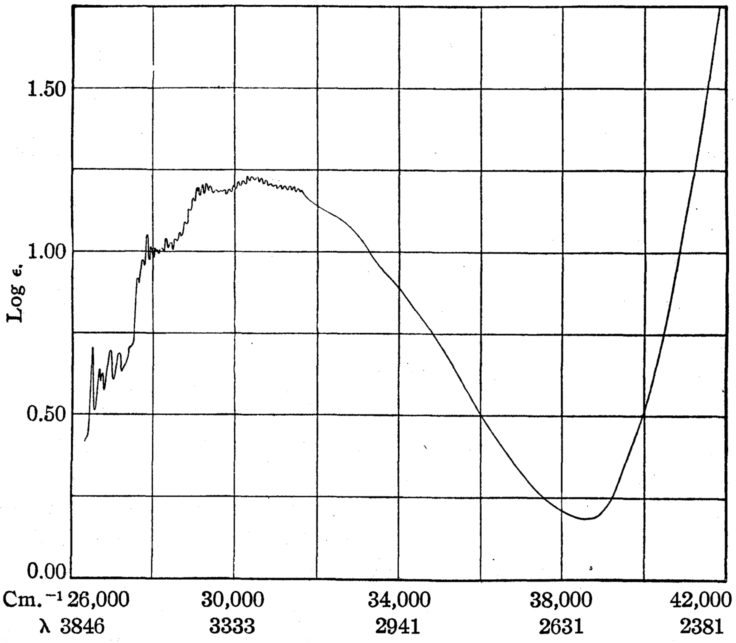

Fig. 3.—Logarithms of the molecular extinction coefficients of crotonaldehyde *vs.* wave numbers, cm.⁻¹ and wave lengths, λ, in Ångström units.

By using the method described above the extinction coefficients of crotonaldehyde and acrolein were obtained. These results are presented graphically in Figs. 3 and 4. As far as it is possible to make a comparison from the information available they are in general agreement

with those reported by Lüthy.[1c] It does not seem necessary to give detailed tables of extinction coefficients in addition to the results shown in the figures. However, in Table I are presented some typical results obtained in the comparison study of the original crotonaldehyde and the samples which were irradiated in the manner described above. It may be observed that within the limits of error both in regard to the measurement of wave lengths and the evaluation of the extinction coefficients, there is no difference between the two samples.

Discussion of Results

Composition of Crotonaldehyde.—Crotonaldehyde is the starting material in the synthesis of many unsaturated compounds. In order to be sure of the configuration of these products it is of utmost importance to know the exact composition of the crotonaldehyde. The oxidation of both irradiated and non-irradiated aldehydes,[5] under conditions designed to avoid stereomutation, failed to show any evidence for the existence of the *cis* isomer or of vinylacetaldehyde in the original materials. However, there remained the possibility that the mere act of oxidation in the presence of resinous material, which is always formed, would give rise to only *trans*-crotonic acid even though the *cis* aldehyde was originally present. It was therefore desirable to study the composition of crotonaldehyde by a physical method such as the determination of absorption spectra. Although the absorption spectrum of crotonaldehyde has been reported by several investigators,[1b,c,e] the question of *cis–trans* isomerism has not been considered. Consequently, it seemed desirable to obtain extinction coefficients for both the original and irradiated crotonaldehydes. The procedure adopted for the preparation of the irradiated crotonaldehyde takes advantage of the possibility of both photochemical and thermal stereomutation in the presence of hydrochloric acid. Stereomutation of *cis*-crotonic acid by irradiation with sunlight has been reported by Wislicenus.[2a] Likewise stereomutation of *cis*-α-methylcrotonic acid during distillations at approximately 100° has been reported by Blaise[2b] and since corroborated.[6] It was found that during the thermal decomposition of α-methyl-α-hydroxybutyric acid and during the fractional distillation of the decomposition products, it was necessary to avoid even traces of hydrochloric acid in order to obtain a satisfactory yield of *cis*-α-methylcrotonic acid. If appreciable quantities of the catalyst were present only the *trans* isomer could be isolated.

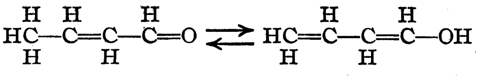
A comparison of results, Table I, indicates that both the extinction coefficients and wave lengths

---

(5) Young, THIS JOURNAL, **54**, 2498 (1932).

(6) Young, Dillon and Lucas, *ibid.*, **51**, 2529 (1929).

of characteristic maxima agree within experimental error for both the original and irradiated samples. If the original aldehyde contained an appreciable quantity of the *cis* isomer and the concentration of this isomer were changed by the method adopted, one might expect a shift in the wave length of the characteristic peaks, thus causing a twinning effect or the appearance of small peaks between the larger ones. Likewise, a difference in extinction coefficients might be expected. Since these differences do not appear, it may be reasoned that commercial crotonaldehyde is essentially the pure *trans* isomer just as the oxidation experiments had indicated.[5] It should be noted that several papers[7] have appeared on the Raman spectra of crotonaldehyde. However, only Gredy and Piaux reported lines which were attributed to traces of the *cis* isomer. Two possible explanations may be suggested to account for the apparent lack of the unstable stereoisomer in crotonaldehyde. One is the occurrence of resonance between the forms  $\mathrm{H}:\underset{\mathrm{H}}{\overset{\mathrm{H}}{\ddot{\mathrm{C}}}}:\overset{\mathrm{H}}{\ddot{\mathrm{C}}}::\underset{\mathrm{H}}{\mathrm{C}}:\overset{\mathrm{H}}{\ddot{\mathrm{C}}}::\ddot{\mathrm{O}}$ and  $\mathrm{H}:\underset{\mathrm{H}}{\overset{\mathrm{H}}{\ddot{\mathrm{C}}}}:\overset{\mathrm{H}}{\dot{\mathrm{C}}}:\underset{\mathrm{H}}{\mathrm{C}}::\overset{\mathrm{H}}{\ddot{\mathrm{C}}}:\ddot{\mathrm{O}}:.$ A second explanation is that crotonaldehyde may consist of a tautomeric system of high mobility.



$$\underset{\mathrm{I}}{\mathrm{H\underset{H}{\overset{H}{C}}{-}\overset{H}{C}{=}\underset{H}{C}{-}\overset{H}{C}{=}O}} \rightleftarrows \underset{\mathrm{II}}{\mathrm{H\overset{H}{C}{=}\underset{H}{C}{-}\overset{H}{C}{=}\underset{H}{C}{-}OH}}$$

I II

The aldehyde group is known to be one of the most efficient groups in activating a prototropic system.[8] The third possible tautomer, vinylacetaldehyde, would not be expected since there is no substitution in the γ-position.[9]

Comparison of Absorption Spectra of Crotonaldehyde and Acrolein.—By an inspection of Figs. 3 and 4, similarities and differences between the absorption spectra of crotonaldehyde and acrolein become obvious. Apparently the fundamental absorption processes are the same in the two compounds and the differences in the spectra result from the variation in length of the carbon chain.

Although the values of log ϵ obtained from different spectrograms varied by about 2% in regions of strong absorption by the vapor, the relative values at successive wave lengths can be obtained quite accurately and hence all of the small peaks and valleys appearing in these figures do exist. That is to say, two absorption curves obtained independently have the same characteristic shapes but one may lie above or below the other. Log ϵ values for all points of inflection shown for both aldehydes are the average values obtained from two or more spectrograms and from two or more pressures recorded on each of these. It was found that extinction coefficients calculated for crotonaldehyde from spectrograms of saturated vapor (42.5 mm. or less) were in substantial agreement with values obtained at lower pressures, indicating that deviations from the perfect gas law were not appreciable under these conditions. For acrolein the pressures used were well below the saturation value. They ranged between 30 and 150 mm. Over this range the values of ϵ reported for the maxima and minima of the discontinuous region are independent of pressure.

The generally accepted interpretation of discontinuous absorption is that the primary act of absorption produces only activated molecules, while, on the other hand, a continuum is thought to signify that dissociation occurs in the primary process. In Fig. 2 it may be observed that the strong lines of the mercury arc are well distributed among the continuous and discontinuous regions of absorption shown by crotonaldehyde. Hence, this aldehyde, as well as acrolein, if studied with the aid of a quartz mercury arc and monochromator, appears to offer an excellent opportunity to correlate these spectral interpretations with photochemical results. Do polymerization or decomposition processes occur in both regions of absorption and, if so, is there a marked change in the quantum yields of these reactions as the studies are shifted from the discontinuous to continuous regions? These questions and related ones are being studied at the present time in this Laboratory.

The authors are indebted to Professor P. A. Leighton for helpful suggestions in regard to this study and for the use of the microphotometer of Stanford University. Substantial aid has been received from Mr. Darrell Osborne in the compilation of experimental data. Likewise, the authors wish to express their appreciation for grants-in-aid from the National Research Council

and the Board of Research of the University of California.

Summary

A modified procedure for obtaining molecular extinction coefficients has been described.

Working with the vapor phase, the ultraviolet absorption spectra of crotonaldehyde and acrolein have been determined quantitatively.

Experiments designed to test for the presence of *cis*-crotonaldehyde in the commercial product gave results which indicate that this form of the aldehyde was not present.

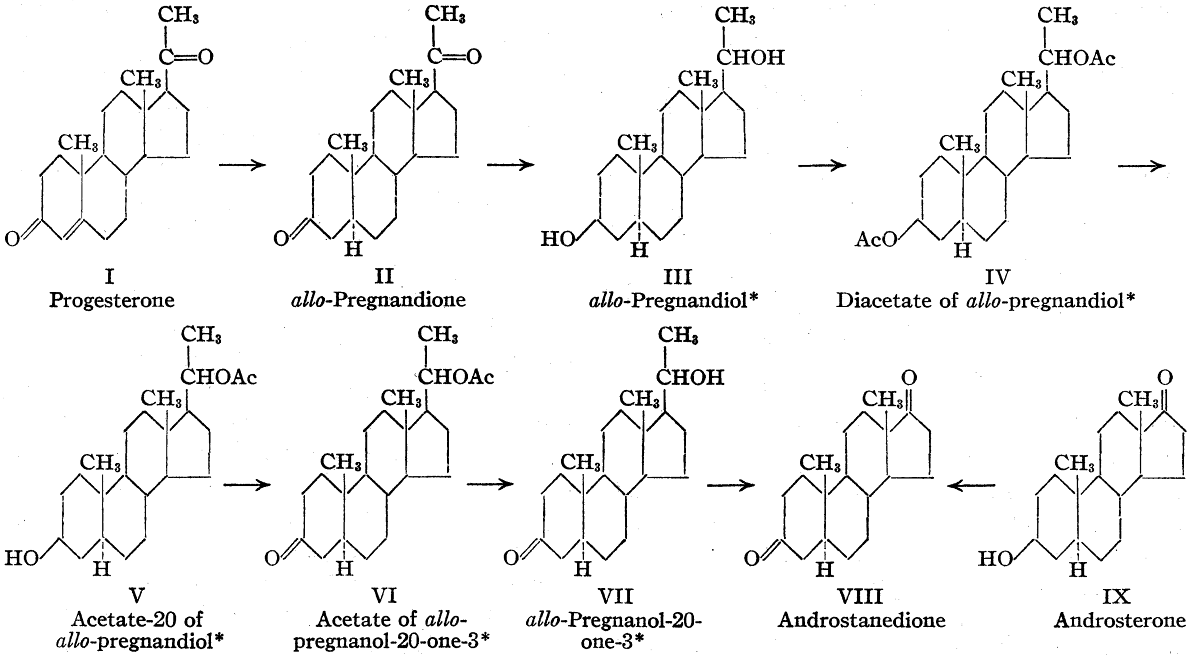
Sterols. VIII. Preparation of Androstanedione from *allo*-Pregnandiol

BY RUSSELL E. MARKER, OLIVER KAMM, DAVID M. JONES AND THOMAS S. OAKWOOD

The present paper serves to establish a complete structural relationship between the female sex hormone, progesterone (I) and the male sex hormone, androsterone (IX). This has been accomplished by supplementing the known preparation[1] of androstanedione (VIII) by oxidation of androsterone, with a new method of preparation of the same compound starting with *allo*-pregnandione (II). The last mentioned compound has been described previously by Butenandt,[2] who obtained it by reducing progesterone to a mixture of pregnandiol and *allo*-pregnandiol, oxidizing the mixture, and separating from it pregnandione and *allo*-pregnandione. The reactions involved in our work are illustrated by formulas II–VIII.



I Progesterone

II *allo*-Pregnandione

III *allo*-Pregnandiol*

IV Diacetate of *allo*-pregnandiol*

V Acetate-20 of *allo*-pregnandiol*

VI Acetate of *allo*-pregnanol-20-one-3*

VII *allo*-Pregnanol-20-one-3*

VIII Androstanedione

IX Androsterone

* The designation *trans* has been omitted at the suggestion of the referee. It seems to us, however, that such a designation is needed to differentiate our new compounds from previously known isomers.

allo-Pregnandione (II) was obtained by oxidation with chromic anhydride of the mixture of pregnandiol and *allo*-pregnandiol obtained from concentrates of human pregnancy urine. Crystallization from acetone gave pure *allo*-pregnandione. The latter was reduced in acetic acid at room temperature with platinum oxide and hydrogen to *allo*-pregnandiol (III). This gave a digitonide readily. The diol was converted to the diacetate (IV). The acetyl group in the 3-

---

(1) Butenandt and Tscherning, *Z. physiol. Chem.*, **229**, 189 (1934).

position was then hydrolyzed with potassium hydroxide in methyl alcohol solution at 15–20°, giving the 3-hydroxy-20-acetoxy compound (V). The 3-hydroxy group was then oxidized to a keto group to give Compound VI. Hydrolysis of the acetyl group at position 20 resulted in *allo*-pregnanol-20-one-3 (VII).

The conversion of the ol-one (VII) to androstanedione was carried out without isolation of the intermediate compounds. The ol-one was dehydrated by heating in acetic acid with anhydrous zinc chloride. The product was freed of acetic acid and the chloride was dissolved in chloroform and ozonized. The ozonide was decomposed by heating with acetic acid. The neutral fraction yielded two products, one a high-melting material of undetermined constitution, and the other androstanedione melting at 126-128°. This was found to be identical with androstanedione obtained by the oxidation of androsterone.

Experimental

allo-**Pregnandione.**—A solution of 50 g. of pregnandiol-*allo*-pregnandiol mixture in 3500 cc. of glacial acetic acid was cooled to 10° and treated with a solution of 50 g. of chromic anhydride in 600 cc. of 90% acetic acid, added over a period of four hours. The resulting mixture was allowed to stand overnight at room temperature, when 100 cc. of methyl alcohol was added and the acetic acid removed under reduced pressure. The residue was extracted with ether and the ether solution washed successively with dilute hydrochloric acid, water, 10% sodium bicarbonate solution, and finally again with water. The ether was then evaporated, giving 45 g. of oily white solid. This was dissolved in 190 cc. of boiling acetone, the solution cooled to 0°, and allowed to stand for twelve hours. The precipitate of *allo*-pregnandione was filtered off, washed with a small amount of acetone, and recrystallized from acetone. Its melting point was found to be 199–200°. The mother liquors contained the isomeric pregnandione.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.4; H, 10.3.

allo-**Pregnandiol.**—To a solution of 3 g. of *allo*-pregnandione in 100 cc. of glacial acetic acid was added 2 g. of platinum oxide. The mixture was shaken with hydrogen at 45 pounds (3 atm.) pressure during seventy-five minutes, the catalyst filtered off, and the acetic acid concentrated under reduced pressure. The residue was crystallized from ethyl alcohol. Its melting point was 195–196°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.7; H, 11.3. Found: C, 78.8; H, 11.4.

allo-**Pregnandiol Diacetate.**—A solution of 300 mg. of *allo*-pregnandiol in 2 cc. of acetic anhydride was refluxed during two hours. The reaction product which solidified on cooling was taken up with water and filtered. After crystallization first from ethyl alcohol and then from ethyl acetate it melted at 142–143°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.2; H, 10.0. Found: C, 74.2; H, 10.1.

allo-**Pregnandiol Monoacetate.**—To a solution of 1.55 g. of the diacetate in 375 cc. of methyl alcohol was added 28.3 cc. of a methyl alcohol–potassium hydroxide solution containing 0.0062 g. of potassium hydroxide per cc. The mixture was kept at 15–20° for forty-two hours. It was then neutralized with dilute hydrochloric acid and evaporated to a small volume. Water was added and the product filtered. After crystallization from petroleum ether it melted at 170–171°.

Anal. Calcd. for $C_{23}H_{38}O_3$: C, 76.2; H, 10.6. Found: C, 76.3; H, 10.7.

Acetate of *allo*-Pregnanol-20-one-3.—To a solution of 360 mg. of the monoacetate of *allo*-pregnandiol in 25 cc. of acetic acid was added 100 mg. of chromic anhydride in acetic acid. The solution was kept at room temperature for sixteen hours after which methyl alcohol was added and the acetic acid removed under reduced pressure. Water was added and the product filtered off. After crystallization from ethyl alcohol and finally from petroleum ether it melted at 156°.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.6; H, 10.1. Found: C, 76.5; H, 10.1.

allo-**Pregnanol-20-one-3.**—A solution of 180 mg. of the acetate of *allo*-pregnanol-20-one-3 in ethyl alcohol was treated with an excess of potassium hydroxide solution and refluxed during two hours. The solution was neutralized with hydrochloric acid and concentrated under reduced pressure. Water was added and the solid filtered off and crystallized from dilute ethyl alcohol when it showed a melting point of 195°.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.7. Found: C, 79.4; H, 10.8.

Androstanedione.—To a solution of 500 mg. of *allo*-pregnanol-20-one-3 in 8 cc. of glacial acetic acid was added 500 mg. of freshly fused zinc chloride. The solution was refluxed for three hours, cooled, and diluted with water. A semi-solid precipitate separated which after standing overnight was filtered off. It was dissolved in 100 cc. of chloroform and ozone was passed into the solution during thirty minutes at 0° at the rate of 7 liters of ozone per hour. The chloroform was evaporated at 25° and the residue taken up in 100 cc. of glacial acetic acid and heated on a steam-bath during one hour. The solution was then cooled to room temperature and 100 mg. of chromic anhydride added. After thirty minutes, methyl alcohol was added, the solvents evaporated at 40° and the residue dissolved in 50 cc. of water and 50 cc. of ether. The ether solution was separated, washed with 5% sodium hydroxide to free it of organic acids, and evaporated to dryness. The residue upon sublimation in a high vacuum yielded two fractions. The higher fraction gave a material melting at 185°. The lower fraction was resublimed at 110°, and then crystallized from acetone. The yield was 40 mg. of a product melting at 128°.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.1; H, 9.8. Found: C, 78.4; H, 9.9.

Oxidation of Androsterone.—To a solution of 335 mg. of androsterone in 120 cc. of acetic acid was added 116 mg. of chromic oxide. This was kept at 15–20° for thirteen hours and then at 25–30° for eight hours. Methyl alcohol was added and the solvents evaporated under reduced pressure. Water was added and the precipitate crystallized from acetone. It melted at 132°.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.1; H, 9.8. Found: C, 79.3; H, 9.7.

A mixture of the two samples of androstandione gave a melting point of 128–129°.

Summary

allo-Pregnandiol, a reduction product of progesterone, was converted into androstanedione, an oxidation product of androsterone, thus establishing a complete structural relationship between the female sex hormone, progesterone, and the male sex hormone, androsterone.

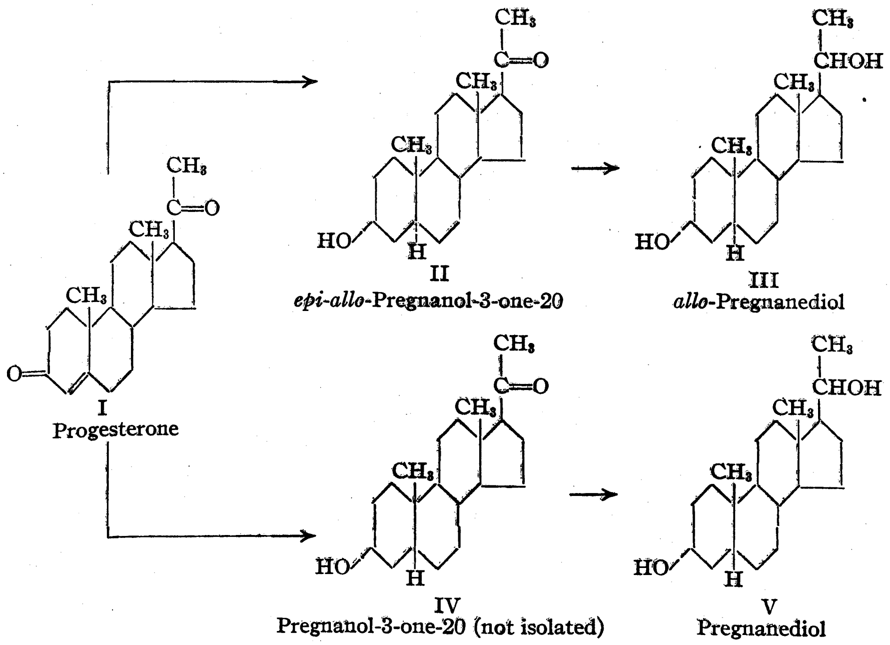
Sterols. IX. Isolation of *epi*-Pregnanol-3-one-20 from Human Pregnancy Urine

BY RUSSELL E. MARKER, OLIVER KAMM AND RALPH V. MCGREW

A reinvestigation of the sterol derivatives contained in human pregnancy urine fails to show the presence of progesterone. Since our experiments were conducted on a large scale using the sterol fraction from 10,000 gallons of human pregnancy urine, it seems reasonable to conclude that the corpus luteum hormone is not excreted as such by the human subject during pregnancy. Whether or not the *normal* female excretes the hormone is the subject of an investigation now in progress.

It is known that the neutral carbinol fraction from human pregnancy urine consists mainly of a mixture of pregnanediol and *allo*-pregnanediol, which differ only in the configuration of rings A and B of the sterol nucleus. We have now found, however, that sterols which may be considered as reduction products intermediate between progesterone and the pregnanediols *are* eliminated. In this article we describe the isolation of a compound of that type, namely, a pregnanolone.



I
Progesterone

II
epi-allo-Pregnanol-3-one-20

III
allo-Pregnanediol

IV
Pregnanol-3-one-20 (not isolated)

V
Pregnanediol

Butenandt[1] in the isolation of progesterone from hog corpora lutea obtained *allo*-pregnanol-3-one-20 melting at *195°* which he prepared later by the degradation of stigmasterol. Since stigmasterol possesses the normal arrangement (of cholesterol) in respect to the hydroxyl group and since his method of synthesis did not produce an inversion of this group, the naturally occurring allopregnanolone also has the hydroxyl group in the normal arrangement.

The epimeric form of *allo*-pregnanol-3-one-20 has been obtained from the residues of human pregnancy urine after removal of the theelin, theelol and other known sterol derivatives. It is present in quantities of 1-2 mg. per gallon of urine. This product does not absorb bromine

---

[1] Butenandt and co-workers, *Ber.*, **67**, 1441, 1897 (1934).

and is not precipitated by digitonin. Upon oxidation it yields *allo*-pregnanedione and upon reduction, *allo*-pregnanediol-3,20. The formula of the new compound and its relationship to other sterol derivatives are represented herewith.

In our study of the sterol residues from human pregnancy urine it was found that the major portion consisted of carbinols together with some ketosterols. The carbinols were separated from the non-carbinol material by means of the sodium salts of their half esters with phthalic acid. The ketonic carbinols were then separated from the plain carbinols through the water soluble betaine hydrazones. The ketonic carbinols were then further separated by crystallization of their semicarbazones. The non-carbinol fraction gave practically no ketones when treated with the betaine hydrazine reagent, thus demonstrating the absence of progesterone in these residues.

Experimental

Separation of Carbinols from Hydrocarbons.—The residue from 10,000 gallons of human pregnancy urine after the separation of theelin and theelol by the Doisy method[2] was hydrolyzed by refluxing with an excess of alkali. This was then steam distilled until no more volatile oils came over. The residue was cooled, filtered, the solid precipitate washed well with water, dried and finally shaken with ice-cold ether. The ether-insoluble portion consists of a mixture of pregnanediol and *allo*-pregnanediol.

The ether-soluble portion was concentrated, leaving 777 g. of tarry residue. This was dissolved in benzene and the carbinols present converted into their acid phthalates according to the following procedure. To 50 g. of the tar was added 25 g. of phthalic anhydride and 25 cc. of dry pyridine. The solution was heated on a steam-bath for two hours, ether was added and the pyridine removed by washing with dilute sulfuric acid. The ether solution was shaken with a solution of 50 g. of sodium carbonate in 200 cc. of water. The ether layer contained the non-carbinol fraction. The carbonate solution, which was extracted thoroughly with ether, was acidified with sulfuric acid and then again extracted with ether. The ether was evaporated and the phthalates saponified by refluxing for two hours with 200 cc. of alcohol containing 50 g. of potassium hydroxide in 40 cc. of water. Water was added and the alcohol distilled. The alkaline solution with its suspended solids was extracted with ether and thus yielded 31.4 g. of a carbinol fraction.

Separation of Ketonic Carbinols from Carbinol Fraction.—To 31.4 g. of total carbinols was added 30 cc. of ethyl alcohol and 5 g. of betaine hydrazine chloride. The reaction mixture was boiled for fifteen minutes on a steam-bath, poured into 200 cc. of water containing ice and the solution thoroughly extracted with ether. The ether layer contained the non-ketonic carbinols, whereas the aqueous layer contained the ketonic carbinols. An excess of hydrochloric acid was added to the aqueous layer and the solution warmed on a steam-bath. The oil which separated was extracted with ether. This gave 2.0 g. of ketonic carbinols. The total urine residue gave 31 g. of ketonic carbinols.

Semicarbazone of *epi-allo*-Pregnanol-3-one-20.—Thirty-one grams of the ketonic carbinol fraction was sublimed in 3-g. quantities in high vacuum, collecting the portion from 140–200° which weighed 23 g. To a solution of 8 g. of the sublimate in 100 cc. of alcohol was added 13.6 g. of sodium acetate and 11.1 g. of semicarbazide hydrochloride. The alcohol was distilled to dryness and the semicarbazone residue washed with hot water and finally with ether. The white solid (7.3 g.) was crystallized from alcohol to a constant melting point of 248–250°, dec.

Anal. Calcd. for $C_{22}H_{37}N_3O_2$: C, 70.3; H, 9.9. Found: C, 69.9; H, 9.9.

***epi-allo*-Pregnanol-3-one-20.**—To a solution of 3 g. of semicarbazone in 150 cc. of alcohol was added 15 cc. of sulfuric acid in 30 cc. of water. The product was refluxed for one-half hour, poured into water and thoroughly extracted with ether. The ether was distilled and the residue sublimed in high vacuum at 130°. The sublimate was crystallized from 70% alcohol and then from 70% acetone, m. p. 162–164°. It does not absorb bromine in the cold, and does not precipitate with digitonin; $[\alpha]^{30}D$ +91.0°, $c = 1\%$ in alcohol.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.3; H, 10.8.

Oxidation of *epi-allo*-Pregnanol-3-one-20 to *allo*-Pregnanedione.—To a solution of 180 mg. of *epi-allo*-pregnanol-3-one-20 in 16 cc. of glacial acetic acid was added 58 mg. of chromic anhydride in 30 cc. of 90% acetic acid. After standing for sixteen hours at 15–20° the solution was diluted with water and the precipitate was collected, dried and sublimed in high vacuum at 115°. The sublimate after crystallization from acetone melted at 198–200° and did not depress the melting point of *allo*-pregnanedione (m. p. 200°).

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.5; H, 10.1.

Acetate of *epi-allo*-Pregnanol-3-one-20.—To 1 g. of *epi-allo*-pregnanol-3-one-20 was added 5 cc. of acetic anhydride. The mixture was refluxed for thirty minutes and the excess acetic anhydride distilled under reduced pressure. The residue was sublimed at 130° with a mercury vapor pump. It was crystallized from 70% alcohol and then from 70% acetone, m. p. 139–140°; $[\alpha]^{30}D$ +112°, $c = 1$ g. per 100 cc. in alcohol.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.8; H, 10.1. Found: C, 77.0; H, 10.0.

3 - *epi* - *allo* - Pregnanediol - 20 - trans.—*epi* - *allo* - Pregnanol-3-one-20 (100 mg.) was hydrogenated in acetic acid solution (100 cc.) using platinum oxide (100 mg.) at a pressure of 45 lb. (3 atm.). The catalyst was filtered off and the acetic acid distilled under reduced pressure. The residue was crystallized from acetone which yielded a product melting at 205–207°. Mixed with *allo*-pregnanediol (m. p. 242°) it gave a depression in melting point to 194°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.8; H, 11.2.

---

Diacetate of 3-*epi-allo*-Pregnanediol-20-*trans*.—A solution of 100 mg. of 3-*epi-allo*-pregnanediol-20-*trans* in 5 cc. of acetic anhydride was refluxed for one hour. The acetic anhydride was evaporated under reduced pressure and the residue recrystallized from 60% acetone. Its melting point was found to be 124°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.4; H, 10.0. Found: C, 74.5; H, 10.2.

Discussion

Although the human corpus luteum contains only traces of progestin,[3] the quantity being so small that it is difficult to imagine that it can be of great significance in the maintenance of pregnancy, it has been demonstrated recently[4] that during pregnancy the placenta may produce its own progestin.

The new sterol that we have isolated, *epi-allo*-pregnanol-3-one-20, probably represents the first stage of the reduction in the body of progesterone to *allo*-pregnanediol; at any rate, it seems logical to expect that the conjugated ketone system would be the easier to reduce, giving as the first reduction products pregnanolone and *allo*-pregnanolone, which on further reduction yield the pregnanediols. So far we have succeeded in isolating only one isomer of pregnanolone (II), but we have evidence that the one represented by formula IV is present also in urine residues.

From our present knowledge of the sterols it is apparent that the utilization of the sterol sex hormones by the body in performing their functions as sex hormones is accompanied by oxidation and reduction reactions. This is shown by the fact that testosterone, which occurs in the testes, after performing its duty as a sex hormone, is eliminated in male urine as its reduction products, of which dehydro-iso-androsterone and androsterone so far have been isolated. In the case of progesterone which functions as a hormone during pregnancy, the products which are eliminated from the body also are its reduction products, the pregnanolones and the pregnanediols. It may be significant that pregnancy urine contains no progesterone.

During pregnancy theelin and theelol are eliminated in the form of their conjugation products with glucuronic acid. The fact that very little theelin is found in the urine of the non-pregnant female who uses it as a hormone would also suggest that theelin may be thrown off from the normal animal in a more extensively altered form just as in the stallion the male sex hormone is eliminated as a theelin conjugate. There is a possibility, therefore, that unchanged progesterone may be obtained from non-pregnancy female urine. The physiological action of the sex hormones, therefore, appears to be chemical as well as physical.

Summary

epi-allo-Pregnanol-3-one-20, a new ketonic sterol, was isolated from human pregnancy urine. This on oxidation gave *allo*-pregnanedione. Catalytic reduction gave *allo*-pregnanediol-3-(*cis*)-20(*trans*). The acetates of these compounds are described.

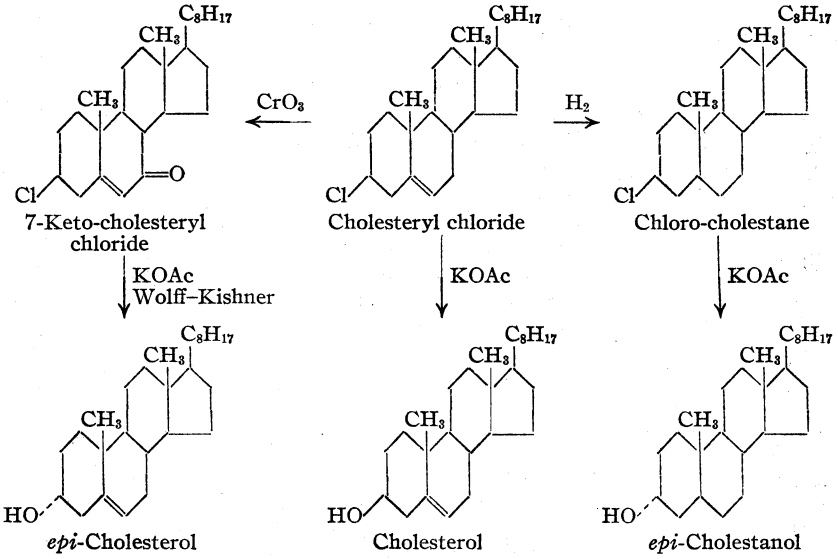
Sterols. X. Cholesterol Derivatives

BY RUSSELL E. MARKER, OLIVER KAMM, GEORGE H. FLEMING, ALEXANDER H. POPKIN AND EUGENE L. WITTLE

In our studies on sterols we have prepared a number of derivatives substituted in ring B. On the oxidation of cholesteryl chloride by chromic oxide in acetic acid, 7-keto-cholesteryl chloride can be isolated in yields of 25%. When this is treated with potassium acetate it gives a mixture of 7-keto-cholesterylene and the acetate of 7-keto-*epi*-cholesterol. The latter when reduced by the Wolff–Kishner method gives *epi*-cholesterol, which is identical with *epi*-cholesterol previously prepared by us.[1]



When cholesteryl chloride is hydrolyzed it gives a compound with the hydroxyl group in the normal (cholesterol) arrangement. However, if the double bond is first reduced to cholestyl chloride and this product is hydrolyzed a Walden inversion occurs leading to an epimeric hydroxyl group. The same is true when 7-keto-cholesteryl chloride is hydrolyzed, giving an epimeric -OH group. This is very unusual in view of the fact that the double bond in both compounds is in the same position. It was noticed that cholesteryl chloride is hydrolyzed readily with potassium acetate in boiling acetic acid whereas with the other two compounds it was necessary to heat to 180° for hydrolysis.

When 7-keto-cholesteryl chloride is reduced by platinum oxide in acetic acid it gives a mixture of 7-hydroxycholestyl chloride and α-cholestyl chloride, the ketonic group of a portion of the material being reduced to a methylene group. Aluminum isopropylate and 7-keto-cholesteryl chloride give 7-hydroxycholesteryl chloride. When the latter compound is reduced by platinum oxide in acetic acid it also gives a mixture of 7-hydroxycholestyl chloride and α-cholestyl chloride in about equal portions. 7-Hydroxycholestyl chloride, on reduction with sodium in amyl alcohol, gives 7-hydroxycholestane. The -OH group of both compounds may readily be oxidized to give the corresponding ketones.

Experimental

7-Keto-cholesteryl Chloride.—To a solution of 203 g. of cholesteryl chloride in 3500 cc. of acetic acid kept at 55° there was added with stirring over a period of one hour a solution of 150 g. of chromic oxide in 100 cc. of water and 100 cc. of glacial acetic acid. Stirring was continued during an additional two hours. Ethyl alcohol was added and the reaction mixture was concentrated under reduced pressure at 55° to a volume of 1.5 liters. To this was added 100 cc. of water and the mixture was cooled overnight. The crystalline material was filtered, washed with 600 cc. of alcohol followed by 300 cc. of acetone and finally was recrystallized from acetone. The yield was 50 g. of a product melting at 145°. The melting point of the semicarbazone was 176°.

Anal. Calcd. for $C_{27}H_{43}OCl$: C, 77.4; H, 10.3. Found: C, 77.8; H, 10.2. *Anal.* Calcd. for $C_{28}H_{46}OClN_3$: C, 70.7; H, 9.7. Found: C, 70.5; H, 10.0.

***epi*-Cholesterol from 7-Keto-cholesteryl Chloride.**—To a solution of 5 g. of 7-keto-cholesteryl chloride in 25 cc. of valeric acid, 7 g. of fused potassium acetate was added and the mixture was refluxed for fourteen hours. The reaction mixture was extracted with ether, and the ether solution washed with sodium carbonate solution. The acetate obtained after evaporation of the ether was hydrolyzed by means of alcoholic potassium hydroxide. The resulting oily material was dried and treated with 2 g. of succinic

---

anhydride in 15 cc. of pyridine, being heated four hours on the steam-bath. The reaction product was dissolved in ether and washed free of pyridine with hydrochloric acid. The succinate was then removed from ether by washing with sodium carbonate solution, the resulting solution being again washed with ether. [The ether solutions were worked up in a later experiment to give 7-keto-cholesterylene.] The alkaline solution was acidified and extracted with ether to remove the succinate, which was then hydrolyzed by boiling with alcoholic potassium hydroxide. The resulting product was then converted to the semicarbazone by heating with alcoholic semicarbazide acetate. This crude product was added directly to 10 cc. of absolute alcohol and to this was added a solution of 0.2 g. of sodium in 10 cc. of absolute alcohol. This was heated at 170–180° for six hours after which water was added and the product extracted with ether. The product was then sublimed at 140° using a mercury vapor pump and the sublimate crystallized from alcohol. Its melting point was 141°. Mixed with cholesterol (m. p. 147°) it gave a depression in melting point of 9°. Mixed with known *epi*-cholesterol it gave no depression.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.9; H, 12.0. Found: C, 84.0; H, 11.8.

7-Keto-cholesterylene.—To 1 g. of 7-keto-cholesteryl chloride dissolved in 30 cc. of alcohol was added 1.5 g. of potassium hydroxide in 2 cc. of water. The solution was refluxed two hours. Water was added and the product extracted with ether. After crystallization from alcohol it melted at 114°.

Anal. Calcd. for $C_{27}H_{42}O$: C, 84.8; H, 10.9. Found: C, 84.4; H, 10.8.

The same product was obtained as a by-product in the preparation of *epi*-cholesterol from 7-keto-cholesteryl chloride.

Reduction of 7-Keto-cholesteryl Chloride with Platinum Oxide Catalyst.—To a solution of 5 g. of 7-keto-cholesteryl chloride dissolved in 200 cc. of glacial acetic acid was added 1.5 g. of platinum oxide. The mixture was shaken with hydrogen under a pressure of 45 pounds (3 atm.) for six hours when the catalyst was filtered off and the acetic acid distilled under reduced pressure. The residue after crystallization from alcohol melted at 114.5°. Mixed with α-cholestyl chloride (m. p. 114°) it gave no depression in melting point.

Anal. Calcd. for $C_{27}H_{47}Cl$: C, 79.6; H, 11.6. Found: C, 79.6; H, 11.6.

The mother liquors from the above reduction contained about 80% of a product which would not crystallize and which was not cholestyl chloride since that product is almost completely insoluble in cold alcohol. The subsequent experiments showed that these mother liquors contained 7-hydroxycholestyl chloride.

7-Keto-cholestyl Chloride.—The solvent from the mother liquors in the previous experiment was evaporated. To 2 g. of the residue was added 20 cc. of acetic acid and a solution of 0.7 g. of chromic oxide in 3.4 cc. of acetic acid. The reaction mass was kept at 50–60° for two hours, then allowed to stand overnight at room temperature. A crystalline product separated and was filtered off and recrystallized from alcohol. Its melting point was 139°.

Anal. Calcd. for $C_{27}H_{45}OCl$: C, 77.1; H, 10.7. Found: C, 77.1; H, 10.6.

Cholestanol-7.—To 6 g. of crude 7-hydroxycholestyl chloride in 175 cc. of dry boiling amyl alcohol was added 12.5 g. of sodium. When the reaction was complete water was added and the alcoholic layer was separated and evaporated under reduced pressure. The residue crystallized from alcohol in needles melting at 117.5°.

Anal. Calcd. for $C_{27}H_{48}O$: C, 83.5; H, 12.4. Found: C, 83.4; H, 12.3.

Cholestanone-7.—To a solution of 2 g. of 7-hydroxycholestane in 35 cc. of acetic acid was added 0.7 g. of chromic oxide in 4 cc. of acetic acid. The product was kept at 50° for four hours and allowed to stand at room temperature for an additional twenty-four hours. Water was then added and the oxidation product extracted with ether. The ether solution was washed with sodium carbonate solution, the ether evaporated and the residue crystallized from acetone. Its melting point was observed to be 117° which is the same as that of 7-hydroxycholestane; mixed with that product, however, it showed a depression of 10°.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.9; H, 12.0. Found: C, 84.3; H, 12.1.

7-Hydroxycholesteryl Chloride.—To a solution of 40 g. of 7-keto-cholesteryl chloride (m. p. 145°) in 510 cc. of dry isopropyl alcohol was added 30 g. of distilled aluminum isopropylate. The mixture was refluxed for five hours, after which 250 cc. of isopropyl alcohol was distilled off over a period of four hours. The residue was poured into 1300 cc. of 3% potassium hydroxide solution and shaken vigorously. The product was extracted with ether, the solvent concentrated to 100 cc. and 100 cc. of acetone added. Crystals separated on cooling which, recrystallized from acetone, melted at 142°. The yield was 31 g.

Anal. Calcd. for $C_{27}H_{45}OCl$: C, 77.1; H, 10.7. Found: C, 77.0; H, 10.8.

Hydrogenation of 7-Hydroxycholesteryl Chloride.—To a solution of 1.2 g. of 7-hydroxycholesteryl chloride in 120 cc. of acetic acid was added 400 mg. of platinum oxide. The mixture was shaken for four hours with hydrogen at 45 pounds (3 atm.) pressure after which the solution was filtered and concentrated. The residue was crystallized from acetone. It melted at 115° and mixed with cholestyl chloride it gave no depression in melting point.

Anal. Calcd. for $C_{27}H_{47}Cl$: C, 79.6; H, 11.6. Found: C, 79.7; H, 11.7.

The mother liquors from the above experiment were evaporated to dryness, the residue was dissolved in 15 cc. of glacial acetic acid at 50° and 0.2 g. of chromic oxide in 2 cc. of acetic acid added. After maintaining the solution at 50° for four hours it was kept at room temperature for an additional fifteen hours. Water was then added, the product extracted with ether, the ether evaporated and the residue crystallized from alcohol. Mixed with 7-keto-cholestyl chloride previously prepared, there was no depression in its melting point of 137°. This showed that the mother liquors contained 7-hydroxycholestyl chloride.

Anal. Calcd. for $C_{27}H_{45}OCl$: C, 77.1; H, 10.7. Found: C, 77.1; H, 10.9.

Benzoate of 7-Hydroxycholesteryl Chloride.—A solution of 22.6 g. of 7-hydroxycholesteryl chloride in 150 cc. of dry pyridine was cooled in ice and 50 cc. of benzoyl chloride was added in small portions with shaking. The solution was allowed to stand at room temperature for two days after which it was poured into 4 liters of water and allowed to stand overnight. The water was decanted and the residue dissolved in ether, the ether solution being washed with sodium carbonate solution after which it was concentrated to 100 cc. and 200 cc. of methyl alcohol added. After standing overnight, crystals formed which were recrystallized from acetone. The yield was 11 g. and the melting point 119°.

Anal. Calcd. for $C_{34}H_{49}O_2Cl$: C, 77.9; H, 9.4. Found: C, 78.2; H, 9.6.

Summary

epi-Cholesterol was prepared from the hydrolysis of 7-keto-cholesteryl chloride with potassium acetate followed by reduction of the ketone group by the Wolff–Kishner method. Catalytic reduction by platinum oxide in acetic acid of either 7-keto-cholesteryl chloride or 7-hydroxycholesteryl chloride gave a mixture of cholestyl chloride and 7-hydroxycholestyl chloride. Derivatives of the various products were prepared.

Physical Studies of Non-aqueous Solvates. II. The Vapor Pressure of Magnesium Bromide–Diethyl Ether Solutions

BY H. H. ROWLEY[1]

The vapor pressure of an ethyl ether solution saturated with magnesium bromide was reported by Evans and Rowley[2] to be 410 mm. at +25°. Scherer and Newton,[3] using the vapor pressure values of magnesium bromide–ethyl ether systems to calculate the free energy of formation of magnesium bromide, also reported a value of 410 mm. at +25° for a solution of ether saturated with magnesium bromide. It is a well established fact[2,4] that magnesium bromide with excess ethyl ether forms two conjugate liquid phases at +25°, the upper layer consisting of ether saturated with magnesium bromide (3.23 g./100 g. Et_2O), the bottom layer containing about 39% magnesium bromide. Re-examination of the data of Evans and Rowley indicated that under the conditions of the experiment the only liquid present was the oily bottom layer containing about 39% magnesium bromide and absolutely none of the light upper layer. Thus, the vapor pressure reported was not for an ethyl ether solution saturated with magnesium bromide.

In order to prove this, the vapor pressure of the two conjugate liquid phases has now been measured over a temperature range from 0 to +25°. The system also has been studied in more detail at +25° varying the ratio of $MgBr_2:Et_2O$ from $^1/_4$ to 1.

Experimental

Apparatus.—The vapor pressures were measured by the static method as shown in Fig. 1. The samples were placed in a flat-bottomed flask (A), about 4 cm. in diameter and 5 cm. in height, sealed to a Pyrex spiral (B) about 4 cm. in diameter and 16 cm. in length, connected to a mercury U-manometer (C). The flexible glass spiral together with the relatively large surface of the sample, allowed the sample to be agitated vigorously by gently tapping the flask (A). Thus, thorough mixing and equilibrium conditions were attained rapidly. The mercury in the manometer (C) could be raised or lowered by adjusting the pressure in reservoir (D) and served also to seal the sample from the rest of the system and protect it from stopcock grease. When it was necessary to evacuate the space above the sample, the mercury was lowered and the sample

connected directly to a Cenco Hy-Vac pump (protected from ether vapor by activated charcoal at −78°) through stopcock (E). During the measurements, stopcock (E) was always connected to the vacuum pump so the vapor pressure values could be read directly on the manometer (C). All the connecting tubes were of 8-mm. Pyrex glass.

Dry, distilled ether was stored in tube (G) sealed to the system and cut off by stopcock (F). Thus, ether could easily be distilled from or added to the sample by lowering the mercury in (C) and immersing the ether tube (G) or the sample flask (A) in a mixture of carbon dioxide and acetone. The ether reservoir was calibrated in 0.5 cc. and the volume could be read to less than 0.2 cc.

This type of apparatus had the advantage of a relatively small volume above the sample, very little of it outside the bath and no stopcocks or joints in contact with the ether vapor whose pressure was being measured. The room temperature was always kept above +25° during the measurements to prevent any condensation of ether vapor when the sample was at +25°.

Procedure.—The magnesium bromide–ethyl ether solution was prepared in an Erlenmeyer flask, taking the usual precautions against moisture and light.[4a] The two-layer system was transferred to a dry sample flask, cooled to −78° in a carbon dioxide–acetone mixture and sealed to the apparatus. The apparatus was evacuated for about thirty minutes with the sample at −78°. The mercury was then raised in the U-manometer and the sample brought to +25° and agitated until it was completely liquid again. The first measurements made at +25° were invariably high due to occluded gases which were released on melting the sample. To remove these, the sample was again cooled to −78°, where the normal vapor pressure is about 0.6 mm. and the "occluded" gases, which did not condense, pumped off. Generally, one such treatment was sufficient to remove these gases and the vapor pressure of the system would give reproducible values at a constant temperature.

Ether was distilled from the sample at intervals and condensed in the reservoir (Fig. 1, G) and its volume measured at +25°. From this value and the density of ether at +25°, the grams and hence the moles of ether distilled could be calculated. When all the ether had been distilled from the sample and the experiment completed, the sample flask was filled with dry air, cut off and weighed. It was then cleaned and weighed again and the weight of anhydrous magnesium bromide determined. From these data, the mole ratio of magnesium bromide to ethyl ether could be calculated for any series of measurements. Some experiments also were made by desolvating the sample and weighing before sealing to the apparatus. Known amounts of ether were then distilled onto the sample and measurements made.

The flasks were kept at constant temperature by means of water-baths in vacuum flasks. At 0° the melting point of ice was used. The 0.1° thermometers were calibrated at 0° and at the transition point of sodium sulfate decahydrate. The temperature measurements were accurate to ±0.03°. The manometer readings were corrected to 0° by values obtained from the "International Critical Tables"[5] and were accurate to ±0.5 mm.

Results.—The values for the vapor pressures of ethyl ether solutions saturated with magnesium bromide between 0 and +25° are shown in Table I. In all cases there was excess ether present. The equilibrium phase at temperatures below 12° is solid magnesium bromide triethyl etherate, between 12 and 22.5° it is the solid diethyl etherate, and above 22.5° the immiscible liquid containing about 39% magnesium bromide.[4a] The vapor pressure for dry redistilled ethyl ether determined in the same apparatus is also included in Table I for comparison. The values for the vapor pressure lowering shown in column 4 were measured directly by connecting one side of the manometer to the ether reservoir at the same temperature as the sample. These readings were made with a Cenco Comparator accurate to ±0.1 mm.

TABLE I

VAPOR PRESSURE OF ETHYL ETHER SOLUTIONS SATURATED WITH MAGNESIUM BROMIDE

Temp., °C.	V. p. of Et_2O, mm.	V. p. of satd. soln., mm.	ΔP^a mm.
0	186.7 ± 0.1	185.7 ± 0.1	1.1
5	234 ± 0.5	233 ± 0.5	
10	292	290	
15	361	359	2.1
20	442	438	
25	537	532	5.1

[a] Values in col. 4 were measured directly on a differential manometer with an accuracy of ±0.1 mm.

A series of experiments also was run at 25° in which the ratio of ethyl ether to magnesium bromide was varied. Whenever sufficient ether was present to form two conjugate liquid phases, the value for the vapor pressure of the system was always 532 mm. at +25°. However, as the ether was removed from the sample at 25°, the light upper layer became smaller and finally disappeared. At this point, the vapor pressure of the system began to decrease as the ratio of ether to magnesium bromide was lowered, fairly rapidly if only one liquid phase was present but not so rapidly if two phases, liquid and crystal, appeared. As the mole ratio of magnesium bromide to ethyl ether approached 1:2.0, the values dropped off very rapidly until they were about 390 mm. when all the liquid phase had disappeared and only crystals remained. This value for the vapor pressure of magnesium bromide diethyl etherate in equilibrium with the monoethyl etherate remained constant from a mole ratio of 1:2.0 to 1:1.0. The results of a group of measurements are shown in Table II.

1:1.28			392

Effect of Moisture.—Inasmuch as the presence of moisture is known to affect the apparent solubility of magnesium bromide in ethyl ether,[4a] several experiments were performed to determine its effect on the vapor pressure of the solutions. The solutions were made in the usual manner and placed in the sample flask. Before sealing to the apparatus, measured amounts of distilled water were added to the samples. In every case, a white precipitate formed at first but redissolved on agitation. The "moist" samples gave the appearance of being perfectly normal.

The measurements were made in exactly the same manner as for a dry sample. The results are shown in Table III. The vapor pressure of a "moist" two-layer system containing excess ether was found to be 531.5 mm. at 25° as compared to 532 mm. for the dry samples. After the disappearance of the light upper layer, the vapor pressure of the system decreased with decreasing amounts of ether as was found with a normal sample. However, for corresponding mole ratios, the values for the "moist" sample were always below those for the normal samples, being 50 to 100 mm. lower when the mole ratio was between 1:3.0 and 1:2.0.

Effect of Age.—The effect of the age of the sample on the vapor pressure was measured on one sample that had been sealed in a glass tube for over three months at +25°. The upper ether layer was colorless but the heavy immiscible layer had become a dark brown. The vapor pressure of the two layer systems at +25° was 531.5 mm. compared to 532 mm. for a fresh sample. The heavy immiscible layer gave values about 20 to 25 mm. below those for a fresh sample of corresponding composition. Whether this was due to some change in the solution (mixture had darkened with age) or to possible presence of moisture could not be determined.

TABLE III

EFFECT OF MOISTURE ON VAPOR PRESSURE AT +25°

1:1.18	1:0.2			327.5

Discussion

The values for the vapor pressures of ethyl ether solutions saturated with magnesium bromide as shown in Table I are only a few millimeters below those for pure ether. The lowering at 0° is 1.1 mm.; at +15°, 2.1 mm.; and at +25°, 5.1 mm.; the solubility of magnesium bromide at these temperatures is, respectively, 0.70 g., 1.72 g., 3.23 g./100 g. ethyl ether.[4a] Assuming the applicability of Raoult's law to solutions of these concentrations, the molecular weight of dissolved magnesium bromide (mol. wt. 184.2) as calculated is 88 at 0°, 220 at +15° and 252 at +25°. This apparent increase in molecular weight with increasing concentration is in agreement with the results of Meisenheimer and Schlichenmaier,[6] who studied the boiling point rise of ethyl ether solutions of ethylmagnesium bromide and magnesium iodide. However, too much stress should not be

---

(6) Jakob Meisenheimer and Walter Schlichenmaier, *Ber.*, **61B**, 720 (1928).

placed on this apparent increase in molecular weight since it is highly probable that Raoult's law is not valid for this type of solution. The fact that these compounds form known solid solvates with ethyl ether and two of them form two conjugate liquid phases at room temperature, indicates that the solutions would not be ideal.

It should be noted that the vapor pressure of pure diethyl ether at 0° as recorded in this work is 186.7 ± 0.1 mm. compared to 185.3 mm. as given in the "International Critical Tables."[7] This value was checked with many carefully purified samples and with several modifications of the apparatus. The values obtained between +10 and +25° agree within the experimental error with the literature values.

Since the vapor pressure of the ethyl ether–magnesium bromide system was always constant at +25° if the mole ratio of magnesium bromide to ether was greater than 1:4.00, it appears justified to call 532 mm. the vapor pressure of a solution of ethyl ether saturated with magnesium bromide. Reference to the solid line in Fig. 2 and to Table II shows that when the mole ratio falls below 1:3.8, the two-layer system disappears leaving only the heavy bottom layer. As the mole ratio is decreased, the vapor pressure of the system falls rapidly along the line ABC as long as only one liquid phase is present. However, the portion of the curve BC appears to be metastable, for if a crystal phase appears the vapor pressure rises to a value on the curve BD. Thus, between the mole ratios 1:3.3 and 1:2.0, the three phase system: magnesium bromide dietherate crystals—a concentrated solution of magnesium bromide in ethyl ether–ether vapor, is stable. As the ether is removed from the system, the liquid phase diminishes with a correspondingly slight decrease in vapor pressure except as the system approaches a mole ratio of one magnesium bromide to two ethyl ethers. At this point (E) the liquid phase disappears, leaving the crystals of magnesium bromide diethyl etherate. Further removal of ether does not change the vapor pressure of the system magnesium bromide dietherate–magnesium bromide monoetherate–ether vapor until the mole ratio has dropped to 1:1.

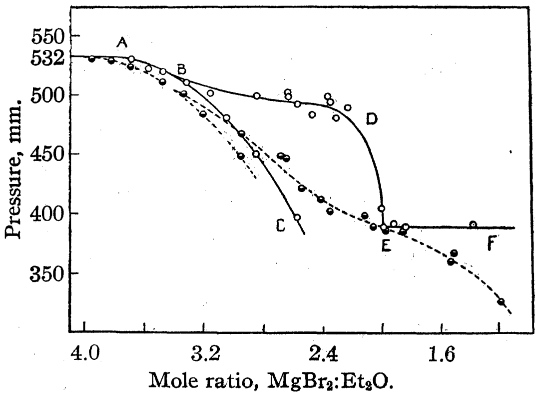

Fig. 2.—○, Dry sample; ◒, "Moist" sample.

The presence of moisture is shown to have a decided effect on the vapor pressure of the system as indicated in Table III and Fig. 2. Above a mole ratio of 1:4.0, the values for a "moist" sample are about 0.5 mm. below those for a normal sample. Below a mole ratio of 1:4.0 the vapor pressure of the liquid phase parallels that of a dry sample but is consistently below it as shown by the broken line in Fig. 2. The appearance of a crystal phase raises the values somewhat but they are considerably below those for a normal sample of the same composition. It is interesting to note that below a mole ratio of 1:2.0, the vapor pressure of the "moist" sample does not appear to remain constant. This might be due to slow equilibrium, though several of the values showed no increase after twenty-four hours.

The present work appears to show that the vapor pressure of an ethyl ether solution saturated with magnesium bromide is not 410 mm. at +25° as reported by Evans and Rowley[2] and Scherer and Newton[3] but is 532 mm. In the case of Evans and Rowley, it is definitely known that under the conditions of the experiment, the mole ratio of the system measured was below 1:3.0 and that there was the possibility of a trace of moisture being present. Reference to Fig. 2 shows that under these conditions it would be very possible to obtain a value such as was reported. It is likewise probable that Scherer and Newton[3] encountered the same difficulty.

Summary

1. The vapor pressure of diethyl ether saturated with magnesium bromide has been measured over the temperature range from 0 to +25°, and in more detail at 25° with variations in the ratio between magnesium bromide and ether from $^1/_4$ to 1.

2. The presence of small amounts of moisture

---

[7] "International Critical Tables," Vol. III, 1928, p. 219.

was found to alter greatly the vapor pressure of the magnesium bromide–ethyl ether system. This fact was advanced as a possible explanation for the low values reported in the literature by several authors.

The Effect of Iodine on the Rates of Decomposition of Formaldehyde, Acetaldehyde and Propionaldehyde

BY G. K. ROLLEFSON AND R. FRANCIS FAULL

In a previous note[1] we have presented data which show that the accelerating effect of iodine in a number of decompositions of simple organic molecules is due to a cycle of reactions involving destruction and re-formation of the iodine molecules. That work has been extended for the aldehydes so that now it is possible to give the mechanism in detail. These systems were found to be more complex than was indicated previously in that the rate of disappearance of aldehyde was definitely greater than the rate of reaction between the corresponding alkyl iodide and hydrogen iodide as calculated from Ogg's data[2] on those reactions. In fact as the temperature was lowered from the range discussed before this discrepancy increased until with acetaldehyde (to take an extreme case) the observed rate was several times as large as the one calculated on our earlier assumptions. In this paper we shall show that this discrepancy may be accounted for if we take into consideration the free radicals and iodine atoms which are present under the experimental conditions.

The reaction vessel was of Pyrex, cylindrical in shape, 15 cm. long with plane windows at both ends; the volume was approximately 250 cc. The vessel was mounted in an electric furnace that was fitted with windows so as to allow a beam of light to be directed lengthwise through the reaction vessel. The temperature was measured by a chromel–alumel thermocouple that was placed in a well extending into the reaction vessel in such a manner as not to lie in the optical path through the vessel. The furnace could be kept constant within a degree by manually regulated rheostats. The pressure was measured by a click gage, used as a null instrument, and a system that consisted of a mercury manometer and a sulfuric acid manometer connected so the mercury manometer could be used for high pressures and the sulfuric acid manometer for low pressures. The reaction vessel was connected to a vacuum line and to an iodine storage bulb, each through a heated glass valve. The iodine storage bulb was immersed in a small oil-bath that could be heated to distil iodine into the reaction vessel. The connecting tubing to the click gage and glass valves was capillary, wound with resistance wire and electrically heated to prevent the condensation of iodine. The dead space in the connections was about 2 cc.

The concentration of iodine during the course of a reaction was determined by measuring the intensity of a beam of light which passed through the reaction vessel. The light source was a thirty-two candle power automobile lamp connected through a resistance to a storage battery. A Corning glass filter No. 428 was placed between the lamp and the furnace window. The light transmitted by this filter is in the region of the maximum absorption by iodine. It has been pointed out by Cuthbertson and Kistiakowsky[3] that good results may be obtained in measuring the absorption of iodine with a blue filter while without the filter the effect of foreign gases on the absorption of iodine would cause a large error. The intensity of the beam was measured by a Weston Photronic Cell, No. 594, connected to a D'Arsonval galvanometer.

The acetaldehyde and propionaldehyde were taken from the center fractions of carefully dried Eastman Kodak Co. stock. Each sample was distilled several times and stored in three-liter bulbs connected to the vacuum line. No trouble from polymerization was experienced in storing the gases. The formaldehyde was prepared by heating trioxymethylene in a 500-cc. flask in an oil-bath. Above 200° the amount of polymer that exists in gaseous formaldehyde is very small; so no polymer could have existed in our experiments at 500°. The methyl iodide was prepared and stored similarly to the acetaldehyde. The iodine was a Merck reagent.

In order to determine the concentration of iodine present during the course of an experiment, it was necessary to make a calibration of the intensity measuring system. This was done by introducing certain amounts of iodine into the reaction vessel and by taking both the pressure reading and the galvanometer deflection. A curve could be constructed giving the relation of the light absorbed to the pressure of the iodine. To compensate for the small changes in light intensity and absorption in the reaction vessel due to tarring the galvanometer deflection with no iodine in the system was adjusted by varying the current passing through the light source.

The general procedure during a particular experiment was to introduce a certain desired amount of iodine vapor and read the pressure with the sulfuric acid manometer. The aldehyde, under higher pressure, was then introduced rapidly and an electric clock started simultaneously.

Pressure readings could be obtained conveniently with the mercury manometer at one-half or one minute intervals. In order to find the initial pressure of aldehyde a graphical extrapolation to zero time was made. This value was corrected for the iodine present and also for the initial rapid increase due to the formation of three molecules from one of aldehyde and one of iodine. This latter correction was necessary because in every case the iodine had disappeared almost completely before the first pressure reading could be made.

In regard to the measurements on the iodine during the steady state it was observed that the concentrations were very low. In no case was the concentration over 5% of the initial iodine. The tarring that inevitably accompanies a reaction of this type made an exact determination impossible. To avoid these uncertainties we assumed in our calculations that the concentrations of hydrogen iodide and alkyl iodide were equal to the iodine added during the steady state. No great error could have been introduced by this assumption. When the reactions were complete the observed end-point was never quite equal to the theoretical end-point. This discrepancy was caused by a simultaneous condensation reaction and amounted to about 10 or 15% in the pressure reading. The magnitude of the difference was distributed quite randomly through the different runs. As nothing is known about this side reaction no correction was made in the calculation.

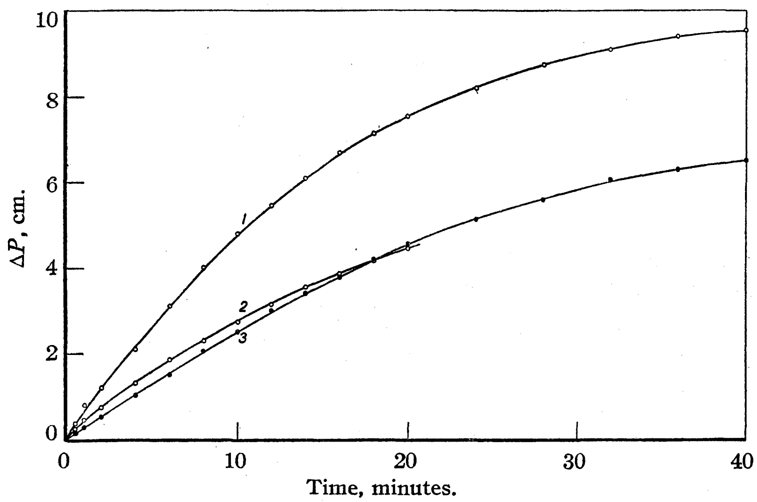

Fig. 1.—Curves 1 and 2 show the pressure increase in reactions with the initial pressure of formaldehyde 14.00 cm. and 11.20 cm., respectively. Curve 3 shows the pressure increase in a reaction mixture containing 11.38 cm. of formaldehyde and 1.06 cm. of iodine. The temperature was 500° in all experiments.

Results and Discussion

Formaldehyde.—Formaldehyde is known to decompose into hydrogen and carbon monoxide at temperatures in the neighborhood of 500° and above at an appreciable rate.[4] On introducing iodine to the thermal reaction mixture at 500° there is no noticeable increase in the rate of decomposition as shown by the curves in Fig. 1 although the iodine color disappears rapidly. Assuming that iodine reacts with formaldehyde according to the equation

$$\mathrm{HCHO} + \mathrm{I_2} = 2\mathrm{HI} + \mathrm{CO}$$

the limiting rate of any cycle of reactions is the rate of regeneration of iodine by the bimolecular decomposition of hydrogen iodide. This rate may be calculated from the work of Bodenstein as summarized by Kassel[5] the equation being

$$\mathrm{d(I_2)/d}t = 5.65 \times 10^{12} T^{1/2} e^{-46,116/RT}\ \mathrm{(HI)^2\ cc./mole/sec.}$$

At 500°, expressing the concentrations in cm. and the time in minutes, this equation reduces to

$$\mathrm{d(I_2)/d}t = 1.74 \times 10^{-3}\ \mathrm{(HI)^2}$$

On the introduction of 1 cm. of iodine the pressure of hydrogen iodide would become 2 cm., and the time required to produce a 1-cm. change is two hours and twenty-four minutes. This rate is only about one-fiftieth as fast as the thermal decomposition of formaldehyde, so no appreciable catalytic effect of iodine should be observed. Also, since there is no observed effect other than the disappearance of iodine, we may conclude that there is no reaction between formaldehyde and hydrogen iodide that is comparable to the thermal decomposition.

Acetaldehyde and Propionaldehyde.—The decompositions of acetaldehyde and propionaldehyde into methane and carbon monoxide and ethane and carbon monoxide, respectively, at temperatures above 350° are markedly accelerated by the addition of a small amount of iodine. Above 400° these systems change rapidly to a condition in which the concentration of free iodine is so low that it cannot be detected by absorption measurements. In this state the net reaction is the decomposition of the aldehyde. As the aldehyde concentration is decreased a point is reached at which the iodine color begins to reappear and as the aldehyde concentration decreases the free iodine concentration increases until when the aldehyde is completely decomposed all the original iodine is in the free state. At

(5) Kassel, "The Kinetics of Homogeneous Gas Reactions," The Chemical Catalog Co., New York, 1932, p. 150.

lower temperatures the free iodine is not removed so completely although at 350° it is still less than 5% of the amount originally added. Furthermore our measurements show that this low concentration is constant (within 10%) so that we may consider that we are dealing with a steady state in which the net result is a catalysis. If we assume that the catalysis is due to the reactions

$$RCHO + I_2 = RI + HI + CO$$
$$RI + HI = I_2 + RH$$

then the rate determining step will be the one between the alkyl iodide and hydrogen iodide. The rates of reaction between methyl iodide and hydrogen iodide and ethyl iodide and hydrogen iodide have been studied by Ogg over a temperature range from 250 to 320°.[2] If we extrapolate his rate equations to temperatures of the systems under consideration we find the results tabulated in Tables I and II. The first table shows the data for a typical experiment with acetaldehyde. The third column gives the observed rate and the fourth the rate calculated assuming that every molecule of iodine has reacted to give one of methyl iodide and one of hydrogen iodide. The difference tabulated in the last column shows a marked trend with the aldehyde pressure. Similar results were obtained with propionaldehyde as shown in Table II, although in this case the discrepancy between the observed and calculated rates is less at all pressures than with acetaldehyde. At low aldehyde pressures the system goes out of the steady state and the calculated rates are no longer valid; so the discrepancy cannot be followed to its limiting value.

TABLE I

ACETALDEHYDE WITH 0.41 CM. OF IODINE AT 364°

Time, min.	Press. ald., cm.	Obsd. rate, cm./min.	Calcd. rate, cm./min.	Diff., cm./min.
2	17.02	1.31	0.20	1.11
4	14.67	1.01	.20	0.81
6	13.02	0.79	.20	.59
8	11.52	.68	.20	.48
10	10.57	.59	.20	.39

14	8.27	.41	.20	.21

TABLE II

PROPIONALDEHYDE WITH 0.42 CM. OF IODINE AT 350°

Time, min.	Press. ald., cm.	Obsd. rate, cm./min.	Calcd. rate, cm./min.	Diff., cm./min.
2	12.64	1.10	0.44	0.66
4	10.69	0.90	.44	.46
6	9.09	.77	.44	.33
8	7.49	.68	.44	.24
10	6.29	.57	.44	.13
12	5.09	.44	.44	.00

In seeking an explanation for this high rate of reaction we turned to a consideration of the mechanism given by Ogg for the reactions between the alkyl iodides and hydrogen iodide. His rate laws are of the form

$$\frac{-d(RI)}{dt} = k_1\,(RI)\,(HI) + k_2\,\frac{(RI)(HI)}{(HI) + (I_2)}$$

In this equation the first term is attributed to a simple bimolecular reaction and the second term is due to a series of reactions involving dissociation of the alkyl iodide into an iodine atom and an alkyl radical as the primary step. Now it has been shown by Leermakers,[6] Allen and Sickman[7] and Fletcher and Rollefson[8] that the decomposition of acetaldehyde is catalyzed at these temperatures by free radicals. Therefore if Ogg's mechanism is correct the high rate of reaction of the aldehyde might be accounted for as due to the catalysis by the free radicals produced in the thermal dissociation of the methyl iodide. In order to test this hypothesis several experiments were performed in which a small amount of methyl iodide was added to the acetaldehyde. Some reaction occurred but it was only about one-tenth as fast as with a corresponding amount of iodine. The observed rates in these experiments were found to be proportional to the square root of the pressure of the methyl iodide as it should be if the free radical mechanism were correct. Similar tests with hydrogen iodide showed no marked effect. This result shows that it is necessary to assume that either there is some source of free radicals other than the decomposition of methyl iodide or the iodine atoms present have a marked catalytic action for the decomposition of the aldehyde. We have tested a number of possibilities but the following set of reactions is the most completely in accord with the experimental facts, while the system is in the steady state.

$$I_2 \rightleftarrows 2I \qquad (1)$$
$$RI \rightleftarrows R + I \qquad (2)$$
$$R + RCHO \longrightarrow R + RH + CO \qquad (3)$$
$$I + RCHO \longrightarrow R + HI + CO \qquad (4)$$
$$R + HI \longrightarrow RH + I \qquad (5)$$
$$R + I_2 \longrightarrow RI + I \qquad (6)$$

In this set of reactions it is to be noted that the sum of (4) and (5) is essentially the decomposi-

---

(8) Fletcher and Rollefson, *ibid.*, **58**, 2135 (1936).

tion of the aldehyde catalyzed by iodine atoms. Also according to Ogg the specific reaction rates of (5) and (6) are equal and since in our experiments the concentration of hydrogen iodide was always at least twenty times that of iodine, (6) is of minor importance and is included only for the sake of completeness. If we apply the usual methods of equating the rates of formation and removal of the intermediates R and I we find that the above set of reactions leads to the equation

$$k_1(\mathrm{I_2}) + 2k_2(\mathrm{RI}) = 2k_2'(\mathrm{R})(\mathrm{I}) + k_1'(\mathrm{I})^2$$

in which k_1' and k_2' represent the specific reaction rates for the reverse of (1) and (2), respectively, and k_1 and k_2 refer to the direct reactions. From an inspection of the reactions listed it may be seen that the net over-all reaction is the decomposition of the aldehyde. Under such conditions the equilibria in reactions (1) and (2) will not be disturbed, therefore we may write

$$\begin{aligned} k_1(\mathrm{I_2}) &= k_1'(\mathrm{I})^2 \\ k_2(\mathrm{RI}) &= k_2'(\mathrm{R})(\mathrm{I}) \end{aligned}$$

and

$$\begin{aligned} (\mathrm{I}) &= \sqrt{K_1(\mathrm{I_2})} \\ (\mathrm{R}) = K_2\frac{(\mathrm{RI})}{(\mathrm{I})} &= K_2(\mathrm{RI})/\sqrt{K_1(\mathrm{I_2})} \end{aligned}$$

in which K_1 and K_2 are the equilibrium constants for (1) and (2), respectively. Calculating the rate of disappearance of aldehyde by these reactions we have

$$\begin{aligned} -\frac{\mathrm{d(RCHO)}}{\mathrm{d}t} &= k_3\frac{K_2(\mathrm{RI})(\mathrm{RCHO})}{\sqrt{K_1(\mathrm{I_2})}} + k_4(\mathrm{RCHO})\sqrt{K_1(\mathrm{I_2})} \\ &= (\mathrm{RCHO})\left[\frac{k_3K_2(\mathrm{RI}) + k_4K_1(\mathrm{I_2})}{\sqrt{K_1(\mathrm{I_2})}}\right] \end{aligned}$$

In any given experiment when the system has reached the steady state (RI) and $(\mathrm{I_2})$ are constant and proportional to the initial amount of iodine. Let $(\mathrm{I_2})_0$ equal the pressure of iodine added and α be the fraction remaining as $\mathrm{I_2}$ with $1-\alpha$ the fraction as RI and HI. Then our equation becomes

$$-\frac{\mathrm{d(RCHO)}}{\mathrm{d}t} = (\mathrm{RCHO})(\mathrm{I_2})_0{}^{1/2}\left[\frac{k_3K_2(1-\alpha)}{K_1{}^{1/2}\alpha^{1/2}} + k_4K_1{}^{1/2}\alpha^{1/2}\right]$$

All the quantities contained within the brackets are constants when the system is in the steady state so the rate of removal of aldehyde is proportional to the aldehyde pressure and the square root of the initial iodine pressure. The only one of these quantities which could be considered as having a possibility of varying in the steady state is α. The absolute value of α will depend upon the relative rates of formation and disappearance of the iodine. The rate of formation depends upon the concentrations of the alkyl iodide and hydrogen iodide according to the law given by Ogg

$$\frac{\mathrm{d(I_2)}}{\mathrm{d}t} = k_1(\mathrm{RI})(\mathrm{HI}) + k_2\frac{(\mathrm{RI})(\mathrm{HI})}{(\mathrm{HI}) + (\mathrm{I_2})}$$

In what we have called the steady state (RI) = (HI) and both are constant and approximately equal to the iodine added. The rate expression just given therefore reduces to ($(\mathrm{I_2})_0$ is the iodine originally added)

$$\mathrm{d(I_2)d}t = k_1(\mathrm{I_2})_0^2 + k_2(\mathrm{I_2})_0$$

and since under the conditions of our experiment the second term is much larger than the first we may say that the rate of formation of iodine is approximately proportional to the amount originally added. In the steady state the rate of disappearance of iodine, whatever law it follows, is the same as its rate of formation. Under these conditions the only reactant which is changing appreciably is the aldehyde, therefore if the rate is to depend on α and the aldehyde pressure it must do so in such a way that the effect of any change in the aldehyde pressure is offset by a corresponding change opposite in sign in α. Our measurements in the steady state are sufficiently accurate to show that this is definitely not the case but that α is independent of the aldehyde as long as the steady state conditions exist. Since there is no other variable we must conclude the α is constant.[9] The breakdown of the steady state at pressures of 5–6 cm. of acetaldehyde or 3–5 cm. of propionaldehyde corresponds to the deviation of α from constancy.

The rate equation just derived does not give the total rate of disappearance of aldehyde but only that part due to the presence of free radicals and iodine atoms. There still remains a certain amount of decomposition according to the mechanism

$$\begin{aligned} \mathrm{I_2} + \mathrm{RCHO} &\longrightarrow \mathrm{RI} + \mathrm{HI} + \mathrm{CO} \\ \mathrm{RI} + \mathrm{HI} &\longrightarrow \mathrm{RH} + \mathrm{I_2} \end{aligned}$$

These reactions contribute a term $k(\mathrm{RI})(\mathrm{HI})$ which is identical with the first term of the rate law given by Ogg for the reaction between the alkyl iodide and hydrogen iodide. The second term of Ogg's law corresponds to reactions which have already been taken into account in the

---

(9) A law for the disappearance of iodine which would fit these conditions is $-\mathrm{d(I_2)}/\mathrm{d}t = k\alpha(\mathrm{I_2})_0(\mathrm{RCHO})/1 + k'(\mathrm{RCHO})$ but we have no direct evidence for such a law nor is it obvious how such a law could be obtained.

mechanism involving free radicals. The total rate of disappearance of aldehyde may be written

$$-\mathrm{d}(\mathrm{RCHO})/\mathrm{d}t = k(\mathrm{RI})(\mathrm{HI}) + k'(\mathrm{RCHO})(\mathrm{I_2})_0^{1/2}$$

where the first term may be calculated from Ogg's data and the second term is that due to the free radical mechanism already discussed with all the constants grouped together in k'. In order to test this expression we have determined the rates of reaction in the region where the iodine is principally in the form of alkyl iodide and hydrogen iodide. The observed rates for a typical experiment are given in column three, Table III. The next column gives the difference between this rate and the k(RI)(HI) as calculated from Ogg's equation. The last column gives the values of k' assuming our rate law to hold. In Tables IV and V the results are given for acetaldehyde and propionaldehyde, respectively, in a number of experiments with different amounts of iodine added. From the constancy of the value of k' the results may be said to be in agreement with the rate law as given above.

1.21	7.37–3.42	.455	.144	.131

The equation we have been discussing is strictly valid only when the system is in what may be called a steady state with respect to iodine, *i. e.*, the amount of free iodine present is essentially constant. This condition is fulfilled when the ratio of aldehyde to iodine added is large. Toward the end of an experiment when this ratio is becoming small the values of k' decrease due to the increase in α. Experimentally it was found that the decrease in k' coincided with the return of the iodine color.

On the basis of our mechanism the apparent order of the reaction with respect to aldehyde will depend on the relative importance of the two terms in the rate law. Thus with acetaldehyde the second term accounts for the major portion of the rate and therefore the reaction appears to be of approximately first order with respect to acetaldehyde. With propionaldehyde the first term is more important and therefore the apparent order with respect to propionaldehyde is somewhat less than the first order.

Summary

The addition of iodine markedly accelerates the decompositions of acetaldehyde and propionaldehyde but does not affect the decomposition of formaldehyde appreciably. It is shown that these effects can be explained by assuming that the iodine reacts with the aldehyde first and this step is followed by two parallel sets of reactions. The first is a simple bimolecular reaction of the alkyl iodide and hydrogen iodide formed from the above-mentioned reaction. The second is a series of reactions involving the free radicals and iodine atoms produced by the thermal dissociations of the alkyl iodide and the residual iodine. Detailed mechanisms are presented and it is shown that they fit the experimental facts.

The Formula of Ammonium Paramolybdate

BY J. H. STURDIVANT

In 1917 Rosenheim[1] advocated for the paramolybdates the formula $R_5H_5[H_2(MoO_4)_6]$. The previously accepted formula had described the compounds as heptamolybdates, $R_6Mo_7O_{24}\cdot 4H_2O$. Analytical methods were unable to decide between the two formulas until recently, when the heptamolybdate formula was reaffirmed on the basis of analyses of mixed paramolybdates of ammonia and triethanolamine.[2]

In the present paper additional evidence for the heptamolybdate formula will be described, based on X-ray measurement of the lattice constants and a determination of the density of crystalline ammonium paramolybdate.[3]

Cooling a saturated ammoniacal solution of Powers–Weightman–Rosengarten ammonium molybdate, C. P. grade, produced crystals in the form of rhomboidal plates about 2 mm. × 1 mm. × 1/3 mm. Forms observed, in the notation of Groth,[4] were $b(010)$, $o(111)_G$, $n(310)_G$, $m(110)_G$. As foreshadowed by the habit of the crystals, the X-ray investigation required a new assignment of axes, which will be used throughout this paper. The new axis **a** is taken parallel to $[10\bar{1}]_G$ of Groth, and the new axis **c** parallel to $\mathbf{c}_G$ of Groth. From the monoclinic angle 91°12′ given by Groth and the axial ratios of Groth, the value $\beta = 115°59'$ is calculated. From direct goniometric measurements on the plates used in this investigation, β was found to be $116°0' \pm 4'$. Monochromatic X-ray photographs were prepared by oscillating a crystal through small angles on each side of the primary beam to give selected orders of reflection from the *a*, *b* and *c* planes. The cylindrical camera of 5 cm. nominal radius was calibrated by the use of calcite as a standard crystal with the grating space given by Siegbahn.[5] Film shrinkage was allowed for by marks imposed on the film before development. The radiation was from a copper target. The following spacings[6] were obtained at about 24°:

$d_{(100)}$ = 7.534 ± 0.010 Å. from measurements of (100), (200), (300).
$d_{(010)}$ = 36.125 ± 0.008 Å. from measurement of (0·36·0).
$d_{(001)}$ = 9.405 ± 0.005 Å. from measurement of (0·0·10).

Layer line measurements and data from a Laue photograph proved that the corresponding axes describe a true unit of structure of minimum volume, and the unit was further shown by Laue data to be simple. Groth describes ammonium paramolybdate as monoclinic prismatic. Two Laue photographs taken with the X-ray beam approximately parallel to **a** indicated that interferences (*h*0*l*) with *l* odd do not occur. On oscillation photographs interferences (0*n*0) with *n* odd were absent. The space-group is therefore $C_{2h}^5 - P2_1/c$.

The density was measured of a 7-g. sample of the original commercial product, ground to pass through a 150-mesh sieve, and weighed in a pycnometer filled with carbon tetrachloride. During addition of the carbon tetrachloride the air was exhausted from the pycnometer and powder. The density was found to be 2.871 ± 0.003 at 25°.

The weight of a mole of unit cells is $0.6064 \times 10^{24} \times \rho \times d_{(100)} \times d_{(010)} \times d_{(001)} \times (\sin\beta)^{-1} = 4958 \pm 20$. The formula $(NH_4)_5H_5[H_2(MoO_4)_6]$ corresponds to a molecular weight of 1057; this number is contained 4.7 times in 4958; and 4.7 differs from an integer by more than the experimental error. On the other hand, four molecules of the heptamolybdate formula in the unit cell would give a weight equal to 1236.3 × 4 = 4945. The conclusion is therefore reached that the formula of ammonium paramolybdate is $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$.

The author is indebted to Professor Linus Paul-

(5) M. Siegbahn, "Spektroskopie d. Röntgenstrahlen," Verlag von J. Springer, Berlin, 1931, pp. 44–45.

(6) The fundamental translations calculated from these spacings and $\beta = 116°0'$ are a = 8.382 Å., $b = d_{(010)}$, c = 10.464 Å. Thence the axial ratios $a_G:b_G:c_G$ = 0.6258:1:0.2897 are calculated. Groth gives, however, $a_G:b_G:c_G$ = 0.6297:1:0.2936. The disagreement is not surprising in view of the generally poor quality of the faces of ammonium molybdate crystals, which is reflected, for example, in the detailed measurements reported by P. Rossoni, *Atti soc. toscana sci. nat., proc. verb.*, **42**, 10–19 (1933). The nature of the imperfections, particularly the development of vicinal faces in the zone of [001], is, however, not such as to diminish seriously the accuracy of direct measurement of *β*.

ing for suggesting the study of ammonium paramolybdate.

Summary

The lattice constants, space groups and density of crystalline ammonium paramolybdate were determined. From the weight of the unit of structure it is concluded that the compound is a heptamolybdate, with the formula $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$.

The Solubilities of Barium and Strontium Carbonates in Aqueous Solutions of Some Alkali Chlorides

BY R. W. TOWNLEY AND W. B. WHITNEY WITH W. A. FELSING

Object of the Investigation

A number of investigations dealing with the change in solubilities of the alkaline earth carbonates in aqueous salt solutions have been recorded. In each case an increase in solubility was noted. Muir[1] studied the solubility of calcium carbonate in sodium chloride solutions. Cameron and Robinson,[2] Cantoni and Goguelia,[3] and Dubrisay and François[4] studied the influence of potassium chloride upon the solubility of calcium carbonate and the last-named investigators also studied the influence of potassium chloride upon the barium carbonate solubility. De Coninck and Arzalier[5] briefly mention their study of the solubility of strontium carbonate in the presence of potassium chloride. In no case, however, was the study made with the view of determining the activity of these alkaline earth carbonates by the method outlined by Lewis and Randall.[6]

The purpose of this investigation, hence, was the determination of the influence of increasing concentrations of lithium, sodium, and potassium chlorides upon the solubilities of the normal carbonates of barium and strontium. It was hoped that the data obtained would yield information of value regarding the activities of these carbonates.

Previous Investigations

The solubility of barium carbonate in pure water has been reported[7] at various temperatures; McCoy and Smith's value at 25°, as calculated from their solubility product, is 0.90×10^{-4} g. moles/1000 g. of water. The solubility of strontium carbonate is also recorded by several investigators.[8] McCoy and Smith's value at 25° is 0.396×10^{-4} g. moles/1000 g. water.

Experimental Methods

The method of this investigation consisted of saturating solutions of lithium, sodium, and potassium chlorides at different concentrations (approx. 0.02, 0.06, 0.10, 0.2, 0.3, 0.5, 1.0, and 3.0 *M*) with the solid barium and strontium carbonates at both 25 and 40°. The finely divided solids, in large excess, were agitated with the various solutions in a shaking device immersed in a thermostat maintained at 25 ± 0.02° and at 40 ± 0.04°. After an interval of twenty-four to forty-eight hours of agitation (some samples were shaken for much longer periods without yielding different results, however), the flasks were allowed to stand for several hours in the thermostat; filtered samples were withdrawn at the thermostat temperature and were immediately titrated against hydrochloric acid, using phenolphthalein as indicator; each sample was heated to the boiling point as the end-point was approached. Weight burets were used throughout. Duplicate equilibrium determinations were made for each concentration and each determination was made in duplicate.

Water.—The best grade of conductivity water was used throughout, the final distillation being made from and into quartz. All water and solutions were protected against carbon dioxide.

The Carbonates.—(a) The barium carbonate was prepared from Merck C. P. precipitated barium carbonate. The carbonate was converted into the bicarbonate to form a very dilute solution; it was then re-precipitated by boiling, collected on a filter, washed with conductivity water, and dried for twelve hours at 250°. (b) The strontium carbonate was prepared from C. P. strontium chloride by the addition, in hot dilute solution, of the required amount of ammonium carbonate of reagent grade. The carbonate was repeatedly washed, filtered and dried for twelve hours at 250°.

The Chlorides.—(a) The lithium chloride was obtained by recrystallizing E. & A. "Pure" lithium chloride. The

solution was concentrated by slow evaporation in a vacuum desiccator containing concd. sulfuric acid. The filtered crystals were dried for ten hours at 250°. (b) The sodium chloride was prepared from Baker reagent grade by precipitation from solution by means of hydrogen chloride; the product was dried and then heated to the "crackling" point in a platinum dish. (c) The potassium chloride was recrystallized twice from conductivity water, washed, and dried for ten hours at 250°.

Hydrochloric Acid.—Constant boiling acid was used in preparing the 0.01 *M* acid for the titration of the equilibrium filtrates.

The Salt Solutions.—The chloride solutions were prepared by adding weighed quantities of water to carefully weighed quantities of the dried salts.

Experimental Data

The experimentally determined solubilities, both at 25 and 40°, were plotted to large scale against the molalities of the added chlorides. A "best" line was drawn through each set of data points; the data of Tables I and II at rounded concentrations were read off this best line.

Discussion and Treatment of Results

The solubilities of barium carbonate at 25 and 40° in pure water, as determined during this investigation, were 0.9114 and 1.2217 × 10^{-4} g. moles/1000 g. of water, respectively. The value at 25° agrees well with the value of McCoy and Smith,[7b] indicating that the method of analysis of this investigation yielded satisfactory results. The solubilities of strontium carbonate at 25 and 40° in pure water were found to be 0.5525 and 0.7026 × 10^{-4} g. moles/1000 g. of water, respectively. The value at 25° lies between that of Kohlrausch and Rose[8b] at 24° and that of McCoy and Smith[8c] at 25°. The average heats of solution for barium carbonate and strontium carbonate into their saturated solutions are, from these solubilities, 3625 and 2973 cal./mole, respectively.

The normal carbonate hydrolyzes in solution to form the bicarbonate ion

$$CO_3^{=} + H_2O = HCO_3^{-} + OH^{-}$$

A correction must be applied for this hydrolysis in the various salt solutions. If x is the concentration (moles per liter) of HCO_3^- and of OH^- produced, then $(C - x)$ is the *true* concentration of the carbonate ion (from barium carbonate or strontium carbonate). Consideration of the hydrolytic equation above leads to the relation $x^2/(C - x) = K'_w/K'_2$, where K'_w is the stoichiometric ion product for water and K'_2 is the second ionization constant (stoichiometric) for carbonic acid at any particular value of the ionic strength.

Values of K'_w at 25 and 40° at different values of the ionic strength were found in the work of Harned[9] and Harned and Hamer.[10] At 25°, Harned gives values for K'_w for solutions of potassium and sodium chlorides. These values were plotted against values of the square root of the ionic strength, $\mu^{1/2}$; values of K'_w could be read off this large scale plot for any value of $\mu^{1/2}$ for both of these salts. For lithium chloride solutions, for which no K'_w data were given, the values of K'_w for sodium chloride solutions were assumed to yield data sufficiently accurate for our purposes. At 40°, Harned and Hamer gave only K'_w data for potassium chloride solutions. Again, these data were taken as sufficiently accurate for our solutions in lithium and sodium chloride solutions.

Values for K'_2 for carbonic acid at 25 and 40° (38°) were taken from the papers by MacInnes and Belcher;[11] they give empirical equations relating K'_2 and $\mu^{1/2}$ for solutions of potassium carbonate, bicarbonate and chloride. They do

---

(9) Harned, This Journal, **47**, 930 (1925).

(10) Harned and Hamer, *ibid.*, **55**, 2194 (1933).

(11) MacInnes and Belcher, *ibid.*, **55**, 2630 (1933); **57**, 1685 (1935).

not give data at 40 but at 38°; these values of K_2' are *assumed* to hold at 40°.

Corrections were then applied by means of the relation $x^2/(C - x) = K'/K_2'$ for each value of "C" listed in Tables I and II and for each value of $\mu^{1/2}$. The resulting values of $(C - x)$, the true $[CO_3^=]$, were then related to the ionic strength by plotting $1/m\pm$ against $\mu^{1/2}$. Extrapolation of these curves to zero value of $\mu^{1/2}$ yielded the following values.

TABLE III

EXTRAPOLATED VALUES OF $1/m\pm$ AT $\mu^{1/2} = 0$

Salt	$BaCO_3$		$SrCO_3$	
Temp., °C.	25	40	25	40
$[1/m\pm]_{\mu=0}$	42,880	58,100	95,800	151,500

These extrapolated values of $1/m\pm$ were used to calculate the values of the activity coefficients of the carbonates in their various solutions, according to the method of Lewis and Randall,[6] by means of the relation

$$f = [1/m\pm]_\mu/[1/m\pm]_{\mu=0}$$

The following tables present these calculated values, in which "Total m" is the ionic strength.

Summary

1. The solubilities at 25 and 40° of barium and strontium carbonates have been determined in pure water and in solutions of lithium, sodium and potassium chlorides. The solubilities in solutions of the alkali chlorides are presented tabularly.

2. The activity coefficients of these carbonates in the alkali chloride solutions have been calculated and recorded.

3. The average heats of solution of these carbonates into their saturated solutions have been calculated for the temperature range 25–40°.

The Magnetic Properties and Structure of Ferrihemoglobin (Methemoglobin) and Some of its Compounds

BY CHARLES D. CORYELL, FRED STITT AND LINUS PAULING

Our studies of the magnetic properties of hemoglobin derivatives containing ferrous iron,[1,2] including ferroheme, several hemochromogens, hemoglobin, and carbonmonoxyhemoglobin, led to the discovery that in two of these substances (ferroheme, hemoglobin) there are four unpaired electrons per heme, indicating that the bonds attaching the iron atoms to the rest of the molecule are essentially ionic in character, whereas the others contain no unpaired electrons, each iron atom being attached to six adjacent atoms by essentially covalent bonds. We have now investigated ferrihemoglobin[3] (acid methemoglobin), ferrihemoglobin hydroxide (alkaline methemoglobin), ferrihemoglobin fluoride, ferrihemoglobin cyanide, and ferrihemoglobin hydrosulfide, and have found a variety in magnetic properties greater than that for the ferrohemoglobin derivatives; the magnetic susceptibilities

[2] L. Pauling and C. D. Coryell, *ibid.*, **22**, 210 (1936).

[3] The nomenclature used in this paper is described in ref. 2.

of ferrihemoglobin and its fluoride appear to correspond to five unpaired electrons per heme, those of the cyanide and hydrosulfide to one, and that of the hydroxide to three. The structural significance of these results is discussed in the last section of this paper.

Technique of the Magnetic Measurements.—The Gouy method was used to determine the magnetic susceptibilities of solutions of hemoglobin derivatives, the difference in susceptibility of solution and water being measured with use of a glass tube divided by a glass partition into two compartments, one containing solution and the other water.[4] The tubes used were about 18 mm. in internal diameter and 30 cm. long, and were provided with ground glass caps for the ends and with suitable supports for suspension from the balance arm. Fields of about 7640 and 8810 gausses were used; forces measured at 8810 gausses were changed to 7640 gausses by multiplication by the experimentally determined factor 0.752, and all measurements made (usually four) averaged to give a mean value of Δw (in milligrams). Measurements were made in several tubes with slightly different diameters. Each tube was calibrated by the measurement of Δw for water against air, these values being close to 47. Experimentally determined corrections have been applied for dilution and for the diamagnetism of added reagents. All susceptibility measurements were made at temperatures between 22 and 26°.

The concentration of each hemoglobin solution used was determined by reducing to ferrohemoglobin with 0.3 or 0.6 g. of sodium hydrosulfite (for 30 ml. of solution), determining Δw, then saturating with carbon monoxide in the dark or in diffuse daylight and again determining Δw. The change in Δw corresponds to a change in molal susceptibility (per heme) of $12{,}430 \times 10^{-6}$ c. g. s. u. at 24°, the effective magnetic moment of ferrohemoglobin per heme being taken[2] as 5.46 Bohr magnetons. Representing Δw for ferrohemoglobin solution by Δw_{Hb}, that for carbonmonoxyhemoglobin solution by Δw_{COHb}, and that for the solution being studied by Δw (these Δw's corresponding to the same molal concentration), the molal susceptibility (per heme) at 24° for the solution being studied is given by the equation

$$\chi_{\mathrm{molal}} = \frac{\Delta w - \Delta w_{\mathrm{COHb}}}{\Delta w_{\mathrm{Hb}} - \Delta w_{\mathrm{COHb}}} \cdot 12{,}430 \cdot 10^{-6}\ \text{c. g. s. u.} \quad (1)$$

and the effective magnetic moment per heme by the equation

$$\mu = \left(\frac{\Delta w - \Delta w_{\mathrm{COHb}}}{\Delta w_{\mathrm{Hb}} - \Delta w_{\mathrm{COHb}}}\right)^{1/2} \cdot 5.46\ \text{Bohr magnetons} \quad (2)$$

Measurements of pH values were made with a Beckman glass-electrode pH meter generously furnished by Professor A. O. Beckman of these Laboratories. As a standard 0.05 M potassium hydrogen phthalate solution, pH 3.97, was used. Corrections were applied in alkaline solutions for error due to sodium and potassium ions present as recommended by the manufacturer of the instrument.

Preparation of Ferrihemoglobin Solutions.—In the preliminary work ferrihemoglobin solutions were prepared by oxidation of oxyhemoglobin solutions with potassium ferricyanide, the excess of this reagent then being converted to ferrocyanide (which has zero magnetic moment) by the addition of sodium sulfite, which does not reduce ferrihemoglobin. It was also found that on addition to oxyhemoglobin solutions of sodium hydrosulfite and then of potassium ferricyanide the hemoglobin is oxidized to ferrihemoglobin and the excess ferricyanide reduced to ferrocyanide by the sulfite formed earlier by oxidation of the hydrosulfite by oxyhemoglobin.

In order to avoid the possibility of magnetic effects of the added iron the following very satisfactory method of preparing ferrihemoglobin solutions was developed, involving the auto-oxidation of oxyhemoglobin solutions at pH 4.8 to 5.3. Corpuscles obtained by centrifuging bovine blood are washed three times with 0.14 M potassium chloride solution, laked with ether, and centrifuged, the ether then being removed by bubbling air through the solution. To this solution enough 6 N lactic acid solution is added (about 16 ml. per liter) to bring the pH to about 4.9. At this pH the auto-oxidation reaction is complete after the solution has remained for forty-eight hours at room temperature. The solution, now at pH about 5.15, is brought to pH 7.0 by the addition with vigorous stirring of 1 N potassium hydroxide solution and centrifuged to remove the small amount of denatured protein formed during acidification. For different preparations used in this work the concentration of ferrihemoglobin, determined magnetically as described above, ranged from 0.0113 to 0.0176 formal in heme-iron.

By following the concentration of oxyhemoglobin magnetically it was found that in twenty-four hours at pH 5.2 and temperature 22° the amount of oxyhemoglobin present had fallen to 1% of its initial value;[5] in order to ensure completion of the reaction it is recommended that the solution stand for another twenty-four hours.

Ferrihemoglobin and Ferrihemoglobin Hydroxide.—The pronounced change in spectrum of ferrihemoglobin solutions accompanying change in pH from the acid to the alkaline range corresponds to the addition of hydroxyl ion to ferrihemoglobin (acid methemoglobin) to form ferrihemoglobin hydroxide (alkaline methemoglobin). Spectrophotometric studies of this reaction made by Austin and Drabkin[6] have shown that the amounts of substances present at intermediate pH values correspond closely to the equilibrium[7]

$$\mathrm{HbOH} \rightleftarrows \mathrm{Hb^+ + OH^-} \quad (3)$$

In Table I there are given magnetic data for ferrihemoglobin solutions of low ionic strength

---

[4] S. Freed and C. Kasper, *Phys. Rev.*, **36**, 1002 (1930).

[5] The reaction is approximately first-order in oxyhemoglobin and first-order in hydrogen ion; the rate-determining step may be

$$\mathrm{HbO_2 + H^+ \longrightarrow Hb^+ + HO_2}$$

with the production of hydrogen superoxide. The temperature coefficient of the rate is high, about 5 for 10°.

[6] J. H. Austin and D. L. Drabkin, *J. Biol. Chem.*, **112**, 67 (1935); see also F. Haurowitz, *Z. physiol. Chem.*, **138**, 68 (1924).

[7] We use the symbol $\mathrm{Hb^+}$ to represent the amount of ferrihemoglobin containing one heme, and HbOH, Hb, $\mathrm{HbO_2}$, etc., to represent corresponding amounts of ferrihemoglobin hydroxide, ferrohemoglobin, oxyhemoglobin, etc., respectively.

in the pH range 6.7 to 12.0. The data represent experiments made with three solutions, A, B and C. Two of these, A and B, were prepared by the lactic acid auto-oxidation method described above, and the third by a similar method, hydrochloric acid being used for acidification in place of lactic acid. The results for the three solutions show no differences greater than the experimental error. The hemoglobin concentration of each solution was determined by the ferrohemoglobin–carbonmonoxyhemoglobin magnetic method.

$\chi_{\mathrm{Hb}^+}\cdot 10^6 = 14{,}060 \pm 50.$

$\chi_{\mathrm{HbOH}}\cdot 10^6 = 8350 \pm 90.$

$pK_{\mathrm{HbOH}} = 8.15 \pm 0.02.$

Ionic strength at pH 8.15 = 0.20.

[a] Paramagnetic contribution to susceptibility per mole of heme.

A portion of ferrihemoglobin solution was placed in one compartment of a tube and Δw determined. Successive small portions of potassium hydroxide solution (0.87 N) were then added with vigorous stirring, the values of pH and Δw being determined after the addition of each portion. The values of Δw were corrected for dilution and the diamagnetism of reagents, and converted into χ_{molal}, the paramagnetic contribution to the susceptibility per mole of heme, by means of equation 1. The data of Table I are shown by the open circles in Fig. 1.

The ionic strength of the hemoglobin solutions, due in part to the salts originally in solution in the erythrocytes and in part to added acid and base, changes somewhat with change in pH, the values at pH 7, 8 and 9 being about 0.17, 0.20 and 0.23, respectively. The contribution of hemoglobin to the ionic strength was ignored.

The data for these solutions represent a typical titration curve, the molal susceptibility changing rapidly over the range pH 7 to 9.5 from an asymptotic value of about $14{,}000\cdot 10^{-6}$, representing ferrihemoglobin, Hb^+, to an asymptotic value of about $8300\cdot 10^{-6}$, representing ferrihemoglobin hydroxide, HbOH. Using these estimated asymptotes to calculate concentrations of Hb^+ and HbOH, it is found that the experimental points when plotted on a graph of log $([\mathrm{Hb}^+]/[\mathrm{HbOH}])$ against pH lie close to a straight line, with slope unity to within about five per cent., showing that the reaction is first-order in hydroxyl ion, as was reported by Austin and Drabkin. A theoretical susceptibility curve was fitted to the experimental points of Fig. 1 by the following procedure. The equilibrium constant K_{HbOH} for the reaction

$$\mathrm{HbOH} \rightleftarrows \mathrm{Hb}^+ + \mathrm{OH}^-$$

is related to the mole fraction x of total ferrihemoglobin in the form Hb^+ by the equation

$$\log x/(1 - x) = pK_{\mathrm{HbOH}} - p\mathrm{H} \qquad (4)$$

in which pK_{HbOH} is log $(K_{\mathrm{HbOH}}/K_{\mathrm{W}})$, with K_{W} the equilibrium constant for the ionization of water. The value of the molal susceptibility χ as a function of pH is then given by the expression

$$\chi = x\chi_{\mathrm{Hb}} + (1 - x)\chi_{\mathrm{HbOH}} \qquad (5)$$

in which x is determined by equation 4. With χ_{HbOH}, χ_{Hb^+} and pK_{HbOH} as variable parameters, this equation was fitted to the experimental points in such a way as to minimize the mean deviation from the curve. The final curve was found to have $\chi_{\mathrm{HbOH}} = 8350 \pm 90\cdot 10^{-6}$, $\chi_{\mathrm{Hb}^+} = 14{,}060 \pm 50\cdot 10^{-6}$, and $pK_{\mathrm{HbOH}} = 8.15 \pm 0.02$, the indicated probable errors for the susceptibility values being half the mean deviations and that for pK_{HbOH} being an estimated value.

The data given in Table II and represented by the solid circles in Fig. 1 were obtained with a solution, D, to which potassium chloride had been added, the ionic strength being increased in this way to the value 1.3 (at pH 8.56). These data also are well represented by a curve corre-

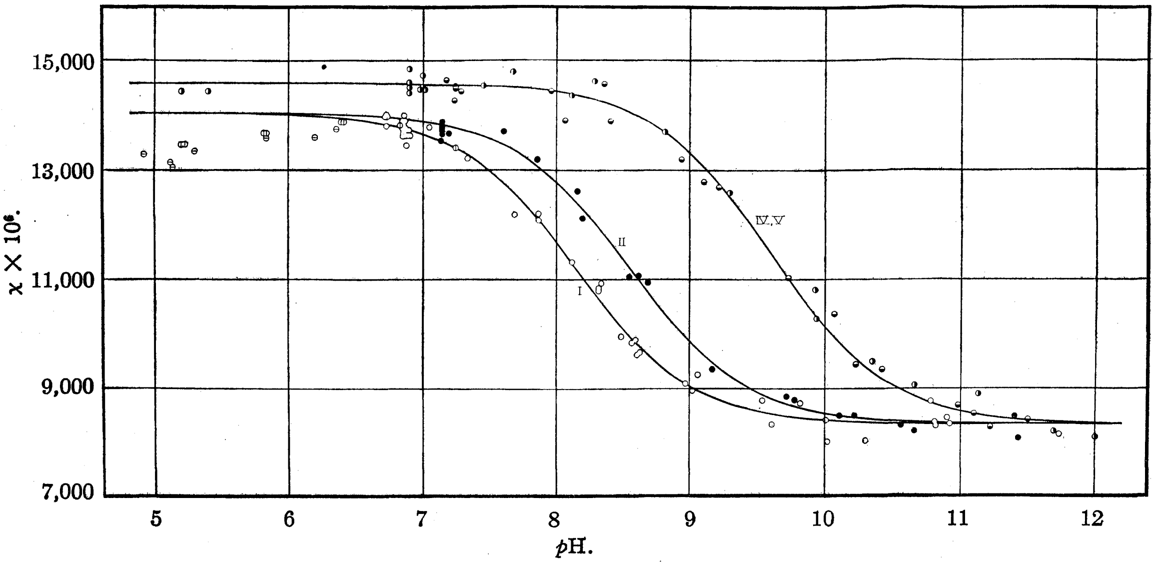

Fig. 1.—The dependence of the magnetic susceptibility of ferrihemoglobin solutions on pH: ○, solutions of low ionic strength, Table I; ●, solutions of high ionic strength, Table II; ⊖ ⦶, solutions in low pH range, Table III; ◑, solutions of low ionic strength with added fluoride, Table IV; ◒, solutions of high ionic strength, with added fluoride, Table V.

sponding to equations 5 and 4, the values of the parameters for the curve giving the best fit being $\chi_{\text{HbOH}} = 8320 \pm 60 \cdot 10^{-6}$, $\chi_{\text{Hb}^+} = 14{,}000 \pm 70 \cdot 10^{-6}$, and $pK_{\text{HbOH}} = 8.56 \pm 0.02$.

TABLE II

MAGNETIC SUSCEPTIBILITY OF FERRIHEMOGLOBIN SOLUTIONS OF HIGH IONIC STRENGTH

Solution D

pH	$\chi_{\text{molal}} \cdot 10^6$	pH	$\chi_{\text{molal}} \cdot 10^6$
7.14	13,530	8.62	11,070
7.15	13,880	8.69	10,940
7.15	13,650	9.17	9,350
7.15	13,760	9.72	8,850
7.15	13,790	9.78	8,780
7.15	13,720	10.11	8,500

7.61	13,700	10.56	8,325
7.86	13,190	10.66	8,220
8.16	12,620	11.40	8,480
8.20	12,120	11.43	8,080
8.55	11,050		

$\chi_{\text{Hb}^+} \cdot 10^6 = 14{,}000 \pm 70$.
$\chi_{\text{HbOH}} \cdot 10^6 = 8320 \pm 60$.
$pK_{\text{B}} = 8.56 \pm 0.02$.
Ionic strength at pH 8.56 = 1.3.

The values found for χ_{HbOH} and χ_{Hb^+} in solutions at high and low ionic strength are in excellent agreement. For χ_{Hb^+} we accept the average value $14{,}040 \cdot 10^{-6}$, giving double weight to the asymptote of curve I. For χ_{HbOH} we obtain the mean value $8340 \cdot 10^{-6}$ by considering in addition to the two values $8350 \cdot 10^{-6}$ and $8320 \cdot 10^{-6}$ discussed above the values $8370 \cdot 10^{-6}$ and $8320 \cdot 10^{-6}$ obtained from solutions containing fluoride ion, discussed in the following section. The structural interpretation of the susceptibility values will be considered in the concluding section of the paper.

The equilibrium constant K_{HbOH} is dependent on the ionic strength of the solution, pK_{HbOH} changing from 8.15 to 8.56 with increase in ionic strength from 0.20 to 1.3. This dependence was observed by Austin and Drabkin, who found that pK_{HbOH} could be represented approximately by the equation

$$pK_{\text{HbOH}} = \text{constant} + \alpha\sqrt{\mu} \qquad (6)$$

in which μ is the ionic strength, the value for α being about 0.6. Our measurements support this,[8] the change for curves I and II corresponding to $\alpha = 0.59$.

The value $pK_{\text{HbOH}} = 8.12 \pm 0.01$ reported by Austin and Drabkin for canine hemoglobin at ionic strength 0.10 agrees reasonably well with our value 8.15 ± 0.02 at ionic strength 0.20 (corresponding to 8.07 at ionic strength 0.10) for bovine hemoglobin; complete agreement would, of course, not be expected for hemoglobins from different species.

It has been reported by Drabkin and Austin

---

(8) An experiment carried out involving the determination of change in Δw and pH for a portion of solution A, initially at pH 8.57, on the addition of successive portions of potassium chloride solution led to rough verification of the form of equation 6.

that ferrihemoglobin solutions become turbid at *p*H values less than 6. Two series of magnetic experiments were made in this *p*H range. In the first series a portion of solution A was made more and more acid by the addition, with rapid stirring, of successive small portions of 1 *N* hydrochloric acid solution, values of *p*H and Δw being determined after each acidification. These data are given in Table III and shown by the horizontally barred circles in Fig. 1. The formation of a small amount of coagulum in the acid solution was noticed; in order to eliminate possible error due to this coagulation, the following series of measurements was made. A portion of solution C was brought to *p*H 5.2 by the addition of hydrochloric acid, and centrifuged to remove the coagulum formed on acidification. The solution obtained in this way (solution E) was then made more and more alkaline by the addition of small portions of potassium hydroxide solution, values of *p*H and Δw being determined at each step. No coagulum was formed during this treatment. The ferrihemoglobin concentration, made uncertain by the loss of the coagulum resulting from the initial acidification, was determined by identifying the measured susceptibility at *p*H 7.25 (the most alkaline point) with that corresponding to the theoretical curve I. The data obtained in this way, given in Table III and represented in Fig. 1 by vertically barred circles, are in reasonably good agreement with those obtained by acidification. The measurements correspond to a decrease of about 5% in molal susceptibility in very acid solutions.

Ferrihemoglobin Fluoride.—The absorption spectrum of an acid ferrihemoglobin solution is changed in a pronounced manner by the addition of fluoride, indicating the formation of a compound. A crystalline compound was prepared and analyzed by Haurowitz,[9] who reported the substance to contain one atom of fluorine per atom of iron. Our magnetic studies have verified this, and have led to the evaluation of the equilibrium constants for the reactions

$$\mathrm{HbF} + \mathrm{OH}^- \rightleftarrows \mathrm{HbOH} + \mathrm{F}^-, \text{ and} \qquad (7)$$
$$\mathrm{HbF} \rightleftarrows \mathrm{Hb}^+ + \mathrm{F}^-$$

The data given in Tables IV (for solutions A, B, C) and V (for solution D) were obtained by adding 0.5 g. of sodium fluoride to a 32-ml. portion of ferrihemoglobin solution and adding small portions of 0.87 *N* potassium hydroxide solution, with vigorous stirring, *p*H and Δw being determined after the addition of each portion. The

[9] F. Haurowitz, *Z. physiol. Chem.*, **138**, 68 (1924).

points for solutions A, B and C, with low ionic strength (0.54 at pH 9.6), and those for solution D, with high ionic strength (1.6 at pH 9.6), lie close to the same curve, showing that there is no appreciable salt effect for the reaction. This provides support for the postulate that the reaction consists essentially in the conversion of ferrihemoglobin fluoride into ferrihemoglobin hydroxide (eq. 7), for which no appreciable salt effect would be expected. Further evidence for equation 7 will be mentioned later.

The molal susceptibility values of Tables IV and V can be approximated closely by curves of the type used above for the ferrihemoglobin–ferrihemoglobin hydroxide equilibrium. For reaction 7 the equilibrium constant $K_{\mathrm{OH,F}}$ has the value

$$K_{\mathrm{OH,F}} = [\mathrm{HbOH}][\mathrm{F}^-]/[\mathrm{HbF}][\mathrm{OH}^-] \qquad (9)$$

and the molal susceptibility is given by the equation

$$\chi = y\chi_{\mathrm{HbF}} + (1 - y)\chi_{\mathrm{HbOH}} \qquad (10)$$

in which y is the mole fraction of total ferrihemoglobin in the form of ferrihemoglobin fluoride, given by the equation

$$\log y/(1 - y) = pK_{\mathrm{OH,F}} - p\mathrm{H} \qquad (11)$$

in which $pK_{\mathrm{OH,F}}$ is $-\log (K_{\mathrm{OH,F}}K_{\mathrm{W}}/[\mathrm{F}^-])$. The asymptotes of the curves which fit the data most closely are $14{,}630 \cdot 10^{-6}$ and $8{,}370 \cdot 10^{-6}$ for solutions A, B and C, and $14{,}500 \cdot 10^{-6}$ and $8320 \cdot 10^{-6}$ for solution D. The values $8370 \cdot 10^{-6}$ and $8320 \cdot 10^{-6}$, representing χ_{HbOH}, are in excellent agreement with the values $8350 \cdot 10^{-6}$ and $8320 \cdot 10^{-6}$ found for solutions without added fluoride.

The values for the other asymptote represent molal susceptibility not of ferrihemoglobin fluoride itself but of ferrihemoglobin fluoride containing a small fraction of ferrihemoglobin (Hb^+). From the equilibrium constants given below the values of the concentration ratio $[\mathrm{Hb}^+]/[\mathrm{HbF}]$ are found to be 0.047/0.953 for solutions A, B and C, and 0.094/0.906 for solution D. Using these ratios and the known value of χ_{Hb^+} to correct for the ferrihemoglobin present, the values $\chi_{\mathrm{HbF}} = 14{,}660 \pm 70 \cdot 10^{-6}$ and $14{,}550 \pm 80 \cdot 10^{-6}$ are obtained; we accept for χ_{HbF} the mean of these closely agreeing values, $14{,}610 \cdot 10^{-6}$.

The values 9.63 and 9.60 for $pK_{\mathrm{OH,F}}$ given by the curves lead on similar consideration of the $[\mathrm{Hb}^+]/[\mathrm{HbF}]$ ratio to the corrected values 9.65 and 9.64, which agree to within their estimated probable error of 0.01. Introducing the values of $[\mathrm{F}^-]$ (0.34 at pH 9.6) and K_{W} ($10^{-14.01}$), we obtain for the equilibrium constant $K_{\mathrm{OH,F}}$ at 24° the value $0.78 \cdot 10^4$.

The equilibrium constant K_{HbOH} for reaction 3 is given by the equation

$$\log K_{\mathrm{HbOH}} = -6.12 + 0.59\sqrt{\mu} \qquad (12)$$

Combining with this the value of $K_{\mathrm{OH,F}}$, we obtain for K_{HbF}, the equilibrium constant for the reaction

$$\mathrm{HbF} \rightleftarrows \mathrm{Hb}^+ + \mathrm{F}^- \qquad (13)$$

the expression

$$\log K_{\mathrm{HbF}} = -2.23 + 0.59\sqrt{\mu} \qquad (14)$$

Three sets of measurements were made to test these equilibrium constants by direct titration with potassium fluoride solution. In the first run a portion of solution A was brought to pH 8.60, and values of pH and Δw were measured after the addition of successive small portions of known volume of 2.00 f potassium fluoride solution. The average of nine values of K_{HbF} corresponding to the nine added portions of fluoride solution is 0.0145, with a mean deviation of 0.0012; this value is in good agreement with the value 0.013 given by equation 14 for $\mu = 0.34$. When the formality of fluoride in the solution had reached 0.28, the pH was observed to have changed to the value 8.89, an increase of 0.29; this agrees well with the calculated change in pH expected because of the replacement of hydroxyl in ferrihemoglobin hydroxide by fluorine, 0.30. A less reliable set of six measurements made on solution D at pH 8.6 gave the average value 0.049 for K_{HbF}. This is somewhat larger than the value 0.029 given by equation 14 for $\mu = 1.4$, perhaps because of experimental error, the total change in Δw values during the run being less than 1 mg. A set of five measurements made on solution A at pH 6.2 gave for K_{HbF} the average value 0.008, somewhat lower than the value 0.010 expected for $\mu = 0.22$; the difference may be due to error in the measurement of Δw, which changed by only 0.40 mg. during the run.

A determination of the value of K_{HbF} by a spectrophotometric method has been reported by Lipmann.[10] The value found, about 0.015, for a solution of swine hemoglobin of uncertain ionic strength agrees with that calculated from equation 14 with μ given the reasonable value 0.5. Lipmann also reported a decrease of the constant in very acid solutions.

Ferrihemoglobin Cyanide.—Crystalline ferrihemoglobin cyanide was first obtained by Zey-

---

[10] F. Lipmann, *Biochem. Z.*, **206**, 171 (1929).

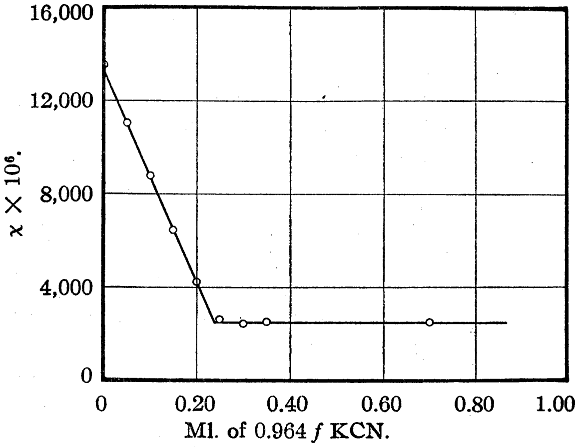

Fig. 2.—The magnetic titration of ferrihemoglobin with potassium cyanide at pH 6.75.

nek,[11] who by analysis showed the substance to contain one cyanide per heme. We have verified this by titration of a ferrihemoglobin solution with cyanide. The data represented in Fig. 2 were obtained with a solution containing equal volumes of ferrihemoglobin solution B and a phosphate buffer, the pH of the solution being 6.75. To 31.25 ml. of this solution there was added from a 1-ml. glass syringe graduated in hundredths successive measured volumes (0.050 ml.) of 0.964 *f* potassium cyanide solution. When the molal susceptibility is plotted against the amount of cyanide added the first five points fall close to a straight line and the last four to a horizontal straight line. The intersection of these lines occurs at 0.235 ml., which agrees to within the experimental error with the value 0.236 ml. calculated for one cyanide per heme. The value found for χ_{HbCN} in this experiment is $2520 \cdot 10^{-6}$. A similar experiment performed at pH 10.8 gave similar results.

In order to determine the molal susceptibility of ferrihemoglobin cyanide accurately sets of duplicate measurements were made with unbuffered solution B at pH 6.7 and with solution B brought to pH 10.9 by the addition of potassium hydroxide solution, an excess of potassium cyanide solution being added in each case. The values found for $\chi_{HbCN} \cdot 10^6$ are 2590 and 2620 at pH 6.7 and 2630 and 2590 at pH 10.9. There is accordingly no dependence of χ_{HbCN} on pH. The average of the measured values is $2610 \cdot 10^{-6}$. Values approximating this were also obtained in several preliminary measurements and in measurements made incidental to other experiments.

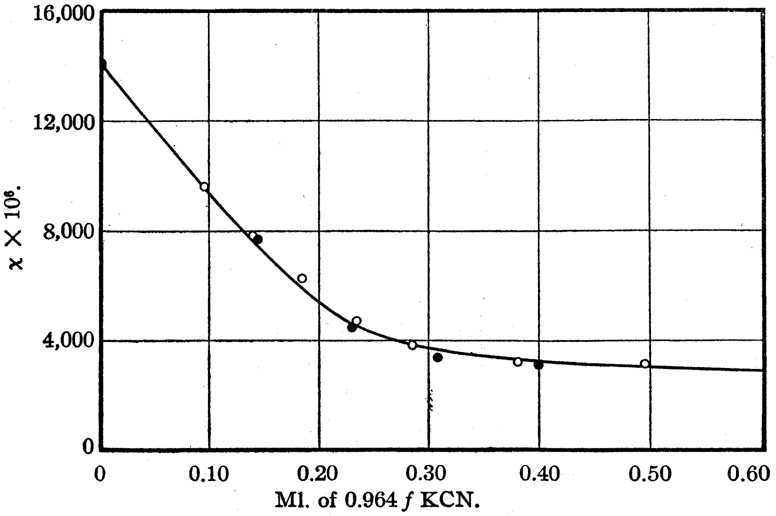

Fig. 3.—The magnetic titration of ferrihemoglobin with potassium cyanide at pH 4.77.

In order to obtain an approximate value for the equilibrium constant K_{HbCN} for the reaction

$$HbCN \rightleftarrows Hb^+ + CN^- \qquad (15)$$

two cyanide titration experiments were made with ferrihemoglobin solution B brought to pH 4.77 by the addition of an equal volume of an acetate buffer solution 2 *M* in acetic acid and 2 *M* in sodium acetate. A portion of the solution was placed in one compartment of a tube, which was then closed with a thin rubber stopper. Portions of 0.964 *f* potassium cyanide solution were then added by means of a syringe, the needle being inserted through the rubber stopper, and Δw values were measured. The corresponding values of χ_{molal} for the two runs are shown in Fig. 3. When about one-half of the stoichiometric amount of cyanide has been added it is almost entirely in the form of HbCN. With larger amounts of cyanide the formation of HbCN is incomplete, the amount of cyanide present as HCN becoming appreciable. The ratio $[CN^-]/[HCN]$ is about 10^{-4}, so that the equilibrium measured is essentially

$$Hb^+ + HCN \rightleftarrows HbCN + H^+ \qquad (16)$$

The experimental points lie close to the theoretical equilibrium expression, represented by the curve in Fig. 3; the value found for the corresponding

---

[11] R. v. Zeynek, *Z. physiol. Chem.*, **33**, 426 (1901).

equilibrium constant (presumably essentially independent of ionic strength) is 18. This value multiplied by the ionization constant of HCN, $2.0 \cdot 10^{-9}$, gives for K_{HbCN} the value $3.6 \cdot 10^{-8}$, at zero ionic strength.[12] The dependence on ionic strength is probably nearly the same as for K_{HbOH} and K_{HbF}; we hence write for K_{HbCN} the equation

$$\log K_{\text{HbCN}} = -7.44 + 0.59\sqrt{\mu} \qquad (17)$$

Ferrihemoglobin Hydrosulfide.—It was discovered by Keilin[13] that ferrihemoglobin forms a compound with hydrogen sulfide,[14] containing one sulfur atom per heme. By analogy with other compounds of ferrihemoglobin we consider it likely that this compound is ferrihemoglobin hydrosulfide, HbSH.

Solutions of ferrihemoglobin hydrosulfide made by addition of sodium hydrosulfide to ferrihemoglobin solution buffered to *p*H values in the range 5 to 7 were found to decompose rapidly, apparently undergoing auto-reduction to ferrohemoglobin, as shown by its spectrum and molal susceptibility and by the spectrum (that of oxyhemoglobin) observed after air is admitted to the solution. In order to evaluate χ_{HbSH} the following experiments were performed. To a portion of ferrihemoglobin solution B an equal volume of acetate or phosphate buffer was added. About 30 ml. of the solution was then placed in a compartment of a tube, which was closed with a thin rubber stopper, and 0.5 ml. (or, in one experiment, 0.1 ml.) of 4 *f* sodium hydrosulfide solution was added through the stopper with a syringe. The tube was then placed in position, and readings of Δw were taken at intervals of about two minutes, the first being made about six minutes after the addition of the hydrosulfide. The measured values of Δw correspond to a rapid increase of the molal susceptibility with time, χ being at first linear in t and then approaching an asymptote. The data are represented by the theoretical expression for a reaction first order with respect to HbSH, with the asymptotic value of χ_{molal} equal to that for ferrohemoglobin. To evaluate χ_{HbSH} the susceptibility values over the nearly linear portion of the curve were extrapolated to zero time; for four solutions, with *p*H 5.1, 5.7, 5.7, and 7.0, respectively, the values 2240, 2110, 2260 and 1930.10^{-6}, average $2140 \cdot 10^{-6}$, were obtained. A value for the dissociation constant of the substance is not provided by our data.[15]

The rate constant $k = -\text{d}(\ln[\text{HbSH}])/\text{d}t$ has the approximate value $5 \cdot 10^{-3}$ (with t measured in minutes), the observed values of $k \cdot 10^3$ being 5.0 at *p*H 5.08, 12.0 at *p*H 5.73, 5.2 at *p*H 7.02, and 3.0 at *p*H 5.73. (The third experiment was made with phosphate buffer, the others with acetate buffers; the fourth was made with 0.1 ml., the others with 0.5 ml. of 4 *f* sodium hydrosulfide solution added.) It is seen that no more than about 2-fold variation was observed over the *p*H range 5.1 to 7.0, and that the rate seems to increase with increase in the concentration of hydrosulfuric acid.

The Interpretation of the Molal Susceptibility Values

The values of the paramagnetic part of the molal susceptibility (per heme) at 24° of the substances studied in this investigation are collected in Table VI. If it be assumed that these values result from the independent orientation of the magnetic moments of the hemes and that Curie's law is applicable, they correspond to the values of the magnetic moment μ, in Bohr magnetons, shown in the last column of the table, calculated with the equation

$$\mu = 2.84\sqrt{\chi_{\text{molal}}T}$$

in which T is the absolute temperature.

TABLE VI

VALUES OF THE PARAMAGNETIC MOLAL SUSCEPTIBILITY AND EFFECTIVE MAGNETIC MOMENT (PER HEME) OF FERRIHEMOGLOBIN AND SOME OF ITS COMPOUNDS

	$\chi_{\text{molal}} \cdot 10^{6\,a}$	μ^b
Ferrihemoglobin, Hb^+	14,040	5.80
Ferrihemoglobin hydroxide, HbOH	8,340	4.47
Ferrihemoglobin fluoride, HbF	14,610	5.92
Ferrihemoglobin cyanide, HbCN	2,610	2.50
Ferrihemoglobin hydrosulfide, HbSH	2,140	2.26

[a] At 24°. [b] In Bohr magnetons.

---

[12] An effort to check this result was made by determining magnetically the ratio ferrihemoglobin–ferrihemoglobin cyanide in a solution in equilibrium with solid silver cyanide and solid silver chloride. Three measurements, made with concentrations 0.20, 0.43 and 1.00 *f* of chloride ion, gave for the ratio $[\text{Hb}^+]/[\text{HbCN}]$ the values 0.20, 0.093 and 0.040, respectively. Taking $1.7 \cdot 10^{-10}$ as the solubility product of AgCl and $7 \cdot 10^{-15}$ as that of AgCN [as given by M. Randall and J. O. Halford, THIS JOURNAL, **52**, 178 (1930)], these measurements lead to $K_{\text{HbCN}} = 1.6 \cdot 10^{-6}$, in rather poor agreement with the value $1 \cdot 10^{-7}$ given by equation 17. It is possible that the disagreement is due to error in the solubility product of AgCN, inasmuch as an older value $4.5 \cdot 10^{-17}$ [Bodländer and Eberlein, *Z. anorg. Chem.*, **39**, 197 (1904)] leads to $K_{\text{HbCN}} = 1 \cdot 10^{-8}$.

[13] D. Keilin, *Proc. Roy. Soc.* (London), **B113**, 393 (1933).

[14] Keilin emphasized the fact that this compound is different from the green substance formed from ferrohemoglobin in the presence of hydrogen sulfide and oxygen.

[15] Keilin performed experiments to determine this dissociation constant. No mention of the auto-reduction reaction which we observed is made in his paper.

The possibility should be considered that the moments of the four hemes in a molecule of molecular weight 68,000 are not oriented independently, but instead are combined to a resultant constant moment for the molecule, with magnitude twice that given for μ in the table. This possibility was discussed in connection with ferrohemoglobin,[2] and reasons were advanced for rejecting it in favor of the alternative simple interpretation in terms of hemes which interact with one another only weakly; it was suggested that the observed effective moment per heme for ferrohemoglobin, 5.46, is somewhat larger than the expected value for four unpaired electrons (spin moment alone, 4.90; expected orbital contribution, about 0.1 to 0.4) because of a partial stabilization of parallel orientations of the heme moments through heme–heme interaction. Some of the arguments advanced in support of this interpretation for ferrohemoglobin are applicable to ferrihemoglobin and its compounds also, and we have, moreover, been able to interpret the susceptibility values in a reasonably satisfactory manner on this basis and not on the basis of constant moments for the four-heme molecules; hence we believe that in these substances too the heme moments are entirely or almost entirely independent of one another.[16]

The effective moment per heme observed for ferrihemoglobin fluoride is 5.92, which is identical with the theoretical spin moment for five unpaired electrons, 5.917. Moreover, for five unpaired *d* electrons the total moment is equal to the spin moment, the orbital contribution vanishing because of the occupancy of each orbit in the subgroup by one electron; there is actually very close agreement between the theoretical spin moment and the experimental values for iron-group ions and complexes with five unpaired electrons, representative observed moments being 5.94 for Mn^{++} and 5.86–5.98 for Fe^{+++} in aqueous solution, 5.88 for the fluoferriate complex $[FeF_6]^{\equiv}$, and 5.91 for the complex $[FeF_5 \cdot H_2O]^{=}$. The observed moment for ferrihemoglobin fluoride shows that in this substance, as in the fluoferriate complex, the bonds from iron to the surrounding atoms (fluorine, the four porphyrin nitrogens, one globin nitrogen atom) are essentially ionic in character.

The effective moment per heme for ferrihemoglobin itself, 5.80, shows that in this complex too the bonds from the iron atom to the surrounding atoms are essentially ionic. It is possible that the coördination number of iron is here only five; it seems to us probable, however, that the sixth octahedral position is occupied by a water molecule,[17] the complex being $[HbOH_2]^+$ rather than Hb^+. The transition to ferrihemoglobin hydroxide would then involve loss of a proton (with change in bond type—*v. infra*) rather than addition of an hydroxyl ion.

The difference[18] between the observed moment 5.80 and the theoretical value 5.92 we attribute to heme–heme interaction operating to stabilize configurations in which the heme moments are opposed. Why the interaction should decrease the effective moment of ferrihemoglobin, increase that of ferrohemoglobin, and leave that of ferrihemoglobin fluoride unchanged we do not know.

The observed decrease in susceptibility (by about 5%) of ferrihemoglobin solutions in the low *p*H range may be due to change in the heme–heme interactions. Further experimental data are needed before a reliable explanation of this phenomenon can be given.[19]

The susceptibilities of ferrihemoglobin cyanide and ferrihemoglobin hydrosulfide correspond to the effective heme moments 2.50 and 2.26, respectively. These are close to the value expected for one unpaired electron (1.732 plus an orbital contribution of 0.3 to 0.5), showing that in these molecules two *d* orbitals of each iron atom are involved in covalent bond formation. Without doubt the structures are similar to that of the ferricyanide ion[20] (with $\mu = 2.33$), the iron atom being attached by essentially covalent bonds to six surrounding atoms arranged octahedrally, consisting of the four porphyrin nitrogens, one globin nitrogen, and the carbon of cyanide or sulfur of hydrosulfide. The observed moments

---

[16] The possibility that the moments of the hemes in pasri are combined to constant resultants also seems unlikely to us.

[17] It is of interest that one fluorine in $[FeF_6]^{\equiv}$ is easily replaced by a water molecule, forming $FeF_5 \cdot H_2O^{=}$.

[18] The reality of the difference is shown by the directly observed increase in susceptibility of ferrihemoglobin solution on the addition of fluoride.

[19] During the cyanide titrations it was observed that in solutions heavily buffered (with acetate) at *p*H 4.8 the molal susceptibility of ferrihemoglobin has the value $14,020 \cdot 10^{-6}$, which agrees well with the asymptotic value given by the curves rather than with the values observed for unbuffered solutions.

[20] We have made a determination of the molal susceptibility of potassium ferricyanide in solution by the differential method, the diamagnetic correction being made by using the susceptibility of the ferrocyanide solution obtained by reduction with sodium sulfite. Five measurements made at concentrations of 0.608 and 0.304 *f* gave for the paramagnetic molal susceptibility at 22.0° the value $2280 \pm 10 \cdot 10^{-6}$, corresponding to $\mu = 2.33 \pm 0.01$ Bohr magnetons.

are somewhat higher than expected, indicating some heme–heme interaction; it is possible, on the other hand, that the orbital contribution is greater than usual.

None, or one, or two of the $3d$ orbitals of trivalent iron atom in a complex may be involved in covalent bond formation, the number of unpaired electrons being five, three, or one, respectively, and the moment 5.92, about 4.2, or about 2.0 Bohr magnetons. Many complexes of the first type and many of the third type are known, whereas iron complexes of the intermediate type are very rare.[21] Ferrihemoglobin hydroxide apparently is of this type; the observed effective moment 4.47 is only slightly larger than that expected for three unpaired electrons (spin moment 3.88, orbital contribution about 0.4).

The nature of the bonds in this complex is somewhat uncertain, since, although the value of the magnetic moment is that which is associated with square coördination (as in nickel protoporphyrin[1]), there is little doubt that the configuration about the iron atom is octahedral. Four dsp^2 covalent bonds directed to the corners of a square would utilize one d orbital; in ferrihemoglobin hydroxide it is probable that these four covalent bonds resonate among the six adjacent atoms, each of which is then attached to the iron atom by a bond with roughly two-thirds covalent character (or perhaps somewhat less).

Summary

Magnetic measurements at approximately 24° of solutions of ferrihemoglobin and some of its compounds have been made, leading to values of the paramagnetic part of the molal susceptibility which correspond to the following values of the effective magnetic moment per heme, in Bohr magnetons: ferrihemoglobin, 5.80; ferrihemoglobin hydroxide, 4.47; ferrihemoglobin fluoride, 5.92; ferrihemoglobin cyanide, 2.50; ferrihemoglobin hydrosulfide, 2.26. For ferrihemoglobin and its fluoride these correspond to five unpaired electrons per heme, indicating essentially ionic bonds; for the cyanide and hydrosulfide to one, indicating essentially covalent bonds; and for the hydroxide to three, indicating bonds of an intermediate type.

Values determined by magnetic titrations are reported for the dissociation constants of ferrihemoglobin hydroxide, fluoride and cyanide.

Arsonated Derivatives of Mixed Ketones

BY ROBERTA ELEANOR OMER AND CLIFF S. HAMILTON

In a study of arsonated aliphatic–aromatic ketones[1–4] a number of attempts were made to condense *p*-hydroxyphenylarsonic acid with nitriles in various solvents with and without catalysts. There was no evidence of condensation in any case, results which were not entirely unexpected in view of the fact that the literature does not report condensations with nitrophenols and hydroxybenzenesulfonic acids.

Although direct arsonation of resorcinol[5] gives good yields of resorcinol arsonic acid, 2,4-dihydroxyacetophenone[6] and the corresponding propiophenone derivative did not react with arsenic acid to form more than traces of the arsonic acids. Protection of the phenolic hydroxyl groups by acetylation[7] or methylation[8] before heating with arsenic acid failed to give any arsonic acid although a few instances of direct arsonation of compounds containing no free hydroxyl groups are recorded.[5] Methylation of the products before their separation from the reaction mixture gave 10% yields.

The introduction of arsenic into hydroxyaromatic–aliphatic ketones through the diazo reaction[9] was exceedingly difficult. Attempts to condense *p*-nitrophenol and nitroresorcinol[10] with

nitriles proving unsuccessful, it was found necessary to prepare the amines of the hydroxy ketones for use in the diazotization from 2,4-dihydroxyacetophenone and the corresponding propiophenone derivative by nitration and reduction of the nitro compounds. The instability of the resulting amines required their isolation as amine hydrochlorides. The same sort of difficulty was encountered in arsonation through the diazo reaction as in direct arsonation. Both 2,4-dihydroxy-5-aminoacetophenone and 2,4-dihydroxy-5-aminopropiophenone were easily diazotized; but, under the wide variety of conditions tried, no more than a very small amount of an unstable impure material showing arsonation could be obtained.

However, methylation of the hydroxyl groups in 2,4-dihydroxy-5-nitroacetophenone and the corresponding propiophenone derivative resulted in very stable compounds. These were reduced catalytically and the somewhat unstable amines isolated through their hydrochlorides. Arsonation of these compounds proceeded easily, giving good yields of 2,4-dimethoxy-5-arsonoacetophenone and 2,4-dimethoxy-5-arsonopropiophenone.

Experimental

2,4-Dihydroxypropiophenone.[11,12]—Prepared from resorcinol and propionitrile by a method similar to that used by Hoesch in making 2,4-dihydroxyacetophenone[6]; yield 65%.

2,4-Dimethoxypropiophenone.—From 2,4-dihydroxypropiophenone following the method of Perkin, Robinson and Turner.[8] The yellow oily solid thus obtained was recrystallized twice from 50% ethyl alcohol solution, giving a white solid with a pleasant ethereal odor; m. p. 67°; 68% yield.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.00; H, 7.21. Found: C, 67.93, 67.76; H, 7.22, 7.21.

2,4-Dihydroxy-5-nitroacetophenone.—Fifty grams of 2,4-dihydroxyacetophenone was added in small portions with constant stirring to 400 cc. of nitric acid (1.42) cooled in an ice-bath. The addition was carried on at such a rate that each portion of the solid was dissolved completely before the next was introduced and so that the temperature remained below 10°. The stirring was continued for an hour, during which time a dark red solid separated, and the mixture then poured into a 2-liter beaker half full of chipped ice. The nitro compound was filtered out, washed with water and boiled with 500-cc. portions of water until all of the red color had been removed. The light yellow solid was then filtered out, dried and recrystallized from ethyl alcohol, giving 46 g. of the mononitro derivative; m. p. 142°.

Anal. Calcd. for $C_8H_7O_5N$: N, 7.11. Found: N, 7.13, 7.12.

2,4-Dihydroxy-5-nitropropiophenone.—Nitration of 2,4-dihydroxypropiophenone by a procedure similar to that used with the corresponding acetophenone derivative gave a 77% yield of the white nitro compound; m. p. 131°.

Anal. Calcd. for $C_9H_9O_5N$: N, 6.64. Found: N, 6.68, 6.66.

2,4-Diacetoxy-5-nitropropiophenone.—From 2,4-dihydroxy-5-nitropropiophenone by the method of Brüll and Friedlaender.[7] Recrystallization from carbon tetrachloride gave a 90% yield of the cream colored product; m. p. 89°.

Anal. Calcd. for $C_{13}H_{13}O_7N$: N, 4.98. Found: N, 5.04, 4.92.

2,4-Dimethoxy-5-nitroacetophenone.—Nineteen and seven-tenths grams of 2,4-dihydroxy-5-nitroacetophenone was dissolved in 33 cc. of 20% sodium hydroxide solution. To this solution in a 250-cc. flask was added 30 cc. of dimethyl sulfate. The mixture was stirred thoroughly, heated gently until the strongly exothermic reaction started and shaken until cool. The solid brown cake which formed was filtered out and ground up in *N* sodium carbonate solution to remove any material not entirely methylated. The solid remaining was filtered out, washed thoroughly with water, dried and recrystallized from hot ethyl alcohol; yield 15.5 g. of a finely divided cream colored product; m. p. 177°.

Anal. Calcd. for $C_{10}H_{11}O_5N$: N, 6.22. Found: N, 6.32, 6.25.

2,4-Dimethoxy-5-nitropropiophenone.—By a procedure similar to that used with 2,4-dihydroxy-5-nitroacetophenone, a 75% yield of cream colored dimethoxy derivative, m. p. 155°, was obtained.

Anal. Calcd. for $C_{11}H_{13}O_5N$: N, 6.70. Found: N, 6.64, 6.81.

Amine Hydrochlorides

General Procedure.—The hydrochloride of the amine was prepared from the corresponding nitro compound by catalytic reduction[13] in acetone solution using Raney catalyst.[14] At the end of the reaction the catalyst was filtered out, half the acetone removed by distillation under reduced pressure, and the hydrochloride prepared by passing dry hydrogen chloride into the remaining solution. In cases where the hydrochloride was somewhat soluble in acetone, ether was added to throw it out. The amine hydrochloride was filtered out, dried and recrystallized from

[a] With decomposition.

2,4 - Dimethoxy - 5 - arsonoacetophenone.—(a) 2,4 - Dimethoxy-5-arsonoacetophenone was prepared from the hydrochloride of 2,4-dimethoxy-5-aminoacetophenone by diazotization followed by coupling with sodium arsenite. Twenty-three and a half grams of the amine hydrochloride was dissolved in water and 16.5 cc. of 12 *N* hydrochloric acid added. This was cooled to 0° and diazotized by adding slowly 105 cc. of *N* sodium nitrite solution. The resulting solution was stirred for an additional fifteen minutes, cooled, and 20 cc. of 5 *N* sodium hydroxide solution stirred in, followed at once by a mixture containing 75 cc. of 2 *N* disodium monohydrogen arsenite solution, 2.5 cc. of 12 *N* hydrochloric acid, 200 cc. of water, 200 cc. of ice and 40 cc. of 10% copper sulfate solution. Nitrogen was evolved rapidly, and a few cc. of ethyl acetate was added to prevent excessive foaming. The reaction mixture was stirred for three hours, and, after standing overnight, it was heated to 50–60° on a steam-bath and filtered. The filtrate was made acid to litmus with acetic acid and concentrated to half its former volume on a steam-bath. The mixture was filtered twice through a charcoal filter to remove the color. On making the filtrate acid to Congo red paper with hydrochloric acid, the white arsonic acid separated. It was filtered out, washed, dried and purified by recrystallizing twice from "cellosolve"; yield 17 g.; m. p. 250°.

(b) Methylation of the reaction mixture obtained on heating 2,4-dihydroxyacetophenone and arsenic acid for five hours at 150–155° gave a 7% yield of 2,4-dimethoxy-5-arsonoacetophenone.

Anal.[15] Calcd. for $C_{10}H_{13}O_6As$: As, 24.35. Found: As, 24.30, 24.32.

2,4-Dimethoxy-5-arsonopropiophenone.—(a) A 61% yield of 2,4-dimethoxy-5-arsonopropiophenone was obtained from 2,4-dimethoxy-5-aminopropiophenone through the diazo reaction and coupling with sodium arsenite; m. p. 243°. (b) Methylation of the reaction mixture from the direct arsonation of 2,4-dihydroxypropiophenone by heating with arsenic acid for seventy-five hours at 100° gave an 11% yield of 2,4-dimethoxy-5-arsonopropiophenone.

Anal. Calcd. for $C_{11}H_{15}O_6As$: As, 23.55. Found: As, 23.42, 23.44.

Summary

1. 2,4-Dimethoxy-5-arsonoacetophenone and 2,4-dimethoxy-5-arsonopropiophenone were prepared by diazotization of the corresponding amino derivative followed by coupling with sodium arsenite. The same compounds were formed also by methylation of the product from the direct arsonation of 2,4-dihydroxyacetophenone and 2,4-dihydroxypropiophenone.

2. 2,4-Dihydroxypropiophenone was obtained by the nuclear condensation of propionitrile and resorcinol under the conditions of a Hoesch reaction.[6]

3. Several intermediate compounds and compounds incidental to the problem were prepared and identified for the first time.

4. All attempted arsonations of 2,4-dihydroxyacetophenone and 2,4-dihydroxypropiophenone by the Bart reaction[9] were unsuccessful.

Influence of Cyclohexene Concentration in the Alkylation of Benzene by Cyclohexene. Dealkylation of Cyclohexylbenzenes

BY B. B. CORSON AND V. N. IPATIEFF

Direct alkylation of benzene with cycohexene, using aluminum chloride[1] or sulfuric acid[2] as catalyst, offers a convenient method for the preparation of cyclohexylbenzenes.

Bodroux employed a large excess of benzene and obtained monocyclohexylbenzene together with a small quantity of substance melting at 169–170° which had the carbon–hydrogen ratio of diphenylcyclohexane. He assumed that the latter resulted from the dehydrogenation and rearrangement of dicyclohexylbenzene. Truffault obtained monocyclohexylbenzene and 1,4-dicyclohexylbenzene.

This paper describes the effect of varying the amount of cyclohexene. Using aluminum chloride as catalyst, the following products were obtained: monocyclohexylbenzene, 1,4-dicyclohexylbenzene, 1,3,5-tricyclohexylbenzene and 1,2,3,5-tetracyclohexylbenzene. The tri and tetra derivatives are new. With sulfuric acid as catalyst, the products were: monocyclohexylbenzene, 1,4-dicyclohexylbenzene and 1,2,3,5-tetracyclohexylbenzene. The yields of the various products depend upon the relative proportions of benzene and cyclohexene, catalyst and conditions being constant.

Both catalysts gave some liquid product which analyzed for di derivative. Von Braun,[3] also, obtained liquid di derivative as by-product from the reaction between benzene and cyclohexylbromide. Although our product remained liquid at −77°, it still contained 1,4-dicyclohexylbenzene as shown by dehydrogenation.

Mono-, di- and tricyclohexylbenzenes can be alkylated to higher derivatives by cyclohexene. Both mono- and dicyclohexylbenzenes can be converted to tetra derivative. Tricyclohexylbenzene was not isolated. Tri derivative can be alkylated to tetra derivative, but the yield is small, the main product being liquid. Attempts to obtain penta- and hexacyclohexylbenzenes were unsuccessful.

Di-, tri- and tetracyclohexylbenzenes can be dealkylated to lower derivatives by the action of benzene in the presence of aluminum chloride. 1,4-Dicyclohexylbenzene and 1,3,5-tricyclohexylbenzene are converted to monocyclohexylbenzene. 1,2,3,5-Tetracyclohexylbenzene is dealkylated to monocyclohexylbenzene and 1,3,5-tricyclohexylbenzene. From the di, tri and tetra derivatives there was also obtained a small yield of material melting at 168–169° which had the carbon–hydrogen ratio of diphenylcyclohexane.[4]

The proof of structure of the mono derivative consisted in dehydrogenation by bromine to diphenyl. The di derivative was identical with 1,4-dicyclohexylbenzene prepared according to the method of von Braun,[3] who established its structure by dehydrogenation to 1,4-diphenylbenzene and by oxidation to terephthalic acid. Hydrogenation of the di derivative gave the two isomeric 1,4-dicyclohexylcyclohexanes described by von Braun.[5] The structure of the tri derivative was established by dehydrogenation to 1,3,5-triphenylbenzene and by hydrogenation to 1,3,5-tricyclohexylcyclohexane.[6]

The structure of the tetra derivative was based upon its easy dealkylation to 1,3,5-tricyclohexylbenzene and also upon its hydrogenation (accompanied by dealkylation) to 1,4-dicyclohexylcyclohexane and 1,3,5-tricyclohexylcyclohexane.[7]

Experimental

Benzene, Cyclohexene and Aluminum Chloride.—To a stirred, ice-cooled mixture of 176 g. (2.3 moles) of benzene and 60 g. of anhydrous aluminum chloride was added 246 g. (3 moles) of cyclohexene (b. p. 82–85°; d^{20}_{4}, 0.811; n^{20}_{D} 1.446). The time of addition was two and eight-tenths hours. The reaction temperature was 3–18°. After stirring an additional hour, the catalyst was decomposed with dilute acid and the mixture was filtered. Distillation and crystallization separated four cyclohexylbenzenes: 58 g. of monocyclohexylbenzene, 31 g. of 1,4-dicyclohexylbenzene, 158 g. of 1,3,5-tricyclohexylbenzene and 1 g. of 1,2,3,5-tetracyclohexylbenzene.

The constants of monocyclohexylbenzene are: b. p. 238.6–238.8° (756 mm.); m. p. 6.6–7.0°; d^{20}_{4} 0.944; n^{20}_{D} 1.5254.

(7) Tetraphenylmethane also dealkylates during hydrogenation; Ipatieff, "Catalytic Reactions at High Pressures and Temperatures," The Macmillan Co., New York, 1936, p. 239.

Anal. Calcd. for $C_{12}H_{16}$: C, 89.9; H, 10.1; mol. wt., 160. Found: C, 90.2; H, 9.9; mol. wt., 158.

1,4-Dicyclohexylbenzene (m. p. 102–103°) was found in the mother liquor from the crystallization of the tri derivative.

Anal. Calcd. for $C_{18}H_{26}$: C, 89.2; H, 10.8; mol. wt., 242. Found: C, 89.1; H, 10.8; mol. wt., 241.

Six cc. of oil was obtained which also had the carbon-hydrogen ratio of dicyclohexylbenzene. Its constants were: b. p. 335–340° (756 mm.); d^{20}_4 0.966; n^{20}_D 1.5357; C, 88.8; H, 10.9; mol. wt., 242. Dehydrogenation with bromine gave some 1,4-diphenylbenzene, showing that the original liquid contained 1,4-dicyclohexylbenzene.

1,3,5-Tricyclohexylbenzene melts at 68.5–69° after crystallizing from acetone. The air-dried material melts low, but after warming in a vacuum the melting point is sharp. It is very soluble in benzene, cyclohexane, carbon tetrachloride, and chloroform; less soluble in acetone, dioxane, and the lower alcohols.

Anal. Calcd. for $C_{24}H_{36}$: C, 88.8; H, 11.2; mol. wt., 324. Found: C, 88.5; H, 11.2; mol. wt., 350.

1,2,3,5-Tetracyclohexylbenzene melts at 264–265° after crystallizing from benzene. It is soluble in benzene, cyclohexane, carbon tetrachloride and chloroform; less soluble in acetic acid, acetone, ether and the lower alcohols.

Anal. Calcd. for $C_{30}H_{46}$: C, 88.6; H, 11.4; mol. wt., 406. Found: C, 88.3; H, 11.4; mol. wt., 414.

A fair yield of tetra derivative was obtained by increasing the ratio of cyclohexene to benzene, and using cyclohexane as solvent. In the absence of solvent, the mixture became too thick for effective stirring. To a mixture of 156 g. (2 moles) of benzene, 60 g. of aluminum chloride and 150 g. of cyclohexane was added 328 g. (4 moles) of cyclohexene. The time of addition was three and one-half hours. The reaction temperature was 3–20°. The products were: 20 g. of monocyclohexylbenzene, 35 g. of 1,4-dicyclohexylbenzene, 150 g. of 1,3,5-tricyclohexylbenzene and 80 g. of 1,2,3,5-tetracyclohexylbenzene.

Benzene, Cyclohexene and Sulfuric Acid.—Monocyclohexylbenzene was obtained as main product when 164 g. (2 moles) of cyclohexene was added to a stirred, ice-cooled mixture of 408 g. (6 moles) of benzene and 92 g. of 96% sulfuric acid. The time of addition was two hours. The hydrocarbon layer was washed with two 50-cc. portions of cold 96% sulfuric acid,[8] followed by water, 3% caustic, and water. The dried hydrocarbon was twice distilled through a short column. The yield of monocyclohexylbenzene was 200 g. (b. p. 239–245° at 760 mm.). The hydrocarbon fractions boiling at 78–83°, 83–235°, 235–239°, 245–265°, 265–300° and above 300° weighed 320, 2, 2, 11, 4 and 63 g., respectively.

The filtrate from the semi-solid bottoms was freed from unsaturates by shaking with cold 96% sulfuric acid, followed by distillation. The distillate did not solidify at −77°. Its constants were similar to those of the liquid mixture of isomeric dicyclohexylbenzenes obtained with aluminum chloride as catalyst (b. p. 332–335° at 742 mm.; d^{20}_4 0.969; n^{20}_D 1.5366; C, 88.8; H, 10.9; mol. wt., 253).

A satisfactory yield of 1,4-dicyclohexylbenzene could not be obtained by increasing the cyclohexene–benzene ratio.

A reaction mixture of 164 g. (2 moles) of cyclohexene, 156 g. (2 moles) of benzene, and 92 g. of sulfuric acid gave mono derivative as main product, 143 g. Fifty-one grams of crude solid was filtered from the bottoms (90 g.). Crystallization of the solid gave 26 g. of pure di compound and 11 g. of impure material melting at 95–99°.

Starting with 246 g. (3 moles) of cyclohexene, 156 g. (2 moles) of benzene, and 92 g. of sulfuric acid gave 95 g. of crude monocyclohexylbenzene and 170 g. of bottoms distilling above 300°. The latter deposited solid on standing. Filtration gave 94 g. of solid and 69 g. of oil. Seventy-one grams of pure 1,4-dicyclohexylbenzene was obtained by recrystallizing the crude solid.

When the cyclohexene–benzene ratio was greater than 1.5, there was excessive tar formation. An experiment was made with 328 g. (4 moles) of cyclohexene, 156 g. (2 moles) of benzene, and 92 g. of sulfuric acid. The reaction mixture was so dark that it was difficult to separate the acid layer. Troublesome emulsions were encountered when the hydrocarbon layer was washed. Seventy-five grams of monocyclohexylbenzene and 199 g. of bottoms (above 300°) were obtained. From the latter was obtained 61 g. of 1,4-dicyclohexylbenzene and 1.5 g. of 1,2,3,5-tetracyclohexylbenzene. The filtrate (110 g.) was not investigated.

Alkylation of Mono-, Di- and Tricyclohexylbenzenes.—Ninety-eight grams (1.2 moles) of cyclohexene was added during one hour to a mixture of 160 g. (1 mole) of monocyclohexylbenzene, 80 g. of cyclohexane, and 92 g. of 96% sulfuric acid. The reaction temperature was 2–14°. The following compounds were isolated: 70 g. of monocyclohexylbenzene, 23 g. of 1,4-dicyclohexylbenzene and 12 g. of 1,2,3,5-tetracyclohexylbenzene. The greater part of the tetra derivative separated from the catalyst acid on standing.

Forty-one grams (0.5 mole) of cyclohexene was added to a mixture of 58 g. (0.24 mole) of 1,4-dicyclohexylbenzene, 80 g. of cyclohexane and 20 g. of anhydrous aluminum chloride. The time of addition was one hour. The reaction temperature was 3–7°. Forty-nine grams of 1,4-dicyclohexylbenzene and 16 g. of 1,2,3,5-tetracyclohexylbenzene were isolated. When the reaction was run at 80°, the products were 35 g. of 1,4-dicyclohexylbenzene and 9 g. of 1,2,3,5-tetracyclohexylbenzene, plus 25 g. of liquid boiling from 300 to 425°.

Twelve and three-tenths grams (0.15 mole) of cyclohexene was added to a mixture of 32.4 g. (0.1 mole) of 1,3,5-tricyclohexylbenzene, 80 g. of cyclohexane, and 20 g. of aluminum chloride. The time of addition was one hour. Different reaction temperatures were tried; 11–15°, 34–37° and 80–83°. The solid products isolated from these experiments were: 19 g. of tri and 1 g. of tetra derivative; 15 g. of tri and 0.3 g. of tetra derivative; 7.7 g. of tri derivative, respectively.

Dealkylation of Di-, Tri- and Tetracyclohexylbenzenes.—1,4-Dicyclohexylbenzene (24.2 g.; 0.1 mole) was stirred for two hours at 80–83° with 195 g. (2.5 moles) of benzene and 20 g. of aluminum chloride. Eighteen grams of monocyclohexylbenzene was obtained; also 5 g. of liquid which distilled at 330–350°, and 6 g. of bottoms. Both of the

---

[8] The purpose of the sulfuric acid was to remove esters which would otherwise decompose to tar during distillation; see Ipatieff, Corson and Pines, THIS JOURNAL, **58**, 919 (1936).

latter fractions deposited crystals which melted at 168–169° after crystallizing from acetone.

1,3,5-Tricyclohexylbenzene (32.4 g., 0.1 mole) was stirred for two hours at different temperatures with 195 g. (2.5 moles) of benzene and 20 g. of aluminum chloride. Depending on the temperature, the main product was monocyclohexylbenzene or unchanged tri derivative. At 22–27° the products were 4.2 g. of mono derivative and 20.8 g. of tri derivative; at 50–55°, 23 g. of mono derivative; at 80–83°, 15 g. of mono derivative. The amount of viscous bottoms increased with the temperature. There was also a small fraction boiling at 330–350° which deposited solid on standing which melted at 168–169° and which was identical with the solid obtained from the di derivative. With anhydrous ferric chloride as catalyst, neither monocyclohexylbenzene nor the 330–350° fraction was obtained. The viscous bottoms were not investigated.

1,2,3,5-Tetracyclohexylbenzene (40.6 g., 0.1 mole) was stirred at 20–23° for two and one-half hours with 98 g. (1.25 moles) of benzene and 20 g. of aluminum chloride. Eleven grams of monocyclohexylbenzene (b. p. 235–241°; n^{20}_D 1.525) and 20 g. of 1,3,5-tricyclohexylbenzene were isolated. The identity of the mono derivative was established by dehydrogenation to diphenyl (m. p. 68–69°; mixed m. p. 69–70.5°). The tri derivative melted at 67–68° and showed no depression when melted with an equal quantity of 1,3,5-tricyclohexylbenzene. A fraction boiling at 330–350° was also obtained. This liquid deposited solid melting at 168–169°, which was identical with that obtained in the dealkylation of 1,4- and 1,3,5-tricyclohexylbenzenes.

Anal. Calcd. for $C_{18}H_{20}$: C, 91.5; H, 8.5. Found: C, 91.2; H, 8.6.

Repetition of this experiment at 80°, using 40.6 g. (0.1 mole) of tetra compound, 195 g. (2.5 moles) of benzene, and 20 g. of aluminum chloride gave 25 g. of monocyclohexylbenzene and 4 g. of material boiling at 300–350°. The latter deposited crystals of the 168–169° compound.

Proof of Structure.—Monocyclohexylbenzene was dehydrogenated to diphenyl. Forty-eight grams of bromine was added during two hours to 16 g. of monocyclohexylbenzene at 165°. The bromine was consumed quickly and hydrogen bromide was evolved. The product distilled at 253–273° (755 mm.) and the distillate solidified. The recrystallized solid melted at 68–69° (yield 14 g.). The mixed melting point with diphenyl was 69–70.5°.

Dicyclohexylbenzene was identical by mixed melting point with 1,4-dicyclohexylbenzene prepared according to the method of von Braun,[3] from cyclohexyl bromide, benzene and aluminum chloride.

Hydrogenation of dicyclohexylbenzene gave two isomeric dicyclohexylcyclohexanes. Forty-eight grams of di derivative (dissolved in 100 cc. of cyclohexane) was heated fourteen hours at 220° with 5 g. of nickel catalyst and an initial hydrogen pressure of 100 kg./sq. cm. The main product was the isomer melting at 159.5–161° (calcd.: C, 87.0; H, 13.0. Found: C, 86.9; H, 13.0). The other isomer melted at 54–56° (Found: C, 86.9; H, 13.0.)

Tricyclohexylbenzene was dehydrogenated to 1,3,5-triphenylbenzene. Thirty-six grams of bromine was added to 8 g. of tricyclohexylbenzene at 165°. Hydrogen bromide was evolved. The reaction product was distilled at 4 mm., 7 g. boiling at 230–250°. The distillate solidified. It was crystallized from absolute alcohol; m. p. 168–170°. Combustion gave low figures for carbon (calcd.: C, 94.07; H, 5.93. Found: C, 92.68, 92.74; H, 5.97, 5.98). A 50–50 mixture of 1,3,5-triphenylbenzene (m. p. 171–172°)[9] and dehydrogenation product melted at 170–171°.

Hydrogenation of the tri derivative gave tricyclohexylcyclohexane; m. p. 158–159° after crystallizing from cyclohexane–acetone. Thirty grams of tricyclohexylbenzene (dissolved in 100 cc. of cyclohexane) was heated for twenty hours at 240° with 5 g. of nickel catalyst and an initial hydrogen pressure of 120 kg./sq. cm.

Anal. Calcd. for $C_{24}H_{42}$: C, 87.2; H, 12.8. Found: C, 86.9; H, 12.9.

Tetracyclohexylbenzene was assumed to be the 1,2,3,5-derivative because of its easy dealkylation to 1,3,5-tricyclohexylbenzene.

Hydrogenation of the tetra derivative gave mainly 1,3,5-tricyclohexylcyclohexane, together with a smaller amount of 1,4-dicyclohexylcyclohexane. Fifty-one grams of tetracyclohexylbenzene (dissolved in 100 cc. of cyclohexane) was heated for twelve hours at 250° and twelve hours at 280° with 5 g. of nickel catalyst and an initial hydrogen pressure of 100 kg./sq. cm. A small amount of liquid product, obtained from the mother liquor, was not investigated.

Acknowledgment.—The authors express their thanks to Mr. Wilbur Shand for assistance in the experimental work and to Mr. Reno Moehl for carbon–hydrogen analyses.

Summary

Benzene reacts with cyclohexene to form mono-, di-, tri- and tetracyclohexylbenzenes. The nature of the product depends upon the relative amount of cyclohexene. The reaction is catalyzed by aluminum chloride and also by sulfuric acid.

Mono-, di- and tricyclohexylbenzenes react with cyclohexene to form higher derivatives.

Di-, tri- and tetracyclohexylbenzenes react with benzene, in the presence of aluminum chloride, to form lower derivatives.

Di- and tricyclohexylbenzenes are hydrogenated to di- and tricyclohexylcyclohexanes, respectively. Tetracyclohexylbenzene is dealkylated during hydrogenation, the products being di- and tricyclohexylcyclohexanes.

The Ternary Systems Barium Hydroxide and Water with Barium Chloride, Thiocyanate, Chlorate or Acetate at 25°

BY H. W. FOOTE AND F. C. HICKEY, O.P.

It has been shown by phase-rule methods that barium forms a basic chloride,[1] bromide and iodide[2]; and that it forms no basic nitrate.[3] The conditions for the formation of the so-called basic salt $BaOH{\cdot}SH{\cdot}5H_2O$ have been determined by Terres and Brückner[4] but there appears to be no reason why this compound may not be more simply considered as $BaS{\cdot}6H_2O$, a compound which has been known for many years. In fact, the work of these investigators shows that no basic barium sulfide exists over a wide range of temperature. Except for these cases, no systematic attempts have been made to determine to what extent barium forms basic salts. On account of the considerable solubility of the hydroxide, however, basic barium salts, if they form, can readily be determined by isothermal solubility diagrams. The results obtained on four systems at 25° are given in the present paper.

Materials and Methods

Barium hydroxide, chlorate and chloride were recrystallized before use, the first in a special apparatus which excluded carbon dioxide. We were fortunate in having samples of the thiocyanate and acetate of excellent purity which were used without further purification.[5]

Barium hydroxide was determined by titration with standard hydrochloric acid, using nitrazine yellow as indicator in the presence of the chloride, thiocyanate and chlorate; and phenolphthalein in the presence of the acetate. The acid was standardized by titrating barium hydroxide solutions whose concentration was determined by converting the hydroxide to the chloride, evaporating and drying to constant weight. This standard agreed closely with that obtained by determining the chloride gravimetrically as silver chloride. In the systems containing chloride, chlorate or acetate, total barium was determined by evaporating with hydrochloric acid, and weighing barium chloride. In the system containing thiocyanate, this radical was determined directly by the usual method with standard silver nitrate, using ferric alum as indicator.

Mixtures of the three components in suitable proportions were rotated in the thermostat at 25° for several days. In no case was difficulty experienced in obtaining equilibrium in two days. The temperature variation of the thermostat was not greater than ±0.03° which affects the results less than can be detected by analysis. Samples of solution for analysis were drawn off through asbestos or glass wool filters, or, when the solid settled properly, without filtering, and weighed. When barium hydroxide alone or a single barium salt was present in the residue, it was in most cases not analyzed as qualitative tests were sufficient to identify it. When an analysis was necessary, the residues were removed and dried almost completely between filter papers as rapidly as possible. This material, as it contained a small amount of residual solution, involved the use of the well-known Schreinemakers method for deriving the composition of the residues free of solution. By drying the residues almost completely only a short extrapolation of the results is necessary, which is of importance in the case of hydrated compounds for the accurate determination of the amount of water. On the other hand, the hydroxide, during exposure to the air, becomes slightly carbonated, which in the analysis, gives a somewhat low result for the hydroxide and a correspondingly high result for the salt present. The error from this source, however, is less important than the error from a long extrapolation as there is no difficulty in determining the ratio of the hydroxide to the salt with sufficient accuracy, and the chief difficulty is in determining the water of hydration. From the nature of the case, the composition of the solutions can be determined more accurately than the composition of the residues.

System: $Ba(OH_2)$–$BaCl_2$–H_2O.—This system has been investigated at 30° by Schreinemakers,[1] who found the basic salt $BaOHCl{\cdot}2H_2O$. We have determined the solubility curve at 25° to make the results comparable with the other systems, all of which have been determined at this temperature. The data for the curves where barium chloride or barium hydroxide alone were the solid phases were obtained with considerably more care and are more numerous than was perhaps necessary for the system, as the results were needed in connection with another investigation. These determinations were made in duplicate and the titration of the hydroxide was carried out with a weight buret.

The solubility results are given in Table I. Only enough wet residues were analyzed to confirm the formula of Schreinemakers,[1] $BaOHCl{\cdot}2H_2O$. All data represent percentages by weight.

The solubility data are plotted in Fig. 1 together with the composition of the three wet residues analyzed, which were in equilibrium with pure double salt. Results at univariant points were averaged. To avoid confusion, the data have been omitted along the short curve where barium chloride was the solid phase.

[5] Barium thiocyanate crystallizes at room temperatures as the compound $Ba(CNS)_2{\cdot}3H_2O$. It was originally described incorrectly as the dihydrate and this error has been retained in many references to the compound. Whether a dihydrate is formed at a higher temperature has not been determined.

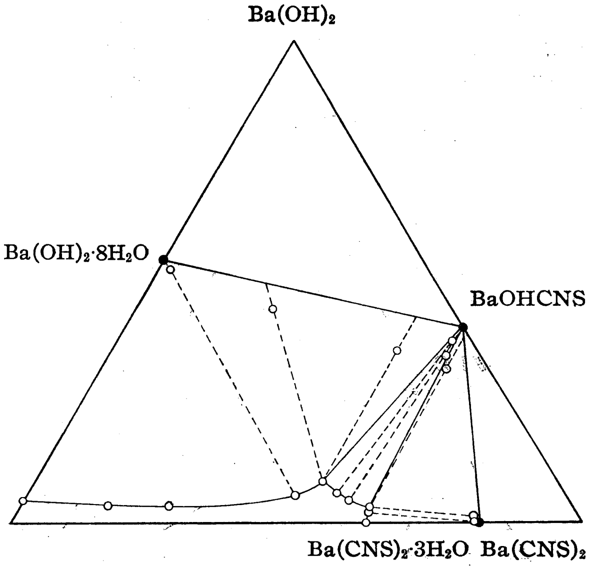

Fig. 2.—System $Ba(OH)_2$–$Ba(CNS)_2$–H_2O. Solid phases are $Ba(OH)_2·8H_2O$, $Ba(CNS)_2·3H_2O$ and BaOHCNS.

The results in Table II are plotted in Fig. 2. Tie lines connecting solutions and residues are shown as dotted lines. The solid in one of the wet residues at the univariant point where basic salt and thiocyanate are in equilibrium was nearly pure basic salt and the point representing the composition of the residue has been shifted slightly to the right for clarity.

It was difficult to obtain the basic salt in pure condition as the crystals were very small and only formed in solutions containing a large excess of thiocyanate. A sample of the salt for analysis was prepared by crystallizing a small amount at 25° from a solution of the proper concentration. This material gave on analysis

$Ba(OH)_2$, 38.53; $Ba(CNS)_2$, 59.16; H_2O (diff.), 2.31

corresponding to the molecular ratio 1:1.04:0.57. As the material could not be dried properly, the water is undoubtedly from the solution and the result confirms the formula mentioned above.

System: $Ba(OH)_2$–$Ba(ClO_3)_2$–H_2O.—This system forms no basic salt at 25° and the only solids occurring are hydrated barium hydroxide and barium chlorate, which crystallizes as the anhydrous salt. The solubility results are given in Table III. They are plotted in Fig. 3 together with the composition of the only two wet residues which it was necessary to analyze.

Table III

Summary

Isothermal solubility determinations (at 25°) have been made in the ternary systems composed of barium hydroxide and water with barium chloride, thiocyanate, chlorate or acetate. The basic salt $BaOHCl \cdot 2H_2O$, investigated by Schreinemakers at another temperature, has been found. A new basic salt BaOHCNS also has been found. No basic chlorate or acetate forms at this temperature, the solid phases being the same that crystallize in the binary systems with water alone.

Fluorochlorobromides of Silicon

BY WALTER C. SCHUMB AND HERBERT H. ANDERSON

By the use of methods previously employed successfully in the preparation of mixed halides of silicon, such as the fluorochlorides, fluorobromides, and chlorobromides, we have prepared for the first time halides of silicon containing three different halogens, namely, $SiFClBr_2$ and $SiFCl_2Br$.[1] In the course of this work new methods of preparation of the silicon chlorobromides also have been developed.

In a previous paper[2] we have described the reaction of silicon tetrabromide with antimony trifluoride, in the absence of any catalyst, by which a mixture of fluorobromides of silicon was obtained. It seemed wholly reasonable, therefore, to expect that the partial fluorination of a chlorobromide, such as $SiClBr_3$ or $SiCl_2Br_2$, should yield products containing three different halogens. The following experimental work bears out the correctness of this assumption.

A. Reactions of Antimony Trifluoride with Silicon Chlorobromides

The silicon chlorobromides needed for these experiments were prepared by the following methods, of which all but the first have not been described previously.

1. A mixture of chlorine and bromine was passed over metallic silicon at 700°, and the products were subjected to repeated distillation. In this way silicon chlorotribromide (b. p. 126–130°) and silicon dichlorodibromide (b. p. 102–106°) were obtained, together with some trichlorobromide and tetrabromide.

2. A mixture of the three chlorobromides of silicon was also prepared by refluxing silicon tetrabromide for forty-eight hours in an atmosphere of chlorine, contained in a sealed liter bulb, a microburner supplying the heat and the upper portion of the flask serving as a condensing surface. The mixture was separated by fractional distillation.

3. It was found that the reaction of antimony trichloride, mixed in the proper proportions with silicon tetrabromide, and subjected to the proper mode of distillation, may also serve as a convenient method for preparing any one of the three chlorobromides, $SiCl_3Br$, $SiCl_2Br_2$ or $SiClBr_3$, in yields of approximately 80%.[3]

4. A liquid mixture of bromine and hexachlorodisilane, Si_2Cl_6, was dropped from a separatory funnel into a horizontal Pyrex tube maintained at 500° in a gas furnace. A slow stream of pure carbon dioxide passing through the tube carried the products of the reaction to condensers, cooled by ice, and thence to a drying tube. As the mixture of liquids entered the heated tube vaporization occurred, followed immediately by reaction accompanied by flame. The free bromine left in the reaction products was removed quantitatively by shaking with mercury. From an original 100 g. of Si_2Cl_6 and 65 g. of bromine which was actually used in the reaction, about 40 g. was obtained of each of the three substances, silicon tetrachloride, trichlorobromide and dichlorodibromide.

In a similar manner, 90 g. of octachlorotrisilane, Si_3Cl_8, with 44 g. of bromine (1:1.1 mol.) gave as final, colorless products:

	B. p., °C.	Grams
$SiCl_4$	57	20
$SiCl_3Br$	80	30
$SiCl_2Br_2$	105	18
$SiClBr_3$	128	8
Si_2Cl_6	147	6

A small, higher boiling residue was also obtained

During a period of one hour 230 g. of sublimed antimony trifluoride was added gradually with rapid stirring to 900 g. of silicon chlorotribromide, $SiClBr_3$, contained in a three-necked flask, which was provided with a mercury-sealed stirrer and connected to a series of condensing traps provided with circular coils. Distillation of the product formed in the first condenser, maintained at 0°, yielded about 75 g. of silicon fluorochlorodibromide, $SiFClBr_2$, b. p. 59.5°; and from the second condenser, maintained at −65°, about 20 cc. of a liquid was obtained which contained no bromine and proved to be a mixture of the fluorochlorides, SiF_2Cl_2 and SiF_3Cl, in molar proportions approximately 2:1.

The fact that a dichloro compound is formed from a monochloro compound in this process may be explained when it is realized that antimony trichloride, formed in the interaction of SbF_3 and $SiClBr_3$, is capable of bringing about replacement of bromine atoms by chlorine in such compounds as silicon tetrabromide, as stated above. Consequently, in the reaction of antimony trifluoride with silicon chlorotribromide the formation of a dichloro compound is to be interpreted as due to side reactions in which both antimony trifluoride and antimony trichloride are involved in interaction with $SiClBr_3$.

In a similar manner, 130 g. of antimony trifluoride was added to 400 g. of silicon dichlorodibromide, $SiCl_2Br_2$, over a period of eighty minutes, the condensers being cooled with ice and with a mixture of carbon dioxide and alcohol, respectively. The contents of the first receiver

---

(1) The third possible compound containing the same elements, SiF_2ClBr, has not as yet been isolated, although several methods for its preparation have been tried.

(2) Schumb and Anderson, THIS JOURNAL, **58**, 994 (1936).

(3) From a mixture of equal weights of $SiBr_4$ and PCl_5 heated for one hour, a mixture of $SiClBr_3$ and $SiCl_2Br_2$ was also obtained.

consisted of 40 g. of a liquid boiling at about 39°. Repeated distillation of this mixture finally yielded 10 g. of pure $SiFCl_2Br$, b. p. 35.1 ± 0.2° at 752 mm. (corr.). The analyses of the new compounds, as well as determinations of their molecular weights and vapor pressures, are given below (section D).

B. Chlorination of Silicon Fluorobromides

Silicon fluorotribromide and chlorine were mixed in a liter globe in the molar ratio $4SiFBr_3:3Cl_2$, the initial pressure of chlorine being two atmospheres. Although reaction began upon standing at room temperature, the globe was gently heated at the bottom with a very small flame for two hours; at the end of this period the reaction was complete. Mercury was then introduced into the cooled globe and the free bromine quantitatively removed thereby. Distillation of the product yielded a mixture of nearly equal weights of $SiFClBr_2$ and $SiFCl_2Br$, together with some $SiFCl_3$, and a residue containing a small quantity of unchanged $SiFBr_3$. The chief reaction may be represented as

$$4SiFBr_3 + 3Cl_2 \longrightarrow 2SiFClBr_2 + 2SiFCl_2Br + 3Br_2$$

The reaction between gaseous silicon difluorodibromide and chlorine proceeded very slowly at temperatures below 400°. Radiation with a 500-watt lamp for several hours did not noticeably increase the rate of reaction. When a mixture of SiF_2Br_2 and chlorine in the molar ratio of 3:2 was passed repeatedly through a 20-mm. Pyrex tube, 80 cm. long, placed in a furnace at 500°, the reaction was sufficiently rapid for study. Bromine was liberated copiously, and its removal from the products was effected by shaking with an excess of mercury. The resulting gas mixture, after being transferred to the usual fractionating system, gave a fraction which proved to be substantially pure silicon difluorodichloride (v. p. 59 mm. at −78°) and a small residue consisting mainly of silicon difluorodibromide. Hence the original reaction taking place proceeded essentially as follows

$$SiF_2Br_2 + Cl_2 = SiF_2Cl_2 + Br_2$$

and no fluorochlorobromides were formed in this case.

C. Reaction of Antimony Trichloride with $SiFBr_3$

In view of the fact, referred to in section A, that antimony trichloride brings about the replacement of bromine by chlorine in silicon tetrabromide, it was felt that interaction of antimony trichloride and $SiFBr_3$ might yield fluorochlorobromides. In one experiment 50 g. of the fluorotribromide was added to 30 g. of anhydrous antimony trichloride in a 50-cc. flask, provided with a 15-cm. fractionating column (8 mm. o. d.) containing within it a glass rod and aluminum spiral. The mixture was heated cautiously with a microburner and a distillate passed over at 58–64°, the products consisting of $SiFCl_2Br$, $SiFClBr_2$ and unchanged $SiFBr_3$, in the approximate ratio of 2:1:1. The fluorochlorodibromide was purified by distillation, and its boiling point was determined as 59.5 ± 0.2° at 760 mm. It was quite free from silicon tetrachloride (b. p. 56.8°).

In another experiment a water-jacketed fractionating column (45 cm. long and 6 mm. o. d., without spiral) was used, the temperature of the jacket being kept at 35°. In this experiment a mixture of 50 g. of $SiFBr_3$ and 43 g. of $SbCl_3$ was warmed very cautiously in the 50-cc. flask for one hour, the antimony trichloride remaining solid. The original distillate, weighing 32 g., in this case passed over between 34–38°, and consisted of $SiFCl_2Br$, $SiFCl_3$ and $SiFClBr_2$ in the approximate ratio 8:3:1.

D. Analysis and Properties of Silicon Fluorochlorobromides

In the analysis of the two fluorochlorobromides the sample, contained in a small weighed bulb, supplied with a cap consisting of a 20 mm. ground joint and stopcock, was hydrolyzed by ice-cold water, which was caused to enter the bulb by opening the stopcock under the water, the bulb being cooled. The products of hydrolysis are silicic, hydrochloric, hydrobromic and hydrofluoric acids. If the temperature is low and the concentration of hydrofluoric acid is small, very little fluosilicic acid is formed.

The analysis itself consisted of weighing the silica; of liberating bromine by means of cold 10% potassium permanganate solution and nitric acid, and after extraction of the bromine with carbon tetrachloride, determining it iodimetrically; and of determining the chlorine in solution as silver chloride after treatment with nitrous acid. Direct determination of fluorine was made in the case of $SiFClBr_2$, by hydrolyzing the sample, and after the filtration of the silica, which was washed with hot water, the filtrate was made alkaline and heated to 90° to convert any fluosilicate into fluoride. The filtered solution was acidified with acetic acid in the correct excess, and an excess of a solution of calcium chloride was added. After standing for two weeks, the precipitated calcium fluoride was filtered, washed, ignited and weighed. A summary of the analytical results is given in Table I.

The molecular weights, determined by the gas density method, as described in our previous paper (1), are also shown in the table.

TABLE I

ANALYTICAL RESULTS AND MOLECULAR WEIGHTS

Substance	Si, %	F, %	Cl, %	Br, %	Mol. wt.
$SiFClBr_2$	11.87	..	14.78	66.13	246.8
	10.97	7.78	14.57	65.81	245.8
Calcd.	11.58	7.84	14.63	65.94	242.3
$SiFCl_2Br$	13.64	..	...	...	...
	14.11	..	35.41	40.02	202.8
	...	..	36.02	40.15	202.0
Calcd.	14.18	9.60	35.84	40.38	197.9

The fluorochlorobromides of silicon are colorless, mobile liquids, which hydrolyze instantly when their vapors are allowed to come into contact with moist air, resembling the other known fluorohalides of this element in this and other respects. They do not attack pure mercury at room temperature.[4]

The vapor pressure of silicon fluorodichlorobromide was measured by the static method, that of the fluorochlorodibromide was measured both by the static and by a dynamic method, previously described.[1] The plotting of log P against $1/T$ gave very satisfactory straight lines, and the pressure data are summarized in the following table.

---

(4) A stopcock lubricant consisting of 95% white vaseline and 5% paraffin was found to be very satisfactory in resisting attack by these substances.

TABLE II

VAPOR PRESSURE DATA

Substance	B. p., °C.	Log P	ΔH, cal.	Trouton's constant
$SiFClBr_2$	59.5	$7.5669 - (1558/T)$	7,095	21.38
$SiFCl_2Br$	35.4	$7.0982 - (1301/T)$	5,954	19.30

The melting points were determined by the method described by Skau,[5] the specimens being sealed in wafer-thin ampoules provided with thermocouple wells in which a copper–constantan thermocouple was inserted. Heating and cooling curves were then taken potentiometrically in the Skau apparatus. The melting points so determined are −112.3 ± 0.2° and −99.3 ± 0.2° for $SiFCl_2Br$ and $SiFClBr_2$, respectively.

Summary

1. Two fluorochlorobromides of silicon have been prepared for the first time, silicon fluorochlorodibromide, $SiFClBr_2$, and silicon fluorodichlorobromide, $SiFCl_2Br$. These substances are the first halides of silicon to be reported in which silicon is linked to three different halogen atoms.

2. The new compounds were prepared by three methods: the fluorination of silicon chlorobromides, the chlorination of silicon fluorotribromide, and the reaction of antimony trichloride with silicon fluorotribromide. The formulas of the compounds were established by analysis and molecular weight determinations.

3. $SiFClBr_2$ is a colorless, mobile liquid of b. p. 59.5°, m. p. −99.3°. Its vapor pressure is represented by the equation, $\log P = 7.5669 - (1558/T)$. $SiFCl_2Br$, also a colorless, mobile liquid, boils at 35.4°, and melts at −112.3°. Its vapor pressure is given by the equation, $\log P = 7.0982 - (1301/T)$.

4. Both liquids hydrolyze completely in moist air. In ice-cold water the hydrolysis products are silicic, hydrochloric, hydrobromic and hydrofluoric acids, with practically no fluosilicic acid.

5. Incidental to the main objective of the work, several new methods of preparing the three chlorobromides of silicon were developed, including the reaction of antimony trichloride or phosphorus trichloride with silicon tetrabromide; the refluxing of silicon tetrabromide for forty-eight hours in a sealed container in an atmosphere of chlorine; and the reaction of hexachlorodisilane with bromine.

[CONTRIBUTION FROM THE COMMITTEE ON DETERMINATION OF GEOLOGIC TIME, DIVISION OF GEOLOGY AND GEOGRAPHY, NATIONAL RESEARCH COUNCIL]

Atomic Weight of Lead from Galena, Great Bear Lake, N. W. T., Canada

BY JOHN PUTNAM MARBLE[1]

The fundamental assumption on which we base the "lead-ratio" method for measuring geologic time is that a given mineral has neither lost nor gained lead, uranium, or thorium since its first crystallization. As the writer recently pointed out,[2] further evidence on this point, either general or specific, is greatly desired in determining the age of the pitchblende at Great Bear Lake, Canada.

One of the mineral systems at this locality is a replacement band of sulfides in the country rock, which is cut by the pitchblende veins. Mr. Hugh S. Spence of the Mines Branch, Canada Department of Mines kindly furnished a generous sample of this material, with the following description:[3]

"Fine-grained galena from chalcopyrite-galena band in the country rock, cut by the No. 2 Vein at LaBine Point, Great Bear Lake, N. W. T., in the No. 2 pit on the easterly (siliceous) portion of the vein. The pieces were taken from the band approximately at the contact with the vein, and the galena carries some fine native silver, presumably introduced from the vein."

The question at once arises: "Is the lead in this ore 'common' lead, 'uranium' lead, or a mixture of the two?" If the first, it offers a source for the "common" lead found in the pitchblende;[4] if the second or third, it indicates that more or less lead may have been leached from the pitchblende, which would make it valueless as an "age-index" mineral.

Preliminary work showed that if the sample contained uranium or thorium, the amounts were too

				Average	1.28902	207.205

Total $PbCl_2$ = 4.49830. Total Ag = 3.48971. $PbCl_2/2Ag$ = 1.289018.
Atomic Weight Pb = 207.205.

small to detect by careful qualitative tests on a fair-sized sample, and a radiograph produced no trace of darkening on a photographic plate in forty-eight hours. A quantitative determination by the sulfate method showed 15.53% lead, and since over 100 g. was available, the lead was extracted, purified, and its atomic weight determined to see if an answer to the above question could be obtained.

The greater part of the sample was broken up on a clean hardened steel anvil, coarsely ground with a hardened steel muller, and finely powdered in a clean agate mortar. The powder in separate portions was decomposed with aqua regia, and the lead precipitated as sulfate, which was then extracted with hot ammonium acetate solution. A very small residue was decomposed by hydrofluoric acid, and a trace of lead recovered in the same way. The lead was then precipitated as sulfide, which was dissolved in hydrochloric acid, and again precipitated as sulfate. After several repetitions of this cycle, the lead was precipitated as sulfide from acid solution, again dissolved in hydrochloric acid, converted to nitrate, repeatedly crystallized as nitrate with centrifugal draining, converted to chloride, repeatedly crystallized as chloride, distilled in pure dry hydrogen chloride, and finally fused in pure dry hydrogen chloride, cooled in pure dry nitrogen and bottled in pure dry air in a Richards bottling apparatus. The water, acids and ammonia used were redistilled according to the customary Harvard technique, and hydrogen sulfide was obtained from cylinders of the purest commercial gas. Except for the sulfide precipitations, all operations were carried out in quartz or platinum.

The weighed sample was dissolved in warm water containing 1 or 2 drops of dilute nitric acid, and the chloride precipitated with purest silver in the dark room. The final concentration of lead and silver was about 0.03 *N*. The end-point was adjusted by equal opalescence nephelometry in the usual way. Weighings were made in duplicate by substitution on a sensitive balance at virtually constant temperature, using weights standardized by the Richards method. Vacuum corrections of +0.000058 g. per gram for lead chloride and −0.000031 g. per gram for silver were applied. The silver used had been found adequately pure in other atomic weight investigations.

The weight of lead chloride in Analysis III, made on the same portion as Analysis II, was incorrectly recorded due to an accident, and this analysis is omitted from the calculations. As a large part of the first lot worked up was lost by accident, Analyses II and IV were made on further portions of the sample. The method of purification was essentially the same for each.

The results of this work are in agreement with the most recent values for the atomic weight of "common" lead, by the chloride–silver ratio,[5] and indicate that the lead from this sulfide replacement band contains virtually no "uranium" lead. The possibility that we have a balancing of "uranium" and "thorium" leads to give the observed value is most improbable, as there is neither uranium nor thorium present in the ore, and the pitchblende at Great Bear Lake is essentially thorium-free. From this we may perhaps draw the following conclusions.

1. At Great Bear Lake there are at least two separate sources of mineralizing solutions, which have had little effect on each other, either during or after the first periods of deposition.
2. The pitchblende has not lost appreciable quantities of lead by leaching, as "uranium" lead has not travelled into the galena.
3. The small amount of "common" lead in the pitchblende may perhaps have come from the nearby galena, which might thus be older than the pitchblende.

General Conclusions

This work may be considered from another point of view as adding one more to the list of determinations of the atomic weight of "common" lead, in which the geologic provenance and horizon of the material is known, as shown in Table II.[6] This table lists only those determinations made on material of known provenance, using the ratio $PbCl_2/2Ag$, so as to provide a standard of comparison. In all cases the methods used for the purification of the lead chloride and the determination of the ratio have been described in sufficient detail to allow an evaluation of the precision

of the work. The total variation, 2 parts in 20,000, is close to the limit of error of careful nephelometric titration, especially when small samples of lead chloride have been taken. No evidence is present of any variation of the atomic weight of "common" lead as a function of geologic age. It seems worth while making this point, as Vernadsky[7] has recently brought up the question as to the constancy of atomic weight of various elements once more.

One further point may perhaps be made, but with extreme caution. The constancy of the atomic weight of "common" lead indicates that it probably cannot have been formed by processes of radioactive decomposition in the crust of the earth, with the generated lead removed and concentrated away from its parents by processes of solution and subsequent precipitation or crystallization. Since uranium and thorium have different half-lives, lead formed by radioactive decomposition at different times would have a varying isotopic composition and hence a varying atomic weight. If such a process is responsible for the formation of "common" lead, it must have taken place during "pretelluric" time, when the earth had no solid crust containing radioactive elements disintegrating as such in place. There seems to be little unequivocal cosmic evidence for such a process, as distinct from the processes by which other elements came into being. This leads to the conclusion that "common" lead owes its existence as such to the ordinary cosmic processes, whatever they may be, while leaving still unexplained the reason for the chemical identity of this element with the stable end-products of radioactive disintegration.

Acknowledgments.—Especial thanks are due to the Director of the U. S. Geological Survey, and to Professor Gregory P. Baxter of Harvard University, for permitting the use of their laboratories for this investigation. Dr. R. C. Wells of the Survey coöperated in the preliminary investigations, and Dr. J. H. Faull, Jr. and Mr. F. D. Tuemmler at Harvard aided in the purification of reagents and the setting up of apparatus. Professor Alfred C. Lane, Chairman of the Committee on the Measurement of Geologic Time, has provided constant inspiration.

Summary

1. The atomic weight of lead from galena at Great Bear Lake is 207.21.

2. The "common" lead contaminating the "uranium" lead of the pitchblende may have come from this source.

3. Presumably the pitchblende has not lost appreciable quantities of lead by leaching.

4. Further evidence is presented as to the constancy of the atomic weight of "common" lead as a function of its geologic age.

The Reaction between Hydrogen and Oxygen above the Upper Explosion Limit[1]

BY GUENTHER VON ELBE[2] AND BERNARD LEWIS[3]

The application of the isothermal chain-branching theory to the explosion limits of hydrogen and oxygen makes it necessary to ascribe to the reaction above the upper limit a different mechanism than that which governs the limits themselves.[4] Moreover, since the theory demands that the chain-breaking reactions be of the same order, with respect to the chain carriers, as the chain-branching reactions, and since plausible branching reactions are all of the first order with respect to the carriers, the most plausible reaction for breaking chains in the gas phase becomes

$$H + O_2 + M = HO_2 + M \tag{1}$$

M being any third molecule. This demands that the reaction between HO_2 and H_2 to form another chain carrier shall be a rare event in comparison with such reactions of HO_2 from which no chain carrier emerges.

It may now be assumed that in the low-pressure region where the limits occur, HO_2 is removed efficiently by diffusion to the wall but that at higher pressures there is an increasing probability for either or both of the chain continuing reactions

$$HO_2 + H_2 = H_2O_2 + H \tag{2}$$
$$HO_2 + H_2 = H_2O + OH \tag{3}$$

This conception makes it unnecessary to resort to the hypothesis of energy chains, the difficulties of which have been amply dealt with elsewhere.[5]

The necessity to introduce reaction (1) as a chain-breaking mechanism was originally demonstrated in a study of the inhibition of the photochemical reaction of hydrogen and chlorine by oxygen,[6] although it is to be remembered that the temperature in these experiments was low. More recently it has been shown that the formation of HO_2 in a ternary collision adequately accounts for the photochemical oxidation of HI[7] and that the earlier concept of a long-lived excited HO_2 molecule formed in a binary collision[8] should be abandoned. This latter fact uniquely determines from the "catalog" of possible reactions[4] the chain mechanism responsible for the explosion limits. The reactions are

$$H + O_2 = OH + O \tag{4}$$
$$O + H_2 = OH + H \tag{5}$$
$$OH + H_2 = H_2O + H \tag{6}$$

to which must be added the ternary reactions

$$H + O_2 + H_2 = H_2O_2 + H \tag{7}$$

and

$$H + O_2 + H_2 = HO_2 + H_2 \tag{1a}$$

which are contained in the "catalog" in their kinetic equivalents. Therefore, H_2 is able either to react or to stabilize the HO_2 molecule. The selection of reaction (7) instead of the alternative $H + O_2 + H_2 = H_2O + OH$ must be made on the basis of the results of the mercury-sensitized hydrogen–oxygen reaction.[9] Reaction (7) also harmonizes the results of the photochemical hydrogen–chlorine–oxygen reaction.[10] As far as can be seen, there is no contradictory evidence in the literature to any of the proposed reactions.[11]

(9) J. R. Bates, *J. Chem. Phys.*, **1**, 457 (1933). This author's successful description of the mercury-sensitized reaction by assuming the consecutive steps

$$H + O_2 = HO_2$$
$$HO_2 + H_2 = H_2O_2 + H$$
$$HO_2 + HO_2 = H_2O_2 + O_2$$

may be duplicated by substituting the above ternary collision reactions (1a) and (7) for the first two steps.

(10) M. Bodenstein and P. W. Schenck's[6] mechanism requires that as a consequence of a successful collision between $H + O_2 + H_2$ two chains must be broken and two molecules of H_2O must be formed. For this reason they originally objected to the reaction products being $H_2O_2 + H$ as in Bates' scheme[9] since the H is capable of continuing the chain, and adopted instead the products $H_2O + OH$. Later, however, they postulate (p. 439) that for every H_2O_2 molecule formed, two chains are broken and two molecules of H_2O are formed by a series of reactions involving two chlorine atoms and two HCl molecules. Indeed, they prove that H_2O_2 readily reacts with chlorine atoms (p. 440). Thus their claim to be able to distinguish between the two mechanisms ($H_2O_2 + H$ or $H_2O + OH$) and their objection to Bates' scheme may be considered withdrawn.

(11) Reaction (4) has an energy of activation of at least 13 kcal., since it is endothermic to this extent. Reaction (5) also possesses a considerable energy of activation [Harteck and Kopsch, *Z. physik. Chem.*, **12B**, 327 (1931)]. Experiments of Kistiakowsky [THIS

The description of the explosion limits follows the treatment of Kassel and Storch.[4] For a given temperature the upper limit is reached when

$$2k_4 = k_1(\mathrm{M})\,^{12} \tag{8}$$

Frost and Alyea's[13] lower limit equation determined in a potassium chloride-coated vessel is obtained and Hinshelwood and Moelwyn-Hughes,[14] lower limit equation determined in a silica vessel can be approximated if it is assumed that on a silica surface H, O and OH are destroyed at the same rate, whereas on a potassium chloride surface H is destroyed[15] preferentially.

For the reaction rate above the upper explosion limit it is necessary to introduce the chain-initiating reaction. A decision must first be made whether chains are initiated at the surface or in the volume of the vessel. It has been demonstrated[16] that up to 540° at pressures below the upper explosion limit (20 to 100 mm.) two streams of hydrogen and oxygen may be crossed at some distance from the nozzles without inflaming, and that inflammation will occur if a silica rod is inserted at the junction of the streams; an aluminum rod was ineffective. These experiments were not extended to temperatures at which the gas would inflame in the absence of a surface. It has been demonstrated,[17] however, that streams of hydrogen and oxygen will inflame without the aid of a surface when crossed at atmospheric pressure and 560°. Of the different initial conditions in these two sets of experiments, namely, temperature and pressure, the former must be assigned a greater role. Thus, it appears that between 540 and 560° chain initiation becomes appreciable in the gas phase.

The reaction rate above the upper explosion limit has been studied largely with quiescent gas mixtures in vessels of silica and porcelain. If it is tentatively assumed that in the usual sized vessels volume initiation becomes predominant over surface initiation from 540 to 560° upward, then the observations made in such vessels on the effect on inert gases, the influence of diameter, the order of reaction, and the absence of any effect of poisoning the surface may be explained. There are, however, other experimental facts not easily explained on the basis of this assumption. These will be discussed more advantageously after the silica and porcelain vessel experiments have been treated in the light of the above hypothesis.

Chain Initiation in the Gas Phase

For reasons given below only the spontaneous formation of hydrogen atoms need be considered as a chain-initiating reaction. Their rate of formation per unit volume is denoted by I_{H}. Chains are broken by diffusion of HO_2 to, and their destruction at, the wall.

$$\mathrm{HO_2} \xrightarrow{\text{surface}} \text{destruction} \tag{9}$$

For the kinetic treatment the same formal result will be obtained by the use of either reaction (2) or (3), provided hydrogen peroxide decomposes to form water. It is thus sufficient to consider only one of them, say reaction (3).

From reactions (1), (3), (4), (5), (6) and (9) the expression for the reaction rate above the upper explosion limit is easily shown to be

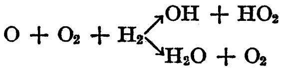
$$\frac{\mathrm{d(H_2O)}}{\mathrm{d}t} =$$

$$I_{\mathrm{H}}\,\frac{2k_3(\mathrm{H_2})(\mathrm{M})d^2 + \dfrac{2k_4}{k_1(\mathrm{M})}\,(k_3(\mathrm{H_2})(\mathrm{M})d^2 + k_9)}{k_9\left(1 - \dfrac{2k_4}{k_1(\mathrm{M})}\right) - \dfrac{2k_4}{k_1}\,k_3(\mathrm{H_2})d^2} \tag{10}$$

k_1, k_3, etc., being the velocity coefficients of reactions (1), (3), etc., and *d* the diameter of the vessel. It is assumed here that the gas is quiescent and that the rate of diffusion is inversely proportional to the total pressure and inversely as the square of the vessel diameter, an assumption that is ideally true only if the chain carriers are not reflected from the walls,[4] but which holds with suffi-

---

JOURNAL, **52**, 1868 (1930)] and Smith and Kistiakowsky [*ibid.*, **57**, 835 (1935)] with photochemically generated oxygen atoms in hydrogen–oxygen mixtures at room temperatures and pressures of the order of one atmosphere can be interpreted according to these authors, by



$$\mathrm{O + O_2 + H_2} \begin{cases} \nearrow \mathrm{OH + HO_2} \\ \searrow \mathrm{H_2O + O_2} \end{cases}$$

the competing reaction (5) being too slow under these conditions. These facts, however, do not make it improbable that reactions (4) and (5) should become sufficiently fast at the high temperatures in question in the present paper. For the same reason, it may be proposed that reaction (6) is so fast here that the recombination $OH + OH + M = H_2O_2 + M$ is slow in comparison. (For the requirement of a third body in the recombination of two OH, see Oldenberg, *J. Chem. Phys.*, **3**, 266 (1935).) The inclusion of reaction (6) in Smith and Kistiakowsky's reaction scheme appears to furnish a suitable representation of the water yields obtained by these authors. These yields increase with lower total pressure, but not at the expense of either the ozone or hydrogen peroxide yields. Reaction (6) predicts this effect, short chains being formed, whose length increases toward lower pressures because of the decreased probability of the OH recombination reaction.

[12] This follows from Kassel and Storch's equation 19 if the constants k_1, k_{12} and k_{13} equal zero.

[16] H. N. Alyea and F. Haber, *Z. physik. Chem.*, **B10**, 193 (1930).

[17] F. Goldman, *ibid.*, **B5**, 316 (1929).

cient accuracy provided $\lambda/\epsilon r$ is small compared with 1.[18] λ is the mean free path, r the radius of the vessel, and ϵ the fraction of collisions of chain carriers with the wall that lead to destruction.

From equation (10) the condition for explosion is given by

$$k_9\left(1 - \frac{2k_4}{k_1(\mathrm{M})}\right) - \frac{2k_4}{k_1}\,k_3(\mathrm{H_2})d^2 = 0 \qquad (11)$$

which may be written in the form

$$k_1(\mathrm{M}) = 2k_4\left(1 + \frac{k_3(\mathrm{H_2})}{k_9/(\mathrm{M})d^2}\right) \qquad (12)$$

This agrees with the relationship (8) for the upper explosion limit if $k_9/(\mathrm{M})d^2 \gg k_3(\mathrm{H_2})$; that is, if at the upper limit the assumption made earlier holds, namely, that reaction (3) is a rare event compared with the destruction of HO_2 at the wall.

As the pressure is raised somewhat above the upper limit, the reaction rate drops sharply to small values as equation (11) increases rapidly from zero to finite positive values. On increasing the pressure still further, $2k_4/k_1(\mathrm{M})$ becomes small compared with 1, and $(2k_4/k_1)k_3(\mathrm{H_2})d^2$ increases until eventually a third explosion limit is reached at approximately

$$k_9 = (2k_3k_4/k_1)(\mathrm{H_2})d^2 \qquad (13)$$

It is doubtful that the observed third explosion limit is governed exactly by this condition. It is more likely that explosion occurs already at some lower pressure due to the very rapid increase of the reaction rate with pressure, which destroys the isothermal condition (see also reference 5).

For the further comparison of the theoretical expression for the reaction rate above the upper limit with experiment, it is necessary to introduce specific assumptions concerning the chain-initiating reaction. Experiments show that an increase in the oxygen concentration has no more effect than the addition of an equal amount of nitrogen,[5] that is, the oxygen concentration as such does not enter into the expression for the reaction rate. There remain, therefore, as initiating reactions only the formation of hydrogen atoms by dissociation of hydrogen and the formation of hydroxyl and hydrogen atoms or of oxygen atoms by dissociation of water. In initially dry mixtures the second reaction can be appreciable only after the reaction has progressed for some time. An accelerating influence of water actually has been observed.[5] It is to be noted, however, that part of the accelerating effect of water, as that of other inert gases, is caused by the change in diffusion characteristics due to different molecular weights and diameters; that is, k_9 is decreased. It is easily shown that the radical HO_2 should diffuse through oxygen about as readily as through water. However, the accelerating influence of water has been found to be considerably in excess of that of oxygen. Thus, the possibility that part of the accelerating effect of water is due to the above initiating reaction may remain open to consideration.

Assuming that a fraction of collisions of H_2 with other molecules leads to dissociation, the rate of chain initiation is given by

$$I_\mathrm{H} = k_{14}(\mathrm{H_2})(\mathrm{M}) \qquad (14)$$

A corresponding expression would apply for the water dissociation.

Equations (10) and (14) determine the change in reaction rate with the total pressure, the partial pressure of hydrogen and the vessel diameter at constant temperature. Whereas, at the upper limit itself the order of the reaction is minus infinity, the order increases continuously with rising pressure depending on the values of $2k_4/k_1(\mathrm{M})$ and $2k_4/k_1k_3(\mathrm{H_2})d^2$, until at the third explosion limit it becomes plus infinity.

The variable order is fully supported by experiment. For example, for a stoichiometric hydrogen–oxygen mixture at 569° the upper explosion limit was found to be at about 120 mm., almost unaffected by the size or material of the vessel,[19] as demanded by equation (12). In a porcelain bulb having a capacity of 200 cc. the order of the reaction rose from 2.6 at 225 mm. to over 6 at 600 mm.[20] The third explosion limit (not determined) was at a pressure above 600 mm.[20] Similar results were found in a silica vessel at 567°.[21]

Since k_3 and k_4/k_1 increase markedly with temperature the order of the reaction changes more rapidly with pressure at higher temperatures in agreement with experiment.[20,21] At a given pressure an increase in temperature may result in an increase or a decrease in the order depending upon the relative importance of k_3 and k_4/k_1, that is, upon the location of the pressure and temperature of the mixture with respect to the upper limit.

Reaction rates have been determined in silica vessels of different sizes from 1.7 to 7.7 cm. in diameter using stoichiometric mixtures at 300

[18] G. von Elbe and Bernard Lewis, "The Steady State Rate of a Chain Reaction for the Case of Chain Destruction at Walls of Varying Efficiencies" submitted.

[19] H. W. Thompson and C. N. Hinshelwood, *Proc. Roy. Soc.* (London), **122**, 610 (1929).

[20] C. H. Gibson and C. N. Hinshelwood, *ibid.*, **119**, 591 (1928).

[21] C. N. Hinshelwood and H. W. Thompson, *ibid.*, **118**, 170 (1928).

and 600 mm. pressure at 560°.[5] The rate was found to increase approximately with the square of the diameter, a relation that may be obtained from equation (10) if $2k_4/k_1(\mathrm{M}) \ll 1$ and $\frac{2k_4}{k_1} k_3(\mathrm{H_2})d^2 \ll k_9$ and $k_3(\mathrm{H_2})(\mathrm{M})d^2 \gg \frac{k_4 k_9}{k_1(\mathrm{M})}$. These experiments are in an intermediate pressure range between the upper and third explosion limits characterized by an order of about four.[21] The fact that the proportionality of the rate with d^2 has been observed over a considerable range of pressure and vessel diameter can be considered to justify the assumption that the chain-breaking efficiency of the wall is not very small, thus allowing neglect of $\lambda/\epsilon r$ compared with 1, as has been done in deriving equation (10). It may be pointed out that for chain-breaking efficiencies less than 100%, the theory[18] predicts that the ratio, reaction rate/d^2, shall be constant only over a limited range of diameters, increasing toward small as well as large diameters. The minimum becomes more pronounced toward larger values of $\lambda/\epsilon r$, that is, lower pressures. Therefore, it is of interest to reproduce the experimental results of Williamson, Pickles and Hinshelwood,[5] in the following table.

TABLE I

REACTION RATE IN SILICA BULBS OF STOICHIOMETRIC MIXTURES OF HYDROGEN AND OXYGEN AT 560°

	d, mm.	17	32	56	77
Initial pressure 600 mm.	Rate/d^2	0.0030	0.0034	0.0030	0.0057
Initial pressure 300 mm.	Rate/d^2	.00062	.0005	.0003	.00058

Furthermore, reaction rates have been determined[20] in the intermediate pressure range by adding increasing amounts of hydrogen to a constant amount of oxygen, or *vice versa*, or by adding an inert gas like nitrogen to a mixture of hydrogen and oxygen. In order to compare these results with those derived from equation (10) it is necessary to consider, in addition to the inert gas effect expressed by the variable (M) in equation (10), the change in the diffusion characteristics of the mixtures due to differences in molecular weights and molecular diameters. An exact expression for the diffusion of $\mathrm{HO_2}$ through a mixture of hydrogen and oxygen and sometimes a third gas cannot be given. However, one may determine the diffusion coefficient of a hypothetical gas having an average molecular weight and diameter depending on the mole fraction, f, of hydrogen. The average molecular weight $\overline{m}$ of a mixture of hydrogen and oxygen may be given by $2f + 32(1 - f)$ and the average molecular diameter $\sigma_{\mathrm{av.}}$ by $f\sigma_{\mathrm{H_2}} + (1 - f\sigma_{\mathrm{O_2}})$. $\sigma_{\mathrm{HO_2}}$ may be identified with $\sigma_{\mathrm{O_2}}$. If a third inert gas is present the average molecular weight and diameter are calculated in a corresponding way. The substitution of this hypothetical gas should not be seriously in error, especially when relative rates are compared. Equation (10) reduces to

$$\frac{\mathrm{d(H_2O)}}{\mathrm{d}t} = \text{const.}\ \frac{(\mathrm{H_2})^4}{f^2} \frac{\bar{\sigma}^2}{\sqrt{\frac{1}{m_{\mathrm{HO_2}}} + \frac{1}{\overline{m}}}} \left[f\sigma^2_{\mathrm{H_2}} \sqrt{\frac{1}{m_{\mathrm{H_2}}}} + (1 - f)\sigma^2_{\mathrm{H,O_2}} \sqrt{\frac{m_{\mathrm{H_2}} + m_{\mathrm{O_2}}}{m_{\mathrm{H_2}} m_{\mathrm{O_2}}}}\right] \quad (15)$$

where $\bar{\sigma} = {}^1/_2(\sigma_{\mathrm{HO_2}} + \sigma_{\mathrm{av.}})$.

The following table contains the observed and calculated ratios of the reaction rates at the pressures indicated in the first two columns for different mixtures.

TABLE II

COMPARISON OF OBSERVED AND CALCULATED RATIOS OF REACTION RATES

Oxygen pressure = 100 mm. 569°. $\sigma_{\mathrm{O_2}} = \sigma_{\mathrm{HO_2}} = 2.93 \times 10^{-8}$ cm.; $\sigma_{\mathrm{H_2}} = 2.36 \times 10^{-8}$ cm.[22]

Increase in $\mathrm{H_2}$ pressure, mm. From	To	Ratio of reaction rates Obsd.	Calcd.
200	300	3.0	3.3
300	400	2.8	2.5

Hydrogen pressure = 300 mm. 569°.

Increase in $\mathrm{O_2}$ pressure, mm. From	To	Ratio of reaction rates Obsd.	Calcd.
100	200	2.4	2.0
200	250	1.5	1.3

Hydrogen pressure = 300 mm. Oxygen pressure = 100 mm. 569°. $\sigma_{\mathrm{N_2}} = 3.10 \times 10^{-8}$ cm.[22]

Increase in $\mathrm{N_2}$ pressure, mm. From	To	Ratio of reaction rates Obsd.	Calcd.
0	100	2.3	2.0
100	150	1.4	1.3

Hydrogen pressure = 300 mm. Oxygen pressure = 150 mm. 569°. $\sigma_{\mathrm{He}} = 1.89 \times 10^{-8}$ cm.[22]

Increase in He pressure, mm. From	To	Ratio of reaction rates Obsd.	Calcd.
0	300	2.45	2.51
300	500	1.59	1.55

Hydrogen pressure = 200 mm. Oxygen pressure = 100 mm. 559°. $\sigma_{\mathrm{A}} = 2.84 \times 10^{-8}$ cm.[22]

Increase in A pressure, mm. From	To	Ratio of reaction rates Obsd.	Calcd.
0	200	5.24	2.78
200	500	2.71	2.78
500	700	1.35	1.64

The agreement is good, on the whole, considering the uncertainties in the underlying assumptions.

---

(22) R. C. Tolman, "Statistical Mechanics," Chemical Catalog Co., New York, 1927, Appendix 3.

In the range of gas-phase chain initiation a change in the character of the surface should have little or no effect on the reaction rate under the conditions of the foregoing experiments, since $\lambda/\epsilon r \ll 1$. Whereas coating a surface with potassium chloride strongly inhibits the reaction under conditions of predominance of surface initiation (Pease[23]), such coating, according to unpublished experiments referred to by Hinshelwood and Williamson,[5] has "failed to reveal any effect on the reaction in a silica vessel under conditions corresponding to most of the experiments" described in this section of gas-phase initiation.

Chain Initiation at the Wall

A plausible assumption concerning the surface initiating reaction is that H_2O_2 formed catalytically at the wall dissociates sometimes into 2OH.[23] Thus

$$H_2 + O_2 \xrightarrow{\text{Surface}} (H_2O_2) \longrightarrow 2OH \qquad (16)$$

If I_{OH} denotes the rate of chain initiation per unit area and γ is the ratio of surface to volume of the vessel, then $\gamma\, I_{OH}$ is the rate of chain initiation per unit volume.

If $K(HO_2)$ denotes the rate per unit volume of destruction of HO_2 at the surface, then reactions (1), (3), (4), (5), (6), (9) and (16) lead to the following relation between initiation, branching and breaking of chains

$$\frac{k_1(M)}{k_1(M) - 2k_4}\gamma I_{OH} + \frac{2k_4}{k_1(M) - 2k_4}k_3(H_2)(HO_2) = K(HO_2) \qquad (17)$$

The first term in equation 17 is the equivalent of the rate of release of HO_2 from the surface.

In a spherical vessel

$$K = \frac{\epsilon r}{2\lambda}\left(\frac{\pi^2 D}{r^2} - \frac{2k_4}{k_1(M) - 2k_4}k_3(H_2)\right) \qquad (18)$$

where D is the diffusion coefficient.[24]

For π^2D/r^2 one may substitute $k_9/(M)d^2$, k_9 being the same as in equation (10). For $\epsilon r/2\lambda$ one may substitute $k\epsilon(M)d$. Therefore

$$K = k\epsilon(M)d\left(\frac{k_9}{(M)d^2} - \frac{2k_4}{k_1(M) - 2k_4}k_3(H_2)\right) \qquad (19)$$

The rate of formation of H_2O then becomes, for $\lambda/\epsilon r \ll 1$

$$\frac{d(H_2O)}{dt} = \frac{\gamma I_{OH}}{1 - \frac{2k_4}{k_1(M)}}\left[\frac{\left(1 - \frac{2k_4}{k_1(M)}\right)2k_3(H_2)d}{\epsilon k\left(k_9\left(1 - \frac{2k_4}{k_1(M)}\right) - \frac{2k_4}{k_1}k_3(H_2)d^2\right)} + 1\right] \qquad (20)$$

It is seen that the conditions for explosion remain the same as before.

According to equation (20), the reaction rate between the upper and third explosion limits again has a variable order, which increases with pressure, and for $2k_4/k_1(M) \ll 1$, that is, at pressures sufficiently above the upper limit, increases with temperature. This is in agreement with experiment.[19,20]

If the temperature is not much above 500°, the rate of the chain reaction given by equation (20) is unimportant compared with a catalytic water-forming surface reaction.[20,21] This catalytic surface reaction possibly involves the primary formation of hydrogen peroxide[23] and predominates up to much higher temperatures if the vessel is packed. It is of zero order in a Worcester porcelain vessel and of first order with respect to hydrogen in a silica vessel. In an unpacked Worcester porcelain vessel the order of the total reaction was found to be 0.6 at 506° and more than 2 at 529° at intermediate pressures[19] due to the increased part played by the chain reaction.

Over a temperature range 520 to about 560° at intermediate pressures a gradual increase in the temperature coefficient of the reaction rate was found.[20,21] This may be understood to reflect essentially the transition from surface initiation with low temperature coefficient to gas-phase initiation with high temperature coefficient, as is indicated by equations (20) and (10) for intermediate pressures.

Equation (20) indicates that the reaction rate should be independent of the diameter of the vessel at intermediate pressures. No experiments in this temperature–pressure range are available.

Further Discussion of Volume Initiation Versus Surface Initiation

Experiments on quiescent gas mixtures in a silver vessel up to 700°, that is, in a temperature

---

[23] This would account for the observation of Pease [THIS JOURNAL, **52**, 5106 (1930)] that coating of the wall with potassium chloride slows down the reaction rate very markedly. Potassium chloride destroys peroxidic substances efficiently, as is borne out by Pease's and other authors' experiments on the oxidation of hydrogen, aldehydes and hydrocarbons (see von Elbe and Lewis, *ibid.* (in print), thus preventing the release of chain carriers from the wall. However, Pease's results may also be interpreted as being due to an increase in the efficiency of destruction of HO_2 on a potassium chloride surface. Some of Pease's experiments were conducted in a temperature range in which gas phase initiation would be expected to predominate. However, his experiments were made by a flow method, and the gases were far from quiescent. This has a dual effect. In the first place, it enhances the release of chains from the surface and, second, it increases the dependence of the rate of chain breaking on the efficiency of the wall beyond that obtaining were the transport of chain carriers to the wall governed solely by diffusion.

[24] See ref. 18. ϵ is assumed to be small compared with 1.

range where volume initiation was assumed to occur, show that the chain reaction is practically suppressed.[25] Even at temperatures at which the reaction has become very fast or even explosive in a silica vessel, only a slow catalytic surface reaction occurs in a silver vessel. If the initiation is occurring in the gas phase, these facts cannot be explained by the presumably very high efficiency of chain breaking at a silver surface, because an increase in the chain-breaking efficiency from a moderate value, such as is found in silica vessels, to perfect efficiency, should have, according to the theory, no pronounced effect on the reaction rate; this is different for surface initiation (compare equations 10 and 20 and also reference 18). If one attempts to attribute the above effects to high chain-breaking efficiency of a silver surface, one must reconsider the results obtained at high temperatures in silica and porcelain vessels on the basis of surface initiation. This leads to difficulties. In the first place, it is evident that surface initiation is inconsistent with the observation that coating of a silica vessel with potassium chloride does not affect the reaction in the high-temperature range. In the second place, equation (20) does not describe the facts concerning vessel diameter and inert gases.

A possible answer to this latter objection is that OH radicals that are formed by reaction (16) and for which a silica or porcelain but not a silver surface is highly reflective, may diffuse for a considerable distance, on the average, into the gas phase before they react to form HO_2. This would be equivalent to gas-phase initiation as far as inert-gas effect is concerned, but it would demand a dependence of the rate on d instead of d^2. It would also conflict with the fact that the introduction of a silica rod into a silver vessel failed to initiate reaction even at pressures and temperatures within the explosive region below the upper limit.[25] It will be recalled that a silica rod caused ignition in crossed stream experiments under similar conditions. Thus, one is faced with several new difficulties not accounted for by high chain-breaking efficiency of a silver surface.

This leads to an alternative hypothesis, namely, that in a silver vessel chain carriers are destroyed in the gas phase by the action of silver or some compound of silver in the vapor form. The presence of silver in the gas phase need not necessarily arise from the thermal evaporation of silver at the temperature of the experiments. It is well known that atomic hydrogen, for example, on recombining in contact with metals causes sputtering of the metal. This sputtering phenomenon has been observed especially well on silver.[26] In addition to the possible sputtering effect of atoms and radicals in a hydrogen–oxygen mixture, it is entirely possible energetically for the catalytic formation of water on the surface of silver to give rise to the same phenomenon. It may also be mentioned that in an atmosphere of pure hydrogen the volatility of silver is increased somewhat.[27]

Once this hypothesis is conceded,[28] then the assumptions made earlier in this paper regarding gas phase and surface initiation remain plausible. Should it fail and if all experimental observations mentioned in this paper are correct, then the treatment of the reaction between hydrogen and oxygen would require a radically new approach.

Summary

The only mechanism for the interaction of hydrogen and oxygen consistent with photochemical experiments (mercury-sensitized reaction, photoöxidation of hydrogen iodide, inhibition by O_2 of the photochemical reaction between hydrogen and chlorine) and experiments on the lower and upper explosion limits is

$$\begin{aligned} H + O_2 + M &= HO_2 + M \\ H + O_2 + H_2 &= H_2O_2 + H \\ HO_2 + HO_2 &= H_2O_2 + O_2 \\ H + O_2 &= OH + O \\ O + H_2 &= OH + H \\ OH + H_2 &= H_2O + H \\ H, O, OH + \text{surface} &\longrightarrow \text{destruction} \end{aligned}$$

to which is to be added the chain-initiating reaction at the surface or in the gas phase.

If it is now assumed that in the thermal reaction HO_2 is normally destroyed at the surface but at high temperatures and pressures is capable of undergoing reaction with H_2 to an appreciable extent either by

$$HO_2 + H_2 = H_2O_2 + H$$

or

$$HO_2 + H_2 = H_2O + OH$$

the reaction above the upper limit can be described adequately, provided chains are initiated

predominantly in the gas phase above about 540–560°. The latter assumption makes it necessary to ascribe the suppression of the reaction in a silver vessel to gas-phase deactivation due to silver. This is discussed in some detail.

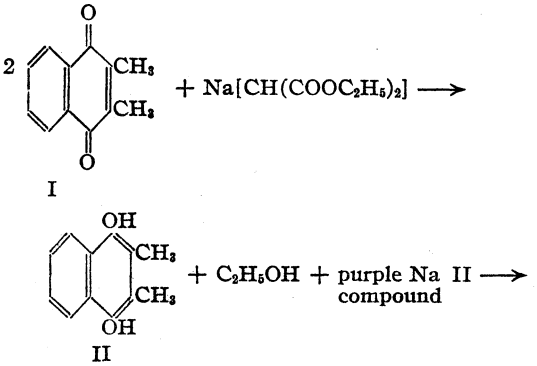
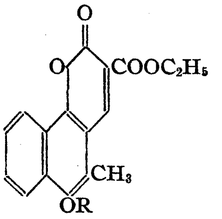
The Reaction between Quinones and Sodium Enolates. V. 2,3-Dimethylnaphthoquinone and Sodium Malonic Ester[1]

BY LEE IRVIN SMITH AND ISABELLA M. WEBSTER[2]

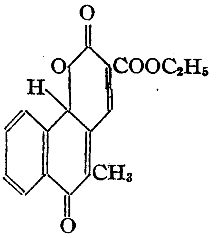
Previous papers in this series have dealt with the reaction between sodium enolates and two types of quinones: (1) duroquinone, a fully methylated para benzoquinone, and (2) trimethylquinone, a para benzoquinone with one unsubstituted position in the ring. In case 1, the reaction involved one of the methyl groups attached to the nucleus, and led ultimately to a coumarin derivative. In case 2 the reaction was most simply interpreted as involving an initial 1,4-addition of the reagent to the conjugated system which terminated in the unsubstituted position of the ring. In the latter case, the final products were benzofuran derivatives. In both cases only one molecule of reagent (sodium malonic ester) could be made to react.

In order to explore somewhat further the limits of the coumarin formation shown by duroquinone (case 1) the work described in this paper was undertaken and a benzolog of duroquinone, 2,3-dimethylnaphthoquinone (I), was selected for study. This quinone, like duroquinone, has two methyl groups attached to the quinone nucleus in positions 2 and 3, but positions 5 and 6, instead of holding methyl groups, are fused to a benzene ring. This quinone, if it were to react with sodium malonic ester in the same manner as duroquinone, should give rise to an intermediate sodium compound (II), which on hydrolysis would produce an α-naphthocoumarin derivative (III)[3] together with an equivalent amount of the hydroquinone.





III R = H
IV R = Ac



IIIa

This quinone, however, proved to be far more difficult to handle than duroquinone, and it was only after the original procedure used by Smith and Dobrovolny[4] had been modified considerably that a crystalline product could be obtained in good yield by decomposition of the sodium derivative II. In several experiments, the black quinhydrone derived from I was produced as a by-product. As this quinhydrone was apparently fairly stable in ether (the solvent used) it was necessary to allow time for the air to oxidize it back to the quinone in order to obtain the maximum yield of III from I, otherwise 3 moles of I were required to produce 1 mole of III.

The product III formed fine yellow needles melting at 212–213° with decomposition, and it had the composition and molecular weight corresponding to the formula $C_{17}H_{14}O_5$. No carbonyl derivatives could be formed using hydroxylamine or 2,4-dinitrophenylhydrazine, but the presence of one hydroxyl group was shown by the formation

---

[1] Paper IV, THIS JOURNAL, 58, 629 (1936).

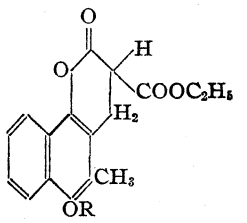
[3] These compounds are more correctly termed 7,8-benzocoumarins. However, in the literature the term α-naphthocoumarin is used to designate them; therefore this term will be used throughout this discussion.

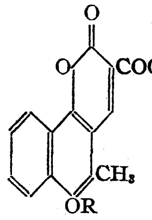
[4] Smith and Dobrovolny, THIS JOURNAL, 48, 1701 (1926).

of a pale greenish-yellow monoacetate (IV). The failure of the carbonyl reagents to react indicated that the structure was III, rather than IIIa, and the fact that the acetate IV was colored showed conclusively that it was not necessary to postulate a tautomerism between IIIa and III to explain the color of these hydroxycoumarins or the lack of it when the hydroxyl group was fixed by acetylation or methylation.[4]

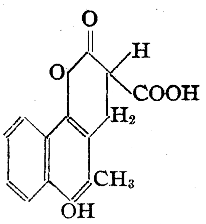
The double linkage in the pyrone ring was shown by the formation of a dihydro compound (V) when III was reduced catalytically: the dihydro compound V likewise formed a monoacetate (VI), and this same monoacetate VI was obtained when the acetate IV was reduced.



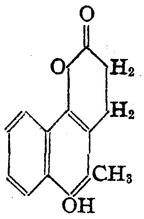
V $R = H$
VI $R = Ac$



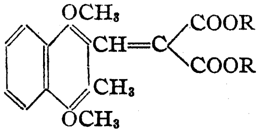
VII $R = H, R' = H$
VIII $R = Ac, R' = H$
XI $R = CH_3, R' = H$
XII $R = CH_3, R' = CH_3$



IX



X

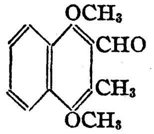


XIIa $R = CH_3$
XIIb $R = H$

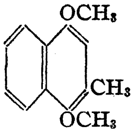
The formation of the same acetate VI regardless of whether reduction preceded or followed acetylation eliminated the possibility that the reduction had occurred at the carbonyl group of such a structure as IIIa and established the presence of a double bond in the pyrone ring of III.

The presence of the ester grouping in III was shown by the hydrolysis of III to the corresponding acid VII, which formed a monoacetyl derivative VIII. Catalytic reduction of the acid VII led to a mixture which contained at least two colorless substances. In analogy with the work of Smith and Denyes[5] this product is represented as a mixture of IX and X. These substances could not be separated by fractional crystallization, nor could IX be removed by shaking with any alkaline reagent because of the extreme ease with which the solutions were oxidized. For the same reason hydrolysis of V to IX was unsuccessful; the products in every case were yellow mixtures, and no better results were obtained when the acetate VIII was reduced. In none of these reductions, however, was there evidence of any substance which would correspond to the dimolecular products found by Smith and Denyes in the case of the coumarin from duroquinone.

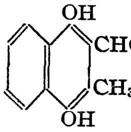
With a view to opening the coumarin ring so that the substance could be degraded further, several of the compounds in this series were methylated. It was hoped to prepare the dimethoxy compounds XIIa and XIIb, and to cleave one of these by oxidation to the aldehyde XVII which would then be synthesized. Although both methyl sulfate and methyl iodide were used, and, although the conditions were varied widely, all attempts to methylate the sodium derivative II, the ester III, the acetate IV, the acid VII or its barium salt, led only to the two methyl derivatives XI and XII, and attempts to methylate further these two products were unsuccessful. The hetero ring in this naphthocoumarin is therefore much more stable than is the case with the corresponding coumarin derived from duroquinone. The ester III reacted with diazomethane to give a *colorless* product, melting at 138–139°. From the analysis of this product, the lack of color (all of the compounds in this series except the reduced products are colored), and the reactions, it was obvious that the substance could not be either XIIa or XIIb. The substance was therefore not investigated further in connection with this work although a later research on the reaction between coumarins and aliphatic diazo compounds is planned.



XVII



XVI



XVIII

Since the coumarin ring could not be opened it was necessary to abandon further attempts at degradation, and to establish the coumarin struc-

ture by direct synthesis. It was first planned to synthesize the acid XIIb as this should melt with loss of methanol to give the monomethyl derivative XI. This synthesis was unsuccessful, for the diether XVI could not be prepared from either the hydroquinone XV or its diacetate (XIV). The hydroquinone–aldehyde XVIII was prepared from the hydroquinone (XV),[6] and this aldehyde when condensed with malonic ester led directly to the ester III; when the aldehyde was condensed with malonic acid, the product was the coumarin acid VII. The reactions of III and VII, together with the syntheses of these two products from the aldehyde XVIII, leave no doubt as to the structure of the products obtained from the reaction between 2,3-dimethylnaphthoquinone and sodium malonic ester. These products are coumarin derivatives, and the course of the reaction is entirely analogous to that of the reaction between duroquinone and sodium malonic ester. The most conspicuous differences between the two series of compounds lie in the much greater stability of the hetero ring in the naphthocoumarins and in the fact that *all* of the compounds in the naphthocoumarin series (except the reduced products) are colored.

Experimental Part[6a]

2,3-Dimethylnaphthoquinone (I).—The following directions for the preparation of this quinone were found to give consistent results and excellent yields (60–80%). To a solution of 2,3-dimethylnaphthalene (10 g.) in acetic acid (350 cc.) at room temperature was added with stirring a solution of chromic acid (25.6 g.) in dilute acetic acid (130 cc. acid, 35 cc. water). The temperature was kept between 20 and 30° throughout the addition of the chromic acid, which required about fifteen minutes. The reaction mixture, after standing at room temperature for three days, was diluted with about 1.5 liters of water and allowed to stand for several hours. The quinone was filtered and washed thoroughly with water. Crystallized from alcohol, the product melted at 126–127°. Contrary to the experience of Wieser[7] it was found that the acetic acid filtrate from the quinone contained only negligible amounts of material. Steam distillation of the quinone was found to be an unsatisfactory method of purification, for considerable amounts of tars and resins were formed and the loss was great. The best method found for purification was that of Fieser,[8] which gave a product melting sharply at 127°.

1,4 - Diacetoxy - 2,3 - dimethylnaphthalene (Ib).—The quinone I (0.3 g.) was dissolved in acetic acid (10 cc.) and zinc dust was added. To the resulting red solution was added acetic anhydride (10 cc.) and a drop of sulfuric acid and the mixture was refluxed until it became colorless (thirty minutes). The cooled solution was decanted from the zinc into excess water, and the zinc was washed with hot acetic acid which was poured into the water. The white crystals melted at 184–189°; after five recrystallizations from alcohol the product melted at 189–190°.[9]

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.55; H, 5.92. Found: C, 70.55; H, 5.99.

Quinhydrone (Ic) of 2,3-Dimethylnaphthoquinone.—The quinone I (1.86 g., m. p. 121–125°) was dissolved in acetic acid (10 cc.), zinc dust was added and the mixture was refluxed until it became colorless. Water was added, and the hydroquinone was filtered. When dissolved in methanol, the hydroquinone gave a deep purple solution from which a black solid melting at 129° was isolated. Crystallized several times from 50% acetic acid, the melting point rose to 134–138°. One preparation melted at 139–144°. The quinhydrone was very unstable, even in the solid state, yellow crystals of the quinone appearing on the surface after a day in a desiccator.

Addition of Sodium Malonic Ester to the Quinone.—To a warm solution of the quinone (4.65 g.) in absolute ether (160 cc.) was added with stirring a solution of sodium malonic ester (made from sodium (0.6 g.) dry ethyl alcohol (60–80 cc.) and malonic ester (4 g.)). The addition of the reagent required about one hour; the solution turned brown, then green. Refluxing (41–43°) and stirring were continued for five and one-half hours. After about one hour the purple color of the sodium derivative II began to appear and at the end of the reaction the green color had disappeared entirely. After standing for some time, the solvent was decanted (it contained chiefly quinone and quinhydrone) from the deep purple solid. The solid was transferred to a filter with ether, washed with a small amount of water and alcohol and a large amount of ether (300 cc.) and dried. It weighed 4.3 g. From the various filtrates and washings, about 25% of the quinone used was recovered.

5 - Methyl - 6 - hydroxy - 3 - carbethoxy - α - naphthocoumarin (III) was obtained when a suspension of the sodium derivative II (4 g.) in ethyl alcohol (50 cc.) was acidified with hydrochloric acid (10 cc.). The products were 3.05 g. of III melting at 208–211° and a dark, tarry solid which yielded about half a gram of quinone when steam distilled. The coumarin crystallized from absolute ethyl alcohol in yellow needles melting at 212–213°.

Anal. Calcd. for $C_{17}H_{14}O_5$: C, 68.43; H, 4.73; mol. wt., 298. Found: C, 68.39; H, 4.83; mol. wt. (Rast), 301, 299.

It was not necessary to isolate the sodium derivative, however, for the coumarin could be obtained by adding dilute acetic acid directly to the reaction mixture and allowing it to stand in the ice-box for some time. The product contained unchanged quinone, which was removed by boiling ether, and the residue, crystallized from absolute alcohol, melted at 211–213°. Often, especially when too much ether was used in the condensation, the quinhydrone Ic was recovered instead of the quinone.

The addition could also be carried out in dry benzene, according to the original method of Smith and Dobrovolny[4]

although the time required was long (seven days) and the yield was only about half that obtained by the procedure given above.

The coumarin III was decomposed by hydroxylamine in alkaline solution or in a solution buffered with sodium acetate, and no oxime could be obtained.

6 - Acetoxy - 5 - methyl - 3 - carbethoxy - α - naphthocoumarin (IV).—The coumarin III (1 g.) was refluxed in acetic anhydride for one hour and the solution then poured into water. The product, crystallized from acetic acid or absolute ethanol, weighed 0.9 g. and melted at 195–196°. It was pale greenish-yellow.

Anal. Calcd. for $C_{19}H_{16}O_6$: C, 67.09; H, 4.71. Found: C, 67.26; H, 5.05.

6 - Hydroxy - 5 - methyl - 3 - carbethoxy - 3,4 - dihydro-α-naphthocoumarin (V).—The coumarin (III) and about half its weight of a palladium catalyst[10] were suspended in ethanol or methanol and shaken with hydrogen under 35–40 pounds (1.16–1.34 atm.) until the mixture was colorless. The catalyst was allowed to settle, the supernatant liquid poured off through a filter, and the filtrate evaporated under reduced pressure. The product was recrystallized from ethanol, but it was necessary to exclude air as much as possible since the compound was readily oxidized. The substance was white and melted at 175–176°. Of the two solvents, ethanol was found to be much the better for the dihydro compound was much more readily oxidized in methanol than in ethanol.

Anal. Calcd. for $C_{17}H_{16}O_5$: C, 67.97; H, 5.37. Found: C, 67.70; H, 5.52.

6 - Acetoxy - 5 - methyl - 3 - carbethoxy - 3,4 - dihydro - α-naphthocoumarin (VI) was obtained when the acetyl derivative IV was reduced catalytically as above; the same product resulted when the dihydrocoumarin V was acetylated by refluxing with acetic anhydride for thirty minutes. Crystallized from alcohol, the substance was white, and the m. p. and mixed m. p. of specimens prepared by the two methods was 145–145.5°.

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.66; H, 5.27. Found: C, 66.34; H, 5.35.

6 - Hydroxy - 5 - methyl - 3 - carboxy - α - naphthocoumarin (VII).—The action of most hydrolyzing agents was accompanied by considerable decomposition and gave products which were very difficult to purify. This was especially true of 80% sulfuric acid, the reagent used by Smith and Dobrovolny[4] for hydrolysis of their ester. Sodium hydroxide caused complete decomposition and no hydrolysis product could be isolated. When applied to the *pure* ester, the following procedure was found to give good yields of a product which was readily purified. The ester III (3.6 g.) was suspended in acetone (150 cc.) and dilute hydrochloric acid (400 cc. 1:1) and the mixture was refluxed for eight hours. The mixture was then cooled and the solid filtered, washed with water and dried. It weighed 3.1 g. (95%) and formed fine orange needles melting (dec.) at 275–276° when the bath was preheated to 240° and at 263° (dec.) when the bath was at room temperature at the beginning. The acid was insoluble in benzene and petroleum ether, very slightly soluble in ether, alcohol, chloroform or ethyl acetate, and quite soluble in acetone. For recrystallization, which was difficult, acetic acid was the best solvent, although alcohol could be used.

Anal. Calcd. for $C_{15}H_{10}O_5$: C, 66.65; H, 3.73. Found: C, 66.60; H, 3.87.

Catalytic reduction of the acid VII in ethyl alcohol, using the method described for the reduction of the ester III, gave a colorless solution in about three hours. The solution acquired a yellow color when it was decanted from the catalyst through a filter. The solvent was evaporated to 15 cc. under reduced pressure and the solution allowed to stand, tightly stoppered, overnight. No solid separated during this time, but the solution turned deep red in color. The solvent was then evaporated completely, leaving a solid melting at 142° which was very soluble in all the common solvents except petroleum ether. Crystallization from chloroform–petroleum ether was accompanied by great losses of material and the product was tinged with red and could not be obtained pure. The highest melting point obtained was 153–161° (dec.) (IX?) and this material, after the melt had solidified, re-melted at 129–130° with no evolution of gas (X?). Although 1.4 g. of the acid VII was reduced, it was not possible to isolate from the product enough pure material for analysis. Catalytic reduction of the acid VII in sodium carbonate solution gave only red oils from which no solid could be obtained.

When the dihydro ester V was subjected to the procedure used for hydrolysis of the coumarin ester III, the colorless solution became first yellow and then orange. The solid which precipitated melted at 155–159°; addition of excess water to the cold filtrate gave a solid which melted at 120–125°. The amounts of both were very small.

6 - Acetoxy - 5 - methyl - 3 - carboxy - α - naphthocoumarin (VIII).—The acid VII was boiled for four hours with acetic anhydride, the orange color fading to yellow. The mixture was then poured into ice water and allowed to stand for some time. The product, crystallized from acetic acid, melted at 258° (dec.).

Anal. Calcd. for $C_{17}H_{12}O_6$: C, 65.37; H, 3.87. Found: C, 64.97; H, 3.87.

Catalytic reduction of this acetyl derivative in ethyl alcohol, using the palladium catalyst, gave only oils from which in only one of many experiments was any solid obtained and then in extremely small amounts.

6 - Methoxy - 5 - methyl - 3 - carboxy - α - naphthocoumarin (XI).—The coumarin acid VII (0.2 g.) in methyl sulfate (3–4 g.) and methanol (25 cc.) was refluxed while 20% aqueous potassium hydroxide was added in small portions. Each portion of the alkali caused a red color to develop, which then faded. When a color change no longer occurred, an excess of the alkali was added and the mixture was refluxed for fifteen minutes. The cold solution was acidified with sulfuric acid, sufficient water was added to dissolve the potassium salts, and the yellow insoluble precipitate was removed and crystallized several times from methyl alcohol. It melted at 222–225°, was soluble in ethyl alcohol, methyl alcohol, ether and chloroform and almost insoluble in benzene.

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.58; H, 4.26; OCH_3 (one), 10.92. Found: C, 67.66, 67.55; H, 4.69, 4.61; OCH_3, 11.87.

Methylation of the ester III or the acetyl derivative IV in methyl sulfate, using the general procedure above and

---

[10] Busch and Stöve, *Ber.*, **49**, 1064 (1916).

1% aqueous sodium hydroxide as the alkali, gave the same product (XI) in yields of about 70%.

6 - Methoxy - 5 - methyl - 3 - carbomethoxy - α - naphthocoumarin (XII).—The coumarin acid VII (1 g.) was dissolved in 4% sodium methoxide–methanol (6 cc.); heated gently for thirty min. (purple color) and cooled. Methyl sulfate (1 cc.) and 4% sodium methoxide–methanol (6 cc.) were then added and the flask shaken vigorously for ten minutes. The addition of like quantities of reagents at ten-minute intervals, with vigorous shaking in between, was continued until a total of 19 cc. of methyl sulfate and 114 cc. of the alkali were added, after which the mixture was allowed to stand for fifteen hours. Concentrated ammonia (5 cc.) and water (30 cc.) were added and the mixture warmed on the steam-bath for thirty minutes. An excess of water was then added, the solution cooled and the solid removed and crystallized from methanol. It melted at 182–183° and the yield was 90%. In ether the substance showed a green fluorescence. These directions had to be followed carefully, otherwise the product was a mixture of the ethers XI and XII which was very difficult to separate, or else only the mono-ester XI resulted. The hydrolysis of the ester group in XII occurred with great ease and in most methylation reactions only the monomethyl derivative XI resulted. The dimethyl derivative was somewhat less soluble in alcohol than the monomethyl derivative.

Anal. Calcd. for $C_{17}H_{14}O_5$: C, 68.46; H, 4.69; OCH_3 (two), 20.80. Found: C, 68.46; H, 4.78; OCH_3, 21.03.

The dimethyl derivative XII when refluxed for three to four hours with 10% aqueous potassium hydroxide gave a clear yellow solution, which on acidification gave the monomethyl derivative XI, m. p. and mixed m. p. 223–225°.

The dimethyl derivative XII was also obtained (impure, m. p. 175–177°, mixed m. p. 177–182°) when the purple sodium derivative II was suspended in methanol and refluxed with excess methyl iodide. This impure specimen of XII, when hydrolyzed, gave the methoxy acid XI, m. p. and mixed m. p. 221–223°.

Many other experiments were carried out in the attempt to open the coumarin ring of the ester III or the acid VII in the hope of obtaining the ester XIIa or the acid XIIb. The procedures of various authors[11] were tried several times. All of these methods, except the ones described above, gave the monomethyl derivative XI, unchanged material or decomposition products. The barium salt of the acid XI was prepared by the method of Marschalk[12] but when refluxed with methyl sulfate and methanol it charred completely.

Aside from the substances XI and XII, the only other methyl derivative obtained was by action of diazomethane upon the ester III. This reaction led to a *white* crystalline solid (from alcohol) which melted at 138.5–139° (dec.). The analysis indicated a carbon–hydrogen ratio of approximately 1:1; qualitative tests for nitrogen were negative. No satisfactory formula for this compound has as yet been written.

2-Methylnaphthoquinone (XIII).[13,6]—2-Methylnaphthalene (12.5 g.) was dissolved in acetic acid (118 cc.) and a suspension of chromic acid (50 g.) in 80% acetic acid (90 cc.) was added in a continuous stream. After the highly exothermic reaction was over, the mixture was allowed to stand for an hour and then was diluted with water. The yellow precipitate was removed, washed well with water, dissolved while still wet in ether and the ethereal solution was filtered and dried over calcium chloride. If the crude material was orange in color, the ethereal solution was treated with charcoal before drying it. Evaporation of the ether to crystallization yielded bright yellow needles; the yield was 25–40% and the product melted at 105–107°. The quinone could be purified by steam distillation or crystallization from alcohol or 50% acetic acid. It was unstable in the light, turning from yellow to a dull tan in color.

2-Methylnaphthohydroquinone.—The quinone XIII could be reduced by any of several methods, but the isolation of the product was difficult because of the extreme ease with which the hydroquinone was oxidized to the purple quinhydrone and then to the quinone. Catalytic reduction in ether or methanol with hydrogen under 40 pounds (1.34 atm.) pressure and in the presence of the palladium catalyst gave colorless solutions, which could be used directly if a solution of the hydroquinone were desired, but from which the pure solid hydroquinone was isolated only with difficulty. Reduction with zinc and sulfuric acid gave only deep red solutions and continued boiling with the reducing agent did not cause the color to disappear. Reductive acetylation of the quinone (10 g.) in acetic acid (25 cc.), acetic anhydride (100 cc.) and sodium acetate (5 g.) by refluxing the solution with zinc dust (10 g.) gave 1,4-diacetoxy-2-methylnaphthalene in 82% yield. Crystallized from methanol, the substance was white and melted at 112.5–114°.[13]

All attempts to prepare the dimethyl ether of the hydroquinone (XVI) led to red oils which distilled with complete decomposition.

1,4 - Dihydroxy - 3 - methyl - 2 - naphthaldehyde (XVIII).[5b]—The most successful procedure for this preparation consisted in the catalytic reduction of the quinone in absolute ether, and the use of the resulting ethereal solution of hydroquinone directly for introduction of the aldehyde group. The quinone (7.5 g.) was suspended in absolute ether (160 cc.), palladium catalyst (4 g.) was added and hydrogen passed in under 40 pounds (1.34 atm.) pressure. The color disappeared in five minutes, but the reaction was allowed to continue for about thirty minutes. The catalyst was allowed to settle, the solution was decanted, the catalyst was washed with absolute ether and the solution and washings were placed immediately in the reaction flask for the next step. Zinc cyanide (9.1 g.) was added, and with stirring and cooling (0°), dry hydrogen

chloride was passed in rapidly until the solution became saturated (one and one-half hours) and then more slowly for two hours longer.[14] The milky solution gradually cleared and then an orange solid slowly separated. The ether was decanted, and after washing the solid with fresh ether it was warmed with water (50–100 cc.) until all the imide hydrochloride decomposed. The mixture was cooled and the aldehyde was removed and crystallized from 50% acetic acid, dilute alcohol or chloroform–petroleum ether. The yield was 5.6 g. (64%) and the melting point was 158–160°. The chief impurity in the crude aldehyde was a black substance (quinhydrone?). Steam distillation of the aldehyde gave only quinone in the distillate and a residue of red oil which solidified on cooling; vacuum distillation was also unsatisfactory as a method of purification. The aldehyde could not be converted into an oxime, but with aniline it gave a precipitate of beautiful red needles.

Condensation with Malonic Ester.—To the aldehyde (1.44 g.) in alcohol (2 cc.) there was added piperidine (0.76 g.) and ethyl malonate (2 cc.). The mixture was warmed on the steam-bath until a clear solution resulted, then set aside for a day. The product which had crystallized from the solution was allowed to stand with hydrochloric acid for fifteen to twenty minutes, filtered and washed with cold alcohol and ether. Crystallized from alcohol, the product weighed 0.43 g. and melted at 209–211°; the mixed melting point with a specimen of III (m. p. 208–209°) was 208–209°. Acetylation of this product gave the same acetyl derivative (IV) as was obtained from the ester III; m. p. and mixed m. p. 193–195°.

Condensation of the aldehyde (1 g.) with malonic ester (2 cc.) in acetic acid (2 cc.) led to a solid (0.05 g.) which was chiefly the acetyl derivative VIII. It melted at 248–253°; the mixed m. p. with VIII (m. p. 258°) was 246–250°.

Condensation with Malonic Acid.—To the aldehyde (1.4 g., crude) and malonic acid (0.7 g.) in dry methanol (7 cc.) was added one drop of piperidine and the solution was refluxed on the steam-bath for eighteen hours. A small amount of chloroform was added and the solution was filtered. The chloroform was evaporated from the filtrate, a little methanol was added and the yellow solid was filtered and washed with water and dilute hydrochloric acid. The solid melted at 273–275°; the mixed melting point with a specimen of the acid VII (m. p. 273–275°) was also 273–275° (copper block).

Summary

1. Sodium malonic ester reacts with 2,3-dimethylnaphthoquinone to give a purple sodium derivative which when treated with acid gives 5-methyl-6-hydroxy-3-carbethoxy-α-naphthocoumarin.

2. The physical and chemical properties of this coumarin and a number of its derivatives have been described, and the structure of the coumarin was proved by an independent synthesis from 1,4-dihydroxy-3-methyl-2-naphthaldehyde.

3. The course of the reaction between the methylated naphthoquinone and sodium malonic ester is entirely analogous to that between duroquinone and sodium malonic ester, but the hetero ring in the naphthocoumarin is much more resistant to opening by alkaline reagents.

The Reaction between Quinones and Sodium Enolates. VI. Duroquinone and Sodium Acetoacetic Ester[1]

BY LEE IRVIN SMITH AND DAVID TENENBAUM[2]

In the first paper of this series[3] it was shown that the fully methylated quinone, duroquinone, reacted with sodium malonic ester to give a coumarin derivative (I). In a later paper, Smith and MacMullen[4] showed that trimethylquinone, with one unsubstituted position in the ring, reacted with malonic ester and with acetoacetic ester to give benzofuran derivatives, malonic ester giving only one product (Ia), while acetoacetic ester gave two products (Ia and Ib). These products were the result of an initial 1,4-addition of the reagent to the quinone conjugated system which terminated in the free position, but this reaction was not accompanied by the oxidative step which occurred when the coumarin was formed from duroquinone. The fact that acetoacetic ester gave two products suggested a study of the reaction between this reagent and duroquinone. If the reaction followed the same course as that of malonic ester, the product would be the acetylcoumarin II; but there was also the possibility that the intermediate addition product (IIa) would be oxidized to a form which could undergo self-condensation leading to the *amphi*-naphthoquinone derivative IIb. These products would themselves be of interest,

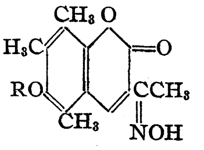
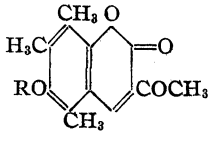
for few representatives of either acetylcoumarins or *amphi*-naphthoquinones are known; but, in addition, if the naphthoquinone derivative were formed, it might be possible, by a detailed study of the reaction, to gain some information as to the oxidative step in the process.

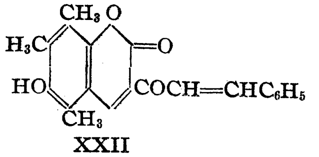
When duroquinone and acetoacetic ester were condensed according to the method of Smith and Dobrovolny[3] there resulted a *purple* sodium compound (IIa). The reaction mixture poured into iced hydrochloric acid gave a solid which crystallized from acetic acid in the form of tan needles melting at 222–226°. The wide melting point range of this substance and the failure to obtain concordant analyses led to the discovery that the substance held duroquinone tenaciously. When this was removed by treatment of the acetic acid solution with charcoal, a bright yellow substance (II), melting at 227–228°, was obtained. The substance had the composition $C_{14}H_{14}O_4$ corresponding to the acetylcoumarin II; it could be readily converted into a yellow oxime (III), a *colorless* acetyl derivative (IV), and a benzal derivative XXII.



III R = H
VIII R = CH_3



IV R = Ac
V R = Na
VII R = CH_3
XXI R = C_6H_5CO



XXII

It was not possible to obtain anything but high melting, amorphous products when the coumarin II was subjected to the action of methyl sulfate and potassium hydroxide in methanol, but aqueous sodium hydroxide (10%) converted the coumarin into a *red* sodium derivative, represented as V, and when methyl iodide, or better methyl sulfate, was added to this sodium derivative suspended in methanol, the methoxy compound VII separated in the form of pale *yellow* needles. The red sodium compound V, refluxed with a solution of benzoyl chloride in benzene, gave the benzoate XXI.

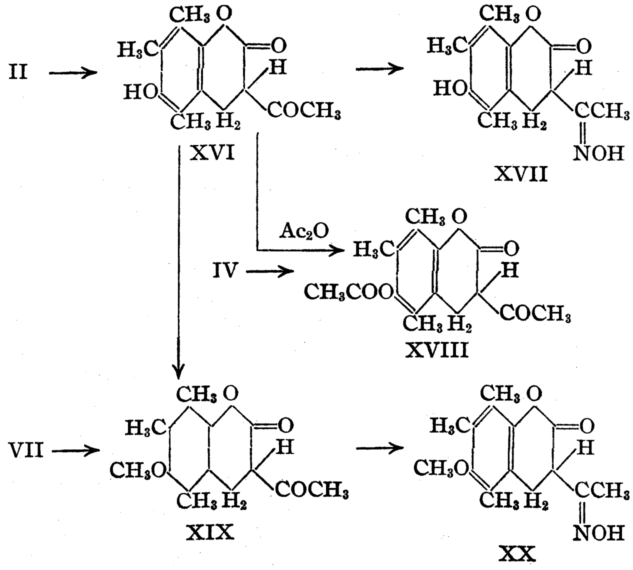
Catalytic reduction of the coumarin II led to a dihydro compound (XVI) which formed an oxime (XVII), as well as an acetyl derivative (XVIII), and could be methylated with methyl sulfate and potassium hydroxide to give the methyl ether XIX. Reduction of the acetyl derivative IV also gave XVIII, and similarly reduction of the methyl ether VII gave XIX—that is, the same methyl or acetyl derivative resulted regardless of whether reduction preceded or followed methylation or acetylation. These reactions proved the presence of a double bond in the coumarin II and also proved conclusively that reduction of the acetylcoumarin involved only the double bond. The methyl derivative XIX gave an oxime (XX), but the acetyl derivative XVIII gave the hydroxy oxime XVII, the acetyl group being removed during the reaction between XVIII and hydroxylamine.

Numerous attempts were made to oxidize the acetylcoumarin II by hypohalites, and thus convert it into the carboxycoumarin VI, a known substance prepared several years ago by Smith and Dobrovolny.[3] But the acid VI was itself attacked by hypohalites, and in only one case, by action of sodium hypobromite on the red sodium compound V, was it possible to isolate the acid VI in quantity sufficient for identification.

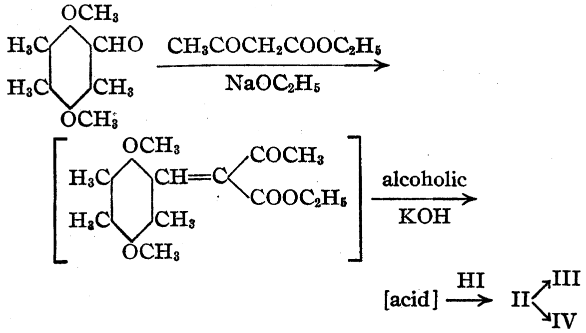
The reactions given so far indicated quite clearly the structure of the product from the reaction between duroquinone and sodium acetoacetic ester, but the final proof of this structure was furnished by an independent synthesis of the acetylcoumarin II. Dimethoxydurylic aldehyde[5] was condensed with acetoacetic ester. Unfortunately neither the benzalacetoacetic ester nor the acid obtained from it by hydrolysis could be made to crystallize. Nevertheless, when the resulting oil

---

[5] Smith, THIS JOURNAL, **56**, 472 (1934).



was boiled with hydriodic acid, it gave the acetylcoumarin II, and the synthesized coumarin gave the same oxime and acetyl derivative as those given by the coumarin obtained from duroquinone and sodium acetoacetic ester.



Hence the reaction between duroquinone and sodium acetoacetic ester follows the same course as that taken by this quinone and sodium malonic ester. The product is 5,7,8-trimethyl-3-acetyl-6-hydroxycoumarin and half of the quinone is converted to the hydroquinone. The failure to obtain any *amphi*-naphthoquinone derivative (IIb) from the reaction shows that the oxidation is confined to the side chain (or coumarin ring) of the product.

Since the oximes III and VIII were obtained readily, considerable study was devoted to their behavior in the Beckmann rearrangement. The oxime III did not react with sulfuric acid below 100°; above that temperature complete decomposition resulted. Both phosphorus pentachloride and benzene sulfonyl chloride reacted, but the resulting product was a mixture from which no pure compounds could be separated. The methoxy oxime VIII was more tractable, and when it was treated with benzene sulfonyl chloride and pyridine, an isomer resulted. Depending upon the configuration of the oxime VIII, structures IX or X were possible for this product.

Since the quantity of material was small, no attempt was made to hydrolyze this product until after the methyl amide IX was synthesized from the acid XI[3] via the acid chloride. The methyl amide IX so obtained was different from the rearrangement product of the oxime VIII. The structure of the latter was therefore strongly indicated to be X, a result in agreement with the work of Linch[6] who found that the oximes of 3-acetylcoumarin and 6-bromo-3-acetylcoumarin, when rearranged, gave the corresponding acetylaminocoumarins rather than the methyl amides of the coumarin acids. When hydrolyzed, the rearrangement product gave a crystalline compound containing nitrogen, the analysis of which corresponded to that required by formula XII, 3-amino-6-methoxy-5,7,8-trimethylcoumarin. Attempts were made to convert the acid XI into XII and so prove the structure X. The hydrazide (XIV) and the hydroxamic acid (XV) of XI were prepared, but these could not be rearranged. Attempts to prepare XII via the azide (XIII) of XI were also made, but neither the procedure of Newman[7] nor that of Nelles[8] was successful. The only product isolated was a non-basic substance containing nitrogen (XIII?) which melted at 210° with violent decomposition.

product with IX, together with its reactions, point fairly conclusively to structure X. If then the Beckmann rearrangement of the oxime VIII is a *trans* migration, it follows that the configuration of the oxime is as represented in formula VIII with the hydroxyl group *anti* to the coumarin ring.

Experimental Part

The Addition Reaction: 3-Acetyl-6-hydroxy-5,7,8-trimethylcoumarin, (II).—Acetoacetic ester (80 g.) was added in small portions to a suspension of powdered sodium (13 g.) in boiling benzene (1000 cc.). The addition of the ester required forty-five minutes, after which the mixture was refluxed, with frequent shaking, for two hours. Duroquinone (35 g.) dissolved in dry benzene (400 cc.) was added and the mixture refluxed for eight days. The color of the solution changed from yellow through brown to reddish-brown, and a purple solid (IIa) precipitated. The entire reaction mixture was poured into hydrochloric acid (500 cc.) and ice (500 g.). The tan solid was removed, washed twice with benzene and dried *in vacuo*. It was crystallized twice from acetic acid using Norite, which removed unchanged duroquinone. The product crystallized in bright yellow needles melting at 227–228°. It was insoluble in petroleum ether, benzene or methanol; difficultly soluble in boiling ethanol, chloroform or cold acetic acid. The yield of tan solid was 20 g.; that of the purified product was 12 g.

Anal. Calcd. for $C_{14}H_{14}O_4$: C, 68.29; H, 5.69. Found: C, 68.05, 67.97; H, 5.61, 5.88.

3 - Acetyl - 6 - acetoxy - 5,7,8 - trimethylcoumarin (IV) resulted when the coumarin II (1 g.) was warmed with acetic anhydride (10 cc.) and a drop of sulfuric acid. Crystallized from acetic acid (with charcoal to remove the dark color) the product formed pale yellow needles melting at 201–202.5°. The yield was 0.8 g.

Anal. Calcd. for $C_{16}H_{16}O_5$: C, 66.64; H, 5.60. Found: C, 67.00; H, 5.70.

3 - Acetyl - 6 - benzoyl - 5,7,8 - trimethylcoumarin, (XXI).—The purple sodium compound IIa from the reaction between duroquinone and acetoacetic ester was filtered and triturated twice with benzene. The salt (0.5 g.) was suspended in a solution of benzoyl chloride (2 cc.) in benzene (10 cc.) and the mixture refluxed for three hours. Unchanged salt (0.25 g.) was filtered off and the filtrate was stirred vigorously into water. Ether was added and the layers were separated. Evaporation of the organic layer left an oily residue containing benzoyl chloride, which was decomposed by adding alcohol and allowing to stand for five hours. The white solid was removed and crystallized from alcohol (using Norite). It weighed 0.12 g. and melted at 162–163°.

Anal. Calcd. for $C_{21}H_{18}O_5$: C, 71.97; H, 5.18. Found: C, 71.45; H, 5.49.

The oxime III resulted when the coumarin II (0.2 g.) was suspended in water (2 cc.) and ethanol (5 cc.) containing hydroxylamine hydrochloride (0.5 g.) and sodium hydroxide (2 cc., 10%) and the mixture warmed on the steam-bath for ten minutes. The oxime formed long, pale yellow needles melting at 258–260° (dec.). The yield was 0.2 g. The same oxime III resulted when the acetyl derivative IV reacted with hydroxylamine.

Anal. Calcd. for $C_{14}H_{15}O_4N$: C, 64.34; H, 5.79. Found: C, 63.92; H, 6.18.

The oxime III could not be made to undergo the Beckmann rearrangement. Benzene sulfonyl chloride in pyridine, as well as phosphorus pentachloride in ether, gave only impure amorphous products; sulfuric acid, at room temperature or at 100°, was without action.

Synthesis of II.—To the solution obtained by dissolving sodium (0.1 g.) in methanol (15 cc.) were added acetoacetic ester (1 cc.) and dimethoxydurylic aldehyde (0.5 g.). The mixture was warmed until the aldehyde dissolved and then allowed to stand at room temperature for three days. Water was added and the mixture was steam distilled. Dimethoxydurylic aldehyde (0.2 g.) was recovered from the distillate. The residual alkaline solution was acidified, extracted with ether (three times) and the ether was evaporated. As the oily residue could not be made to crystallize it was dissolved in ethanol (5 cc.) and boiled for ten minutes with potassium hydroxide (1 g.) in ethanol (10 cc.).

The solution was diluted with water, acidified, extracted with ether and the ether evaporated. The product was again an oil, which was warmed for an hour with constant boiling hydriodic acid (2 cc.). The solution was poured into ice water, and the precipitate was removed and crystallized from acetic acid with the aid of a little Norite. The product (0.2 g.) formed bright yellow needles melting at 226–227°; when mixed with the coumarin II from duroquinone, the melting point was 226–227°. The oxime melted at 257–260° (dec.), and when mixed with the oxime III the melting point was 257–260° (dec.).

Oxidation of II to VI.—To a solution of sodium hydroxide (3.4 g.) in water (30 cc.) was added the coumarin II (1 g.). The red sodium salt (V) precipitated. Bromine (1.8 cc.) was dropped slowly into the cold, stirred suspension of the sodium salt. Bromoform was removed by extracting with ether, and bisulfite was added to remove the excess hypobromite. The solution was acidified, extracted three times with ether and the ether evaporated. The residue was an orange oil which slowly deposited a small amount of solid. Washing with ethanol removed the oil, and the residual solid was crystallized from acetic acid. The product weighed 0.05 g., and the melting point was 260° (dec.). The mixed melting point with a specimen of 3-carboxy-6-hydroxy-5,7,8-trimethylcoumarin (VI) (m. p. 256–257°, dec.) was 257–260° (dec.). No other solid could be isolated; the low yield was due to the fact that VI was itself oxidized by hypobromite, giving only oils and bromoform (odor).

3 - Acetyl - 6 - methoxy - 5,7,8 - trimethylcoumarin, (VII).—The usual procedures for methylation with methyl sulfate and alkali failed when applied to the coumarin II but the methyl derivative VII was obtained as follows: the sodium salt V was precipitated by suspending the coumarin II (0.64 g.) in sodium hydroxide (20 cc., 10%). The salt V was filtered, washed several times with cold acetone and suspended in methanol (50 cc.). Methyl sulfate (3 cc.) was added with shaking. In about three minutes the red color changed to yellow and the methoxy compound began to crystallize. The product was filtered, suspended in ether and extracted several times with sodium hydroxide (2%) to remove unchanged II. From the ether solution was obtained 0.41 g. of the methoxy compound VII melting at 158.5–159.5° and crystallizing in long, pale yellow needles.

Anal. Calcd. for $C_{15}H_{16}O_4$: C, 69.23; H, 6.15. Found: C, 69.26; H, 6.30.

Oxidation of the methyl derivative VII by hypoiodite or by hypobromite gave iodoform (or carbon tetrabromide) and either unchanged VII or else only oily tars.

3 - Benzalacetyl - 6 - methoxy - 5,7,8 - trimethylcoumarin, (XXII).—To the methoxycoumarin VII (0.56 g.) and benzaldehyde (5 cc.) in methanol (30 cc.) was added dilute sodium hydroxide (5 cc.) and the mixture was refluxed for three hours. The product was obtained by acidifying with acetic acid (3%), diluting with water and cooling. Crystallized from methanol, it melted at 187–189° and weighed 0.28 g.

Anal. Calcd. for $C_{22}H_{20}O_4$: C, 75.83; H, 5.79. Found: C, 75.45; H, 6.12.

Treatment of the benzal derivative with chromic acid in acetic acid in the cold gave unchanged material as the only isolable product; when the reaction mixture was warmed, the substance was oxidized completely.

The oxime VIII resulted when the methoxycoumarin (VII) (0.2 g.) was warmed for ten minutes with hydroxylamine hydrochloride (0.5 g.), water (1.5 cc.), sodium hydroxide (1.5 cc., 10%) and methanol (5 cc.). Crystallized from toluene, it weighed 0.18 g., and formed white needles melting at 225–227° (dec.).

Anal. Calcd. for $C_{15}H_{17}O_4N$: C, 65.42; H, 6.23. Found: C, 65.34; H, 6.68.

Beckmann Rearrangement: 3-Acetylamino-6-methoxy-5,7,8-trimethylcoumarin, (X).—To a solution of the oxime VIII (0.175 g.) in dry pyridine (2 cc.) was added benzene sulfonyl chloride (2 cc.). A dark brown color developed at once. After standing at room temperature (26°) for three hours, the solution was poured into ice (5 g.) and hydrochloric acid (5 g.). The mixture was extracted with ether and the ether, as well as the suspended solid, washed with water. Both the ether and the water were filtered and the solids were combined and crystallized from methanol. A second crop was obtained by concentrating the ether solution. The product weighed 0.075 g., melted at 237–238°, and formed long white needles. The mixed melting point with the oxime VIII (m. p. 225–227°, dec.) was 190–195°.

Anal. Calcd. for $C_{15}H_{17}O_4N$: C, 65.42; H, 6.23. Found: C, 65.74; H, 6.60.

3 - Amino - 6 - methoxy - 5,7,8 - trimethylcoumarin, (XII).—The acetylaminocoumarin X (0.04 g.) was refluxed with hydrochloric acid (6 *N*, 15 cc.) for fifteen minutes. The cooled solution was neutralized with sodium carbonate and the precipitate taken up in ether. The ether was evaporated and the residue crystallized from aqueous methanol. The product weighed 0.02 g., and melted at 150–151°.

Anal. Calcd. for $C_{13}H_{15}O_3N$: C, 66.92; H, 6.49; N, 6.00. Found: C, 66.62; H, 6.70; N, 6.40.

Methylamide of 3-Carboxy-6-methoxy-5,7,8-trimethylcoumarin, (IX).—The methoxy acid[3] (p. 1706) (1 g.) was warmed with thionyl chloride (5 cc.) and the thionyl chloride was then removed under reduced pressure, leaving a pale yellow solid. This was dissolved in dry benzene (5 cc.) and methylamine was passed into the solution. The yellow color disappeared and a white solid precipitated. The solvent was evaporated and the product crystallized from dilute acetic acid. It weighed 0.85 g., and melted at 214–215°. The mixed melting point with X (m. p. 237–238°) was 205–207°.

Anal. Calcd. for $C_{15}H_{17}O_4N$: C, 65.42; H, 6.23. Found: C, 65.28; H, 6.23.

Attempts to Prepare the Aminocoumarin, XII.—A chloroform solution of hydrazoic acid was prepared[7] using technical sodium azide (0.15 g.) and sulfuric acid (0.6 cc.). This solution was added dropwise, with stirring, to a solution of the methoxy acid XI (0.56 g.) in sulfuric acid (5 cc.) at a temperature of 40°. No gas was liberated; after standing for thirty minutes the mixture was poured onto ice. The only product was unchanged acid XI.

The methoxy acid XI (0.5 g.) was refluxed for one hour with thionyl chloride (5 cc.) and the excess thionyl chloride then removed under reduced pressure. The acid chloride was taken up in dry benzene and stirred for two hours with activated sodium azide.[8] No gas was evolved. Hydrochloric acid (10 cc.) was then added and the mixture was refluxed for an hour. Evaporation of the solvents left an oily material from which no pure product could be isolated. Repetition of the experiment, heating the acid chloride with sodium azide at 50°, gave a small amount (0.12 g.) of white solid which could not be purified. It melted at about 210° with violent decomposition, and was unaffected by boiling with hydrochloric acid in acetone.

The methoxy acid XI (0.5 g.), sodium azide (1 g.) and sulfuric acid (5 cc.) were sealed in a Carius tube and heated at 150° for an hour. The material was recovered unchanged.

Hydrazide of 3-Carboxy-6-methoxy-5,7,8-trimethylcoumarin, (XIV).—To a suspension of the methoxy acid XI (0.5 g.) in alcohol (10 cc.) was added with shaking, a few drops of hydrazine hydrate solution (40%). The white solid, crystallized from alcohol, weighed 0.5 g. and melted at 184–185° with violent decomposition.

Anal. Calcd. for $C_{14}H_{16}O_4N_2$: C, 60.84; H, 5.84. Found: C, 60.48; H, 6.10.

The hydrazide (0.25 g.) in ether was stirred with a solution of sodium nitrite (0.5 g.) in water (10 cc.). To the mixture, at 5°, was added slowly hydrochloric acid (6 *N*, 2 cc.). No product, other than a small amount of unchanged hydrazide, could be isolated and the same result was obtained when the experiment was repeated substituting acetic acid for the ether.

Hydroxamic Acid of 3-Carboxy-6-methoxy-5,7,8-trimethylcoumarin, (XV).—The acid XI (0.25 g.) was suspended in alcohol and hydroxylamine hydrochloride (0.5 g.) was added. Sodium hydroxide (3%) was dropped in slowly and with shaking, until a faint alkaline reaction resulted. The solution was acidified with dilute acetic acid (5%), an equal volume of water was added and the mixture was allowed to stand for several hours. The product, crystallized from aqueous alcohol, was pale yellow, melted at 236–237° and weighed 0.15 g.

Anal. Calcd. for $C_{14}H_{15}O_5N$: C, 60.62; H, 5.46. Found: C, 60.39; H, 5.70.

The hydroxamic acid was recovered unchanged after boiling in acetone and acetic anhydride.

3 - Acetyl - 6 - hydroxy - 5,7,8 - trimethyl - 3,4 - dihydrocoumarin (XVI).—The coumarin II (0.5 g.) and a palladium catalyst (0.5 g.)[9] were suspended in alcohol (100 cc.) and the solution was subjected to the action of hydrogen under 45 pounds (3.0 atm.) pressure. Reduction was complete in forty-five minutes. The solution was decanted from the catalyst and diluted to three times its volume with water. The product, crystallized from petroleum ether–benzene, weighed 0.45 g. and formed white needles melting at 164–165°.

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.71; H, 6.50. Found: C, 67.36; H, 6.85.

Methylation.—A solution of potassium hydroxide (5 g.) in methanol (25 cc.) was added dropwise to the boiling solution of the reduced coumarin XVI (0.2 g.) in methanol (10 cc.) and methyl sulfate (5 cc.). The reaction was stopped as soon as the red color remained permanent for about ten seconds. Most of the methanol was evaporated, water was added and the solution was extracted with ether. Evaporation of the ether left an oily solid which was digested with dilute ammonium hydroxide (3%) to remove excess methyl sulfate. The solid, crystallized from aqueous alcohol, weighed 0.05 g. and melted at 111–113°. It was identical (m. p. and mixed m. p.) with the product XIX obtained by reduction of VII.

Acetylation.—The dihydrocoumarin XVI (0.25 g.) was warmed for thirty minutes with acetic anhydride (5 cc.) and sulfuric acid (2 drops). The reaction mixture was poured into ice water and the product was crystallized from aqueous alcohol. It weighed 0.15 g., and melted at 123–125°. It was identical (m. p. and mixed m. p.) with the product XVIII obtained by reduction of the acetyl derivative IV.

The oxime XVII resulted when the hydrocoumarin XVI (0.2 g.) followed by sodium hydroxide (1 cc., 10%) was added to a suspension of hydroxylamine hydrochloride (0.5 g.) in alcohol (10 cc.). After warming on the water-bath the solution was filtered and the filtrate concentrated to half its volume. Water (10 cc.) was added and the solution was cooled. The product (0.2 g.) crystallized from aqueous alcohol, formed long white needles melting at 179–180° (dec.).

Anal. Calcd. for $C_{14}H_{17}O_4N$: C, 63.85; H, 6.51. Found: C, 63.47; H, 6.81.

3 - Acetyl - 6 - methoxy - 5,7,8 - trimethyl - 3,4 - dihydrocoumarin, (XIX).—Catalytic reduction of the methoxycoumarin VII (0.5 g.) by the method described above gave 0.5 g. of the dihydro compound XIX. Crystallized from aqueous alcohol, the substance melted at 112–113.5°.

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.67; H, 6.92. Found: C, 68.39; H, 7.23.

The oxime XX, prepared in the same manner as XVII, crystallized from aqueous methanol in colorless needles melting at 156–157° (dec.).

3 - Acetyl - 6 - acetoxy - 5,7,8 - trimethyl - 3,4 - dihydrocoumarin, (XVIII).—Catalytic reduction of the acetyl derivative IV (0.25 g.) in ethanol (75 cc.) by the method described above gave 0.24 g. of the dihydro compound XVIII. Crystallized from aqueous alcohol, it melted at 124–125°.

Anal. Calcd. for $C_{16}H_{18}O_5$: C, 66.17; H, 6.25. Found: C, 65.93; H, 6.25.

Summary

1. Sodium acetoacetic ester has been added to duroquinone. The reaction follows the same course as that of the reaction between this quinone and malonic ester, and involves one of the methyl groups of the quinone.

2. The product is a methylated 3-acetyl-6-hydroxycoumarin; no evidence of any naphthoquinone derivative was obtained. The structure of the coumarin was proved by an independent synthesis.

3. Several reactions of the coumarin and its derivatives were investigated, particularly the Beckmann rearrangement of the oxime of the methoxycoumarin, which led to an aminocoumarin, indicating that the hydroxyl group was *anti* to the coumarin ring in this oxime.

The Reaction between Quinones and Sodium Enolates. VII. Bromopseudocumoquinone and Sodium Malonic Ester[1]

BY LEE IRVIN SMITH AND KENNETH C. JOHNSON[2]

So far, in the work described in this series of papers, two types of quinones have been investigated: (a) completely methylated para benzoquinones, represented by duroquinone[3] and by 2,3-dimethylnaphthoquinone[4]; (b) a quinone with one free position, pseudocumoquinone.[5] In the reactions with sodium enolates, such as sodium malonic ester, quinones of type (a) have behaved as pentad-enol systems and have given coumarin derivatives, while the quinone of type (b) reacted through the conjugated system terminating in the free position, and gave benzofuran derivatives. At the beginning of this work, duroquinone was selected for investigation because a fully substituted quinone, containing no *replaceable* group, was desired in order that the reaction might be with certainty confined to an addition.

A great variety of active methylene compounds has been used in reactions with halogenated quinones, such as 2,3-dichloro-α-naphthoquinone.[6] In general, one or both of the halogen atoms were replaced, but when only one halogen atom was present this might or might not react, and the reaction has involved the replacement even of an ether group by a malonic ester residue although halogen was available.[7] Moreover, the halogen in 2-bromo-3-mesityl-α-naphthoquinone was inert toward sodium malonic ester.[8]

The mononuclear halogenated quinones also have shown the same irregularities. Chloranil[6a,9] reacted with replacement of two (para) chlorine atoms by malonic ester residues; in the diethers of chloroanilic acid both ether groups were replaced;[10] and in dibromothymoquinone only one halogen (ortho to the methyl group) was replaced by the malonic ester residue, while with aniline, the *methyl group* was replaced by the anilino group.[11]

Because of the variety of the reactions shown by halogenated quinones, it was of interest to examine the behavior of bromopseudocumoquinone (I) toward sodium malonic ester. This quinone could react by replacement of the halogen by the malonic ester residue and it also offered the possibility of a reaction of the type (a) quinones already studied which would involve a methyl group and lead to a coumarin derivative. In the latter case, three different coumarins (A, B, C) could result, since the three methyl groups in the quinone were not equivalent (*o*-, *m*- or *p*- to the bromine atom). If only one of the methyl groups were involved, it was hoped that a study of the reaction would yield information concerning the activating effects of the groups upon each other as transmitted through the quinone ring.

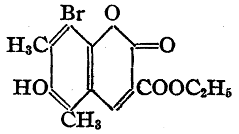
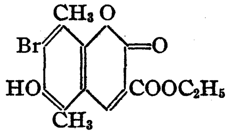
A (ortho)



B (meta)
III



C (para)

When bromopseudocumoquinone (I) was added to a solution of sodium malonic ester in absolute alcohol, there resulted a red sodium derivative (II) which, when decomposed by hydrochloric acid, gave a golden-yellow substance (III). Analysis and determination of the molecular weight showed this substance to have the composition $C_{14}H_{13}O_5Br$. The equation which Smith

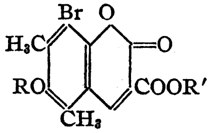
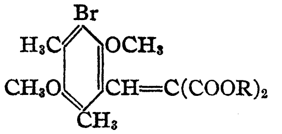
and Dobrovolny[3a] found to hold for the reaction between duroquinone and malonic ester, when applied to I, would lead to a product having the composition of III.

$$\underset{\text{I}}{2C_9H_9O_2Br} + C_7H_{12}O_4 \longrightarrow \underset{\text{III}}{C_{14}H_{13}O_5Br} + C_2H_5OH + C_9H_{11}O_2Br$$

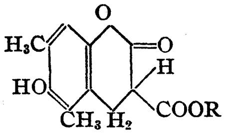
It was obvious at the outset, therefore, that the bromine atom in the quinone I had not reacted, but that one of the methyl groups had been involved and that the product III was undoubtedly one of the coumarin esters A, B and C. The substance III was an ester, for it could be hydrolyzed to an acid (IV). The yellow ester III also contained one hydroxyl group for it could be converted into a white monoacetate (V); likewise the yellow acid IV could be converted into a white monoacetate (VI). Only a single product (VII) could be obtained by methylation of the ester III with methyl sulfate and alcoholic potassium hydroxide, and the same methyl derivative VII was obtained from the acid IV, or from the acetates V and VI. The composition of this methyl derivative was $C_{13}H_{11}O_5Br$—hence the ester grouping in III was hydrolyzed during the methylation, and VII was a monomethyl derivative of IV. Catalytic reduction of the ester III gave a colorless product (VIII) $C_{14}H_{16}O_5$, which contained no bromine. This composition corresponded to that required by reduction of one double bond, and replacement of the bromine by hydrogen, in the ester III.



III, R = H, R' = C_2H_5
IV, R = H, R' = H
V, R = Ac, R' = C_2H_5
VI, R = Ac, R' = H
VII, R = CH_3, R' = H



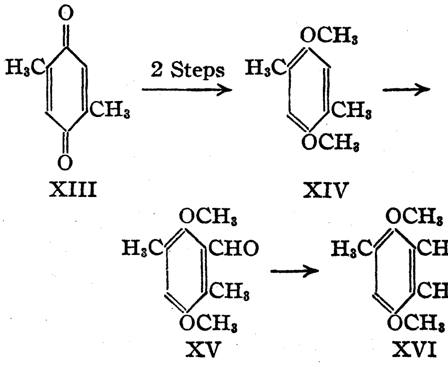
D, R = C_2H_5
E, R = H



VIII, R = C_2H_5
VIIIa, R = H

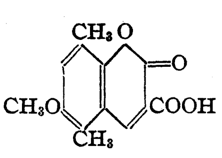
It was planned to open the coumarin ring by methylation and so obtain the ester D or the acid E which could then be synthesized or degraded to simpler compounds, analogous to the method used by Smith and Dobrovolny[3a] in handling the product from duroquinone. But the replacement of a methyl group by bromine in position 8 of the coumarin rendered the hetero ring surprisingly resistant to opening, and it was not possible to obtain any product other than VII by any of the methods tried.

Since it was not possible to degrade the ester III to any simpler compound, it became necessary to synthesize either the ester III or one of its derivatives. At this point nothing about the chemistry of III or its derivatives was known which would point to a choice among the possible structures A, B and C for III, consequently the choice of which of these to synthesize first was governed by the accessibility of the starting materials. Of the three xyloquinones which constituted the starting points for the respective series, the para isomer was most readily obtained; hence the first attempt was directed toward a synthesis of C. *p*-Xyloquinone (XIII) was converted to 1,4-dimethyl-2,5-dimethoxybenzene (XIV) and the latter was converted to 2,5-dimethyl-3,6-dimethoxybenzaldehyde (XV). The aldehyde was difficult to brominate, and when subjected to rather vigorous conditions it gave a product which could not be purified. It was therefore condensed with malonic acid to give the benzalmalonic acid XVI and this, when heated above its melting point, lost methyl alcohol to give 3-carboxy-6-methoxy-5,8-dimethylcoumarin XVII.[3a]

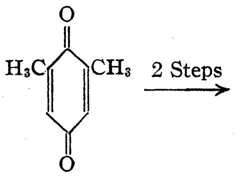


XIII XIV
XV XVI

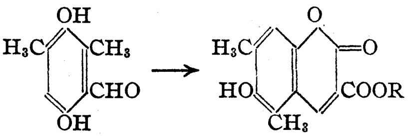
Bromination of XVII to give C was unsuccessful; the product showed only a slight test for halogen and even after several recrystallizations melted over a wide range. But the melting point of XVII, 230°, was 20° higher than that of the bromocoumarin VII, and since all previous experience with these compounds had shown that the introduction of a bromine atom into the ring raised the melting point considerably, it appeared



XVII



XVIII



XIX

XX R = H
XXI R = C_2H_5

quite certain that the ester III did not belong in the para series (C).

At this point, attention was turned to the meta series and hence to a synthesis of B or some compound derived from it.[12] *m*-Xyloquinone XVIII was prepared by oxidation of mesidine, and by a series of reactions similar to that outlined above the quinone was converted into 2,4-dimethyl-3,6-dihydroxybenzaldehyde (XIX). Condensation of XIX with malonic acid gave 3-carboxy-6-hydroxy-5,7-dimethylcoumarin, (XX). Malonic ester did not condense well with the aldehyde XIX, but the ethyl ester XXI was easily prepared from the acid XX. Bromination of the coumarin acid XX to the bromocoumarin IV was unsuccessful, but when the ethyl ester XXI was catalytically reduced, a dihydro ester resulted which was identical in all respects with the ester VIII prepared by reduction of III. A specimen of VIII prepared by reduction of I gave, when oxidized with ferric chloride, a coumarin acid identical in all respects with the acid XX.

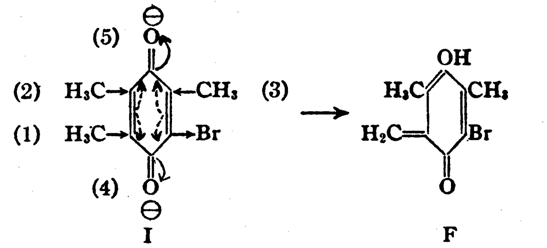
The substance III obtained from the reaction between bromopseudocumoquinone and sodium malonic ester therefore possesses the structure B and is 3-carbethoxy-6-hydroxy-5,7-dimethyl-8-bromocoumarin. In this reaction the bromine atom of the quinone is unaffected; the quinone behaves as a pentad–enol system and it is the methyl group meta to the bromine which is involved in the reaction. It is proposed to explore the limits of this reaction in a series of brominated alkyl quinones and to discover how far this inertness of the bromine atom extends.

Although the initial experiments on the reaction between the quinone and sodium malonic ester were carried out in alcohol, the yield of product III by this procedure was very low and it was possible to account for but a small fraction of the quinone used. This was due to the action of sodium ethoxide which rather rapidly converted the quinone to tarry products. When the red sodium compound (II) was prepared in benzene, according to the original procedure of Smith and Dobrovolny,[3a] the ester III obtained from it was accompanied by large amounts of a highly fluorescent viscous oil, and the yield of III was low. Better results were obtained when the quinone was added to a suspension of sodium malonic ester (free from alcohol) in ether, but it was possible to account for only about 30% of the starting quinone when this procedure was used. When, however, the quinone was added to an alcoholic solution of malonic ester in which finely divided magnesium ethoxide was suspended, a reddish solid soon precipitated with very little tarry by-product. This magnesium compound (IX) when filtered and dried was light tan in color. Dilute acids readily converted it to the ester III and with dilute hydrochloric acid the reaction was quite vigorous. The yield of coumarin ester III when prepared in this way was approximately the theoretical assuming two moles of quinone necessary to form one mole of III. The alcoholic filtrate from the magnesium compound yielded the fairly stable, brilliant black quinhydrone of I. Practically all of the quinone used was accounted for by ester III and quinhydrone recovered.

While the discovery that this magnesium derivative was readily formed and that it could be

---

[12] While this synthesis was in progress, Dr. I. M. Webster and Mr. T. A. Geissman of this Laboratory called the attention of the authors to the fact that an application of the electronic principles used extensively by the English School of Organic Chemists [see C. K. Ingold, *Chem. Rev.*, **15**, 225 (1934)] would lead to the prediction that B was the correct structure for III.

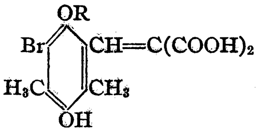


I F

In the quinone I, the electrons tend to shift as shown by the arrows. One-half of the molecule is symmetrical, so that the effects of the methyl groups 1 and 2 are the same. But in the other half of the molecule, the bromine atom has a strong electron affinity and this counteracts the tendency for the electrons to shift to the oxygen atom 4, while the methyl group 3 augments the tendency for the electrons to shift to the oxygen atom (5). As a result of these effects, oxygen atom 5 is more electronegative than 4. Consequently, when enolization occurs in the pentad–enol system, the hydrogen would shift to the more negative oxygen atom (5); and the enol would have structure F in which the methyl group (1) meta to the bromine atom, is part of the new conjugated system.

converted to III in good yield was of great practical value in these researches, the most interesting and significant property of the substance was the fact that it could be converted into a series of derivatives closely related to, but different from the series of derivatives obtained from the ester III or from the sodium compound II. When the magnesium compound (IX) was decomposed by freshly distilled methyl sulfate in methanol, a *yellow* product (X) melting at 240° was obtained. Analysis of this product X showed a composition closely approximating $C_{13}H_{16}O_6Br$, and it contained one methoxyl group. The substance was unaffected by boiling it in acetone solution with hydrochloric acid, but hydrobromic acid in acetic acid converted it to the coumarin acid IV. The action of acetic anhydride converted X into a colorless acetyl derivative (XII), which was different from any acetate obtained from the ester III or from its derivatives. Methylation of X by methyl sulfate and alkali gave the same methyl ether VII as was obtained by methylation of III. When the magnesium compound IX was subjected to the action of acetyl chloride (distilled from dimethylaniline directly onto the substance) it gave an oily reaction product from which yellow, solid acetyl derivative (XI) was finally isolated.

When methylated, the acetyl derivative XI gave the methyl ether VII; hydrolysis of XI by acetone–hydrochloric acid gave the coumarin acid IV. Because of the formation of a series of products entirely different from those obtained from the coumarins III and IV, it is believed that these substances are derived from the primary metallic derivative formed by 1,4-addition to the conjugated system in F. While much more work remains to be done on this series of compounds, the methyl ether X and the acetate XI are provisionally given the structures shown.[13]



X R = CH_3
XI R = Ac

Experimental Part[13a]

Synthesis of the Quinone I. 5-Bromo-3,6-dinitropseudocumene.—A solution of 5-bromopseudocumene (50 g.) in chloroform (200 cc.) was floated on to sulfuric acid (200 cc.). Fuming nitric acid (50 g., d. 1.5) was added dropwise (forty-five minutes) with cooling (−5 to 0°) and stirring. The initial dark color gradually lightened and a solid began to separate. Stirring was continued for thirty minutes after adding the nitric acid; this was followed by stirring for thirty minutes at room temperature. The reaction mixture was a thick emulsion, which did not separate well into layers, but the layers were separated as completely as possible and the acid was extracted once or twice with fresh chloroform. The oil and the chloroform solutions were combined, washed with water, dilute alkali and again with water. Ethanol (300 cc.) was added and the solution concentrated to half its volume. The mixture was cooled to 0°, and the solid was removed, washed with cold alcohol and dried. The white product weighed 61 g. (84%) and melted at 216–217°. When crystallized twice from chloroform–ethanol, the substance melted at 221–222°.[14] From the filtrates about 6 g. more was obtained, bringing the total yield to 93%. The substance could be recrystallized from benzene–alcohol or chloroform–alcohol, but the reaction product, isolated as described, was quite pure.

Anal. Calcd. for $C_9H_9O_4N_2Br$: C, 37.37; H, 3.14; Br, 27.6. Found: C, 37.38; H, 3.16; Br, 27.8.

The stannichloride of 5-bromo-3,6-diaminopseudocumene was obtained when a hot solution of stannous chloride (350 g.) in hydrochloric acid (400 cc.) was added quickly to a hot solution of the bromonitro compound (53 g.) in acetic acid (400 cc.). The reaction was vigorous and it was necessary to use a large flask (5 liters). The reaction mixture was cooled to 0°, the solid filtered and washed with alcohol (80 cc.) and ether (60 cc.). The product was contaminated with tin salts; it weighed 85 g. (theory 73 g.).[15]

The amine was isolated by extracting with ether a suspension of the stannichloride in alkali. Crystallized from alcohol, it was almost white (darkened at 150°) and melted at 155° to a black liquid.

Anal. Calcd. for $C_9H_{13}N_2Br$: C, 47.16; H, 5.72; Br, 34.9. Found: C, 47.07; H, 5.59; Br, 35.3.

The stannichloride (58 g.) was added to a solution of ferric chloride (275 g.) in water (275 cc.) and hydrochloric acid (25 cc.) in a flask equipped for steam distillation. After standing at room temperature for thirty minutes, the mixture was warmed on the steam-bath for thirty minutes and then steam distilled. The quinone I, isolated from the distillate, weighed 26 g. (82% based on the dinitro compound taken) and melted at 79–80°. It could be crystallized from alcohol in golden-yellow needles, but the crude product was sufficiently pure for most purposes.

Anal. Calcd. for $C_9H_9O_2Br$: C, 47.16; H, 3.97; Br, 34.9. Found: C, 47.43; H, 4.02; Br, 34.9.

When the quinone (0.2 g.) in alcohol (25 cc.) was added to the hydroquinone (0.2 g.) in alcohol (50 cc.) and the yellow solution concentrated on the steam-bath until the color darkened, there resulted the black, stable quinhydrone melting at 148.5–149.5°.

Bromopseudocumohydroquinone.—To the quinone (1 g.) suspended in alcohol (5 cc.) was added a solution of stannous chloride (2 g.) in dilute hydrochloric acid (25

(13) Farmer, Ghosal and Kon [*J. Chem. Soc.*, 1804 (1936)] have recently obtained two types of metallic derivatives by the addition of sodium malonic esters to α-β acetylenic esters. These two types of metallic derivatives are closely related, but each gives its own series of alkyl derivatives.

(13a) Microanalyses by J. W. Opie.

(14) Fittig [*Ann.*, 147, 14 (1868)] reports the m. p. as 214–215°.

(15) Nietzki and Schneider, *Ber.*, 27, 1428 (1894).

cc.). The mixture was warmed until the color disappeared, and the product appeared on cooling. Crystallized from dilute alcohol containing a little stannous chloride and hydrochloric acid, the product formed white needles (0.9 g.), darkened at 170° and melted at 185° (dec.).

The dimethyl ether resulted when the hydroquinone (0.5 g.) in methanol (5 cc.) and methyl sulfate (3 cc.) was warmed and treated with small portions of saturated potassium hydroxide in methanol until the reaction mixture was strongly alkaline. The solution was acidified, the solid was removed and crystallized from methanol. The yield of white product, melting at 71–72°, was nearly quantitative.

Anal. Calcd. for $C_{11}H_{15}O_2Br$: C, 50.97; H, 5.83; Br, 30.9. Found: C, 51.79; H, 6.04; Br, 30.8.

The diacetate, prepared in the usual way, and crystallized from alcohol, formed white needles which melted at 178–179°.

Anal. Calcd. for $C_{13}H_{15}O_4Br$: C, 49.52; H, 4.79; Br, 25.4. Found: C, 49.92; H, 4.92; Br, 25.4.

The dibenzoate, prepared by the Schotten–Baumann method and crystallized from chloroform–alcohol, was white and melted at 253–255°.

Anal. Calcd. for $C_{23}H_{19}O_4Br$: C, 62.87; H, 4.37; Br, 18.2. Found: C, 63.28; H, 4.56; Br, 18.1.

Addition of Malonic Ester to the Quinone I. (a) In Alcohol.—A solution of the quinone (11.5 g.) in dry alcohol (100 cc.) was added dropwise to a solution of malonic ester (8 g.) and sodium ethoxide in dry alcohol (1.5 g. sodium, 50 cc. alcohol). The color became bluish-violet at once, then changed to red and a dark solid began to separate within ten minutes. After standing for thirty minutes the solution was poured onto ice (500 g.) and hydrochloric acid (50 cc.). The precipitate gradually collected together into a dark spongy mass which solidified on standing overnight. The dark solid was dissolved in hot alcohol and the solution was filtered. The cooled filtrate deposited 2 g. (25%) of **3-carbethoxy-6-hydroxy-5,7-dimethyl-8-bromocoumarin** (III) in the form of dark yellow needles melting at 200°. The rest of the reaction product was a dark oil from which no other solids could be isolated.

Anal. Calcd. for $C_{14}H_{13}O_5Br$: C, 49.26; H, 3.84. Found: C, 48.93; H, 4.26.

(b) In Ether.—Sodium (0.5 g.) was dissolved in dry alcohol (10 cc.) and after ethyl malonate (3.5 g.) was added the solvent was removed under reduced pressure. The residual white powder was suspended in ether (150 cc.) and a solution of quinone I (1 g.) in ether was added. After refluxing on the steam-bath for twelve hours, the red sodium compound (II) was filtered, washed with ether and dried. Decomposition of the sodium compound with acids gave III melting at 200° in about 25% yield and from the ethereal filtrates some quinone could be recovered.

(c) In Benzene.—The procedure of Smith and Dobrovolny[3a] was followed, but the yield of III was very low. Apparently the prolonged heating (eight days) in the presence of alkali largely destroyed both the quinone and the product.

(d) Using Magnesium Malonic Ester.—Magnesium ethoxide (6 g., freshly pulverized) was refluxed with malonic ester (6 g.) and dry alcohol (250 cc.). The quinone I (8 g.) in alcohol was added dropwise while a current of air was bubbled through the reaction mixture. Refluxing was continued, with air passing through, for twelve hours longer. The tan solid IX was filtered and washed with ether; the first crop of material weighed 10.8 g., and from the filtrate and washings 1.6 g. more was obtained. The substance was contaminated with magnesium ethoxide and it was not analyzed. When decomposed by hydrochloric acid the magnesium compound IX (1 g.) gave slightly more than 0.4 g. of the coumarin III melting at 200°. The ether filtrates when evaporated gave a dark oil consisting of malonic ester and quinhydrone.

3 - Carbethoxy - 6 - acetoxy - 5,7 - dimethyl - 8 - bromocoumarin (V).—The ester III (1 g.) was boiled with acetic anhydride (20 cc.) and sulfuric acid (5 drops). After thirty minutes the solution was poured into water and the mixture made alkaline with ammonia. The solid was dissolved in chloroform, the solution filtered, alcohol added and the filtrate and the solvents evaporated to a small volume. The solid was removed and recrystallized from alcohol. It was white, weighed 0.9 g. (88%) and melted at 160–161°.

Anal. Calcd. for $C_{16}H_{15}O_6Br$: C, 50.13; H, 3.95. Found: C, 50.36; H, 4.15.

3 - Carboxy - 6 - hydroxy - 5,7 - dimethyl - 8 - bromocoumarin (IV).—The ester III (0.5 g.) was dissolved in acetone (25 cc.) and refluxed for three hours with hydrochloric acid (25 cc.) and water (25 cc.). The hot solution was filtered and the filtrate on cooling deposited a yellow solid. Crystallized from benzene, the substance weighed 0.3 g. (65%) and formed bright yellow needles melting at 250°.

Anal. Calcd. for $C_{12}H_9O_5Br$: C, 46.00; H, 2.90. Found: C, 46.41; H, 2.99.

3 - Carboxy - 6 - acetoxy - 5,7 - dimethyl - 8 - bromocoumarin (VI).—Acetylation of the acid IV gave white cottony needles of VI melting at 223°.

Anal. Calcd. for $C_{14}H_{11}O_6Br$: C, 48.32; H, 3.12. Found: C, 48.35; H, 3.29.

3 - Carboxy - 6 - methoxy - 5,7 - dimethyl - 8 - bromocoumarin (VII).—To the ester III (0.5 g.) in boiling methanol (10 cc.) and methyl sulfate (4 g.) was added dropwise an excess of a saturated solution of potassium hydroxide in methanol. The reaction mixture was diluted with water, acidified with hydrochloric acid, and extracted with ether. Evaporation of the ether left a yellow oil which solidified when rubbed with cold methanol. The product, crystallized from methanol, was almost white. It weighed 0.1 g. and melted at 210°. Methylation of the acid IV or the acetate V also gave VII.

Anal. Calcd. for $C_{13}H_{11}O_5Br$: C, 47.71; H, 3.40; OCH_3, 9.5. Found: C, 47.98; H, 3.63; OCH_3, 9.4.

3 - Carbethoxy - 6 - hydroxy - 5,7 - dimethyl - 3,4 - dihydrocoumarin (VIII).—The ester III (0.2 g.) was dissolved in ethanol (100 cc.) and a palladium catalyst[16] (0.2 g.) was added, and the mixture was shaken for two hours under hydrogen at 42 pounds (2.8 atm.) pressure. The catalyst was removed, the filtrate concentrated under

---

[16] Busch and Stöve, *Ber.*, **49**, 1064 (1916).

reduced pressure and then diluted with water until precipitation started. After standing in the icebox for two hours, the solid was removed and recrystallized from dilute ethanol. The substance formed silvery white needles melting at 142–143°.

Anal. Calcd. for $C_{14}H_{16}O_5$: C, 63.61; H, 6.06. Found: C, 63.31; H, 5.75.

Synthesis of XVII from *p*-Xyloquinone (XIII).—*p*-Xyloquinone (XIII) was prepared in 40% yield by oxidation of pseudocumidine-5 by chromic acid. It was isolated by steam distillation from the reaction mixture. The melting point was 124–125°.[17] Reduction of the quinone by stannous chloride and hydrochloric acid in aqueous alcohol gave the **hydroquinone** in nearly quantitative yield. Crystallized from water, the white needles melted at 215–216°.[18]

1,4-Dimethyl-2,5-dimethoxybenzene (XIV) was obtained in good yield by methylating the hydroquinone in methanol with methyl sulfate and methyl alcoholic potassium hydroxide. The product, steam distilled and crystallized from methanol, melted at 110–111°.[19]

2,5-Dimethyl-3,6-dimethoxybenzaldehyde (XV).—The dimethyl ether XIV (3.1 g.) was dissolved in benzene (200 cc.). Zinc cyanide[20] (4.5 g.) was added, the mixture was strongly cooled and dry hydrogen chloride was passed in with stirring for four hours. At this point aluminum chloride (5 g.) was added, and hydrogen chloride again passed in for eight hours. The temperature was then allowed to rise to 25° and the gas was passed in for twelve hours longer. The reaction mixture was then kept at 60° for eight hours, then allowed to stand overnight at room temperature. The benzene was decanted and the oily solid washed with dry benzene. Dilute hydrochloric acid was added and the mixture was steam distilled. The waxy solid in the distillate was crystallized from dilute methanol. The aldehyde (3 g., 83%) formed yellow needles melting at 59–60°. It could be purified by dissolving it in bisulfite, filtering off any insoluble material and acidifying the filtrate.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 67.99; H, 7.27. Found: C, 67.57; H, 7.09.

The oxime, prepared in the usual way and crystallized from dilute alcohol, formed white needles melting at 118–119°.

Anal. Calcd. for $C_{11}H_{15}O_3N$: C, 63.12; H, 7.23. Found: C, 63.35; H, 7.23.

2,5 - Dimethyl - 3,6 - dimethoxybenzalmalonic Acid (XVI).—The aldehyde XV (1 g.) and malonic acid (0.6 g.) were dissolved in methanol (10 cc.) and piperidine (0.6 g.) was added. After warming for four days at 65°, the reaction mixture was acidified with dilute hydrochloric acid and the solid was removed and crystallized from dilute methanol. It formed white needles, melting at 195° with evolution of a gas and the melt, on cooling, solidified to a bright yellow solid which remelted at about 215° (XVII).

Anal. Calcd. for $C_{14}H_{16}O_6$: C, 59.97; H, 5.76. Found: C, 59.67; H, 5.60.

3 - Carboxy - 6 - methoxy - 5,8 - dimethylcoumarin (XVII).—The coumarin was obtained by fusion of the acid XVI, but it also resulted by prolonged heating of the aldehyde XV (0.1 g.) with malonic acid (0.1 g.) in ethanol (5 cc.) and piperidine. Each day for a period of four days, 3 drops of piperidine was added and the mixture was warmed on the steam-bath for six hours, then allowed to stand overnight. The deep yellow solution was acidified with hydrochloric acid, and the solid was removed and crystallized from dilute methanol. The yellow needles weighed 0.1 g. and melted at 229–230°.

Anal. Calcd. for $C_{13}H_{12}O_5$: C, 62.88; H, 4.87. Found: C, 62.13; H, 4.81.

Synthesis of XX from *m*-Xyloquinone (XVIII).—The quinone XVIII was prepared by oxidation of mesidine[21] in dilute sulfuric acid by chromic acid.[17] The quinone was isolated by steam distillation and ether extraction of the distillate. Crystallized from dilute methanol it formed light orange needles melting at 74–75°. The yield was 40%. Reduced by stannous chloride in hydrochloric acid, the quinone (1 g.) was converted to the hydroquinone (0.9 g.) which, after crystallization from water, melted at 147–148°.[17]

2,4 - Dimethyl - 3,6 - dihydroxybenzaldehyde (XIX).—The aldehyde group was introduced into the hydroquinone by the same procedure as that used for the preparation of the aldehyde XV. The aldehyde, crystallized from dilute methanol, was yellow and melted at 145°. It was soluble in bisulfite solution.

Anal. Calcd. for $C_9H_{10}O_3$: C, 65.09; H, 6.07. Found: C, 65.35; H, 5.93.

3 - Carboxy - 6 - hydroxy - 5,7 - dimethylcoumarin (XX).—The aldehyde XIX (0.1 g.) and malonic acid (0.1 g.) were dissolved in ethanol (5 cc.). Piperidine (3 drops) was added and the mixture was allowed to stand for three days at room temperature. The deep red solution was acidified with dilute hydrochloric acid, precipitating a yellow solid. Crystallized from dilute methanol, this weighed 0.15 g. and melted at 235–236°.

Anal. Calcd. for $C_{12}H_{10}O_5$: C, 61.54; H, 4.30. Found: C, 61.90; H, 4.43.

3 - Carbethoxy - 6 - hydroxy - 5,7 - dimethylcoumarin (XXI).—The coumarin acid XX (0.1 g.) was esterified by refluxing it with dry ethanol (100 cc.) and sulfuric acid (5 drops) for three days. Crystallized from dilute ethanol, the substance melted at 165–166°.

Anal. Calcd. for $C_{14}H_{14}O_5$: C, 64.12; H, 5.38. Found: C, 64.11; H, 5.33.

When hydrolyzed by boiling acetone–hydrochloric acid, the ester XXI gave the acid XX.

3 - Carbethoxy - 6 - hydroxy - 5,7 - dimethyl - 3,4 - dihydrocoumarin (VIII).—When the ester XXI was reduced catalytically using the palladium catalyst, the product was the ester VIII, melting point and mixed melting point 140–143°. Specimens of the ester VIII prepared by two methods gave on oxidation with ferric chloride the coumarin acid XX, melting point and mixed melting point 233°.

---

[17] Nölting and Baumann [*Ber.*, **18**, 1151, 2667 (1885)] reported the melting point as 123–124°.

[18] Conant and Fieser, This Journal, **45**, 2194, 3348 (1923).

[19] Nölting [*Ber.*, **23**, 3251 (1890)] reported the melting point as 108°.

[20] Adams and Levine, This Journal, **45**, 2373 (1923).

[21] The mesidine used for this preparation was prepared by A. C. Keyl from bromomesitylene.

Derivatives of the Magnesium Compound (IX).—The magnesium derivative IX (2 g.) was heated with methanol (20 cc.) and methyl sulfate (5 g.). The hot solution was filtered and the dark yellow filtrate, on cooling, deposited fine yellow needles. Crystallized from acetic acid, the product (X) weighed 0.9 g. and melted at 240–241°.

Anal. Calcd. for $C_{13}H_{13}O_6Br$: C, 45.22; H, 3.80; OCH_3, 9.0. Found: C, 45.75; H, 3.90; OCH_3, 9.7.

The substance X was unchanged after refluxing for three hours with acetone–hydrochloric acid, but when refluxed with acetic acid (15 cc.) and hydrobromic acid (5 cc., 40%), X gave the coumarin acid IV, melting point and mixed melting point 250°. Acetylation of X by warming it with acetic anhydride and a drop of sulfuric acid gave a white substance (XII) which melted at 187–188° after crystallization first from dilute acetic acid and then from methanol. The substance was analyzed but the analysis did not correspond to that required for any simple acetyl derivative of IX.

The yellow acetyl derivative XI resulted when the magnesium compound IX (1 g.) was warmed with pure acetyl chloride (freshly distilled from dimethylaniline). Crystallized from acetic acid, the product formed yellow needles which melted at 231–232°.

Anal. Calcd. for $C_{14}H_{13}O_7Br$: C, 45.04; H, 3.50. Found: C, 45.08; H, 3.87.

When the yellow acetyl derivative XI was methylated by methyl sulfate and methyl alcoholic potassium hydroxide, the product was the methyl derivative VII, melting point and mixed melting point 210°.

Summary

1. Sodium and magnesium ethoxides have been used as condensing agents for the addition of malonic ester to bromopseudocumoquinone leading to the formation of a sodium and a magnesium derivative, respectively.

2. Both metallic derivatives were converted by acids to the same substance, 3-carbethoxy-6-hydroxy-5,7-dimethyl-8-bromocoumarin (III), the structure of which was proved by conversion to the bromine-free coumarin acid (XX) and synthesis of the latter from *m*-xyloquinone.

3. The chemical properties of the coumarin ester III and many of its derivatives have been described.

4. In the reaction with the enolates of malonic ester, the bromine atom of the bromoquinone was unaffected. The quinone behaved as a pentadenol system, the methyl group meta to the bromine atom reacting.

5. The magnesium compound gave rise to two series of derivatives: one identical with the series of derivatives obtained from the sodium compound and the other closely related to, but different from, this series.

6. Starting with *p*-xyloquinone, 3-carboxy-6-methoxy-5,8-dimethylcoumarin (XVII) was synthesized.

The Action of Alkaline Reagents on Diphenylbenzoylbutyrolactone

BY C. F. H. ALLEN, E. E. MASSEY[1] AND R. V. V. NICHOLLS

The γ-lactone ring is usually opened by alkaline reagents with the consequent formation of a salt of a γ-hydroxy acid; upon acidification an equilibrium mixture is formed, which is usually preponderantly in the lactone form. This behavior is exhibited by α,β-diphenyl-γ-benzoylbutyrolactone I, but if the alkaline solution is not acidified immediately it becomes yellow and deposits a mixture of solids and oil when treated with acids. The new substances are obviously secondary products resulting from the action of alkalies on the highly substituted salt obtained on ring opening. The nature of these products varies to some extent with the reagent used, and hence it is convenient to describe separately the action of each basic substance.

The lactone is insoluble in ammonium hydroxide but gradually dissolves in alcoholic ammonia to give a substance, the properties of which are in best agreement with the open chain hydroxy amide structure II. Thus, analysis shows that

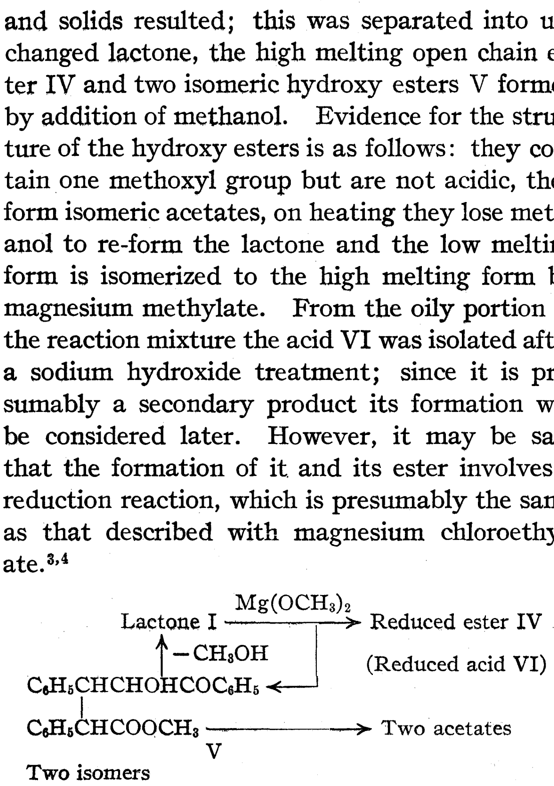
one ammonia has added; recrystallization from glacial acetic acid removes this and re-forms the lactone, while treatment with hydrogen chloride in methanol dehydrates it to the known cyclopropane amide III.[2] The direction of the latter reaction is reversed by concentrated sulfuric acid.

When alcoholic magnesium methylate was allowed to react with the lactone a mixture of oil and solids resulted; this was separated into unchanged lactone, the high melting open chain ester IV and two isomeric hydroxy esters V formed by addition of methanol. Evidence for the structure of the hydroxy esters is as follows: they contain one methoxyl group but are not acidic, they form isomeric acetates, on heating they lose methanol to re-form the lactone and the low melting form is isomerized to the high melting form by magnesium methylate. From the oily portion of the reaction mixture the acid VI was isolated after a sodium hydroxide treatment; since it is presumably a secondary product its formation will be considered later. However, it may be said that the formation of it and its ester involves a reduction reaction, which is presumably the same as that described with magnesium chloroethylate.[3,4]



The action of sodium methylate, alcoholic potash or sodium hydroxide on the lactone was very drastic, and only products of secondary reactions could be identified. These were a cyclopentadienone VII, one isomeric form of the acid VI, diphenylmaleic anhydride, diphenylsuccinic acid, the lactone VIII, benzaldehyde, stilbene and acetophenone. With the exception of the diketone, these substances are the ones that would be expected, taking into account the known action of alkaline reagents on α-hydroxy ketones[5] and hydrolysis. Opening of the lactone ring gives the salt of a hydroxy acid IX; part of this is reduced to the sodium salt of acid VI, and a part isomerized to a δ-hydroxy-γ-ketone X. Hydrolysis of the latter and oxidation would account for the diphenylsuccinic acid. Dehydrogenation of X either before or after reduction would give the salt of the unsaturated acid XI; one of the hydrolysis products of the latter is diphenylmaleic acid. The unsaturated acid XI (not isolated), as will become evident, is the intermediate in a series of reactions between the unsaturated lactone and the diketone. The ease of formation of benzaldehyde by hydrolysis of the several members of this series renders its detection of no significance.

On acidification, the free acids would be expected, though anhydride or lactol formation may occur when the configuration is favorable. Thus, the unsaturated acid XI at once gives the lactol XII, which loses water to form the lactone VIII actually isolated.

When the lactone VIII is dissolved in sodium hydroxide and carefully acidified and manipulated, the lactol XII is separated easily, in spite of the ease with which it loses water.

Both the lactone and lactol were known previously though obtained in another way.[6] By heating in a sealed tube with ammonia the lactone was reported to give a hydroxy amide XIII and lactam XIV and this was confirmed, as was the reduction by hydrogen iodide to give the 1,2-diphenyl-3-benzylcrotolactone XVI. The latter was also obtained in this paper by the action of zinc and acetic acid. The action of alkalies on the lactone is intimately connected with the diketone VII and is considered below.

The principal product (35%), resulting from the action of sodium methylate on lactone I is the bright yellow unsaturated 1,3-diketone VII. Its deep purple alkaline solutions are hydrolyzed very slowly and the products, after acidification, are the lactone VIII, diphenylmaleic anhydride and benzaldehyde; the last two are formed from the lactone VIII on similar treatment. Further evidence that the lactone and diketone are easily intraconvertible in alkaline solution is given by the fact that the same hydroxy amide XIII and lactam XIV are obtained from both by use of ammonia in a sealed tube. Hence the carbon chain and location of phenyl groups must be unchanged. Reduction of the diketone by zinc dust or hydriodic acid gives α,β-diphenyl-γ-benzal-

(4) It was important to know with certainty the structure of the hydroxy esters, since a single instance is recorded where a saturated lactone ring has been opened in the opposite way; butyrolactone and sodium ethylate give γ-ethoxybutyric acid and a dilactone. It may be a coincidence, but the b. p. of both γ-ethoxy- and γ-hydroxybutyric acids are the same, 231° [Fittig and Strom, *Ann.*, **267**, 191 (1892)].

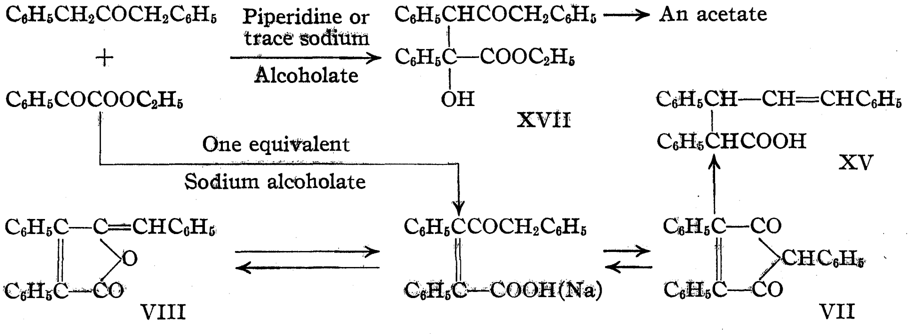
butyric acid XV, confirming the chain. It gives a mono-2,4-dinitrophenylhydrazone but does not form a quinoxaline. In the Grignard machine it shows one active hydrogen and gives slowly two additions. These reactions suggest the structure of a 1,3-diketone, and this was confirmed by a synthesis that also gave the unsaturated lactone VIII.



Dibenzyl ketone readily adds to benzoylformic ester in the presence of piperidine or a trace of sodium alcoholate at room temperature, but if the mixture is heated in the presence of an equivalent of alcoholate, water is eliminated and the product isolated depends on operating conditions; the use of sodium methylate favors the diketone, whereas with sodium ethylate the lactone or lactol XII (as sodium salt) separates during the heating, owing to insolubility. It cannot be said with certainty that the ester XVII is an intermediate product, because it is not converted into the other substances by sodium alcoholates.

The diketone is oxidized by permanganate to benzaldehyde, benzoic acid and carbon dioxide; chromic acid gives benzoic acid and a bimolecular product, while selenium dioxide forms the latter quantitatively. Though the diketone can be sublimed and is stable in air for a short time at the melting point, it is readily oxidized by atmospheric oxygen at this temperature to the bimolecular product. Mineral acids are without action at room temperature but destroy it at 100°. Hydrogen peroxide adds an atom of oxygen. The structure of the new derivative was not determined; it is altered by acetyl chloride, but the result is neither dehydration nor esterification. Other properties are recorded in the experimental part.

A comparison of the highly phenylated keto-hydroxy acid described in this paper with those previously known shows that the introduction of an additional phenyl has greatly increased the reactivity of the various groups. The most conspicuous differences are the facilitation of cleavage, the occurrence of dehydrogenation products and the tendency for the unsaturated lactone obtained to isomerize to a cyclic diketone. It is believed that the latter is the first representative of a new series.

Experimental

The bromination of a variety of δ-ketonic esters and the properties of the products has been well described[7] and there was no difficulty in adapting the procedure to the synthesis of methyl α,β-diphenyl-γ-benzoylbutyrate IV. The mixture of stereoisomers obtained by the addition of methyl phenylacetate to benzalacetophenone was used without separation, since all the bromo esters gave the lactone I as the principal product. The position of the bromine atom was thus made evident, the four monobromo substitution products being γ-bromo esters XVIII; their interrelation was shown by treatment with hydrogen bromide in acetic acid. Pyrolysis of the bromo esters gave the expected variety of substances. Thus, when methyl bromide was evolved[7a,c,8] the lactone resulted, but loss of hydrogen bromide[7,9] gave the reduced ester IV, the stereoisomeric acids VI, and a trace of what may be diketo acid.[10]

A. Preparation and Properties of the Lactone I.—1. Methyl α,β-diphenyl-γ-benzoylbutyrate IV was obtained by the addition of methyl phenylacetate[12] to benzalacetophenone in the presence of slightly over one equivalent of sodium methylate.[10] Since it was found unnecessary to use the separated bromo esters in a subsequent step, the mixture of esters, after recrystallization from benzene to remove some insoluble acid, was brominated directly. This gave four monobromo substitution products, m. p. 120, 147, 158 and 176°.

Seventy grams of the mixed keto ester was suspended in 400 cc. of carbon tetrachloride or glacial acetic acid, a few cc. of bromine added and the whole warmed in sunlight until the reaction commenced. Then the remainder of the bromine (total = 32 g.) was added slowly, during which time the suspended ester gradually dissolved. The thick, pasty solid that separated on cooling was filtered, washed and dried. The separation into the stereoisomeric forms involved a tedious fractionation, using ethyl acetate and methanol. The 176° isomer is isolated easily owing to its insolubility but the 158° isomer is the principal product; a constant melting (125°) mixture of the 158 and 147° isomers complicated the fractionation. When pure high melting ester (178°) was used, the yield of the 158° isomer was 60% if the bromination was done in acetic acid, but only 40% in carbon tetrachloride; this ester does not give the 176 or 120° forms.

The 176° form is sparingly soluble in all solvents; it separated in prisms from ethyl acetate. The other forms are moderately to very soluble in all solvents except petroleum ether. The 158° isomer separated from ethyl acetate in rods, and the other two from methanol as fine needles.

Anal. Calcd. for $C_{24}H_{21}O_3Br$: Br, 18.3. Found: (176°, 120°) 18.5; (158°) 18.2; (147°) 18.9.

One gram of each isomer in acetic acid was saturated with hydrogen bromide and worked up after three days. The 158 and 176° isomers were unchanged, but the 147° had completely isomerized to the 158° form and the 120°

[10] The relation between the acids and esters is known from Avery's work, THIS JOURNAL, **52**, 3628 (1930).

[11] DNPH = 2,4-dinitrophenylhydrazone.

[12] We are grateful to Compagnie Parento Limited for the gift of a quantity of this ester.

to the 176° form. This is in agreement with the fact that only the 158 and 176° isomers are readily obtained.

The lactone I was most conveniently prepared from the mixed bromo esters by refluxing for two hours a mixture of 20 g. of the latter, an equal weight of potassium acetate and 100 cc. of glacial acetic acid; potassium bromide separated fairly rapidly. After pouring into water, the lactone was isolated by appropriate manipulations; the average yield of once recrystallized product was 65%. The filtrate contained considerable amounts of reddish oils and gums, with traces of lactone. The use of pyridine and dimethylaniline for an hour gave the same product but isolation was more laborious.

α,β-Diphenyl-γ-benzoylbutyrolactone is very soluble in benzene and chloroform, slightly soluble in the alcohols and ether, insoluble in petroleum ether, but moderately soluble in the other usual solvents. It is conveniently recrystallized from *n*-butanol or a chloroform–methanol mixture, from which it separates as rods, m. p. 157°.

Anal. Calcd. for $C_{24}H_{18}O_3$: C, 80.7; H, 5.0. Found: C, 80.8; H, 5.2.

A Zeisel determination was negative. In the Grignard machine it showed no active hydrogen, but gave two additions.

Pyrolysis of the pure bromo esters gave mixtures of products consisting of the reduced keto esters, the corresponding keto acids, the lactone and traces of what is probably a diketo acid. The 176° isomer gave the lactone nearly quantitatively; the methyl bromide (80% yield) evolved was collected in a freezing mixture. The diketo acid separated from methanol in long rods, m. p. 160°.

Anal. Calcd. for $C_{23}H_{18}O_4$: C, 77.1; H, 5.0. Found: C, 76.6, 76.7, 77.1; H, 4.4, 4.5, 4.3.

The phenylhydrazone (C; pale yellow cubes from ethanol m. p. 180°) and 2,4-dinitrophenylhydrazone (A; yellow prisms from methanol m. p. 210°) were prepared in the usual manner.

Anal. Calcd. for (A); $C_{29}H_{22}O_6N_4$: N, 10.7; for (C) $C_{29}H_{24}O_2N_2$: N, 6.5. Found: N; (A) 10.5; (C) 6.6.

2. **Reduction.**—The lactone was reduced by zinc and acetic acid to the low melting open-chain acid VI, but by hydrogen bromide to the high melting isomer. In the latter case the γ-bromoketo acid corresponding to the ester XVIII was presumably formed as an intermediate product; the reduction of α-bromo ketones by hydrogen bromide is well known.[13]

A mixture of 10 g. of the lactone, 20 g. of zinc dust and 100 cc. of glacial acetic acid was boiled for two hours, poured into water, and the precipitated solid filtered and recrystallized from acetone. It was identified as the low melting form (187°) of the acid VI by a mixed melting point, and conversion into the corresponding ester (155°). The same acid resulted if methanol was used as a solvent.

The lactone was unchanged after twenty-four hours of standing at room temperature in methanol, or after a week in chloroform or acetic acid, each saturated with hydrogen bromide, as well as after refluxing for two hours in acetic acid solution through which hydrogen bromide was passed. However, when 1 g. in 25 cc. of acetic acid, saturated with hydrogen bromide at room temperature, was heated in a sealed tube at 100° for eight hours it gave as the single product the high melting form (261°) of the acid VI, identified by mixed melting point and conversion into the ester (178°).

3. **Action of Ammonia: α,β-Diphenyl-γ-hydroxy-γ-benzoylbutyramide II.**—A suspension of 10 g. of the lactone in 125 cc. of absolute ethanol was saturated with dry ammonia; most of the solid dissolved. The supernatant liquid was decanted and left in a closed flask overnight; fine needles separated in a nearly quantitative amount. The amide melts with decomposition at about 202°, and after a few minutes at 205° all the ammonia has been evolved and the lactone re-formed. Recrystallization from glacial acetic acid, or heating with phosphorus pentoxide in xylene, also removes the ammonia.

Anal. Calcd. for $C_{23}H_{21}O_3N$: C, 76.8; H, 5.8; N, 3.9. Found: C, 76.0, 76.1; H, 5.5, 5.5; N, 3.7.

The cyclopropane III resulted when an absolute alcoholic solution of the amide, saturated with hydrogen chloride, was allowed to stand for a day. On recrystallization from a methanol–chloroform mixture it formed rods, m. p. 179°; a mixed melting point with an authentic specimen[2] was not depressed, and on dehydration it gave the cyclic nitrile, m. p. 166°. When dissolved in acetic anhydride containing a trace of sulfuric acid, and poured upon ice and sodium carbonate, the cyclic amide gave an oil, which, on long standing, became solid and proved to be the hydroxyamide.[14]

4. **Action of Magnesium Methylate; Methyl α,β-Diphenyl-γ-hydroxy-γ-benzoylbutyrate V.**—The magnesium methylate from 5 g. of magnesium and 80 cc. of methanol, and 25 g. of the lactone were shaken mechanically for an hour at room temperature and decomposed by pouring upon 400 g. of ice and 25 cc. of concd. hydrochloric acid. The pale yellow, oily solid was separated by the usual manipulations into a yellow oil and 6 g. of the 178° keto ester. After standing for several days, 1 g. of the hydroxy ester (180°) had separated and after several more days, 8 g. of the 118° isomer was collected. When the time of contact with the magnesium methylate was short, the quantity of the latter ester was higher, but if prolonged, more of the high melting isomer was found. The low melting form was isomerized to the other by fifteen minutes of shaking with cold magnesium methylate but the 180° variety was unchanged by this reagent. From the residual oils were isolated high melting ketoacid, unchanged lactone, and benzaldehyde. Sodium methylate brought about removal of alcohol and reformation of the lactone.

The esters were recrystallized from methanol, from which they separated as fine rods, melting at 180 and 118°.

Anal. Calcd. for $C_{24}H_{22}O_4$: C, 77.0; H, 7.9; OCH_3, 8.3. Found: (180°) C, 76.8, 76.8; H, 7.8, 7.8; OCH_3, 8.6; (118°) C, 76.6, 76.5; H, 7.6, 7.7; OCH_3, 8.4, 8.5.

Reactions.—(a) The esters were heated in an apparatus arranged to sweep out and condense any gas formed. At 190°, each ester evolved methanol (identified as the 3,5-dinitrobenzoate) and left the lactone as a residue. (b) On treatment of the high melting form in boiling methanol

---

[13] Kröhnke and Timmler, *Ber.*, **69**, 614 (1936).

[14] The "stereoisomeric amide"[2] (p. 161) is really this hydroxyamide; thus there is a little ring opening of the cyclopropane by sulfuric acid.

with 2,4-dinitrophenylhydrazine and a little hydrochloric acid, and allowing to stand, bright red rods of a dinitrophenylhydrazone (B) separated and were filtered; the filtrate then deposited yellow leaflets, the dinitrophenylhydrazine (A) of the lactone. Under the same conditions, the 118° ester gave only derivative A. When a chloroform solution of B containing a little hydrogen chloride was refluxed, the substance was converted into A, whereas in methanol A was partially converted into B. The derivative B crystallized from methanol in red rods, m. p. 224°.

Anal. Calcd. for $C_{30}H_{26}O_7N_4$: N, 10.1. Found: N, 10.0, 9.9.

(c) The acetate of the 180° ester was obtained by allowing an acetyl chloride solution of the ester to evaporate spontaneously after standing for sixteen hours, but it was necessary to reflux the 118° form for four hours to get the derivative. Both were recrystallized from methanol. The acetate of the 180° ester formed rods, m. p. 145°, while its isomer separated in rosets of rods, m. p. 132°.

Anal. Calcd. for $C_{26}H_{24}O_5$: C, 75.0; H, 5.8; OCH_3, 7.4. Found: C, 74.8, 74.7; H, 5.8, 5.9; OCH_3, 7.5.

5. Action of Sodium Methylate. (a) 2,4,5-Triphenyl-1,3-diketocyclopentene-4, VII.—A suspension of 20 g. of the lactone in 300 cc. of methanol, containing the methylate from 4 g. of sodium, was shaken for ten hours when all had dissolved. The dark brown solution was decomposed by adding to dilute acetic acid and the semi-solid mass that separated was filtered. After trituration with methanol the bright yellow solid that remained undissolved was filtered, and recrystallized from a 2:1 methanol–chloroform mixture. It formed fine, yellow rods, m. p. 166°; the yield was 6.5 g. or 32%. It was not found when sodium or potassium hydroxide was used instead of sodium methylate. A Zeisel determination was negative.

Anal. Calcd. for $C_{23}H_{16}O_2$: C, 85.2; H, 4.9. Found: C, 85.3, 85.4; H, 5.1, 5.3.

(b) Other Products.—After several months of standing, the only other solid that had separated was unchanged lactone, so a chloroform solution of the oil was submitted to a systematic extraction with sodium bicarbonate, potassium carbonate, copper acetate and sodium hydroxide, and then given a water wash. Nothing was obtained from the potassium carbonate or copper acetate, but the substances listed were found as indicated: (1) from the bicarbonate, the high melting acid VI and diphenylmaleic anhydride; (2) from the sodium hydroxide, high melting form of diphenylsuccinic acid; (3) from the final water wash, the lactone VIII; (4) by steam distillation of the residual oil, benzaldehyde. The oil gave no phenylhydrazone or phenacyl ester. It decomposed badly on attempted vacuum distillation; from the distillate were isolated benzoic acid, acetophenone and stilbene, obviously decomposition products. An unexplained phenomenon was the production of a green color in the chloroform during the sodium hydroxide wash, while the latter became orange. When the green solution was washed with water, the latter became green and the chloroform turned yellow. On greatly diluting the wash water, the unsaturated lactone VIII separated. On acidifying this basic solution, a thick yellow oil was obtained, but beyond noting its lactonic nature (insoluble in carbonates, soluble in hydroxides) nothing definite was learned.

The identification of each substance was assured by comparison with authentic specimens at hand or prepared by directions in the literature; *e. g.*, diphenylmaleic anhydride, m. p. 154°,[15] the unsaturated lactone VIII, m. p. 175°,[6] and diphenylsuccinic acid, m. p. 229°.[15b]

B. Reactions of the Unsaturated Lactone VIII.—For further identification, and for purposes of obtaining reference samples, the action of ammonia to form a hydroxy amide XIII, m. p. 199–201° dec., and a lactam XIV, m. p. 241°, reduction by hydrogen iodide to give α,β-diphenyl-γ-benzylcrotolactone XVI, m. p. 127–128°,[6] and alkaline fusion to give the lactol XII, m. p. 181°, were repeated and confirmed. The drastic procedure in the latter reaction is unnecessary; one only needs to acidify the solution of the sodium salt at room temperature with dilute acetic acid and recrystallize from this reagent, to obtain the lactol at will. To dehydrate, it may be recrystallized from anhydrous solvents—the phosphorus oxychloride treatment is unnecessary.

The new reactions determined were reduction by zinc and acetic acid (one hour) which gave the dihydro derivative XVI, hydration and dehydration, just described, and the action of alkaline solutions.

(1) A solution of 2 g. of the lactone in 30 cc. of absolute alcohol containing 0.4 g. of potassium hydroxide was refluxed for twenty-four hours and the mixture distilled with steam. The distillate contained benzaldehyde, which was identified as the phenylhydrazone (0.05 g., m. p. 156°). After acidification to remove the reagent, the distillate was shaken with ether, to remove toluene, if present, but nothing was found in the extract. From the residual solution in the steam distillation flask, 0.8 g. of unchanged lactone was recovered, and, on adding acetic acid, 0.6 g. of diphenylmaleic anhydride was obtained.

(2) A similar solution containing an equivalent of sodium ethylate turned purple on an hour's boiling and the diketone VII was isolated after acidification. On shaking 1 g. of the lactone with 15 cc. of absolute methanol containing 9.2 g. of sodium for ten hours, the solution became purple, but 0.65 g. of lactone was still undissolved. From the colored solution, 0.25 g. of the diketone was isolated on acidification.

C. Reactions of the Diketone VII.—In the Grignard machine, the diketone evolved one equivalent of methane and slowly consumed three moles of reagent.

(1) The 2,4-dinitrophenylhydrazone was prepared in the usual manner; it separated from a methanol–chloroform mixture in fine, orange needles, m. p. 235°.

Anal. Calcd. for $C_{29}H_{20}O_5N_4$: N, 11.1. Found: N, 11.1, 11.1.

(2) Alkaline Reagents.—The diketone dissolves in alcoholic sodium or potassium hydroxide and in alcoholates, producing a deep purple color, and is recovered on acidification. After prolonged refluxing (twenty-four hours) as in (1) above, it gave the same products.

(3) Alcoholic Ammonia.—A mixture of 1 g. of the diketone and 15 cc. of alcohol was saturated with ammonia at 0° and heated at 100° in a sealed tube for six hours. The initially formed deep purple color changed to brown. On

(15) Reimer, (a) *Ber.*, **13**, 742 (1880); (b) *ibid.*, **14**, 1802 (1881).

opening, crystals of the lactam XIV were filtered, and on concentrating the solution and decoloring by Nuchar, a mixture of the hydroxy amide XIII and lactam separated; they were identical with the specimens prepared above. Meyer[16] has made an extensive study of the action of ammonia on a variety of lactones and in no case was an amino acid obtained, but only hydroxy amides or lactams.

(4) Reduction; α,β-Diphenyl-γ-benzalbutyric Acid XV.—(a) A mixture of 10 g. of the diketone, 200 cc. of acetic acid and 20 g. of zinc dust was refluxed for a half hour; the yellow color had disappeared after ten minutes. It was filtered into 400 cc. of water and the precipitated acid collected; 9 g. was obtained after one recrystallization from methanol. It forms white needles, m. p. 204–205°.

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.1; H, 6.0; mol. wt., 328. Found: C, 83.9; H, 5.8; mol. wt., 345.

(b) A mixture of 2 g. of the diketone, 1 g. of red phosphorus and 10 cc. of constant boiling hydriodic acid was refluxed for two hours and decanted from the resinous deposit. The latter was treated by sodium bisulfite several times and then the organic material extracted with hot methanol and worked up as above; the same acid resulted. It was soluble in aqueous carbonate and recovered unchanged on acidification. An acetone solution instantly decolorized permanganate, and a chloroform solution instantly added bromine. It did not give a carbonyl derivative.

(c) The chromic acid oxidation was performed in acetic acid in the usual manner; the isolation of diphenylsuccinic acid was difficult, owing to the unfavorable nature of the material. It was eventually purified and shown to be the high melting isomeric form of diphenylsuccinic acid by melting and mixed melting point (229°). A permanganate oxidation was carried out in such a way that the benzaldehyde could be distilled as formed; identification was made through the phenylhydrazone. From the residual solution the same diphenylsuccinic acid was isolated.

(5) Oxidation. (a) The Bimolecular Product.—To a solution of 0.4 g. of selenium dioxide in 15 cc. of boiling dioxane was added 1 g. of the diketone and the whole refluxed with stirring for one and one-half hours. After filtering, the solution was poured into water, ammonium chloride added to hasten coagulation and the solid filtered. It was recrystallized from chloroform–methanol, and formed microscopic yellow prisms, m. p. 247°; the yield was nearly quantitative.

Anal. Calcd. for $C_{46}H_{30}O_4$: C, 85.6; H, 5.3; mol. wt., 646. Found: C, 85.0; H, 5.1; mol. wt., 716.

The same substance was obtained, along with benzoic acid, by the action of chromic acid, with benzaldehyde and unreacted lactone from dilute sulfuric acid at water-bath temperature, and from the mixture resulting on ozonization in ethyl bromide. Permanganate, however, destroyed the molecule completely, giving benzaldehyde, benzoic acid and carbon dioxide. Dilute nitric acid gave oils and a little *p*-nitrobenzoic acid. Potassium hypobromite was without action.

(b) Hydrogen Peroxide Product.—To a solution of 0.5 g. of the diketone in 15 cc. of acetone, 10 cc. of 30% hydrogen peroxide was added; this precipitated the diketone. A 10% solution of potassium hydroxide was then added, dropwise from a buret, each drop being admitted only after the deep purple coloration was discharged by shaking; this took 0.3 cc. and a period of an hour. A yellow precipitate (0.3 g.) was filtered and recrystallized from methanol; it formed yellow prisms, m. p. 185°.

Anal. Calcd. for $C_{23}H_{16}O_3$: C, 81.2; H, 4.7; mol. wt., 340. Found: C, 81.0, 81.2; H, 4.5, 4.5; mol. wt., 372.

The new substance is soluble in warm, aqueous sodium hydroxide, does not decolorize bromine and is unaffected by hydrogen chloride in acetic acid. It did not give a dinitrophenylhydrazone.

A solution in acetyl chloride gave a new yellow solid on evaporation, which separated from methanol–chloroform in rods, m. p. 155°.

Anal. Found: C, 80.0, 79.8; H, 4.9, 4.8.

A Zeisel determination was negative; it did not contain halogen. The composition shows fair agreement with $C_{50}H_{34}O_7$, a diacetate of a dehydrated bimolecular product.

D. Synthesis.—To a warm solution of 6.1 g. of dibenzyl ketone and 5 g. of ethyl benzoylformate in 15 cc. of absolute alcohol was added the freshly prepared sodium ethylate from 0.6 g. of sodium and 15 cc. of alcohol (absence of water is essential) and the solution refluxed. It at once became deep yellow and after fifteen minutes a solid began to separate.[17] After an hour it was acidified with acetic acid and the pale yellow lactone filtered; the average yield of several runs was 3 g. or 27%. It was best recrystallized from *n*-propanol. By acidifying with diluted acid, the lactol could be isolated. When the same amounts of reactants were taken but in methanol, using enough of the latter to keep everything in solution, a deep purple color was noted and after two hours of acidification gave the diketone in a 40% yield. With larger quantities an excess of sodium methylate is advisable.

With the same amounts but 0.5 g. of piperidine or a trace of sodium ethylate as a catalyst, white needles of the ester XVII shortly separated. The first crop weighed 3.5 g., and on standing and evaporation, successive amounts were obtained. It recrystallized from ethanol in fine needles, m. p. 128°.

Anal. Calcd. for $C_{25}H_{24}O_4$: C, 77.3; H, 6.2; OC_2H_5, 11.6. Found: C, 77.0, 69.9; H, 6.0, 5.1; OC_2H_5, 11.4, 11.7.

This ester gave only oils with alcoholates.

After refluxing for four hours with acetyl chloride, an acetate resulted; this was very soluble in the usual solvents. It separated from methanol in rods of m. p. 101°.

Anal. Calcd. for $C_{27}H_{26}O_5$: C, 75.3; H, 6.0. Found: C, 75.1, 75.1; H, 6.0, 6.1.

(6) Other Reagents.—The lactone was unaffected by ozone and only slightly attacked by chromic acid. Bromine was decolorized very slowly, with some evolution of hydrogen bromide; 40% of the lactone was recovered, while the remainder of the reaction product was a sticky gum.

This work has been assisted by a generous grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

---

[16] Meyer, *Monatsh.*, **20**, 717 (1899).

[17] The white sodium salt sometimes separated if the amount of solvent was less.

Summary

1. When dissolved in alkaline solutions, α,β-diphenyl-γ-butyrolactone undergoes a diversified series of reactions, involving oxidation and reduction, cleavage and hydrolysis.

2. Among new products are a pair of stereoisomeric ketohydroxyesters and a highly phenylated cyclopentadienone.

3. The latter is capable of a great variety of reactions; in general, it shows a marked resemblance to 2-phenylindandione-1,3.

Gamma-Benzoylbutyronitrile

BY C. F. H. ALLEN AND W. L. BALL

Up to the present time all δ-ketonic nitriles (I) investigated have been highly substituted[1]

$$\begin{matrix} RCHCH_2COR \\ | \\ RCHCN \end{matrix} \qquad \begin{matrix} CH_2CH_2COC_6H_5 \\ | \\ CH_2CN \end{matrix}$$

I II

Therefore it was of interest to prepare the simplest member of the series, γ-benzoylbutyronitrile (II), and compare its properties with those of the more complex homologs.

There are several series of reactions that might be expected to yield the desired nitrile, but those that seemed to involve the fewest steps and utilize readily available materials gave other products. Thus, the action of potassium or cuprous cyanide on γ-chlorobutyrophenone was to remove hydrogen chloride, giving an excellent yield of benzoylcyclopropane.[2]

$$ClCH_2CH_2CH_2COC_6H_5 \longrightarrow \underbrace{CH_2\text{——}CHCOC_6H_5}_{\diagdown CH_2 \diagup}$$

The nitrile was finally obtained by dehydration of the corresponding amide (III) in a particular manner; the amide was secured from γ-benzoylbutyric acid by the following series of reactions

$$C_6H_5COCH_2CH_2CH_2COOH \longrightarrow$$
$$C_6H_5COCH_2CH_2CH_2COOCH_3 \xrightarrow{NH_3}$$
$$C_6H_5COCH_2CH_2CH_2CONH_2{\cdot}NH_3 \longrightarrow$$
$$C_6H_5COCH_2CH_2CH_2CONH_2$$

Kugel[3] prepared the lower homolog, β-benzoylpropionamide, in a similar manner, though Biedermann[4] had obtained cyclic compounds by a like procedure. Our results resembled those of Kugel and will be described in the experimental part.

The nitrile forms carbonyl derivatives and is very easily hydrolyzed to γ-benzoylbutyric acid; it is possible to arrest the hydrolysis at the intermediate amide stage. It reacts with bromine with immediate evolution of hydrogen bromide; most of the reaction product is an untractable oil, but a small amount of 2-phenyl-α-pyridone (VI) can be isolated.

The two characteristic properties of δ-ketonic nitriles are isomerization to a tetrahydropyridine (through the amide) on treatment with mineral acids in indifferent media, and the formation of 2-bromopyridines on bromination in acetic acid.[1a] As mentioned above, it was not possible to determine completely the course of bromination of γ-benzoylbutyronitrile. The formation of the 2-phenylpyridone is probably best explained as follows: the nitrile is isomerized to the cyclic isomer by some of the hydrogen bromide evolved, the hydropyridine then being dehydrogenated to the pyridone by bromine in the usual manner.[1a] This mechanism could not be confirmed, since no pyridone resulted when the pure cyclic substance was brominated in a similar manner.

All attempts at isomerization gave either the amide or the acid; this is not a real difference because it has been shown that the hydropyridine formation proceeds through the amide.[1b] The reactions are thus essentially the same as with the substituted homologs, but owing to less favorable physical properties, all the products cannot be determined.

The isomeric tetrahydropyridine (V) can be obtained in a variety of ways; in fact, it is usually obtained by reactions that might be expected to yield the nitrile, *e. g.*, dehydration of the amide

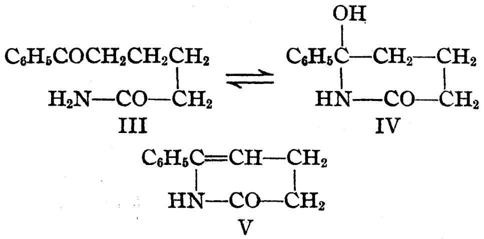
[4] Biedermann, *Ber.*, **24**, 4074 (1891).

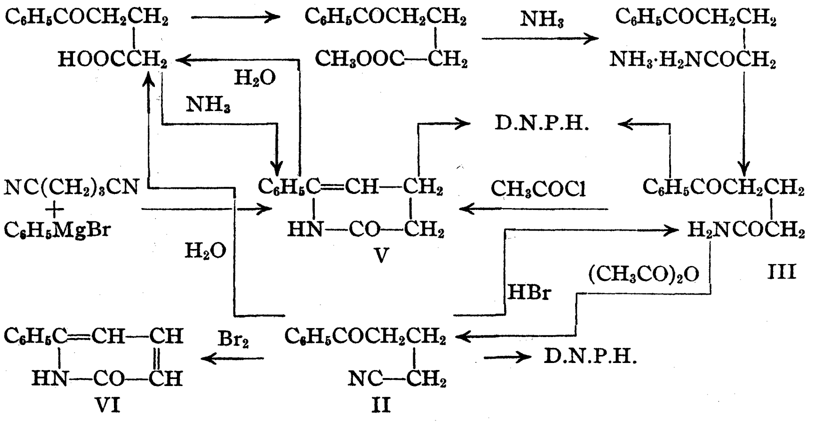
by the use of acetyl chloride or by heating alone, or from the reaction between phenylmagnesium bromide and glutaronitrile. The relative ease of formation may indicate that the amide exists as one component of a tautomeric mixture (III $\rightleftharpoons$ IV)



In the case of other delta ketonic amides, the available evidence points to their existence only in the cyclic form.[1b,5]

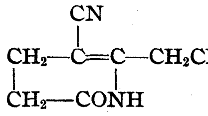
The reactions of the cyclic form (V) are in accordance with the structure written. Thus, acid hydrolysis leads to γ-benzoylbutyric acid. It decolorizes bromine instantly; after about two-thirds of the calculated amount of bromine has been added, hydrogen bromide begins to be evolved. A bromide–bromate titration shows one double bond. When treated with 2,4-dinitrophenylhydrazine in the usual manner (acid solution) the ring is opened with addition of a molecule of water, and the dinitrophenylhydrazone of the amide is obtained.

These reactions are conveniently summarized in the flow-sheet.



D.N.P.H. = 2,4-Dinitrophenylhydrazone.

Bruylants[6] has examined the action of several Grignard reagents on glutaronitrile and, among the numerous products, found substances which he believed to be open chain δ-ketonic nitriles; thus, he wrote structure (II) for the substance obtained when phenylmagnesium bromide was used. We have repeated the reaction following Bruylants' directions and isolated the product having the properties[7] as described, and found it to be identical with (V), the cyclic isomer of (II). It is easy to understand the confusion, for both give the same hydrolysis product and react with bromine, the tests employed by Bruylants; the differences on bromination would hardly be noticed unless one were expecting them. Aliphatic Grignard reagents brought about condensation, and gave, as the principal product, a substance $C_{10}H_{11}ON_3$, for which he wrote an open chain keto-trinitrile structure; from the available data, supplemented by the results just mentioned, it probably should have the ring formula (VII).



VII

Experimental

A. Action of Ammonia on Methyl γ-Benzoylbutyrate; γ-Benzoylbutyramide, III.—Cyclopentanone was oxidized to glutaric acid by 50% nitric acid;[8] the latter was dehydrated by acetic anhydride[9] and converted into γ-benzoylbutyric acid by the Friedel–Crafts reaction.[10] A mixture of 5 g. of the methyl ester,[11] 10 cc. of alcohol and 50 cc. of concd. ammonium hydroxide were shaken mechanically for four hours, and the solvent allowed to evaporate; a solid of m. p. 110–125° separated. A similar product resulted after spontaneous evaporation of a solution of 25 g. of the ester in 75 cc. of alcohol that had been saturated with ammonia. This solid was dissolved in a slight excess of a warm 1:1 mixture of chloroform and ether; on cooling, white needles, m. p. 118–120°, separated from a purple solution. Two recrystallizations from benzene raised the melting point to 120–121°. By continued reworking of all filtrates, additional amounts of solid of varying degrees of homogeneity resulted.

[11] Allen and Cressman, THIS JOURNAL, **55**, 2953 (1933).

This substance was unstable; after standing overnight the melting point became much less sharp. It evolved ammonia on being heated; it decolorized bromine and permanganate on warming with the reagents in appropriate solvents. It dissolved in warm chloroform, carbon tetrachloride, and benzene to give a reddish solution; if not cooled at once, a colorless solid, m. p. 140–142°, separated; treatment with boiling water gave this same substance. This was the amide III, which, when pure, formed flat rods, m. p. 144°. The amide was also obtained from the purple melt of the 120° solid, and from the various oily by-products by repeating the ammonia treatment, dissolving the dark oil in benzene and decolorizing with charcoal. The total yield was thus raised to 70%.

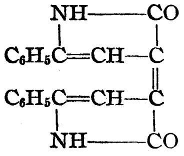
Anal. Calcd. for the ammonia addition product: (a), $C_{11}H_{16}O_2N_2$: C, 63.5; H, 7.7; N, 13.5; for the amide III, $C_{11}H_{13}O_2N$: C, 69.1; H, 6.8; N, 7.3. Found: (A), C, 63.9; H, 7.6; N, 13.8; (III) C, 69.4; H, 6.8; N, 7.3.

The amide was hydrolyzed easily to γ-benzoylbutyric acid. The 2,4-nitrophenylhydrazone of the amide was prepared in the usual manner; it separated from a methanol–ethyl acetate mixture in clusters of orange rods having square ends, m. p. 195–196°.

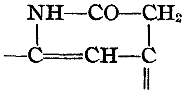
Anal. Calcd. for $C_{17}H_{17}O_5N_5$: N, 18.8. Found: N, 18.6.

A mixed melting point with the reagent (m. p. 198°) was depressed 20°.

With a view to securing a higher yield in the alcohol–ammonia method, the saturated solution was allowed to stand for three weeks; it became a deep red, then purple. A small amount of a black, crystalline solid was removed; from the solution a poor yield of amide and ammonia addition product were separated. The black solid did not melt below 320°, but sublimed in brown fumes when heated on porcelain. It gave a blue solution in concd. sulfuric acid, being precipitated unchanged on dilution, but dissolved to a colorless solution in sodium hydroxide. In all its properties it resembles Kugel's product obtained from ammonia and ethyl β-benzoylpropionate[3] for which he wrote the structure VIII.



VIII



IX

By analogy, our substance would be the homolog IX; it was not investigated further.

B. γ-Benzoylbutyronitrile, II.—A solution of 5 g. of the amide in 25 cc. of acetic anhydride was unchanged after being allowed to stand overnight, but on refluxing an hour and distilling *in vacuo*, an oil, b. p. 135–140°, at 10 mm., was obtained; this solidified on standing, only if a pure amide had been used. The yield was 3.5 to 4.9 g. (82–94%); it is very soluble in the usual solvents. It formed plates, m. p. 38°.

Anal. Calcd. for $C_{11}H_{11}ON$: C, 76.3; H, 6.4. Found: C, 76.2, 76.0; H, 6.4, 6.5.

The 2,4-dinitrophenylhydrazone separated as red-brown plates from (1:2) alcohol–ethyl acetate, m. p. 173–175°.

Anal. Calcd. for $C_{17}H_{15}O_4N_5$: N, 19.9. Found: N, 19.5.

The semicarbazone, prepared in the usual way, separated from chloroform as plates, m. p. 176–177°. It is only sparingly soluble in alcohol.

Anal. Calcd. for $C_{12}H_{14}ON_4$: N, 24.3. Found: N, 24.1.

The nitrile was easily hydrolyzed to γ-benzoylbutyric acid in moist solvents in the presence of acid. When a solution in chloroform (that had been dried with calcium chloride) was saturated with hydrogen bromide and allowed to stand overnight, a brownish paste remained as the green solution evaporated. When this was washed with dry ether, a white solid (m. p. 205–210°—a red liquid) that could not be purified, remained; treatment with alcohol or acetic acid gave γ-benzoylbutyric acid. If the white residue was dissolved in absolute alcohol containing freshly fused potassium acetate, and evaporated to dryness, the benzene extract deposited the amide III. The properties of the white substance agree with those of an "imide bromide."

Bromination is described in section D.

C. 2-Keto-6-phenyl-1,2,3,4-tetrahydropyridine, V.—This substance was obtained in several ways. The purest product resulted on refluxing an acetyl chloride solution of the amide for a half hour, filtering the solid, and washing it with dry ether. On vacuum distillation, the oily residue gave a further quantity. The properties agreed with those given by Bruylants[6] but repeated recrystallization of crude material was necessary to get a pure substance; dry benzene or carbon tetrachloride was found preferable to alcohol.

The cyclic compound was also obtained in the following ways, the identification in each case being by mixed melting point and comparable behavior in solvents: (a) when the amide was heated alone, the melt changed colors, blue, red, brown; the residue was taken up in alcohol and decolorized by charcoal; (b) dry ammonia was passed through molten γ-benzoylbutyric acid at 160–170° for nine hours;[12] (c) by repetition of Bruylants' directions, through the action of phenylmagnesium bromide on glutaronitrile.

The tetrahydropyridine was shown to have one double bond by titration; 0.200 g. used 0.195 g. of bromine (calcd., 0.185 g.). Hydrolysis gave γ-benzoylbutyric acid. The action of nitrous acid was indeterminate. On treatment with 2,4-dinitrophenylhydrazone in the usual manner (acid solution) the derivative of the amide III resulted. Bromine gave oils.

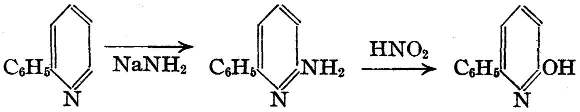
D. 2-Phenyl-α-pyridone, VI.—An excess (3 g.) of bromine was added to 3 g. of γ-benzoylbutyronitrile in 50 cc. of chloroform; the solution turned black and hydrogen bromide was evolved. The solvent was removed on the steam-bath and the residue distilled *in vacuo*, since preliminary attempts had shown the futility of any other kind of manipulation. At 20 mm. a preliminary, nondescript fraction came over up to 180°, but from the second (mostly at 190°) a solid separated; the latter was very soluble in benzene, carbon tetrachloride, and chloroform, soluble in hot water but insoluble in cold, and recrystal-

---

[12] Work of Mr. L. F. Somerville.

lized best from methanol in flat rods with square ends, m. p. 195°; although it appeared to crystallize well from petroleum ether the melting point was lower by 10°. A hydrochloride of m. p. 101–103° was prepared as directed in the literature, which gave the melting point 104°. All the properties agree with those described by Leben.[13] In order to establish the identity with certainty, a specimen was prepared as directed in the literature,[14,15] the melting point was not depressed on admixture.

Owing to the roundabout method of synthesis, several attempts were made to obtain it by a simpler procedure, but without success. It was relatively easy to prepare 2-aminopyridine and 2-phenylpyridine but impossible to introduce both groups into the same molecule. The action of sodium amide on 2-phenylpyridine led to a high melting, bimolecular product.



This work has been assisted by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Summary

γ-Benzoylbutyronitrile has been prepared by the dehydration of the corresponding amide with acetic anhydride. Other dehydrating agents gave a cyclic, isomeric derivative of tetrahydropyridine. The characteristic properties of each have been determined.

On the Naturally Occurring Linolic Acid in Cottonseed and Soya Bean Oils and the Regenerated Linolic Acid from Alpha Linolic Acid Tetrabromide of These Oils

BY D. M. BIROSEL

In a previous paper,[1] it was reported that only two isomeric linolic acid tetrabromides were isolated from the products of direct bromination of the free fatty acids of lumbang or candle nut (*Aleurites moluccana*) oil and of the regenerated linolic acid; that only two tetrahydroxystearic acids were isolated from the products of oxidation with alkaline permanganate solution of the free fatty acids of lumbang oil and of the regenerated linolic acid; and that the β- and δ-linolic acid tetrabromides which have been reported by other workers as obtainable from the bromination product of the free fatty acids of lumbang oil are ethyl ester mixed with varying amount of free solid acid tetrabromide.

Considerable work[2] has been done on linolic acid but the literature presents conflicting observations and conclusions. The present work is primarily intended to supplement the observations previously recorded by the writer. It is desired to report in this paper the observations made on linolic acid naturally present in soya bean and in cottonseed oils and on the regenerated linolic acid from α-linolic acid tetrabromide prepared by direct bromination of the free fatty acids of these oils.

From the direct bromination of the dried free fatty acids of soya bean and cottonseed oils, using ether as reaction medium and low boiling point petroleum ether[3] as vehicle of crystallization, α-linolic acid tetrabromide (m. p. 114°) was the only

---

(1) Birosel, *Natural and Applied Science Bulletin of the University of the Philippines*, **2**, 103 (1932).

(2) Meyer and Beer [*Monatsh.*, **33**, 325 (1912)] obtained β-sativic acid of m. p. 174° and α-sativic acid of m. p. 163° from the oxidation with cold alkaline permanganate solution of the free fatty acids of "Jimson weed" *Datura Stramonium*. Nicolet and Cox [THIS JOURNAL, **44**, 144 (1922)] doubted the existence of these sativic acids on the ground that the fatty acids of Jimson weed seeds yield α-linolic acid tetrabromide, m. p. 117°, whereas the highest melting point recorded in the literature is 114°. A. P. West and co-workers [*Philippine J. Sci.*, **32**, 41 (1927); *cf. C. A.*, **21**, 1720 (1927); *ibid.*, **32**, 297 (1927); *cf. C. A.*, **21**, 2250 (1927); *ibid.*, **42**, 251 (1930)] reported having isolated three solid linolic acid tetrabromides from the free fatty acids of lumbang oil. They claimed that their β-linolic acid tetrabromide corresponds to the compound which was reported by Takahashi [*J. Tokyo Chem. Sci.*, **4**, 233 (1919); *C. A.*, **13**, 1583 (1919)] but regarded their α-linolic acid tetrabromide of lumbang oil as different from a similar compound from soya bean oil on the ground that their regenerated linolic acid did not yield the β-linolic acid tetrabromide of Takahashi. Birosel[1] has shown that the β- and δ-linolic acid tetrabromides of West are ethyl ester of the acid mixed with varying amount of free α-linolic acid tetrabromide.

(3) Birosel[1] reported that with ethyl alcohol as vehicle of crystallization for the crude solid acid tetrabromide, the β- and δ-acids of West[2] were obtained whereas if low boiling petroleum ether was used none was obtained. West's[2] compounds were also obtained when pure α-linolic acid tetrabromide, m. p. 114°, was refluxed with ethyl alcohol until oil separated upon cooling the solution. The supposedly β- and δ-acids did not give neutralization value but their alcoholic solutions to which a few drops of phenolphthalein solution were added turned red upon addition of the first drop of standard alkali.

solid tetrabromide[4] isolated from the bromination products.

When the linolic acid regenerated from the α-linolic acid tetrabromide prepared from the free fatty acid of soya bean oil by direct bromination, was subjected to the action of bromine in the proper way, and using petroleum ether as crystallization medium, α-linolic acid tetrabromide,[5] m. p. 114°, was the only solid product obtained. No solid acid tetrabromide of lower melting point was isolated.

On oxidizing the free fatty acid of soya bean and cottonseed oils with cold alkaline permanganate solution, only two tetrahydroxystearic acids[6] were isolated. The corresponding acids prepared from the two oils have identical melting points.

Oxidation with cold alkaline permanganate solution of the regenerated linolic acid from the α-linolic acid tetrabromide (m. p. 114°) prepared from the free fatty acids of cottonseed and soya bean oils by direct bromination gave α-sativic acid (m. p. 164°) and β-sativic acid (m. p. 174°).

It is thus seen that the observations previously made by the writer on the naturally occurring linolic acid in lumbang oil and on the regenerated linolic acid from α-linolic acid tetrabromide prepared from the said oil by direct bromination find support in the experimental observations recorded in this paper.

Experimental Part

Soya Bean Oil.—This oil was prepared from soya bean seed by extraction with ether in the usual way. A liter of oil was prepared.

Preparation of Free Fatty Acids of Soya Bean Oil.—Five hundred grams of soya bean oil was treated in the usual way with a little more than the equivalent amounts of potassium hydroxide in aldehyde-free alcohol solution. When a homogeneous product after digestion on the steam-bath was obtained, the alcohol was distilled off and the soap solution was treated with excess dilute sulfuric acid. The mixture was digested to complete hydrolysis. The oil which floated was separated and taken with ether and washed several times with water until the washing was neutral. The ethereal solution was dried with anhydrous sodium sulfate, after which it was filtered and the solvent distilled. The residue which was free from solvent was further dried in a desiccator.

Preparation of α-Linolic Acid Tetrabromide.—Two hundred and twenty-eight grams of the dried free fatty acid of soya bean oil was dissolved in two liters of dry ether in a three-necked, round-bottomed flask of three-liter capacity. The solution was cooled down to −10°, with ice–salt mixture. Sixty-five cc. of bromine was added slowly while the solution was stirred mechanically. The temperature was not allowed to rise above 0°. Bromination took four hours to complete. Due to excess bromine, the solution was orange in color. The ether-insoluble precipitate was filtered off and washed with the same solvent. The filtrate and washing were washed together with dilute sodium thiosulfate solution until the color disappeared. The ethereal solution was dried with anhydrous sodium sulfate and filtered. The solvent was distilled off and the residue was taken up in low boiling petroleum ether from which the α-linolic acid tetrabromide separated on cooling. The compound was found to melt at 111–113°. Two recrystallizations in the same solvent increased the melting point to 114°.

After exhausting the mother liquor of its α-linolic acid tetrabromide content, it was worked out for other solid tetrabromides of lower melting points. None was isolated from the mother liquor and from the concentrated filtrate of recrystallization.

Preparation of Linolic Acid.—Twenty grams of the α-linolic acid tetrabromide (m. p. 114°) was refluxed with zinc in 8% alcoholic solution of hydrochloric acid for seventy-two hours continuously. The ester of the regenerated unsaturated acid was saponified with excess potassium hydroxide and the soap solution was hydrolyzed with dilute hydrochloric acid. The oil that separated out was taken up in ether and the ethereal solution was washed several times with distilled water and then dried with anhydrous sodium sulfate, after which it was filtered and washed with anhydrous ether. The filtrate and washing were distilled together, after which the residue was dried in the desiccator. In all these operations care was exercised to prevent loss of product. The dried residue weighed 9.662 g. From the figures the percentage yield and purity of the product is 98%. This percentage was checked by the result of a subsequent reduction.

Linolic Acid Tetrabromides from the Regenerated Linolic Acid.—9.55 grams of the regenerated linolic acid was brominated as described above. Care was exercised to avoid missing products previously reported by Takahashi.[5] Using petroleum ether as vehicle of crystallization, I obtained from the first crystallization a product which melted sharply at 114°. The amount of α-linolic acid tetrabromide was 8.8 g., which represents 45% of the regenerated linolic acid used. No solid tetrabromide of lower melting point was isolated from the mother liquor from which liquid γ-linolic acid was obtained.

Oxidation of the Free Fatty Acids of Soya Bean Oil.—Fifteen grams of the dried fatty acids of soya bean oil was oxidized with cold alkaline permanganate solution according to the procedure of Rollet.[7] The acid was treated with a little excess more than the equivalent amount of potassium hydroxide and the soap was dissolved in two liters of water. Twenty-two grams of potassium permanganate was dissolved and made up to one liter of solution. This

---

(4) Reformatzky, *J. prakt. Chem.*, **41**, 529 (1890); Hazura, *Monatsh.*, **9**, 180 (1888), and others, obtained only one solid linolic acid tetrabromide on brominating linolic acid.

(5) Takahashi[2] obtained β-linolic acid tetrabromide, m. p. 60°, from the regenerated linolic acid of α-linolic acid tetrabromide of soya bean oil. When petroleum ether was used as vehicle of crystallization as was done in this work no β-acid tetrabromide was isolated.

(6) Meyer and Beer[2] and Birosel[1] have obtained only α-sativic acid, m. p. 163°, and β-sativic acid, m. p. 174°, by directly oxidizing the free fatty acids of the oils which they studied with cold alkaline permanganate solution.

(7) A. Rollet, *Z. physiol. Chem.*, **62**, 410 (1909).

solution was added slowly to the soap solution which was shaken after each addition. After a quarter of an hour when the last drop of permanganate solution was added, sulfur dioxide was passed into it until the precipitate in the flask became white. The precipitate was filtered off and washed until free from acid. It was dried and then extracted with ether. The ether insoluble residue weighed 11.2 g. and was found to melt at 155–160°. After washing several times with hot benzene the compound was found to melt at 160–168°. The solid was then taken up in hot water. Ten hot water extractions were made. Each one of the first eight extractions was 1 liter while each of the last two was 2.5 liters. On cooling the solutions, a white solid precipitated which was separately filtered. Ten fractions were then collected.

TABLE I

FRACTIONS AND THEIR MELTING POINTS

Fractions	M. p., °C.	Fractions	M. p., °C.
1	160–170	6	155–160
2	160–170	7	155–158
3	160–170	8	165–171
4	155–158	9	165–171
5	156–160	10	167–172

The various fractions were combined to form three new fractions. Fractions 1–3 were designated as fraction A; 4–7, fraction B; 8–10, fraction C.

Fraction A was washed with hot benzene and then recrystallized in hot alcohol. A solid melting at 155 to 160° was obtained. It was added to fraction B which was washed with hot benzene. The residue of B was crystallized in hot alcohol and while the solution was still warm a fraction was obtained which melted at 156 to 158°. On reducing the volume of filtrate, a second crop of solid was obtained which melted at 163°. The first crop of B was recrystallized fractionally in hot alcohol and two crops of solid were obtained; the first crop melted at 168–171° and a second crop at 163°. The higher melting portion was added to C fraction and together were washed with hot benzene, and fractionally crystallized in hot alcohol. The solid in the warm solution was filtered off and found to melt sharply at 174°. On reducing the volume of the filtrate a second crop was obtained which melted at 174°.[8]

All the residual filtrates from the various fractional crystallizations were added and reduced in volume and upon cooling a solid compound was obtained which melted at 155–158°. It was subjected to the same fractional crystallization and the same results were obtained. A small amount of residual solid remained melting at 156–158°. This was undoubtedly a mixture of the two sativic acids. When the fraction melting at 163° was recrystallized, its melting point was raised to 164°.

Oxidation of the Regenerated Linolic Acid of Soya Bean Oil.—4.55 grams of the regenerated linolic acid was oxidized as described above with cold alkaline permanganate solution and 1.4 g. of hot water-soluble compound was obtained. The dried compound was extracted with ether and there remained 1.25 g. of ether-insoluble residue which was found to melt at 158–162°. None dissolved in hot benzene. It was fractionally crystallized as above and the first fractional crystallization gave two fractions, one melting at 166–169° (fraction A) and the other at 159–161° (fraction B). Fraction A on fractional crystallization gave fractions melting at 165–168° and at 161–163°. The lower melting fraction was added to B and upon fractional crystallization the mixture gave α-sativic acid, m. p. 164°. The fraction melting at 165–168° was fractionally crystallized also. The solid obtained from the filtration of the warm solution was found to melt sharply at 174°. The residual filtrates of crystallization were added together and reduced in volume. From the solid obtained two sativic acids were isolated, but a small residue melting at 156–158° remained which was undoubtedly a mixture of the two acids. Oxidation was repeated and the same results were obtained.

Free Fatty Acids of Cottonseed Oil.—The free fatty acids of cottonseed oil were prepared in the same way as the free fatty acids of soya bean oil. The oil is from a stock of commercial oil in the Department of Chemistry, University of the Philippines.

Oxidation of the Free Fatty Acids of Cottonseed Oil.—Thirty grams of the dried fatty acids from cottonseed oil was oxidized in the same manner as previously described for the fatty acids of soya bean oil; 6.07 g. of ether insoluble solid was obtained. This solid was extracted thoroughly with hot water. The aqueous extract was allowed to cool down, and from it was obtained 1.66 g. of dried product. This dry material was subjected to fractional crystallization in hot alcohol. The solid which separated from the warm solution was found to melt at 174°. Upon evaporating the filtrate, a second crop was obtained melting at 158–161°. After reducing the volume of the filtrate, a third crop was obtained. It was a very small amount, melting at 158–160°. The two lower fractions were fractionally crystallized together. While the solution was still warm, a fraction of solid was obtained which was found to melt at 164°. A second fraction was obtained melting at 156–158° from which a small quantity of solid melting at 164° was isolated. A small portion melting at 155–158° remained. This was undoubtedly a mixture of the two sativic acids. Oxidation was repeated and the same results were obtained.

Preparation of Linolic Acid Tetrabromide of the Free Fatty Acids of Cottonseed Oil.—Bromination of the dry ethereal solution of 336 g. of the free fatty acids of cottonseed oil was carried out in the same manner as previously described. Crystallization of the solid tetrabromide was done in low boiling petroleum ether. The compound obtained after two recrystallizations melted at 114°. No solid tetrabromide of lower melting point was isolated.

Regenerated Linolic Acid of Cottonseed Oil.—This was prepared as previously described elsewhere in this paper: 34.918 g. of α-linolic acid tetrabromide, m. p. 114°, was the starting material. Digestion on the water-bath was continued for a period of fifty-two hours. Care was exercised in the different operations to avoid loss of material; 16.885 g. of product was obtained. From these figures the percentage yield and purity of product was found to be 97.6%.

---

(8) Tsujimoto [*Chem. Rev. Fett- Harz-Ind.*, **18**, 111 (1911)] reported having obtained a tetrahydroxystearic acid from soya bean oil melting at 156–157.5°. This is probably not a pure acid and undoubtedly a mixture of the two sativic acids melting, respectively, at 164 and 174°.

TABLE II

ANALYTICAL DATA[a]

Substance	Sample used, mg.	CO₂, mg.	H₂O, mg.	%, C Found	%, C Calcd.	%, H Found	%, H Calcd.
β-Sativic	5.548[b]	12.553	5.074	61.70	62.1	10.24	10.3
acid	5.647[c]	13.023	5.280	62.85	62.1	10.45	10.3
α-Sativic	5.732[b]	13.110	5.211	62.38	62.1	10.18	10.3
acid	5.395[c]	12.287	4.900	61.70	62.1	10.16	10.3
α-Linolic acid tetrabromide	5.761[d]	7.759	2.753	36.73	36.02	5.35	5.34

[a] The writer wishes to acknowledge his indebtedness to Prof. A. C. Santos of the College of Pharmacy, University of the Philippines, for the micro-analysis.

[b] Analysis of the sativic acids obtained from linolic acid present in the oil of soya bean oil and from the regenerated linolic acid from α-linolic acid tetrabromide of this oil. The sample is a mixture of the corresponding acids obtained from the free acids of the oil and from the regenerated acid.

[c] Analysis of sativic acids from the free fatty acids of cottonseed oil and its regenerated linolic acid. Samples were made in the same manner as with soya bean.

[d] Sample was a mixture of α-linolic acid tetrabromide prepared from the free fatty acid of soya bean oil and its regenerated linolic acid and from the free fatty acids of cottonseed oil. When the sample was recrystallized from a solution of petroleum ether and ordinary ether (1:1), the melting point was raised up to 115–116°. W. C. Smit [*Rec. trav. chim.*, **49**, 539 (1930)] obtained 116–117° as the melting point of the same compound.

Oxidation of the Regenerated Linolic Acid[9] from α-Linolic Acid Tetrabromide of Cottonseed Oil.—5.198 grams of the regenerated linolic acid was oxidized with cold alkaline permanganate solution in the same manner as already described; 3.026 g. of product was obtained. The dried product was washed with ether and then extracted with hot water. The extracted fraction amounted to 1.874 g., m. p. 156–158°. It was washed with hot alcohol. The first fraction of solid obtained while the solution was still warm was found to melt at 174°, second fraction at 156–158°, third fraction at 156–158°. The lower fraction was fractionally recrystallized from hot alcohol. The first crop was found to melt at 163–164°, second crop at 163–164°, third crop at 156–159°. The third crop was undoubtedly a mixture of the two sativic acids. Oxidation was repeated and the same results were obtained.

The purity of the compounds here reported was checked by micro-analysis.

Summary

1. Only one solid tetrabromide, α-linolic acid tetrabromide (m. p. 114°), is obtainable from the direct bromination of the free fatty acids of soya bean and cottonseed oils.

2. Only one solid tetrabromide, α-linolic acid tetrabromide (m. p. 114°), is obtainable from the bromination of the regenerated linolic acid from the α-linolic acid tetrabromide (m. p. 114°) of soya bean oil.

3. Only two tetrahydroxystearic acids, α-sativic acid (m. p. 163°) and β-sativic acid (m. p. 174°) are obtainable from the free fatty acids of soya bean and of cottonseed oils.

4. Only α-sativic acid (m. p. 164°) and β-sativic acid (m. p. 174°) are obtainable from the oxidation with cold alkaline permanganate solution of the regenerated linolic acid from the α-linolic acid tetrabromide prepared from soya bean and cottonseed oils.

MANILA, P. I.

RECEIVED DECEMBER 16, 1936

---

(9) Nicolet and Cox[2] reported their β-sativic acid as melting at 170° and their α-sativic acid as melting at 153°. Their acids melted appreciably much lower and may still be impure. Meyer and Beer's[2] observation which was doubted by Nicolet and Cox finds strong support in the result of the oxidation of linolic acid actually present in cottonseed oil and of the regenerated linolic acid. S. R. Benson and H. N. Calderwood [THIS JOURNAL, **58**, 523 (1936)] have reported two tetrahydroxystearic acids, m. p. 152 and 173°, which they considered identical to the compounds of Nicolet and Cox. T. G. Green and T. P. Hilditch [*Biochem. J.*, **29**, 1552 (1935)] reported two solid tetrahydroxystearic acids melting at 155 and 173°.

Photoiodination of the Butenes, Propylene and Ethylene at Low Temperatures. Preparation and Photolysis of 1,2-Diiodobutane

BY GEORGE S. FORBES AND ARTHUR F. NELSON

Before undertaking the experiments described below, we had attempted to follow the photobromination of butenes in liquid dichlorodifluoromethane (freon). As the thermal reaction was complete within a few minutes, even at −150°, we substituted iodine monobromide, but the combined bromine still reacted rapidly. The resulting purple solution, stable in the dark, slowly became colorless when irradiated at −150° with a tungsten lamp.[1] Starting next with iodine and excess of butene under the same conditions, the iodine disappeared as before, but reappeared quickly upon exposure to a spark between tungsten steel electrodes.[1] Both the photoiodination of olefins and the photolysis of olefin iodides can thus be studied without interference from competing thermal reactions. At −55° in chloroform, where the solubility of iodine is greater than in freon, the situation was found to be even more favorable.

DeRight and Wiig[2] have reported that iodine reacts rapidly with ethylene in carbon tetrachloride when exposed to a tungsten lamp behind a red filter having maximum transmission at λ 700 mμ. The possibility thus indicated, that the iodination can proceed through excited iodine molecules, without participation of iodine atoms, deserves further investigation.

Materials.—All samples of olefins, ethylene excepted, had been prepared in a state of exceptional purity by Professor G. B. Kistiakowsky and co-workers.[3] We are greatly indebted to them for their coöperation. The bulbs, provided with capillary inner seals and free from air, had been stored at 0°. We distilled each butene in a vacuum into a new container provided with several capillary inner seals, so that successive samples could be withdrawn without introduction of air. The propylene was condensed to a liquid, and the first portion to vaporize was discarded. A sample of commercial ethylene known to be very pure[4] was drawn from a steel cylinder and similarly treated.

Chloroform of "analytical" grade was shaken once with 9 *M* sulfuric acid, and the alcohol extracted by five washings with water. A treatment with aniline eliminated phosgene. The product was distilled from an all-glass Podbielniak still[5] having a 150-cm. column and a spiral of nichrome wire as packing. The reflux ratio exceeded 5, and the range was not over 0.02°.

Iodine of "analytical" grade, stated to be free from cyanogen and 99.97% pure, was resublimed from iodide and preserved in a desiccator without grease.

Apparatus and Procedure.—The reaction cell was a rectangular prism of thin fused quartz 1 × 2 cm. in horizontal cross section and 5 cm. high. It had a cylindrical neck 7 cm. long and 2 cm. in diameter. The hollow ground-glass stopper was surmounted by tubes to admit a small high-speed stirrer and to deliver or pump out gases. The jacket was made from a short Dewar vessel, to the top of which was cemented a cylinder of Pyrex 11 cm. high and 5 cm. in diameter. A rectangular opening was cut in this tube just large enough to admit a closed quartz cell 3 × 7 cm. having plane polished faces 0.5 cm. apart, which served as a double window. The jacket was insulated with cellulose wool, and enclosed in a wooden box having a hole corresponding to the window. The reaction cell behind the window was held at −55 ± 5° by liquid air added at suitable intervals. The outer surface of the double window was kept free from moisture by a current of warm air.

A bulb containing olefin vapor was fused to a gas buret through a three-way stopcock and the intervening space evacuated. A capillary inner seal was broken by a magnetic hammer and enough vapor drawn out over mercury to make 100 cc. of 0.01 *M* solution. By turning the stopcock the vapor was dissolved readily under chloroform at −60° in a 100-cc. flask, and a millimole of iodine was added. The stock solution was stored, transferred and weighed without exposure to actinic light. It is shown below that the olefin iodide formed on standing was without influence upon the results.

The mercury vapor lamp,[6] monochromator and thermopile-galvanometer system[7] have been described. Before and after each photoiodination the linear thermopile was placed successively in three positions 1 mm. apart, close behind the exit slit so that the emerging beam was wholly covered. The sum of the three galvanometer deflections $\Sigma\Delta$ equaled kL, where L was the energy flux. Fifteen times during the research, uranyl oxalate was exposed in the reaction cell behind the double window, intercepting the whole of the beam. $\Sigma\Delta$ was redetermined before and after each exposure. When L had been found from the oxalate decomposed and the time, k was evaluated. Reflection corrections canceled out, quite nearly. Chatelet's extinction coefficients, ϵ, for iodine in chloroform at 18° were used at −55° without change.[8] The contraction of the chloroform solutions, 20 to −55°, tended to counteract a possible decrease in ϵ over the same range.

On this basis less than 2% of incident light was ordinarily transmitted and the indicated correction factor never exceeded 1.07.

The photolyzed solution, also an unexposed sample weighed with equal care, were shaken separately in the dark with excess of 0.01 *N* thiosulfate. After drawing off the decolorized chloroform solutions, the water solutions were titrated back with standard iodine. The olefin iodides in the chloroform layers liberated no visible iodine in the dark at room temperature in twelve hours, but in diffused daylight a purple color appeared within a few minutes.

Data on Quantum Yields.—Table I gives quantuum yields, ϕ in terms of molecules of iodine reacting with olefin in light of λλ 436 and 546 mμ. An initial series of *cis*-butene, yielding very high values, could not be repeated, and was rejected. Initial concentrations were uniformly 0.01 *M* in olefin and in iodine. Experiments not marked (*b*) employed stock solutions described above containing some olefin iodide. Experiments (*b*) were started by weighing finely divided

iodine into olefin solution in the cell at −60° in the dark, so that no olefin iodide was present at the start. As such a variation in procedure had no visible effect upon ϕ, it was concluded that the iodine-sensitized photodecomposition of the olefin iodides was negligible at −60°. According to Schumacher and Wiig[9] this reaction, rapid at 100°, becomes unimportant at 20°, so that our finding is consistent with theirs. Olefin iodide does not itself absorb light perceptibly unless $\lambda < 360$ mμ.[10]

Oxygen reacts photochemically with methylene iodide[11] and accelerates the photolysis of iodoform.[12] Emschwiller[13] reports that in ultraviolet light CH_3CHI_2 and CH_2CI_2 react completely with atmospheric oxygen, while $(CHI)_2$ and $(CH_2I)_2$ are unaffected. Though we believed that our addition product was symmetrical[14] the effect of oxygen on certain photohalogenations[15] suggested caution. DeRight and Wiig froze, pumped out and melted their solutions, of ethylene and iodine, twice before exposing them to red light. In experiments marked (*c*) we carried out the above cycle three times; the solution was photolyzed in a vacuum and shaking was substituted for stirring. In experiments marked (*a*) oxygen was partially removed by bubbling gaseous freon through the cell during photolysis. The results appeared to be the same whether oxygen was removed almost completely, partially, or not at all.

Professor E. O. Wiig kindly lent his approval to our suggestion that we compare ethylene with propylene and butenes. Our procedure remained unchanged. To our surprise the total reaction after one hour scarcely exceeded the probable error of analysis. With ethylene iodide absent at the start, but without exclusion of air

λ 436 ϕ = 0.07 0.10
λ 546 ϕ = 0.00 0.03

Starting with a solution containing ethylene iodide, and without exclusion of air

λ 436 small increase in free iodine
λ 546 ϕ = 0.06 0.06 0.04
λ 577 ϕ < 0.01
λ 644 ϕ (red line of cadmium spark[16,17]) ϕ = 0.01

To decide whether the low value of ϕ at λ 644 was peculiar to the ethylene, *cis*-butene was substituted, with similar results

λ 644 ϕ = 0.01 0.02

To correlate our single experiment at λ 644 with those of DeRight and Wiig, we determined the spectral transmission of a sheet of red cellophane, and the spectral energy distribution of a 200-watt tungsten lamp, including all the infra-red. Using these data together with the energy consumption of two such lamps, and the dimensions of the apparatus, we calculated that 3.3×10^7 ergs/sec. of radiation λ 800 to 546 mμ, entered our reaction mixture. In two hours about 2.0×10^{19} molecules of iodine disappeared.

Two experiments were performed without removal of oxygen: at −55 ± 5°, $\phi = 0.007$; at 25°, $\phi = 0.004$. Also two experiments at −55 ± 5°, after removal of air by freezing, pumping and melting three times, gave 0.006 and 0.005, respectively. As DeRight and Wiig state that ethylene and iodine react rapidly in red light, it is evident that their light flux was considerably greater than ours.

The reaction scheme of Schumacher[18] has proved adequate for the discussion of previous results, photochemical as well as thermal, at room temperature.

$$I_2 + h\nu \longrightarrow I + I \quad (1)$$
$$I + C_2H_4 \longrightarrow C_2H_4I \quad (2)$$
$$C_2H_4I \longrightarrow C_2H_4 + I \quad (3)$$
$$C_2H_4I + I_2 \longrightarrow C_2H_4I_2 + I \quad (4)$$

It permits ϕ to exceed 2 (*e. g.*, *cis*-butene), and is not incompatible with small values of ϕ (*e. g.*, ethylene). We could discover no correlation between ϕ (at λ 546 and −55.0°) and $\Delta F°$ at 25° for the olefins[19] as a whole. Apparently, then, ϕ does not depend upon the stability of the olefin as a whole, as it would if stability influenced the position of equilibrium in a partial reaction involving olefin. The same holds for ϕ in its relation to the stabilities of the ethylenic linkages considered separately.[20]

To test further the adequacy of Schumacher's reaction scheme at −55°, concentrations and light intensities were varied. Owing to the labor involved, *cis*-butene alone was thus investigated. Little variation in iodine concentration was practicable. A 0.01-molar solution at −55° is nearly saturated, while light transmission and

Preparation and Photolysis of 1,2-Diiodobutane.—A solution of iodine with excess of butene-1 in freon at −70° was illuminated by two gas-filled tungsten lamps through liter beakers filled with water and serving as lenses until the solution became colorless. The freon was evaporated under reduced pressure below its boiling point, −29.8°, carrying off the excess of butene (b. p. −6°). The white crystals, only about 10 mg. in weight, could not be purified readily by recrystallization, but were believed to be mainly the symmetrical compound.[14] After drying below −25° for several hours, the melting point was −15 ± 1°; the oily liquid was stable at −15° in the dark for some time, but iodine was liberated promptly upon exposure to diffused daylight. A microanalysis of the compound was performed in Converse Laboratory: found 15.56 and 16.49% of C, also 2.84 and 2.94% of H. Calculated for $C_4H_8I_2$, 15.48% of C and 2.60% of H.

We prepared 2,3-diiodobutane in similar fashion from butene-2 (*trans*) also as a white solid. This melted at −11 ± 2° with immediate decomposition, so that attempts at analysis were unsuccessful.

The quantum yield for photolysis of 1,2-diiodobutane in light of λ 254 was determined, using a special argon-filled quartz mercury vapor lamp ("Fluorolight"). As we found 77% of the whole to be resonance radiation,[21] we dispensed with the monochromator. The solution of 1,2-diiodobutane, prepared as above, was slightly purple at the start. The quantum yields appear in Table III under the assumption that diiodobutane absorbed all the resonance radiation. DeRight and Wiig[10] found that ethylene iodide began to absorb at λ 360 and absorbed strongly at λ 313. No allowance was made for absorption by the iodine, since at its mean concentration it could have absorbed only 12% of the incident light even if the strongly absorbing diiodobutane had been absent.

Table III

Quantum Yields of Photodecomposition of 1,2-Diiodobutane

T, °C.	*t*, sec.	Quanta per sec. $\times 10^{-14}$	Molecules decomposed $\times 10^{-18}$	Quantum yield
−55	3600	10.6	2.7	0.7
−55	3600	10.1	2.4	.65
−55	3600	12.2	3.5	.75
−20	3600	12.1	4.1	.95
−20	3600	11.4	4.3	1.05
24	2400	11.4	3.1	1.15
25	2400	11.5	3.1	1.15
25	3600	12.6	4.9	1.1

DeRight and Wiig[10] (p. 2414) have reported for ethylene iodide at room temperature ϕ = 0.71, 0.74, 0.75, 0.81, 0.81. We calculate 1.06 as the ten-degree temperature coefficient from ϕ at −55 and at 25°. From ϕ at −55 and −20° we find 1.08.

We are indebted to the du Pont Fund of the Division of Chemistry for a part of the apparatus used in this investigation.

Summary

The four butenes, propylene and ethylene, all exceptionally pure, were quantitatively photoiodinated in chloroform at −55° in light of λλ 436, 546 and in two cases 644 mμ. Competing thermal reactions were paralyzed.

The quantum yields for the different olefins at −55° (concentrations and light intensity being the same) vary as much as fortyfold, due perhaps to a difference in the activation energy of a secondary thermal reaction common to all the photoiodinations.

Quantum yields at −55° fall off with decreasing frequency to a value of the order of 0.01 at λ 644 mμ.

The thermal reaction scheme of Schumacher does not harmonize with the photochemical results at −55°. The rate of photoiodination is more nearly in proportion to concentration of olefin and of iodine and to light intensity.

At low temperatures diiodobutane (presumably the 1,2-isomer) was prepared as a white solid in a state of reasonable purity, and photolyzed at −60, −20 and +25°. The quantum yield at 25° is nearly the same as that for symmetrical ethylene iodide.

The Adsorption and Decomposition of Carbon Monoxide on Zinc Oxide Catalysts

BY ROBERT L. BURWELL, JR., AND HUGH S. TAYLOR

The results of an investigation into the rate of the activated adsorption of hydrogen at constant pressure on zinc oxide have been reported by Taylor and Strother.[1] It appeared desirable to extend this work by studying the rate of the activated adsorption of carbon monoxide on the same catalyst.

Experimental

Accordingly the technique and the apparatus of Taylor and Strother were employed. Zinc oxide was prepared in the manner described in their communication. Carbon monoxide was prepared by dropping formic acid into hot sulfuric acid. The effluent gas was passed successively over copper wool heated to 450°, soda lime, calcium chloride and phosphorus pentoxide.

The observed rates of adsorption fell off progressively with an accompanying change in color of the adsorbents from pure white to gray. The results of typical rate determinations are listed in Table I.

TABLE I

RATES OF ADSORPTION OF CARBON MONOXIDE ON 22.7 G. OF ZINC OXIDE, PREPARATION 3C, AT A PRESSURE OF ONE ATMOSPHERE

Adsorption in cc., N. T. P.

Time, min.	2	4	8	12	20	40	60	100
Run 6 184°	2.1	2.75	3.45	4.0	4.7	5.9	6.75	7.9
Run 7 218°	3.45	4.45	5.7	6.55	7.85	9.8	11.1	12.9
Run 8 184°	1.9	2.45	3.2	3.65	4.35	5.4	6.1	7.15

Twenty-one runs in all were made on preparation 3C at the two temperatures listed in Table I. They were similar to the ones in the table and showed a progressive deactivation of the catalyst surface. Similar results were obtained on another zinc oxide sample, preparation 3B.

Hydrogen was then substituted for carbon monoxide and a number of rates of adsorption of that gas were determined at temperatures of 184 and 218°. After a few runs it was observed that the initial white color of the adsorbent had been regenerated. Adsorptions of hydrogen were very much greater and more rapid during the first few runs than in the subsequent ones.

These phenomena may be explained plausibly by the assumption that carbon monoxide is decomposed on the catalyst surface in accordance with the equation

$$2CO \longrightarrow C + CO_2$$

On admission of hydrogen, the deposited carbon is assumed to react to produce methane. Such a mechanism may account for the small amount of methane produced by similar catalysts in the methanol synthesis.[2] The decomposition of carbon monoxide corresponds to a considerable decrease in the free energy of the system at the temperatures under consideration.[3] Such a decomposition of carbon monoxide has been reported for other oxide catalysts.[4]

To test this hypothesis, an apparatus was constructed which permitted the passage of carbon monoxide over copper wool at a temperature of 400°, then successively through two spiral bubbling bottles containing solutions of barium hydroxide (no turbidity ever appeared in the second bottle), a tube containing calcium chloride and one containing phosphorus pentoxide. The gas passed thence through a tube containing 15 g. of zinc oxide. The off gas was passed through a bubbling tube into which a solution of barium hydroxide could be directly filtered and thence through a bubbling bottle containing barium hydroxide.

(1) Tank nitrogen purified in a manner similar to that of carbon monoxide, was passed over the sample of zinc

oxide maintained at a temperature of 425–450° for twenty hours at a rate of 2 to 5 cc. per minute. The catalyst was cooled to room temperature and the apparatus was flushed out with carbon monoxide. The temperature of the catalyst was elevated and maintained at 184° by means of an aniline vapor-bath. Barium hydroxide solution was inserted in the test bubbler. Turbidity appeared in ninety minutes.

The catalyst was cooled to 20° and the system was flushed out with nitrogen. The temperature was elevated gradually by means of a furnace. Turbidity appeared in a fresh barium hydroxide solution at 175°. Larger amounts of barium carbonate appeared as the temperature rose. The bulk of the precipitate formed between 340 and 400°.

The nitrogen passage was continued at a rate of 4 cc. per minute. After fourteen hours with the temperature of the catalyst maintained at 435°, no turbidity appeared in fresh barium hydroxide solution in two hours.

(2) The catalyst was cooled to room temperature and carbon monoxide passed through the system for twenty hours. No turbidity was evident in the test bubbler. On elevating the temperature to 184° faint turbidity appeared only after twelve hours.

Nitrogen was substituted for carbon monoxide and the temperature of the catalyst elevated in the same fashion as described in (1). Similar results were obtained. After nitrogen passage for four hours over the catalyst maintained at 420°, new barium hydroxide was inserted in the test bubbler. The temperature of the catalyst and the rate of nitrogen passage were continued. No turbidity was evident after twelve hours.

(3) The sequence of operations described in (2) was repeated. Results were similar save that forty-eight hours were required for the appearance of a faint turbidity at 184°.

(4) Carbon monoxide was passed through the system to displace the nitrogen with the temperature of the catalyst held at 300°. With fresh barium hydroxide solution in the test bubbler, turbidity appeared in half an hour. With the temperature of the catalyst at 370°, fresh barium hydroxide solution gave an immediate precipitate.

(5) During these experiments the catalyst had become markedly gray-brown. Hydrogen was passed over the catalyst for ten hours at 385°. The color of the catalyst lightened considerably and appeared a light gray.

Discussion

The experiments described in (1) to (5) demonstrate that carbon monoxide is in some degree decomposed to carbon dioxide in passage over active zinc oxide catalysts at temperatures above 184°. Only a small part of this carbon dioxide could be ascribed to an oxidation of carbon monoxide by zinc oxide.[5] In the course of the work described in (1) to (5) and especially in (4) large volumes of carbon dioxide were formed. Had such a volume of carbon dioxide been produced by the reduction of zinc oxide, a corresponding amount of zinc should have sublimed into the off tube. No such quantity was observed. It is further impossible to account by such an assumption for the effect of hydrogen in restoring the color of the catalyst.

The fall in catalytic activity of the zinc oxide surface as exemplified by the increasing times required to produce turbidity at a temperature of 184° may be presumed partially at least to have resulted from a covering of the "active spots" by carbon.

The slow reaction in the adsorption process cannot, however, have been the decomposition of carbon monoxide with subsequent adsorption of the carbon dioxide so produced. For were this true, zinc oxide could not act as a catalyst in the methanol synthesis. Further, were all of the adsorbed carbon monoxide to have been decomposed, one would expect all of the active surface to have been covered with carbon in the course of several runs, whereas the adsorption was still 40% of its initial value after twenty-one runs. From the excess hydrogen adsorbed in the first couple of runs after its substitution for carbon monoxide one may estimate that no more than about 15% of the carbon monoxide adsorbed during the twenty-one runs could have been decomposed.

Though it is clear that the observed rates of adsorption refer essentially to the activated adsorption of carbon monoxide on zinc oxide, the disturbing influence of the decomposition reaction renders unreliable any calculation of activation energies for the process. However, the activation energies appear somewhat higher than those reported by Taylor and Strother[1] for the adsorption of hydrogen on the same catalyst.

Garner and Maggs[6] have reported recently their inability to detect any activated adsorption of carbon monoxide on zinc oxide at temperatures up to 313° A. They conclude: "The absence of a discontinuity" (in the adsorption isobar) "in the case of carbon monoxide on zinc oxide supports the contention that such discontinuities do not occur in the absence of capillary flow." It is difficult to understand how the mere presence or absence of activated adsorption can decide which of the various theories of the mechanism of activated adsorption is correct. In any case had Garner proceeded to measurements at higher temperatures, he would have discovered the presence of activated adsorption.

In 1931, Taylor[7] pointed out that certain steps

[7] Taylor, THIS JOURNAL, 53, 578 (1931).

in many sorption processes must involve activation energies frequently of a considerable magnitude. It was at first thought that the rate determining step was the approach of the gas molecule to the surface. That such could not universally be true was indicated by the work of Pace and Taylor[8] and by that of Kohlschuetter[9] demonstrating that, at a pressure of one atmosphere and within limited temperature ranges, hydrogen and deuterium were adsorbed with the same velocity on zinc chromite, nickel, and chromium oxide gel, and by the work of Burwell and Taylor[10] on the effect of pressure on the rate of the activated adsorption of hydrogen on chromium oxide gel.

Garner[6,11] has recently reiterated the contention that in general the slow process in activated adsorption is the "diffusion" of the gas down capillaries from an initial rapid adsorption, a view that derives initially from Ward.[12] The application of the term "diffusion" to the suggested mechanism is misleading since whereas true diffusion increases with the temperature as $\sqrt{T}$, the hypothesized "diffusion" of Ward and Garner increases very much more rapidly. Lennard-Jones[13] has shown that to account for the large temperature coefficient it is necessary to assume that before diffusion can take place, a molecule must be raised from its initially adsorbed state to a higher energy level. While the process proposed by Lennard-Jones may occur in some instances, it cannot be a general one. For this hypothesis requires that the amount of adsorption be initially proportional to the square root of the time, a relation which rarely fits time–adsorption data. Further, such a picture is unable to account for the identity of the rates of adsorption of hydrogen and deuterium on the catalysts mentioned previously.

Summary

Experiments are reported which indicate that: (1) carbon monoxide is decomposed in the sense of the equation, $2CO \longrightarrow C + CO_2$, on surfaces of zinc oxide at temperatures above 184°. (2) Carbon deposited on the catalyst is removed by hydrogen at temperatures of 184° and above, presumably as methane.

The Calculation of Second Order Reaction Velocity Constants

BY JULIAN M. STURTEVANT

Introduction.—In the application of physical methods to the determination of reaction velocities the observed quantity is usually a property of the reacting system which varies linearly with the concentrations of the reactants and products. To evaluate the two constants involved in this linear relation it is, in general, necessary to obtain the values of the observed property at the start and finish of the reaction. In many cases it is impossible to obtain these values reliably; for example, if the reaction is being followed by observation of the temperature changes resulting from the heat evolved in the system under adiabatic conditions, there would obviously be serious experimental difficulties in obtaining the temperature of the system at the completion of the reaction.

A method of calculation which eliminates these difficulties in certain cases has been described by Roseveare.[1] This method involves the analytical or graphical elimination of the "infinity reading." As pointed out by Roseveare, this method has the further advantage of not giving undue weight to the infinity reading in cases where it cannot be obtained with any greater accuracy than the other readings. Roseveare discussed the application of the method to first order reactions and to second order reactions in which the initial concentrations of the reactants are equal.

In extending the method to more complicated reactions one finds that the algebraic treatment becomes excessively cumbersome. In the present communication it will be shown that these difficulties are avoided by a simple application of the methods of projective geometry. In the course of this treatment there will be developed a very easily applied test as to whether a given set of

---

[1] Roseveare, THIS JOURNAL, **53**, 1651 (1931).

experimental data follows a certain kinetic equation.

Kinetic Equation.—The general equations[2] for several types of reactions may be written in the form

$$kt = \ln c\,\frac{a - x}{b - x} \qquad (1)$$

where k is proportional to the velocity constant, $a \neq b$, c are constants, and x is the extent of the reaction at time t, or some quantity varying linearly with it. If $x = x_0$ at $t = 0$, $c = (b - x_0)/(a - x_0)$. Included among the types of reactions following this equation are bimolecular irreversible and reversible reactions (reverse reaction also bimolecular) in which the concentrations of the reactants are not equal, autocatalytic bimolecular irreversible reactions, and trimolecular irreversible reactions in which one reactant is a catalyst or its concentration is much greater than those of the other two reactants.

In equation (1) the constants a, b, c will in general involve the initial concentrations of the reactants, the equilibrium constant for the reaction if it is reversible, and x_0 and x_∞, the value of x at $t = \infty$. Our problem is to determine k from the observed values of x without using x_0, x_∞.

Determination of *k*, *a*, *b*, *c*.—Proceeding in a manner analogous to that recommended by Roseveare[1] for first order reactions we suppose readings x_1, x_2, x_3, x_4 are taken at t, $t + \Delta t$, $t + 2\Delta t$, $t + 3\Delta t$, readings x_1', x_2', x_3', x_4' at t', $t' + \Delta t$, $t' + 2\Delta t$, $t' + 3\Delta t$, and so on. Substitution of these values in equation (1) and subtraction gives a series of simultaneous equations

$$\frac{(a - x_2)(b - x_1)}{(a - x_1)(b - x_2)} = \frac{(a - x_3)(b - x_2)}{(a - x_2)(b - x_3)} = \frac{(a - x_4)(b - x_3)}{(a - x_3)(b - x_4)} = \frac{(a - x_2')(b - x_1')}{(a - x_1')(b - x_2')} = \ldots \equiv \alpha = \text{constant} \qquad (2)$$

from which a, b may be determined in terms of x_1, x_2, ... Substitution of these values in any of the equations

$$k\,\Delta t = \ln \frac{(a - x_2)(b - x_1)}{(a - x_1)(b - x_2)} = \ldots = \ln \alpha \qquad (3)$$

would enable us to obtain k. However, treatment of equations (2) by the usual algebraic methods leads immediately to cumbersome equations the simplification of which is difficult.

The observation[3] that the quantity $\frac{a - x_2}{b - x_2}\Big/\frac{a - x_1}{b - x_1}$ is the so-called anharmonic ratio[4] or cross-ratio of the range of points a, b, x_2, x_1 suggests that the methods of projective geometry may find application here.

The anharmonic ratio of a range of four collinear points, P_1, P_2, P_3, P_4 may be defined as

$$[P_1P_2P_3P_4] = \frac{P_1 - P_3}{P_2 - P_3} \times \frac{P_2 - P_4}{P_1 - P_4} \qquad (4)$$

In this notation equations (2) become

$$[abx_2x_1] = [abx_3x_2] = [abx_4x_3] = [abx_2'x_1'] = \ldots = \alpha \qquad (5)$$

If we consider a, b as fixed points on a line the position of any other point P_i on the line is fixed by the ratio

$$\alpha_i = (a - P_i)/(b - P_i) \qquad (6)$$

It is easily shown that $[abP_iP_j] = \alpha_i/\alpha_j$, so that equations (5) become

$$\alpha = \frac{\alpha_2}{\alpha_1} = \frac{\alpha_3}{\alpha_2} = \frac{\alpha_4}{\alpha_3} = \frac{\alpha_2'}{\alpha_1'} = \ldots \qquad (7)$$

Using equations (6) and (7) and the definition of the anharmonic ratio we readily find that

$$[ax_1x_2x_3] = [ax_2x_3x_4] = [ax_1'x'x_3'] = \ldots = 1 + \alpha^{-1} \qquad (8)$$

$$[bx_1x_2x_3] = [bx_2x_3x_4] = [bx_1'x_2'x_3'] = \ldots = 1 + \alpha \qquad (9)$$

and

$$-[x_3x_1x_2x_4] = -[x_3'x_1'x_2'x_4'] = \ldots = \alpha + 1 + \alpha^{-1} = \text{constant} \equiv A \qquad (10)$$

Equation (10) gives us a simple method for calculating k and a criterion as to whether experimental data follow equation (1). Evidently

$$\alpha = \frac{A - 1}{2} \pm \sqrt{\left(\frac{A - 1}{2}\right)^2 - 1} \qquad (11)$$

where

$$A = \frac{(x_3 - x_2)(x_4 - x_1)}{(x_2 - x_1)(x_4 - x_3)} = \frac{(x_3' - x_2')(x_4' - x_1')}{(x_2' - x_1')(x_4' - x_2')} = \ldots > 3 \qquad (12)$$

so that

$$k\,\Delta t = \ln \alpha = \cosh^{-1}((A - 1)/2) \qquad (13)$$

According to equation (12) data which conform to equation (1) should give a constant value of $A > 3$. This test of the conformity of the data requires no knowledge of the concentrations of the reactants and, as stated before, x may be any quantity varying linearly with the concentrations.

From the value of A the constant k may be calculated. The determination of the sign of the radical in equation (11) offers no difficulty, since

---

(2) See the summary of equations, Vol. II, in "*Treatise on Physical Chemistry*," edited by H. S. Taylor, D. Van Nostrand Company, New York, 1931, p. 960.

(3) The author is indebted to Professor H. T. Engstrom of the Department of Mathematics for suggesting the use of projective geometry in this problem.

(4) See, for example, "*The Principles of Projective Geometry*," by J. L. S. Hatton, Cambridge University Press, 1913.

the quantity with the plus sign is the reciprocal of that with the minus sign, and one can readily tell whether $k\Delta t$ should be positive or negative. Unfortunately there will be a serious magnification of errors in cases where A is not much larger than 3, since α varies rapidly with A in this vicinity. Means of avoiding this difficulty are described below. In passing it may be pointed out that expansion of the inverse hyperbolic cosine gives the expression

$$k^2\Delta t^2 = (A - 3)\,[1 - (A - 3)/12 + \ldots] \quad (14)$$

In cases where α may be calculated accurately by this method we may evaluate a, b from equations (8) and (9)

$$a = \frac{\alpha x_1(x_3 - x_2) - x_3(x_2 - x_1)}{\alpha(x_3 - x_2) - (x_2 - x_1)}, \qquad b = \frac{x_1(x_3 - x_2) - \alpha x_3(x_2 - x_1)}{(x_3 - x_2) - \alpha(x_2 - x_1)} \quad (15)$$

and similar equations involving the other x's. Also c is readily obtained from equation (1)

$$c = \frac{\alpha(x_3 - x_2) - (x_2 - x_1)}{(x_2 - x_2) - \alpha(x_2 - x_1)}\,\alpha^{(t + \Delta t)/\Delta t} \quad (16)$$

In such cases it would thus be possible in general to evaluate one of the initial concentrations or the equilibrium constant from the observed data, in addition to x_0 and x_∞.

The magnification of errors involved in equation (11) in many cases may be avoided by using the experimentally determined values for the initial concentrations (and the equilibrium constant if the reaction is reversible). In general it will be possible to calculate one of the quantities a, b, c (or some combination of them) accurately from the known initial concentrations. Then one merely has to calculate α from the appropriate one of equations (15) and (16) (or the appropriate combination of them). If c is the constant whose value is considered as being accurately known, α will have to be calculated by successive approximations, the first of which may be obtained from equation (11).

In connection with this method of calculation two things may be pointed out. It is only necessary to have three readings x_1, x_2, x_3 in each set so that the time interval Δt may be taken larger. Also, in cases where α is very sensitive to the value of A, there will be a corresponding sensitivity of c and either a or b to α, so that the value of α may be obtained accurately.

It may be emphasized again that this extension of Roseveare's method of calculation will be of greatest importance in cases where it is physically impossible to obtain initial or final values of x. For example, in the determination of reaction velocities by following the rate of heat evolution[5] it will evidently be out of the question to observe directly either the value of x_0 because of the heat of mixing, or of x_∞ because of calorimetric difficulties. On the other hand, the concentrations of the reactants at $t = 0$ will be known from the make-up of the reacting solution with an accuracy great enough to warrant their use in the manner described above. As a matter of fact, if it is possible to make the original observations at uniform time intervals, the present method of calculation may result in a considerable saving of time even in cases where initial and final values of x can be obtained with good accuracy, both in enabling one to cease observations before the reaction is finished and in simplifying the calculations.

Example.—The data of Harned and Pfanstiel[6] for the bimolecular reversible hydrolysis of ethyl acetate catalyzed by acids have been treated by the above method. These data follow equation (1) very closely when calculated in the usual way.

In this particular case of a bimolecular reversible reaction the constants k and c are given by

$$k = K\sqrt{(A - B)^2 + 4ABC} \quad (17)$$

$$c = \frac{A + B + \sqrt{(A - B)^2 + 4ABC}}{A + B - \sqrt{(A - B)^2 + 4ABC}} \quad (18)$$

where A, B are the initial concentrations of water and ester, K is the velocity constant (natural logarithms) and C is the equilibrium constant. Naturally k and c have different values with reactions of other types. The quantity x in this case is the titer of the reacting solution, and may be observed in terms of alkali of unknown strength. Since there is acid present as catalyst $x_0 > 0$.

The experimental data[7] given by Harned and Pfanstiel for one run were plotted on a large scale, and four sets of values of x were read off the plot, with $\Delta t = 300$ minutes. These sets gave the values $A = 3.153, 3.144, 3.142, 3.110$. The trend observed here is possibly somewhat outside the experimental error, though it should be observed that the quantity $x_4 - x_3$ (≈ 13) is the difference of considerably larger quantities (≈ 60). At any rate, it is obvious that a satisfactory value of K could not be otained from these readings. The

---

[5] This method of determination will be the subject of a future communication.

[6] Harned and Pfanstiel, THIS JOURNAL, 44, 2194 (1922).

[7] The quantity recorded by Harned and Pfanstiel is $x - x_0$, but since only differences in x appear in the calculations we may use $x - x_0$ in place of x.

mean value of A leads to $K = 2.20 \times 10^{-5}$, while Harned and Pfanstiel found $K = 2.342 \times 10^{-5}$. It is thus necessary to calculate K from the known value of c. The constants a, b involve x_0, x_∞ and therefore cannot be used.

Four sets of three readings each were interpolated with $\Delta t = 400$ minutes. From these sets, together with the value $c = -39.86$ calculated from the initial concentrations and equilibrium constant, the values $\alpha = 1.701, 1.700, 1.698, 1.691$ were calculated by successive approximations. The trend here, amounting to a total of 0.6%, may be partially due to inaccuracies introduced by the graphical interpolation. From the mean value of α one obtains $K = 2.365 \times 10^{-5}$, which is 1% higher than the value of Harned and Pfanstiel. This method of calculation eliminates the necessity of calculating the initial and final values of the titer as done by Harned and Pfanstiel. It should be emphasized that the value of α would be changed by less than 0.1% by a change of 5% in c.

Summary

An application of the methods of projective geometry to a series of measurements of a property x (of a system reacting in accord with the kinetic equation $kt = \ln c\,(a - x)/(b - x)$) which varies linearly with the progress of the reaction, taken at uniform time intervals, Δt, gives the result

$$A \equiv \frac{x_3 - x_2}{x_2 - x_1} \times \frac{x_4 - x_1}{x_4 - x_3} = 1 + 2 \cosh (k\,\Delta t)$$

By means of this result the necessity of obtaining initial and final values of x is eliminated.

The method is illustrated using the data of Harned and Pfanstiel on the hydrolysis of ethyl acetate.

[CONTRIBUTION FROM THE T. JEFFERSON COOLIDGE, JR., MEMORIAL LABORATORY, HARVARD UNIVERSITY]

The Atomic Weights of Some Radiogenic Leads

BY G. P. BAXTER, J. H. FAULL, JR.,[1] AND F. D. TUEMMLER

In connection with the programs of the Committee on Geophysical Research of Harvard University and the Committee on Determination of Geologic Time of the National Research Council the atomic weights of some new specimens of radiogenic leads have been determined.

Samarskite from Glastonbury, Connecticut, U. S. A.—The original ground sample, weighing 1130 g., had been cleaned by gravity and magnetic methods by Mr. Harry Berman of the Harvard Mineralogical Laboratory. A preliminary analysis of a part of this material by R. C. Wells[2] shows 6.91% uranium, 3.05% thorium, 0.311% lead.

Treatment with redistilled hydrofluoric acid in platinum followed by repeated evaporation with nitric acid to remove the hydrofluoric acid and extraction of the insoluble residue with nitric acid, all in platinum, was carried out by Dr. C. M. Alter. The nitric acid solution on standing for several months deposited much columbic acid (40 g.). The dried insoluble residue weighed 970 g. This residue was found spectroscopically to contain most of the lead.

Lead was separated from the nitric acid solution by double precipitation of basic acetates and treating the filtrates with hydrogen sulfide. The original insoluble residue and that which separated from the nitric acid solution were digested for long periods with redistilled hydrochloric acid and the lead precipitated from the extract after neutralization with ammonium acetate. About 0.1 g. of lead was obtained from the extract, 1.6 g. from the insoluble residues, together representing about half the lead content of the original mineral.

Purification included the following processes: conversion of sulfide to sulfate through the chloride, solution of the sulfate in ammonium acetate and reprecipitation with hydrogen sulfide, solution of the sulfide in hydrochloric acid and conversion of the chloride to nitrate by repeated evaporation with nitric acid, four recrystallizations of the nitrate from nitric acid in quartz, conversion of nitrate to chloride with hydrochloric acid in quartz, four recrystallizations of chloride in quartz, and distillation of the chloride in dry hydrogen chloride in a quartz tube. All the product was used in one analysis. Lead was recovered from the solution of lead nitrate resulting from the first analysis and from the mother liquors remaining from the purification by precipitation as sulfide, and after conversion to the nitrate through the chloride it was re-purified as above.

Beaverlodge Lake Pitchblende.—This specimen was collected and contributed by Dr. Fred Joliffe from a quartz vein near Beaverlodge Lake, Northwest Territories, Canada, about one hundred miles south of Great Bear Lake. The mineral consists chiefly of an intimate mixture of pitchblende and specularite. Weighted averages from analyses of five lots of similar material, representing 3000

[2] R. C. Wells, Reports of the Committee on Determination of Geologic Time, of the National Research Council, April, 1935, and Sept., 1936.

lb. (1360 kg.), made in the Canadian Mines Branch, Ottawa, Canada, show 28.9% uranium and 1.57% lead with no thorium. Analysis by Baxter and Averill (see following paper) of material cleaned as below showed 51.2% uranium, 2.49% lead and no thorium.

After being crushed in a diamond mortar the pitchblende (514 g.) was finely pulverized in a specially cleaned grinder. Much of the iron ore was removed by suspension in water. The dried residue (433 g.) was then fractionated electromagnetically. This process was not particularly successful, apparently because of the intimate nature of the original mixture. A considerable quantity of material which could be picked up with an ordinary magnet, as well as a non-magnetic fraction, largely quartz, were thus eliminated. Galena could not be discovered in the non-magnetic fraction but a microscopic examination of a polished section by Dr. R. S. Moehlmann suggests a trace of this substance.

Of 415 g. remaining, 25 g. was set aside for analysis. The remaining 390 g. was treated with hot 8 *N* nitric acid and after separation from a slightly soluble residue of iron ore, the solution was evaporated with an excess of sulfuric acid and taken up with water. The residue (112 g.) was dissolved in hydrochloric acid and after separation from a nearly white residue (7 g.) the solution was evaporated with an excess of sulfuric acid and taken up with water. Very little lead sulfate was obtained from the hydrochloric acid solution of the iron ore.

The combined precipitates of lead sulfate were dissolved in ammonium acetate, and, after filtration of the solution, lead sulfide was precipitated. This was dissolved in hydrochloric acid, and the chloride was converted to nitrate by evaporation with nitric acid. At this point we had 14.6 g. of lead nitrate. This was further purified as described above in the case of the samarskite lead.

Katanga Pitchblende.—Some years ago Baxter and Alter[3] found the atomic weight of the lead contained in the yellow, hydrochloric acid soluble portion of a specimen of Katanga pitchblende to be 205.97 while that of lead from the black insoluble portion of the same specimen was found to be 206.00. A little later Hönigschmid, Sachtleben and Baudrexler[4] extracted a specimen of Katanga pitchblende with dilute hydrochloric acid and found the atomic weight of the lead in the extract to be 206.02. Recently Hecht and Kroupa [*Z. anorg. allgem. Chem.*, **226**, 248 (1936)] found the atomic weight of the lead contained in the black, less soluble portion of this specimen to be 206.04. Through the great kindness and generosity of Professor H. Buttgengach of the University of Liège we came into possession of a fine specimen of Katanga pitchblende weighing 1150 g. Aside from a considerable mass of yellow secondary minerals at one point, this specimen differed markedly from the one examined by Baxter and Alter in having a much larger proportion of veins of yellow secondary minerals. This was apparent even to the eye in the slightly greenish color, whereas the former specimen was black.

About 615 g. (free from masses of yellow) was broken up on a steel plate and ground in a steel mortar by hand. Nearly half, 298 g., was then extracted with 5% hydrochloric acid until lead chloride ceased to crystallize from the solution and the extract was nearly colorless. The black residue was then thoroughly washed and dried. The weight of this residue, 100 g., was 33% of the original whereas Baxter and Alter found 77% by a similar process with the earlier specimen.

The lead chloride which separated from the extract was collected. The remainder of the lead was precipitated as sulfate and converted to the chloride through the sulfide. In all 18.0 g. of lead chloride was obtained.

The black insoluble portion was dissolved in nitric acid and the greater part of the lead precipitated as chloride. The remainder was separated as sulfate and converted to chloride. The total weight of lead chloride was 8.73 g.

Both samples of lead chloride were converted to nitrate and purified as already described.

A rough determination of uranium was made in aliquot portions of both solutions from which the lead had been removed. The percentages of lead and uranium are given in the following table.

	Pb, %	U, %	Pb/U
Black	6.50	76.7	0.0847
Yellow	6.76	67.5	.1001
Whole	6.67	70.6	.0945

Baxter and Alter (*loc. cit.*) found the following percentages with the first specimen of Katanga pitchblende.

Black	6.7	74.9	0.089
Yellow	8.4	58.5	.144
Whole	7.1	71.2	.100

In an experiment to find the composition of the mineral more accurately, the proportion of black (pitchblende) decreased from 34.9% after one treatment with hydrochloric acid to 31.4 and to 30.8 after two additional treatments. Apparently the pitchblende dissolves slowly in 5% hydrochloric acid. Analysis of the hydrochloric acid extract and the residual material gave the following results:

	Pb, %	U, %	Pb/U
Black	6.48	77.2	0.0839
Yellow	6.74	68.5	.0983
Whole	6.66	71.2	.0935

These values are confirmed by the approximate analysis of the main bulk of material. The lead–uranium ratio in the case of the black material is in general agreement with values obtained by others.[5]

With all the radiogenic samples it was necessary to recover and repurify in order to secure the necessary material.

Common Lead.—Cerussite from Wallace, Idaho, U. S. A., was dissolved in nitric acid, and after filtration of the solution the lead nitrate was four times recrystallized in Pyrex vessels. The nitrate was then converted to chloride and the chloride four times recrystallized in quartz and twice redistilled in hydrogen chloride. Baxter and Grover[6] have already examined lead from this mineral and found it to possess a normal atomic weight (207.21).

The early stages in the purification of the various samples were carried on in Pyrex vessels, but in the crystallization

of the nitrate and chloride only quartz or platinum vessels were used. Residual silica and organic matter were eliminated easily in the final distillation of the chloride in hydrogen chloride in a quartz tube. No reagents were used which were not free from lead.

Spectroscopic examination of the final products in a carbon arc failed to show any evidence of impurity. Difficulty was experienced in securing graphite electrodes of sufficient purity, especially as regards silver, but this difficulty was finally overcome by the conventional method of heating the electrodes to 1000° in a current of chlorine in a quartz tube for long periods.

In every case the purified lead chloride was prepared for analysis by fusion in a current of dry hydrogen chloride containing more or less nitrogen. No variation in the composition of the salt with the proportion of hydrogen chloride could be detected. The salt was contained in a quartz boat placed in a quartz tube during the fusion. After the fusion it was transferred by means of a Richards bottling apparatus to the weighing bottle in which the empty boat had originally been weighed. The boat remained constant in weight throughout the whole series of experiments.

After the salt had been weighed it was dissolved in warm water to which a small amount of nitric acid had been added to prevent hydrolysis. The solution was then compared with silver in the conventional way, with the use of a nephelometer and 0.01 normal silver and chloride solutions, by the equal-opalescence method. In the precipitation, the solutions were 0.05 normal or less. The silver nitrate solution was always poured into the lead chloride solution.

The weights of lead chloride were corrected to vacuum by adding 0.000058 g. per gram and those of silver by subtracting 0.000031 g. per gram.

				Average	1.28363	206.042

The average value for common lead is in good accord with recent evidence.

If the samarskite is free from common lead, the atomic weight to be expected from the proportions of uranium and thorium reported (see page 702) may be calculated on the assumptions (1) that uranium lead ($Pb^{206} + Pb^{207}$) has the atomic weight 206.00[7] and thorium lead (Pb^{208}) the value 207.96, and (2) that the relative rates of production of lead by uranium and thorium are 1.00: 0.36. The value thus found is 206.22, and indicates that about 12% of the lead in the samarskite is common lead and that in calculating the age of the samarskite the percentage of lead should be reduced by one-eighth. This assumes, however, that the relative proportions of uranium and thorium in the mineral have not altered with time.

The atomic weight of Beaverlodge Lake lead appears to be slightly higher than that of Great Bear Lake lead (206.06)[8] and since there is no appreciable amount of thorium in the pitchblende, about 7% of the lead is apparently common lead and the age 93% as high as calculated from the total percentage.

The Katanga pitchblende is noticeably different from that examined by Baxter and Alter.[3] In the first place the percentage of black unaltered material is one-half as large. In the second place not only does the lead have a higher atomic weight but the difference between the leads from the black and yellow material, if real, is in the opposite direction from that previously observed, 206.04 and 206.05 against 206.00 and 205.97. Furthermore, if thorium is absent in appreciable amount, as has generally been reported for Katanga lead, about 4% of the lead appears to be common lead and a corresponding correction is necessary in computing the age of the mineral from the percentages of lead and uranium.

Other determinations of the atomic weight of Katanga lead,[9] from both pitchblende and curite,

[7] Baxter and Alter, This Journal, **57**, 470 (1935).

[8] Marble, *ibid.*, **56**, 854 (1934); Baxter and Alter, *ibid.*, **57**, 467 (1935).

[9] Hönigschmid and Birckenbach, *Ber.*, **56**, 1837 (1923), 206.048; Hönigschmid, Sachtleben and Baudrexler, *Z. anorg. allgem. Chem.*, **214**, 104 (1933), curite 206.031, yellow 206.023; Baxter and Alter,[8] curite 206.027.

have yielded values close to 206.03. The specimen described in this paper is particularly interesting in affording additional evidence that the atomic weight of Katanga lead is not constant and therefore by inference may contain common lead in varying proportions. This idea is substantiated by the recent work of Rose,[10] who finds the isotope Pb^{208} in a specimen of Katanga lead.

Summary

1. The atomic weights of certain radiogenic leads have been determined.

Source	Atomic weight
Cerussite, Wallace, Idaho, U. S. A. (common)	207.21
Samarskite, Glastonbury, Conn., U. S. A.	206.34
Pitchblende, Beaverlodge Lake, N. W. T., Canada	206.08
Pitchblende, Katanga, Africa	
Black, insoluble portion	206.04
Yellow, hydrochloric acid-soluble portion	206.05

2. It is pointed out that these values, together with the percentages of important components, point to the presence of several per cent. of common lead in all three radioactive minerals.

The Lead–Uranium Ratio of Beaverlodge Pitchblende

BY G. P. BAXTER AND M. E. AVERILL

A sample of the ground and mixed specimen of pitchblende from Beaverlodge Lake, N. W. T., Canada, which had been utilized in the determination of the atomic weight of lead described in the preceding paper, was analyzed for lead, uranium and thorium.

Weighed portions were first treated with 8 *N* nitric acid which dissolved the pitchblende but left most of the associated hematite insoluble. After separation, the hematite was dissolved in 7 *N* hydrochloric acid. Both solutions were evaporated to dryness, and siliceous residues were treated with hydrofluoric and sulfuric acids. Lead was separated from both solutions by evaporation with sulfuric acid, and the filtrate of the lead sulfate scavenged with hydrogen sulfide at suitable acidity. Lead so recovered was converted to sulfate and added to the main portions. All the lead sulfate was purified by solution in ammonium acetate and evaporation with sulfuric acid and the filtrate worked up for traces of lead.

Both the nitric and hydrochloric acid solutions were freed from iron by double precipitation of basic ferric acetate. Ammonium uranate was then precipitated from solution in an excess of ammonium carbonate, and collected. The filtrate was evaporated to dryness and after expulsion of ammonium salts a small amount of uranium was recovered as above.

The uranyl sulfate solution resulting from the extraction of lead from about 390 g. of mineral (see preceding paper) yielded several grams of rare earth oxalates, but we were unable to convince ourselves that thorium was present in more than traces. This is in accord with the results of analyses of similar material made by the Canadian Mines Branch (see preceding paper, p. 703).

TABLE I

Sample, g.	$PbSO_4$, g.	Pb, %	U_3O_8, g.	U, %	Pb/U
2.3005	0.0845	2.505	1.3963	51.47	0.0488
1.9146	.0699	2.490	1.1587	51.32	.0485
2.2185	.0807	2.481	1.3265	50.70	.0490
	Average	2.492		51.16	.0486

Baxter, Faull and Tuemmler (see preceding paper) have found the atomic weight of the lead contained in this sample of Beaverlodge pitchblende to be 206.08, indicating, in the almost complete absence of thorium, that about 7% of this lead is common lead. With the per cent. of uranium 51.16, and that of lead 2.318 (corrected for common lead) the Pb/U ratio is 0.0453. Analyses by the Canadian Mines Branch give 0.054 (see page 703 of preceding paper). Barring alteration and other unknown effects the approximate age of the mineral is 344 million years, while the logarithmic formula gives 336 million.

Natural and Synthetic Rubber. XVII. The Separation of Sol Rubber and Gel Rubber[1]

BY THOMAS MIDGLEY, JR., AND ALBERT L. HENNE

The sol rubbers, on which reliable physical and chemical measurements have been made, have been prepared either by fractional precipitation[2] from a mixture of benzene and alcohol, or by slow diffusion in absolute ethyl ether.

The separation of sol from gel rubber by diffusion assumes that the components can be separated from one another like sugar from sand and disregards the possibility that sol and gel rubbers may be mutually soluble in each other. If this latter condition actually exists, then the diffusion may only be expected to produce a two-phase, three-component system in equilibrium, and the relative amounts of sol and gel rubbers in the sol phase should be determined and not assumed. The same general reasoning applies to the fractional precipitation method of separation. Thus there is no "absolute" method of determining the relative quantities of sol and gel rubbers in any sample.

However, the relative efficiencies of separation by these two methods may be evaluated by preparing samples of "sol" rubber by each method and then attempting a further separation of each of these samples by the other method. This has been done with the following results.

Samples of sol rubber were prepared by fractional precipitation from sprayed latex rubber and were allowed to diffuse in ether. They dissolved rapidly and completely. They were quantitatively recovered unchanged from the ether by evaporation at reduced pressure. Also 30 g. of sprayed latex was allowed to diffuse in absolute ether, yielding 24 g. of soluble and 6 g. of insoluble material. The insoluble portion was leathery, rich in nitrogen; it was not analyzed further. The 24 g. of soluble material was recovered from the limpid ether solution by evaporation at reduced pressure, then subjected to fractional precipitation from a mixture of alcohol and benzene, with the following results:

Fractions	A_0	A_1	A_2	A_3	A_4	A_5	B
Amount, g.	3	6	1	1.5	1	0.5	10.5

One-half gram was lost during the operation. The A_0 fraction contained the so-called "acetone soluble" portion of natural rubber, since it was recovered by the evaporation of the benzene–alcohol mixture after completion of the fractionation. The A_1 fraction was found free of nitrogen, but not free of rubber degraded by oxidation, as it had a glossy appearance and gave 0.06% oxygen by the active hydrogen method[3] instead of 0.02 or 0.03% which is normal for good samples. This is not surprising, as it has always been found that two and sometimes three successive precipitations are needed to remove all traces of such oxidized material. Fractions A_2 to A_4 were typical high grade sol samples. Fraction A_5, which was very small and obtained with considerable difficulty, was obviously a mixture of A and B. Fraction B, the insoluble part, proved to be nitrogen free. In view of this last unexpected result, B was subjected to another fractionation, which removed only a small amount of impure A, amounting to about 2 g., and left a little more than 8 g. of a substance which was called BB. The characteristics of this BB fraction were: no nitrogen; 4.65% oxygen by combustion; 1.48% oxygen by active hydrogen measurement; slow solubility in benzene; extremely slow solubility in ether; no "leathery" feeling, no "tackiness" and no resemblance whatever to rubber degraded by oxidation. The high oxygen content of this material may safely be assumed to be due to an impurity.

The viscosities of the several fractions were measured in 0.23% solutions in benzene at 20°. The viscosities expressed in C. G. S. units × 10^3 were:

Benzene	A_1	A_2	A_3	A_4	BB
6.47	12.40	17.20	17.30	17.20	21.03

The low viscosity of A_1 is due to the accumulation therein of rubber degraded by oxidation. A_2 to A_4 are good samples of sol rubber. Their viscosities compare favorably with those recorded for thrice refractioned sol rubber (17.70) or twice re-

[1] Original manuscript received October 22, 1936.

[2] THIS JOURNAL, 53, 2733 (1931).

[3] *Ibid.*, 57, 2318 (1935).

fractioned rubber (17.40 to 17.65) prepared in this Laboratory.

These results indicate quite clearly that a single diffusion of rubber into ether is insufficient completely to separate sol from gel rubber. They also show that while there is no absolute criterion by which the fractional precipitation method may be judged, it is decidedly more efficient than the ether diffusion method.

Summary

Sol rubber prepared by a single diffusion in ether can be separated into two components by fractional precipitation, whereas sol rubber prepared by a single fractional precipitation completely diffuses in ether, thus indicating the superiority of the fractional precipitation method as a means of preparing sol rubber.

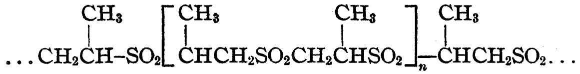
The Reaction between Sulfur Dioxide and Olefins. V.[1] The Structure of the Polysulfones from Olefins of the Type RCH=CH$_2$

BY F. J. GLAVIS, L. L. RYDEN AND C. S. MARVEL

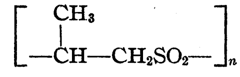
It has been demonstrated[2] that propylene and sulfur dioxide combine to form a polysulfone (I)



$$\ldots \mathrm{CH_2\overset{\overset{CH_3}{|}}{C}H{-}SO_2}\left[\mathrm{\overset{\overset{CH_3}{|}}{C}HCH_2SO_2CH_2\overset{\overset{CH_3}{|}}{C}HSO_2}\right]_n\mathrm{\overset{\overset{CH_3}{|}}{C}HCH_2SO_2}\ldots$$

I

in which the propylene units are oriented so that like parts of the hydrocarbon residues are linked through the sulfone groups. The hydrolysis of the polysulfone with alkali gave products which could not be reconciled with the structure II,

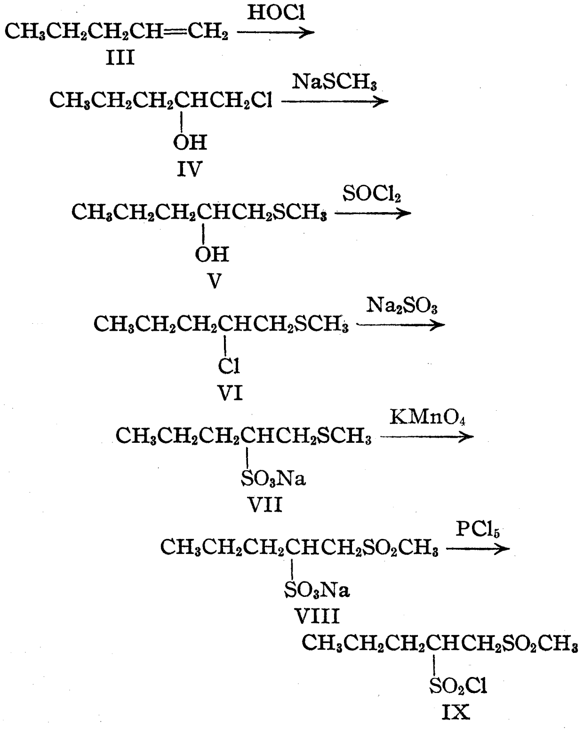


$$\left[\mathrm{{-}\overset{\overset{CH_3}{|}}{C}H{-}CH_2SO_2{-}}\right]_n$$

II

which had previously been assigned to the addition product.[3] The experiments described in this communication were undertaken to determine whether the polysulfones from other olefins of the type RCH=CH$_2$ would be structurally comparable to propylenepolysulfone (I), or would have a simple symmetrical unit similar to that indicated in formula II.

1-Pentenepolysulfone, prepared as described previously,[4] can be hydrolyzed by warming it with 20% sodium hydroxide solution to yield *n*-butyraldehyde and a sodium salt of composition $C_6H_{13}S_2O_4Na$. This salt can be oxidized readily by hydrogen peroxide to give a compound $C_6H_{13}S_2O_5Na$, which, with phosphorus pentachloride, yields a sulfonyl chloride melting at 64–65°. The same sulfonyl chloride (IX) has been synthesized from 1-pentene by the following series of reactions



$$\mathrm{CH_3CH_2CH_2CH{=}CH_2} \xrightarrow{\mathrm{HOCl}}$$

III

$$\mathrm{CH_3CH_2CH_2\underset{\underset{OH}{|}}{C}HCH_2Cl} \xrightarrow{\mathrm{NaSCH_3}}$$

IV

$$\mathrm{CH_3CH_2CH_2\underset{\underset{OH}{|}}{C}HCH_2SCH_3} \xrightarrow{\mathrm{SOCl_2}}$$

V

$$\mathrm{CH_3CH_2CH_2\underset{\underset{Cl}{|}}{C}HCH_2SCH_3} \xrightarrow{\mathrm{Na_2SO_3}}$$

VI

$$\mathrm{CH_3CH_2CH_2\underset{\underset{SO_3Na}{|}}{C}HCH_2SCH_3} \xrightarrow{\mathrm{KMnO_4}}$$

VII

$$\mathrm{CH_3CH_2CH_2\underset{\underset{SO_3Na}{|}}{C}HCH_2SO_2CH_3} \xrightarrow{\mathrm{PCl_5}}$$

VIII

$$\mathrm{CH_3CH_2CH_2\underset{\underset{SO_2Cl}{|}}{C}HCH_2SO_2CH_3}$$

IX

This synthesis of the sulfonyl chloride (IX) establishes the structure of the sulfonic acid salt $C_6H_{13}S_2O_5Na$ (VIII). Likewise, it shows that the salt $C_6H_{13}S_2O_4Na$ must have the structure shown in formula XII. 1-Pentenepolysulfone must, accordingly, have the structure shown in formula X, and thus be strictly comparable to propylenepolysulfone (I) in the arrangement of the hydrocarbon residues.

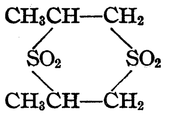
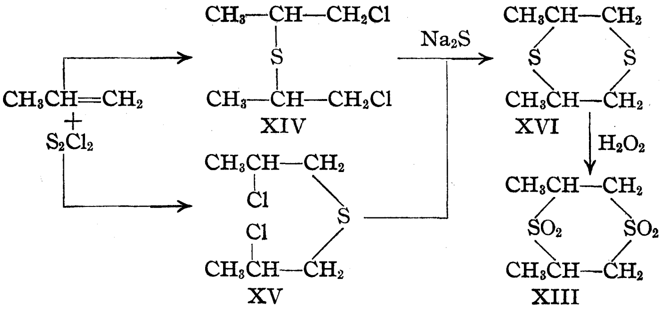
X XI XII

A further proof that these two polysulfones have similar structural units has been obtained by studying the breakdown of the polymers in liquid ammonia solutions. Propylenepolysulfone dissolves in liquid ammonia, and on evaporation of the solvent and crystallization of the residue from an organic solvent, yields the same cyclic disulfone (XIII) which was previously obtained[2,3] by the



XIII

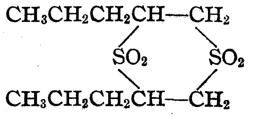
action of cold alkalies on propylenepolysulfone. This cyclic disulfone (XIII), whose structure was established[2] by alkaline cleavage, has now been synthesized in the following manner



XIV XV XVI XIII

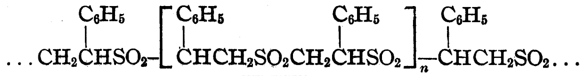
The structure of the intermediate dichlorosulfide is probably that given in formula XV[5] rather than that given in formula XIV, but the same cyclic disulfide (XVI) would be obtained from either.

1-Pentenepolysulfone in liquid ammonia is also broken down into a cyclic disulfone (XVII), and the same product was obtained from 1-pentene by the synthesis used above in the case of propylene.

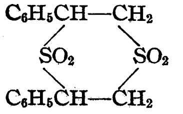


XVII

Styrenepolysulfone (XVIII), which has not been described previously, has now been prepared by the general method which has been developed for other polysulfones,[4] and its structure has been established by hydrolysis with alkali to give benzaldehyde and a salt of a sulfone sulfinic acid,  $CH_3SO_2CH_2\underset{C_6H_5}{\underset{|}{C}}HSO_2Na$. In liquid ammonia solution, styrenepolysulfone is converted to a cyclic disulfone (XIX), and the structure of this product was established by its synthesis from styrene by the methods described above for the analogous products from propylene and 1-pentene.



XVIII

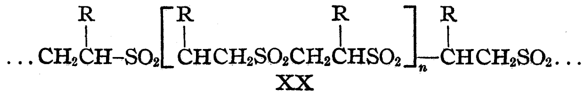


XIX

1-Octenepolysulfone and 1-nonenepolysulfone[4] also undergo rearrangement in liquid ammonia solution to yield dimeric products which are presumably cyclic disulfones of the general structure which has been established in the above cases.

There can no longer be doubt that, in the addition of sulfur dioxide to an olefin of the type $RCH{=}CH_2$, there is a definite orientation of the hydrocarbon residues, so that like parts are joined through sulfone linkages (XX).

The fact that these olefin–sulfur dioxide addition polymerization reactions so generally yield the "head to head–tail to tail" type of polymer seems to us to make it logical to assume that other addition polymerization reactions may take place in a similar manner, and thus to make it desirable to investigate more carefully the structure of the products of such reactions.



XX

Experimental

Styrenepolysulfone.—A mixture of 10 cc. of styrene, 10 cc. of liquid sulfur dioxide, 2 cc. of ethyl alcohol, 2 drops of

---

(5) Pope and Smith, *J. Chem. Soc.*, **119**, 396 (1921).

30% hydrogen peroxide and 5 cc. of paraldehyde containing peroxides was placed in a pressure bottle and allowed to stand for twelve to eighteen hours at room temperature. The paraldehyde must be added at the start of the reaction in this preparation as otherwise only polystyrene is formed. The reaction mixture was poured into 100 cc. of ether, and the polymer was collected on a filter. When the reaction mixture was poured into water, it was very difficult to obtain a good product free from water. The yield of polysulfone was 0.5 to 2.5 g. in various experiments. The product darkens on heating and melts, with decomposition, at 185–190°. It is slightly soluble in acetone, but insoluble in most other common organic solvents.

Anal. Calcd. for $(C_8H_8SO_2)_n$: S, 19.05. Found: S, 18.64.

1-Octenepolysulfone.—A mixture of 10 cc. of 1-octene, 10 cc. of liquid sulfur dioxide, 2 cc. of ethyl alcohol, 2 cc. of 3% hydrogen peroxide and 5 cc. of "old" paraldehyde was allowed to stand as described above. The product was precipitated by pouring the reaction mixture into water. The yield was 2 to 4 g. in various runs. This product is first rather pliable, but eventually sets to a very hard product. It is soluble in acetone, but not in other common organic solvents. It becomes opaque at 100°, and melts, with decomposition, at 175–200°.

Anal. Calcd. for $(C_8H_{16}SO_2)_n$: S, 18.18. Found: S, 17.82.

Alkaline Hydrolysis of 1-Pentenepolysulfone.—A suspension of 2 g. of 1-pentenepolysulfone in 10 cc. of 20% sodium hydroxide was heated to boiling, and a current of steam was passed through the mixture. The distillate was condensed and collected in a vessel containing a solution of 1 g. of 2,4-dinitrophenylhydrazine, 75 cc. of alcohol, 10 cc. of concentrated sulfuric acid and water to give a total volume of 250 cc. A precipitate of *n*-butyraldehyde 2,4-dinitrophenylhydrazone came down. The yield was 1.2 g. (85%) of a product melting at 121.5–122°. The literature[6] gives the melting point of *n*-butyraldehyde 2,4-dinitrophenylhydrazone at 122°.

The alkaline residue, after steam distillation had removed all of the butyraldehyde, was evaporated to dryness, and this residue was extracted with hot 95% alcohol. On cooling this solution, a white crystalline salt separated. The yield of salt was about 1 g. (60%). The salt contained one molecule of water of crystallization when dried in a desiccator over phosphorus pentoxide at room temperature, but lost this at 125°. The analyses for carbon, hydrogen and sodium were made on the anhydrous sample.

Anal. Calcd. for $C_6H_{13}S_2O_4Na \cdot H_2O$: H_2O, 7.1. Found: H_2O, 7.0. *Anal.* Calcd. for $C_6H_{13}S_2O_4Na$: C, 30.9; H, 5.5; Na, 9.7. Found: C, 30.4; H, 5.3; Na, 10.1.

Oxidation of the Salt $C_6H_{13}S_2O_4Na$.—To a solution of 10 g. of the above salt in 20 cc. of water was added 30 cc. of 30% hydrogen peroxide solution over a period of about thirty minutes. Considerable heat was liberated during the oxidation. The reaction mixture was allowed to stand for about fifteen minutes, and then evaporated to dryness on a steam-bath. The residue was recrystallized from 200 cc. of hot 95% alcohol. The yield was 7 g. (69%) of a white crystalline salt. The product was dried at 100° at 3 to 4 mm. before analyzing.

Anal. Calcd. for $C_6H_{13}S_2O_5Na$: S, 25.4. Found: S, 25.2.

Preparation of the Sulfonyl Chloride.—The salt obtained in the preceding experiment was recrystallized four times from alcohol and dried. Then 1 g. of this highly purified salt was ground in a mortar with 1 g. of phosphorus pentachloride. One hundred cubic centimeters of ice water was added immediately, and an oily precipitate separated. On stirring the mixture, the oil solidified. The solid was separated and recrystallized from a mixture of petroleum ether and benzene. It melted at 64–65°.

Anal. Calcd. for $C_6H_{13}S_2O_4Cl$: S, 27.12. Found: S, 26.99.

1-Chloro-2-pentanol.—1-Pentene was converted to the chlorohydrin, according to the method which Coleman and Johnstone used for 1-chloro-2-cyclohexanol.[7] From 50 g. of 1-pentene, there was obtained 37 g. (43%) of 1-chloro-2-pentanol, b. p. 68–75° at 30 mm.; d^{20}_{20} 1.037; n^{20}_D 1.4520.

Anal. Calcd. for $C_5H_{11}OCl$: Cl, 26.35. Found: Cl, 26.78.

1-Methylthiol-2-pentanol.—The directions for the preparation of methylthiolethyl alcohol[8] were used for this synthesis. From 35 g. of the above chlorohydrin, there was obtained 18 g. (45%) of a product boiling at 90° under 18 mm.; d^{20}_{20} 0.943; n^{20}_D 1.4792.

Anal. Calcd. for $C_6H_{14}SO$: S, 23.88. Found: S, 22.78.

1-Methylthiol-2-chloropentane.—The directions for the preparation of β-chloroethylmethylsulfide[9] were adopted for this synthesis. From 18 g. of the above methylthiol alcohol and 21 g. of thionyl chloride, there was obtained 14 g. (70%) of a product boiling at 84–86° at 20 mm.; d^{20}_{20} 1.0090; n^{20}_D 1.4860.

Anal. Calcd. for $C_6H_{13}SCl$: Cl, 23.26. Found: Cl, 23.48.

Sodium 1-Methylthiol-2-pentanesulfonate.—To a solution of 14 g. of sodium sulfite in 50 cc. of water, 12.5 g. of 1-methylthiol-2-chloropentane was added over a period of about one hour. The mixture was well stirred with a mechanical stirrer, and heating and stirring were maintained for an hour after the addition of the chloro compound. The solution was evaporated over a water-bath, and the residue was recrystallized from 95% alcohol. The yield of salt was about 2 g.

Anal. Calcd. for $C_6H_{13}S_2O_3Na$: S, 10.44. Found: S, 10.68.

1-Methylsulfonepentane-2-sulfonyl Chloride.—To a solution of 3 g. of the above salt in 10 cc. of water was added 1 drop of 10% sodium hydroxide solution, and enough 5% potassium permanganate solution so that the color persisted after the solution was boiled. The excess potassium permanganate was then destroyed with hydrogen peroxide solution, and the reaction mixture was filtered. The filtrate was evaporated to dryness, and the residue was re-

Styrene	25	Alcohol, dioxane and glacial acetic acid	280	$C_{16}H_{16}S_2O_4$	..	..	19.05	..	...	19.35

[a] This product is identical with a product isolated by treatment of propylenepolysulfone with cold sodium hydroxide solution, and reported as melting at 320°.[2]

crystallized from alcohol four times. The yield of recrystallized salt was 1.3 g. (40%). This salt was then converted to the sulfonyl chloride in the manner described for the sulfone–sulfonate salt obtained from the breakdown of 1-pentenepolysulfone.

The sulfonyl chloride from this synthetic salt melted at 64–64.5°, and when a sample of this synthetic product was mixed with the sulfonyl chloride prepared from the breakdown of the polysulfone, the mixture melted at 64–65°.

Alkaline Hydrolysis of Styrenepolysulfone.—A mixture of 10 g. of styrenepolysulfone and 100 cc. of 10% sodium hydroxide solution was distilled with steam. The distillate contained benzaldehyde, which was identified by preparing the 2,4-dinitrophenylhydrazone, which melted at 235°, and showed no depression in melting point when mixed with an authentic specimen of the benzaldehyde derivative.[10] The solution remaining in the distilling flask was filtered and evaporated to dryness. The resulting salt was recrystallized from alcohol. The yield was 4 g. Ten grams of this salt was oxidized by dissolving it in 20 cc. of water and treating with 30 cc. of 30% hydrogen peroxide solution. This reaction mixture was evaporated, and the sulfonic acid salt was recrystallized from alcohol.

Anal. Calcd. for $C_9H_{11}S_2O_5Na$: S, 22.38. Found: S, 22.51.

Liquid Ammonia Cleavage of Polysulfones.—Several polysulfones were treated with liquid ammonia to test their solubility. It was observed that those which dissolved were changed by the treatment. The long polymeric molecules were broken up and cyclic disulfones were produced. The experiments were carried out by dissolving about 1 g. of polysulfone in 50–100 cc. of liquid ammonia, and then allowing the solvent to evaporate. The crystalline residue was then recrystallized from an organic solvent. The results are summarized in Table I.

Neither cyclohexenepolysulfone nor isobutylenepolysulfone would dissolve in liquid ammonia, and were recovered unchanged after the treatment. 2-Pentenepolysulfone dissolved slowly in liquid ammonia, and the polymer was destroyed, but no crystalline products could be isolated.

2,6-Disubstituted-1,4-dithians.—Three representatives of this series of compounds were prepared from the olefins by first adding sulfur monochloride according to the procedure of Pope and Smith,[5] and then converting the crude β,β'-dichlorosulfides to the 1,4-dithians by the action of sodium sulfide. In each case, to 72 g. (0.5 mol) of sulfur monochloride was added 1 mol of olefin. After the completion of the addition reaction, the crude mixture was added to a solution of 0.5 mol of sodium sulfide in absolute alcohol, prepared as described by Bost and Conn.[11] The reaction mixture was boiled overnight, and then poured into 2 liters of 25% sodium chloride solution. The dithian derivative was extracted with petroleum ether (b. p. 40–110°), and purified by distillation under reduced pressure. The results of these experiments are given in Table II.

2,6 - Disubstituted - 1,4 - dithian - 1,4 - bis - (dioxides).—These synthetic cyclic disulfones were obtained by oxidizing about 2 g. of the corresponding 1,4-dithian derivative in 10 cc. of glacial acetic acid with 5 cc. of 30% hydrogen peroxide. The reaction mixture was heated to boiling under a reflux condenser for about fifteen minutes, and diluted with about 50 cc. of water. The precipitate which came down was then recrystallized from dioxane or alcohol. The synthetic product in each case proved to be identical with the product obtained by dissolving the corresponding polysulfone in liquid ammonia. These experiments are recorded in Table III.

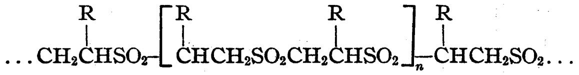
Summary

1. Those polysulfones prepared from sulfur dioxide and olefins, which dissolve in liquid ammonia, are converted by this treatment into cyclic disulfones.

2. Styrene (phenylethylene) adds sulfur dioxide to give a polysulfone.

3. Evidence is presented to show that polysulfones prepared from olefins of the type $RCH=CH_2$ have the general formula



$$\ldots CH_2\overset{R}{C}HSO_2-\left[\overset{R}{C}HCH_2SO_2CH_2\overset{R}{C}HSO_2\right]_n-\overset{R}{C}HCH_2SO_2\ldots$$

in which like parts of the hydrocarbon residues are joined to each other by sulfone linkages.

Studies in the Ketone Sugar Series. VI. The Effect of Zinc Chloride on Ketose Acetates

BY FRANCIS B. CRAMER[1] AND EUGENE PACSU

In preparing new sugar derivatives for testing the isorotation rules in the aldose group, Hudson and co-workers have made extensive use of zinc chloride dissolved in acetic anhydride as a reagent in converting the β-acetates into the α-forms. An earlier physico-chemical investigation of the process by Jungius[2] showed that in the case of glucose pentaacetates equilibrium was reached when the proportion was nine moles of the α- to one mole of the β-form. In the case of most aldose acetates the equilibrium contains the two forms in similar proportion. Exceptions are found in the pentaacetates of galactofuranose[3] and galactoseptanose[4] where the equilibrium is in favor of the β-isomers. In 1915, Hudson and Brauns[5] attempted to apply this method to β-pentaacetylfructose. When zinc chloride was added to a solution of this substance in acetic anhydride, only a very small change in rotation was observed whereas a large one was anticipated. Since some coloration occurred, the authors evidently ascribed the change in rotation to slight decomposition and after recovering about one-third of the starting material and conducting confirmatory experiments, concluded that the method was not applicable in the ketose series. It has now been discovered that the small change in rotation observed by Hudson and Brauns was due to the formation of the new isomer described in Part V[6] as the true α-pentaacetylfructopyranose.

The structure of β-pentaacetylfructose is generally accepted as that of a normal acetate possessing a <2, 6> ring. The evidence leading to this conclusion is extensive and will not be reviewed here. To establish the structure of the new fructose acetate as the normal α-pentaacetate, it would be sufficient to show that it differs from the known β-compound only in the configuration of carbon atom 2. If this glycosidic carbon atom were selectively inverted, the β-pentaacetate should result.

When a trace of zinc chloride was added to the acetic anhydride solution of the new fructose acetate, the rotation dropped rapidly, changing sign, and within a few minutes became constant at −107°. From the rotations of α- and β-pentaacetylfructose in acetic anhydride (42.3 and −122°, respectively) it may be calculated that the equilibrium mixture contained 91% of the β-form. When the solution was worked up a large amount of β-pentaacetylfructose was obtained.

Similarly, when pure β-pentaacetylfructose was treated with zinc chloride in acetic anhydride after the manner of Hudson and Brauns,[5] the rotation again became −107°. On carefully working up this mixture, a small amount of the α-compound was isolated in pure form.

This interconversion of the two acetates gives definite proof that the new compound is the true α-pentaacetylfructose <2,6>. Supporting evidence is afforded by the method of preparation, both α- and β-pentaacetates being formed simultaneously by replacing the chlorine atom in β-acetochlorofructose with the acetoxyl radical. In

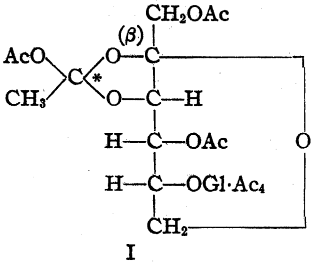
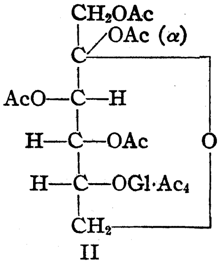
addition, both isomers are reconverted into the starting material by treatment with titanium tetrachloride in chloroform solution. The structure of the new pentaacetate is thus established.

The discovery of the effect of zinc chloride in acetic anhydride solution upon the acetates of fructose suggested the application of this isomerization to the acetates of other ketoses. In Part I,[7] there have been described four isomeric octaacetates of turanose which are referred to by giving the ordinal number of their sequence in discovery. The third octaacetate has been shown in Part III[8] to have an open-chain structure. Since this compound can possess no α- or β-isomer, it holds no interest in connection with the action of zinc chloride. The first and fourth octaacetates have been described as representing a pair of isomeric orthoester acetates which differ only in the configuration of the newly formed asymmetric carbon atom C* (I). This carbon atom is not part of the turanose skeleton and both compounds have been regarded as derivatives of β-turanose. The second octaacetate (II) has been *assumed* to be an α-derivative of turanose with a normal <2, 6> ring in the fructose residue.



I



II

When the solution of the second octaacetate in acetic anhydride was treated with zinc chloride at room temperature, a rapid though small change in rotation from the original value of 106.5° to the equilibrium value of 98° was observed. Although this equilibrium can scarcely be regarded as favorable, an attempt was made to prepare the expected new acetate by this method. Out of 10 g. of the second octaacetate 7 g. of pure starting material was recovered. The residual sirup could not be brought to crystallization. The rotation of this material was 63.1° in acetic anhydride, indicating a considerable concentration of the expected β-compound. Treatment of the sirup on the steam-bath with acetic anhydride and sodium acetate produced no change in the rotation of the material. However, when the sirup dissolved in acetic anhydride was treated with zinc chloride at room temperature, the rotation rose almost immediately to the equilibrium value of 98°. Upon working up the solution and recrystallizing the product, the pure second octaacetate was obtained in good yield.

The above evidence indicates definitely that a fifth octaacetate of turanose of β-configuration exists. The position of the equilibrium with zinc chloride as well as several other facts[7] sharply differentiate the behavior of the turanose acetate under consideration from that of the normal α-pentaacetylfructose. The structure of the second octaacetate of turanose may, therefore, be regarded as still open to investigation.

Attention may now be turned to the first and fourth octaacetates of turanose (I) which have been characterized in Part I[7] as a diastereomeric pair having orthoester structure. The first has the low positive rotation of 20.5°. The other has a positive rotation of 103.2°. When this higher-rotating isomer was treated with zinc chloride in acetic anhydride solution, the rotation dropped rapidly to 40° indicating the formation of an equilibrium mixture containing 87% of the first octaacetate which was isolated easily from the reaction mixture. This bears a striking resemblance to the behavior of the normal pentaacetates of fructose under like conditions, where the positive-rotating α-compound is converted 90% into the negative-rotating β-compound. Indeed, comparison of these two pairs of ketose acetates reveals much similarity and little difference.

The lower-rotating acetates may be converted[7,9] into the corresponding β-acetohalogeno compounds, and the latter react with a metal acetate to give the higher-rotating acetates.[6,7] These higher-rotating acetates when treated according to standard methods give the original β-acetohalogeno compounds as sole products.

Further facts for comparison now appeared highly desirable. The problem is more difficult because no test for orthoester structure in the case of sugar acetates is available. The conversion of these acetates to glycosides where orthoester structure can be proved may involve unpredictable changes in structure.[10]

Attention was directed to the acetohalogeno compounds as the only derivatives which are

prepared directly from the acetates. It is known that acetobromoturanose reacts with methyl alcohol and silver carbonate to give an orthoester glycoside acetate.[10] When similarly treated, acetobromofructose also yielded an orthoester glycoside acetate. Some of Schlubach's normal α-tetraacetylmethylfructoside was simultaneously formed, exactly as when acetochlorofructose was used.[11]

It has been reported in Part I[7] that acetobromoturanose undergoes a marked change when dissolved in pyridine. The observed rotation, at first negative (−3.1°), becomes strongly positive (6.3°) where it remains constant. When a stronger solution is prepared, it soon turns to a jelly, the latter shortly becoming a clear solution again. The aged solution acquires the ability to reduce an acetone solution of potassium permanganate very rapidly. This reaction was assumed to be due to the formation of a ketene-acetal which would have definitely indicated orthoester structure for the acetobromoturanose. It has now been found that this behavior is closely paralleled by a solution of acetobromofructose in pyridine. A large drop of the highly negative rotation almost to zero was observed and the solution acquired the ability to reduce an acetone solution of potassium permanganate with great rapidity.

Acetochlorofructose has been shown to undergo no change when dissolved in pyridine.[11] The same behavior was displayed by acetochloroturanose. Attempts to prepare the pyridinium salts of the acetochloro compounds by the method of Fischer[12] resulted in the recovery of unchanged starting material.

A correct interpretation of the experimental results enumerated above is not an easy matter. The use of Hudson's rules provide two apparent facts to start with. These facts are, first, α- and β-pentaacetylfructose do not possess orthoester structure and, second, the first and fourth octaacetates of turanose do not possess the same structures as the fructose acetates.

The first conclusion follows from the fact that the value for $b_{\text{fruct. Ac.}}$ can be used to calculate the rotations of the methyl- and ethylfructoside acetates. These latter compounds are of normal structure and have properties sharply differentiating them from the known methyl- and ethylfructoside acetates of orthoester structure.[11]

The second conclusion follows from the fact that it is impossible by means of the customary mathematical manipulation of the rotations of turanose octaacetates to obtain a value for a_{OAc} which would agree satisfactorily with the value of a_{OAc} calculated from the α,β pair of fructose pentaacetates <2, 6>. It may, therefore, be concluded that the glycosidic portion of the turanose acetate molecule possesses a fundamentally different structure from that of the glycosidic portion of the fructose acetates.

At present, only two types of structure about the glycosidic carbon atom of the acetylated sugars are recognized, these being the normal and the orthoester structures. Unfortunately, as stated above, it is not possible to determine by any chemical or physical means whether a sugar acetate possesses an orthoester structure or a normal structure. The only conclusion, therefore, is that the acetates of fructose possess normal structures and the first and fourth acetates of turanose have orthoester structures. Careful consideration of the behavior of the acetohalogeno compounds derived from these acetates reveals little or nothing concerning the structures of the parent acetates. On the basis of Hudson's rules, the similarity between the pairs of turanose octaacetates and fructose pentaacetates which has been mentioned earlier must be regarded as coincidental until new contradictory evidence is discovered.

Experimental Part

Action of Zinc Chloride on the Pentaacetates of Fructose.—The specific rotation[13] of α-pentaacetylfructose in pure acetic anhydride was found to be 42.3°. In 20 cc. of distilled acetic anhydride was dissolved 0.3132 g. of this substance and the solution was made up to 25 cc. with a solution of 0.1 g. of fused zinc chloride in 20 cc. of the same solvent. The following specific rotations were observed after 54, 85, and 270 seconds, respectively: 12, −10.4, and −71.5°. After twenty minutes the rotation remained constant at −107°. Two and eight-tenths grams of pure α-pentaacetylfructose was treated similarly and the equilibrated solution was evaporated to a sirup *in vacuo*, the residue taken up in chloroform, and washed with sodium bicarbonate solution until neutral. The chloroform solution was then dried with calcium chloride, filtered, and evaporated to a thin sirup *in vacuo*. This was taken up in absolute ether and placed in the ice box. After separation as described in Part V[6] and recrystallization, 1.9 g. of β-pentaacetylfructose and 0.028 g. of the original α-pentaacetate were isolated in pure form.

Ten grams of pure β-pentaacetylfructose was dissolved by heating in 10 cc. of distilled acetic anhydride. To the

(13) Unless otherwise indicated, the rotations here recorded were measured at 20°, using light of the wave length of the sodium D lines, and chloroform as solvent.

cooled solution was added 0.1 g. of fused zinc chloride dissolved in 5 cc. of the same solvent. After standing for half an hour at room temperature, the solution was poured into cracked ice and triturated with ice water until the gummy residue solidified. This was filtered off, washed and dried. Seven grams of material having the specific rotation −113° was obtained. The acidic aqueous mother liquor and washings were combined, neutralized with sodium bicarbonate, and placed in the ice box, when 1.9 g. of material having the specific rotation −97.3° separated. The aqueous mother liquor of this was extracted three times with chloroform, the extracts combined, dried with calcium chloride and evaporated *in vacuo*. The residual sirup was taken up in absolute ether and placed in the ice box. The solution deposited 0.7 g. of sticky crystals which had the rotation −96.6°. Upon working up the three crystalline fractions as before, 7.2 g. of pure starting material was recovered, and 0.2 g. of α-pentaacetylfructose was isolated in pure form.

Action of Zinc Chloride on the Second Octaacetate of Turanose.—The specific rotation of the second octaacetate of turanose in acetic anhydride was found to be 106.5°. A 0.2656-g. sample of this material was dissolved in 20 cc. of distilled acetic anhydride. The solution was made up to 25 cc. using a solution of 0.1 g. of fused zinc chloride in 20 cc. of the same solvent. Four minutes after mixing the specific rotation had fallen to 101°. In thirty minutes the rotation became 98° and remained constant at that value. Ten grams of the pure second octaacetate was now dissolved in 50 cc. of distilled acetic anhydride by warming on the steam-bath. To the cooled solution was added 0.1 g. of fused zinc chloride dissolved in 10 cc. of the same solvent. In thirty minutes the rotation of the solution became constant. After an additional half hour, the mixture was poured into 400 g. of crushed ice. After three hours of intermittent stirring, the material was left overnight in the ice box, the suspension of white powder was filtered and washed with water. The dried solid was taken up in 25 cc. of absolute ether and placed in the ice box where it crystallized; yield 7.4 g., and specific rotation, 101.8°. After two recrystallizations from hot alcohol, 7 g. of pure starting material was recovered. On systematically working up the mother liquors including the acidic aqueous mother liquor, 2.9 g. of a sirup was obtained having a specific rotation of 67.4°. In an acetyl estimation by the method of Kunz[14] 0.280 g. of material used 31.9 cc. of 0.1 normal sodium hydroxide solution. The value calculated for 8 acetyl groups is 33.0 cc. A sample of this material weighing 0.5776 g. was dissolved in 10 cc. of distilled acetic anhydride. The specific rotation in this solvent was 63.1°. To this solution was added 0.05 g. of fused zinc chloride and the rotation rose within ten minutes to 94.2° where it remained constant. The solution was poured into 100 g. of crushed ice. After two hours the solid material was filtered out, washed with ice water, and dried; yield 0.4 g. After two recrystallizations from hot alcohol, 0.3 g. of beautiful crystals of the α-octaacetate having the specific rotation 105.5° was obtained. Another portion of the sirup was acetylated with fused sodium acetate and acetic anhydride by heating the mixture on the steam-bath for half an hour. Upon working up the mixture a sirupy product was obtained showing the unchanged rotation of 67.6°.

Action of Zinc Chloride on the Fourth Octaacetate of Turanose.—In 8 cc. of distilled acetic anhydride was dissolved 0.1012 g. of the fourth octaacetate of turanose and the solution made up to 10 cc. with a solution of 0.1 g. of fused zinc chloride in 20 cc. of the same solvent. The following specific rotations were observed after 1.5, 5, 10, and 30 minutes, respectively: 84.5, 60.8, 47.3 and 41.5°. After two hours, the rotation remained constant at 40.6°. The mixture was then worked up in the usual way using sodium bicarbonate solution and the product recrystallized from absolute ether; yield, 0.06 g. having the specific rotation 28.1°. After recrystallizing from alcohol, 0.048 g. of the first octaacetate of turanose having the correct specific rotation 19.6° was obtained.

Action of Pyridine on β-Acetochloro-fructose and -turanose.—Following the procedure of Fischer in preparing the pyridinium salt of acetobromoglucose,[12] 5 g. of crystalline acetochlorofructose was dissolved in 10 cc. of pyridine freshly distilled from barium oxide. The solution was kept for two days in a glass-stoppered flask. The only observable change was a slight darkening. Neither the aged nor the fresh solution reduced an acetone solution of potassium permanganate. The solution was poured into a beaker and kept in a vacuum desiccator over concentrated sulfuric acid until the odor of pyridine had almost disappeared. The sticky brown residue was extracted with *ca.* 50 cc. of absolute ether at room temperature. A small gummy residue remained. The ether solution at 0° deposited 3.2 g. of the pure starting material. The same experiment was repeated with 0.38 g. of acetochloroturanose dissolved in 25 cc. of absolute pyridine. The yield of recovered unchanged starting material was 0.25 g. of crystals showing the correct m. p. of 166°.

Action of Pyridine on β-Acetobromofructose.—In 25 cc. of absolute pyridine was dissolved 1.0822 g. of crystalline acetobromofructose. Three and one-half minutes after adding the solvent the specific rotation was −188°. In ten minutes the rotation had dropped to −166° and in one hour to −50°. After three hours the rotation reached the value of −5.53°. The direction of the change then reversed and the rotation slowly became more negative. After slowly changing for three weeks, the rotation became constant at −45°. In 10 cc. of absolute pyridine was dissolved 2.0 g. of acetobromofructose. In a few minutes a gelatinous precipitate formed in the clear solution and on shaking soon redissolved. The material slowly acquired the ability to reduce an acetone solution of potassium permanganate. After several days, the reduction took place within a few seconds. No pyridinium hydrobromide separated on careful addition of absolute ether in contrast to the behavior of acetobromoturanose as reported in Part I.[7]

Reaction of β-Acetobromofructose with Methyl Alcohol.—The general procedure given in Part IV[11] for the acetochloro compound was followed. To a suspension of 10 g. of silver carbonate in 25 cc. of absolute methyl alcohol in a glass-stoppered flask was added 2.3 g. of acetobromofructose, and the mixture vigorously shaken. A very rapid reaction ensued, the evolution of carbon dioxide ceasing in less than one minute. After shaking for fifteen

---

(14) Kunz and Hudson, This Journal, **48**, 1892 (1926).

minutes, the solution no longer gave a test for labile bromine when boiled with alcoholic silver nitrate and nitric acid. The solution, which showed no action toward Fehling's solution, consisted of a mixture of α-methylfructoside tetraacetate and a large amount of β-methylfructoside tetraacetate with orthoester structure. In order to prove the presence of the latter compound, a few drops of the solution was diluted with 2 cc. of cold water and 1 drop of dilute hydrochloric acid was added. After *ca.* ten seconds at room temperature, considerable reduction took place on boiling with Fehling's solution. To isolate the normal α-methylfructoside tetraacetate, the reaction mixture was now filtered free of silver salts, and evaporated *in vacuo* to a thick sirup. To this was added 50 cc. of boiling water, and the mixture kept at 100° with vigorous shaking to hydrolyze the orthoester. In ten minutes a clear yellow solution was obtained. After filtering with charcoal, the colorless solution was placed in the ice box. Upon seeding with α-methylfructoside tetraacetate, the solution deposited 0.28 g. of crystals having the specific rotation 42.3°, and m. p. 110–111°. The aqueous mother liquor reduced Fehling's solution strongly due to the tetraacetylfructose formed by the hydrolysis of the orthoester. The crystalline material obtained above reduced Fehling's solution only after long boiling with acid.

Summary

The recent discovery of the true α-pentaacetylfructose $<2, 6>$ has made possible for the first time the study of the behavior of the α,β pair of ketose acetates toward different agents.

It has been shown that the use of zinc chloride as a catalyst in the isomerization of the sugar acetates is applicable in the ketose series.

The application of this method to the first and fourth octaacetates of turanose of supposed orthoester structure has revealed a strong similarity in properties to those of the normal fructose acetates. This similarity has been shown to exist also between the corresponding acetohalogeno derivatives of fructose and turanose although the former are generally assigned normal structure whereas an orthoester structure had been advanced for the latter. Application of Hudson's rules confirms the normal structure of the fructose acetates but excludes such for the turanose acetates.

The formation of a fifth octaacetate of turanose from the so-called second or α-octaacetylturanose $<2, 6>$ has been observed. Marked difference in the behavior of this pair from that of the normal fructose pentaacetates makes the structure assumed for the second octaacetate of turanose uncertain.

The behavior of the crystalline acetochloro compounds of fructose and turanose toward pyridine has been found to be radically different from that of the corresponding acetobromo compounds.

The Synthesis of Long Chain Substituted Isocyclics and Similarly Substituted Adipic Acids.[1] The Preparation of γ-*t*-Octylcyclohexanol, Hexene, Hexanone, Hydroxylamine, Amine, Phenol and β-*t*-Octyl Adipic Acid

BY JOSEPH B. NIEDERL AND RICHARD A. SMITH

Introduction

On account of the renewed interest and present-day commercial importance of the alkyladipic acids[2] it was considered appropriate to give in this communication an account of the synthesis of a long chain adipic acid, namely, the β-diisobutyladipic acid. For the preparation of this acid (VI) the γ-diisobutylcyclohexanol (I), obtained by the catalytic hydrogenation of *p*-diisobutylphenol (*p*-($\alpha,\alpha,\gamma,\gamma$-tetramethyl)-butylphenol),[3] served as the starting material in the subsequent oxidation processes. The cyclic ketone (γ-diisobutylcyclohexanone) (III) as well as the above β-diisobutyladipic acid (VI) were obtained in excellent yields employing the conventional oxidation processes.[4] The oxime (IIIa) of the above ketone was prepared in the usual manner and from this oxime the γ-diisobutylcyclohexylhydroxylamine (IV) was prepared by catalytic hydrogenation. More strenuous reduction with sodium and alcohol yielded the γ-diisobutylcyclohexylamine (V). Dehydration of the γ-diisobutylcyclohexanol (I) yielded the corresponding γ-

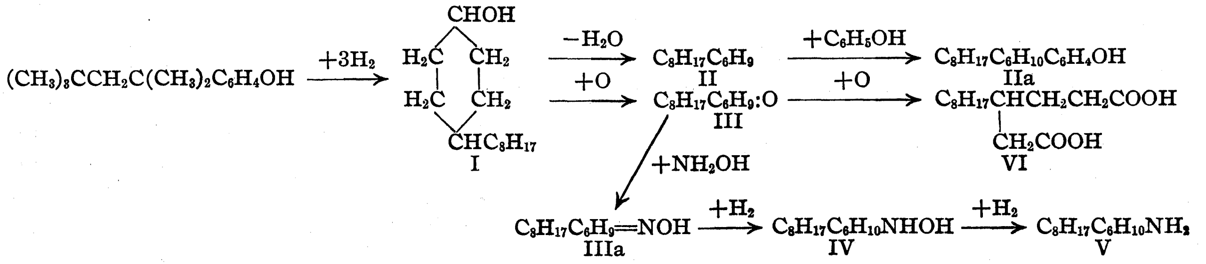
diisobutylcyclohexene (II) which in turn was condensed with phenol according to the method of Niederl and co-workers[5] to form a *p*-diisobutylcyclohexylphenol (IIa).

The methods of preparation and the structural relationship of the various new products described herein may be illustrated as follows



as the reaction proceeded. At the completion of the reaction (one-half hour after heat ceased to be evolved), the whole was allowed to cool. The product was separated and purified by vacuum distillation. The yield was approximately 85%; b. p. 142–144° (11 mm.); sp. gr. (20°) 0.9850; $n^{23}\text{D}$ 1.4768.

Anal. Calcd. for $C_{14}H_{26}O$: C, 80.0; H, 12.6. Found: C, 79.3; H, 12.3.

Experimental

Methods of Preparation

I. 4-(α,α,γ,γ-Tetramethyl)-butylcyclohexanol-1.—This compound was prepared by catalytic hydrogenation under high pressure and at elevated temperature of *p*-diisobutylphenol:[6] m. p. 55.5–56°; b. p. 148–150° (11.5 mm.).

Anal. Calcd. for $C_{14}H_{18}O$: C, 79.24; H, 13.21. Found: C, 79.16; H, 13.22.

II. 4-(α,α,γ,γ-Tetramethyl)-butylcyclohexene-1.—To 42 g. of the above *t*-octylcyclohexanol (I) 0.6 cc. of sulfuric acid (95%) was added and the mixture, contained in a Claisen flask, was heated on an oil-bath at 130–140° at 12 mm. The *t*-octylcyclohexene distilled over as rapidly as it formed: b. p. 113° (12 mm.), sp. gr. (25°) 0.8565; $n^{25}\text{D}$ 1.4741.

Anal. Calcd. for $C_{14}H_{26}$: C, 86.60; H, 13.40. Found: C, 86.76; H, 13.37.

IIa. 4-(α,α,γ,γ-Tetramethyl)-butyl-1-(4-hydroxy)-phenylcyclohexane.—To a 0.1 molar mixture of the above *t*-octylcyclohexene (II) and phenol, 2 cc. of sulfuric acid (95%) was added slowly at 60° and the mixture was then allowed to stand overnight. The reaction product was worked up according to the procedure of McGreal and Niederl[7] and then subjected to fractional distillation under reduced pressure: m. p. 81° (uncorr.); b. p. 110–120° (2 mm.).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.28; H, 11.10. Found: C, 83.52; H, 11.08.

III. 4-(α,α,γ,γ-Tetramethyl)-butylcyclohexanone-1.—Twenty-eight grams of the above *t*-octylcyclohexanol (I) was added in four portions over a period of half an hour to a solution of 30 g. of crystalline potassium dichromate, 150 cc. of water, and 25 g. of sulfuric acid (sp. gr. 1.84) contained in a flask fitted with a mechanical stirrer. The temperature was held at 50–55° by means of an external bath. Heat was evolved during the additions, and a double compound which formed during the reaction disappeared

IIIa. 4-(α,α,γ,γ-Tetramethyl)-butylcyclohexanone-1-oxime was prepared from the above cyclic ketone (III) in an alcoholic solution of hydroxylamine with heating on a steam-bath. The oxime was recrystallized from 70% alcohol; m. p. 152° (uncorr.).

Anal. Calcd. for $C_{14}H_{27}NO$: C, 74.66; H, 12.00; N, 6.23. Found: C, 74.60; H, 12.21; N, 6.17.

IIIb. Sodium Bisulfite Addition Compound of 4-(α,α,γ,γ-Tetramethyl)-butylcyclohexanone-1.—A saturated solution of sodium bisulfite (50% excess) was shaken with the *t*-octylcyclohexanone (III); white crystals separated. The crystals were heated with boiling 50% alcohol and cooled. A mass of fine snow-white crystals separated which were filtered off and washed with water and alcohol. A saturated solution of sodium carbonate was used to regenerate the ketone in a pure form.

IV. 4-(α,α,γ,γ-Tetramethyl)-butylcyclohexylhydroxylamine-1.—Ten and one-half grams octylcyclohexanonoxime (IIIa), 1 g. of active nickel catalyst, and 150 cc. of 95% ethyl alcohol as a solvent were shaken up in an atmosphere of hydrogen at a pressure of 50 pounds per sq. in. (3.3 atm.). One molar equivalent of hydrogen was taken up. The liquid was decanted, acidified with hydrochloric acid, and evaporated to dryness on a steam-bath. The resulting crystalline compound was purified by dissolving in the minimum quantity of absolute alcohol and precipitating with absolute ether; m. p. 240–245° with decomposition.

Anal. Calcd. for $C_{14}H_{30}ONCl$: N, 5.32. Found: N, 5.29.

V. 4-(α,α,γ,γ-Tetramethyl)-butylcyclohexylamine-1.—Two and one-half grams of octylcyclohexanonoxime (IIIa) was dissolved in 100 cc. of absolute alcohol, and the whole brought to boiling. Three grams of sodium in small pieces was added rapidly. The whole was then acidified with hydrochloric acid, cooled, and the solid sodium chloride filtered off. The solid was washed with dilute hydrochloric acid; the hydrochloric acid solutions were combined and evaporated to dryness. The residue was treated with 40% sodium hydroxide and extracted twice with ether. Concentrated hydrochloric acid was added to the ether extracts and the whole was again evaporated to dryness

on a steam-bath. The product was purified by recrystallizations from alcohol and acetone, m. p. 260–265° with decomposition.

Anal. Calcd. for $C_{14}H_{30}NCl$: N, 5.67. Found: N, 5.79.

VI. β - (α,α,γ,γ - Tetramethyl) - butyl - adipic Acid.—This compound was prepared both by the oxidation of the corresponding alcohol (I), cyclohexene (II) and ketone. Oxidations with and without the aid of a vanadium catalyst were employed. The most satisfactory oxidation was the following: 125 cc. of nitric acid (50%) was heated to 110° in a flask fitted with a stirrer. A pinch of sodium vanadate (about 0.2 g.) was added. A few grams of the *t*-octylcyclohexanol (I) was then added, fumes of oxides of nitrogen being given off immediately. The whole was then cooled to 60° by means of an external bath. Then more diisobutylcyclohexanol (I) was added (42 g.) at such a rate that the temperature was kept within 55–65°. Rapid stirring was maintained throughout the entire reaction; the stirring was continued for one hour after the final addition of alcohol. Upon completion, the whole was cooled with an external ice-bath, and the mass of white crystals filtered off and air dried. The product was quite pure at this stage. The crystals were further purified by recrystallization from concentrated nitric acid; a saturated solution was made up at 65°, and allowed to cool. The yield of pure product was 60%; m. p. 133–134° (uncorr.).

Anal. Calcd. for $C_{14}H_{26}O$: C, 65.11; H, 10.08. Found: C, 64.94; H, 9.88.

This work was done in collaboration with the Chemical Laboratories of the Röhm and Haas Company, Philadelphia, Penna., who furnished the intermediate hydrogenated *p*-diisobutylphenol.

Summary

1. γ-Diisobutylcyclohexanol, hexene, hexanone, oxime, hydroxylamine amine and phenol were prepared, identified and their physical and chemical characteristics described.

2. β-Diisobutyladipic acid was prepared by a simple oxidation process, indicating the feasibility of preparing long chain adipic acid by similar methods.

The Synthesis of Long Chain Substituted Isocyclics and Similarly Substituted Adipic Acids.[1] The Preparation of α-*t*-Octylcyclohexanone and a Method of Indirect Structure Proof for Ortho and Para Alkylphenols

BY JOSEPH B. NIEDERL AND J. BRADLEY WHITMAN

Introduction

The existing methods of structure proof for ortho and para substituted alkylphenols can be divided into two main classes, the direct[2] and the indirect[3] methods. Both types of methods can be subdivided into analytical methods, and into procedures involving synthesis. The following report gives an indirect method which appears to be capable of wide application and which has served as a method of structure proof for ortho- and para-substituted alkylphenols. First a comparison of the solid derivatives (esters) of the hydrogenation products of the phenols, α- or γ-cyclohexanols may be made. These cyclohexanols can then be further oxidized conveniently to the corresponding α- or γ-cyclohexanones, of which solid, crystalline derivatives, such as the oximes, the semicarbazones, the phenylhydrazones, etc., can be prepared easily and again subjected to comparison by mixed melting points. Since the α-alkylcyclohexanones can be prepared independently by the interaction of the sodium salt of the desmotropic cyclohexanol,[4] ortho substitution of the original phenol certainly can be proved conclusively by the absence of a depression in the melting points of the cyclo ketone derivative, other constants having been determined to be identical. On further oxidation of the alkylcyclohexanones, only the γ-alkylcyclohexanone yields the corresponding β-alkyladipic acid, whereas the α-alkylhexanone yields adipic acid itself as the final oxidation product. Schematically such a structure proof can be presented as follows

---

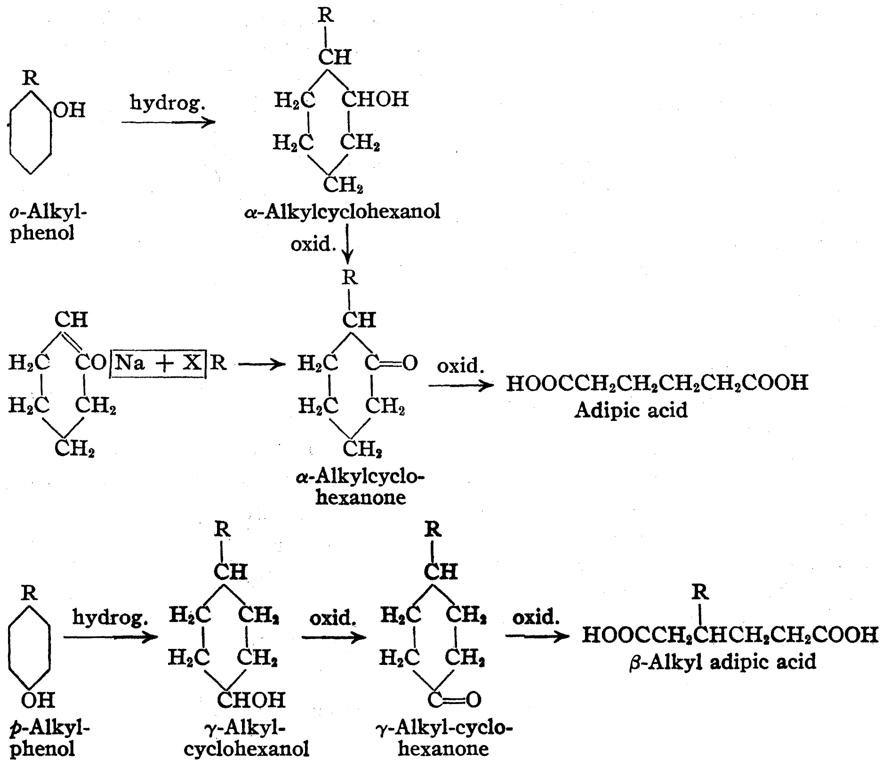
(4) Haller, *Compt. rend.*, **138**, 1140 (1904); Tarbouriech, *ibid.*, **149**, 604 (1909); Bouveault and Chereau, *ibid.*, **142**, 1086 (1906); Mannich and co-workers, *Ber.*, **39**, 1594 (1906); **41**, 467 (1908); Koetz and co-workers, *J. prakt. Chem.*, [2] **80**, 505 (1909); *Ann.* **350**, 210 (1906).



Application of this method of structure proof was made in the following case and manner. The oxime of the γ-diisobutylcyclohexanone prepared from the catalytic hydrogenation product of *p*-diisobutylphenol by subsequent mild oxidation of the hexanol to the corresponding γ-diisobutylhexanone, was proved to be different by the depression in the melting point, from the oxime of the α-diisobutylcyclohexanone prepared from the desmotropic sodium enolate of cyclohexanone and diisobutylene hydrogen bromide, $(CH_3)_3CCH_2C(CH_3)_2Br$.[5] Oxidation of the γ-diisobutylcyclohexanone yielded β-diisobutyl adipic acid, whereas oxidation, under similar conditions, of the α-isomer, gave adipic acid itself as the main and final oxidation product.

Experimental

2 - (α,α,γ,γ - Tetramethyl) - butylcyclohexanone - 1.—One molar equivalent of sodamide was added slowly to 100 g. of cyclohexanone in 300 cc. of absolute ether. When no more ammonia was evolved (after about four or five hours), one mole of diisobutylene hydrobromide, prepared by the addition of hydrogen bromide to diisobutylene,[6] was added and the whole refluxed for two days. The product was washed with water, dried over sodium sulfate, the ether distilled off and vacuum distilled. Large amounts of diisobutylene were recovered; yield 16%; b. p. 140–144° (11 mm.).

2 - (α,α,γ,γ - Tetramethyl) - butylcyclohexanonoxime - 1 was prepared from the above ketone and hydroxylamine; m. p. 147–148° (uncorr.); mixed melting point with the oxime prepared from the 4-isomer 123–125°.

Anal. Calcd. for $C_{14}H_{27}NO$: C, 74.66; H, 12.00; N, 6.23. Found: C, 74.33; H, 11.70; N, 6.50.

The Oxidation of 2-(α,α,γ,γ-Tetramethyl)-butylcyclohexanonoxime.—The oxime was oxidized with 50% nitric acid in the presence of a vanadium catalyst in exactly the same manner as was the 4-diisobutylcyclohexanol in the concomitant communication by J. B. Niederl and R. A. Smith. The reaction did not proceed as smoothly. The product melted at 152°. The analysis indicated it to be adipic acid. A mixed melting point with pure adipic acid, obtained commercially, was the same as either sample alone.

Summary

1. α-Diisobutylcyclohexanone was prepared from cyclohexanone by the method of Haller, involving the action of the diisobutylene hydrohalide upon the desmotropic sodium cyclohexenolate.

2. An indirect method of structure proof for ortho- and para-substituted alkylphenols was described.

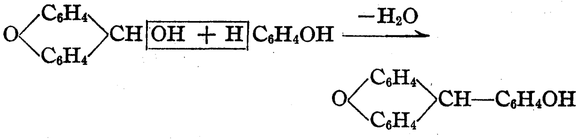
Monohydroxyphenylxanthanes[1]

BY JOSEPH B. NIEDERL AND WILLIAM F. HART[2]

In the course of the systematic investigation of the condensation of alcohols with phenols[3,4] the reaction of xanthydrol with phenols was studied using glacial acetic acid, sulfuric acid or anhydrous aluminum chloride as condensing agent. The phenolic products obtained in each case were the corresponding hydroxyphenylxanthanes. The method employing glacial acetic acid was found to be most satisfactory, indicating the extreme reactivity of the hydroxyl group in xanthydrol. This fact had been noticed previously also by Fabre, Fosse and Robyn,[5] who condensed the three dihydroxybenzenes (resorcinol, catechol and hydroquinone) and their derivatives with xanthydrol and obtained the respective mono and dixanthyl compounds.

This reaction was extended to include phenol (I), *p*-chlorophenol (II), *p*-hydroxyacetophenone (III), α-naphthol (IV), *p*-*t*-(2′-phenyl)-butylphenol (V), and *p*-*t*-(2′-phenyl)-amylphenol (VI). Condensation was effected in each case and crystalline products were obtained also in cases where conventional methods for obtaining crystalline derivatives had failed. Such phenols were the *p*-*t*-(2′-phenyl)-butylphenol and *p*-*t*-(2′-phenyl)-amylphenol.[6] These compounds were first condensed with xanthydrol and then methylated to yield the crystalline 1-methoxy-2-xanthyl-4-(2′-phenyl)-butylbenzene (V) and 1-methoxy-2-xanthyl-4-(3′-methyl-2′-phenyl)-butylbenzene (VI), respectively.

The reaction in all these condensations appears to involve the elimination of one mole of water between the hydroxyl group of xanthydrol with either the ortho or para hydrogen atom of the respective phenol, as follows



$$O\left\langle\begin{matrix}C_6H_4\\C_6H_4\end{matrix}\right\rangle CH\boxed{OH + H}C_6H_4OH \xrightarrow{-H_2O} O\left\langle\begin{matrix}C_6H_4\\C_6H_4\end{matrix}\right\rangle CH—C_6H_4OH$$

The products obtained by condensing phenol itself with xanthydrol (I), as well as its methyl ether (Ia), were found to be identical with 4-hydroxyphenylxanthane and 4-methoxyphenylxanthane, respectively, prepared by Gomberg and co-workers.[7]

Of interest is the observation that compounds in the xanthyl group (xanthydrol, xanthone, etc.) in general, and also the relatively non-toxic xanthylphenols described above, the phenol coefficient of which is less than one,[8] appear to produce in adult ovariectomized rats and mice physiological symptoms which are usually associated with feeble estrogenic substances.

Experimental

Condensation Method.—Four grams (0.02 mole) of xanthydrol was dissolved in 6 cc. of glacial acetic acid and the mixture warmed gently on the water-bath to effect solution. To this solution was added 2 g. (0.04 mole) of phenol, whereupon the solution turned red. The condensation flask was stoppered and allowed to stand for twenty-four hours at room temperature. Excess of water was then added to wash out acetic acid and unreacted phenol. If the phenol employed was not water soluble the condensation product was washed further with ammonium hydroxide of sufficient concentration (usually 10%) to dissolve that particular phenol. The condensation product was then dissolved in benzene and this solution was extracted three times with Claisen solution (50% potassium hydroxide plus an equal volume of methanol). The Claisen solution insoluble fraction contained unreacted xanthydrol, xanthone and other products not yet identified. The combined Claisen solution extracts were washed with benzene, diluted with water and acidified with dilute hydrochloric acid (10%). This acid solution was extracted with ethyl acetate or ether, the solvent removed and the residue recrystallized from an appropriate solvent, such as methanol or benzene. Decolorizing carbon was used to remove highly colored impurities. When the phenolic product obtained was difficult to crystallize, its methyl ether was prepared by methylation with dimethyl sulfate.

IV	α-Hydroxy-*x*-xanthylnaphthalene	$C_{23}H_{16}O_2$	195	85.15	4.97	84.91	5.10
V	1-Methoxy-2-xanthyl-4-(2′-phenyl)-butylbenzene	$C_{30}H_{28}O_2$	210	85.66	6.71	85.19	6.95
VI	1-Methoxy-2-xanthyl-4-(3′-methyl-2′-phenyl)-butylbenzene	$C_{31}H_{30}O_2$	202	85.71	6.91	85.95	7.05

The same phenolic condensation products were obtained when using sulfuric acid as the condensing agent. In this case 0.02 mole of sulfuric acid was added to 0.02 mole of xanthydrol and 0.04 mole of phenol. The initial condensation was carried out at 0° and was worked up as described above. Anhydrous aluminum chloride was also employed as a condensing agent; in this instance benzene was used as inert solvent and the reaction mixture was refluxed for eight hours.

Summary

A number of new monohydroxyphenylxanthanes were prepared by simple condensation methods. The physical, chemical and some physiological properties of these crystalline condensation products have been described.

"Hydro-polymerization"[1]

BY V. N. IPATIEFF[2] AND V. I. KOMAREWSKY[2]

In our study of catalytic hydrogenation, it was of great importance to investigate whether olefinic hydrocarbons could be hydrogenated by hydrogen *in statu nascendi*, obtained by decomposing water with iron in the presence of different salts as promoters.[3] For this purpose amylene and isobutene were heated (300°) in a rotating autoclave in the presence of water, reduced iron and magnesium chloride. The results were negative, although a sufficient amount of hydrogen was formed under this condition. In order to see whether magnesium chloride may act as a poison for amylene hydrogenation, a usual hydrogenation of amylene was made with hydrogen, using iron as catalyst in the presence of magnesium chloride. The hydrogenation took place,[4] but an additional new phenomenon was observed, namely, simultaneous polymerization and hydrogenation which produced *decane*. Therefore, investigation was made of other polymerization agents, such as aluminum chloride, zinc chloride and phosphoric acid,[5] in combination with different hydrogenating catalysts (Fe·NiO). In the presence of such mixed catalyst two reactions were found to take place simultaneously: (1) polymerization of the olefin hydrocarbon; (2) hydrogenation of the polymer formed. It is suggested that this reaction be called "hydropolymerization."

As is evident from the experiments, magnesium chloride and zinc chloride alone do not act as polymerizing agents under the conditions mentioned. However, in the presence of hydrogenating catalysts, polymerization takes place. It is possible that the energy given off during hydrogenation is sufficient to cause the polymerization of olefins by the weak polymerizing catalyst.

(1) Thus, amylene and isobutene, when treated at 300° and under 80 atm. hydrogen pressure in the presence of reduced iron as catalyst, produced pure pentane and isobutane.

(2) Amylene, under the same conditions, in the presence of magnesium chloride alone did not polymerize.

(3) Amylene and isobutene, under the same conditions, in the presence of a mixed catalyst iron and magnesium chloride containing water, produced decanes and octanes.

---

(1) Presented before the Division of Organic Chemistry at the 92nd Meeting of the American Chemical Society in Pittsburgh, Pa., September 7–11, 1936.

(2) Research and Development Laboratories, Universal Oil Products Co., Riverside, Illinois.

(3) Benzene, under similar conditions, could not be hydrogenated (Ipatieff, unpublished results).

(4) V. Ipatieff and A. V. Grosse showed the possibility of hydrogenating the olefins in the presence of aluminum chloride (unpublished work).

(5) V. Ipatieff and V. Komarewsky, unpublished work.

Additional evidence that the reaction of hydro-polymerization is a real simultaneous reaction was given by the fact that when the experiments were conducted under conditions not favorable to the hydrogenation in a glass liner placed in the autoclave, the hydrogenation did not take place even in the presence of a hydrogenation catalyst, and at the same time *no polymerization occurred.*

This paper describes the "hydro-polymerization" of amylene and of isobutene in the presence of the hydrogenating catalysts, reduced iron and nickel oxide, together with the polymerizing agents magnesium, zinc and aluminum chlorides.

Experimental Part

Apparatus and Procedure.—All the experiments were carried out in an electrically heated rotating autoclave of the Ipatieff type (800-cc. capacity). The gaseous products of the reaction were analyzed. The liquid products were fractionated by means of a Podbielniak column.

Experiments with Amylene.—(Trimethylethylene containing methylethylethylene, b. p. 35–37°.)

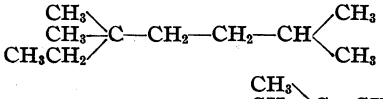
Experiment 1.—Amylene 40.0 g., reduced iron 10.0 g., hydrogen 80 kg./sq. cm., produced at 300° during four hours 32.0 g. of completely saturated (permanganate test) liquid, insoluble in 96% sulfuric acid; b. p. 35°, that of pure isopentane. Gas remaining at the end of the reaction was pure hydrogen.

Experiment 2.—Amylene 40.0 g., reduced iron 10.0 g., magnesium chloride ($MgCl_2 \cdot 6H_2O$) 2.0 g., hydrogen 80 kg./sq. cm., produced at 300° during four hours 30.0 g. of liquid with b. p. 35–173°. The liquid contained only 5% of unsaturated hydrocarbons (96% sulfuric acid treatment). By fractionation of the liquid 10.0 g. of product was obtained which boiled at 170–173° and was completely stable toward permanganate and sulfuric acid.

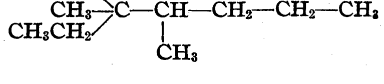
Anal. Calcd. for $C_{10}H_{22}$: C, 84.51; H, 15.49. Found: C, 84.35; H, 15.63; mol. wt., 140; n^{25}_D 1.4130.

These data show that pure decane was present. Its formation can be explained as the polymerization of two molecules of amylene to its dimer with simultaneous hydrogenation to decane, $2C_5H_{10} + H_2 = C_{10}H_{22}$.

On the basis of the established facts[6] of the polymerization of olefins, we can ascribe to the obtained isodecane the constitution



or



The gas remaining after the reaction contained H, 84%; C_2H_6, 5.1%; C_3H_8, 2%; C_4H_4, 1.0%; CH_4, 8.0%.

Experiment 3.—Forty grams of amylene and 2.0 g. of magnesium chloride heated at 300° during four hours remained unchanged.

Experiment 4.—Amylene (40.0 g.) was unchanged after heating during four hours at 300° with 62.0 g. of reduced iron, 24.6 g. of water and 2.0 g. of magnesium chloride.

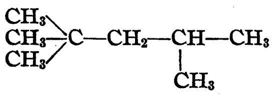
Experiments with Isobutene

Experiment 5.—At 250° under 80 kg./sq. cm. hydrogen pressure in the presence of reduced iron, isobutene hydrogenated to pure isobutane during four hours.

Experiment 6.—Fifty grams of pure isobutene (obtained by dehydration of isobutyl alcohol over activated alumina), 12.5 g. of reduced iron, 2.5 g. of magnesium chloride under 80 kg./sq. cm. of hydrogen produced at 250° during eight hours, 23.0 g. of liquid, b. p. 50–210°, which contained 10% of unsaturated hydrocarbons (sulfuric acid treatment). After the treatment with sulfuric acid (96%) the remaining liquid hydrocarbon was completely stable toward permanganate solution and nitrating mixture. By distillation two fractions were separated: (1) 100–110° and (2) 170–180°. The first fraction had the following properties: n^{25}_D 1.3990; d^{20}_4 0.6970; mol. wt., 110, and octane number, 100.

Anal. Calcd. for C_8H_{18}: C, 84.21; H, 15.79. Found: C, 84.17; H, 15.8.

On the basis of these data the first fraction consisted mainly of isooctane, 2,2,4-trimethylpentane.



The second fraction (b. p. 170–180°) had properties and analysis corresponding to those of an isododecane. The condensable gas (21.5 g.) from the reaction contained 65% of unreacted isobutene and 31.2% of isobutane. The uncondensable gas was pure hydrogen. It is evident that pyrolysis did not take place.

Experiment 7.—The isobutene treated under the same conditions as above but in the presence of magnesium chloride alone did not undergo change.

Experiment 8.—One hundred thirty-five grams of isobutene, 12.5 g. of reduced iron, 5.0 g. of nickel oxide, 5.0 g. of zinc chloride under 80 kg./sq. cm. of hydrogen at 275° during eight hours yielded 109.0 g. of liquid boiling at 32–175° and containing traces of unsaturated hydrocarbons.

Fractionation of this liquid gave 46.5 g. boiling from 100–120° with n^{25}_D 1.3976; d^{20}_4 0.6960; mol. wt., 112.

Anal. Calcd. for C_8H_{18}: C, 84.21; H, 15.79. Found: C, 84.15; H, 15.84.

The gas remaining from the reaction consisted of 92.8% hydrogen and 7.2% isobutane.

Experiment 9.—Isobutene treated under the same conditions but with zinc chloride alone remained unchanged.

Experiment 10.—One hundred and thirty-three grams of isobutene, 10.0 g. of reduced iron, 5.0 g. of nickel oxide and 2.5 g. of aluminum chloride under 80 kg./sq. cm. of hydrogen produced at 275° during twelve hours 115.0 g. of a liquid (b. p. 40–350°) from which 30.0 g. of isoöctane fraction was fractionated which boiled at 100–110°; n^{25}_D 1.4040; d^{20}_4 0.7050; mol. wt., 110.

---

(6) V. N. Ipatieff, *Ind. Eng. Chem.*, **27**, 1067 (1935). In this case we have as the catalyst Cl—Mg—OH which forms the ester Cl—Mg—O—C_5H_{11}; and V. N. Ipatieff, "Catalytic Reactions at High Temperatures and Pressures," The Macmillan Co., New York, 1936.

Anal. Calcd. for C_8H_{18}: C, 84.21; H, 15.79. Found: C, 84.10; H, 15.87.

The product isolated was completely stable toward permanganate and nitrating mixture. The yield of isooctane, 2,2,4-trimethylpentane, was less than in some of the other experiments because aluminum chloride is a very strong polymerizing catalyst.

EXPERIMENT 11.—Aluminum chloride alone completely polymerized isobutene under the conditions of the experiments and produced a viscous oil.

Summary

1. A new simultaneous reaction of hydropolymerization was discovered and studied in the case of amylene and isobutene.

The Hydration of Unsaturated Compounds. V. The Rate of Hydration of Acetylene in Aqueous Solution of Sulfuric Acid and Mercuric Sulfate[1]

BY R. H. FRIEMAN,[2] E. R. KENNEDY AND H. J. LUCAS

In the usual commercial process of hydrating acetylene to acetaldehyde in the presence of mercuric sulfate and sulfuric acid, there is present an insoluble or slightly soluble amorphous substance, a mercury organic compound or compounds. It is probable that the composition of these precipitates varies with conditions, as pointed out by Whitmore.[3] As to whether these precipitates are intermediates in the hydration process, the evidence is conflicting. Whitmore points out that the hydration of the triple bond may merely be catalyzed by mercuric ions in acid solution, as in the case of piperonylacetylene.[4] It has been postulated that organo-mercury compounds are intermediates.[5]

The Analytical Method.—The procedure finally developed for the analysis of acetylene in aqueous solution, based upon the methods of Davis, Crandall and Higbee[6] and of Eberz and Lucas[7] follows. Into a 300-ml. conical flask having a ground glass stopper with sealed-in stopcock, is pipetted 25.00 ml. of 0.0500 *N* potassium bromate–bromide solution and the flask is evacuated to about 25 mm. with a water aspirator. Then 5 ml. of 6 *N* sulfuric acid is added, the mixture is allowed to stand for two to three minutes, and then in order are pipetted in, 10 ml. of 0.2 *M* mercuric sulfate, 25 ml. of water, and finally 2 to 10 ml. of the sample to be analyzed, a dilute aqueous solution of acetylene. The last is thoroughly rinsed into the flask from a special pipet of the type described by Eberz and Lucas[7] and the flask, still under vacuum and wrapped in a black cloth to exclude light, is shaken mechanically for five to seven minutes. At this time, 5 ml. of 2.0 *N* sodium chloride and 10 ml. of a freshly prepared 20% potassium iodide solution are added. The shaking is continued for another five to seven minutes, the black cloth is removed, the vacuum is then broken, 50 to 100 ml. of water is added to dilute the solution, and titration is made with 0.03 *N* sodium thiosulfate solution. A blank is run at the same time, omitting only the sample.

Discussion of the Analytical Method.—The simple bromate–bromide method of determining unsaturation is not satisfactory for the triple bond, as pointed out by Davis, Crandall and Higbee[6] in the case of acetylene, because of the interference due to oxygen, and by Mulliken and Wakeman[8] in the case of liquid alkynes, for which the analytical results were low. The former authors showed that aluminum, nickel and mercury salts are an aid in the quantitative determination of acetylene. In the present work it has been found that the bromination of acetylene proceeds rapidly and smoothly if the molal ratio of mercuric sulfate to the total halide present is greater than unity, but under these conditions the iodine end-point with starch is uncertain. The addition of sodium chloride overcomes this difficulty, making reproducible results possible.

The accuracy of the method has been demonstrated by (a) varying the time of bromination, in order to test the possibility of substitution, and (b) varying the ratio of acetylene to bromine in order to determine upper and lower limits. It was found that the same volume of thiosulfate solution was required to back titrate equal volumes of a given aqueous acetylene solution, when the time of bromination was 4, 8, 12, 16, 20 or 24 minutes. This indicates that no substitution takes place. In Fig. 1, in which per cent. of bromine reacted is plotted against the molal ratio of acetylene to bromine, a 45° angle line is drawn, which is the theoretical curve, on the assumption that one-half of the moles of bromine reacted represent the moles of acetylene. An analysis was made of four different aqueous acetylene solutions, in order to establish the acetylene content. These results do not appear on the plot, since they would automatically fall upon the curve. Volumes of the four solutions, different from those taken for the analysis, were then analyzed and the results plotted. It is apparent that the values fall upon the theoretical curve when the initial molal ratio of bromine to acetylene is four or more, *i. e.*, at least twice the theoretical amount, but deviate when this ratio is less. Even when the bromine is in very large excess, *viz.*, one hundred to one, the results are comparable, showing again that no substitution takes place. Because of the good agreement over a wide range of conditions, it is believed that the analytical method is reliable. This procedure of testing the method was resorted to when it was found that pure acetylene was not available, as discussed under purification. The method was not always reliable in the presence of acetaldehyde, as discussed under interference of acetaldehyde.

Materials.—Mercuric sulfate solutions were prepared from C. P. mercuric oxide and C. P. sulfuric acid. Acetaldehyde was prepared by the depolymerization of paraldehyde and was distilled three times through a fractionating column. Solutions of acetaldehyde of known concentration in water were made up by weight. The acetylene was taken from a "Prestolite" cylinder.

Purification of Acetylene.—The acetylene supposedly was purified by passing through solutions in spiral wash bottles, *viz.*, sodium bisulfite, for removing acetone coming from the cylinder, copper sulfate (made acid by the addition of a few drops of sulfuric acid), for removing phosphine, chromic anhydride in 50% (by volume) sulfuric acid, for oxidizing impurities, especially phosphine, and finally sodium hydroxide. The gas then passed through towers packed with solids, *viz.*, calcium chloride, calcium hypochlorite (H. T. H.), and flake sodium hydroxide.[9] The acetylene from this system was still impure for it absorbed more than the theoretical amount of bromine (a variable amount, usually about 114% of the theoretical), its vapor density was 26.60 (against a theoretical value of 26.02), and an aqueous bromine solution, through which a large volume of the gas had been passed, gave a positive phosphomolybdate test for phosphate. Slow passage of the gas through the purifying apparatus enhanced the purity of the gas, for the lowest value of the vapor density, 26.30, was obtained under these conditions. If the per cent. of sulfuric acid in the chromic acid wash bottle was much greater than 50%, there was rather rapid reduction of the chromic acid due to oxidation of the acetylene. Variations in the method of purification, or even a lack of purification, did not alter greatly the bromine value of different samples of gaseous acetylene. The error involved in this determination is 1 to 2% and is due to the difficulty in accurately measuring the small sample of 2 to 3 cc. of gas, and in quantitatively transferring it to the bromine flask.[10] Even though the acetylene contained phosphine, it is believed that the reaction rate data are not influenced by it, since the amount dissolved in the hydrating solutions was so small that a positive phosphomolybdate test could not be obtained.

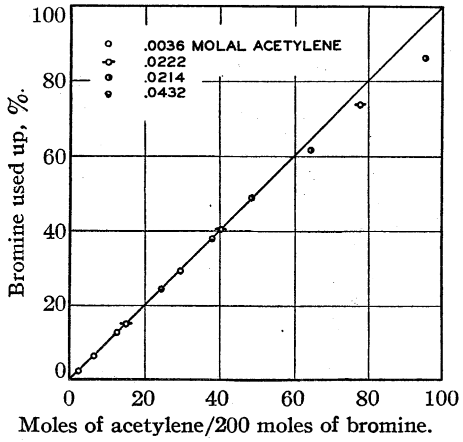

Fig. 1.—Limitations of the analytical method.

Apparatus and Method.—The apparatus previously described[7b] was used for this work. The method consisted in passing acetylene into a sulfuric acid solution of known concentration, 5.000 weight formal (*wf.*),[11] until a sufficient amount was dissolved, and adding a measured volume of standard mercuric sulfate in 5.000 *wf.* sulfuric acid, all at 25°. After shaking, the resulting clear solution[12] was quickly transferred to the apparatus, kept at 25 ± 0.04°, from which samples were removed for analysis at intervals of twenty to forty minutes.

---

[9] This train was believed to embody the best features of numerous purification methods described by others. See Mathews, THIS JOURNAL, **22**, 106 (1900); Kahutani and Yamada, *C. A.*, **25**, 1655 (1931); Cummings, Hopper and Wheeler, "Systematic Organic Chemistry," D. Van Nostrand Co., New York, 1931, p. 171; Livingston and Schiflett, *J. Phys. Chem.*, **36**, 750 (1932).

[10] The weight of acetylene was calculated by the use of the *P–V–T* relation given in "International Critical Tables," Vol. III, McGraw-Hill Book Company, Inc., N. Y., 1928, p. 3.

[11] Or 4.167 formula weights per liter (*vf.*).

[12] If any cloudiness developed the liquid was discarded.

Interference of Acetaldehyde with the Analytical Method.—The reaction product, acetaldehyde, interferes with the acetylene analysis. It is not possible to correct for this effect, because of the variability of results when aldehyde solutions are added to the analytical mixture. There appeared to be a qualitative relationship between the amount of bromine used up and the age of the added aldehyde solution; moreover, this amount appeared to increase more rapidly as the concentration of the acid was raised. It is probable that the variations in the amount of bromine used up by added acetaldehyde, which in some cases were as much as 100%, were due to its partial conversion to other products, such as paraldehyde, aldol and crotonic aldehyde. The error due to the interference of aldehyde with the analytical procedure was estimated to be of the same order of magnitude as the precision of measurement by the time the acetylene was about one-fourth reacted. In the initial stages of the hydration, where the concentration of aldehyde (and consequently the bromine reactive substance) was very small, the analytical procedure was regarded as reliable.

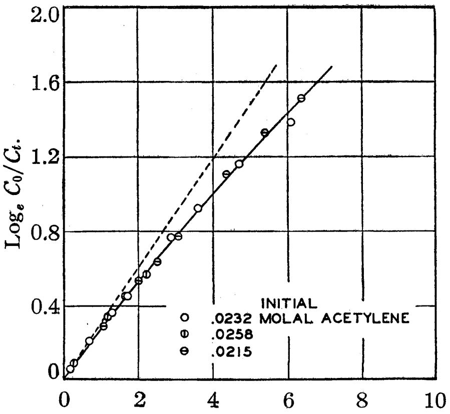

Fig. 2.—Hydration of acetylene in 5.00 weight formal sulfuric acid and 5.00 × 10^{-5} weight formal mercuric sulfate.

The Initial Hydration Rate.—In order to obtain the initial slope of $\log_e C_0/C_t$ against t (in hours), it was necessary to extrapolate to zero time. The data and the initial slopes of fourteen experiments are shown in Table I. When the mercuric sulfate is 5.00 × 10^{-5} *wf.*, and when no aldehyde has been added, the values of the initial reaction rate constants (taken from the initial slopes) lie between 0.285 and 0.322, with 0.290 as the average. The satisfactory agreement here, over a five-fold change in initial acetylene concentration, shows that the initial rate is first order with respect to the acetylene concentration. The similarity of different runs is shown by plotting $\log_e C_0/C_t$ against t, as in Fig. 2, which gives the results of three typical experiments, *viz.*, 4, 5 and 6. Here the data of all three fall upon the solid curve; the dotted straight line is the average initial slope of eight experiments. It is evident that the rate subsequent to the initial one does not obey the first order equation, but apparently is dependent upon some higher power, which proved to be the four-thirds power.

Table I

Hydration Experiments in 5.00 Weight-Formal Sulfuric Acid

Run	k initial, hrs.$^{-1}$	Initial concentration C_2H_2 *vf.*	CH_3CHO *vf.*	$HgSO_4$ *wf.* × 10^5
1	0.292	0.0225	zero	5.00
2	.285	.0252	zero	5.00
4	.302	.0232	zero	5.00
5	.288	.0215	zero	5.00
6	.285	.0285	zero	5.00
7	.260	.0123	zero	5.00
13	.322	.0052	zero	5.00
14	.293	.0245	zero	5.00
Average	.290			
3	.186	.0229	zero	4.00
10	.415	.0275	zero	6.00
9	zero	.0470	zero	zero
8	.201	.0257	0.042	5.00
11	.198	.0248	.083	5.00
12	.285	.0275	.083	6.00

The initial hydration rate is second order with respect to the concentration of mercuric sulfate, for the plot of the initial rate constant against the square of the mercuric sulfate concentration gives a straight line, as shown in Fig. 3. This must pass through the origin, because sulfuric acid alone, in the absence of mercuric sulfate, did not cause hydration of acetylene. It is worthy of note that dependence of rate upon the square of the mercuric sulfate holds when aldehyde is present (experiments 11 and 12, Table I).

The dependence of the rate upon the concentration of the sulfuric acid was not studied. The rate appears to be dependent upon a higher than first power acid concentration because, in 1 *wf.* sulfuric acid (0.963 *vf.*), the hydration proceeds too slowly to be measured.

The Effect of Acetaldehyde upon the Hydration Rate.—The apparent four-thirds power relationship between the reaction rate constant during the course of the hydration, and the acetylene concentration, a relationship which is true of experiments 4, 5 and 6, held in some other cases.

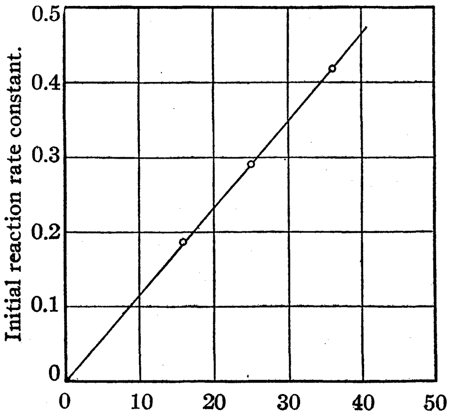

Fig. 3.—Relationship of initial rate constant to the concentration of mercuric ion.

However, it is not typical of all the experiments, for example, those in which the initial acetylene concentration was low (7 and 13) and those in which recently distilled aldehyde was added (8, 11 and 12). Figure 4, in which is plotted the curve for experiment 8 (solid line), indicates a first power relationship to the acetylene. However, the slope of this line is below the value when no aldehyde has been added, shown by the broken line. The effect is not due to interference with the analytical procedure, for the time hardly permitted the formation of the substance responsible for the interference. On the other hand, erratic data and no smooth curves resulted when aldehyde solutions in sulfuric acid which had stood for two to three days, were used instead of a freshly prepared solution. There was no dependence upon the first power relationship in these cases. Since erratic results were associated with some runs in which freshly prepared aldehyde solution was added (for instance, the constants are practically identical in experiments 8 and 11, in which the initial aldehyde concentrations differed by a factor of 2), the best basis for considering the effect of acetaldehyde lies with those experiments which had no acetaldehyde originally. Assuming that the acetaldehyde concentration at the time, *t*, is given by the acetylene which has undergone hydration up to that time, the rate varies approximately as the inverse three-halves power of the aldehyde concentration in those experiments in which the four-thirds power relationship to acetylene held.

The four-thirds power dependence of the rate upon the acetylene concentration, characteristic of such runs, the apparent inverse three-halves power relationship to acetaldehyde concentration, the drop in the initial rate constant when aldehyde is added initially, and the first power relationship of the rate to acetylene concentration under these conditions, probably depend upon the formation of a complex between mercuric ion and acetaldehyde.[13,14]

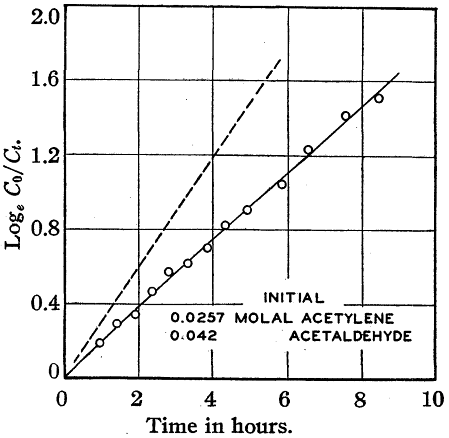

Fig. 4.—Influence of added acetaldehyde upon the hydration of acetylene.

Discussion of the Hydration Mechanism.—Since the homogeneous hydration rate of acetylene is first order with respect to the acetylene concentration, and second order with respect to the mercuric sulfate (or acid sulfate) concentration, the simplest interpretation of the reaction mechanism is the assumption that an intermediate complex, from one molecule of acetylene and two molecules of mercuric sulfate (or bisulfate), is the substance which undergoes hydration:

$$C_2H_2 + 2Hg(HSO_4)_2 \rightleftharpoons C_2H_2Hg_2(HSO_4)_4$$

$$C_2H_2Hg_2(HSO_4)_4 + H_2O + nH_3O^+ \longrightarrow CH_3CHO + 2Hg(HSO_4)_2 + nH_3O^+$$

It is probable that mercuric bisulfate is the reactive substance, since in the strongly acid solution bisulfate ions predominate over sulfate ions. The assumed higher than first power dependence of the hydration rate upon sulfuric acid is in part accounted for by the presence of the two bisulfate radicals in the complex. Because of the additional catalytic effect of hydrogen ion,

---

(13) Denigès, *Ann. chim. phys.*, [7] **18**, 396 (1899), describes a compound of mercuric sulfate and acetaldehyde, $CH_3CHO \cdot HgSO_4 \cdot 2HgO$, which is destroyed by hydrochloric acid with regeneration of the aldehyde.

(14) The referee has suggested that the effect may be due to the fact that mercuric ion suffers reduction in the presence of oxygen.

one might reasonably expect a third power, or even higher, dependence. The importance of bisulfate ion in the hydration of acetylene is shown by the work of Vogt and Nieuwland,[5] whose best catalytic mixtures were saturated solutions of potassium (or similar) bisulfate in contact with mercuric sulfate.

One could propose a plausible mechanism for the hydration reaction, based upon the above equation, but the information at present available is still insufficient to permit of a definite decision.

Summary

Acetylene undergoes homogeneous hydration to acetaldehyde in aqueous solutions in the presence of mercuric sulfate and sulfuric acid. The initial rate of hydration is first order with respect to the acetylene concentration and second order with respect to the mercuric sulfate concentation, while the rate at time *t* has an apparent four-thirds power dependence upon the acetylene. This last is believed to result from the formation of a complex between mercuric sulfate and acetaldehyde.

A probable mechanism of the hydration involves the formation of an intermediate complex between one molecule of acetylene and two molecules of mercuric bisulfate, and the reaction of this complex with water, in the presence of an acid, to form vinyl alcohol, which rearranges to acetaldehyde.

The bromate–bromide method of determining unsaturation is applicable to aqueous solutions of acetylene, provided there is present a soluble mercuric salt whose molal ratio to total halide is greater than unity.

Pharmacologically Active Compounds from Alkoxy-β-phenylethylamines

BY WALTER S. IDE AND JOHANNES S. BUCK

Considerable pharmacological data have been accumulated on compounds connected with or prepared from methoxy-β-phenylethylamines. It is therefore of great interest to examine the corresponding ethoxy compounds, for this would allow an exact comparison of the pharmacological effects of the ethoxy and methoxy groups to be made. The authors have therefore prepared seven such β-phenylethylamines and from them several series of compounds (N-methylamines, ureas, *unsym*-methylureas, barbituric acids, isoquinolines, N-methylisoquinolines, benzyl-β-phenylethylamines, and characterizing compounds).

Experimental

The amines were prepared by the series of reactions used by Buck.[1,2] As starting materials aldehydes with the following substituents were used (hereafter these letters refer to the same substituents):

A 2-Ethoxy-
B 3-Ethoxy-
C 4-Ethoxy-
D 2-Ethoxy-3-methoxy-
E 3-Methoxy-4-ethoxy-
F 3-Ethoxy-4-methoxy-
G 3,4-Diethoxy-

The aldehydes A, B, C, D and E were prepared by ethylating (ethyl sulfate and sodium hydroxide) the corresponding phenolic aldehydes. Aldehyde F was prepared by methylating 3-ethoxy-4-hydroxybenzaldehyde and aldehyde G by ethylating the same phenolic aldehyde.

The aldehydes, together with a number of intermediates, have been described previously (see references, where *Cf.* indicates a different method of preparation or an indirect reference). New intermediates are given in the table.

Alkoxy-β-phenylethylamines.—These were prepared from the corresponding amide by a Hofmann reaction, using sodium hypochlorite. They are colorless liquids, insoluble in water, and having a faint musty odor when freshly distilled. After standing they smell of ammonia. They form solid carbonates very readily in the air.

Alkoxy-β-phenylethylmethylamines are prepared from the above amines by the Decker method, through the Schiff base and methyl iodide, as described by Buck.[1,2] The amines are colorless liquids, sparingly soluble in water and having a faint musty odor. They do not form solid carbonates as readily as the primary amines. The Schiff bases were not isolated at this point. The hydriodides are soluble in water and alcohol. They were recrystallized from alcohol–ether mixture.

Alkoxy-β-phenylethylamine hydrochlorides were prepared either from the amines by dissolving them in absolute alcohol and passing in dry hydrogen chloride, after which they were recrystallized from alcohol–ether mixture, or by the use of silver chloride on the hydriodides. They are very soluble in cold water, soluble in cold alcohol, spar-

Alkoxy-β-phenylethylureas and *unsym*-methylureas were prepared by using the nitrourea method as described earlier.[8–11] They are moderately soluble in benzene and alcohol, sparingly soluble in petroleum ether. Urea D was also prepared by the potassium cyanate method but the product requires more treatment.

1-(Alkoxy-β-phenylethyl)-5,5-diethyl Barbituric Acids.—The barbituric acids were prepared from the corresponding ureas by a method described by Buck.[8,12,13] B and C reaction mixtures were diluted and made acid to Congo red. The product separated as an oil and soon solidified. In the case of A, D, E, F, G, the reaction mix-

crystallized by taking up in a little absolute alcohol–ether mixture from which the crystals separate on evaporation of the solvent.

Benzyl-(alkoxy-β-phenylethyl)-amine Hydrochlorides.—These were prepared by condensing the amine with the appropriate aldehyde to form the Schiff bases and reducing these by the Adams method.[14] While no attempt was made to isolate the Schiff bases, a number of these separated on removing water from the reaction mixture and are recorded. A few amines were obtained solid and are recorded but the majority were converted directly into the hydrochloride by the addition of concentrated hydrochloric acid. The amines are rather soluble in the ordinary solvents. A small amount of absolute alcohol–ether mixture was found best for recrystallization. The hydrochlorides are in general moderately soluble in alcohol and benzene, sparingly soluble in hot water, ether and petroleum ether.

Alkoxytetrahydroisoquinoline and N-Methyltetrahydroisoquinoline Hydrochlorides.—The hydrochlorides were prepared by treating the corresponding amines with 40% formalin and then cyclizing the product with hydrochloric acid, as described elsewhere.[15] In line with previous experience it was found that, unless a substituent (alkoxy) was present meta to the side-chain of the amine, cyclization did not proceed normally under the conditions used.[16] The two series of hydrochlorides show little difference. They are readily soluble in cold water, moderately soluble in cold absolute alcohol, sparingly soluble in ether and ethyl acetate, and readily soluble in cold concd. hydrochloric acid.

4 - Nitrobenzoyl - (alkoxy - β - phenylethyl) - amines and N-Methylamines.—The 4-nitrobenzoyl compounds were prepared by treating the amine hydrochloride in benzene with 4-nitrobenzoyl chloride.[17] After heating for a short time the benzene was evaporated and the solid residue further heated on the steam-bath. The compound was taken up in a little benzene, shaken with dilute potas-

sium hydroxide, and washed with water, and further purified by recrystallizing from alcohol. They are insoluble in water and moderately soluble in alcohol.

The amines, N-methylamines, benzylphenylethylamines, isoquinolines and N-methylisoquinolines were not O-dealkylated as the corresponding hydroxy derivatives required for the pharmacological work have been prepared previously by demethylating the appropriate methoxy derivatives.[1,2,14,15]

The pharmacological work will be reported in another place. Some of that previously done is reported elsewhere.[11,18-21]

Nitrogen determinations were carried out by a micro-Dumas method. Melting points are corrected.

Summary

A series of seven alkoxy-β-phenylethylamines has been prepared, and from these amines the corresponding N-methylamines, ureas, *unsym*-methylureas, barbituric acids, isoquinolines, N-methylisoquinolines, benzyl-β-phenylethylamines and characterizing compounds have been made. Over one hundred and twenty of these compounds have not been described previously.

The Measurement of the Conductance of Electrolytes.[1,2] VIII. A Redetermination of the Conductance of Kohlrausch's Standard Potassium Chloride Solutions in Absolute Units

BY GRINNELL JONES AND MAURICE JOSEPH PRENDERGAST

Most of the experimenters who have measured the electrical conductance of solutions have calibrated their cells by means of either a 1 or 0.1 or 0.01 N solution of potassium chloride whose absolute conductance was assumed to be known from the measurements of Kohlrausch, Holborn and Diesselhorst.[3] Unfortunately, Kohlrausch gives alternative definitions of these solutions. Kraus and Parker[4] have shown that although the alternative definitions of the 1 N solution are mutually consistent, the alternative definitions of the 0.1 N and of the 0.01 N solutions are not mutually consistent. Parker and Parker[5] have redetermined the absolute values of the conductance of the Kohlrausch solutions with substantially different results. They proposed new definitions of three different standard solutions, which they call 1, 0.1 and 0.01 demal and gave the results of measurements of the absolute conductance of these solutions. The experimental method used by Parker and Parker was in principle similar to that used by Kohlrausch although evidently improved in many details.

The Editors of the "International Critical Tables" accepted Parker and Parker's work as more reliable than that of Kohlrausch, Holborn and Diesselhorst and have applied corrections to the data in the literature based on the Kohlrausch standards to make them conform to the newer standards of Parker and Parker. As a result very few of the figures for the conductance of solutions found in the "International Critical Tables" agree with the original literature.

In the fifth paper of this series Jones and Bradshaw have described a new and more precise method of making absolute measurements and have redetermined the specific conductance of the three solutions defined by Parker and Parker at 0, 18 and 25°. These results indicate that on the whole the results obtained by Parker and Parker are not as accurate as the earlier work of Kohlrausch, Holborn and Diesselhorst, and that the corrections recommended by Parker and Parker and used by the "International Critical Tables" are unreliable. We have, therefore, undertaken to redetermine the absolute specific conductivity of three standard potassium chloride solutions used by Kohlrausch at 0, 18, 20 and 25° by the new method developed by Jones and Bradshaw. It is hoped that the re-

sults will be helpful in reconciling the great mass of data already in the literature which is based on Kohlrausch's standards with data based on the new standards of Jones and Bradshaw.

The Definitions of the Kohlrausch Standard Solutions.—The book "Das Leitvermögen der Elektrolyte" by Kohlrausch and Holborn, published in 1898, which has probably been used by chemists more than the original article, gives the following definitions (page 76): "Normal Potassium Chloride Solution, that is 74.59 grams of KCl in 1 liter of solution at 18°. Specific gravity at 18°, 1.04492. $\kappa_{18} = 0.09822$. 74.555 grams of KCl, weighed in air, are made up to 1 liter of solution at 18° (for ±1° in temperature the volume is to be taken as ±0.3 ccm. greater), or also 71.422 grams of KCl to 1000 grams of solution, weighed in air, or 76.727 grams in one liter of water at 18°. . . ."

The actual procedure used in the preparation of the solutions which were measured is shown by a study of the original paper which says[3] (p. 435) "Normal Potassium Chloride Solution. For this purpose three varieties of salt were used of which always 74.555 grams were weighed in air and dissolved at 18° to one liter . . . . The determination of the specific gravity gave the value 1.04482 at 18.31° or 1.04492 at 18°." The conductance was measured at 0, 9, 18, 27 and 36° and the values for each 1° interval were obtained by interpolation. The specific conductivity at 18° is given as 0.09822.

The advantages of defining standard solutions in terms of grams of potassium chloride per 1000 g. of solution with both weights corrected to vacuum are discussed in the paper of Jones and Bradshaw and therefore the argument will not be repeated. In order to reproduce Kohlrausch's 1 *N* solution we shall have to assume that the density of the air in his Laboratory was 0.0012 g./ml. and that he used brass weights. On these assumptions the vacuum correction for potassium chloride ($d = 1.987$) is +0.000461 and 74.555 g. in air is equivalent to 74.5894 g. in vacuum. Kohlrausch states that the specific gravity of his normal solution at 18° is 1.04492, but does not state definitely whether this figure is for d^{18}_4 or d^{18}_{18}. However, we have verified this figure experimentally for d^{18}_4 and therefore conclude that Kohlrausch must have meant d^{18}_4 1.04492. Therefore, one kilogram of Kohlrausch's normal solution must have contained 74.5894/1.04492 = 71.3828 g. of potassium chloride per kilogram of solution (both weights corrected to vacuum).

The second alternative definition given in Kohlrausch and Holborn's book is 71.422 g. of potassium chloride in 1000 g. of solution (both weighed in air). Applying the vacuum corrections on the assumption stated above this is equivalent to 71.4549 g. in 1.001006 kg. of solution or 71.3831 g. of potassium chloride per kilogram of solution in vacuum. This agrees with the first definition within four parts per million. Since Kohlrausch only used five significant figures in his definition these two definitions are consistent. Most later experimenters have probably used this definition.

The third alternative definition of the 1 *N* solution in the book is 76.727 g. (air weight) dissolved in 1 liter of water at 18°. Applying vacuum corrections to the salt and taking 1 liter of water at 18° as 998.623 g. (vac.) this definition is equivalent to 71.3813 g. of potassium chloride per kilogram of solution. This is about 0.002% less than the first definition. These three definitions agree within the degree of precision with which the conductivity is given and therefore may be regarded as mutually consistent.

Turning now to the 0.1 *N* solution we find discrepancies between the alternative definitions as has been pointed out by Kraus and Parker. The book (p. 77) says "Tenth Normal Potassium Chloride Solution. One dissolves 7.455 grams, weighed in air, to 1 liter, or 7.430 grams to 1000 grams of solution. Or one dilutes 100 ccm. normal solution to 1000 ccm. This gives $\kappa_{18} = 0.01119$." Here again the original paper (p. 436) reveals the actual method of preparation in the statement "Diluted Potassium Chloride Solutions. The solutions of concentration 1/10, 1/50 and 1/100 were in general prepared from the normal solutions by dilution by volume." The solutions actually measured were evidently prepared by the third alternative method given in the book. Since Kohlrausch does not describe his volumetric procedure in any detail, there is no advantage in attempting to duplicate it experimentally, but we shall have to assume that it was correct and compute the equivalent gravimetric definitions. Since the 1 *N* solution contained 74.5894 g. per liter the 0.1 *N* solution obtained by volumetric dilution should have contained 7.45894 g. per liter at 18°. Kohlrausch does not give the density of this solution but Kraus and Parker give d^{18}_4 1.00343 and we have also verified this figure experimentally. Therefore Kohlrausch's 0.1 N solution must have contained 7.45894/1.00343 = 7.43344 g. of potassium chloride per kilogram of solution (both in vacuum).

The other methods given in the book are not equivalent. 7.455 Grams in air is 7.45844 g. in vacuum which if dissolved in 1 liter of 1.00343 kg. gives 7.43294 g. per kilogram of solution (vac.). 7.430 Grams per kilogram of solution in air is equivalent, after applying the vacuum correction, to 7.43343 g. dissolved in 1.001053 kg. or 7.42561 g. dissolved in 1 kg. of solution. This definition is in error by 0.1%.

The book says (p. 77) "Fiftieth and Hundredth Normal Potassium Chloride Solution. The weighing out of 1.4860 or 0.7430 grams becomes inconvenient. Dilution according to the ratio by volume 1:50 or 1:100 from normal or 1:5 or 1:10 from tenth normal solution is the usual way. κ_{18} = 0.002397 or 0.001225."

Kohlrausch does not give the density of his hundredth normal solution but Kraus and Parker give d_4^{18} 0.99911 and we have verified this figure. A hundredth normal solution prepared by dilution of the normal solution would contain 0.745894 g. (vac.) in 999.11 g. or 0.746558 g. of potassium chloride per kilogram of solution both corrected to vacuum. The alternative definition of 0.7430 g. per kilogram in air is equivalent to 0.742557 g. per kilogram in vacuum. This definition is therefore in error by 0.54% as has already been pointed out by Kraus and Parker.

Experimental

The experimental technique need not be described in detail since it resembled very closely that used by Jones and Bradshaw with some minor improvements suggested by the earlier experience. The chief innovation was that the measurements were carried out at 20° in addition to 0, 18 and 25°, as in the earlier work. In order to avoid any question as to error due to the "Wenner Effect" as discussed in the earlier paper, the entire process of determining the cell constants by the use of mercury as a primary standard was carried through from the beginning with a cell designed so as to avoid error from this cause. Since the earlier experience showed that the cell constants of the Wenner type of cell could be determined by the use of mercury with greater precision than the other parts of the work only one primary cell was used. Most of the other cells were made from the old cells but the cell constants were altered slightly by sealing on new standard-taper ground joints to the filling tubes or new electrode tubes at the ends which made it necessary to anneal the entire cell and remove and replace the platinization. The new platinization was lighter than the old. The differences between the cell constants reported in the two papers should therefore not be interpreted as showing that either the old or new figures are in error.

The data are presented in a different form than was used in the earlier paper, which it is hoped will not only save space in printing but will more readily permit a judgment as to the precision of the data. For this purpose instead of giving the data in full we give the maximum deviation of any measurement of a series from the mean and the "probable error" of the mean, computed by the customary rules given in any book on the theory of errors. It is, of course, well known that these rules assume that the number of determinations is great enough so that the laws of probability may be used and that only accidental unsystematic errors which are as apt to be plus as minus remain. Since systematic errors can never be avoided completely, the "probable error" tends to suggest an overoptimistic judgment as to the precision of the data. We were, of course, acutely aware that the real precision of the data would depend mainly on the success in avoiding systematic errors. The earlier papers in this series explain in some detail the procedures and precautions in our technique which have a claim to novelty. We have endeavored to avoid neglecting other possible sources of systematic error, such as a shift in the ice point of thermometers, but must refrain from a detailed description of such routine matters since their general character is well known.

A very important matter of routine is to make all measurements of resistance with at least two frequencies, since many electrical sources of error which might otherwise be overlooked may be detected in this manner. By measuring each solution in two cells which differ substantially in cell constant, systematic errors in the calibration of the resistance boxes would be revealed if they were appreciable.

Table I gives the results for the cell constant of the primary cell, Z_7, obtained by measurements on the Kelvin bridge when filled with mercury at 0° against two different standard one-ohm coils designated as H and J, each with its Bureau of Standards certificate. As will be seen the two coils give essentially identical results.

TABLE I

CELL CONSTANT OF PRIMARY CELL AT 0°C.

Cell	Based on	Cell constant	Probable error	No. of meas.	Av. dev. from mean
Z_7	Coil H	10584.02	±0.016	5	0.06
Z_7	Coil J	10584.00	± .011	5	.04
Z_7	Accepted av.	10584.01	± .01		

Table II gives the values for the cell constant ratios determined with an alternating current bridge of the new type built by the Leeds and Northrup Company[6] in accordance with the

---

(6) P. H. Dike, *Rev. Sci. Instruments*, **2**, 379 (1931).

principles of design developed by Jones and Josephs. It was calibrated against standard coils having Bureau of Standards certificates. These ratios were determined in an oil thermostat at either 18 or 25°, or both.

Table II

Cell Constant Ratios

	Cell constant ratio	Probable error × 10^6	No. of measurements	Av. dev. from mean × 10^6
Y_3/Z_7	0.1080923	±0.5	8	1.4

Tables IV, V and VI give the specific conductance, κ, (in ohm^{-1} cm.$^{-1}$) of the three standard solutions at 0, 18, 20 and 25° as obtained from each of the cells together with the average deviation of the separate measurements from the mean, and the "probable error" of the mean. In the work on 1 and 0.1 N solutions the measurements at 18 and 25° were usually made in succession without removing the solution from the cells. A different series of solutions were used for the measurements at 20 and 0°, which were also made in succession without removing the solutions from the cells. With the 0.01 N solutions the procedure was different in that the measurements were made at 18, 20 and 25° without removing the solutions from the cells and an independent series of solutions was used for the measurements at 0°. The measured specific conductivity has been corrected in each case for the conductivity of the water used, amounting to about 1.1 × 10^{-6} at 25°. The "probable error" of the mean is computed from the deviations of the individual measurements and the probable error of the cell constant, but any errors in the temperature scale will not be reflected in the computed probable error since such errors are systematic. The thermometers used were the same as in the previous work and have been described in the previous paper. Although these thermometers were of exceptionally good quality, it seems probable that the greatest systematic errors in the final results may be in the temperature scale. The data are possibly less reliable at 0° than at the other temperatures because of the difficulty in maintaining this temperature inside of an oil-bath. The method of maintaining the cells at 0° by packing them inside a solid block of paraffin formerly used was abandoned in favor of immersion in a liquid paraffin oil in a metal container which was completely immersed in ice. This oil cannot be stirred without causing overheating because the heat generated thereby cannot be dissipated rapidly enough. A thermometer cannot be inserted into the oil because the heat conductivity of the thermometer itself would maintain the temperature above 0°. It is necessary to be patient until the resistance readings become independent of time. The maximum resistance obtainable was accepted. On the other hand, at the higher temperatures the thermostat can be stirred with advantage because the thermostat contained a cooling coil with cold water circulating in it and the automatic adjustment of the heat balance takes care of the heat generated by stirring.

Although the experience gained in the earlier similar investigation in this Laboratory was very helpful and much of the same apparatus was used, nevertheless the actual experimental data are entirely independent of any measurements made by Dr. Bradshaw. Everything which could influence the numerical results, such as the calibration of the weights and resistance coils and the ice points of the thermometers, was checked independently.

Table VII summarizes the results and compares the corrections recommended by Parker and Parker and used by the "International Critical Tables" for a systematic recalculation of the data in the literature with the corrections computed from our measurements. As will be seen our results do not confirm the reliability of the corrections recommended by Parker and Parker. In only one of the nine cases is our correction within 0.03% of that recommended by Parker and Parker. In six of the nine cases our results agree with Kohlrausch better than they do with Parker and Parker and in four of the nine cases we even differ as to the sign of the correction which should be applied to Kohlrausch's values. In attempting to apply corrections to the data in the literature due consideration must be given to the possibility of confusion caused by the alternative definitions given in the book, "Das Leitvermögen der Elektrolyte." Many authors do not make it clear which one of the alternative definitions they actually used.

Our new measurements make it probable that on the whole the accuracy of the data on the conductance of solutions given in the "International Critical Tables" has not been improved by the recalculation by the use of Parker and

Parker's standards instead of the Kohlrausch standards originally used by most experimenters.

Summary

1. The absolute specific conductances of the 1, 0.1 and 0.01 *N* potassium chloride solutions recommended by Kohlrausch as a standard of reference for conductivity measurements have been redetermined.

2. The results indicate that the corrections used by the "International Critical Tables" in the recalculation of the conductance data are unreliable.

CAMBRIDGE, MASS. RECEIVED FEBRUARY 26, 1937

Kinetics of Activated Sorption of Hydrogen on Chromic Oxide Gel[1]

BY LOYAL CLARKE,[2] L. S. KASSEL[3] AND H. H. STORCH[4]

Introduction

Burwell and Taylor[5] have recently presented more than usually complete data on the kinetics of activated sorption of hydrogen on a chromium oxide catalyst as a function of pressure and temperature. The present paper derives from their data an empirical relationship which is satisfactory, except for small and for very large sorption. The form of this relation suggests a model of the sorption process, which permits derivation of the equation for moderate sorptions, and accounts at least qualitatively for its failure at extreme conditions.

When the amount of hydrogen sorbed computed by Burwell and Taylor is plotted against time and a smooth curve drawn through the points, it was found that extrapolation to the starting time would, taken naïvely, indicate an appreciable amount of sorption coincident with the beginning of the experiment. The results of these extrapolations are given in Table I. It will be seen that for all the experiments at 1 atmosphere this initial amount is about 1.3 cc., at one-half atmosphere about 0.8, and at a quarter atmos-

[5] R. L. Burwell, Jr., and H. S. Taylor, THIS JOURNAL, **58**, 697–705 (1936).

TABLE I

EXTRAPOLATION OF SORPTION DATA TO STARTING TIME

Temp., °K.	383.5	405	427	457	491	457
Catalyst	9	9	9	9	9	10
Extrapolation in cc. when pressure is:						
1 atmosphere	1.34	1.42	1.26	1.30	1.20	1.21
$^1/_2$ atmosphere	0.76	0.86	0.80	0.80	0.80	0.96
$^1/_4$ atmosphere	.57	.50	.43	.50	.50	.43
$^1/_8$ atmosphere						.15

phere 0.5, or approximately $0.2 + 1.1\,p$. It is quite possible that the dead-space determination using helium is not the correct dead space available for hydrogen,[6] but regardless of cause it is believed that a large fraction of these initial amounts represents a phenomenon other than the slow sorption process.[7] Accordingly the amounts sorbed, as given by Burwell and Taylor, have been corrected by subtraction of the extrapolations given in Table I. The corrected figures appear to approximate the true amount of activated sorption. This is indicated by the improved correlations obtained by means of the revised data.

Burwell and Taylor observed that the data of the separate experiments would approximate a common curve when the amount of sorption, S, is plotted against bt, where b is a constant whose relative value is characteristic of the pressure and the temperature. This relation is, as Burwell and Taylor themselves state, only approximate, but it is improved somewhat by the use of our revised values instead of the uncorrected data. The representation of b by the equation $b = p^nAe^{-Q/RT}$ suggested by Burwell and Taylor is also improved but still inadequate, since the best values of n computed at 383.5, 405, 427, 457, and 491°K. were, respectively: 1.00, 1.00, 0.84, 0.74, and 0.60. Values of Q in the temperature range of 405 to 491°K. as graphically computed from mean values of $p^{0.8}t$ at sorptions of 1, 2, 3, 4, 5 and 6 cc. were, respectively: 15.3, 18.3, 19.0, 19.2, 19.7 and 21.0 kcal. Little impart may be attached to the 1 cc. value and the trend in the other values is comparable with the accuracy of computation and would not be serious were it not that the fluctuation of n impairs the utility of the relation and obscures the interpretation of Q as an activation energy.

Kinetic Model

The existence of a pressure effect definitely less than first order seems to force the assumption that the initial sorption process is followed by some more or less slow rearrangement. We propose to investigate the consequences of this assumption in a relatively simple form. It will be supposed that the sorbent contains n primary adsorption centers and N secondary centers, only the former of which are capable of capturing gas molecules. The secondary centers can take molecules from, and give molecules to, the primary centers but have no kinetic relations with the gas. The fraction of primary centers covered is Θ, that of secondary centers is α, and the gas pressure is p. The rates of the various allowed transfers, in molecules per secondary are then taken to be as

gas ⟶ primary centers $npk_1\,(1 - \Theta)$
primary ⟶ secondary centers $nNk_2\Theta\,(1 - \alpha)/(1 + R\alpha)$
secondary ⟶ primary centers $nNk_3\alpha\,(1 - \Theta)/(1 + R\alpha)$
primary centers ⟶ gas $nk_4\Theta$

The significance of the factor $1 + R\alpha$ will be discussed later in the paper. The controlling differential equations are then

$$\mathrm{d}N\alpha/\mathrm{d}t = nN[k_2\Theta\,(1 - \alpha) - k_3\alpha\,(1 - \Theta)]/(1 + R\alpha)$$
$$\mathrm{d}(n\Theta + N\alpha)/\mathrm{d}t = n[pk_1\,(1 - \Theta) - k_4\Theta]$$

If n and N are of the same order of magnitude we proceed as follows:

(1) Define a new variable β, proportional to the total adsorption, by the relation

$$n\Theta + N\alpha = n\beta$$

and use this relation to eliminate α from the differential equations.

(2) Introduce for Θ the power series expansion

$$\Theta = \beta + u_2\beta^2 + u_3\beta^3 + \ldots$$

obtaining two differential equations of the form

$$\mathrm{d}\beta/\mathrm{d}t = f\,(\beta)$$

(3) Expand the two right-hand members and determine the parameters u_i by equating coefficients of like powers of β.

(4) Solve the resulting single differential equation for t as a power series in β.

The result is

$$t = \beta/pk_1 + (1/pk_1 + k_4/p^2k_1^2)(\beta^2/2) + \ldots$$

The coefficients of β and β^2 do not have the form of pressure dependence necessary to give an

(6) *Cf.* experiments reported by Benton at Pittsburgh meeting of American Chemical Society, September 7-12, 1936.

(7) Burwell and Taylor also suggested that a certain amount of the hydrogen loss was due to causes other than the one of interest and treated their data both with and without appropriate corrections therefore. We found difficulty in understanding the method of deduction of these values and have chosen the above method because it is direct, independently reproducible, and reasonably free from predisposition toward any particular relationship connecting the data at various pressures and temperatures.

apparent order less than unity and this model is thus unsatisfactory. The secondary centers, in fact, do not enter into these coefficients at all; k_2 first appears in the coefficients of β^3, and k_3 in that of β^4.

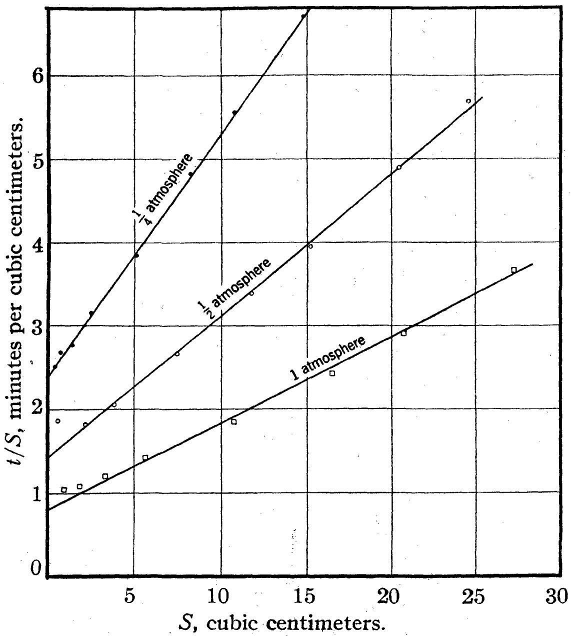

Fig. 1.—Sorption data at 457°K.

If n is very small compared to N, which is certainly a plausible condition, the foregoing analysis remains perfectly correct, but is no longer useful. Moderate values for β, such that terms beyond β^2 may be discarded, correspond to extremely small values of the total absorption, quite outside the range of measurement. A more appropriate solution for this case is obtained by a method similar to that used for chain reactions. Since, beyond the very earliest stages of the reaction, $n\Theta \ll N\alpha$, it follows that $dn\Theta/dt \ll dN\alpha/dt$. We may therefore use

$$dn\Theta/dt = 0$$

to determine a steady state value of Θ as a function of α. This functional relation is used to eliminate Θ, giving a differential equation of the form $d\alpha/dt = f(\alpha)$ which has as a solution the power series expansion

$$\begin{aligned} nt = {} & [1/k_2 + (N/k_1 + k_4/k_1k_2)(1/p)]\alpha \\ & + (1/2)\{((R + 1)/k_2 + [(R + 1)k_4/k_1k_2 + Nk_3/k_1k_2 \\ & + k_3k_4/k_1k_2^2)](1/p) \\ & + (Nk_3k_4/k_1^2k_2 + k_3k_4^2/k_1^2k_2^2)(1/p^2)\}\alpha^2 + \ldots \end{aligned}$$

When $k_4 \ll k_1p$, which is true at pressures where the equilibrium adsorption is large, the terms in $(1/p^2)$ make a negligible contribution to the coefficient of α^2.

Using the assumptions $k_4 \ll k_2N$ and $k_4 \ll k_1p$, both of which are probably justified, we obtain

$$nt = (1/k_2 + N/k_1p)\alpha + 1/2[(R + 1)/k_2 + Nk_3/k_1k_2p]\alpha^2$$

Application to Data of Burwell and Taylor

$N\alpha$ is obviously the amount of sorption and is conveniently designated by a single letter S. We make the further substitutions

$$\frac{1}{nk_1} = B_1,\ \frac{1}{nKk_2} = B_2,\ \frac{k_3}{2nNk_1k_2} = C_1,\ \frac{R + 1}{2nN^2k_2} = C_2$$

and obtain

$$pt = (B_1 + B_2p)S + (C_1 + C_2p)S^2$$

The experiments of Burwell and Taylor were performed at constant pressures so that the coefficients of S and S^2 should be constant for any single experiment.

A plot of t/S against S should therefore be a straight line. Burwell and Taylor's data (corrected as described) for catalyst 9 at 457°K. are so plotted in Fig. 1. The relation is adequate for values of adsorption between 2.5 and 25 cc. The B_2 and C_2 terms are relatively unimportant at 383.5 and 405°K., so that the data for different pressures fall on a comparatively straight line when pt/S is plotted against S as in Fig. 2.

The best values of these constants are given in Table II under the heading "experimental."

Returning to the significance of these constants in the kinetic derivation

$$\begin{aligned} k_1 &= 1/nB_1 \\ k_2 &= 1/nNB_2 \\ k_3 &= 2C_1/nB_1B_2 \\ R + 1 &= 2NC_2/B_2 \end{aligned}$$

TABLE II

BEST VALUES OF CONSTANTS IN THE EQUATION $pt = (B_1 + B_2p)S + (C_1 + C_2p)S^2$. UNITS p IN ATM., t IN MINUTES, S IN CC.

	B_1		B_2		C_1		C_2	
T, °K.	Exptl.	Theor.	Exptl.	Theor.	Exptl.	Theor.	Exptl.	Theor.
383.5	1.2	23.5	0	11.5	11.6	12.4	0	0.92
405	2.9	6.67	0	3.80	3.14	2.31	0	.30
427	2.05	2.09	1.275	1.38	0.44	0.47	0.11	.11
457	0.49	0.47	0.43	0.41	.064	.063	.033	.033
491	.112	.122	.125	.123	.0101	.0103	.0095	.0098

The "theoretical" values of the constants given in Table II are computed from the equations

$$\log \frac{B_1}{\sqrt{T}} = \frac{4110}{T} - 10.63$$

$$\log B_2 = \frac{3450}{T} - 7.94$$

$$\log \frac{C_1}{B_1 B_2} = -\frac{2060}{T} + 4.03$$

$$C_2/B_2 = 0.08$$

The values for the lower temperatures are in disagreement with these equations; however, the total amount of sorption at these temperatures is small and, in fact, of the order for which the relation fails at higher temperatures. This failure is consistent with the theoretical analysis made above. Furthermore, this is not unexpected since the subtractive corrections as determined by the experimental intercepts are of the same order of magnitude as the total sorption at the lower temperatures.[8] The relation $pt = (B_1 + B_2p)S + (C_1 + C_2p)S^2$ is therefore of a semi-empirical nature when used in experiments involving very small sorptions.

The theoretical value of the ratio C_2/B_2 is $(R + 1)/2N$. The experimental value is approximately 0.08, and hence $\alpha = 0.16\ S/(R + 1)$. If $R = 0$, $\alpha = 1$ would correspond to $S = 6.25$ cc., whereas actually the saturation absorption is probably 100 cc. or more. The value of R needed to agree with these data is therefore at least 15. This necessary correction factor, $(1 + R\alpha)^{-1}$, may be interpreted as representing a reduced rate of transfer between primary centers and non-adjacent secondary centers; its form, however, is determined by mathematical convenience rather than physical considerations.

The experimental results for the highest three temperatures then give for k_1 an activation energy of 18.75 kcal., for k_2, 15.75 kcal. and for k_3, 9.4 kcal. The relative activation energies for k_2 and k_3 indicate a heat of adsorption for the primary centers 6.3 kcal. greater than for the secondary centers. This difference is consistent with the greater activity of the primary centers in adsorbing gas molecules. If the rate of adsorption on the primary centers is equal to the rate of collision of gas molecules $Xe^{-19,000/RT}$, the area of these centers must be 1600 sq. cm. They would then have an adsorptive capacity of the order of 0.5 cc. This value is sufficiently small to justify the assumption $n \ll N$. It is, at the same time, large enough to make this assumption slightly erroneous, and thus perhaps to account for the observed systematic distortions in the experimental curves for adsorptions less than 2.5 cc.

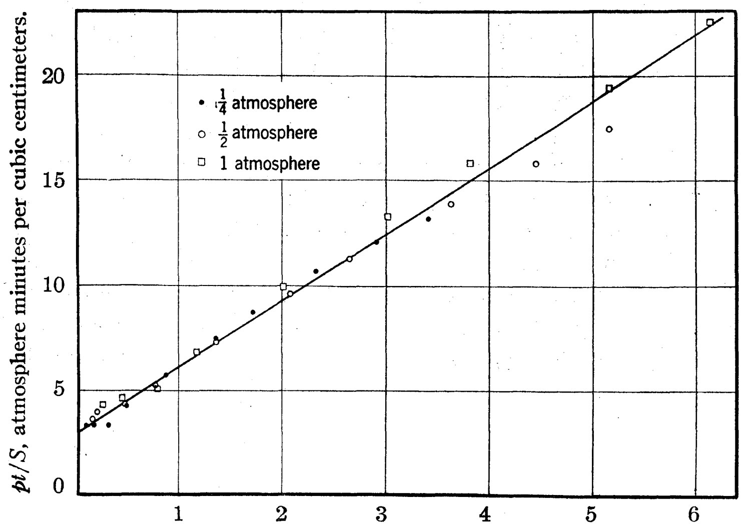

Fig. 2.—Sorption data at 405°K.

Discussion

The failure of results at the lowest temperatures to agree with extrapolated constants is quite possibly associated with the great importance of the amount of primary adsorption for the

---

(8) The method used in adjusting the data implicitly assumes that the activated sorption of hydrogen on secondary centers is the only process resulting in an appreciable withdrawal of hydrogen after the first few minutes. Burwell and Taylor have suggested that some of the sorption occurring after several minutes also represents phenomena other than that of interest and should be included in the subtractive corrections. It has been found possible to secure excellent agreement between equations obtained by the use of the theoretical constants given in Table II and the data for the latter portion of the runs at 383.5°K. (after forty minutes) and 405°K. (after twenty minutes) by subtraction from the original data of the following constants:

p, atm.	383.5°K.	405°K.
1	2.25 cc.	2.08 cc.
0.5		1.38
.25	1.30	0.85

The difference between these values and our previous corrections may represent either primary sorption or an entirely unrelated process, or both. This suggests the adoption of a more refined method of determining the corrections. This could be done by fitting the original data to equations of form: $t = a + bS + cS^2$ and computing the subtractive corrections and the other constants therefrom. The foregoing analysis would be used only for rejection of points outside of the expected range of validity. Such a revision has not been undertaken however, because the high temperature experiments would still have to carry the burden of the proof and their interpretation would not be materially altered.

small sorptions to which data at these temperatures are limited.[8] It does not appear possible to decide definitely whether this type of analysis is applicable to the lower temperatures without extensions of the data to larger sorptions. For the higher-temperature region, however, there seems little doubt that the model yields a satisfactory interpretation of the experimental data. It does not follow that the underlying assumptions are entirely correct. As has already been suggested, the correction factor $(1 + R\alpha)^{-1}$ is introduced in an arbitrary way.

A precise treatment of the diffusion factor would necessitate a consideration of the geometry of the model. Such an analysis might conceivably result in a decision as to whether the phenomenon of slow sorption on chromic oxide gel corresponds more closely to a surface diffusion from active centers,[9] to surface adsorption followed by diffusion to the interior,[10] or to diffusion into Smekal cracks.[11] The assumption that there is no direct sorption on the secondary centers can represent at best merely an approximation to the case where the amount of such sorption is small. The sorptive regions of a real catalyst may not be amenable to a classification as simple as that which we have used, and although the introduction of more types of centers would probably lead to equations of the same form as we have found, the experimental constants would be less simply related to the fundamental rate constants. The model makes no assumption with regard to the physical nature of the sorption centers, and its success therefore contributes nothing to the solution of this problem.

Summary

An analysis of Burwell and Taylor's data on the activated sorption of hydrogen by chromium oxide has led to the derivation of a rate equation that fits the data for moderate amounts of sorption very well. The derivation is based on a simple model of the sorption process, involving primary adsorption followed by diffusion to secondary centers. This model also accounts, qualitatively at least, for the failure of the equation at extreme conditions.

Acylselenoureas

BY IRWIN B. DOUGLASS

The investigation of the acyl isothiocyanates and certain acylthiourea derivatives by the author[1] and a review of certain organic selenium derivatives by Bradt[2] suggested the possibility that acid chlorides might react with metallic selenocyanates in a manner analogous to their reaction with the thiocyanates.

The work thus far accomplished indicates that there is a vigorous reaction when acid chlorides and KSeCN are brought together in acetone solution. In no case has the product (I) been

$$\mathrm{RCOCl + KSeCN \longrightarrow RCOCSeN\ (I) + KCl} \quad (1)$$

isolated and the evidence thus far accumulated does not definitely establish it as a selenocyanate, an isoselenocyanate, or an equilibrium mixture of the two. The fact, however, that (I) in acetone solution when treated with amines forms selenoureas according to reaction (2) indicates

$$\mathrm{RCOCSeN + R'NH_2 \longrightarrow RCONHCSeNHR'} \quad (2)$$

that (I) must have the structure RCONCSe or at least must consist of an equilibrium mixture containing a large proportion in that form. On the basis of this evidence, the acyl derivatives resulting from the reactions between acid chlorides and potassium selenocyanate will be referred to as acyl isoselenocyanates or acylselenocarbimides.

This paper describes the properties of a few acylselenoureas prepared by reactions (1) and (2). The grouping RCO– was varied to include acetyl, carbethoxy, pyromucyl and benzoyl so as to gain some idea of the behavior of various acyl isoselenocyanates when treated with aniline, and the group R′ was varied to determine the behavior of benzoyl isoselenocyanate when treated with different amines.

[2] Bradt, *J. Chem. Ed.*, **12**, 363 (1935).

Experimental

Acyl isoselenocyanate solutions were prepared by dissolving slightly more than 0.1 mole of potassium selenocyanate in 200 ml. of acetone and adding to the solution exactly 0.1 mole of acid chloride. In each case an immediate exothermic reaction took place with the separation of potassium chloride and the formation of a colored solution. The solutions were used immediately to react with amines to form selenoureas. No attempts have been made as yet to isolate the acyl isoselenocyanates.

With the addition of the last acid chloride to the selenocyanate solution, 0.1 mole of amine, in acetone solution, was added as rapidly as the vigorous boiling of the reaction mixture would permit. Lower yields of selenourea seemed to be obtained when the addition of amine was delayed. When the reaction had subsided, the mixture was poured slowly with stirring into 600–800 ml. of cold water. The solid selenourea which separated was removed by filtration and crystallized from a suitable solvent.

Potassium selenocyanate was prepared by fusing together potassium cyanide and slightly more than an equivalent amount of black powdered selenium.[3] The black melt was dissolved in water, and the solution boiled to coagulate the undissolved selenium. The solution was then filtered and evaporated with stirring until the temperature of the melted residue had reached 190°. The product was broken up as it cooled, pulverized, and used without further purification.

Constitution of the Selenoureas.—An alcoholic solution of the product resulting from benzoyl chloride, potassium selenocyanate, and aniline was boiled with alcoholic silver nitrate solution. After removing the precipitated silver selenide white needles having a melting point of 209° (corr.) separated from the alcoholic solution. Similar treatment of α-benzoyl-β-phenylthiourea yielded an identical product. A mixed melting point of the two was not lowered. The highest melting point recorded for α-benzoyl-β-phenylurea is 210°.[4]

Anal. Calcd. for $C_{14}H_{12}O_2N_2$: N, 11.67. Found (deselenized product): N, 11.49.

Bitter Taste of Benzoylselenourea.—While working with benzoylselenourea it was noticed that when the crystals were disturbed a very bitter dust arose. Since certain of the thioureas are very bitter to some individuals but have no taste to others,[5] it seemed of interest to determine whether there would be individuals taste-blind to benzoylselenourea. Strips of filter paper, dipped into a dilute alcoholic solution of benzoylselenourea, were cut into small pieces and given to Northern Montana College students to taste. Of 175 cases 131 reported the papers as having a decidedly bitter taste whereas 44 reported either no taste or some taste other than bitter.

Yields.—The percentage yields of the selenoureas varied somewhat with the acid chloride used and also with the amine used. The data in regard to yields can be considered as only of a qualitative nature, however, for there was considerable variation in yield with successive preparations of the same selenourea. It would seem that there are factors affecting yield not yet fully understood. Low yields were usually accompanied by the production of colored by-products.

Acetyl Isoselenocyanate and Aniline.—The reaction of acetyl isoselenocyanate with aniline seems to follow the same two courses as acetyl isothiocyanate and aniline.[6] In the preparation of α-acetyl-β-phenylselenourea a yield of only 12% was obtained. From the water into which the reaction mixture was poured a 27% yield of acetanilide, based on the original quantity of aniline was obtained as a first crop.

Selenoureas

Benzoyl-.—White prisms from alcohol, m. p. 194–195° (corr.), yield 27%. Spontaneously oxidized in alcoholic solutions to selenium and benzoylurea. *Anal.* Calcd. for $C_8H_8ON_2Se$: N, 12.34. Found: N, 12.25.

α-Benzoyl-β-phenyl-.—Long yellow needles from alcohol, m. p. 144–145° (corr.), yield, 72%. A mixed melting point of this compound with the corresponding thiourea was not lowered appreciably. *Anal.* Calcd. for $C_{14}H_{12}ON_2Se$: N, 9.24. Found: N, 9.09.

α-Benzoyl-β-o-tolyl-.—Long yellow prisms from alcohol, m. p. 124–125° (corr.), yield 70%. *Anal.* Calcd. for $C_{15}H_{14}ON_2Se$: N, 8.83. Found: N, 8.99.

α-Benzoyl-β-p-tolyl.—Yellow needles from a mixture of dioxane and alcohol, m. p. 154–155° (corr.), yield 56%. *Anal.* Calcd. for $C_{15}H_{14}ON_2Se$: N, 8.83. Found: N, 8.90.

α-Benzoyl-β,β-naphthyl-.—Yellow prisms from dioxane, m. p. 171–172° (corr.), yield 58%. *Anal.* Calcd. for $C_{18}H_{14}ON_2Se$: N, 7.93. Found: N, 7.86.

α-Benzoyl-β-benzyl-.—Long orange prisms from alcohol, m. p. 115–116° (corr.), yield 19%. *Anal.* Calcd. for $C_{15}H_{14}ON_2Se$: N, 8.83. Found: N, 8.93.

α-Benzoyl-β,β-diethyl-.—Yellow needles and yellow prisms, m. p. 110° (corr.), yield 49%. *Anal.* Calcd. for $C_{12}H_{16}ON_2Se$: N, 9.93. Found: N, 9.76.

α-Acetyl-β-phenyl-.—Pink plates from alcohol, m. p. 184–185° (corr.), yield 12%. *Anal.* Calcd. for $C_9H_{10}ON_2Se$: N, 11.62. Found: N, 11.43.

α-Phenyl-β-pyromucyl-.—Yellow needles from alcohol, m. p. 106–107° (corr.), yield 24%. *Anal.* Calcd. for $C_{12}H_{10}O_2N_2Se$: N, 9.56. Found: N, 9.52.

An attempt was made to prepare α-carbethoxy-β-phenylselenourea, but no solid product was isolated. The reaction between ethyl chlorocarbonate and potassium selenocyanate was smooth and resulted in the formation of practically no colored by-products. Likewise the reaction of the supposed carbethoxy isoselenocyanate with aniline appeared to be normal. The colorless oil which separated when the mixture was poured into water would not solidify, however, and on standing for several days acquired such an offensive odor that it was discarded.

Summary

1. The action of acid chlorides on acetone solutions of potassium selenocyanate yields compounds which react with amines to form selenoureas.

Optical Properties and Polymorphism of Paraffins

BY C. D. WEST

When a molten paraffin or similar long chain compound is allowed to solidify in a film on a flat glass surface, the film, in spite of being turbid to the naked eye, and showing many randomly oriented small crystals under the microscope, still has sufficient homogeneity to show a peculiar effect when examined with a total reflection refractometer. Instead of one boundary between total and ordinarily reflected light, two such boundaries of a somewhat diffuse character are observed, separated by an interval of up to 0.05 unit in the refractive index scale. The state of polarization of the light at these boundaries proves that the film is optically equivalent to the basal section of a uniaxial positive crystal.

This effect was first described in a paper by Camerer,[1] then by Gaubert,[2] and by Walter.[3] Vorländer and Selke[4] showed that the effect is to be observed with a great variety of pure long chain compounds (paraffins, unsaturated fatty acids, esters of fatty acids, alcohols and ketones, etc.) which solidify in soft solid crystals.

In the past year Page[5] published measurements on five natural paraffins with melting points in the range 49.4–60.6°. Page assigned an incorrect optical character to his films; he arbitrarily called the ordinary refractive index the extraordinary, and *vice versa*. His calculations based on this error are accordingly incorrect. He carried his measurements for each specimen through a considerable temperature range. The irregularity of these curves at temperatures near the melting points suggests that at least some of his materials (for example, that melting at 60.6°) underwent polymorphic transitions in the course of the measurements, as they would be expected to do according to the X-ray structure work that has been published on this point.

More recently Seyer and Fordyce[6] gave refractive index data for the pure paraffin dicetyl (dotriacontane, $C_{32}H_{66}$) in the solid state from 30° up to the melting point, 70°. These writers failed to note the double edge of total reflection, nor did they take into consideration the fact that this material has a sharp reversible inversion at 5° below its melting point. Rather they concluded from their refractive index curve, together with the solubility curves in propane and butane, that dicetyl has a transition at 55°.

The prior work of Piper and co-workers[7] showed clearly that dicetyl has a sharp reversible transition at about 65°. This was observed macroscopically, microscopically and by means of X-rays. Other straight chain paraffins near to dicetyl all exhibit the same transition about 5° below the melting point.[8]

In the following is described a repetition of the work of Seyer and Fordyce with dicetyl, rather for the purpose of illustration than to give the precise numerical constants of this material in a state of known purity.

Experimental

An Abbe refractometer with front opening for the front or refracting prism (Bausch and Lomb) was used. The dicetyl was obtained from Eastman Kodak Company; it melts sharply at 69.5–69.7°, and solidifies at 68.8–67.7°. For some of the measurements the molten material was poured onto the refracting prism and allowed to solidify without closing the back prism; for others the back prism was closed after melting the material on the front prism. The character and position of the edges is the same in the

two cases, but of course the temperature control is better when the prisms are closed and water circulates about both of them.

The character of the edges was identified with a polarizing disk (obtainable from the Polaroid Corporation, Boston, or other dealers) over the ocular. The well-known rule for uniaxial sections or films perpendicular to the optic axis may be stated: When the vibration direction of the polarizer is vertical, *i. e.*, parallel to the plane of incidence, the boundary marking the ordinary index disappears, the sharpness of the extraordinary boundary is enhanced; when the vibration direction of the polarizer is horizontal, *i. e.*, perpendicular to the plane of incidence, the extraordinary boundary disappears, the sharpness of the ordinary boundary is enhanced. If the film under examination is isotropic, the boundary marking its refractive index does not disappear for any azimuth of the polarizer. These statements are true, whether the light is admitted through the front prism (reflection position) or through the back prism (grazing incidence position). A polarizer is indispensable in work with materials that may form anisotropic films, in *finding*, in *identifying*, and in *setting on the cross hairs* the boundaries observed with a total reflection refractometer.

Other materials known to form, under suitable conditions, uniaxial films on flat glass surfaces are liquid crystalline substances, cellulose derivatives, gelatine, agar, etc. I hope to describe some of these films at a later date.

Results

Refractive index measurements of dicetyl, believed to be accurate to better than 0.001 unit, are shown in Table I and by the smoothed curve of Fig. 1. For the transition temperature Piper's mean value of 64.6° is assumed to be correct. On cooling through this temperature a marked change in the appearance of the film between the Abbe prisms is noted (the same changes are seen in a film formed on a slide under a cover glass): the texture changes from fine-grained to coarse-grained, and air bubbles appear, probably because of the contraction in volume. At the transition temperature both refractive indices change by 0.018 unit.

TABLE I

REFRACTIVE INDICES OF DICETYL IN THE LIQUID AND TWO SOLID PHASES

Temp., °C.	ε		ω
20	1.5645		1.5148
30	1.5625		1.5126
40	1.5593		1.5096
50	1.5553		1.5053
60	1.5500		1.5000
64.6	1.5472		1.4971
64.6	1.5290		1.4788
67.5	1.5270		1.4768
69.6	1.5257		1.4756
69.6		1.4358	
75		1.4338	
80		1.4325	

It will be noted that the birefringence of a solid dicetyl film is the same, about 0.050, in its two phases, and does not vary sensibly with temperature. It might have been expected to be higher for the high temperature form, for Piper and his co-workers found the molecular axes to be perpendicular to the basal plane in the high temperature or A-form (d_{001} 42.33 Å.), but to have some obliquity thereto in the low temperature or C-form (d_{001} 37.8 Å.).

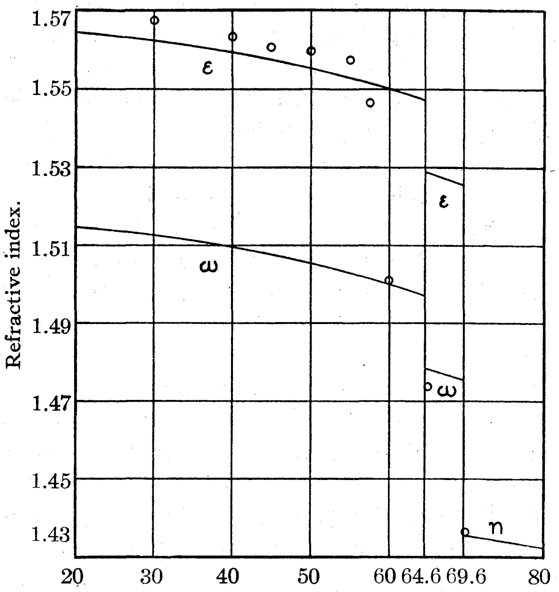

Fig. 1.—Refractive indices of dicetyl in the liquid and two solid phases.

The circles in Fig. 1 represent the measurements of Seyer and Fordyce. It is seen that while their points agree with the interpretation that dicetyl has a transition about 5° below the melting point, their conclusion that a transition occurs at 55° is forced and erroneous.

Summary

The simple procedure is described for measuring, by means of a total reflection refractometer equipped with a cap polarizer, the refractive indices of materials which solidify to form transparent uniaxial films. The dimorphism of solid dicetyl is demonstrated by refractometric measurements, and approximate values of its optical constants are given over a range of temperatures.

On 1,2- and 1,4-Addition. I. The 1,4-Addition of Potassium Isocyanide[1]

BY ARTHUR MICHAEL AND NATHAN WEINER

The synthesis of β-cyano ketones, esters and nitriles through the action of potassium isocyanide on the corresponding α,β-ethylenic ketones, esters and nitriles is a general reaction.[2] It has been and is assumed that it proceeds by addition of liberated hydrocyanic acid to the α,β-ethylenic carbons, analogously to the addition of strong mineral acids,[3] or primarily by the union of the cyano ion to the β-carbon.[2i] However, hydrogen cyanide[4] functions very weakly acidic ($k^{25}_{\mathrm{HCN}} = 7.2 \times 10^{-10}$), and the facility with which an acid adds to an ethylene group is in direct relation to the strength of the acid.[5] Obviously, so weak an acid as hydrogen cyanide cannot add to ethylenic carbons. Further, the supposed addition of hydrogen cyanide occurs only in the presence of alkali isocyanide and to compounds containing an ethylenic group conjugated with a carbonyl, carbalkoxyl, nitro or nitrile group. The synthesis of pyrotartaric dinitrile from an allyl halide, or allyl cyanide, and isocyanide may seem an exception. However, the reactions were carried out in a partially aqueous medium,[2a,6] in which alkali isocyanides show strongly alkaline properties. Such conditions favor the allyl into propylene shift and allyl cyanide undoubtedly first undergoes a change to crotononitrile. That the formation of pyrotartaric dinitrile proceeds in this manner was proved by the recovery of considerable unchanged allyl cyanide after protracted boiling with isocyanide in absolute methyl alcoholic solution and that no dinitrile was formed under these conditions. Bredt and Kallen[2c] attributed the function of the isocyanide to the formation of *nascent* hydrogen cyanide; but its greater reactivity could be connected only with a greater heat of reaction and hydrogen cyanide does not add even at higher temperatures. Lapworth[2g] believed the reaction proceeds primarily through the —CN ion of a complex salt, formed from hydrogen cyanide and isocyanide, and that it proceeds analogously to Thiele's view, by union of hydrogen with carbonyl oxygen and a cyano group with the β-Δ-carbon; although Thiele[2d] accepted 1,2-addition and his 1,4-viewpoint had been shown untenable.[7a] Lapworth[2i] also thought that the addition may occur to an unconjugated ethylene group, since an analogous addendum, sodium acid sulfite, unites with the α,β-Δ-carbons of cinnamyl alcohol. If the sulfite, $NaSO_2OH$,[7b] added as $NaSO_2O$— and H— a poorly neutralized sulfite derivative would be formed, but, if the H— joins the α-Δ-carbon, with migration of sodium to its place, and the sulfur radical the β-Δ-carbon, then in the well-neutralized sodium sulfonate the maximum possible energy degradation is attained. Obviously, no connection exists between the mechanisms of the two addenda. Recently, Ingold[8] compared the hydrogen cyanide addition to α,β-Δ-esters to that of enolates; the latter and isocyanide providing the anions and the cations uniting with the carbonyl oxygen. This comparison is not tenable; the additivity of malonic ester depends upon the free chemical energy in the ethylenic group,[9] and the pure sodium enolate adds instantaneously in organic solvents with low dielectric and dissociating constants; further the addition does not depend upon an imagined dissociation of the addenda, but upon the possible formation of a new, chemically better neutralized, system.[10] The

(4) According to Michael [*Ber.*, **34**, 4030, footnote 3 (1901)], hydrogen cyanide contains an extremely small content of the corresponding isocyanide (HNC), in reversible equilibrium with the nitrilic form. E. H. Usherwood [*J. Chem. Soc.*, **121**, 1604 (1922)] concluded from specific heat measurements that gaseous hydrogen cyanide contains several tenths of one per cent. of the acidic form. K. H. Meyer [*Ber.*, **54**, 1709 (1921)], apparently under the belief that an appreciable proportion of the latter is present, endeavored, unsuccessfully, to isolate it by fractionation. The formation of hydroxynitriles from aldehydes and aqueous hydrogen cyanide should proceed through the more energetic acidic form and the addition forms a nitrile because of the greater affinity of the formyl carbon for the C than for the N of HNC and that this course leads to the maximum degradation of energy.

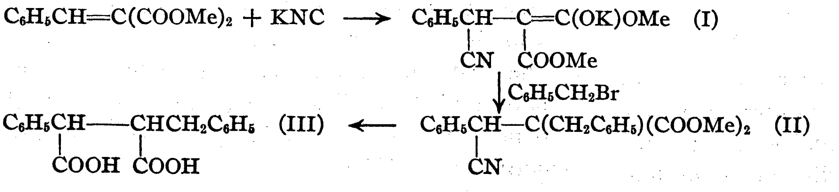
theoretical importance of 1,2-addition of hydrogen cyanide has long been and is still emphasized as proving that no relation exists between 1,4-addition and structure; for example, Hinrichsen[11] in 1902 and Hückel[12] in 1934. However, the following experimental results prove conclusively that hydrogen cyanide is not essential for, nor does it enter into, these reactions, and that they take place exclusively by 1,4-addition, through the isocyanide; thus invalidating all the above speculations.

Previous investigators of the isocyanide reaction used aqueous ethyl alcohol, as the salt is sparingly soluble in absolute alcohol. Under these conditions it seemed possible that primarily formed intermediates may be decomposed by the action of water. Bredt and Kallen[2c] found that a mixture of aqueous potassium isocyanide and an alcoholic solution of benzalmalonic ester, followed by hydrochloric acid, gave β-cyanobenzylmalonic ester and the ester in alcoholic solution with an aqueous solution of isocyanide at 60° gave β-cyanophenylpropionic ester. These results were explained when absolute methanol was used as a solvent. The addition of isocyanide to ester proceeds so rapidly that the salt, suspended in a small volume of absolute methanol, dissolves almost immediately upon addition of ester and a good yield of potassium compound quickly separates, which represents an equimolecular addition product of isocyanide and ester. Acidification of this potassium derivative yielded β-cyanobenzylmalonic ester (IV), identical with the compound prepared according to Bredt and Kallen,[2c] but in far better yield. The potassium compound (I) is an enolate; it reacts with benzyl bromide to give the α-benzyl derivative (II), the structure of which is established by hydrolysis to α-benzyl-β-phenylsuccinic acid (III):

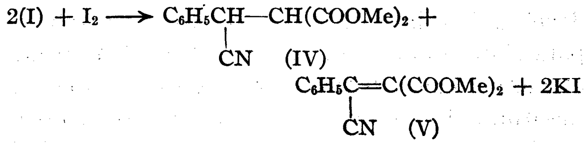


$$\mathrm{C_6H_5CH{=}C(COOMe)_2 + KNC \longrightarrow \underset{CN}{C_6H_5CH}-\underset{COOMe}{C}{=}C(OK)OMe}\quad (I)$$

$$\Big\downarrow \mathrm{C_6H_5CH_2Br}$$

$$\mathrm{\underset{COOH}{C_6H_5CH}-\underset{COOH}{CHCH_2C_6H_5}}\ (III) \longleftarrow \mathrm{\underset{CN}{C_6H_5CH}-C(CH_2C_6H_5)(COOMe)_2}\quad (II)$$

With iodine, instead of the usual C-copulation, equivalent amounts of β-cyanobenzylmalonic ester (IV) and β-cyanobenzalmalonic ester (V) are formed



$$2(I) + I_2 \longrightarrow \mathrm{\underset{CN}{C_6H_5CH}-CH(COOMe)_2}\ (IV) + \mathrm{\underset{CN}{C_6H_5C}{=}C(COOMe)_2} + 2KI\ (V)$$

The reaction follows in the first stage the mechanism suggested for the coupling of enolates,[13] which postulates the intermediate formation of an α-iodo compound and its interaction with unchanged enolate. However, the α-iodo compound, $C_6H_5CH(CN)CI(COOMe)_2$ (VI), contains the halogen in the β-position to the nitrile group and belongs to a class of β-derivatives from which halogen hydride is separated with great ease. As (VI) is formed, hydrogen iodide is eliminated by unchanged enolate and (IV) and (V) therefore appear in equal amounts.

Since the addition of potassium isocyanide to benzalmalonic ester is very rapid[14] and the primary product is an enolate, the explanation of Bredt and Kallen's results is apparent. In the experiment with aqueous alcohol at 60°, the enolate was formed practically at once and was changed upon heating into $C_6H_5CH(CN)CH(COOK)COOEt$, which upon further heating, analogously to similarly structured compounds,[15] broke up into potassium bicarbonate and β-cyanophenylpropionic ester. In the reaction at room temperature, the enolate had formed before the addition of mineral acid, which simply set free a poor yield of the corresponding enolic derivative.

The above reaction is an ideal illustration of the interpretation of 1,4-addition from Michael's standpoint.[16] Benzalmalonic ester contains a malonic ester group, without the essential α-hydrogen necessary to yield an enolate; the carbonyl oxygen of a carbmethoxy group has, however, a

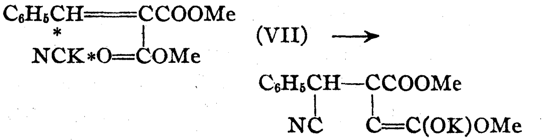
(13) Michael, *J. prakt. Chem.*, **60**, 286 (1899).

(14) So rapid, that an attempt to measure the rate of disappearance of potassium isocyanide by titration was unsuccessful; more than 50% of the isocyanide had disappeared before the first titration could be carried out.

(15) Michael, *J. prakt. Chem.*, **72**, 544 (1906).

(16) Michael, *J. prakt. Chem.*, **60**, 299, 467, 470, 481 (1899); **68**, 512, 521 (1903); **79**, 418 (1909). A theoretical development of 1,4-addition, based upon the chemical affinity and the chemical energy of the atoms involved in the reacting chemical systems, and a theoretical and exper imental refutation of Thiele's [*Ann.*, **306**, 89 (1899)] mechanical speculations. Straus [*Ber.*, **42**, 2866 (1909)] took exception to the implication of the affinity factor, since he found that Br_2 added 1,2 and Wieland [*Ann.*, **360**, 311 (1908)] that nitrogen tetroxide added NO_2 in 1,4-position to 1,4-diphenylbutadiene. However, Wieland's conclusion is based upon inconclusive experimental results and the more important experiments could not be repeated in this Laboratory.

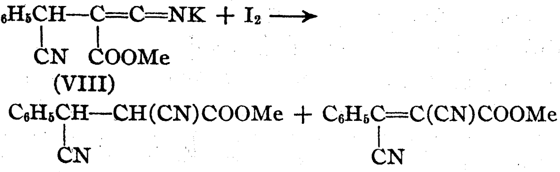
developed affinity for the slightly neutralized potassium atom of the isocyanide and a strong attraction exists between it and the respective, unsaturated oxygen. Further, the β-Δ-carbon of the ester shows the necessary free chemical energy and affinity, *i. e.*, the chemical potential,[17] to unite with the cyano group. The first formed, cyclic, polymolecule[18] (VII) passes over into the β-cyano enolate (I)



$$\begin{array}{l} C_6H_5CH{=\!=}CCOOMe \\ \quad {*}\qquad\;\; | \\ NCK{*}O{=}COMe \end{array} \quad (VII) \longrightarrow \quad \begin{array}{l} C_6H_5CH{-}CCOOMe \\ \quad\; |\qquad\; | \\ \;\;NC\quad\; C{=}C(OK)OMe \end{array}$$

(I)

For, the β-Δ-carbon has a far more developed affinity for the carbon than the nitrogen of the addendum and the introduction of the decidedly negative cyano group leads to a far better neutralized enolate (I) than would **the** basic isocyano group. The combination of the ester molecule, loaded with free, negative chemical energy at Δ-oxygens and Δ-carbons, and the isocyanide, with free, positive, chemical energy in large excess, to form the almost neutral enolate molecule, represents the possible maximum degradation of energy of the original chemical system and, therefore, the inevitable course of the chemical change. The above considerations apply also to the reaction between benzalcyanoacetic ester and isocyanide. This facile reaction leads to the iminolate of β-cyanobenzylcyanoacetic ester (VIII),[19] which with iodine gives equimolecular amounts of β-cyanobenzylcyanoacetic ester (IX) and β-cyanobenzalcyanoacetic ester (X)



$$\begin{array}{l} C_6H_5CH{-}C{=}C{=}NK + I_2 \longrightarrow \\ \qquad |\qquad | \\ \quad\; CN\;\; COOMe \\ \qquad (VIII) \\ C_6H_5CH{-}CH(CN)COOMe + C_6H_5C{=}C(CN)COOMe \\ \qquad | \qquad\qquad\qquad\qquad\qquad\qquad\quad | \\ \quad\;\; CN \qquad\qquad\qquad\qquad\qquad\qquad CN \\ \qquad (IX) \qquad\qquad\qquad\qquad\qquad\quad (X) \end{array}$$

To confirm these views further, the reaction between fumaric ester and potassium isocyanide was examined under varied conditions. In 90% methanol reaction occurs readily at room temperature; after acidification, 1-cyano-2,3,4-carbmethoxybutane (XV), along with considerable acid fumaric ester, were obtained. In absolute methanol at room temperature, after acidification, the products were methoxysuccinic ester and 2-cyano-3,4,5-carbmethoxycyclopentanone (XVII), the relative proportions depending on the time, the methoxy ester disappearing for the cyclopentanone derivative (XVII) on longer standing. Finally, in boiling absolute methanol, only the cyclopentanone derivative (XVII) was formed in appreciable yield. These relations support the proposed 1,4-mechanism. In methyl alcohol, potassium isocyanide is undoubtedly in equilibrium with potassium methylate and the presence of the methylate brings about reversible formation of methoxysuccinic ester.[20] The reaction is, therefore, competitive between isocyanide and methanol for addition to fumaric ester. Without water, enolate (XI) should mainly rearrange to the much better neutralized iminolate (XII) with some of the corresponding enolate (XIII), which undergo the enolate addition[21] with unchanged fumaric ester, to form the potassium derivative of 1-cyano-1,2,3,4-carbmethoxybutane (XIV).[22] In absolute methanol the new potassium derivative undergoes a Dieckmann condensation and the iminolate (XVI) yields with mineral acid the cyclopentanone derivative (XVII).[23] In the presence of water, however, even at room temperature, the iminolate ester (XIV) is partially saponified and, in the subsequent manipulation, it is decarboxylated to (XV).

When the metal is insufficiently neutralized in the KNC addition product, the following phase of the reaction should, as it does, proceed slowly and, under such conditions, the product behaves exactly like other imperfectly neutralized enolates toward compounds of the type RCH═CHCOOR. The formation of the more complex addition products in the isocyanide reactions is, therefore, experimental proof that, in the first phase, they add normally to form enolates and the addition reaction is experimental evidence that the isocyanide has the iminolate structure, *i. e.*, KNC.

Michael and Schulthess[24] showed that sodium malonic enolate added to citraconic ester in ether solution and gave the expected addition product;

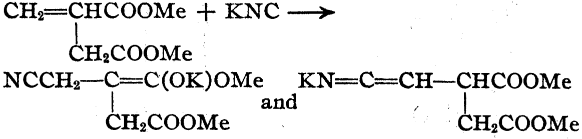
but in alcoholic solution[25] a condensation occurred with loss of alcohol and the enolate of a cyclic ketone derivative was formed. Hope[26] proved that citraconic ester first isomerized to itaconic ester and that the ketone was a cyclopentanone derivative. In absolute methanol, at room temperature, citraconic methyl ester and isocyanide gave, after acidification, two products; one by addition of methyl alcohol and a second with the empirical constitution $C_7H_9O_4N$, their relative proportions depending on time; $C_7H_9O_4N$ being formed with disappearance of the methoxy ester. In boiling methanol only $C_7H_9O_4N$ could be isolated. After heating with acid, or base, it yielded tricarballylic acid, or its salt, which showed that citraconic ester must have rearranged to itaconic ester, before the addition of isocyanide.

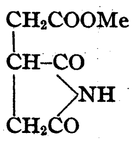


$$CH_2{=}\underset{\displaystyle\overset{|}{CH_2COOMe}}{C}HCOOMe + KNC \longrightarrow$$

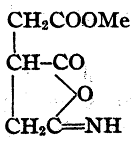
$$NCCH_2{-}\underset{\displaystyle\overset{|}{CH_2COOMe}}{C}{=}C(OK)OMe \quad \text{and} \quad KN{=}C{=}CH{-}\underset{\displaystyle\overset{|}{CH_2COOMe}}{C}HCOOMe$$

(XVIIIa) (XVIIIb)

The resulting product (XVIIIa, b) underwent rearrangement and condensation to give an imidic (XIX) or imidolactonic (XX) derivative

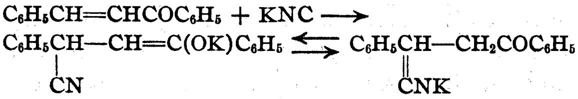


(XIX)



(XX)

β-Cyanobenzylacetophenone (XXI) has been prepared by the action of the isocyanide on benzalacetophenone under varied conditions[2b,27] Hann and Lapworth[27a] treated the ketone, in 92% alcohol, with two equivalents of potassium isocyanide and one equivalent of diluted acetic acid. Along with (XXI) a small yield of compound, $C_{31}H_{23}ON$,[27a] was obtained; it was also formed by condensation of benzalacetophenone with (XXI) by strong alkali. In boiling absolute methanol, benzalacetophenone reacts with isocyanide to give, directly, $C_{31}H_{25}O_2N$, which, with alkali or acid, lost water and gives Hann and Lapworth's $C_{31}H_{23}ON$. The first stage of the reaction evidently results in enolate (XXII), in which the metal is poorly neutralized and which should rearrange to a mixture containing, largely, the still imperfectly neutralized iminolate (XXIII)

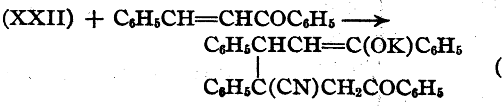


$$C_6H_5CH{=}CHCOC_6H_5 + KNC \longrightarrow$$

$$C_6H_5\underset{\displaystyle\overset{|}{CN}}{C}H{-}CH{=}C(OK)C_6H_5 \rightleftarrows C_6H_5\underset{\displaystyle\overset{\|}{CNK}}{C}H{-}CH_2COC_6H_5$$

(XXII) (XXIII)

The potassium enolate (XXII) can attain a better neutralization by reacting with another molecule of benzalacetophenone, but iminolate (XXIII) cannot do so. The reaction, therefore, proceeds through enolate (XXII), which is reformed as it disappears in the addition process



$$(XXII) + C_6H_5CH{=}CHCOC_6H_5 \longrightarrow \begin{array}{l} C_6H_5CHCH{=}C(OK)C_6H_5 \\ \quad\;\; | \\ C_6H_5C(CN)CH_2COC_6H_5 \end{array}$$

(XXIV)

This formula (XXIV) is the enolate of the structure suggested by Hann and Lapworth for the hitherto unisolated, second phase of the addition process. Since the cyclic intramolecular condensation product is formed from $C_{31}H_{25}O_2N$ in alkaline solution, *i. e.*, from the enolate, the reaction can proceed in one direction, not in two, as Hann and Lapworth assume. However, two isomeric compounds of the formula $C_{31}H_{23}ON$ may be formed, through aldolization, with ring

---

[25] Michael, *Ber.*, **33**, 3757 (1900).

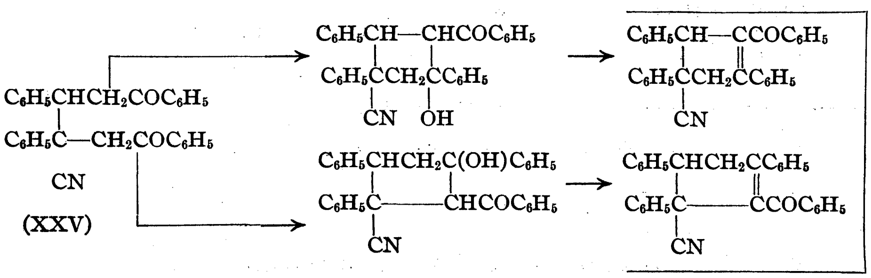
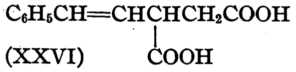
[27] (a) Hann and Lapworth, *ibid.*, **85**, 1358 (1904); (b) Lapworth and Wechsler, *ibid.*, **97**, 38 (1910).

formation and elimination of water, of the corresponding free compound

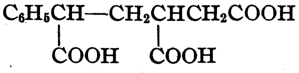


We attempted, without success, to prove definitely the structures of $C_{31}H_{25}O_2N$ and $C_{31}H_{23}ON$. The first compound resists hydrolysis with concentrated acid and alkali, but is dehydrated to $C_{31}H_{23}ON$, which is, as stated above, probably a ring compound. Hydrolysis in sealed tubes with concentrated hydrochloric acid, at temperatures from 140 to 200°, gave only intractable tars, and treatment with chromic anhydride in glacial acetic acid, or potassium permanganate in acetone, brought about dehydration to $C_{31}H_{23}ON$. In agreement with Hann and Lapworth, we found the latter compound very resistant to hydrolysis or oxidation, reaction taking place under very drastic conditions and giving nothing more significant than benzoic acid or acetophenone. Suspended in glacial acetic acid, $C_{31}H_{25}O_2N$ gave $C_{31}H_{22}ONBr$ with bromine, by substitution of one of the hydrogens for bromine and elimination of water. This compound is apparently not directly related to $C_{31}H_{23}ON$ since it could not be produced by bromination of that compound. The bromination product lost hydrogen bromide by the action of sodium methylate and gave a bright yellow compound $C_{31}H_{21}ON$. This was oxidized by chromic acid to give a poor yield of $C_{24}H_{17}ON$.

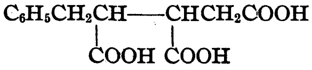
Cinnamalmalonic ester and isocyanide reacted in absolute methanol at room temperature and gave, after acidification, $C_{29}H_{29}O_8N$, formed by union of the primary β-cyano enolate with unchanged ester. In aqueous alcohol, with isocyanide and ester in molecular proportions, by subsequent hydrolysis, Thiele and Meisenheimer[2d] obtained styrylsuccinic acid (XXVI). With three moles of isocyanide to one of ester a product was obtained which on hydrolysis gave tribasic acid (XXVII).



$$C_6H_5CH{=}CH\underset{COOH}{\underset{|}{C}H}CH_2COOH$$
(XXVI)

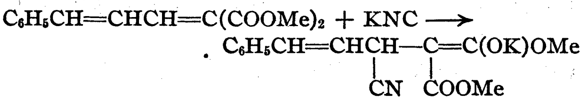


$$C_6H_5\underset{COOH}{\underset{|}{C}H}-CH_2\underset{COOH}{\underset{|}{C}H}CH_2COOH$$
(XXVII)

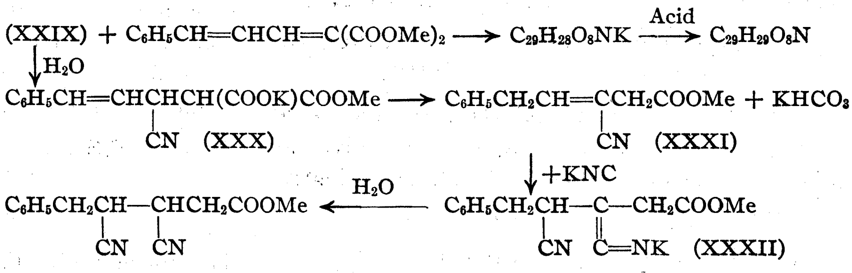


$$C_6H_5CH_2\underset{COOH}{\underset{|}{C}H}-\underset{COOH}{\underset{|}{C}H}CH_2COOH$$
(XXVIII)

Thiele and Meisenheimer assumed that the reaction leading to (XXVI) was 1,2-addition of hydrogen cyanide, and to (XXVII), first 1,4- and then 1,2-addition. Duff and Ingold[28] proved the correct structure, (XXVIII), the formation of which was explained by assuming α,β-addition to give $C_6H_5CH{=}CHCH(CN)CH(COOR)_2$, which rearranged to $C_6H_5CH_2CH{=}C(CN)CH(COOR)_2$, and which by a second β,γ-addition of hydrogen cyanide yielded the dinitrile $C_6H_5CH_2CH(CN)CH(CN)CH(COOR)_2$ corresponding to (XXVIII). Since hydrogen cyanide does not add, the primary product must be enolate (XXIX), which under the first experimental conditions gave potassium salt (XXX). With excess of isocyanide (XXX) rearranges to (XXXI), which by 1,4-addition of isocyanide forms iminolate (XXXII). Without water, enolate (XXIX) is stable and adds to unchanged ester, forming $C_{29}H_{28}O_8NK$.



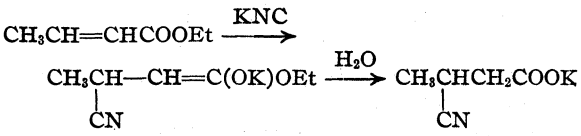
$$C_6H_5CH{=}CHCH{=}C(COOMe)_2 + KNC \longrightarrow C_6H_5CH{=}CH\underset{CN}{\underset{|}{C}H}-\underset{COOMe}{\underset{|}{C}}{=}C(OK)OMe$$
(XXIX)



In absolute methanol, isocyanide acts slowly and incompletely on crotonic ester, giving enolates of complex, high boiling esters, probably formed by interaction of primarily formed enolates with unchanged ester. In the presence of water, the enolate is hydrolyzed to the corresponding salt, thus preventing secondary reactions, and by hydrolysis pyrotartaric acid was obtained.[2i]

---

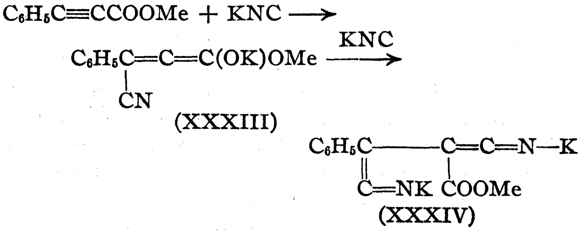
[28] Duff and Ingold, *J. Chem. Soc.*, 87 (1934).



$$CH_3CH{=}CHCOOEt \xrightarrow{KNC}$$

$$CH_3\underset{\underset{CN}{|}}{C}H{-}CH{=}C(OK)OEt \xrightarrow{H_2O} CH_3\underset{\underset{CN}{|}}{C}HCH_2COOK$$

Cobb[29] heated phenylpropiolic ester, isocyanide and aqueous alcohol and isolated $C_6H_5CH(CN)CH_2CN$ with potassium bicarbonate obviously formed by decomposition of $C_6H_5CH(CN)C(CN){=}C(OK)OEt$. In boiling absolute methyl alcohol, phenylpropiolic methyl ester reacts with isocyanide to give after acidification, mainly a mixture of β-methoxycinnamic ester and benzoylacetic ester and about 20% of β-cyanobenzylcyanoacetic ester (IX). The first-formed β-methoxycinnamic ester undoubtedly adds a second molecule of alcohol to form $C_6H_5C(OCH_3)_2CH_2COOMe$,[30] which is converted by isocyanide into benzoylacetic ester enolate. In aqueous alcohol, at room temperature, the addition of methanol is suppressed in favor of isocyanide, and a better yield of (IX) is obtained by the way of the enolate (XXIII) and the diiminolate (XXXIV).



$$C_6H_5C{\equiv}CCOOMe + KNC \longrightarrow$$

$$C_6H_5\underset{\underset{CN}{|}}{C}{=}C{=}C(OK)OMe \xrightarrow{KNC}$$

(XXXIII)

$$C_6H_5\underset{\underset{C=NK}{\|}}{C}{-\!-\!-}\underset{\underset{COOMe}{|}}{C}{=}C{=}N{-}K$$

(XXXIV)

The di-iminolate (XXXIV) contains two potassium atoms in different states of neutralization; that at the cyanoacetic ester grouping is better neutralized than that attached to the β-cyano group, and the latter yields, with water, the free nitrile group and potassium hydroxide which saponifies unchanged phenylpropiolic ester.

Malonic enolates add to monobasic α,β-acetylenic esters, with migration of the metal from the malonic to the mono-carbmethoxy group;[31] to this new type of stable enolates belongs (XXXIII), which also derived from an α,β-Δ-ester through enolization of the α-Δ-CH group. Earlier attempts to prepare such enolates directly from esters and sodium[32] led to the formation of enolates of depolymerized esters; in recent experiments, using a solution of sodium in liquid ammonia, we obtained analogous results.

Experimental

Action of Potassium Isocyanide on Allyl Cyanide.—The allyl cyanide (6.7 g.), b. p. 117.5–119°, was added to a suspension of 6.5 g. of potassium isocyanide in 50 cc. of absolute methanol and boiled. At the end of four hours the solution started to turn yellow and at the end of twenty-four, when the reaction was stopped, the solution had become dark brown. The solvent was removed as completely as possible on the water-bath and the residue diluted with 100 cc. of dry ether. The precipitate was filtered and the filtrate was concentrated, leaving a residue of 6.0 g. This was distilled and yielded 5.5 g. of allyl cyanide, b. p. 115–120°.

β-Cyanobenzylmalonic Dimethyl Ester, (I) and (IV), (a).—Benzalmalonic dimethyl ester (5.5 g.) was added to a suspension of 1.63 g. of potassium isocyanide in 20 cc. of boiling absolute methanol. The salt dissolved immediately; one-half of the solvent was distilled off, which resulted in the separation of a voluminous, white, crystalline potassium compound. One hundred cc. of dry ether was added and the mixture cooled in an ice-bath. The solid was filtered, washed repeatedly with ether and dried *in vacuo* at 100°; yield 7.0 g. (100%).

Anal. Calcd. for $C_{13}H_{12}O_4NK$ (I): K, 13.7. Found: K, 13.4.

The potassium compound was suspended in ether, dilute acid added and the mixture shaken until solution was complete. The dried solution was freed of ether and the colorless residual oil was dissolved in an equal volume of methanol and cooled to −20°, when it completely solidified; yield 6.0 g. (100%). The compound was recrystallized by dissolving in the minimum volume of methanol at room temperature and cooling in a freezing mixture; it separated in rosets of needles, m. p. 47.5–48.5°.

Anal. Calcd. for $C_{13}H_{13}O_4N$ (IV): C, 63.16; H, 5.26. Found: C, 63.25; H, 5.43.

(b).—Benzalmalonic dimethyl ester (5.5 g.) was dissolved in 50 cc. of methanol and a solution of 1.65 g. of potassium isocyanide in 20 cc. of water was added. The solution stood ten minutes, 3 cc. of concentrated hydrochloric acid was added, and then allowed to stand for twenty-four hours. It was diluted with sufficient water to cause precipitation of an oil, which was extracted with ether and the residue from the dried ether solution was dissolved in methanol. By seeding and cooling to −20°, 3 g. of a solid separated, identical with the β-cyanobenzylmalonic ester (IV) obtained above.

α-Benzyl-β-cyanobenzylmalonic Dimethyl Ester (II).—Potassium enol β-cyanobenzylmalonic ester (I), (12.2 g.), was suspended in 75 cc. of dry toluene and boiled with 7.3 g. of benzyl bromide for three hours. The solid was separated by centrifuging and was washed repeatedly with ether; weight 10.2 g. (theoretical for potassium bromide, 5.1 g.). The solid was suspended in ether, shaken with dilute acid, and the dried ether solution yielded, on concentration, 5.5 g. of β-cyanobenzylmalonic ester (IV). The ether–toluene solution was concentrated *in vacuo* and the residue taken up in ether. Dilution with petroleum ether and cooling to −20° yielded 4 g. of crystalline solid, which, after recrystallization from ether–petroleum ether, melted at 117.5–118°.

Anal. Calcd. for $C_{21}H_{19}O_4N$ (II): C, 71.22; H, 5.64. Found: C, 70.90; H, 5.56.

α-Benzyl-β-phenylsuccinic Acid (III).—One gram of (II) was heated in a sealed tube with 25 cc. of concentrated hydrochloric acid at 200° for five hours. The resulting solution was extracted with ether and the ether washed with saturated sodium bicarbonate solution. Acidification of the washings, extraction with ether and concentration of the dried ether solution yielded 0.6 g. of acid, which, after recrystallization from 30% methanol, melted at 175–176° and had a neutral equivalent of 144. Calcd. for $C_{17}H_{16}O_4$: (dibasic) 142. It is therefore α-benzyl-β-phenylsuccinic acid.[33]

β-Cyanobenzalmalonic Dimethyl Ester (V).—Potassium enol β-cyanobenzylmalonic ester (I), (10.5 g.) was suspended in 75 cc. of boiling toluene and a solution of 4.6 g. of iodine in 25 cc. of toluene was added dropwise. The iodine was decolorized immediately until the last drop, which colored the supernatant liquor faintly pink. The potassium iodide was separated by centrifuging and was washed repeatedly with ether; weight 6.1 g. (theoret.). The solution and washings were concentrated *in vacuo*, the residue was dissolved in ether, diluted with petroleum ether and cooled to −20°. A small amount of solid crystallized out and repeated concentration of the mother liquor and cooling finally yielded 3.85 g. of this compound, leaving 4.25 g. of brown oil. The solid was recrystallized from ether–petroleum ether, giving flat needles, m. p. 74°.

Anal. Calcd. for $C_{13}H_{11}O_4N$ (V); C, 63.67; H, 4.47; mol. wt., 245. Found: C, 64.17, 63.81; H, 4.36, 5.02; mol. wt. (Pirsch, camphor), 247, 250.

One gram of this compound was shaken with hydrogen in the presence of 0.05 g. of Adams catalyst and absorbed 120 cc. (one mole) in four minutes. The filtered solution yielded β-cyanobenzylmalonic ester (IV).

The residual brown oil from the iodine reaction was freed of ether and dissolved in an equal volume of methanol and cooled to −20°. Inoculation with a seed crystal caused separation of 4 g. of β-cyanobenzylmalonic ester (IV).

β-Cyanobenzylcyanoacetic Methyl Ester, (VIII) and (IX).—Benzalcyanoacetic methyl ester (9.35 g.) was added to a suspension of 3.25 g. of potassium isocyanide in 25 cc. of absolute methanol. The salt disappeared almost immediately after warming the mixture but no solid separated when half the solvent was distilled off. The residual solution, cooled and diluted with 100 cc. of dry ether, gave a crystalline potassium compound. This was filtered, washed repeatedly with ether and dried *in vacuo* at 100°; yield 12 g. (100%).

Anal. Calcd. for $C_{12}H_9O_2N_2K$ (VIII): K, 15.5. Found: K, 14.7.

The potassium compound was suspended in ether and shaken with dilute acid until completely decomposed. The resulting compound was only sparingly soluble in ether and was filtered, washed with ether and cold methanol. The washings were combined with the ether layer, dried and concentrated, yielding a small additional quantity of the compound; yield 10.5 g. (100%). After recrystallization from benzene it melted at 107–108°.

Anal. Calcd. for $C_{12}H_{10}O_2N_2$ (IX): C, 67.30; H, 4.67. Found: C, 67.21; H, 4.89.

β-Cyanobenzalcyanoacetic Methyl Ester (X).—Potassium enol β-cyanobenzylcyanoacetic ester (VIII), (12.6 g.), was suspended in 50 cc. of dry toluene and a solution of 6.3 g. of iodine in 50 cc. of toluene was added dropwise to the boiling mixture. When the addition was completed the hot solution was filtered and the salt washed with hot benzene. The combined filtrate and washings was washed with sodium thiosulfate solution, dried and concentrated to about 10 cc. Dilution with ether and petroleum ether gave 7.0 g. of solid and concentration of the mother liquor yielded an additional gram. The solid was extracted several times with ether, leaving undissolved 3.8 g. of β-cyanobenzylcyanoacetic ester (IX). The ether was concentrated, and, after 0.2 g. of (IX) was obtained, dilution with petroleum ether gave 3.8 g. of a new substance. This was recrystallized from ether–petroleum ether and melted at 87–88°.

Anal. Calcd. for $C_{12}H_8O_2N_2$ (X): C, 67.93; H, 3.77. Found: C, 67.91; H, 4.36.

Catalytic reduction of this compound gave a quantitative yield of β-cyanobenzylcyanoacetic ester (IX).

1 - Cyano - 2,3,4 - carbmethoxybutane (XV).—Fumaric methyl ester (7.2 g.) was suspended in a solution of 3.25 g. of potassium isocyanide in 5 cc. of water and 50 cc. of methanol. Solution of the ester was complete at the end of two hours, but the mixture stood for forty-eight hours. It was then neutralized with an equivalent of hydrochloric acid, diluted with 50 cc. of ether, and the potassium chloride filtered. The solution was concentrated and the residue fractionated at reduced pressure, yielding (1) 1 g., b. p. 85–100° (2 mm.); (2) 3.9 g. CH(COOMe)=CH-COOH, b. p. 145–155° (2 mm.), m. p. 143°; (3) 2.5 g. of viscous oil, b. p. 190–200° (3 mm.). Fraction I was identified as methoxysuccinic ester, as described below. Fraction 3 was redistilled and boiled at 178–180° (3 mm.).

Anal. Calcd. for $C_{11}H_{15}O_6N$ (XV): C, 51.37; H, 5.83; N, 5.45; OCH_3, 36.19. Found: C, 51.0, 50.83; H, 5.63, 6.03; N, 5.1; OCH_3, 36.86.

Three and four-tenths grams of this compound was heated in a sealed tube at 200° with 10 cc. of concentrated hydrochloric acid for four hours. The resulting solution was evaporated to dryness on the water-bath, and the crystalline residue dissolved in 15 cc. of boiling acetic anhydride, which on cooling deposited an anhydride that melted at 245–248°. This anhydride was dissolved in boiling water, the solution concentrated and the acid allowed to crystallize. This acid melted at 185–188°. These are, therefore, the lower melting butane-1,2,3,4-tetracarboxylic acid and its anhydride, described by v. Auwers and Jacob.[22]

2 - Cyano - 3,4,5 - carbmethoxycyclopentanone (XVII), (a), and Methoxysuccinic Ester.—Fumaric methyl ester (14.4 g.) was added to a suspension of 6.5 g. of potassium isocyanide in 50 cc. of absolute methanol, which stood at room temperature for four days. The undissolved potassium isocyanide was filtered, washed with ether and, when dry, weighed 3.0 g. The filtrate was neutralized with a

---

(33) Avery and Upson, *Am. Chem. J.*, **30**, 600 (1902).

solution of dry hydrochloric acid in absolute methanol and the potassium chloride filtered. The solvent was removed at room temperature under reduced pressure, leaving a residue of 16.3 g. This was fractionated into (1) 5.5 g., b. p. 75–85° (2 mm.); and (2) 5.4 g., b. p. 196–205° (2 mm.).

When the same quantities of reagents stood for six days and the mixture was worked up as above, the same weight of isocyanide was recovered. There was a residue of 14.7 g. which was fractionated into (1) 3.0 g. and (2) 6.6 g. The combined low boiling fractions boiled completely at 119° (21 mm.), and was identified as methoxysuccinic ester by saponification to methoxysuccinic acid,[20] m. p. 107–108°. Fraction 2 of both experiments was identified as the cyclopentanone derivative (XVII), obtained also in the following experiment, by its boiling point, brilliant coloration with ferric chloride and complete solubility in sodium bicarbonate solution.

(b).—A solution of 14.4 g. of fumaric methyl ester in 150 cc. of absolute methanol was boiled for two hours with 3.25 g. of potassium isocyanide. The solvent was then removed completely, the gummy residue suspended in ether and shaken with acid until completely dissolved. The residue from the dried ether extract weighed 10.8 g. and boiled at 190–200° (4 mm.). On redistillation it was obtained as a colorless, extremely viscous liquid, b. p. 196° (4 mm.). The substance is completely soluble in sodium bicarbonate solution and is recovered unchanged on acidification of that solution. With ferric chloride it gives a brilliant scarlet coloration.

Anal. Calcd. for $C_{12}H_{13}O_7N$ (XVII): C, 50.89; H, 4.59; N, 4.95; OCH_3, 32.86. Found: C, 50.72; H, 4.67; N, 5.4; OCH_3, 32.08.

Six grams of this viscous liquid was boiled for two hours with 50 cc. of concentrated hydrochloric acid. The solution was evaporated to dryness, leaving a crystalline residue which was absolutely insoluble in organic solvents, nor did it melt below 300°, but charred and sublimed. This was not investigated further, but was boiled with concentrated hydrochloric acid and amyl nitrite. The dark solution was concentrated to about 5 cc., and diluted with 100 cc. of acetone to precipitate any unaltered infusible substance, which was filtered. The filtrate was decolorized with charcoal and concentrated, yielding a crystalline acid, which after recrystallization from acetone–ether melted at 188° with decomposition. This was suspended in ether and treated with excess of diazomethane, giving a clear solution, from which was obtained an ester, crystallizing from petroleum ether in needles, m. p. 63–64°. This fixes the acid as cyclopentanone-3,4-dicarboxylic acid,[23] and establishes the structure of the cyclopentanone derivative (XVII). The infusible compound is undoubtedly an amide sufficiently stable to withstand hydrolysis with acids.

Action of Potassium Isocyanide on Citraconic Methyl Ester, (a), at Room Temperature.—Citraconic methyl ester (15.8 g.) was added to a suspension of 6.5 g. of potassium isocyanide in 50 cc. of absolute methanol, which then stood at room temperature for four days. The undissolved salt, when filtered, washed with ether and dried, weighed 3.5 g. The filtrate was neutralized with a solution of dry methyl alcoholic hydrochloric acid, the potassium chloride filtered, and the solution concentrated to a solvent-free residue of 17.8 g. This was fractionated into (1) 10 g., b. p. 120–135° (20 mm.); and (2) 4.6 g. of viscous liquid, b. p. 167–175° (1 mm.), which solidified on standing.

When the same quantities of reagents were allowed to stand for six days and worked up in the same manner, 2.6 g. of isocyanide was recovered, and 17.2 g. of oil was obtained, which was fractionated into (1) 7 g., and (2) 6.5 g. The solid (fraction 2) was recrystallized from acetone–petroleum ether and ether–petroleum ether and melted at 80–81°.

Anal. Calcd. for $C_7H_9O_4N$, (XIX) or (XX): C, 49.12; H, 5.26; N, 8.19; OCH_3, 18.13; mol. wt., 171. Found: C, 48.87, 48.93; H, 5.32, 5.51; N, 8.34; OCH_3, 17.93; mol. wt. (b. p. of acetone), 173, 174, 178.

The compound is very soluble in water, reacting neutral to litmus and sodium carbonate solution. When boiled with 50% hydrochloric acid, or excess of 20% caustic soda followed by acidification, the solution evaporated to dryness, the resulting acid, extracted from the residue with acetone, was tricarballylic acid, identified by m. p. and mixed m. p. with an authentic sample.

(b), In Boiling Methanol.—Citraconic methyl ester (15.8 g.) was boiled with 6.5 g. of potassium isocyanide in 100 cc. of absolute methanol for four hours, when all the potassium cyanide had dissolved. The solution was cooled and neutralized with dry methyl alcoholic hydrochloric acid. The solution was diluted with ether, the potassium chloride separated by centrifuging, and the solution concentrated at reduced pressure. The residue was distilled at reduced pressure and gave 7.0 g. of $C_7H_9O_4N$, (XIX) or (XX).

1,2-Dicarbmethoxy-3-methoxypropane.—Fraction 1 of the above room temperature reactions was distilled through a Fenske column, and, after removal of a trace of starting material, boiled at 80.5° (1 mm.) and had n^{22}D 1.4294.

Anal. Calcd. for $C_8H_{14}O_5$: C, 50.56; H, 7.37. Found: C, 49.88, 50.10; H, 7.20, 7.42.

Saponification of this ester yielded an acid, which, after recrystallization from ether–petroleum ether, melted at 102–103°. Hope[26] gave a m. p. of 92° for $CH_3OCH_2CH(COOH)CH_2COOH$, prepared from the diethyl ester. To check this, the methoxy ester was prepared by an unequivocal procedure. Citraconic methyl ester (15.8 g.) was added to a solution of 0.2 g. of sodium in 50 cc. of absolute methanol and allowed to stand at room temperature for four days. The solution was neutralized and concentrated. The residue was dissolved in ether and a small amount of gelatinous material removed by filtration. The ether-free residue was distilled in a Fenske column and yielded 1.4 g. of starting material and 14.1 g., b. p. 82° (1.5 mm.), n^{22}D 1.4292. and, therefore, identical with the product obtained in the citraconic ester–potassium isocyanide reaction. The acid obtained from this ester melted at 102–103° and did not depress the m. p. of the acid obtained in the previous reaction. Therefore, Hope's acid of m. p. 92° was impure, or the figure given is a typographical error.

Action of Potassium Isocyanide on Benzalacetophenone, $C_{31}H_{25}O_2N$, (XXV).—Benzalacetophenone (10.4 g.) was added to a boiling suspension of 3.3 g. of potassium isocyanide in 50 cc. of absolute methanol. The salt dissolved and, after an hour, a voluminous solid separated. This was filtered from the cooled solution, and when washed colorless with ether and dried it weighed 7.4 g. An additional gram was obtained by concentration of the mother liquor. It is sparingly soluble in all solvents, hot or cold, except hot alcohol and benzene. Recrystallized from the latter solvent, it melted at 237°.

Anal. Calcd. for $C_{31}H_{25}O_2N$ (XXV): C, 83.95; H, 5.64; N, 3.16; mol. wt., 443. Found: C, 84.00; H, 5.75; N, 3.48; mol. wt. (camphor), 418.

In an attempt to oxidize (XXV), 2 g. was added to a solution of 1.1 g. of chromic anhydride in 10 cc. of glacial acetic acid. The mixture was warmed on the water-bath and turned green in about five minutes. The solution was poured into water, and the resulting precipitate separated by filtration. When dry it weighed 1.8 g., and after recrystallization from benzene was identified as $C_{31}H_{23}ON$[27a] by m. p. and mixed m. p. with an authentic sample.

In an attempt to hydrolyze or cleave $C_{31}H_{25}O_2N$ (XXV), 1 g. was treated with a solution of 5 g. of sodium hydroxide in 25 cc. of 50% alcohol at 100° for eighteen hours. The undissolved solid was filtered and dried; weight 0.8 g. After recrystallization, it was identified as $C_{31}H_{23}ON$.

Action of Br_2 on $C_{31}H_{25}O_2N$, (XXV); $C_{31}H_{22}ONBr$.—Five grams of $C_{31}H_{25}O_2N$ (XXV) was suspended in 50 cc. of glacial acetic acid containing 2 g. of bromine. The solution was boiled for ten minutes before the evolution of hydrogen bromide started, but the reaction then proceeded rapidly resulting in a clear pale yellow solution. The cooled solution was poured into water and the precipitated yellow solid separated by filtration. This was dissolved in cold benzene, the water layer drawn off and the benzene dried. Concentration of the benzene solution, and dilution with petroleum ether gave 4.5 g. of colorless solid, which after repeated crystallization from benzene–petroleum ether, melted at 188–189°.

Anal. Calcd. for $C_{31}H_{22}ONBr$: C, 73.81; H, 4.36; Br, 15.85. Found: C, 74.35; H, 4.47; Br, 16.21.

Action of Br_2 on $C_{31}H_{23}ON$.—Eleven grams of $C_{31}H_{23}ON$ was suspended in 100 cc. of glacial acetic acid containing 4 g. of bromine and the mixture boiled. The solid dissolved with evolution of hydrogen bromide and gave a deep red solution. This was poured into water, the water extracted with benzene, which was washed with sodium bicarbonate solution, dried and concentrated, leaving a deep red oil from which no solid could be isolated.

Action of Sodium Methylate on $C_{31}H_{22}ONBr$; $C_{31}H_{21}ON$.—Four grams of $C_{31}H_{22}ONBr$ was suspended in a solution of 0.2 g. of sodium in 50 cc. of absolute methanol and boiled for an hour, during which time the white solid dissolved and a yellow solid crystallized, the solution becoming transitorily pink, and finally yellow. The solution was concentrated to 25 cc., and the solid filtered from the cooled solution; weight, 3.2 g. It crystallized from methanol as lemon-yellow needles, m. p. 188°.

Anal. Calcd. for $C_{31}H_{21}ON$: C, 87.94; H, 4.96. Found: C, 87.41; H, 4.70.

Oxidation of $C_{31}H_{21}ON$, $CH_{24}O_{17}N$.—Two grams of $C_{31}H_{21}ON$ was dissolved in 10 cc. of boiling glacial acetic acid and a solution of 1 g. of chromic anhydride in 5 cc. of glacial acetic acid was added dropwise until the red color was no longer discharged immediately. The solution was poured into water and extracted with benzene, which was washed with water and sodium bicarbonate solution. The acidified sodium bicarbonate solution yielded no solid acid. The dried benzene solution was concentrated and 0.5 g. of white crystalline compound separated. This was recrystallized from benzene and melted at 235–237° with decomposition.

Anal. Calcd. for $C_{24}H_{17}ON$: C, 85.97; H, 5.07. Found: C, 85.93; H, 5.17.

Action of Potassium Isocyanide on Cinnamalmalonic Ester.—Five grams of cinnamalmalonic methyl ester was dissolved in 50 cc. of absolute methanol containing 1.3 g. of potassium isocyanide. The solution stood at room temperature for three hours and was then neutralized with an equivalent of concentrated hydrochloric acid. The precipitated solid was filtered and washed with water, leaving, when dry, 1 g. of white solid. The filtrate was concentrated and yielded an additional 1.5 g. of the same solid. It crystallized from methanol as needles, m. p. 143–144°.

Anal. Calcd. for $C_{29}H_{29}O_8N$: C, 67.05; H, 5.59; N, 2.70; mol. wt., 519. Found: C, 67.35, 67.26; H, 5.76, 5.49; N, 3.5; mol. wt. (boiling acetone), 559, 500, 518.

Action of Potassium Isocyanide on Crotonic Ester.—Twenty grams of crotonic methyl ester was treated with 13 g. of potassium isocyanide in 100 cc. of boiling absolute methanol for forty hours. The dark brown solution was concentrated to 50 cc. and cooled, causing crystallization of 7.0 g. of potassium isocyanide. This was removed by filtration and the filtrate concentrated further. The gummy residue was suspended in ether and shaken with dilute acid until completely decomposed. The dried ether solution was concentrated and the residue fractionated into (1) 4.4 g. of crotonic ester, b. p. 58–70° (25 mm.); (2) 2 g., b. p. 135–145° (4 mm.); and (3) 1.4 g. of viscous liquid, b. p. 190–200° (4 mm.). There was a large tarry residue.

Action of Potassium Isocyanide on Phenylpropiolic Ester, (a) in Absolute Methanol.—Eight grams of phenylpropiolic methyl ester was boiled with a suspension of 6.5 g. of potassium isocyanide in 25 cc. of absolute methanol. The solution turned yellow immediately and, finally, at the end of thirty minutes, dark brown. Since the potassium isocyanide did not seem to be dissolving, the mixture was cooled in an ice-bath and the isocyanide filtered, washed with ether and dried; weight 3.7 g. The filtrate was diluted with 50 cc. of dry ether and neutralized by bubbling in gaseous hydrogen chloride. The potassium chloride was filtered and the filtrate concentrated to a solvent-free residue of 9.9 g. This was fractionated into (1) 6.5 g., b. p. 109–120° (2 mm.), and (2) 2.0 g. of β-cyanobenzylcyanoacetic ester (IX), which distilled when the bath was raised to 240°. Fraction 1 was redistilled and boiled completely at 138–139° (8 mm.). This material gave a ferric chloride test, and, so, 1 g. was treated with excess of saturated cupric acetate solution, thus giving 0.3 g. of a copper derivative that was identified as that of benzoylacetic methyl ester by m. p. (200°) and mixed m. p. The distillate had n^{25}_{D} 1.5455; v. Auwers[34] gives

---

[34] Von Auwers, *Ann.*, **413**, 274 (1916); **415**, 230 (1918).

the indices of refraction ($n^{25}D$) of benzoylacetic methyl ester and β-methoxycinnamic methyl ester, respectively, as 1.537 and 1.550. Thus the yield of copper derivative shows a benzoylacetic ester content of 30%, while the index of refraction checks this approximation with benzoylacetic ester content of 35%.

(b). **In Aqueous Methanol.**—Eight grams of phenylpropiolic methyl ester was added to a solution of 6.5 g. of potassium isocyanide in 10 cc. of water and 50 cc. of methanol and allowed to stand at room temperature for four hours and, then, for an additional twenty hours in a bath at −20°. One gram of crystallized potassium salt was filtered and the solution was diluted with 500 cc. of ether, yielding an additional 5.8 g. of potassium salt. The combined potassium salts was suspended in ether and shaken with dilute acid. The dried ether solution yielded 3.5 g. of phenylpropiolic acid. The filtrate from the salt was shaken with dilute acid, changing from deep orange to pale yellow. The dried ether solution was concentrated and left 5 g. of solid, which was extracted repeatedly with petroleum ether, thus leaving 4 g. of pure β-cyanobenzylcyanoacetic ester (IX). The petroleum ether extracts yielded 1 g. of phenyl propiolic acid.

Summary

1. The formation of pyrotartaric dinitrile from potassium isocyanide and allyl cyanide proceeds primarily through rearrangement of allyl cyanide to crotononitrile.

2. The mechanisms hitherto proposed for the syntheses of β-cyano-ketones, -esters and -nitriles from the corresponding α,β-Δ-ketones, -esters and -nitriles, which was assumed to proceed by addition of hydrocyanic acid or through a complex salt with potassium isocyanide to the Δ-carbons of the Δ-compounds has been shown to be impossible.

3. The formation of β-cyano-ketones, -esters and -nitriles from the corresponding α,β-ethylenic compounds proceeds through the formation of enolates, or iminolates, by 1,4-addition of potassium isocyanide to the conjugated groups of the unsaturated compounds, the metal uniting with carbonyl oxygen or cyano nitrogen.

4. When the reaction products from potassium isocyanide and the α,β,Δ-esters are poorly neutralized enolates, in the absence of water, they realize a better intramolecular neutralization by addition to unchanged ester.

5. The action of potassium isocyanide upon fumaric methyl ester proceeds primarily by 1,4-addition; under certain conditions, the enolate adds to unchanged fumaric ester and the addition product condenses to a cyclopentanone derivative. With citraconic methyl ester, the first phase consists in rearrangement to the itaconic ester, which undergoes the 1,4-addition with the isocyanide and is then changed to a cyclic nitrogen derivative.

6. According to the experimental conditions, phenylpropiolic ester unites by 1,4-addition with one and then with a second molecule of isocyanide. The first addition product is an enolate of the structure $C_6H_5C(CN){=}C{=}C(OK)OMe$; a type of enolate involving the enolization of an unsaturated α-CH group of an α,β,Δ-ester.

The Catalytic Hydrogenation and Esterification of C_4-Saccharinic Acid Lactones and the Hydrogenation of Butyl Erythronate[1]

BY J. W. E. GLATTFELD AND ANNE M. STACK

Various reduction methods have been studied in these Laboratories with the object of finding a practical method for the reduction of the C_4-saccharinic acids to the corresponding aldehydes and alcohols and for the reduction of erythronic lactone to erythrose. Low pressure catalytic reduction of aldonic acids was studied by Glattfeld and Shaver[2] and by Glattfeld and Schimpff.[3] The work reported in this paper is a continuation of these experiments and includes a study of the catalytic hydrogenation, under pressures of 2–136 atmospheres, of 2,3-dihydroxybutyric acid lactone and one of its derivatives, of 1,3-dihydroxybutyric acid lactone, and of the butyl ester of *dl*-erythronic acid. The last named compound was first prepared in these Laboratories by Snoddy.[4] His method of preparation was followed in general but, as a few changes were made, the procedure is given in some detail in the Experimental Part. (Hereinafter the 2,3- and 1,3-dihydroxybutyric

---

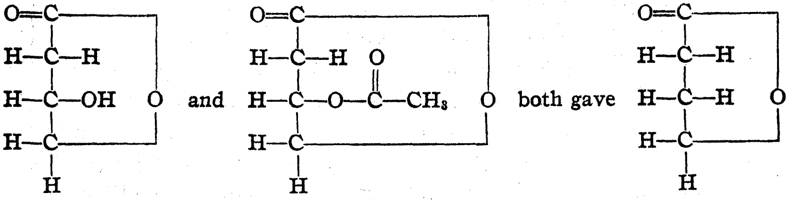
acid lactones will be called, respectively, the 2,3- and 1,3-acid lactones, and the *dl*-butylerythronate, the butyl ester.)

Attempts to reduce the 2,3-acid lactone at low pressures (2–3 atmospheres), with small amounts of catalyst were at first unsuccessful. When the rate of shaking was tripled[3] and the amount of catalyst greatly increased, a 21% reduction of the 2,3-acid lactone and a 67% reduction of the 1,3-acid lactone (products not isolated) were effected. At high pressures (119–133 atmospheres), 37–65% reductions of the 2,3-acid lactone and a 54% reduction of the acetyl-2,3-acid lactone were obtained: the main product was 3-hydroxybutyric acid lactone.

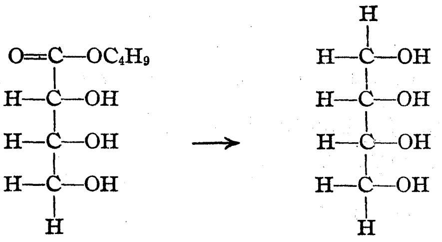


2,3-Acid lactone

Acetyl-2,3-acid lactone

3-Hydroxybutyric acid lactone

The 1,3-acid lactone and the 2,3-acid amide yielded no definite results. A few experiments on the high pressure reduction of erythronic lactone and of erythronamide gave no definite results. The butyl ester was then prepared and reduced to erythritol in good yield under both low and high pressures.



The butyl ester

Erythritol

Further work on catalytic hydrogenation in this field is in progress.

Experimental Part

Apparatus.—The apparatus used for pressures up to three atmospheres was that made by the Burgess–Parr Company of Moline, Illinois. In the work at higher pressures, two different bombs made in the Chemistry Department shop were used. One of these (Bomb A), was essentially the bomb described by Peters and Stanger.[5] We used a glass container with a pin-hole opening inside this bomb. The other bomb (Bomb B) was similar to the one made by the American Instrument Company and diagramed by Tongue.[6] The inside of this bomb was first tinned and then silvered. For valuable help in connection with the construction and testing of these bombs, we wish to thank Dr. F. N. Peters, Jr., and Mr. J. Pokorny of the Quaker Oats Company, Dr. C. W. Lenth of the Miner Laboratories, and the Crane Company of Chicago.

Materials.—(1) The 1,3- and 2,3-acid lactones were prepared according to the procedures developed in these Laboratories and published in previous articles.[7] The crude lactones were twice fractionated and then had the boiling ranges, 110–112° at 2–4 mm., and 148–150° at 2–4 mm., respectively. They were faintly yellow mobile liquids. (2) The acetyl-2,3-acid lactone has been prepared[8] in 52.7% yield by the addition of the 2,3-acid lactone to a cooled (0°) mixture of acetic anhydride and freshly fused zinc chloride. Our product was prepared by the interaction of the sodium salt of the 2,3-acid with acetyl chloride (see below). (3) The *dl*-erythronic lactone was prepared according to the method of Braun.[9] It was a perfectly white crystalline material, m. p. 91–92°. (4) Platinic oxide monohydrate (in the quantities recommended by Schimpff[8]) and palladium oxide were prepared by the procedure of Adams, Voorhees and Shriner.[10] (5) The copper–chromium oxide catalyst was prepared according to Adkins and Connor.[11] (6) The copper–barium–chromium oxide catalyst (37 KAF), was prepared by the method of Connor, Folkers and Adkins.[12] (7) The "Raney" (Ni) catalyst was kindly supplied by the Quaker Oats Company. It had been prepared by the procedure of Covert and Adkins.[13]

Preparation of Acetyl-2,3-acid Lactone.—The sodium salt of the 2,3-acid was prepared by the titration of a heated 10% aqueous solution of the 2,3-acid lactone with a 0.5 N solution of sodium hydroxide. The resulting solution was concentrated to dryness at reduced pressure and the sodium salt obtained in the form of a light brown gum. Six equivalents of acetyl chloride was added to each of a 77 and 79-g. batch of sodium salt. The mixtures were refluxed in a water-bath at 50–60° for four hours and at 60–85° for two hours, at the end of which time all of the sodium salt had disappeared. The solutions were combined, the sodium chloride was separated by filtration and washed with glacial acetic acid and the combined mother liquor and washings concentrated to dryness at reduced pressure at 60°. The residue was fractionated in two batches since it had previously been noted that long continued heating results in some decomposition. A large fraction distilled over at 119–121°, 4 mm. At 121° some

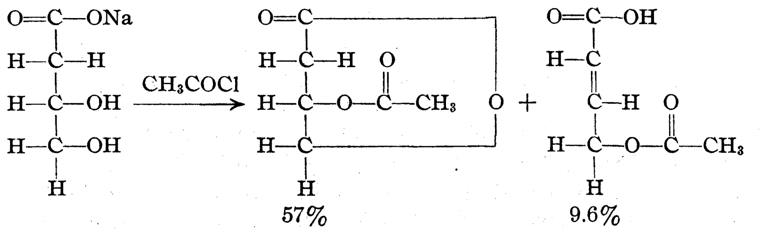
fuming was noted; at 133° crystals appeared in the condenser: a mixture of solid and oil distilled at 133–140°, 4.5 mm. The 119–121° fraction was redistilled to give 90 g. of boiling range 119–121°, 4 mm., a 57% yield of acetyl-2,3-acid lactone. The solid was separated by filtration from the high boiling oil which came over with it, and dried on a porous plate to give 19.5 g. of crude material. This was recrystallized from a small amount of hot ethyl acetate and dried to give 15.3 g. of white crystalline material, melting range 99–102°. It was distilled under reduced pressure for further purification: the distilled solid had the same melting range. This compound, obtained in 9.6% yield, may be the *trans*-3-acetyl crotonic acid, melting point 97–98°, reported by Rambeau.[14]



Anal. Calcd. for $C_6H_8O_4$: C, 49.99; H, 5.60. Found: (liquid, 119–121°, 4 mm.) C, 49.85, 49.98; H, 5.56, 5.53; (solid, m. p. 99–102°) C, 49.92, 50.22; H, 6.27, 5.74.

Neutralization equivalent. Calcd. for $C_6H_8O_4$, 72. Found: liquid, 74.2 and 74.6 (0.2184, 0.2333 g. required 29.44 and 31.28 cc. 0.1 *N* alkali); solid, 72.1 and 72.0 (0.1841, 0.2059 g. required 25.55 and 28.60 cc. 0.1 *N* alkali).

Results of Reduction Experiments.—The results obtained and the conditions used in some representative experiments are recorded in the tables. A few experiments will be discussed in detail to illustrate the experimental procedures used.

Reduction of Lactones

High Pressure Reduction of 2,3-Acid Lactone (Expt. No. 5 in Table I).—Fifty grams of 2,3-acid lactone was put into the glass container of Bomb A and 6.2 g. of copper–barium–chromium oxide catalyst (37 KAF) added. The air was displaced and the bomb placed on two electric heaters mounted in a shell which rocked at the rate of 42 cycles per minute. The material was put under pressure of 88 atmospheres of hydrogen and heating started. After one hour the temperature had reached 167° and the pressure 129 atmospheres, and, after another half hour, 182° and 125 atmospheres. The temperature remained at 182° for three and seven-tenth hours and the pressure continued to drop as hydrogen was used. Heating was then discontinued but the bomb was allowed to rock under pressure for two more hours. At the end of this time the bomb had cooled to 74° and the pressure, 77 atmospheres, could be released without loss of material. The liquid was filtered and fractionated at reduced pressure. The first fractionation yielded 24 g. of material of boiling range 76–78° at 5 mm. This was refractionated at atmospheric pressure and yielded 21.4 g. of material of boiling range 199–202°, 50.8% calculated as 3-hydroxybutyric acid lactone.

The liquid was identified as 3-hydroxybutyric acid lactone by its neutralization equivalent and by oxidation to succinic acid.

Anal. Subs., 0.2038, 0.2613 g.: 0.1 *N* alkali 23.65, 30.39 cc. Neutralization equivalent calcd. for $C_4H_6O_2$, 86.0. Found: 86.2, 86.0.

Conversion to Succinic Acid.—Ten grams of chromic anhydride was made up to 70 cc. with water and 6 cc. of concentrated sulfuric acid. Five grams of the liquid was mixed with 54.3 cc. of this solution, which volume contained 7.75 g. of chromic anhydride, the amount necessary for this oxidation. The mixture was refluxed for one and one-half hours until the original yellow color had changed to green, extracted four times with ether using 150 cc. for each extraction, and the ether extract concentrated at reduced pressure at 60°. The white residue, dried over sulfuric acid, weighed 3.0 g. After two recrystallizations from water 0.6 g. of white crystalline material, melting range 182–184°, 8.7% calculated as succinic acid, was obtained. No attempt was made to rework the mother liquor.

Anal. Subs., 0.2275, 0.2488 g.: 0.1 *N* alkali 38.08, 41.64 cc. Neutralization equivalent calcd. for $C_4H_6O_4$, 59. Found: 59.7, 59.8.

High Pressure Reduction of Acetyl-2,3-acid Lactone (Expt. No. 8 in Table I).—Fifty grams of acetyl-2,3-acid lactone was put into the glass container of Bomb A and 0.4 g. of platinic oxide monohydrate added. The air was displaced, the material was put under pressure of 97 atmospheres of hydrogen, rocked at the rate of 42 cycles per minute, and heating begun. In one hour the temperature had reached 158° and the pressure 129 atmospheres. The temperature remained between 161 and 142° for the next 20.1 hours at the end of which time the pressure had dropped to 82 atmospheres. Heating was stopped but rocking continued. The pressure was released 4.4 hours later when the temperature of the bomb was 31°. The glass container had leaked at the stopper and the bomb now contained only 37.6 g. of filtered material. The liquid, fractionated at reduced pressure, yielded 24.9 g. of material, boiling range 20–68°, 5 mm. On redistillation at atmospheric pressure, 12.2 g. of material, boiling range 195–203°, was obtained. This is a yield of 54.3% calculated as 3-hydroxybutyric acid lactone on the basis of 37.6 g. of original material.

Anal. Subs., 0.2014 g.: 0.1 *N* alkali 23.33 cc. Neutralization equivalent calcd. for $C_4H_6O_2$, 86.0. Found: 86.3.

Alkalinity Developed by $PtO_2 \cdot H_2O$.—Certain results, obtained in the analysis of samples from low pressure reduction experiments, indicated that the acid was being neutralized very slowly during the reduction. That the catalyst was responsible for this was shown by the experiment outlined below.

A 2-g. sample of the catalyst was added to 50 cc. of water and the mixture shaken under pressure of 2.8 atmospheres

[a] The rate of rocking was 42 cycles per minute. [b] 3-Hydroxybutyric acid lactone distils with steam. The distillate was saved and titrated for acidity. Consideration of this factor gave a corrected yield. [c] No solvent was used in Experiments 4–8.

of hydrogen for three-tenths hour. A 1-cc. sample now required 2.49 cc. of 0.01 *N* acid for neutralization. The 49 cc. of solution was again shaken under pressure of 2.8 atmospheres of hydrogen for four-tenths hour. A 1-cc. sample now required 2.60 cc. of 0.01 *N* acid, showing practically no increase in alkalinity during the second period of hydrogenation. A further 2 g. of catalyst was added to the 48 cc. of solution which remained. The mixture was again shaken under pressure of 2.8 atmospheres of hydrogen for one-half hour. A 1-cc. sample now required 5.28 cc. of 0.01 *N* acid, indicating that the second 2 g. of catalyst had generated an alkalinity equivalent to 2.68 cc. of 0.01 *N* acid. From a consideration of these data and others, it was concluded that an average alkalinity equivalent to 2.55 cc. of 0.01 *N* acid was generated by the introduction of 2 g. of the catalyst used in the reduction of the 2,3-acid lactone. The corresponding correction factor on the particular lot of catalyst used in the reduction of the 1,3-acid lactone was found to be 3.26 cc.

These facts and the further fact that water, shaken up with a sample of the catalyst, gave no test for nitrates before reduction, yet gave a test for ammonia after reduction, indicated that the alkalinity developed was due to the formation of ammonia by the reduction of oxides of nitrogen occluded by the catalyst.

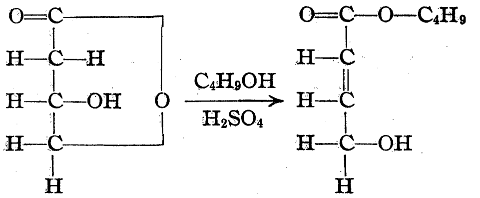
Low Pressure Reduction of 2,3-Acid Lactone.—A 5.06 g. sample of 2,3-acid lactone was dissolved in water, made up to a volume of 100 cc., 2 g. of platinum catalyst added and the solution hydrogenated in the Burgess–Parr apparatus under 2.9 atmospheres of hydrogen for two and six-tenths hours with shaking at the rate of 360 cycles per minute. A 1-cc. sample required 47.11 cc. of 0.01 *N* alkali for neutralization. (This includes the correction introduced because of alkalinity generated by the catalyst.) A 1-cc. sample of the original solution was neutralized by 49.63 cc. of 0.01 *N* alkali. A 5.1% reduction had therefore occurred. Periodic addition of a total of 16 g. of catalyst over a period of 12.4 hours effected a reduction of only 21.4%.

Low Pressure Reduction of 1,3-Acid Lactone.—A 5.06-g. sample of 1,3-acid lactone was dissolved in water and made up to a 50-cc. volume. The procedure was identical with that of the preceding experiment. A 67.3% reduction was effected after the addition of 12 g. of platinum catalyst, in portions, over a period of 36.9 hours.

Attempts to Prepare Esters of C_4-Saccharinic Acids

The direct reduction of the 2,3- and 1,3-acid lactones to the corresponding alcohols not having proved feasible, it was decided to attempt to reduce esters of the acids in the hope that these might be more susceptible to the type of reduction sought. In spite of many trials none of the desired esters could be prepared. The results of some of the experiments, however, may be worthy of record.

Butyl 3-Hydroxyisocrotonate from 2,3-Acid Lactone.—Fifty-one grams of 2,3-acid lactone was dissolved in 112 cc. of absolute butanol, 1.4 cc. of concentrated sulfuric acid added, and the solution refluxed for ten hours. It was concentrated to dryness at reduced pressure, finally at 50°, to give an 88.7-g. residue. Five grams of calcium carbonate and 50 cc. of water were added to the residue and the mixture was concentrated to dryness at reduced pressure finally at 68°. The residue was extracted and the salts were washed thoroughly with ether. The ether



2,3-Acid lactone

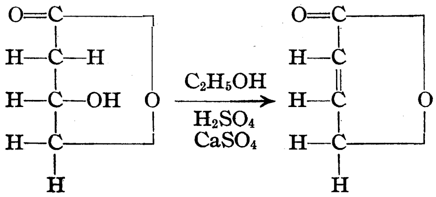
Butyl-3-hydroxy-isocrotonate

extract was dried over anhydrous sodium sulfate and concentrated at atmospheric pressure to give 72 g. of crude residue which, on fractionation, gave 40.2 g. of water-insoluble liquid, boiling range 179–183° (3 mm.), a 50.9% yield calculated as butyl 3-hydroxyisocrotonate. In another experiment in which 102 g. of lactone was treated according to the same procedure, a 75.5-g. sample, 47.8% yield, boiling range 174–181° (2 mm.) was obtained.

Anal. Subs. 0.2701, 0.3089 g.: 0.1 *N* alkali 17.07, 19.64 cc. Neutralization equivalent calcd. for $C_8H_{14}O_3$, 158.1. Found: 158.2, 157.3.

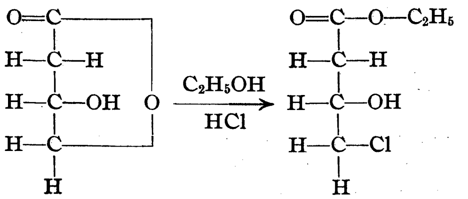
3-Hydroxyisocrotonic Lactone from 2,3-Acid Lactone.—Two hundred and five grams of 2,3-acid lactone was dissolved in 1040 cc. of absolute ethanol, four drops of concentrated sulfuric acid and 100 g. of anhydrous calcium sulfate added, and the mixture refluxed for seventy-five and seven-tenths hours. The solution was filtered and the alcohol was distilled off at reduced pressure to give a 235 g. residue which was dissolved in water. The solution was neutralized with sodium bicarbonate and the water distilled off at reduced pressure, finally at 60°. The residue was dissolved in ether and the ether solution dried over anhydrous sodium sulfate. The ether was distilled off at atmospheric pressure and the residue fractionated to give 99.6 g. of material, boiling point 76–77° (3.5 mm.), m. p. 5°, a 59% yield calculated as 3-hydroxyisocrotonic lactone. The titration results varied due probably to some structural change which the lactone undergoes in hot solution.[7b]

Under the conditions of this experiment, the lactone was simply dehydrated.



2,3-Acid lactone 3-Hydroxyisocrotonic lactone

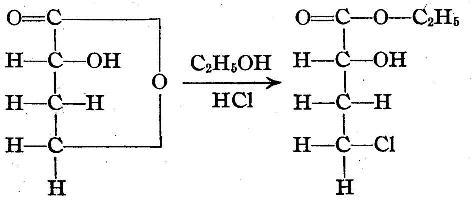
Ethyl 2-Hydroxy-3-chlorobutyrate[15] from 2,3-Acid Lactone.—Ten grams of 2,3-acid lactone was dissolved in 100 cc. of absolute ethanol, the solution was cooled in an ice-bath, and dry hydrogen chloride was passed in to saturation (one and one-half hours). After twelve hours in the ice box, the alcohol was removed by vacuum distillation and the 14 g. of residue was extracted with ether. The ether solution was dried over anhydrous sodium sulfate, the ether distilled off, the residue fractionated, and 7.0 g. of material of boiling range 92–95° (4 mm.), a 42.9% yield calculated as ethyl 2-hydroxy-3-chlorobutyrate, was obtained. Experiments were performed in which the volume of the alcohol varied from five to fifty times that of the lactone: the chief product was always ethyl 2-hydroxy-3-chlorobutyrate.



2,3-Acid lactone Ethyl 2-hydroxy-3-chlorobutyrate

Anal. Subs., 0.2972, 0.3422, 0.2623 g.: 0.1 *N* alkali 35.40, 40.79 cc.; 0.1 *N* silver nitrate 15.43 cc. Calcd. for $C_4H_{11}O_3Cl$: neutralization equivalent, 83.2; Cl, 21.31. Found: neutralization equivalent 84.0, 83.9; Cl, 20.86.

Ethyl 1-Hydroxy-3-chlorobutyrate from 1,3-Acid Lactone.—Fifty-one grams of 1,3-acid lactone was dissolved in 500 cc. of absolute ethanol, the solution was cooled in an ice-bath, and dry hydrogen chloride passed in to saturation (eight and three-tenths hours). The alcohol was distilled from the solution at reduced pressure and 71.6 g. of residue obtained. Water was added and the hydrochloric acid neutralized with sodium bicarbonate. The neutral mixture (two layers) was concentrated to dryness with a water pump finally at a bath temperature of 50°. The residue was extracted with absolute ethanol, the sodium chloride separated by suction filtration, and the filtrate concentrated to dryness with a water pump, finally at 50°, to give a 63.6-g. residue. The residue was shaken with 100 cc. of water, the layers separated, the 43 g. of water-insoluble material dissolved in 220 cc. of ether, and the solution dried over anhydrous sodium sulfate. Removal of the ether and fractionation of the 38.6 g. of residue gave 28.2 g. of material, boiling range 84–87°, 1.5 mm. Refractionation gave 27 g. of material, 92–95°, 1.5 mm., a 32.5% yield calculated as ethyl 1-hydroxy-3-chlorobutyrate.



1,3-Acid lactone Ethyl 1-hydroxy-3-chlorobutyrate

Anal. Subs., 0.2908, 0.2913, 0.2756, 0.2850 g.: 0.1 *N* alkali 34.22, 34.40 cc.; 0.1 *N* silver nitrate 16.04, 16.64 cc. Calcd. for $C_4H_{11}O_3Cl$: neutralization equivalent, 83.2; Cl, 21.31. Found: neutralization equivalent, 85.0, 84.7; Cl, 20.64, 20.70.

Reduction of Butyl Erythronate

Preparation of Butyl Erythronate.—This compound was made by a modification of Snoddy's adaptation of a special method of preparation of the esters of aldonic acids.[16] The necessary calcium erythronate was prepared in 87% yield by the treatment of a water solution of erythronic lactone with calcium carbonate at 90° followed by concentration of the filtered solution at reduced pressure and addition of absolute ethanol to precipitate the salt.

Eighty grams of calcium erythronate, dried to constant weight in an air oven at 95°, was mixed with 288 cc. of absolute butanol in a three-necked tube fitted with a mercury-seal stirrer and inlet and outlet tubes for hydrogen chloride. As dry hydrogen chloride was passed into the suspension, the salt dissolved. In forty-five minutes the

(15) G. Braun, THIS JOURNAL, **52**, 3167 (1930).

(16) Hlasiwetz and Habermann, *Ann.*, **155**, 127 (1870); Herzfeld, *ibid.*, **244**, 294 (1888); Kohn, *Monatsh.*, **16**, 333 (1895).

temperature of the cloudy solution was 61°. At the end of two hours a heavy precipitate was present but the stream of hydrogen chloride was allowed to run during another forty minutes. The mixture of sirup and precipitate was transferred from the tube to a beaker by means of dry ether and stored in a desiccator over calcium chloride. When the fine white precipitate had settled the ether was decanted, fresh ether added and the solid again allowed to settle out in the desiccator. This process, which was repeated a third time, removed the butanol and some of the hydrogen chloride. The white solid $[(C_3H_7O_3COOC_4H_9)_2\cdot CaCl_2]$ was very hygroscopic. It was separated quickly from the ether by suction filtration, washed several times with dry ether, and stored over calcium chloride in a desiccator which was evacuated continuously until all of the ether was removed. Dry air was then drawn through the desiccator until all of the hydrogen chloride had been removed. At this point the salt was added to a similar lot obtained in a previous run from 53 g. of calcium erythronate. The weight of the material from the combined runs was 179 g., a 73.3% yield based on erythronic lactone.

The dried solid was dissolved in a very small amount of water and treated with a little silver oxide to remove residual hydrogen chloride. The procedure from this point on was that of Hlasiwetz and Habermann. A slight excess of sodium sulfate in water solution was added and the calcium sulfate separated by suction filtration. The filtrate was concentrated to dryness at reduced pressure with the bath finally at 50°. The residue was extracted with ether and the ether solution concentrated at reduced pressure until it appeared cloudy. It was then cooled, the solid separated by suction filtration and washed with a little dry ether. The washings and mother liquor were further concentrated and cooled to give more solid. The solid, after drying in a vacuum desiccator over calcium chloride, weighed 102 g. and melted at 62–64°, a 53.9% yield based on erythronic lactone.

Anal. Subs., 0.2962, 0.3156 g.: 0.1 *N* alkali 15.50, 16.42 cc. Neutralization equivalent calcd. for $C_8H_{16}O_5$, 192.1. Found: 191.1, 192.2. A fairly satisfactory analysis for C and H has been reported already by Snoddy.

Butyl erythronate is a glistening white odorless compound, is decidedly "greasy" to the touch, and is very soluble in alcohol, acetone and water. It may be crystallized from ether.

High Pressure Reduction (Expt. No. 1, Table II).—Thirty grams of butyl erythronate was dissolved in 156 cc. of 95% ethanol (solution volume, 179 cc.). A 2-cc. sample was removed for analysis and the remainder of the solution was put into Bomb B. Five grams of platinum oxide catalyst was added, the air was displaced, and the material put under pressure of 97 atmospheres of hydrogen and rocked at the rate of 42 cycles per minute. After 25.6 hours the bomb was opened and a 2-cc. sample removed for analysis. A 53.25 cc. volume of 0.1 *N* sodium hydroxide was added to the sample and the solution was refluxed for 0.75 hour to ensure complete hydrolysis of the ester. Titration with 0.1 *N* hydrochloric acid showed that the sample had neutralized 11.29 cc. of 0.1 *N* alkali. Since a 2-cc. sample of solution before reduction required 18.44 cc. of 0.1 *N* alkali, a 38.8% reduction had been accomplished. Three grams of catalyst was added to the remaining solution which was put under pressure of 95 atmospheres of hydrogen and the above procedure carried out again. This process was continued until a complete reduction of the ester was effected. This required a period of 114.1 hours and the addition, in portions, of 20 g. of catalyst. Erythritol was isolated in 60.1% yield.

Low Pressure Reduction (Expt. No. 2, Table II).—Thirty grams of butyl erythronate was dissolved in 151 cc. of 95% ethanol. A 2-cc. sample was removed, the remaining solution was put into a pressure bottle, 1 g. of platinum oxide catalyst added, the bottle evacuated, and the material put under pressure of 2–3 atmospheres of hydrogen. The procedure for removal of sample, analysis, addition of more catalyst, etc., was identical with that used in the high pressure experiment. Complete reduction of the ester was effected in 329.5 hours by the addition, in portions, of 14.7 g. of catalyst. Erythritol was isolated in 68.5% yield.

Summary	14.7	329.5				68.5

[a] Rate of shaking, 42 cycles per minute; pressure 82–97 atm. [b] Rate of shaking, 360 cycles per minute; pressure 2–3 atm. [c] Crystals of erythritol on sides of pressure bottle. [d] Aerated, 3.3 hours.

Isolation of Erythritol.—The details of the isolation of erythritol from the reported high pressure run will be given. The solution, analysis of which indicated complete reduction of the ester, was separated from the catalyst by suction filtration. The catalyst was washed with water and the combined washings and mother liquor were subjected to distillation to dryness at reduced pressure to give 19.1 g. of residue. The residue was dissolved in a small amount of water, the solution heated with charcoal to 100°, the charcoal removed and the solution again subjected to distillation to dryness at reduced pressure to give 18.7 g. of residue. Several recrystallizations from 95% alcohol gave successively 8.0 g. of crystals, m. p. 119–121.5°; 2.5 g., m. p. 118–121°; and 0.2 g., m. p. 118–120.5°; a total yield of 10.7 g. The total volume of solution in the reported high pressure experiment was 179 cc., but since 12 cc. of this solution had been used for analyses, the maximum possible yield was 17.8 g. Erythritol was therefore isolated in 60.1% yield.

Summary

1. The method of catalytic hydrogenation at high pressures has been applied to two C_4-saccharinic acid lactones and to erythronic lactone.

2. Both the 2,3-dihydroxybutyric acid lactone and its 2-acetylated derivative have been reduced in good yield to 3-hydroxybutyric acid lactone.

3. The 2,3-dihydroxybutyric acid lactone and the 1,3-dihydroxybutyric acid lactone showed, respectively, by analyses, 21 and 67% reduction at low pressures when large amounts of platinum oxide catalyst were used.

4. Butyl erythronate was prepared according to a modification of Snoddy's adaptation of the method of Hlasiwetz and Habermann. It was reduced to erythritol in good yield at both high and low pressures.

5. The butyl ester of 3-hydroxyisocrotonic acid and the ethyl ester of 1-hydroxy-3-chlorobutyric acid have been prepared.

6. The esters mentioned in 4 and 5 above are new to the literature.

7. Reduction of samples of the catalyst ($PtO_2 \cdot H_2O$) resulted in the production of a slight amount of alkali. This fact should not be ignored in hydrogenations of acids, esters, etc.

CHICAGO, ILLINOIS RECEIVED FEBRUARY 8, 1937

NOTES

The Action of the Sulfonyl Group

BY F. ARNDT

In a recent paper[1] Kohler and Potter, after giving reference to a previous work of Arndt and Martius,[2] and after describing the behavior of a series of sulfonyl ketones, conclude as follows: "The view that sulfonyl groups cannot promote enolization is manifestly no longer tenable." This view, however, has not been expressed by the writer and his co-workers, who have even given detailed experimental evidence to the contrary. Thus, malonic ester does not enolize, whereas tosylmalonic ester enolizes appreciably; malonitrile does not tautomerize, but tosylmalonitrile tautomerizes considerably; acetaldehyde and tosylacetaldehyde do not enolize whereas formyl methionide, where the aldehyde group is combined with *two* sulfonyl groups in the β-position, enolizes to a great extent. On the other hand, Kohler and Potter acknowledge that "it is doubtless true that the sulfonyl group is far less effective than the carbonyl group in promoting enolization." This great difference in *degree* has been attributed by Arndt and Martius to a difference in the *nature* of the action of the sulfonyl and carbonyl groups, respectively. The action of the sulfonyl group is purely acidifying, thereby diminishing the factor which is opposed to enolization, *i. e.*, the "prototropic expenditure of work," whereas carbonyl and other groups containing multiple bonds increase, to a great extent, the active factor which promotes enolization, *i. e.*, the "electromeric effect of the molecule," by forming with the enolic double bond a conjugated system. The view that the sulfonyl group does not act in *this* manner, because it does not contain double bonds, is in no way contradicted by the experimental results of Kohler and Potter. The behavior of the group $COC_6H_2(CH_3)_3$ alone and in combination with one or two sulfonyl groups is, in fact,

---

[1] E. P. Kohler and H. A. Potter, THIS JOURNAL, **58**, 2166 (1936).

quite analogous to that of the aldehyde group in the above cases. The difference, emphasized by Kohler and Potter, between mesitylenic and phenyl ketones shows that the electromeric effect of the keto group in the former is much stronger and near to that of the aldehyde group. The writer has no explanation to offer for this new and remarkable fact, but he wishes to point out that he has not attempted theoretically to explain the relative strengths of the electromeric effects even of the simple groups investigated by him, which were only classified according to experimental evidence.

A Crystalline Compound of Semicarbazide and Semicarbazide Hydrochloride

BY H. L. HALLER AND F. B. LAFORGE

In preparing semicarbazones of the pyrethrins and related compounds in this Laboratory it was found[1] that the substitution of pyridine for sodium acetate increased the rate of reaction and resulted in much better yields of the semicarbazones. While using this procedure it was observed that sometimes crystals were deposited immediately from the solution. However, this did not occur in all cases. That this is not due to the formation of a semicarbazone is evidenced by the fact that the same material was sometimes obtained when a concentrated aqueous solution of semicarbazide hydrochloride was added to a mixture of pyridine and ethanol in the absence of ketones. Whether or not the crystallization occurred was found to depend upon the amount of water in the system. The crystalline product was always obtained when 2.5 g. of semicarbazide hydrochloride in 2.5 cc. of hot water was added to 17 cc. of 95% ethanol and 3 cc. of pyridine. The compound appears in the form of large prisms which are almost insoluble in alcohol and in pyridine but are easily soluble in water and aqueous alcohol provided the amount of water exceeds about 10%. It contains ionic chlorine and may be titrated with standard alkali solution. It melts at 132°.

Anal. Calcd. for $C_2H_{11}N_6O_2Cl$: equiv. wt., 186.5; N, 45.05; Cl, 19.03. Found: (36.8 mg. required 2.01 cc. of 0.1 N potassium hydroxide solution) equiv. wt., 183.1; N (Dumas), 45.06; Cl, 18.85.

This empirical formula is satisfied by the postulation that the compound contains one molecule of semicarbazide and one molecule of semicarbazide hydrochloride.

When the compound is dissolved in a small quantity of warm concentrated hydrochloric acid, the solution on cooling deposits semicarbazide hydrochloride, decomposing at 176°.

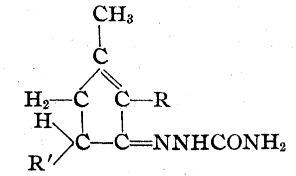
The Solubility of Certain Semicarbazones in Dilute Hydrochloric Acid

BY F. B. LAFORGE AND H. L. HALLER

In our investigations of the constituents of pyrethrum flowers, the semicarbazones of the pyrethrins and related compounds have served for their isolation and identification. Although pyridine has been substituted in all cases for the more commonly used sodium acetate in preparing these semicarbazones,[1] the employment of this base has had no effect on the properties of the derivatives obtained. Semicarbazones have been classed as neutral compounds, and those that are not soluble in water are supposed to be insoluble in dilute acids and alkalies.

In working with the semicarbazone of tetrahydropyrethrone (dihydrojasmone), formula I, $R = C_5H_{11}$, $R' = H$, we first observed that it was easily dissolved in cold dilute hydrochloric acid (about 4 N).



I

In the acid solution the semicarbazone is, of course, hydrolyzed on long standing and rapidly at elevated temperatures. It is, however, precipitated unchanged and in quantitative yield from the cold solution by prompt addition of alkali.

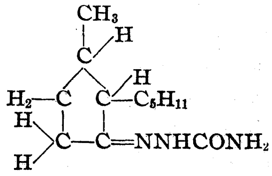
We were led by this observation to examine other related semicarbazones and have found

---

[1] H. L. Haller and F. B. LaForge, *J. Org. Chem.*, **1**, 38 (1936).

them to differ sharply with respect to their solubility in acids. The semicarbazones which we have considered may be divided into two groups, those that are soluble and those that are insoluble in dilute hydrochloric acid.

The former include the semicarbazones of pyrethrone, formula I, R = C_5H_7, R' = H; dihydropyrethrone (jasmone), R = C_5H_9, R' = H; tetrahydropyrethrone (dihydrojasmone), R = C_5H_{11}, R' = H; and tetrahydropyrethrolone, R = C_5H_{11}, R' = OH. The acid-insoluble semicarbazones include those of pyrethrolone, formula I, R = C_5H_7, R' = OH; pyrethrin I, R = C_5H_7, R' = ; pyrethrin II, R = C_5H_7, R' =  and two geometric forms of hexahydropyrethrone semicarbazone of melting points 160 and 194°, respectively, represented by formula II.



II

There seems to be no chemical feature distinguishing the members of each group. The solubility of some of the semicarbazones has been utilized in their separation from other material. All of an acid-soluble semicarbazone present in an impure reaction mixture may be obtained practically pure by extraction with dilute hydrochloric acid, removal of the by-products with a water-immiscible solvent, and precipitation of the semicarbazone with alkali. For example, a reaction product consisting of tetrahydro- and hexahydropyrethrone semicarbazones was separated into the two components by dissolving the one in dilute acid and filtering from the other.

To what extent the property of solubility in hydrochloric acid is shared by the semicarbazones of other ketones is a matter of interest, but one which we have not investigated.

Photoreaction of Chlorine Monoxide and Hydrogen

BY T. IREDALE AND T. G. EDWARDS

According to Finkelnburg, Schumacher and Stieger[1] chlorine monoxide dissociates, in the continuous absorption region of the visible spectrum, into Cl and ClO. We have found that addition of hydrogen accelerates the decomposition, at any rate, up to the stage where the secondary reaction $H_2 + Cl_2 = 2HCl$ becomes prominent. As without the H_2, Cl_2 and O_2 are the main products, but there are now also small amounts of HCl and H_2O. Finally all the Cl_2 goes to HCl.

Since the reaction $Cl + H_2 = HCl + H$ has a collision efficiency of $10^{-4} - 10^{-5}$, and $Cl + Cl_2O = Cl_2 + ClO$[1] a collision efficiency of $10^{-2} - 10^{-3}$, H atoms are not so important as the ClO radical in continuing the chain, that is, where the Cl_2O and H_2 pressures are comparable. The chain must, therefore, be continued by the reactivity of ClO and H_2, a state of affairs not much understood in the literature of this subject.

We may have either $ClO + H_2 = HClO + H$ or $ClO + H_2 = HCl + OH$. The latter reaction seems the more probable. Further details will be forthcoming when we have studied the reaction more closely.

Contrary to the experience of others,[2] we did not find that Cl_2O was explosively unstable in the presence of strong light. A 500 candle power lamp brought within 2.5 cm. of a spherical glass bulb (7.6 cm. in diameter) containing Cl_2O at a pressure of half an atmosphere, did not cause an explosion, nor did it do so when hydrogen was present at the same pressure.

The Heat of Mixing of Diisobutylene and Isooctane

BY WM. D. KENNEDY AND GEORGE S. PARKS

In connection with the recent study by Crawford and Parks[1] of the liquid-phase hydrogenation of diisobutylene (*i. e.*, a material containing about 4 parts of 2,4,4-trimethylpentene-1 and 1 part

(1) B. L. Crawford and G. S. Parks, THIS JOURNAL, **58**, 373 (1936).

of 2,4,4-trimethylpentene-2) to yield isoöctane (2,4,4-trimethylpentane), the assumption was made that mixtures of this paraffin with the parent olefins formed practically "perfect" solutions. Accordingly such solutions should be formed from the components without any appreciable heat of mixing and the partial vapor pressures of the components should follow Raoult's law. In view of the structural similarity of the paraffins and the olefins here involved, this assumption of perfect solutions certainly appeared reasonable on *a priori* grounds. Moreover, Beatty and Calingaert[2] had shown that the total pressures of mixtures of *n*-heptane and *n*-heptene-3 near the boiling point do not exhibit at any concentration more than a 0.5% positive deviation from the requirements of Raoult's law. However, the departure from ideality of such solutions may be appreciably greater at lower temperatures. In view of this possibility and the simplicity of the measurements, we decided to make also some direct calorimetric determinations of the heats of mixing of diisobutylene and isoöctane.

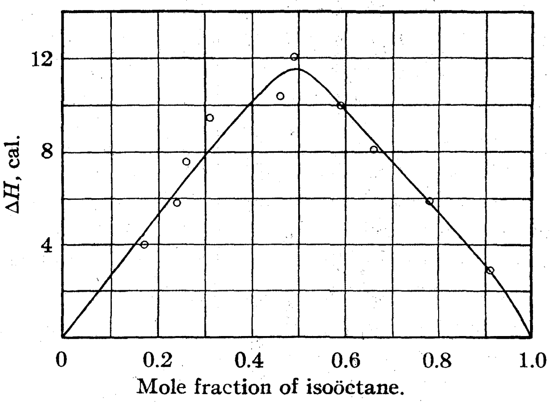

Fig. 1.—The heat absorption per mole of solution formed plotted against the mole fraction of isoöctane.

The vacuum jar calorimeter and the method of mixing employed previously by Parks and Chaffee[3] were used again in the present study. The mixing took place at 23° and the temperature change on formation of the solutions was measured to 0.001° by a copper–constantan thermocouple in conjunction with a White potentiometer. The necessary specific heat data for isoöctane and diisobutylene were taken from previous studies[4] in this Laboratory. Our hydrocarbon samples were carefully prepared materials which had been presented to us by the Shell Development Company. They had boiling ranges of about a degree and crystallized completely when cooled with liquid air; the respective densities at 20° were 0.6912 for the isoöctane and 0.7168 for diisobutylene.

Ten separate determinations of the heat of mixing were made in forming solutions ranging from 0.17 to 0.91 mole fraction of isoöctane. In the isothermal mixing process there appeared, for all concentrations, a small endothermic effect, which we have represented graphically in the accompanying figure. In our experiments this heat absorption reached a maximum for the formation of a solution containing 0.49 mole fraction of the isoöctane. In this case we found $\Delta H_{296} = 12.1\ (\pm 1.0)$ cal. for the process

$$0.49\ C_8H_{18}(l) + 0.51\ C_8H_{16}(l) = 1 \text{ mole of solution}$$

The minuteness of such a heat effect can be further emphasized by noting that it is only 1.3% of the effect previously recorded in the formation of a comparable solution of benzene and *n*-hexane.[5]

The previous assumption that such diisobutylene–isoöctane solutions are practically perfect is thus well justified.

The Transport Number of Silver in Solutions of Sodium Thiosulfate Practically Saturated with Silver Chloride

BY PIERRE VAN RYSSELBERGHE AND S. M. KNAPP

Evidence obtained by Müller and by Carrière and Raulet[1,2] from electrometric titration and conductivity shows that in aqueous mixtures of sodium thiosulfate with a silver salt, the silver is present as a monovalent anion $AgS_2O_3^-$.

We have obtained direct evidence for the existence of such an ion by measuring the transport number of silver in solutions of sodium thiosulfate saturated with silver chloride at 23°. The experiments were run at 25° according to a technique similar to that of Van Rysselberghe

---

[1] Müller, *Z. anorg. Chem.*, **133**, 202 (1924).

[2] Carrière and Raulet, *Compt. rend.*, [7] **192**, 423 (1931).

and Nutting.[3] Salts of the highest purity were used and standard methods of analysis were followed in the determination of the changes in silver content of cathode, anode and middle portions. The results obtained in four experiments are reported in Table I.

TABLE I

DATA FOR THE MIGRATION OF SILVER IN SOLUTIONS OF SODIUM THIOSULFATE PRACTICALLY SATURATED WITH SILVER CHLORIDE AT 25°

No. of experiment	1	2	3	4
Weight Ag in coulometer, g.	0.0739	0.0523	0.0514	0.0504
Moles $Na_2S_2O_3$ per liter	.0976	.1000	.1034	.0967
Equivalents Ag per liter	.0795	.0808	.0843	.0787
Loss Ag at cathode, g.	.0150	.0111	.0126	.0093
Gain Ag at anode, g.	.0165	.0109	.0101	.0123
Average transport number of Ag^+	−.213	−.210	−.221	−.215
Ratio equivalents of $AgS_2O_3^-$ to total number equivalents	.204	.202	.204	.204

The changes in the anode and cathode portions were of the order of 2 to 3% of the original silver content. The changes in the middle portion were equal to zero within the limits of accuracy of the analysis. The numbers in the last line of the table were obtained on the assumption that the whole amount of silver is combined as $AgS_2O_3^-$; the total number of equivalents refers to all ionic species actually present (for instance, in experiment No. 2 we have 0.2 Na^+ + 0.0808 $AgS_2O_3^-$ + 0.0384 $S_2O_3^=$ + 0.0808 Cl^-).

Averaging the results of the four experiments we may say that a 0.1 molar solution of sodium thiosulfate saturated with silver chloride at 23° contains 0.08 equivalent of silver per liter and that the transport number of Ag^+ in such a solution is −0.215 at 25°.

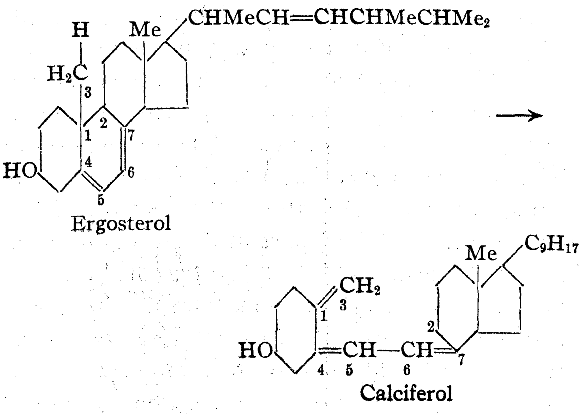
Calculation of the Activation Energy of the Rearrangement of Ergosterol to Calciferol

BY J. R. OWEN AND ALBERT SHERMAN

According to the work of Windaus and Grundmann[1] and of Heilbron, Jones, Samant and Spring[2] the rearrangement of ergosterol to calciferol may be represented by the equation



Ergosterol

Calciferol

This change involves the breaking of the 1,2-carbon–carbon bond and a shift of a hydrogen atom from carbon atom 3 to carbon atom 2, with the subsequent formation of a double bond between carbon atoms 1 and 3.

We have constructed molecular models and calculated the activation energy for the probable mechanism of such a transformation according to the semi-empirical method of Eyring.[3] The constants for the Morse curves used in the calculations are given in Table I.

TABLE I

Bond	r_0, Å.	ω_0 cm.$^{-1}$	D, kcal.
C–C	1.54[a]	990[b]	83.0[c]
	1.46[d]	[e]	74.5[f]
	1.44[g]	990[b]	74.5[f]
C–H	1.12[h]	2930[c]	92.3[h]

[a] Pauling, *Proc. Nat. Acad. Sci.*, **18**, 293 (1932). [b] Mecke, *Z. physik. Chem.*, **17B**, 1 (1932). [c] Pauling, THIS JOURNAL, **54**, 3570 (1932). [d] This value is the average of the C–C distances in a single and a double bond, and was used as the final 1,3-carbon–carbon distance. [e] This value was not needed since no Morse curve was drawn for this bond. [f] This value is one-half the strength of the carbon–carbon double bond and was used in all activation energy calculations involving the final 1,3-carbon–carbon bond, as well as in the construction of the Morse curve for the C–C bond in the ring broken. [g] This value is the carbon–carbon distance in benzene and was used in the construction of the Morse curve for the C–C bond in the ring broken. [h] Mulliken, *Rev. Modern Phys.*, **4**, 1 (1932).

According to Steenbock and co-workers[4] the long wave length limit for the conversion of ergosterol into calciferol by ultraviolet irradiation is 3100 Å. This corresponds to an energy of

(1) Windaus and Grundmann, *Ann.*, **524**, 295–99 (1936).

(2) Heilbron, Jones, Samant and Spring, *J. Chem. Soc.*, 905–907 (1936).

(3) See, *e. g.*, the article by Van Vleck and Sherman, *Rev. Modern Phys.*, **7**, 167 (1935).

(4) Steenbock and co-workers, *J. Biol. Chem.*, **63**, 25 (1925).

approximately 92 kcal. and represents a maximum value of the activation energy, since some of the energy absorbed may be dissipated as heat.

We have considered many mechanisms for this rearrangement and the value which we calculate for the transformation involving the lowest activation energy is 72 kcal. The mechanism of this rearrangement will be described in some detail.

Initially the carbon atoms 1, 2 and 3 and the hydrogen atom taking part in the reaction are in the same plane. The C–H group rotates about the 1,3-carbon–carbon bond until the three carbon atoms are at the corners of an equilateral triangle with the hydrogen atom equidistant (approximately 1.12 Å.) from carbon atoms 2 and 3. Up to this point all four atoms remain in the same plane. The next three steps occur simultaneously: (1) the hydrogen atom moves away from carbon atom 3, at the same time maintaining a constant distance from carbon atom 2; (2) carbon atoms 1 and 2 separate to a distance of approximately 2.07 Å.; and (3) the two parts of the molecule formed by the breaking of the 1,2-carbon–carbon bond rotate about the 5,6-carbon–carbon bond so that the plane of carbon atoms 2, 6 and 7 is at an angle of approximately 26° with that of the carbon atoms 1, 4 and 5. Following these steps the hydrogen atom moves to a final position determined by the ring of which carbon atom 2 is a part, and by the valence angles of this carbon atom. The system is now in the activated state and from this point onward (that is, as the rotation about the 5,6-carbon–carbon bond continues) the energy of the system decreases.

There are two factors which we have not considered that will affect the energy required for activation. The double bond which is formed between carbon atoms 1 and 3 is part of a conjugated system (atoms 3,1,4,5,6,7) and, although quantitative calculations have not been made, we know that this will tend to lower the activation energy slightly. The large size of the molecule introduces steric factors which probably will cause an increase in the activation energy. These two factors will tend to cancel each other, and we have not attempted to estimate them quantitatively. Their effect will not be large.

From the nature of the rearrangement it is evident that another mechanism could involve the breaking of a C–H bond (92.3 kcal.) and a reaction of the H atom with carbon atom number 2. This mechanism would therefore involve an energy of 92.3 kcal., and hence we conclude that the activation energy for the conversion of ergosterol to calciferol lies between 72 and 92 kcal. This is consistent with the value found by Steenbock for the long wave length limit.

A Simple Method for the Preparation of the Chloro Ketone $C_{19}H_{27}OCl$, Dehydroandrosteryl Chloride

BY EVERETT S. WALLIS AND E. FERNHOLZ

In a recent paper by A. Butenandt and W. Grosse[1] the statement is made that replacement of the hydroxyl group in dehydroandrosterone by chlorine by the usual methods is unsatisfactory, low yields of the chloro ketone being obtained. From what is written one gets the impression that the difficulties involved are, indeed, serious, for the authors considered other possibilities and developed a new method which involves the following steps

Dehydroandrosterone ⟶ toluenesulfonate (71%) ⟶ *epi*-dehydroandrosterone methyl ether[2] (99%) ⟶ dehydroandrosteryl chloride (79%); yield over all (56%)

As is readily seen the yield of the chloride is not too satisfactory and even if we could consider the yield as fair the method would still be involved.

In the course of some of our experiments we have had occasion also to prepare this important chloro ketone. In our hands the treatment of dehydroandrosterone with phosphorus pentachloride has always given very satisfactory results. When the reaction is carried out in chloroform solution the yield is 83%, and the preparation involves but one step.

Experimental Part

One gram of dehydroandrosterone was added to a mixture of 10 cc. of dry chloroform and 1 g. of phosphorus

---

[1] A. Butenandt and W. Grosse, *Ber.*, **69**, 2776 (1936).

[2] The experimental results of Wallis, Fernholz and Gephart [THIS JOURNAL, **59**, 137 (1937)] obtained in a study of the action of potassium acetate on cholesteryl *p*-toluene-sulfonate show that a molecular rearrangement takes place during this reaction. In the light of these experiments the naming of this methyl ether may not be justified. It is entirely possible that the compound may have a different structure.

pentachloride. A violent reaction took place. The resulting mixture was kept at room temperature for one hour. Water was then added (100 cc.), the two layers were separated, and the chloroform layer removed to the steam-bath. During the evaporation of the chloroform the chloride crystallized. It was filtered and dissolved in ether. The ether solution was washed with sodium hydroxide to remove acidic esters. The ether residue after one crystallization gave an almost pure chloride; yield 0.76 g.; m. p. 153°. The mother liquor was evaporated and the residue was distilled in high vacuum and recrystallized from methyl alcohol; yield 0.12 g.; total yield 0.88 g. (83%). Further repeated recrystallizations did not raise the melting point above 154° (uncorr.); $[\alpha]^{22}\text{D}$ $+14.6°$ (19.2 mg. in 2 cc. of chloroform solution gave $\alpha^{22}\text{D}$ $+0.14°$, 1-dm. tube).

Summary.—A simple method is described for the preparation of dehydroandrosteryl chloride in good yield. The chloro ketone so prepared melts at 154° and has a specific rotation $[\alpha]^{22}\text{D}$ $+14.6°$.

The Separation of the C_{17}-Epimers of Oestradiol by Digitonin

BY O. WINTERSTEINER

It has been shown by Schwenk and Hildebrandt[1] that two epimeric forms of oestradiol can be obtained by catalytic reduction of the 17-keto group of oestrone (theelin). The lower melting α-isomer (m. p. 178°, $[\alpha]\text{D}$ $+81°$), which occurs in follicular fluid[2] and in the urine of pregnant mares,[3] is the most potent oestrogenic compound known. The higher melting β-isomer (m. p. 223°, $[\alpha]\text{D}$ $+54°$), which is much less active physiologically, has only recently been prepared in pure form. Its properties will be described in more detail in a separate communication.[4] We have found recently that the two isomers can be separated conveniently by digitonin, whereby the laborious separation by fractional crystallization may be avoided. Only the lower-melting α-isomer forms a sparingly soluble digitonide, when treated with a solution of digitonin in 80% alcohol. The molecular compound deposits slowly in form of beautiful needles, which melt at about 265° after partial decomposition at 195°, and from which the diol can be regenerated easily by the usual methods. Also the 3-benzoate of the α-isomer yields a crystalline precipitate with digitonin, though more slowly than the free diol. Neither the high melting β-oestradiol nor its 3-benzoate precipitates with digitonin under identical conditions. These results show clearly that it is the configuration of the 17-carbon atom which determines the capacity to form insoluble digitonides of this type.

The digitonin reaction is also negative with oestriol (theelol), dihydroequilenin (δ-follicular hormone)[5] and 17-*trans*-testosterone.[6] Furthermore, no precipitate was obtained with a crude preparation of androstenediol-3-acetate, which according to the mode of its preparation should have contained some of the 17-*cis*-epimer. The melting point of dihydroequilenin, and that of its benzoate, its low specific rotation ($[\alpha]\text{D}$ $-4.7°$), its low physiological potency, and its failure to precipitate with digitonin would place this compound in the β-series of oestrogenic diols. On the other hand, if the same criteria be applied to 17-*trans*-testosterone, all the data except the negative digitonin reaction speak for its steric relationship to α-oestradiol. Caution is obviously necessary in interpreting the behavior of C_{17}-epimers toward digitonin as an indication of stereochemical relationships.

In the pregnane series, Butenandt and coworkers[7] have employed digitonin for the separation of C_{17}-epimers. *allo*-Pregnanedione, *allo*-pregnanol-3-one-20-3-acetate, and Δ^5-pregnenol-3-one-20, but not their C_{17}-epimers, termed *iso*-compounds by these workers, form insoluble digitonides.

Reaction of Lanthanum Oxide with Ammonium Iodide

BY RALPH C. YOUNG AND JANE L. HASTINGS

By following the general method of Reed, Hopkins and Audrieth[1] for the preparation of the chlo-

---

(1) Reed with Hopkins and Audrieth, THIS JOURNAL, **57,** 1159 (1935).

rides and the bromides of the rare earth metals it has been found possible to carry out the reaction between lanthanum oxide and ammonium iodide in such a manner that the final product contains about 90% of anhydrous lanthanum iodide.

The essential features of the procedure are as follows. One gram of ammonium iodide is poured into a Pyrex tube, 10 mm. in bore and 60 cm. long, closed at one end. There is then added a mixture of 1 g. of lanthanum oxide and 6 g. of ammonium iodide. The tube is inserted in an electric furnace to a distance of 22 cm., being slightly inclined downward at the outer open end, and is heated at 350°, with an occasional rotation, until no more water condenses in that part of the tube outside the furnace. Four hours are required for complete reaction, whereupon the excess ammonium iodide is removed by sublimation in a high vacuum at 250°. During the whole process the vapor from the ammonium iodide, passing over the product, protects it from reaction with oxygen which would otherwise occur even at low pressures. When no more ammonium iodide condenses outside the heated zone, the tube is sealed and quickly cooled to room temperature.

The product obtained by this method is nearly white with a very slight yellow tinge. Its hydration on exposure to air and the vigor of its reaction with water are indicative of the presence of anhydrous lanthanum iodide. On extraction with water 10% or less is insoluble. The atomic ratio of iodine to lanthanum in this insoluble residue varies from 0 to approximately 0.3. In the solution the ratio is 3, and, since no ammonium ion is present, it corresponds to the formula, LaI_3. Lanthanum iodide was also extracted from the raw product with 95% ethyl alcohol.

COMMUNICATIONS TO THE EDITOR

INHIBITION OF THERMAL DECOMPOSITION OF *n*-BUTANE BY NITRIC OXIDE

Sir:

The recent work of Fletcher and Rollefson [THIS JOURNAL, **58**, 2129, 2135 (1936)] has shown that the acceleration of an organic vapor phase decomposition by ethylene oxide, and inhibition of the normal decomposition by nitric oxide give rather conclusive evidence that the decomposition proceeds via a chain mechanism.

We have previously shown [*ibid.*, **58**, 1317 (1936)] that ethylene oxide accelerates the decomposition of propane, *n*- and *i*-butane.

We now find that the decomposition of *n*-butane is strongly inhibited by small amounts of NO, as shown by the following table.

P_0 butane = 200 mm.; temp., 500 ± 1.0°; KCl-coated reaction bulb

P_0(NO), mm.	Init. rate, mm./min.	% Dec. at 120 min. By ΔP	By anal.
0	1.0	26.5	31
20	0.05	7.1	13

The rates as measured by the analysis after 120 minutes indicate that the inhibition is somewhat less than would be concluded from the initial rates. However, the fact that the normal reaction falls off quite rapidly with time, while the inhibited reaction rate increases continuously, can in large part explain this discrepancy. Thus the actual inhibition must lie between a 20/1 ratio of normal to inhibited rate and a 3/1 ratio, as given by the runs to high percentage decomposition. Measurements over a wide range of P_0(NO) indicate a region of maximum inhibition at about 20 mm.

This result, together with the arguments advanced by Hinshelwood [Staveley and Hinshelwood, *Proc. Roy. Soc.* (London), **A154**, 335 (1936)] as to the possible causes of an observed inhibition, lead us to the conclusion that the decomposition of butane under these conditions is largely a chain reaction.

Further work is now in progress, attempting to correlate the two effects in a more quantitative manner. It is also hoped to extend the work to lower hydrocarbons, particularly ethane.

CHEMICAL STUDIES ON TOAD POISONS. FURTHER CONTRIBUTIONS TO THE CHEMICAL CONSTITUTION OF MARINOBUFAGIN, CINOBUFAGIN AND GAMABUFAGIN

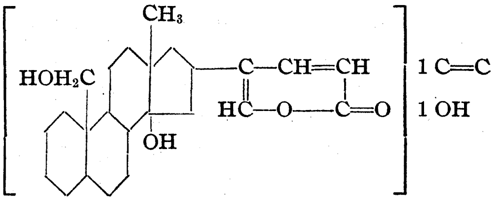
Sir:

Marinobufagin, $C_{24}H_{32}O_5$ [Jensen and Evans, Jr., *J. Biol. Chem.*, **104**, 307 (1934)], and cinobufagin, $C_{26}H_{34}O_6$ [Crowfoot and Jensen, THIS JOURNAL, **58**, 2018 (1936)], are unsaturated hydroxy lactones, cinobufagin being the acetyl derivative of the compound $C_{24}H_{32}O_5$, an isomer of marinobufagin. Tschesche and Offe [*Ber.*, **68**, 1998 (1935)] and independently Jensen [THIS JOURNAL, **57**, 2733 (1935)] showed that cinobufagin on dehydrogenation with selenium yields the Diels hydrocarbon $C_{18}H_{16}$. It has been found that marinobufagin (5 g. used) under the conditions described for cinobufagin [Jensen, *ibid.*, **57**, 2733 (1935)] also yields this hydrocarbon, found m. p. 122–123°, no depression when mixed with methylcyclopentenophenanthrene (m. p. 123–124°). *Anal.* Calcd. for $C_{18}H_{16}$: C, 93.05; H, 6.95. Found: C, 92.92; H, 7.17.

Repetition of catalytic hydrogenation of marinobufagin and cinobufagin has revealed the presence of three double bonds instead of two as previously reported by Jensen and Evans [*J. Biol. Chem.*, **104**, 307 (1934)]; α-hexahydromarinobufagin m. p. 212–213°, β-derivative m. p. 225–227°; α-hexahydrocinobufagin m. p. 230–232°; β-derivative m. p. 210–212°. The found analytical data agree with the calculated. Simultaneously small amounts of acidic products are produced, probably by the opening of the lactone ring. Tschesche and Offe [*Ber.*, **69**, 2361 (1936)] have since reported similar findings.

Ozonization of marinobufagin and cinobufagin (ozone was passed under cooling for three hours through a solution of 1 g. of substance in chloroform, the working up of the reaction product was carried out in the usual manner) was found to yield formic acid, identified by qualitative tests, and glyoxylic acid, identified by color reactions and as the dinitrophenylhydrazone, yellow needles m. p. 190° with decomposition, no depression with the derivative prepared from glyoxylic acid. A small amount of oxalic acid, formed by oxidation of glyoxylic acid, was also found and identified as the calcium salt. These findings indicate the presence of two double bonds in the lactone group, which is a six-membered ring and apparently identical with that in scillaren [Stoll, Hofmann and Peyer, *Helv. Chim. Acta*, **18**, 1247 (1935)]. The third double bond is present in the sterol ring; its exact position is still uncertain.

It has been found that both marinobufagin and gamabufagin contain a —CH_2OH group attached either at C_{10} or at C_{13}, corresponding to one of the angular methyl groups of the sterols. Under the influence of strong acid or alkali this primary alcoholic group is eliminated as formaldehyde. On oxidation with chromic acid marinobufagin gives an aldehyde, the oxidation product giving the typical reactions for an aldehyde group. Evidence has been obtained that a tertiary hydroxyl group is attached at C_{14} in all three principles. Whether or not the third hydroxyl group in marinobufagin is also tertiary is somewhat uncertain, as is its position. Under the influence of acid two hydroxyl groups in marinobufagin are eliminated as water. On the basis of the experimental findings the following structure for marinobufagin is suggested



Analytical data obtained for gamabufagin, acetylgamabufagin and anhydrogamabufagin indicate the empirical constitution of $C_{24}H_{34}O_5$ for gamabufagin, as suggested by Wieland and Vocke [*Ann.*, **481**, 215 (1930)]. Gamabufagin contains only two double bonds, both in the lactone ring. Under the influence of acid gamabufagin loses one molecule of water. Both cinobufagin and gamabufagin have a structure similar to that of marinobufagin.

The author is greatly indebted to Dr. K. K. Chen, Lilly Research Laboratories, Indianapolis, for a supply of the secretion of the Japanese toad.

Owing to the temporary interruption of this investigation, it is necessary to defer publication of the details of the work until a later date.

STEROLS. XII. SYNTHETIC PREPARATION OF *EPI*-ALLO-PREGNANOLONE, THE ANDROGENIC PRINCIPLE OF HUMAN PREGNANCY URINE

Sir:

That human pregnancy urine contains a substance which has male hormone activity has been reported by several workers. Because of the similarity in physiological activities in the male hormone tests between human pregnancy and male urine extracts, it has been assumed that the male principle in pregnancy urine was androsterone. Heretofore this androgenic principle has not been isolated.

Recently, Marker, Kamm and McGrew [THIS JOURNAL, **59,** 616 (1937)] reported the isolation and identification of *epi*-allo-pregnanolone from the sterol fraction of human pregnancy urine after the removal of theelin and theelol. At the time of this report we did not have the physiological assays on this compound. Since then it has been found that the substance isolated from human pregnancy urine promotes the growth of the seminal vesicle in the rat tests. Preliminary tests have shown this to have about the same activity as androsterone.

We have now prepared synthetically *epi*-allo-pregnanolone from 3-chloro-allo-cholanic acid, a by-product from the preparation of chloroandrosterone [Marker, Whitmore and Kamm, THIS JOURNAL **57,** 2358 (1935)]. This was prepared by the stepwise degradation of the side-chain according to the method of Wieland [*Z. physiol. Chem.*, **161,** 80 (1926)].

3-Chloro-allo-cholanic acid, m. p. 180°, was converted into its methyl ester, m. p. 133°. *Anal.* Calcd. for $C_{25}H_{41}O_2Cl$: C, 73.2; H, 10.1; Found: C, 72.8; H, 10.3. This was treated with a phenyl Grignard reagent and the resulting carbinol melted at 171°. *Anal.* Calcd. for $C_{36}H_{49}OCl$: C, 81.1; H, 9.2. Found: C, 81.1; H, 9.3. It was oxidized by chromic acid to 3-chloro-allo-*nor*-cholanic acid. *Anal.* Calcd. for $C_{23}H_{37}O_2Cl$: C, 72.5; H, 9.8. Found: C, 72.8; H, 9.6. This acid was converted to its methyl ester, m. p. 178°. *Anal.* Calcd. for $C_{24}H_{39}O_2Cl$: C, 73.0; H, 10.0. Found: C, 73.3; H, 10.2. By treating with a phenyl Grignard reagent, 3-chloro-allo-bis-*nor*-cholanyldiphenylcarbinol was obtained, m. p. 183°. *Anal.* Calcd. for $C_{35}H_{47}OCl$: C, 80.9; H, 9.1. Found: C, 80.8: H, 9.3. This carbinol was oxidized by chromic acid to 3-chloro-bis-*nor*-allo-cholanic acid, m. p. 231°. *Anal.* Calcd. for $C_{22}H_{35}O_2Cl$: C, 71.9; H, 9.6. Found: C, 71.8; H, 9.3. This acid was converted to its methyl ester, m. p. 150°. *Anal.* Calcd. for $C_{23}H_{37}O_2Cl$: C, 72.5; H, 9.8. Found: C, 72.5; H, 9.8. By treating with a phenyl Grignard reagent the carbinol was obtained, m. p. 146°. *Anal.* Calcd. for $C_{34}H_{45}OCl$: C, 80.8; H, 9.0. Found: C, 80.9; H, 9.2. This carbinol was dehydrated by refluxing with acetic acid and acetic anhydride. The resulting product was ozonized and the ozonolysis product treated with potassium acetate to convert the chloro derivative into an *epi*-OH compound [Marker, Whitmore and Kamm, THIS JOURNAL, **57,** 2358 (1935)]. The hydroxy ketone was purified by means of its half succinic ester and then as the semicarbazone. It gave *epi*-allo-pregnanolone, m. p. 170°. *Anal.* Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.7. Found: C, 78.9; H, 10.9. This was identical with the natural product which we isolated from human pregnancy urine.

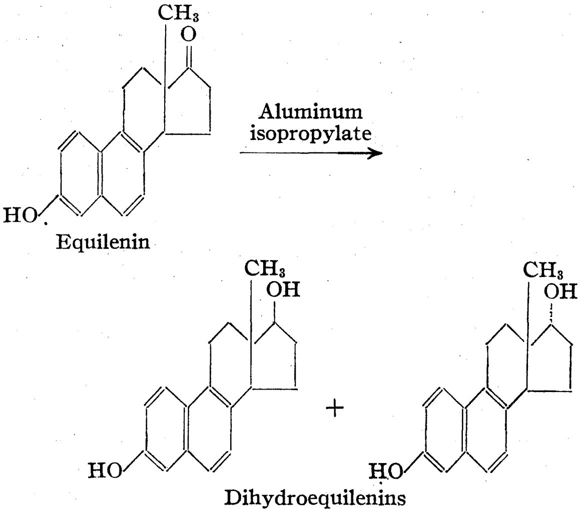
STEROLS. XIII. THE DIHYDROEQUILENINS

Sir:

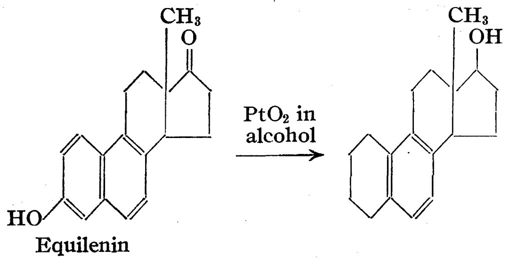
Recently Wintersteiner, Schwenk, Hirschmann and Whitman [THIS JOURNAL, **58,** 2652 (1936)] in their studies on the isolation of the δ-follicular hormone from the phenolic fraction of mare's urine obtained as the δ-follicular fraction a molecular compound of two components, one of which formed a picrate. This was isolated and identified as dihydroequilenin. They suggested that possibly the high estrogenic activity of the originally reported δ-follicular hormone [Wintersteiner, Schwenk and Whitman, *Proc. Soc. Exptl. Biol. Med.*, **32,** 1087 (1935)] is due to the other isomer of dihydroequilenin, differing from their product only in the configuration of the —OH group in the 17-position.

We have now prepared both isomers of dihydroequilenin by the reduction of equilenin with aluminum isopropylate. These isomers were separated by crystallization from alcohol, the more soluble dihydroequilenin melting at 215°. *Anal.* Calcd. for $C_{18}H_{20}O_2$: C, 80.5; H, 7.5. Found: C, 80.4; H, 7.7. This gave a monobenzoate of m. p. 204°. *Anal.* Calcd. for $C_{25}H_{24}O_3$: C, 80.4; H, 6.7. Found: C, 80.4; H, 6.7. These products are identical in melting points with the products isolated by Wintersteiner and co-workers from mare's urine.



From the less soluble reduction product we obtained the epimers of Wintersteiner's dihydroequilenin. This product melts at 248°. *Anal.* Calcd. for $C_{18}H_{20}O_2$: C, 80.5; H, 7.5. Found: C, 80.3; H, 7.6. This gives a diacetate of m. p. 124° [*Anal.* Calcd. for $C_{22}H_{24}O_4$: C, 74.9; H, 6.9. Found: C, 74.8; H, 7.0] and a monobenzoate m. p. 215° [*Anal.* Calcd. for $C_{25}H_{24}O_3$: C, 80.4; H, 6.7. Found: C, 80.5; H, 6.7]. This is the product that Wintersteiner suggests may be the other component of the δ-follicular hormone mixture which causes the high estrogenic activity. Each isomer gives a large melting point depression when mixed with the other, or with the original equilenin.

We attempted to prepare dihydroequilenin by the reduction of equilenin with sodium as tried by David [*Acta brevia Neerland.*, **4,** 63 (1934)]. We duplicated his results, obtaining only an oil. The sodium apparently effects a partial reduction of the naphthol ring. Catalytic hydrogenation of equilenin with Adams platinum oxide catalyst in alcohol reduced the first ring with the loss of an —OH group to give a 70% yield of a product containing only one oxygen atom.



The product melted at 148°. *Anal.* Calcd. for $C_{18}H_{24}O$: C, 84.3; H, 9.4. Found: C, 84.3; H, 9.6. Acetate, m. p. 104°. *Anal.* Calcd. for $C_{20}H_{26}O_2$: C, 80.4; H, 8.8. Found: C, 80.0; H, 9.0.

NEW BOOKS

British Chemicals and Their Manufacturers. The Official Directory of the Association of British Chemical Manufacturers. Published by and available only from the Association, 166 Piccadilly, London W 1, England, 1937. 466 pp. *Gratis* to genuine purchasers of chemicals.

This book, the Official Directory of the Association of British Chemical Manufacturers, gives information as to the products manufactured by the members. It contains a list of the products, with the grades and the manufacturer of each product.

It also contains lists of Proprietary Trade Names and Trade-marks and complete indices.

All different sections are printed in English, French, Spanish, Italian, Portuguese and German.

Genuine purchasers of chemicals can obtain this book *gratis* from the office of the Association. For educational institutions, as well as industry, this book will be found a handy reference to the many chemicals manufactured by the association.

CLIFTON P. ADAMS

Organic Chemistry. The Chemistry of the Compounds of Carbon. By LUCIUS JUNIUS DESHA, Professor of Chemistry, Washington and Lee University. McGraw-Hill Book Company, 330 West 42d Street, New York, N. Y., 1936. xv + 750 pp. Illustrated. 14.5 × 22 cm. Price, $3.75.

"This textbook has been written for college students and primarily for those whose formal instruction in organic chemistry ends with a one-year course .... The guiding policy has been to consider compounds if, where, and as they serve usefully to illustrate and explain the general principles of organic chemistry." The book is conspicuously different from other present-day texts not in this, but in following W. A. Noyes's practice of treating aliphatic and aromatic compounds side by side. The first 128 pages are devoted to hydrocarbons, under the chapter headings: Saturation and Unsaturation—Isomerism—Homology—Natural Gas and Petroleum—Ring Formation; Alicyclic Hydrocarbons—The Aromatic Nucleus; Benzene and its Homologues—Polynuclear Hydrocarbons; By-products of Coking. In the following nine chapters, simple derivatives of the hydrocarbons, aliphatic and aromatic together, are considered in order. Eight chapters follow on polysubstituted and mixed compounds, and five chapters on "Special Results of Certain Structures." The chapter headings in this section are: Variable Strength of Linkages—Tautomerism—Rearrangements—Color and Constitution; Dyes and Dyeing—Stereoisomerism. The final four chapters deal with some important plant and animal products (carbohydrates, fats, lipides, proteins, terpenes, etc.). An appendix includes generalizations on the identification of organic compounds.

There is a restrained but consistent emphasis upon theory throughout the book, which leads to the inclusion of such topics as the theory of affinity–capacity and the mechanisms of molecular rearrangements, frequently reserved for later courses in organic chemistry. This willingness to tackle fundamental problems will be appreciated by the better students, but these are the very students whose instruction in organic chemistry ought *not* to end with a one-year course. In contrast to these inclusions, the experimental facts about conjugated systems are touched only very lightly, and the diene synthesis of Diels and Alder is not mentioned. The benzene problem is discussed at a point where simple conjugated systems are not available for comparison, although cycloöctatetraene is mentioned in a note. Many experimental tests are described throughout the book, but nothing is said about how the molecular formula of a compound is established.

The book is not entirely free from inaccuracies. In alkylating acetoacetic ester it is not usual, as stated on page 517, to add sodium wire to the anhydrous ester. By established usage, the Wurtz reaction (page 24) becomes the Wurtz–Fittig reaction only when carried out between an aliphatic and an aromatic halide. The "chair" form of the cyclohexane ring (page 79), according to models, does not shift into the other form without some slight bond distortion. In the main, however, the statements in the book are well considered. The illustrations are good and the style clear.

One of the greatest aids to a student in studying this necessarily descriptive subject is the consideration, more or less together, of a group of genetically related compounds. The shuttling back and forth between aliphatic and aromatic compounds throughout the book limits the possibility of this. Thus it seems to the reviewer that the distinguishing feature of this text, its order of presentation, is its one serious drawback.

P. D. BARTLETT

Thermodynamic Theory of Affinity. A Book of Principles. By TH. DE DONDER, Professor of Mathematical Physics, University of Brussels, and PIERRE VAN RYSSELBERGHE, Assistant Professor of Chemistry at Stanford University. Stanford University Press, Stanford University, California, 1936. xx + 142 pp. 4 figs. 16 × 24.5 cm. Price, $3.00.

This book presents in a readable form a fairly complete résumé of the theory of affinity developed by De Donder. The use of the international set of thermodynamic symbols makes the reading much easier in this than in the French editions for those not familiar with De Donder's earlier notation. The method of presentation is didactical. The first three chapters are devoted to the two laws of thermodynamics; the next five, to the properties of the affinity and the last eight, to the applications of the affinity function to a discussion of equilibrium, the phase rule, ideal and non-ideal gases, Le Chatelier's principle, heterogeneous and homogeneous equilibria and galvanic cells.

The representation of the status of a chemical reaction in a closed system by the "degree of advancement of the reaction" introduces a very desirable symmetry into such discussions.

The thermodynamic treatment is involved because of the introduction of the uncompensated heat of Clausius. This leads to relations as on pages 16 to 18 which have many unfamiliar added terms all of which are shown to be zero. On page 18 it is implied that the relations containing these zero terms are more general than those heretofore used. The method of Gibbs in which changes in state properties are treated by reversible processes whether or not the actual change under consideration is reversible is more direct and satisfying. An appreciable part of the book is devoted to warning the reader against a mistake which only the most naïve beginner would make, as on pages 34 to 36 where a straw man is thoroughly demolished. On page 54 some new equations of interest are given; a statement in words of the significance of these relations would be a valuable help to the reader.

Throughout the book the affinity function is used and the properties and uses of this function are developed at length. For a chemical change in state in a closed system the affinity A is given by the relation $A = -\Sigma \nu_i \mu_i$ (ν_i = stoichiometric coefficient and μ_i = chemical potential of the i-th constituent). The treatment throughout is almost entirely mathematical; the physical interpretation of some of the results, especially the connection between the affinity and the yield of a chemical reaction under different conditions, would add to the interest in this function.

J. A. BEATTIE

The Mechanism of Contact Catalysis. By R. H. GRIFFITH, D.Phil., Senior Research Chemist, The Gas Light and Coke Co. Oxford University Press, 114 Fifth Avenue, New York, N. Y., 1936. xi + 208 pp. 90 figs. 14 × 22.5 cm. Price, $5.00.

The avowed purpose of this book is to summarize developments in the theory of catalytic mechanism in the decade since the publication of such works as Rideal and Taylor's "Catalysis in Theory and Practice." Studies reported as late as 1936 are included, as well as a number of interesting, unpublished investigations by the author. Chapter heads are: experimental methods, adsorption, promoters and carriers, poisoning and retardation, examination of the catalyst surface, geometry of the catalyst surface, mechanism of catalysis, development of catalysts. The focus of attention is the catalyst and its behavior with reactants and products, rather than the reactions themselves. The author treads the middle road between the extremes of theory and practice, emphasizing laboratory researches to the exclusion of quantum mechanics on the one hand and data from technical operations on the other. His critical comments on recent work should be of interest, particularly to specialists in the field even though their own views may sometimes differ. The treatment is selective rather than exhaustive, but at least a majority of the principal contributions receive attention.

In the exposition of a subject as various and elusive as catalytic mechanism, a certain looseness of organization of material is probably unavoidable. The resulting diffuseness and repetition the author strives to minimize by frequent cross references, an author index and an elaborate subject index. But not all the traditional "mystery" of catalysis is removed. Apparently it must largely remain until more precise concepts are developed and generally understood, so that more precise statements can be used. For example (p. 36): "The significance of these facts [rates of diffusion of hydrogen and deuterium through copper] in connexion with catalytic changes occurring at a surface is probably much greater with regard to determining the character of the surface itself than with respect to any influence on the catalyzed reaction, once the surface has been formed."

The physical make-up of the book is irreproachable.

ARTHUR F. BENTON

Prelude to Chemistry. An Outline of Alchemy, its Literature and Relationships. By JOHN READ, Ph.D., M.A., Sc.D., F.R.S., Professor of Chemistry in the United College of St. Salvator and St. Leonard in the University of St. Andrews, Scotland. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1937. xxiv + 327 pp. Illustrated. 16 × 24 cm. Price, $5.00.

Professor Read's book is devoted primarily to an account of the affiliations of early chemistry, and, for that reason perhaps, succeeds in supplying a correct understanding of the theories of early chemistry and alchemy, of their probable origins and of their nature and development. It does this better than any other single book with which we are acquainted. It contains very little of the actual chemical knowledge of the ancients, but by its thorough examination of the speculative background of that knowledge it throws a clearer light than would otherwise be possible upon the central and dominant doctrine. It shows how the doctrine operated in the laboratory, but also how it operated in the minds of the laboratory workers in their imaginative and metaphorical language, their curious diagrams and symbolic pictures. Professor Read follows the elaborations of alchemical doctrine in considerable detail in a number of special cases, the hieroglyphic pictures of Nicholas Flamel, the *Splendor Solis*, the "Hermetic Museum," the works of Thomas Norton, John Cremer and Basil Valentine, the alchemical pictures of Stolcius, Mylius and Michael Maier (whose interconnections he straightens out), and the alchemical music of the last-named in *Atalanta Fugiens*. The reader cannot fail to see that the alchemists, for all their intellectual and artistic excesses, were men of much sense: he will understand the ideas which were guiding them.

The book is scholarly, interesting and attractive. It is written in a fine literary style, pervaded by the author's gentle sense of humor and sympathetic insight. An Appendix contains an essay on "The Music in *Atalanta Fugiens*" by F. H. Sawyer, together with several of the fugues arranged in the modern manner for choral singing—also a Glossary and Bibliography and Notes. The work is profusely illustrated with a colored frontispiece, 63 other plates, 17 figures and additional small pictures.

"The Garden has been arrayed to lure *Bees* and *Butterflies* alike; but it may be added that a flowery Border, metamorphosed after the manner of alchemy into a bibliography, garnishes the out-going Arbour. Moreover, divers faire Rose-trees, transmuted into cross-references, have been planted in the middest of the Garden. The *Butterflies*, an they list, may hover over these blossoms without settling thereon; but peradventure the *Bees* will find them as full of Honey as of Fragrance."

TENNEY L. DAVIS

Introduction to Theoretical Chemistry. By WILLIAM BUELL MELDRUM, Professor of Chemistry, Haverford College, and FRANK THOMSON GUCKER, JR., Associate Professor of Chemistry, Northwestern University. American Book Company, 88 Lexington Ave., New York, N. Y. 1936. xiv + 614 pp. 155 figs. 15 × 22.5 cm. Price, $3.50.

This text is well worthy of its name. It carries the student through each of the main subdivisions of modern chemistry from the earliest developments to the most recent, without, however, becoming too specialized for the average undergraduate. It has, of course, the disadvantages of the historical presentation—the student must follow each mistake and false premise of the early workers before arriving at the currently accepted point of view on each subject. For this reason it will probably be found unsuited to the needs of beginning students, who are usually confused by a multiplicity of theories. On the other hand, this very treatment could make this book extremely valuable in teaching students who have already completed the elementary course in chemistry. They would be led to examine the theoretical and experimental bases of each of the statements which they had, perhaps, taken for granted in their first course.

In addition to the usual subjects discussed in elementary textbooks on physical chemistry there are interesting chapters entitled: "Modern Theories of Electrolytes," "Radiations and Spectra," "The Nucleus," "Arrangement of External Electrons," and "The Electronic Theory of Valence." Each chapter is provided with a set of problems and exercises as well as a bibliography for outside study.

There can be little doubt that this book will fill the need for a text sufficiently advanced to interest students who have already acquired an elementary knowledge of chemistry, yet it is not too specialized and intricate to discourage them.

D. HARKER

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth Edition. System-Number 36, **Gallium.** Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1936. 100 pp. 17 × 25 cm. Price, RM. 13.87.

This relatively slender volume, entitled "Gallium," discusses the free element itself and its compounds with the elements of smaller "System-Number"; *i. e.*, with the nonmetals, with the metals in the preceding group of the periodic table and with aluminum. The literature of the subject has been covered up to October 1, 1936, so that the important recent work of Goldschmidt and Peters and of I. and W. Noddack on the occurrence and that of Kraus and his collaborators on the preparation, of gallium are included. Indeed a surprisingly large fraction of all the data given in this book is of recent date, presumably because of late gallium and gallium compounds have become more easily available.

ARTHUR B. LAMB

Laboratory Methods of Organic Chemistry. By L. GATTERMANN. Completely revised by Heinrich Wieland. Translated from the Twenty-fourth German Edition by W. McCartney, Ph.D., A. I. C. The Macmillan Company, 60 Fifth Avenue, New York, 1937. xvi + 435 pp. 59 figs. 15.5 × 22.5 cm. Price, $4.50.

Gattermann–Wieland's Laboratory Manual is too well known to require a detailed description.

This edition has been revised in several very important parts. Perhaps the most significant change is the abandonment of all macro methods of analysis, and their replacement by semi-micro ("meso-analytical") procedures which require the use of only 20–30 mg. of sample.

There have also been some changes made in the list of experiments, with the omission of some and the addition of others which are of greater current interest. The new experiments include the preparation of a platinum oxide catalyst for reductions, the ozonization of cyclohexene to give adipic aldehyde and the separation of chlorophyll-*a* and chlorophyll-*b* by the method of chromatographic adsorption. Improved directions for the preparation of diazomethane and octaacetylcellobiose are given.

Space has been given to a short discussion of the Wolff–Kishner reduction and selenium oxide oxidations, and the sections on carbohydrates, porphyrins and chlorophyll, and sterols have been revised to cover recent developments. The pyrones, anthocyanins and oxonium salts are treated in this edition for the first time.

The improvement in indexing should be especially commended. This change has greatly increased the usefulness of this well-known laboratory manual. The new Gattermann–Wieland can be highly recommended to all organic chemists.

C. S. MARVEL

The Scientific Principles of Plant Protection, with Special Reference to Chemical Control. By HUBERT MARTIN, D.Sc., A.R.C.S., F.I.C. Longmans, Green and Company, 114 Fifth Avenue, New York, N. Y., 1936. xii + 379 pp. 14.5 × 22 cm. Price, $8.00.

Since the appearance of the first edition of this book, entomologists, plant pathologists and chemists have been so active in this field that in preparing the second edition, Dr. Martin has found it necessary to rewrite and reset all but the introductory chapter. The present edition gives an excellent up-to-date summary of the scientific literature on the control of insects and plant diseases, with many citations of the literature enabling the reader to go more deeply into any subject in which he is interested. It offers biological information to the chemist and chemical facts to the applied biologist.

Phases of control other than chemical are discussed. Among these are plant resistance, effects of fertilizers, biological control, traps, and the elimination of infection centers or vectors. A chapter is devoted to spreaders, stickers, protective colloids, and dispersing and emulsifying agents. This book should prove of value in clearing up confusing points in recent developments such as a difference between sulfated and sulfonated spreaders. A chapter on the measurement of toxicity and the relationship of chemical constitution to toxic action is of particular interest.

The work is not intended to give definite formulas, but to indicate broadly the field of usefulness of different methods of control and give the principles underlying these methods.

Various commercial products are mentioned and, where possible, the active ingredients are given. The author errs in stating that the calcium cyanide in Cyanogas is manufactured from liquid hydrocyanic acid and calcium carbide. The calcium cyanide in Cyanogas is made from calcium cyanamide, and the calcium cyanide resulting from the reaction of liquid hydrocyanic acid and calcium carbide is sold under the trade name of Calcid. The patent literature which represents much of the research work of commercial firms and which may suggest ideas to all workers in this field has not been covered. It is hoped that in a future edition the author may be able to cover the patent literature dealing with pest control as well as he has the scientific literature in the present edition.

This book should prove of great value to the mycologist, entomologist and chemist working in the field of pest control.

WILLIAM MOORE

Die Fermente und ihre Wirkungen. (Enzymes and their Action.) Supplement. Lieferung 5 (Bd. I Specieller Teil: Haupt-teil XII). By Prof. CARL OPPENHEIMER with the collaboration of Dr. W. ROMAN. W. Junk Verlag, Scheveningsche Weg 74, The Hague, Holland, 1936. 140 pp. 5 figures. 20.5 × 28 cm. Price, Fl. 10.

Lieferung (Installment) 5 is the fifth number in a series of separate supplements, the purpose of which, as stated in the reviews of the previous numbers [THIS JOURNAL, **58**, 538, 2344 (1936)] is to bring up to date the vast amount of information that has been accumulating in the field of enzyme chemistry during the past ten years since the publication of the original main treatise.

The present installment is devoted to the chemistry of the proteinases and various types of peptidases. Not only is the more recent information found in the chemical literature discussed, but considerable space has been devoted to recent studies on the constitution of proteins. About half of the number is given over to the chemistry of the peptidases, their methods of preparation and differentiation, and to a discussion of their properties such as stability, optimum pH, specificity, behavior on adsorption, sensitivity toward foreign substances, etc.

J. M. NELSON

The Nature of Water—Heavy Water. (In russian.) By E. KH. FRITSMAN. ONTI—Khimteoret, Leningrad, U. S. S. R., 1935. 314 pp. 15 × 22 cm. Price, bound cloth, rubles 7.00.

This monograph is one of the first attempts toward a broad discussion on the nature of water from the inorganic point of view. The first 106 pages are devoted to a discussion of the earlier literature on the properties and structure of water and of ice. Two pages are given to the ortho and para modifications of water, and the remainder of the 155 pages of the discussion of fundamental investigation is devoted to heavy water. In the section outlining special investigations, pages 162–206 relate to X-rays, Raman, and ultra-red analysis of water; pages 207–209 to ortho and para hydrogen. The remainder of the book is a review of important investigations relating to deuterium and deuterium oxide. Two pages are devoted to tritium and two to the heavy isotopes of oxygen. The author gives 699 references, about 260 of them relating to work done on heavy water. The reviewer has in his files approximately 1200 titles relating to heavy isotopes of hydrogen and oxygen through 1934. This work is a well written and valuable contribution in a field of wide present interest.

MERLE RANDALL

Thermodynamics of Chemical Reactions and Their Application to Inorganic Technology. By A. F. KAPUSTINSKII, Professor of Physical Chemistry, All-Union Scientific Research Institute of Economic Mineralogy, ONTI, Moscow, U. S. S. R., 1935, 2d edition in Russian. 303 pp. 15 × 22 cm. Price, bound cloth, rubles 5.00.

This book presents a short course in general physical chemistry with emphasis on thermodynamics for students and engineers. Chapters 1 and 2 give a brief elementary outline of the gas laws; Chapter 3, heat capacity including quantum theory; Chapters 4 and 5, first law of thermodynamics and thermochemistry; Chapter 6, liquefied gases; Chapter 7, second law and entropy; Chapter 8, vaporization; Chapter 9, theory of solutions; Chapter 10, phase rule; Chapter 11, chemical equilibrium; Chapter 12, free energy; Chapter 13, third law; Chapter 14, technical reversible reactions. There follows 35 pages of tables of thermodynamic functions and 198 selected equations are brought together in a final table. The American reader will find some difficulty in following the author owing to inconsistencies in terminology. The author recognizing the necessity of a uniform and consistent system of symbols has added his own system in a table summarizing several current systems. At the same time he does not invariably follow his chosen system. This is unfortunate, for otherwise the book appears to be well thought out and well written.

MERLE RANDALL

The Biochemistry of the Lipids. By HENRY B. BULL, Ph.D., Assistant Professor of Physiological Chemistry, Northwestern University Medical School. John Wiley & Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1937. ix + 169 pp. 63 figs. 15.5 × 23.5 cm. Price, $2.75.

This work was first published as a mimeographed book by the Burgess Publishing Company in 1935.[1] Through a happy thought of the author, the subject matter has been rearranged, rewritten and in some cases notably increased, with the result that he has succeeded in the production of a readable up-to-date textbook. As stated in the preface, its object is to give the graduate student in biochemistry an insight into the chemistry and physiology of the lipids. The book contains nine chapters, the titles of which are "The Fatty Acids," "The Soaps," "Alcohols, Waxes, and Hydrocarbons," "The Sterols and Related Compounds," "Fats and Oils," "The Phospholipids," "Cerebrosides," "Carbohydrate Esters of the Higher Fatty Acids" and "Emulsions." Although the treatment of the subject matter for the most part, as would be expected from the size of the volume, is much condensed, it will, with few exceptions, be found satisfactory. In all cases, however, adequate references are given. Also, the author has called attention several times to useful reviews covering a given subject which will prove helpful.

Ternary Systems of Urea and Acids. IV. Urea, Citric Acid and Water. V. Urea, Acetic Acid and Water. VI. Urea, Tartaric Acid and Water

BY LAWRENCE H. DALMAN

In a previous publication[1] dealing with a phase rule study of the solubility relations of aqueous solutions of urea and acids, solubility measurements were reported for the three ternary systems of urea with nitric, sulfuric and oxalic acids. The existence of one or more double compounds was established in each system.

The present investigation is a continuation of this study and presents the results obtained in the determination of the three ternary systems consisting of urea, water and each of the following: citric, acetic and tartaric acids.

Materials

Urea.—The urea used was Mallinckrodt "Analytical Reagent." After recrystallization, analyses by the standard urease method[2] showed an average urea content of 99.8%.

Acetic Acid.—Merck C. P. acid was purified by freezing and preserved in a well-stoppered container. Titration with standard alkali indicated that it was 99.8% pure.

Citric and Tartaric Acids.—The anhydrous citric and *d*-tartaric acids were presented by Charles Pfizer and Company. Both of these acids were dried and stored over sulfuric acid. Titration against sodium hydroxide showed that the citric and tartaric acids averaged 99.9% and 99.8% of their theoretical values, respectively.

Standard Sodium Hydroxide.—This solution was prepared and used according to accepted standards. It was protected against dust, etc., and restandardized at regular intervals.

Procedure.—The description of the apparatus and the method of analysis of the saturated solutions has already been presented in a previous publication.[1] After the original complexes had been rotated to equilibrium at constant temperature, samples were withdrawn for the determination of acid by titration with alkali using phenolphthalein as indicator. Measurements for urea were made by the action of urease obtained from jack bean flour. The corresponding amount of ammonia liberated was taken up by hydrochloric acid and the excess acid titrated against alkali. Water was determined by difference.

This method for determining urea was used in the citric and tartaric acid systems with good results but proved unsatisfactory in the acetic acid system. The high values obtained for urea appear to be due to the fact that acetic acid is lost during the process of aeration for the removal of carbon dioxide. However, this easy volatility of acetic acid suggested an alternate method for the determination of urea which gave satisfactory results. A few cc. of the saturated solution was pipetted into a weighed porcelain crucible and evaporated to dryness in an oven maintained at 50–55°. The residue of urea was then dried to constant weight over sulfuric acid. By this method urea could be measured with an accuracy well within the limit of the urease method.

The composition of the original complexes and the solubility data obtained from the analyses of the saturated solutions have been expressed in weight per cent. and assembled in Tables I–III. The compositions of the solutions at the isothermally invariant points are the average of two or more closely agreeing results and not that of a single determination as the appearance of the isotherm would seem to indicate. In the last column are indicated the saturating solid phases which in the interest of economy of space have been abbreviated as follows: Ur for urea; C for $H_3C_6H_5O_7$; Ur·C for $CO(NH_2)_2 \cdot H_3C_6H_5O_7$; $Ur_2 \cdot C$ for $[Co(NH_2)_2]_2 \cdot H_3C_6H_5O_7$; $Ur_4 \cdot C$ for $[CO(NH_2)_2]_4 \cdot H_3C_6H_5O_7$; HAc for $HC_2H_3O_2$; $Ur \cdot AC_2$ for $CO(NH_2)_2 \cdot 2HC_2H_3O_2$; T for $H_2C_4H_4O_6$; $Ur_2 \cdot T$ for $[CO(NH_2)_2]_2 \cdot H_2C_4H_4O_6$; and $Ur \cdot T_2$ for $CO(NH_2)_2 \cdot 2H_2C_4H_4O_6$.

The identification of the various saturating solid phases was established by the method of extrapolation of the tie lines and confirmed by the analysis of the solids found in

which to compare the data obtained showed but a single reference, namely, that of Seidell[3] whose value given only at 25° was reported to be 61.71%. This compares favorably with 62.08% found in this investigation (average of four determinations).

The solubility of tartaric acid measured by the same method at 25° was found to be 58.51% (average of five determinations). Seidell's figure for the corresponding solubility is given as 57.9%, while Leidie[4] reported 59.79%. At 10° the solubility of Leidie is likewise about 1% higher than the value reported here in Table III.

Since these solubilities were measured by the same method the lack of agreement appears to be due to the quality of the acids used in the investigation. In view of this fact, a systematic determination of the solubility of carefully purified citric and tartaric acids has been undertaken in this Laboratory.

IV. Urea, Citric Acid and Water

This system was studied at 10, 25 and 40°; solubility data are shown in Table I and graphed in Fig. 1. The isotherm at 40°, which is given in complete detail, consists of five solubility curves indicating the existence of five solid phases including three double salts. Reading from left to right, these solid phases are: urea for solutions between points a and b; tetraurea citrate for b–c; diurea citrate for c–d; monourea citrate for d–e; and anhydrous citric acid for e–f.

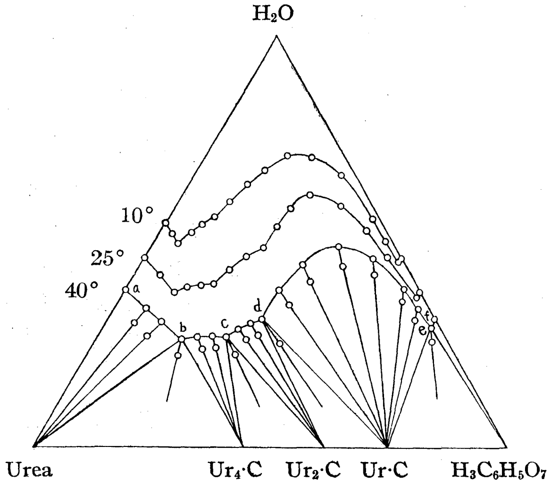

Fig. 1.—10, 25 and 40° isotherms.

The isotherms at 10 and 25° also contain five solubility curves and differ from that at 40° only in that the solid phase corresponding to the curve e–f is citric acid monohydrate instead of the anhydrous acid. This curve, of course, disappears from the system at the temperature of the transition of the monohydrate to the anhydrous acid which has been found to be 35.80°.

The Quintuple Point.—It is evident from these considerations that the curve for anhydrous citric acid originates between 25 and 40° and at the isothermally invariant point e when the system already contains vapor, solution and two solid phases. The introduction of fifth phase results in an invariant system possessing no degrees of freedom. By means of cooling curves this invariant temperature was found to be 33.73°. The composition of the saturated solution at the quin-

---

[3] Seidell, *Bull. No. 67, Hyg. Lab.*, 1910.

[4] Leidie, *Compt. rend.*, **95**, 87 (1887).

tuple point was not determined. Although the tie lines have been omitted from the 10 and 25° isotherms, their extrapolation to the proper solid phases has been found to be quite satisfactory.

Further, while not indicated, the curves a–b and d–e have been found to extend metastably into the area of the tetraurea citrate where they intersect to form a metastable isothermal invariant point.

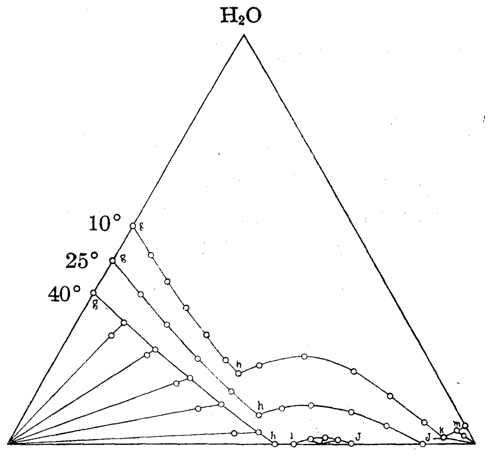

Fig. 2.—10, 25 and 40° isotherms.

It is possible to prepare the salts of monourea and diurea citrate in excellent purity since they form hard, well-defined crystals of considerable size which yield good analytical results.

	Calculated, %			Found, %		
	Urea	Acid	H_2O	Urea	Acid	H_2O
Ur·C	23.82	76.18	0.00	23.7	75.7	0.60
Ur$_2$·C	38.47	61.53	.00	38.1	61.0	.90

Both of these salts have been prepared and described by previous investigators; monourea citrate by Hlasiwetz[5] and diurea citrate by Loschmidt.[6]

The tetraurea citrate, on the contrary, separates slowly from well-cooled solutions, or by proper seeding forming small, lustrous flakes which fail to develop into sizable crystals even on prolonged agitation in the thermostat. After being filtered rapidly and centrifuged at 300 r. p. m., the salt still showed 6–7% of water. Since the salt shows incongruent solubility, its composition could not be determined by evaporating its solutions to dryness. However, the tie lines extrapolated to the composition of tetraurea citrate with suitable accuracy. Moreover, the analyses of the centrifuged wet residue fell satisfactorily on these tie lines and the salt is therefore reported as tetraurea citrate.

V. Urea, Acetic Acid and Water

This system was likewise investigated at 10, 25 and 40°; the experimental results are shown in Table II. The system has been found to produce only one double salt and this has been described by Du Toit.[7] The solubility curves are drawn in Fig. 2. Due to the high solubility of urea diacetate, the isotherms resemble those found in the sulfuric acid system.[1]

At 10° the isotherm consists of three intersecting curves which represent solutions in equilibrium with urea g–h, urea diacetate h–k, and solid acetic acid k–m. The latter curve is missing at 25°, and the curve for urea diacetate therefore terminates at the base line at the solubility of the double salt in pure acetic acid, j. The isotherm at 40° differs from those at 10 and 25° in that the curves for urea and diacetate no longer intersect but exist as two separate curves. This follows as a natural consequence of the downward movement of the isotherm with rising temperatures. Point h now represents the solubility of urea in acetic acid, while i and j denote the limits of solubility of urea diacetate in acetic acid. The curve for this salt has been enlarged somewhat in order to render a clearer picture of its scope.

While no tie lines have been drawn for the double salt, their extrapolation leaves little doubt as to its identity. On analysis it was found to contain: calcd. for $CO(NH_2)_2 \cdot 2HC_2H_3O_2$; urea, 33.34; acid, 66.66. Found: urea, 32.9; acid, 65.6; water, 1.5%.

The melting point of urea diacetate has been reported to be about 35° by Du Toit.[7] Since this solid phase was found to be stable at 40° it was decided to repeat this melting point determination. The results showed that the double salt melts slowly at 35° and more rapidly as the temperature is increased to 41° when the change is quite sudden. Inasmuch as this salt decomposes rapidly on exposure to air through the evaporation of acetic acid, the same decomposition undoubtedly occurs in the open capillary tube, and thus interferes with the melting point determination. This difficulty was eliminated satisfactorily in a closed tube in the following manner. A regular glass-stoppered solubility

---

(5) Hlasiwetz, *J. prakt. Chem.*, **69**, 104 (1856).

(6) Loschmidt, *Jahresb. Chem.*, 658 (1865).

(7) Du Toit, *Verslag. Wetenschschappen*, **22**, 573 (1913).

tube was loaded with urea and acetic acid in the proportions in which they occur in the salt. The contents were warmed until complete solution occurred and then cooled until only a small amount of crystals had formed. The tube was rotated in the bath and the temperature adjusted so that the quantity of crystals appeared to remain constant over a period of a few hours. This temperature was found to lie between 41.25 and 41.30°. However, in view of small impurities present in the urea and acid, the melting point of urea diacetate is reported to be 41.3°.

Above this temperature then the isotherm (providing no new phases enter the system) contains only the curve g–h which represents the solubility of urea ranging from pure water to pure acetic acid.

VI. Urea, Tartaric Acid and Water

In this system solubility measurements were made at 10 and 25°; these data are assembled in Table III. The isotherms which are drawn in Fig. 3 are very similar and consist of four curves which represent solutions in equilibrium with urea n–o, diurea tartrate o–p, urea ditartrate p–r and tartaric acid r–s. The solutions saturated with these double salts were found to be highly viscous.

Diurea tartrate, which has been prepared and described by Loschmidt,[6] was found to consist of rather soft crystals which gave the following results on analysis: calcd. for $U_2 \cdot T$: urea, 44.46; acid, 55.54. Found: urea, 43.4; acid, 54.5; water, 2.1%.

Urea ditartrate, which has been reported by Hlasiwetz,[5] crystallizes exceedingly slowly. As in the case of tetraurea citrate, this salt still contained about 11% of water after being centrifuged thoroughly. However, the analyses of wet residues fell satisfactorily on the tie lines extrapolating to the composition of a 1:2 double salt and its identification is therefore considered to be suitably established.

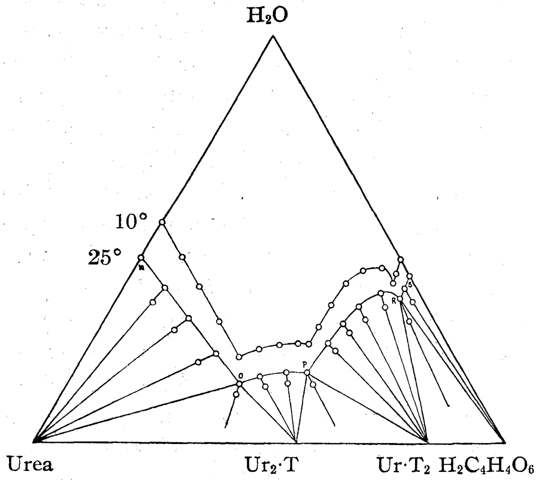

Fig. 3.—10 and 25° isotherms.

Summary

The solubility relationships in the systems urea–citric acid–water and urea–acetic acid–water have been studied at 10, 25 and 40°; the system urea–tartaric acid–water has been studied at 10 and 25°.

The following double salts were found to exist: tetraurea citrate, diurea citrate, monourea citrate, diurea tartrate, urea ditartrate and urea diacetate.

The urea diacetate has been found to exist only below 41.3°; citric acid monohydrate only below 35.80° and anhydrous citric acid only above 33.73°.

Hydrides of Boron. VII. Evidence of the Transitory Existence of Borine (BH_3): Borine Carbonyl and Borine Trimethylammine

BY ANTON B. BURG AND H. I. SCHLESINGER[1]

On account of its position in the periodic system and the composition of its most widely known compounds, boron has generally been regarded as a trivalent element; its hydrides therefore might have been expected to have the "normal" formulas BH_3, B_2H_4, B_3H_5, etc. Actually, however, the simplest known hydride of boron is diborane (B_2H_6), a substance whose formula is characteristic of some compounds of tetravalent elements. This formula has not as yet been explained by any generally accepted rules of molecular structure, nor has there been any obvious reason for the failure of all previous attempts to find evidence for the existence (whether stable or transitory) of the "normal" hydrides, or borines. It is therefore of interest to discover what conditions may be sufficient for the existence of such borines and their derivatives.

Progress in this direction is now given new impetus by the discovery of a gaseous compound having the molecular formula BH_3CO. This new substance is produced by the treatment of diborane with carbon monoxide (present in great excess), which acts according to the equation $B_2H_6 + 2CO \rightleftharpoons 2BH_3CO$. The reaction reaches equilibrium rapidly at 100°; at room temperature, the reverse reaction is slow enough to permit the isolation and study of the product. The molecular formula was established by observing the volumes of diborane and carbon monoxide produced by the decomposition of a known volume of the gas; the result was checked by hydrolytic analysis, and by the determination of the vapor density.

The initial rate of decomposition of BH_3CO at room temperature is relatively high, but decreases very rapidly, long before the final equilibrium is reached. The inhibiting agent is the carbon monoxide produced by the reaction; the other product, diborane, has no appreciable effect upon the rate in the early stages of the process. These observations suggest that the reaction occurs in two steps, the first of which results in the transitory existence of the hitherto unknown compound borine, according to the equation $BH_3CO \rightleftharpoons BH_3 + CO$. This presumably rapid and easily reversible reaction is carried forward by the removal of borine, as a result of the almost irreversible secondary reaction $2BH_3 \leftrightarrows B_2H_6$,[2] a reaction whose rate determines the rate of the entire process in its early stages. As the concentration of carbon monoxide increases, during the course of the whole reaction, its increasing effectiveness in reversing the primary reaction makes the borine less and less available for the secondary reaction, whose rate therefore decreases rapidly.

This interpretation implies the transitory existence of molecules of borine, and at the same time suggests that its isolation is not feasible. Since we are, therefore, unable to present this most direct proof of its existence, we offer the following additional indirect evidence. Any substance capable of uniting with molecules of borine to form a compound more stable than BH_3CO, should displace carbon monoxide from BH_3CO. Ammonia might have been expected to react in this manner, for it is known to form many stable addition products by reaction with "normal" boron compounds, but the actual reaction of ammonia with BH_3CO does not liberate carbon monoxide. Instead, there appears a solid material, stable at room temperature, having the empirical composition represented by the formula $BH_3CO(NH_3)_2$.[3] Considering that this result might be due to the labile character of hydrogen in ammonia, we tried the effect of trimethylamine upon BH_3CO and found that it displaces the carbon monoxide rapidly and completely at ordinary temperature, according to the equation, $BH_3CO + (CH_3)_3N \longrightarrow (CH_3)_3NBH_3$

---

[1] Presented in condensed form at the Chicago Meeting of the National Academy of Sciences, Nov. 17, 1936.

[2] Our reason for supposing this reaction to be nearly irreversible is based upon an experiment by Stock and Kusz, *Ber.*, **56B**, 799 (1923), in which a sample of diborane was heated as high as 155°, without showing the slightest evidence of the formation of borine. Our only evidence that the reaction is reversible at all, is the fact that BH_3CO actually is formed from diborane and carbon monoxide.

[3] This material is in need of further investigation. It reacts with sodium in liquid ammonia to produce the quantity of hydrogen corresponding to two ammonium ions per molecule of BH_3CO, and therefore appears to have the character of a dibasic acid. Nevertheless, it is not yet possible to decide whether it is a pure compound, or a mixture of substances formed by the decomposition of BH_3CO during its reaction with ammonia.

$+ CO$. This reaction is in agreement with our assumption of the transitory existence of borine. The high speed of this displacement seems to justify the conclusion that the reaction $BH_3CO \rightleftarrows BH_3 + CO$ is far more rapid than the association of borine to form diborane.[4]

The reactions here described support the assumption that BH_3CO has the structure of a "borine carbonyl," a compound in which borine and carbon monoxide are joined by a coördinate link consisting of electrons furnished by the carbon monoxide.[5] Another structure which might be considered is  $\mathrm{H}:\overset{\mathrm{H}}{\ddot{\mathrm{B}}}:\overset{\mathrm{H}}{\ddot{\mathrm{C}}}::\ddot{\mathrm{O}}:$, which is an aldehyde type. Aside from the difficulty that such a substance should not easily produce diborane and carbon monoxide, there is the positive objection that it would be expected to add diborane, as acetaldehyde and other organic compounds containing the $=C=O$ group have been found to do.[6] The absence of such a reaction makes the aldehyde structure highly improbable. Other alternative structures which might suggest themselves seem too unlikely for discussion.

The compound $(CH_3)_3NBH_3$, borine trimethyl*ammine*, is extraordinarily stable. During the determinations of molecular weight and vapor tensions, it was heated for hours at a time at temperatures as high as 125°, without showing the slightest sign of a change in physical properties.

The studies here presented are being continued along several major lines. One of these is the investigation of the behavior of the alkyl diboranes and some of the higher boranes with carbon monoxide and with trimethylamine. The methyl derivatives of diborane already have been found to react with carbon monoxide, but the result is a series of compounds far different from BH_3CO.[7] In addition to this program, we are searching for other compounds which, like carbon monoxide and trimethylamine, may unite with the borine molecule to form compounds capable of isolation and study. These lines of work should lead to a better understanding of the nature of the boron hydrides and of the numerous "addition compounds" which they seem to be capable of forming.

Experimental Part[8]

Preparation of Borine Carbonyl.—Comparison of the results of a number of preliminary experiments showed that the equilibrium represented by the equation $B_2H_6 + 2CO \rightleftarrows 2BH_3CO$ is closely approached in fifteen minutes at 90°, but that less severe heating is not adequate for the purpose. Longer heating, or the same duration at a higher temperature, leads to no improvement in the yield; on the contrary, the increased production of less volatile material[9] involves a loss. At room temperature the reaction is very slow: after three hours the yield was only 1% of that obtained from a parallel experiment in which equilibrium was attained at 100°.

This preliminary study was followed by experiments in which mixtures of diborane with high concentrations of carbon monoxide[10] were heated in bomb tubes. In each of these experiments, a known quantity of diborane, and then a much larger, measured volume of carbon monoxide were condensed into the bomb at $-210°$.[11] The bomb was sealed off, removed from the low temperature bath, and inverted just as the diborane melted, in order that the liquid running down might evaporate and mix thoroughly with the carbon monoxide. Adequate mixing was made still more certain by allowing the tube to remain for ten hours or longer at room temperature, before the reaction was carried on by a twenty-minute heating in a steam-bath. After the heating, the bomb was cooled to $-196°$, and the contents introduced into the vacuum apparatus by means of the vacuum tube opener. In two of these experiments, in which data for the calculation of the equilibrium constant were recorded, the first fraction of the carbon monoxide was analyzed for hydrogen by combustion. The diborane and the borine carbonyl were isolated with un-

---

(4) The compound $(CH_3)_3NBH_3$ is also formed very easily by the action of trimethylamine upon diborane, even at temperatures as low as $-110°$. This reaction probably does not depend entirely upon the dissociation of diborane to free borine molecules at such a low temperature; it is more reasonable to suppose that the trimethylamine acts upon diborane directly. Similarly, trimethylamine may react directly with BH_3CO. On account of this possibility, the formation of $(CH_3)_3NBH_3$ is not in itself a clear proof of the free existence of borine.

(5) For the present purpose, we consider it unnecessary to decide whether the carbon atom or the oxygen atom is linked directly to boron. Our use of the term "carbonyl" is solely a matter of convenience.

(6) These results have not yet been published. We have found that diborane reacts rapidly with acetaldehyde to give diethoxyborine, with acetone to give a compound which seems to be diisopropoxyborine, and far more slowly with methyl formate to give dimethoxyborine. The aldehyde and ketone reactions are completed in ten minutes at room temperature.

(7) Experimental work of F. L. McKennon.

(8) The high vacuum methods used in this work have been described quite adequately in the papers of Stock and in earlier papers of this series. All volumes mentioned in this paper refer to gases at standard conditions.

(9) This material in itself is worthy of further study. Like borine carbonyl, it begins to decompose rapidly at room temperature, and this initial reaction is soon hindered by the carbon monoxide which it produces. Unlike BH_3CO, the material produces a white, non-volatile solid which turns brown when heated. These observations suggest a carbonyl of a boron hydride fragment heavier than BH_3.

(10) The diborane was prepared by our usual method [Schlesinger and Burg, THIS JOURNAL, **53**, 4321 (1931)]. The carbon monoxide was prepared *in vacuo* by the action of hot sulfuric acid upon formic acid, and purified by distillation from a tube at $-196°$ to a receiver at $-210°$ (liquid nitrogen, whose temperature had been lowered by pumping).

(11) The uncondensed carbon monoxide was removed by a Töpler pump and measured over mercury. The purity of the sample was checked by combustion of this remainder.

usual care,[12] and the purity of each was checked before the volume was measured. The conditions and results of the bomb tube experiments are shown in Table I. Comparison of the last experiment with the others, shows very clearly the value of a high concentration of carbon monoxide.

TABLE I

Conditions			Results				
Capacity of bomb, cc.	Volume of B_2H_6	Volume of CO	Volume of BH_3CO	Residual volume of B_2H_6	Residual volume of CO	Volume of H_2	Volume of less volatile material
93.0	73.7	297	36.3	49.0	258	5	2.7
87.3	82.4	305	38.6	54.4	263	6.5	3.4
61.5	70.7	670	77.8	24.9	(585)	...	...

All volumes in this table are expressed in cc.

The equilibrium constant for the reaction $B_2H_6 + 2CO \rightleftarrows 2BH_3CO$ may be calculated from the data of the first two experiments in Table I. Expressing the concentrations in terms of partial pressures (in mm.), we have from the first experiment

$$K = (P_{CO}^2 \times P_{B_2H_6})/P_{BH_3CO}^2 = 2.8 \times 10^4$$

The second experiment gave the result $K = 3.0 \times 10^4$. Neither result is to be regarded as very precise, because the side reactions, the possible lack of perfect mixing, the chance that equilibrium was not perfectly attained, and even some slight decomposition of the borine carbonyl during purification, all must be considered as sources of error. The tendency is toward high results; we therefore consider the lower value to be more dependable, and take it to represent a maximum value of the constant.

This result means that a sample of pure BH_3CO, having an initial pressure of 200 mm. at 100°, would be approximately 95% decomposed if brought to equilibrium at that temperature (secondary and side reactions neglected).

Physical Properties.—The uniformity of various samples of the new compound was indicated by the consistent checking of the vapor tension of 25.4 mm. at −111.8° (m. p. of carbon disulfide). As a further check on the uniformity of the material, the melting points of three separately purified samples were measured by the magnetic plunger method of Stock.[13] The three readings of the carbon tetrafluoride vapor tension thermometer were 382, 382 and 381 mm., corresponding to −137.0, −137.0 and -136.9_7°.

In addition to these tests, the vapor tensions at a number of different temperatures were measured, and the results found to be consistent with the Clapeyron equation. The rapid decomposition of the vapor made such measurements difficult, but it was possible, by rapid establishment of the thermal equilibrium, by very fast readings of the temperature and pressure, and by careful repurification between measurements, to obtain satisfactory check values. In order to establish equilibrium rapidly enough, it was necessary to choose samples so small that the thermal capacity of the liquid would be negligible. It was thus possible to obtain each reading within half a minute after warming the sample from −196°. The values, corrected for the expansion of mercury above 0°, are shown in Table II. The equation representing them is $\log_{10} p_{\text{mm.}} = 7.85 - (1040/T)$, from which we calculate the normal boiling point to be −64°, the heat of vaporization 4750 cal./mole, and the Trouton constant 23.0 cal./deg. mole. The high value of the Trouton constant suggests that the complete curve relating log p to $1/T$ would be slightly concave downward, and that the true boiling point may be one or two degrees higher.

TABLE II

$t°$	−137	−122	−121.2	−120.3	−112.8	−111.8	−103.5	−95.6	−87.5	−87.2	−78.8
$p_{\text{mm.}}$ (obsd.)	1.4	9.0	9.7	10.7	22.5	25.4	52.8	98.6	175	181	314
$p_{\text{mm.}}$ (calcd.)	1.6	9.3	10.0	11.1	23.0	25.4	51.9	98.2	177	180	316

Analyses and Molecular Weight.—The most direct evidence of the identity of the new compound came from a quantitative experiment on its decomposition.

The sample was allowed to stand at room temperature for an hour. The carbon monoxide was then removed (through a trap at −196°) by a Töpler pump, and collected over mercury in a gas-measuring tube. The material in the trap was warmed again to room temperature, and the process of decomposing the original substance, and removing the carbon monoxide, was repeated again and again until the mixture no longer gave off more than traces of carbon monoxide. The latter stages of the process were facilitated by heating the mixture to 50°.

A 23.9-cc. sample thus yielded 24.1 cc. of non-condensable gas, 10.4 cc. of diborane, 0.7 cc. of material less volatile than the original sample, and a residue of 0.5 cc. of the original substance. The non-condensable material was analyzed by combustion and found to consist of 22.2 cc. of carbon monoxide and 1.9 cc. of hydrogen. The hydrogen and the least volatile material were unavoidable results of the heating.

---

(12) The material less volatile than borine carbonyl seemed to be trapped out completely at −120°; its elimination was made certain by passing the more volatile materials very slowly through a trap at −145°. Nearly all of the borine carbonyl condensed in pure condition at −155°, but the purification of the diborane required a very slow distillation through a U-tube at −165°. The fraction trapped out at that temperature required further separation.

% decomp.	12.3	13.8	16.2	18.2	19.7	20.7	23.4	25.4	27.5	28.8	30.6

[a] The percentage decomposed at each point was calculated by dividing the total increment of pressure (multiplied by 100) by one-half the initial pressure.

Neglecting these side-reaction products, the results give the empirical molecular formula $B_{0.89}H_{2.82}(CO)_{0.96}$. The neglected material could easily represent the difference between this empirical result and the rounded formula, BH_3CO. At the same time, there could be some doubt that the observed quantities represented all of the material in the original sample, for non-volatile products could have remained unobserved in the form of a thin film on the glass walls of the container. The results therefore were supplemented by a determination of the molecular weight.

The molecular weight was calculated from the vapor density, determined in the usual manner. The sample (20.0 cc.) had a weight of 37.5 mg.: the molecular weight therefore was 42.0 (theoretical for BH_3CO, 41.85; considering the instability of the substance, such close agreement probably was fortuitous).

The formula BH_3CO was checked more definitely by the complete hydrolysis of a measured sample of the pure compound, followed by the combustion of the non-condensable gases and the titration of the boric acid. A 15.95-cc. sample, which was inclosed in a 250-cc. bulb with a liberal excess of water and heated for three hours at 100°,[14] produced 47.3 cc. of hydrogen, 15.7 cc. of carbon monoxide, and 16.0 "cc."[15] of boric acid. These results agree well enough with the expected equation $BH_3CO + 3HOH \longrightarrow B(OH)_3 + 3H_2 + CO$, to remove any doubt concerning the molecular formula of the compound.

The Rate of Decomposition.—The change in the rate of the reaction $2BH_3CO \longrightarrow 2CO + B_2H_6$, at room temperature, was studied by observing the relation of the total pressure to the time. The reaction evidently was not simple, for there occurred 8% decomposition during the first five minutes, 11% in ten minutes, 13% by the end of twenty minutes and only 13.8% at the half-hour point: a further eight-hour period was required to reach 30% decomposition. The detailed results are shown numerically in Table III, which records the progress of the decomposition of a 17.8-cc. sample at 23°, and graphically by curve I in Fig. 1.

The small rate of change toward the end of this experiment was shown not to be due to a close approach to equilibrium, by the behavior of the mixture after it had been heated for four hours at 50–60°. This treatment caused the extent of decomposition to increase from 30.6 to 78%. Nevertheless, the decomposition continued after the resulting mixture had been cooled to 24°.

The cause of the rapid decrease in the velocity of decomposition was made clear by further observations of the pressures registered by the same sample, after the carbon monoxide (accumulated in the course of the experiment described above) had been removed by pumping through a trap at −196°. The materials condensed (6.8 cc. B_2H_6, 3.7 cc. BH_3CO, and a trace of less volatile material) were returned to the reaction tube. The results of observations at 24° are shown in Table IV, and as curve II in Fig. 1. The sharp change in the behavior of the sample, as a result of removing carbon monoxide, leaves but little doubt that carbon monoxide is the main cause of the rapid slowing of the rate of decomposition, for the new rate curve is much like the original.[16]

The effect of carbon monoxide was tested more

---

(14) The use of such a large bulb, and the drastic heating, seemed to be necessary for complete hydrolysis, since a somewhat smaller sample, heated with water for half an hour at 100°, in a space of 17 cc., was only 92% hydrolyzed. Hydrolysis thus appears to be an indirect reaction, in which a product of the decomposition (borine or diborane) is the material reacting with water. The high concentration of carbon monoxide built up in the smaller tube would stabilize the BH_3CO to such a degree as to account for the observed difficulty of hydrolysis.

(15) The symbol "cc." is used to represent the standard gas volume equivalent to a substance determined by titration.

(16) The rate of decomposition was considerably higher at any point in the present experiment than at the corresponding point in the original experiment. The difference no doubt was due mainly to the fact that the smaller sample in the same space built up a far lower partial pressure of carbon monoxide.

% decomposed[a]	33	34.5	36	39	49	54	59.5

[a] The % decomposed was calculated by dividing the total increment of pressure (multiplied by 100) by half the estimated initial partial pressure of BH_3CO (that is, by 0.5 × 33.6). It may be that the decomposition of the trace of less volatile material contributed to the rise of pressure: if so, these calculated values might be high by as much as 10 units. This uncertainty has no effect upon our conclusions, for a suitable correction would not alter the character of the curve.

directly in an experiment in which borine carbonyl and carbon monoxide were allowed to mix by diffusion at −80° (during twelve hours), after which the mixture was suddenly warmed to room temperature. The relation of the total pressure to the time was then observed as before.

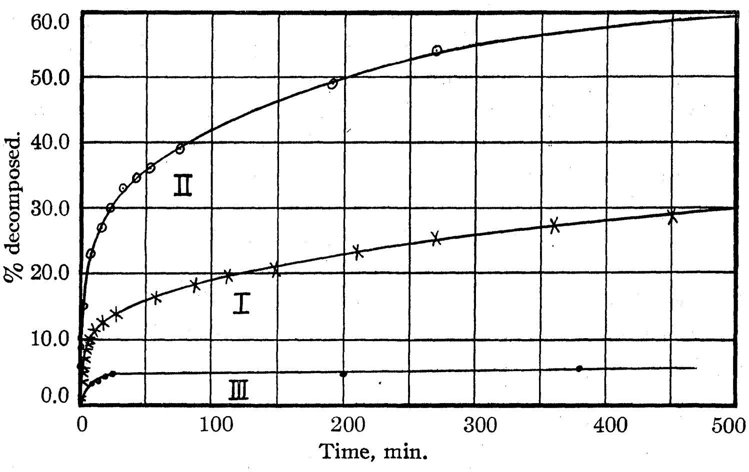

Fig. 1.

Table V shows the results obtained with such a mixture of 15.0 cc. BH_3CO and 22.2 cc. of carbon monoxide at 26°.

TABLE V

Time, min.	0	10	15	20	25	200	380
Pressure, mm.	320	322	322.3	322.7	322.8	323	323.5
Partial pressure of BH_3CO (calcd.)	120	116	115.4	114.6	114.2	114	113
% decomposition	0	3.3	3.8	4.5	4.8	5.0	5.8

At the end of this experiment, the diborane was isolated and measured as 0.4 cc., corresponding well with the 3.5 mm. increase of pressure. The rather rapid beginning of the decomposition probably is best explained by supposing that the mixing was not thorough enough for a perfect result.

Comparison of these results (curve III, Fig. 1) with those of the other rate experiments, fully confirms the conclusion that carbon monoxide is the inhibitor in the decomposition of borine carbonyl.

The Action of Ammonia upon Borine Carbonyl.—The original purpose in the treatment of borine carbonyl with ammonia was discussed in the introduction. The experimental details are as follows.

A pure sample of borine carbonyl (20.5 cc.) was treated with a large excess (114.1 cc.) of sodium-dried ammonia, at −124°. After an hour, the temperature was raised gradually to −80°, and the excess ammonia sublimed off into a trap at −196°. No trace of uncondensed gas was observed during this process. The solid residue now contained three moles of ammonia per mole of borine carbonyl originally used: this ratio was further decreased by warming the residue slowly to room temperature and condensing the ammonia liberated in the process. This second stage in the removal of ammonia was accompanied by the formation of 0.25 cc. of non-condensable gas, and a small sublimate of slightly volatile material. The solid residue in the original reaction tube now had an empirical formula approximating $(BH_3CO)_{0.9}(NH_3)_{2.07}$. It appeared to be fairly stable at room temperature.

In considering the possible ways in which ammonia might add to borine carbonyl, without liberating carbon monoxide, it seemed worth while to learn whether the product contained any ammonium ions. Accordingly, we tried the action of sodium upon a fresh sample of the material, dissolved in liquid ammonia.

The new sample was made from 14.0 cc. of borine carbonyl and a large, undetermined excess of ammonia. The solid was washed down to the bottom of the reaction tube by melting ammonia which had been condensed above it, and the solution was frozen during the introduction of 36.1 mg. of pure sodium (by a technique which blank tests had previously shown to be suitable for the purpose). When the solution was melted (allowing the sodium to enter the liquid phase at −77°), there occurred a very rapid reaction which produced one gram atom of hydrogen per gram molecule of borine carbonyl originally used. A secondary reaction produced a second gram atom of hy-

TABLE VI

Temperature, °C.	−77	−79	−77	−50	−49
Total time, min.	4	45	180	1560	3060

Ratio of H-atoms to BH_3CO used	1.02	1.04	1.04	2.07	2.16

drogen in the course of a day. The course of the whole reaction is shown in Table VI.

The excess over two atoms of hydrogen is properly to be attributed to amide formation.

The sodium reaction thus demonstrated that the product of addition of ammonia to borine carbonyl contains two ammonium ions per molecule of borine carbonyl. The question whether the material is a diammonium salt or a mixture of two salts, has not been decided.

Borine Trimethylammine

Preparation.—The reaction of trimethylamine with borine carbonyl appears to require temperatures as high as those at which the decomposition of the latter compound is observable. For example, there is no observable displacement of carbon monoxide by trimethylamine at −80°, but the reaction proceeds very rapidly at room temperature.

Thus 14.0 cc. of borine carbonyl and 25.0 cc. of trimethylamine, condensed into the tubulature of a reaction bulb (which was sealed while the reactants remained at −196°), and then warmed suddenly to room temperature, produced the solid material so rapidly that there was no further change after one minute. The reaction bulb was opened by a tube-opener, and the carbon monoxide was passed through a trap at −196°, by means of a Töpler pump, and measured as 14.2 cc. The residual trimethylamine was isolated by distillation through a trap at −80°, and measured as 10.8 cc.; the quantity which reacted hence was 14.2 cc., in perfect agreement with the quantity of carbon monoxide. The solid product therefore had the empirical composition $(CH_3)_{3x}(NBH_3)_x$, within the probable error.

Physical Properties and Molecular Weight.—The vapor tensions at various temperatures, and the total volumes of samples used in the determinations of the molecular weight, were measured by the aid of the device represented in Fig. 2. During such work, the sample contained in the bulb B registers its pressure upon the adjacent manometer, whose mercury levels are compared by means of a cathetometer. The complete immersion of the parts containing the sample makes it possible to work at elevated temperatures. In order to introduce or remove the sample, the mercury is lowered in the manometer to the point M, by applying a pump connection at P, and opening the ground-glass valve V.

The measurements so obtained for the vapor tensions of the solid product of the reaction of borine carbonyl and trimethylamine, were corrected for the varying density and vapor tension of mercury at different temperatures. The results are presented in Table VII. In the course of these measurements, the *melting point* was observed to lie between 94 and 94.5°.

TABLE VII

$t°$	23	27	34	39	51	60.3	69.5	77.6	82.7
$p_{mm.}$ (obsd.)	0.8	1.0	1.5	2.6	5.5	9.4	18.7	28.5	37.9
$p_{mm.}$ (calcd.)	0.7	1.0	1.6	2.4	5.5	10.1	17.8	28.4	37.8
$t°$	86.8	96.9	99.3	104.0	111.2	117.2	118.7	119.7	
p (obsd.)	47.8	76.5	84.7	101.7	130.0	159.8	166.0	171.8	
p (calcd.)	47.9	78.2	85.3	101.4	130.6	160.0	167.5	173.4	

The values of the vapor tension below the melting point led to the equation $\log_{10} p_{mm.} = 10.187 - 3061/T$. The values above the melting point gave the equation $\log_{10} p_{mm.} = 7.846 - 2202/T$. Eliminating log p from these equations and solving for T gives a calculated melting point of 94°, in close agreement with direct observation. The heat of vaporization below the melting point is calculated to be 13,991 cal./mole, and above the melting point, 10,064 cal./mole. The calculated *heat of fusion* therefore is 3927 cal./mole. From the equation corresponding to the vapor tensions above the melting point, we calculate the Trouton constant to be 22.7 and the normal *boiling point*, 171°. The slightly high value of the Trou-

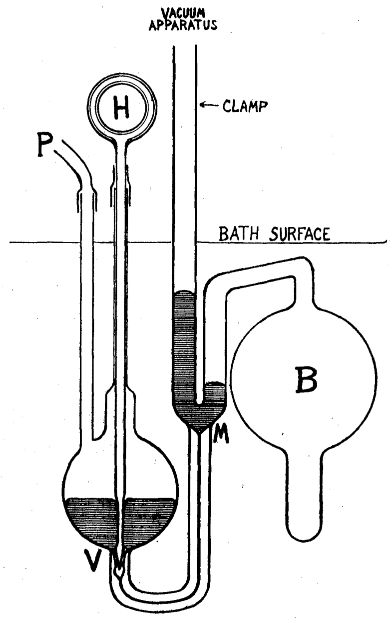

Fig. 2.

ton constant suggests that the true boiling point may be as much as one degree higher.

The sharpness of the melting point, and the character of the vapor tension curves, left no doubt of the uniformity of the material.

The molecular weight was determined by weighing portions of the sample in a small, detachable bulb with stopcock (the grease was not in the least affected), and then measuring the volume by the aid of the special device described above. The data and results of two such determinations are presented in Table VIII. The volume measurements for both of these samples were carried out at temperatures only a little way above the condensation points for the pressures observed; it is therefore reasonable that the results are somewhat higher than the value 72.85, calculated for the formula of borine trimethylammine, $(CH_3)_3NBH_3$.

TABLE VIII

Vol. of bulb, cc.	Temp., °C.	Corr. press.	Sample vol., cc.	Sample wt., mg.	Mol. wt.
118.0	120.0	111.0	11.97	39.6	74.0
118.6	99.5	74.9	8.56	28.6	74.8

This new compound forms hexagonal crystals which may appear in a variety of shapes, from long needles to short lumps having the appearance of broken quartz. Observations indicated that it is very stable, for it was heated at 125° for hours at a time, without the least permanent effect.

The Reaction of Diborane with Trimethylamine.—Diborane is absorbed by trimethylamine (present in 50% excess) rapidly and completely at any temperature at which the latter exerts an appreciable vapor tension. After removal of the excess of trimethylamine, there remains a solid residue having the empirical constitution and properties of borine trimethylammine. It was thought possible that the primary product of the reaction might be an analog of the ammonium salt which is formed by the absorption of diborane by solid ammonia under similar conditions, but an investigation of the behavior of the product toward sodium in liquid ammonia, soon gave an answer to the contrary.[17] The details of an experiment representing these observations are as follows.

A 7.1-cc. sample of diborane was condensed completely upon 20.8 cc. of trimethylamine in the bottom of a plain vertical tube. The tube was then warmed from -196 to $-110°$; the pressure developed by the evaporated diborane diminished practically to zero during five minutes. The excess trimethylamine was then distilled off at $-80°$, and measured as 6.5 cc. The residue hence had the empirical constitution $B_2H_6\cdot 2N(CH_3)_3$, or $BH_3\cdot N(CH_3)_3$, within the probable error.

Ammonia was now distilled into the tube, in quantity sufficient to form 3–4 cc. of solution, and approximately 20 mg. of pure sodium was introduced into the tube, which was kept full of pure hydrogen and at $-196°$ during the process. After the tube was resealed and evacuated, it was warmed to $-75°$; the melting ammonia dissolved the sodium and the solid compound. During five minutes at $-75°$, the solution yielded 0.185 cc. of hydrogen; after half an hour the total hydrogen was only 0.203 cc. It appears reasonable to attribute the hydrogen to impurity, rather than to any appreciable quantity of trimethylammonium ion.

After the solvent ammonia had been removed (by distillation at $-60°$), the residual solid compound was sublimed into the device represented in Fig. 2, and found to exert a vapor tension of 86 mm. at 100°; the melting point was 95°. The volume was measured as 13.2 cc. These results left no doubt that the product of reaction of diborane with trimethylamine is borine trimethylammine. In addition, the molecular weight of a similar sample, which had not been exposed to sodium in liquid ammonia, was measured as 75.6, in good agreement with the values obtained for samples derived from borine carbonyl.

The behavior of trimethylamine toward diborane is thus found to be strikingly different from that of ammonia. At the present time, we see no very clear explanation for the wide contrast between the two reagents.

Acknowledgments.—Credit is due to David M. Ritter for the initial experiment on the reaction of diborane with trimethylamine. We wish also to acknowledge the aid of a grant from the National Research Council, for liquid nitrogen used in this work.

Summary

The new compounds borine carbonyl, BH_3CO, and borine trimethylammine, $(CH_3)_3NBH_3$, have been prepared and characterized. The former decomposes easily, to form diborane and carbon monoxide; the variation in the rate of this decomposition is such as to suggest that free molecules of borine, BH_3, may be involved in the process. Borine trimethylammine, a very stable compound, is formed very easily by the action

---

(17) The diammoniate of diborane reacts with sodium in liquid ammonia to produce hydrogen; the experimental details and conclusions will be published in a separate paper. The product of the reaction of diborane with trimethylamine at low temperature does not react at all with sodium in liquid ammonia. The difference cannot be due to a failure of trimethylammonium ion to react with sodium, for a separate experiment showed that trimethylammonium chloride reacts with sodium in liquid ammonia in just the same manner as ammonium chloride does.

of trimethylamine upon either borine carbonyl or diborane. The behavior of ammonia toward diborane and toward borine carbonyl is quite different from that of trimethylamine toward these reagents.

Principal Optical and Physical Properties of the Carbon Tetrachloride Solvate of Rotenone

BY ERNEST L. GOODEN AND CHARLES M. SMITH

For several years chemists and manufacturers working with rotenone have been familiar with the carbon tetrachloride solvate, in which one molecule of rotenone is combined with one molecule of carbon tetrachloride of crystallization ($C_{23}H_{22}O_6 \cdot CCl_4$).[1] Since this solvate is of great practical importance, especially in the analysis of derris and cubé, it was considered necessary to determine its principal optical and physical properties.

The material used for the study was a sample of rotenone that had been recrystallized several times and subjected to microdetermination of carbon and hydrogen to gain assurance of purity.[2] A portion of this analyzed sample was recrystallized from carbon tetrachloride to form the carbon tetrachloride solvate.

Optical Crystallographic Properties

The optical properties investigated were such as are determinable by the use of the petrographic microscope. The solvate crystals were colorless, with a typical elongated, somewhat flattened prismatic shape (Fig. 1). The crystals were found to be biaxial with the following refractive indices (white light): $\alpha = 1.563$, $\beta = 1.612$, $\gamma = 1.631$. The indication of negative optical character obtained by the selenite plate is fairly distinct, and the observed value of β is so much nearer γ than α as to allow no doubt that the character is truly negative. In all cases observed the elongation is negative, the long edges of the crystal lying in the vibration direction for α. Extinction is sensibly parallel at all stages of rotation about the axis of crystal length, which is the vibration direction for α. It is concluded that the crystal belongs in the orthorhombic system.

Density

The density of the crystals was measured with a pycnometer, with water as the displaced liquid. In view of the volatility of the solvate, the accuracy attainable under the conditions of the experiment is considered as extending to two decimal places only. The observed value is 1.40 g. per cc. at 30°. A comparison of the density of the solvate with the densities of rotenone and carbon tetrachloride indicates that practically no volume change accompanies the combination.

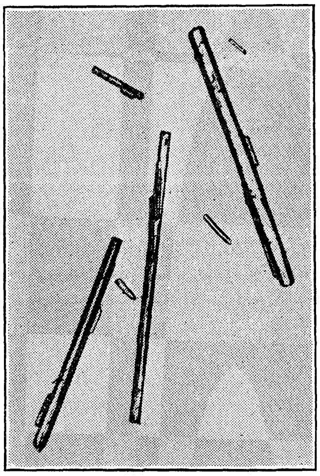

Fig. 1.—Carbon tetrachloride solvate of rotenone (× 175).

Dissociation Pressure

The dissociation pressure was investigated by the static method of vapor pressure measurement.[3] The source of controlled heating for the sample was the vapor above a boiling bath of a pure liquid, acetone, carbon tetrachloride and trichloroethylene being used separately for observations at their respective boiling points.

[1] H. A. Jones, THIS JOURNAL, **53**, 2738 (1931).

[2] This is the sample referred to by Gooden and Smith, *ibid.*, **57**, 2116 (1935), as having been analyzed by J. R. Spies.

[3] The apparatus used was one constructed by O. A. Nelson, a modification of the apparatus described by Nelson and Senseman, *J. Ind. Eng. Chem.*, **14**, 58 (1922).

The temperature readings were corrected by the established correction curve for the individual thermometer, and the manometer readings were corrected for temperaure of the mercury. With each bath liquid the rise in pressure in the space above the sample was observed repeatedly and the gas was released (for the elimination of air) between successive sets of observations, until a sufficiently precise determination of limiting pressure for given temperature was obtained. Two observed values of limiting pressure were obtained with each of the three baths, giving six points for determination of the vapor pressure curve. When these points were plotted as log pressure (in millimeters of mercury) against reciprocal of absolute temperature, they were found to lie almost exactly in a straight line. The best fitting straight line was calculated,[4] and is expressed by the equation

$$\log P = 9.308 - (2313/T)$$

where P is the pressure in millimeters of mercury and T is the temperature on the absolute (Kelvin) scale. The six points and the calculated line are shown in Fig. 2.

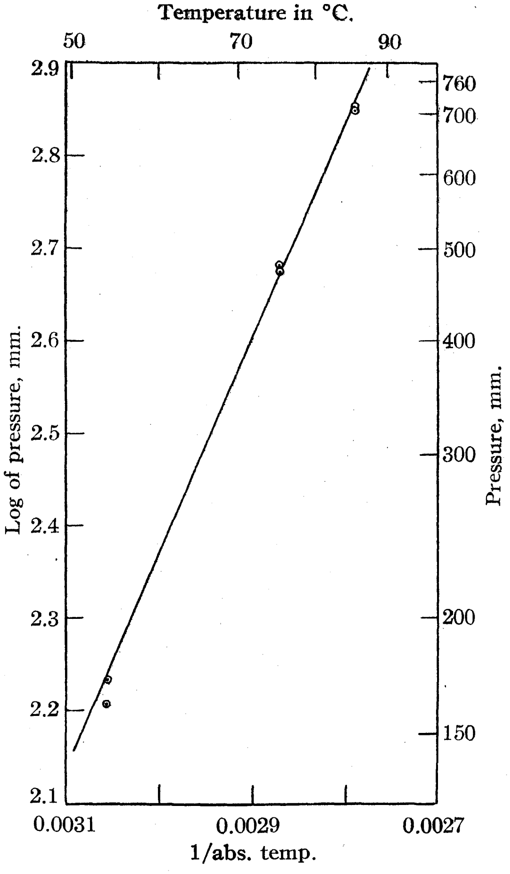

Fig. 2.—Dissociation pressure of the carbon tetrachloride solvate of rotenone (pressure of CCl_4 vapor over $C_{23}H_{22}O_6 + C_{23}H_{22}O_6 \cdot CCl_4$).

This equation leads to a value of 87° for what may be termed the "decomposition temperature" of the solvate, in the sense of the temperature at which the carbon tetrachloride vapor reaches normal atmospheric pressure. The heat of dissociation–vaporization as calculated on the basis of the same equation is 69 cal. per gram of carbon tetrachloride, which is approximately 23 cal. per gram in excess of the heat of vaporization of carbon tetrachloride at the same temperature. These results indicate that the solvate is so unstable as to require careful sealing for storage.

Additional Comparisons and Checks

It is interesting and worth while to compare the optical properties of the carbon tetrachloride solvate of rotenone with those of rotenone itself in the common (m. p. 163°) form. The indices β and γ of the solvate nearly coincide, respectively, with α and β of rotenone (α = 1.616, β = 1.635, γ = 1.662); the maximum birefringence, however, is one and one-half times as great in the solvate as in rotenone. The specific refraction is conspicuously lower in the solvate, as would be expected from the fact that the specific refraction of carbon tetrachloride is approximately 36% lower than that of rotenone. The calculated molecular refraction cannot be arrived at precisely because of the complex structure of rotenone. The various calculated values for the molecular refraction of the solvate are all very close to 129 (cubic centimeters per mole, according to Lorentz–Lorenz formula), if no allowance is made for a linkage refraction for the combination of the rotenone molecule with the carbon tetrachloride molecule. The observed molecular refraction is 134, this value being nearly equal to the sum of the observed molecular refraction (107) for rotenone and the observed value (26.45) for carbon tetrachloride.

Summary

The carbon tetrachloride solvate of rotenone, $C_{23}H_{22}O_6 \cdot CCl_4$, has been studied with respect to refractive indices, density and dissociation pressure.

---

[4] One of the six points, the lowest, showed an appreciable departure from a straight line, and was therefore disregarded; the line was calculated from the other five points by the method of least squares.

The principal results of the optical determinations are: $\alpha = 1.563$; $\beta = 1.612$; $\gamma = 1.631$; optical character, negative; elongation, commonly negative; system, orthorhombic.

The density at 30° is 1.40 g. per cc.

The dissociation pressure in the range 60 to 90° is expressed by the equation $\log P_{\text{mm.}} = 9.308 - (2313/T_K)$. The "decomposition temperature" is consequently 87°, and the heat of dissociation–vaporization 69 calories per gram of carbon tetrachloride.

The Crystal Structure of Selenium Dioxide

BY JAMES D. MCCULLOUGH

Quoting measurements made by C. F. Rammelsburg, Groth[1] describes selenium dioxide as monoclinic prisms with $a:b:c = 1.292:1:1.067$. He states that the measurements were only approximate, however, due to the extreme hygroscopic nature of the crystals, which made rapid work necessary. All crystals examined in the present work were found to be tetragonal needles with the axial ratio $a:c = 1:0.6047$.

Method of Preparation.—Pure selenium dioxide was dried at approximately 200° in a stream of oxygen which had been passed first through a tube containing phosphorus pentoxide. After drying for several hours, the Pyrex tube containing the selenium dioxide was sealed off at both ends and the substance was sublimed very slowly in an electric furnace. The atmosphere of oxygen prevented the decomposition which sometimes accompanies sublimation of the oxide in the open. The tube was opened inside a moisture-free box and selected crystals were mounted in moisture-proofed gelatine capsules. Except when being photographed they were kept in a desiccator. These precautions were found necessary in order to preserve the crystal faces and prevent lines due to selenious acid appearing on the photographs.

The crystals were transparent, colorless needles about 2–10 mm. long and 0.2–0.5 mm. thick with (100), (110) and (111) principally developed.

The Unit Cell and Space-Group

Laue photographs prepared with the incident beam perpendicular to a (100) face showed a vertical as well as a horizontal plane of symmetry as did the photographs normal to a (110) face. The tetragonal nature of the crystals was established by noting that a rotation of 90° about the needle axis gave a Laue photograph indistinguishable from the original one. Further evidence was furnished by the fact that the photographs prepared with the x-ray beam parallel to the needle axis showed a fourfold axis and four planes of symmetry at 45° intervals. The Laue symmetry thus indicated is that of D_{4h}.

A complete set of 15° oscillation photographs was prepared using unfiltered copper radiation with a 5-cm. camera. The oscillation was about the c-axis. One 30° oscillation photograph was prepared using [110] as an axis but was not very satisfactory for intensity considerations due to the shape of the crystal. Attempts to cleave the crystals across the needle or c-axis were unsuccessful and resulted in shattering.

From these photographs the unit edges $a_0 = 8.353 \pm 0.005$ Å. and $c_0 = 5.051 \pm 0.010$ Å. were calculated. Using these dimensions, values of $n\lambda$ were calculated for a completely indexed Laue photograph in which the x-ray beam made an angle of about 2° with the a-axis. The smallest value thus found was $n\lambda = 0.245$ Å. from (810), the short wave length limit being 0.24 Å.

The oscillation photographs and the first order reflections on the indexed Laue photograph showed all varieties of (hkl) and ($hk0$) reflections. The lattice is accordingly simple. Reflections of the type (hhl) were not observed for l odd although many such planes were in position to reflect, especially on the oscillation photograph about [110]. Further, ($h0l$) was not observed for h odd. These conditions indicate D_{4h}^{13} – $P4/mbc$ or C_{4v}^{8} – $C4cb$ as probable space groups. Attempts to detect a pyroelectric effect failed, but this may have been due to the hygroscopic

---

[1] P. Groth, "Chemische Kristallographie," Vol. I, 1906, p. 93.

nature of the crystals. Hence, no further choice of space group can be made at this point.

The Atomic Arrangement

The density of selenium dioxide is given by Clausnizer[2] as 3.95. This value requires 7.59 molecules in the unit. On the assumption of 8 molecules of selenium dioxide in the unit cell, the calculated density is 4.17 g./cc. We have, therefore, to place 8Se and 16O within the cell. Since the selenium atoms will do most of the scattering, to a first approximation we may overlook the oxygen. By means of simple considerations, all positions[3] were excluded to selenium except 8*g* and 8*h* of D_{4h}^{13} and 8*c* of C_{4v}^{8}. At this point some difficulty was encountered so it was considered advisable to resort to the two-dimensional Patterson method[4] in view of the excellent (*hk*0) data available.

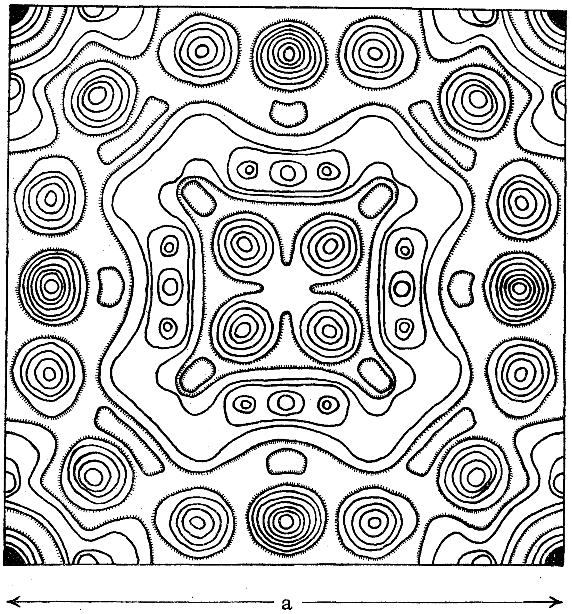

Fig. 1.—Plot of the function $p(x, y)$. Maxima represent the projection of interatomic distance vectors on the plane (001).

The two dimensional Fourier series

$$p(x, y) = \text{constant}\ \Sigma_h \Sigma_k\ |F_{hk0}|^2 \cos 2\pi(hx + ky) \quad (1)$$

will have maxima corresponding to the projection of the interatomic distance vectors on the (001) face of the unit cell. In evaluating this series the values of $|F_{hk0}|^2$ shown in Table I were used. These values were obtained from the visually estimated intensities by use of the equation

$$|F_{hk0}|^2 = \frac{2I_{hk0} \sin 2\Theta}{1 + \cos^2 2\Theta} \quad (2)$$

In estimating the intensities a graduated comparison film of timed exposures was used. The function was evaluated at intervals of *x* and *y* corresponding to $1/48\ a_0$. The result is plotted in Fig. 1. The principal maxima are without doubt due to selenium–selenium interactions and correspond to the positions 8*h* of D_{4h}^{13} or 8*c*

of C_{4v}^{8} with parameters $x = 0.13$ and $y = 0.21$. Maxima due to selenium–oxygen interactions with a separation of 1.25 Å. on the projection occur along the edges of the plot. Because of the symmetry properties of the space-groups under consideration, each crystallographically different set of atoms must produce one or more maxima along the diagonal of the plot. In order to increase the probability of finding the oxygen atoms and in order to get better values of the selenium parameters, the diagonal was evaluated in units corresponding to 1/240 a_0. The result is shown in Fig. 2. The larger selenium–selenium peaks occur at $x_1 = 0.161$ and $x_2 = 0.427$. Since

$$\begin{aligned} x_{\mathrm{Se}} + y_{\mathrm{Se}} &= \tfrac{1}{2} - x_1, \text{ and} \\ x_{\mathrm{Se}} - y_{\mathrm{Se}} &= \tfrac{1}{2} - x_2 \end{aligned} \tag{3}$$

the selenium parameters are $x = 0.133$ and $y = 0.206$. The smaller maximum at $x = 0.284$ was considered to be due to 8O in the positions $8g$ of D_{4h}^{13} or the equivalent in C_{4v}^{8}. The corresponding parameter x_O is obtained by the relationship $2x_O = 1 - x$, from which $x_O = 0.358$. This assumption was considered reasonable since it also accounts for the previously mentioned selenium–oxygen separation both in direction and in magnitude.

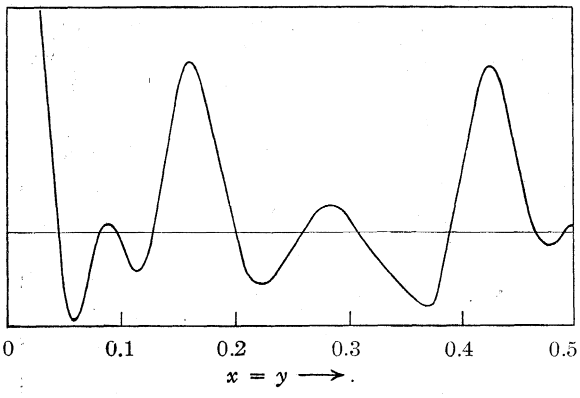

Fig. 2.—Half-diagonal of the function p (x, y).

This still leaves 8O unaccounted for and maxima due to them are either hidden by the larger interactions already mentioned or they fail to appear due to inaccuracies in the intensity data or because of an insufficient number of terms in the summation. In order to locate these oxygen atoms and to further verify the results already obtained, a two-dimensional Fourier synthesis was made using the series

$$\rho\ (x, y) = \text{constant}\ \Sigma_h\Sigma_k\ F_{hk0} \cos 2\pi(hx + ky) \tag{4}$$

The maxima in this case will correspond to the projection of the atomic positions on the plane (001). In carrying out this summation, intervals corresponding to 1/96 a_0 were employed in x and y. The algebraic sign of F_{hk0} was determined in each case from the selenium parameters already given, on the assumption that all the scattering was due to selenium. These signs were later checked and only one minor change was needed. The F_{hk0} values are shown in Table I.

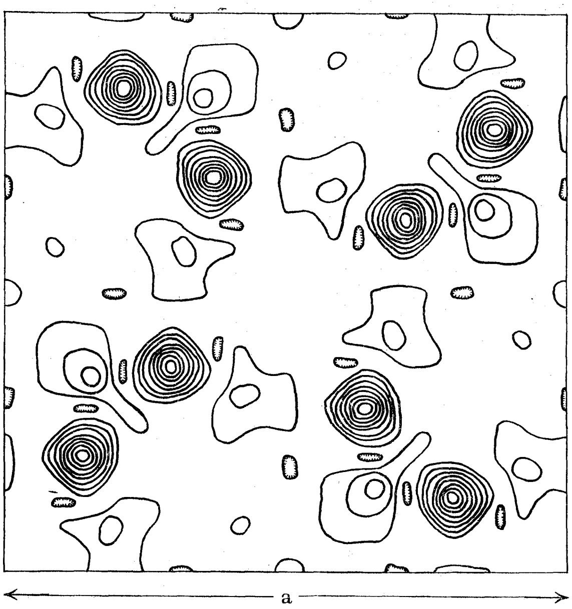

Fig. 3.—Plot of the function ρ (x, y) for selenium dioxide. Projection of scattering matter on (001).

The result of the Fourier summation is shown in Fig. 3. It is seen that the previous findings are confirmed and the remaining oxygens located. The whole projection can be interpreted in terms of either D_{4h}^{13} or C_{4v}^{8} with similar x and y parameters. The final choice was made by means of the layer line intensities which are accounted for nicely by the structure based on D_{4h}^{13} having the following atomic positions

8Se in 8*h*

$x, y, 0;\ \bar{x}, \bar{y}, 0;\ \tfrac{1}{2} + x, \tfrac{1}{2} - y, 0;\ \tfrac{1}{2} - x, \tfrac{1}{2} + y, 0;$
$\bar{y}, x, \tfrac{1}{2};\ y, \bar{x}, \tfrac{1}{2};\ \tfrac{1}{2} + y, \tfrac{1}{2} + x, \tfrac{1}{2};\ \tfrac{1}{2} - y, \tfrac{1}{2} - x, \tfrac{1}{2}.$

$8O_{I}$ in 8*g*

$x, \tfrac{1}{2} + x, \tfrac{1}{4};\ \bar{x}, \tfrac{1}{2} - x, \tfrac{1}{4};\ \tfrac{1}{2} + x, \bar{x}, \tfrac{1}{4};\ \tfrac{1}{2} - x, x, \tfrac{1}{4};$
and corresponding positions with $z = \tfrac{3}{4}$.

$8O_{II}$ in 8*h*.

with parameter values from the Fourier plot
$x_{\mathrm{Se}} = 0.133 \pm 0.001;\ y_{\mathrm{Se}} = 0.207 \pm 0.002$
$x_{O_I} = .358 \pm .005$
$x_{O_{II}} = .425 \pm .010;\ y_{O_{II}} = .320 \pm .010$

These parameter values are seen to be in good agreement with those obtained by the Patterson method.

Intensities were calculated for the equator and first two layer lines by means of the equation

$$I_{hkl} = \text{constant}\ [\Sigma_j f_j\, e^{2\pi i(hx_j + ky_j + lz_j)}]^2\ \frac{1 + \cos^2 2\Theta}{2 \sin 2\Theta} \qquad (5)$$

The Pauling–Sherman f-values[5] were used for f_j and the atomic coördinates x_j, y_j, z_j are the parameter values given above. No temperature factor was introduced. The observed and calculated equatorial intensities are given in Table I, while those for the layer lines occur in Table II. The agreement is believed sufficiently good to establish the structure as correct.

Discussion of the Structure

The structure found for selenium dioxide is shown in Figs. 4 and 5. It is to be noted that the oxygen atoms are of two kinds, both crystallographically and chemically. Accepting small interatomic distances as showing bonds, we see that the oxygen atoms of the first type are bonded to two selenium atoms while those of the second type are bonded to only one. Since each selenium atom is bonded to two oxygen atoms of type one and to one of type two, the result is a series of flat chains parallel to the c-axis of the crystal. The selenium atoms in a given chain all lie in a plane which is parallel to (110). The oxygen atoms of the second type lie in another plane also parallel to (110), while the remaining oxygen atoms are in between, somewhat closer to the plane of the oxygen atoms of type two than to the selenium plane. This causes a difference in charge on either side of the chain, the selenium surface being positive and the oxygen surface negative. The chains are probably held together by the electrostatic attraction of the oxygen atoms in one chain for the selenium atoms in a neighboring chain, which effect would be enhanced by the staggering of atoms which occurs. The chain structure ties in with observance of a fair prismatic cleavage parallel to (100) and (110), and the lack of cleavage parallel to (001).

The observed interatomic distances are 1.78 ± 0.03 Å. for Se–$\mathrm{O_I}$ and 1.73 ± 0.08 Å. for Se–$\mathrm{O_{II}}$. The sum of the normal single bond radii is 1.83 Å., taking 1.17 Å. for selenium and 0.66 Å. for oxygen.[6] The nearest approach of two oxygen atoms is 2.53 Å. for $\mathrm{O_I}$–$\mathrm{O_I}$ and 2.67 Å. for $\mathrm{O_I}$–$\mathrm{O_{II}}$, while the distance between selenium atoms in the same chain is 3.16 Å. The observed bond angles are 98 ± 2° for $\mathrm{O_I}$–Se–$\mathrm{O_{II}}$, 90° ± 30′ for $\mathrm{O_I}$–Se–$\mathrm{O_I}$ and 125° ± 30′ for Se–$\mathrm{O_I}$–Se.

The observed Se–$\mathrm{O_I}$ distance is in fairly good agreement with the value expected for a single covalent bond, but one would expect the oxygen atoms of the second type to be doubly bonded to selenium with a separation of approximately 1.64 Å. When $\mathrm{O_{II}}$ parameters are chosen to satisfy this double bond distance, the calculated intensities are not quite as satisfactory in general, although the changes are not great. The $\mathrm{O_{II}}$ parameters given were taken as the

highest points due to these atoms on the Fourier plot. Actually the closeness of the large selenium maxima may be of influence here and perhaps one should take the highest point above the sloping selenium maximum in the background. Efforts to get a good estimate of this influence were without success due to the ever-present fluctuations introduced when one evaluates an infinite series of this kind by means of a finite number of terms. Further, the estimated intensities used in the summation may have been somewhat in error.

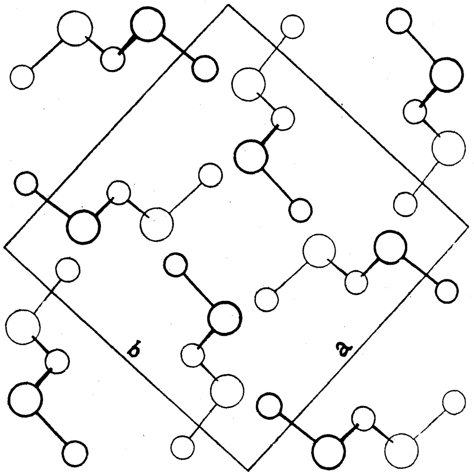

Fig. 4.—Projection of the selenium dioxide structure on the (001) face of the unit. The chains are seen end-on. Large circles indicate selenium atoms, while small circles represent oxygen.

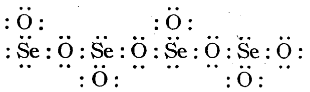
It is interesting to note that selenium dioxide molecules as such do not exist in the solid. However, only one single covalent bond must be broken per selenium dioxide molecule produced in the vapor state. This may account for the relatively high vapor pressure of the solid as shown by its ease of sublimation. The probable electron configuration is



$$\begin{array}{cccccccc} :\overset{\cdot\cdot}{O}: & & & & :\overset{\cdot\cdot}{O}: & & & \\ :\overset{\cdot\cdot}{\underset{\cdot\cdot}{Se}}: & \overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}: & \overset{\cdot\cdot}{\underset{\cdot\cdot}{Se}}: & \overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}: & \overset{\cdot\cdot}{\underset{\cdot\cdot}{Se}}: & \overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}: & \overset{\cdot\cdot}{\underset{\cdot\cdot}{Se}}: & \overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}: \\ & & :\underset{\cdot\cdot}{O}: & & & & :\underset{\cdot\cdot}{O}: & \end{array}$$

with an unshared pair of electrons occupying the fourth tetrahedral position of selenium. The shortening of the selenium–oxygen bonds, especially that for oxygen of the second type, may be attributed to partial double bond character brought about by an unshared pair from oxygen swinging into the bonding position for a fraction of the time. This gives selenium more than eight electrons in its valence shell, and it is probably the resistance to this breaking of the octet rule which prevents permanent double bonds from selenium to oxygen. Assuming a relationship between interatomic distance and percentage of double bond character similar to that for the carbon–carbon bond,[7] it is estimated that the Se–O_I bonds have 10–15% and the Se–O_{II} bonds 20–25% of double bond character.

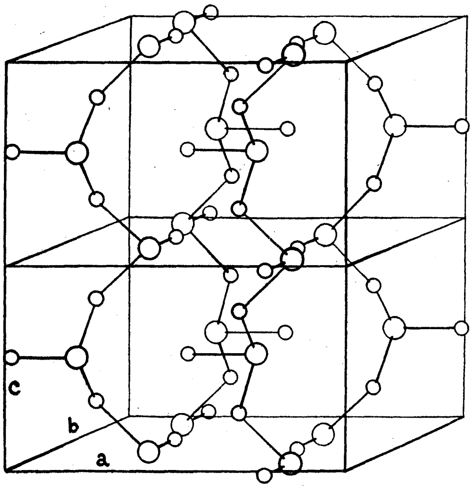


Fig. 5.—Atomic arrangement of selenium dioxide showing two unit cells. Large circles represent selenium atoms and small circles oxygen.

Another feature of the structure worth-while mentioning is that each selenium atom is surrounded by an irregular octahedron of six oxygen atoms. This octahedron consists of two O_I at a distance of 1.78 Å., one O_{II} at 1.73 Å., one O_{II} at 2.63 Å. and two O_{II} at 3.00 Å. The first three atoms belong to the same chain as the selenium while the remaining three belong to neighboring chains.

The author wishes to express thanks to Professor Linus Pauling for his helpful suggestions during the structure determination and to Dr. James H. Sturdivant for much valuable advice and assistance in preparing the X-ray photographs.

Summary

By means of an X-ray investigation, sublimed selenium dioxide has been shown to crystallize in the tetragonal system with unit edges a_0 = 8.353 ± 0.005 Å. and c_0 = 5.051 ± 0.010 Å. The unit of structure contains eight selenium

and sixteen oxygen atoms in the following positions of the space group D_{4h}^{13}:

8Se in 8*h* with $x = 0.133$ and $y = 0.207$
$8O_I$ in 8*g* with $x = 0.358$
and $8O_{II}$ in 8*h* $= 0.425$ and $y = 0.320$

The structure consists of chains of alternating selenium and oxygen atoms along the *c*-axis, with oxygen of a second kind bonded to each selenium atom. The observed separations are 1.78 ± 0.03 Å. for Se–O_I and 1.73 ± 0.08 Å. for Se–O_{II} with bond angles of 98 ± 2° for O_I–Se–O_{II}, 90° ± 30′ for O_I–Se–O_I and 125° ± 30′ for Se–O_I–Se.

The Validity of Raoult's Law for Paraffin Molecules of Very Different Length

BY JOEL H. HILDEBRAND

An interesting and fundamental question was raised during the recent symposium of the Faraday Society by Guggenheim,[1] who pointed out that the ordinarily accepted validity of Raoult's law for solutions whose components possess equal molecular fields has no sure foundation in statistical mechanics except for cases which correspond to the simple model in which molecules are spherical and "sufficiently alike so that each molecule of either species is directly surrounded by the same number of other molecules. Up to the present no one has succeeded in applying statistical mechanics to a more general model." In the discussion which followed the presentation of this paper the writer called attention to various pieces of experimental evidence indicating that the effect, if it exists, is probably a small one, as indeed the formulation by Guggenheim indicated; nevertheless, the modern treatment of solutions on the basis of their deviations from Raoult's law makes the theoretical support of this law a matter of considerable importance. The purpose of this paper is to follow up a suggestion, made during the discussion, of a model which does lend itself to statistical treatment and which, fortunately, corresponds to the actual solutions most appropriate for experimental tests of the matter: those of normal paraffins of different molecular weight. These furnish, moreover, the cases likely to be of greatest practical importance.

Our model will consist of two molecular species of identical cross section but different lengths, close-packed with their axes parallel. The longer paraffin chains are evidently parallel in the solid state and are probably not much disturbed from a similar "cybotactic" grouping in the liquid state.[2] Furthermore, the field strength of such molecules is surely the same function of the distance from the axis, *e. g.*, to separate a decane molecule from another decane molecule, parallel and in "contact," requires the same energy as to separate it from two pentane molecules, except for a slight effect due to the ends, which becomes proportionally still less for longer chains. The intermolecular distances are not strictly the same for the longer and the shorter molecules at the same temperature, for the latter possess a greater amplitude of motion for the same thermal energy. This difference, however, can be minimized by using longer molecules or lower temperatures. This point will be evident from the lower curve in Fig. 1, where the heat of vaporization per gram, $\Delta H/m$, is plotted against the temperature. The values are all evidently asymptotic to a common line as temperature is lowered. The divergence appears to be almost entirely due to more rapid expansion for the lighter species with rising temperature, as shown by the upper curve in Fig. 1, in which $V\Delta E/m^2$ is plotted against temperature, where V is the molal volume, ΔE, the molal energy of vaporization and *m*, the molecular weight. This is equivalent to the product of the volume and heat of vaporization per gram. The departures from a common line appear to be within the experimental errors.

Raoult's law is most often written in the form $p_1 = p_1^0 N_1$, where p_1 is the partial vapor pressure of one component, p_1^0 its vapor pressure in the pure liquid state and N_1 its mole fraction. For the present purpose we shall substitute fugacity, *f*, for vapor pressure. Raoult's law is then

---

[1] E. A. Guggenheim, *Trans. Faraday Soc.*, **33**, 151 (1937).

[2] G. W. Stewart, *Phys. Rev.*, **31**, 174 (1928); A. Müller, *Trans. Faraday Soc.*, **29**, 990 (1933); R. Rigamonti, *Gazz. chim. ital.*, **66**, 174 (1936).

$f_1 = f_1^0\mathrm{N}_1$. Raoult's law follows from simple statistical considerations in the case of two molecular species of identical size and field, but not for species of unequal field and not obviously for those of unequal size. It might seem, offhand, that the fugacity of a hydrocarbon molecule should be proportional to its volume concentration, *i. e.*, $f = kn/\mathrm{V}$, since it is under the same constraints regardless of whether its neighbors are a certain number of, say, decane molecules or half as many eicosane molecules, which would correspond to a very different mole fraction. I have already shown,[3] however, by the aid of the Gibbs–Duhem equation, that the volume concentration can be proportional to fugacity only in the special case that the molal volumes of the components are identical, in which case the above expression reduces to Raoult's law with fugacity proportional throughout to the mole fraction. This does not, of course, prove that the fugacity may not be proportional to some other function of the composition of the solution.

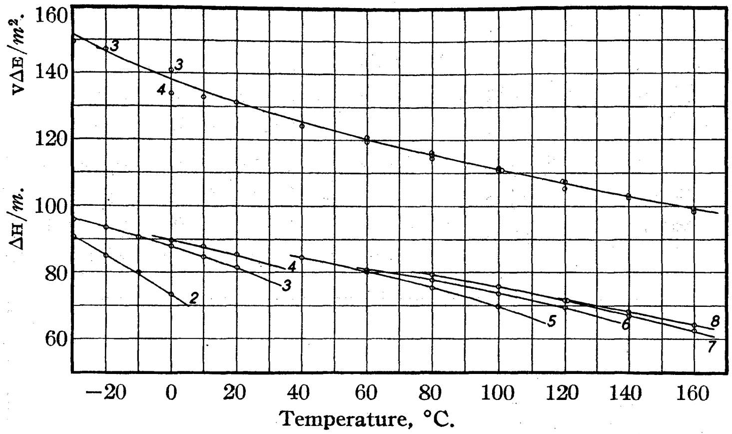

Fig. 1.—Effect of temperature and length of chain for paraffins upon the heat of vaporization per gram and upon the product of this by the specific volume of the liquid.

We may write Raoult's law in the form, $\bar{\mathrm{F}}_1 - \mathrm{F}_1^0 = RT \ln \mathrm{N}$, where $\bar{\mathrm{F}}_1$ is the partial molal free energy and F_1^0 the molal free energy in the pure liquid state. We will split up the free energy according to the general thermodynamic relation, $\mathrm{F} = \mathrm{E} + p\mathrm{V} - T\mathrm{S}$, giving

$$\bar{\mathrm{F}}_1 - \mathrm{F}_1^0 = RT \ln \mathrm{N}_1 = \bar{\mathrm{E}}_1 - \mathrm{E}_1^0 + p(\bar{\mathrm{V}}_1 - \mathrm{V}_1^0) - T(\bar{\mathrm{S}}_1 - \mathrm{S}_1^0)$$

Since we are restricting the case to that in which there is no total energy change on transferring the component from the pure liquid to the solution, we set $\bar{\mathrm{E}}_1 - \mathrm{E}_1^0 = 0$. The next term on the right-hand side is at best small. For example, if we set $\bar{\mathrm{V}}_1 - \bar{\mathrm{V}}_1 = 3$ cc., when $\mathrm{N}_1 = 0$, the order of magnitude seldom exceeded, the term $p(\bar{\mathrm{V}}_1 - \mathrm{V}_1)$ has a maximum value of about 0.07 cal., a quite negligible quantity. Our problem is then to show that, for our model, $-R \ln \mathrm{N}_1 = \bar{\mathrm{S}}_1 - \mathrm{S}_1^0$.

If we follow the analysis of Stern,[4] for the entropy of a solid solution, we can regard the entropy of a lattice as made up, first, of a term due to the difference in specific heat of the molecules in the solution and in the pure substance, and, second, of a term depending upon the number of configurations which the lattice might assume. In the ordinary lattice the number of positions which molecules can occupy is regarded as fixed, and the different configurations are reckoned from the number of different possible arrangements. If the numbers of molecules of the respective species are N_1 and N_2, the total number of lattice positions is $N_1 + N_2$ and the total number of arrangements is $(N_1 + N_2)!$. However, all molecules of one species are alike, hence $N_1!$ are alike and $N_2!$ are alike. The number of different arrangements is then $(N_1 + N_2)!/N_1!N_2!$. In the pure crystal there is only one ($=N_1!/N_1!$) arrangement. The entropy of the mixed crystal is then

$$k \ln \frac{(N_1 + N_2)!}{N_1!N_2!} - k \ln \frac{N_1!}{N_1!} - k \ln \frac{N_2!}{N_2!} = \\ k \ln (N_1 + N_2)! - k \ln N_1! - k \ln N_2!$$

Applying Stirling's formula gives

$$k(N_1 + N_2) \ln (N_1 + N_2) - kN_1 \ln N_1 - kN_2 \ln N_2$$

Differentiating with respect to N_1 at constant N_2 gives $k \ln (N_1 + N_2) - k \ln N_1$. Since the numbers of moles of the components are, respectively, $n_1 = \mathrm{N}_1/N$ and $n_2 = \mathrm{N}_2/N$ where N is Avogadro's number, we get for the transfer of a mole of component one from the pure state to the solution,

$$\bar{\mathrm{S}}_1 - \mathrm{S}_1^0 = -R \ln \frac{n_1}{n_1 + n_2} = -R \ln \mathrm{N}_1$$

In our model of a solution of paraffins, the specific heat term must be practically negligible, hence the entropy must depend mainly upon the possible configurations. It has been customary to calculate the number of configurations as above, with reference to a definite lattice

of points representing the mean positions of the atoms. This has made it necessary to limit consideration to species so nearly alike in size and shape that a given point-lattice can serve to describe the structure. In the case of paraffins, this would require that the length of the longer chain must be an integral multiple of that of the shorter. I wish to suggest that the lattice of points is, after all, artificial, like a given set of coördinate axes, and that it should be possible to determine the number of configurations in a more general way, applicable, at least, to linear molecules of any relative lengths. I propose, therefore, that the number of configurations be determined for our model by the number of possible interchanges, sliding the intervening molecules along in the direction of their axes sufficiently to furnish the proper space for each. This is most easily seen if we arrange long and short molecules linearly, when it is evident that the number of arrangements is the same as it would be if the molecules were of equal length. We will conclude, therefore, that the above equation holds for our model as truly as for a solution whose molecules are of equal size and field strength.[5]

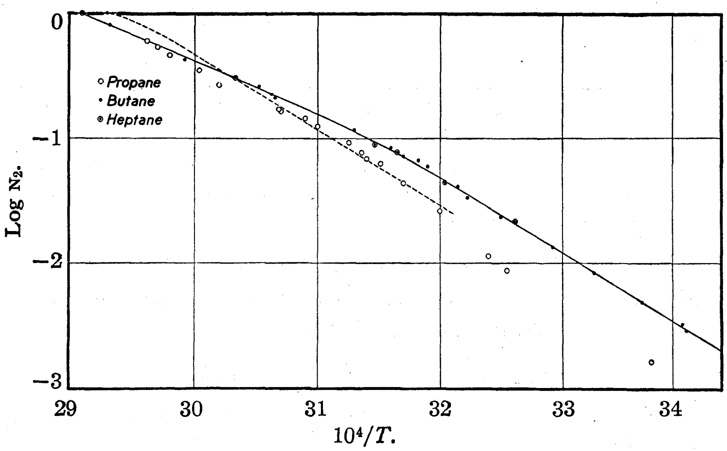

Fig. 2.—Solubility of dicetyl.

The experimental evidence at hand in confirmation of the validity of Raoult's law for solutions of straight paraffins of unequal length is at present rather fragmentary. Indeed, no extremely good agreement is to be looked for, since solutions of paraffins of nearly the same size often show departures from ideal behavior of several per cent., due either to experimental errors or to departures of the vapors from the ideal gas laws. The system investigated from among the lighter paraffins showing the most extreme variation in size is butane–heptane[6] and this obeys Raoult's law very well. Ethane dissolves in heptane almost exactly to the extent demanded by Raoult's law, according to the measurements of McDaniel;[7] however, he reports that its solubility in hexane is much less, which imposes a strain upon one's credulity. The figures for solubility at 20°, calculated to mole per cent., are as follows: ideal, 2.68; in heptane, 2.79; in hexane, 1.84.

Recently Seyer and Fordyce[8] have published solubilities of dicetyl (dotriacontane) in pentane and in heptane. I have had on hand for some time measurements, obtained by Dr. A. Wachter under my direction, of the solubility of this substance in various solvents, including one paraffin, heptane. They were not published because the solubilities in some of the solvents appeared to be larger than the ideal solubility, calculated from the melting point and the heat of fusion. This state of affairs is not known to occur except as the result of solvation, which appeared out of the question in these solutions. The data were therefore withheld pending further confirmation, either experimental or theoretical. Our figures for heptane are here given in Table I and plotted in Fig. 2 in the form of the logarithm of the mole fraction of dicetyl against $1/T$. The results of Seyer and co-workers for propane and butane are shown on the same plot.

---

[5] The above analysis was submitted to Professor O. Stern, whose reply is important enough to be here quoted, with his permission.

"This is certainly a very amusing problem. I am convinced you are absolutely right with respect to your result as well as with the method of calculating.

"At first, I was somewhat puzzled because I could not see how to derive your results by the van der Waals theory, but after some thinking I found the solution. Perhaps you will be interested to learn of my troubles and the solution. It is like this:

"Imagine we have in the one-dimensional case a liquid consisting of two long molecules in equilibrium with the vapor phase. Now, if we break up one of the long molecules into three small ones, we would at first sight, expect the vapor pressure of the long molecules to be one-half of the previous value; because the value of van der Waals b should not be changed by this process. But according to your theory, the vapor pressure should be one-fourth. Now the solution is this: The value of the volume, v, changes. If we call the van der Waals $(v - b)$ the 'effective volume,' then this 'effective volume' is proportional to the number of molecules in the liquid; so that the 'effective volume' for the large molecule is four times as large and the vapor pressure four times as small."

TABLE I

SOLUBILITY OF DICETYL IN *n*-HEPTANE

t, °C.	G. per 100 g.	Mole, %
28.4	4.11	0.905
29.8	4.98	1.095
34.2	8.68	1.89
35.0	10.23	2.22
39.0	20.8	4.42
43.0	36.0	7.41
44.6	44.2	8.95
56.6	198.6	30.6

The nature of the difficulty has recently come to light. It is due to a transition in the solid below the melting point which alters the form of the curve for the ideal solubility. Garner[9] and co-workers have determined the heats of transition and fusion for the normal paraffin hydrocarbons containing 22, 26, 30, 34 and 35 carbon atoms. By interpolating their results we may obtain data for dicetyl, for the molal heat of fusion of the α-form, the heat of transition α to β and the molal heat capacities of the liquid α and β forms. We may then calculate the ideal solubility curve of the α-form from its melting point down to the transition point and the ideal solubility of the β-form from there down. We cannot at present place too much confidence in the result of this calculation, however, on account of some uncertainty regarding the data. The fusion temperature of dicetyl interpolated from the data of Garner and co-workers is 68.4° while the transition temperature is 63.5°. The dicetyl used by Wachter, however, melted at 70.2°. Delcourt,[10] in Timmermans' Laboratory, has found 70° for the melting point, and Deffet[11] reports a melting point of 70.0° and a transition point of 64.3°. The material used by Seyer and Fordyce melted at 69.9°. They also give 55° for the transition temperature. It is possible that the transition between α and β is not a sharp change. Their curve for refractive index against temperature shows no sudden jump at 55° but rather a gradual rise between 55 and 70°. The data of Garner and co-workers for tetratriacontane show a rather rapid increase in the heat content of the β-form as the transition is approached and a somewhat rounded, continuous rather than sharply discontinuous change through the α to the liquid. This behavior is by no means uncommon.[12] It can be handled readily by plotting the heat content per mole of substance from some common lower temperature against $1/T$ and integrating graphically down from the melting point between this curve and the extrapolated heat content curve for the liquid, since $-\log \text{N} = (1/4.575) \int \Delta\text{H}d(1/T)$. The dotted line in Fig. 2 has been obtained in this way using data by Garner and co-workers for $C_{34}H_{70}$, multiplying by the molecular weight ratio, 450/478, and calculating equal distances below the melting points of the two substances. The curve has not been extended very far down on account of the uncertainties involved, the most serious of which is lack of knowledge concerning the change in specific heat of the liquid. The calculation must be regarded as purely tentative and will be corrected in the near future by aid of a direct calorimetric investigation of dicetyl now under way.

The ideal solubility, on the basis of this preliminary calculation, appears to be somewhat less than the observed solubility in the three solvents, although the discrepancy is not great. Most striking, however, is the agreement between the curves for butane and heptane, themselves differing considerably in length of chain. The smaller solvent power of propane is doubtless to be expected, partly, at least, on account of pressure effects not accounted for.

It is worth mentioning in this connection that the system benzene–diphenyl, which is similar in principle to the model here discussed, deviates only slightly from ideal behavior,[13] and that there are other systems composed of molecules of widely different volumes, such as sulfur, 136 cc. per mole, and iodine, 59 cc. per mole, of which this is also true. It may hardly be worth while to attempt a too close check of a pure volume effect because of the doubtful possibility of eliminating completely all differences in other factors, particularly molecular field strength.

Summary

The lattice of fixed points as a frame of reference for calculating the entropy of binary solutions is applicable only to pairs of molecular species of equal size or, at most, to molecules whose size and shape permit them to occupy a

definite number of lattice points. If a solution of long paraffin molecules is somewhat idealized as a parallel arrangement, the number of possible interchanges is the same as it would be for spherical molecules of equal size in a point lattice. This leads to the entropy and free energy of an ideal solution. The rather meager experimental evidence supports the ideal character of such solutions.

Vapor Phase Esterification Equilibria

BY S. K. KULKARNI JATKAR AND N. G. GAJENDRAGAD

A study of various papers[1] on the vapor phase esterification of alcohols and acetic acid would seem to indicate a high temperature coefficient on the basis of Sabatiers[1e] value of 70% at 300° and Edgar's[1h] figure of 97% at 53°, but the large possible error admitted by Edgar and the lack of precision in the data of earlier workers, leaves doubt as to the actual position of equilibrium at intermediate temperatures, especially in view of the agreement of the constants found by Frolich, Carpenter and Knox[1l] at 280–300° and Swietoslawski[1,i,j] at 75°. Parks and Huffman[2] have used these values in calculating the free energy of ethyl acetate, and obtained satisfactory concordance with estimates based on the third law, but in disagreement with results of other workers.

Swietoslawski and co-workers apparently did not correct for acetic acid polymerization nor for the activities of the compounds, both of which are appreciable at 75°. As to the high values of Frolich and coworkers, the only probable explanation for them is that some of the catalyst must have been in the cooler portion of their apparatus. On account of the high temperature coefficient of the equilibrium constant, the reaction products must be "frozen," and it seems probable that temperature errors may account for some of the other experimental discrepancies.

Figure 1 shows a plotting of log Kp against $1/T$ of the results of various workers, and harmonizes out all the values from 77 to 300° except those of Frolich, *et al.* The fact that a straight line can be drawn among most of the values shows that ΔC_p for this reaction is practically zero, and it is only coincidence that our values lie between those extrapolated from the results of others. The acetic acid dissociation and the compressibility corrections are too small to affect our results. Perhaps the dotted line drawn through the more accurate values of Essex and Clark represent the true position of affairs.

The object of the present work was to obtain results with silica and potassium alum catalysts and discuss them in the light of the work of other investigators.

Experimental

The previously described method[1b] was used, in which the alcohol–acid mixture is allowed to flow drop by drop into a copper tube vaporizer (not attacked by acetic acid above 180°), superheated, passed through the catalyst tube and the products condensed in a test-tube in a freezing mixture.

The silica catalysts were prepared from iron-free water glass, analyzing for an $Na_2O:SiO_2$ ratio of 1.07:1 and 30.8% of water. The silicate solution was allowed to flow dropwise into 1.5 liters of vigorously stirred dilute hydrochloric acid contained in a 4-liter beaker, until the resulting gel set and stirring was impossible. The gel was then broken up, washed well with hot distilled water and dried in various ways, the most active catalyst being produced in partial vacuum. For this catalyst the optimum temperature was 260°, and the initial and final total acids agreed well except at temperature extremes.

Esterification of Ethyl Alcohol and Acetic Acid with Silica Catalyst at 260°.—For various rates of passage the esterification limit was found to be 75% for the 1:1 mixture and 91% for the 2:1 mixture (Table I).

The equilibrium also was studied from the hydrolysis side, pure ethyl acetate being taken into the buret and ester vapor saturated with water passed through the superheater into the reaction chamber, the proportion of water being

The calculated equilibrium constants expressed in terms of percentage esterification of an equimolecular alcohol-acid mixture are given in the last column. Our results and those of others show the necessity of slow passage for equilibrium. Plotting the percentage conversion in the last column against rate of passage for direct, reverse and "equilibrium" runs, and extrapolating from different rates of passage, gives values for Kp at zero rate, complicated by difficulty in maintaining the activity of the catalyst constant during a series. The curve for expts. 146–149, carried out with fresh catalyst and initial mixtures of 2:1 ester and water, gives 75% as the limit for the reverse reaction. Experiments 175–180, with another catalyst and a 3:1 mole mixture of ester and water gave 74.4% conversion for an equimolecular mixture. Experiments 197–198 were made with 60 g. of fresh catalyst and a 1:1 mixture of ester and water, the result showing that even with the passage of 20 g. per hour equilibrium is attained within 1%. Some experiments to find the limit of the reverse reaction have been carried out by passing over the catalyst at various rates synthetic mixtures corresponding to the constants 4, 6, 8, 10 and 14 (Table III).

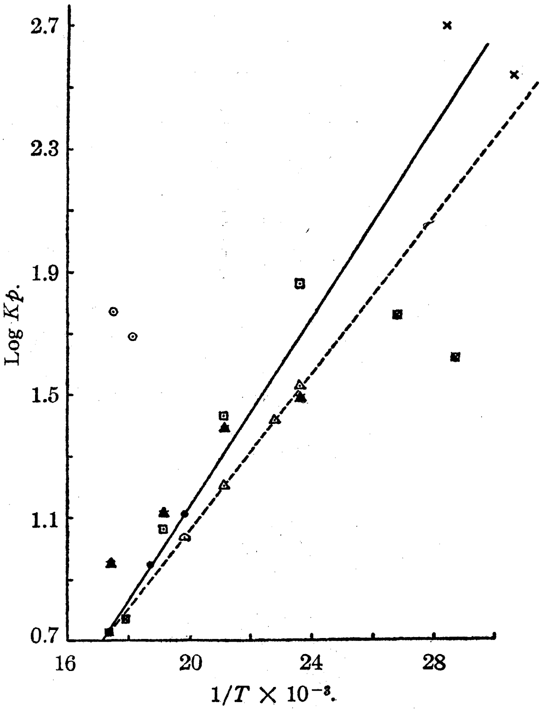

Fig. 1.—Esterification equilibria in the vapor phase: ■, Sabatier and Mailhe, 1911; ⊠, Mailhe and Godon, 1921; □, Milligan, Chappell and Reid, 1924; ▲, Tidwell and Reid, 1931; △, Essex and Clark, 1932; ○, Frolich and co-workers, 1930; ⊗, Swietoslawski and co-workers, 1929, 1934; ×, Edgar, 1924; ●, SiO_2, ⌓, alum, authors, 1931, 1936.

The results in Table III on graphical extrapolation show that the limit is reached when the product composition is such that $C_{\text{ester}}C_{\text{H}_2\text{O}}/C_{\text{alc.}}C_{\text{acid}} = 9$ approximately. The equilibrium point does not change with variation of water content in the initial mixture, the value of Kp remaining sensibly the same in expts. 212–216 with an ester/water ratio of 5, and in expts. 182–191 where the ratio was 1.

Esterification with Silica Gel at 230°.—Various silica catalysts were tested at 230°, but they were found to be relatively inactive, giving no limit of esterification. The maximum conversion was 73%, and in hydrolysis experiments with initial mixtures of 2 moles of ester to 1 mole of water the lowest value was 80% and that extrapolated from different flow rates was 78%. A mixture of ester, water, alcohol and acid in the mole ratio of 30.2:38.7:10.1:15.6 corresponding to $Kp = 4$, was passed at 10 cc. per hour over the catalyst and the mole ratio of the product was 34.9:42.8:11.6:10.8, corresponding to an equilibrium constant of 11.7.

It is evident that silica gel is not sufficiently active at 230°, and as the equilibrium is less favorable for ester at higher temperatures, various other catalysts have been studied, potassium hydrogen sulfate being the best (results to be published elsewhere).

Esterification with Potassium Alum Catalyst at 230°.—The optimum esterification temperature for this catalyst, prepared as described by Jatkar and Watson,[1a] is 230°, just as for ether dehydration of methyl and ethyl alcohols.[1a,b] Some experiments (Table IV) were made passing equimolecular mixtures of ethyl alcohol and acetic acid at 10 cc. per hour over 100 g. of potassium alum catalyst in the space which previously contained 50 g. of silica. Esterification begins at 160–170°, the same temperature at which alcohol begins to dehydrate if passed alone.

TABLE IV

Expt.	48	49	50	51	52	53	54
Temp., °C.	185	200	210	220	230	240	250
Esterification, %	14.0	33.5	41.2	53.2	62.7	60.6	61.9

Experiments also were run to ascertain the maximum esterification at various rates, using a mixture of alcohol 47.6 moles, acetic acid 47.4 moles and water 4.94 moles. In all the experiments (Table V) the initial and final total acid agreed, and the results show that a limit is reached easily, in contrast with silica catalysts.

TABLE V

POTASSIUM ALUM CATALYST, 105 G. AT 230°

Expt.	9	10	19	13	14	15	20	21
Rate	25.0	25.0	20.0	10.0	10.0	5.0	3.8	2.4
Esterif., %	63.7	61.8	64.7	65.5	65.0	65.5	61.5	63.5
Expt.		57	58	55	56	59	60	
Rate		20	20	10	10	5	5	
Esterif., %		64.0	63.7	65.3	64.6	66.1	64.8	

The hydrolysis of ethyl acetate has been studied with the same catalyst in the same apparatus. For rates of 20–10 g. per hour the value of Kp was about 10 (Table VI), while with slower rates hydrolysis went further and gave $Kp = 5$. This was due to ether formation in a side reaction. No ether could be detected in either direct or reverse reactions at rates of 10–20 cc. per hour.

Table VI

Experiment		25	24	23	28
Rate, g.		20	14.6	13	13
Mole % compn. prod.	Ester	32.2	34.1	26.9	22.5
	Water	43.7	42.4	48.4	55.1
	Alc. = acid	12.0	11.7	12.3	11.5
Kp		9.9	10.7	8	9.9

Taking the equilibrium value $Kp_{\text{ether}} = C_{\text{Et}_2\text{O}}C_{\text{H}_2\text{O}}/C^2_{\text{EtOH}} = 7$ at 230° found by Jatkar and Watson for the ether reaction and the limiting esterification value of a 1:1 alcohol-acetic acid mixture as 67% (the lower observed value 65% being due to initial water) the equilibrium constant for ester formation at 230° calculates to be 10.7, in good agreement with the figure found by extrapolation of the results of Essex and Clark.

Acknowledgment.—Our thanks are due to Dr. H. E. Watson for his keen interest during the progress of this work.

Summary

Measurements have been made on the vapor phase esterification equilibria of ethyl alcohol and acetic acid at 230 and 260°, using silica gel and potassium alum as catalysts, and the results found to correspond to 77 and 75% conversion of the equimolecular mixtures.

Although potassium alum is far more active than silica gel for esterification, the lower limit with this catalyst is due to the simultaneous establishment of ether equilibrium.

A New Thiazane Synthesis

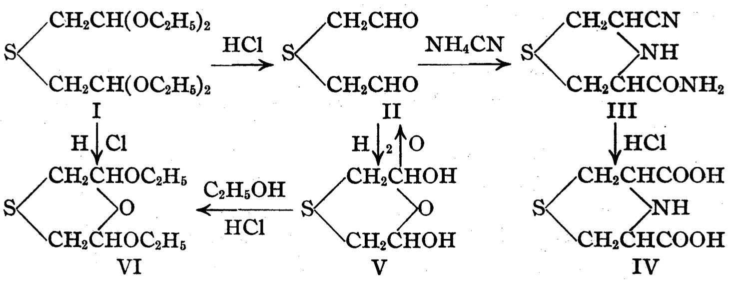
BY ROBERT D. COGHILL

For the purposes of some other research it was desired to obtain a sample of thiazane-3,5-dicarboxylic acid (IV). As this represents a new type of thiazane derivative it was necessary to devise a method of entering the series. It was found possible to do this by means of Strecker's well-known cyanohydrin synthesis.

Acetalyl sulfide (I) was prepared by a modification of Fischer's[1] method. In passing it should be mentioned that this substance is apparently what Curtius[2] prepared and described as mercaptoacetal. The acetalyl sulfide can be hydrolyzed by means of dilute hydrochloric acid to thiodiacetaldehyde (II). This aldehyde cannot be isolated as such but apparently exists in solution in equilibrium with 3,5-dihydroxythioxane (V), which is very reminiscent of the relationship existing between succinic dialdehyde and furan. In this case the 3,5-dihydroxythioxane can be isolated by concentrating the solution. The diethyl acetal of this substance, 3,5-diethoxythioxane (VI), can also be prepared from acetalyl sulfide as noted by Clarke and Smiles.[3]

When a solution of thiodiacetaldehyde is treated with ammonium cyanide, a somewhat complicated reaction sets in, the net result of which is the formation of the amide of 3-nitrilothiazane-5-carboxylic acid (III). Whether the Strecker reaction proceeds with the open chain form of the aldehyde, or whether the ammonium cyanide reacts with the dihydroxythioxane, is problematical. At first thought it seems unreasonable that only one of the nitrile groups should be hydrolyzed during the Strecker reaction, but somewhat similar reactions are not unknown in the chemical literature, and as this substance is quite insoluble and precipitates from the reaction mixture over a period of twenty-four hours, solubility considerations may well be the governing factors.

The nitriloamide resulting from the Strecker reaction can be transformed into the desired thiazane-3,5-dicarboxylic acid by means of concentrated hydrochloric acid. The synthesis can be represented as follows



Experimental

Acetalyl Sulfide.—This substance was prepared from bromoacetal and potassium sulfide as described by Fischer,[1] except that the reaction, instead of being autoclaved, was refluxed overnight. The yield was 75%. When potassium hydrosulfide was used instead of the sulfide, hydrogen sulfide was evolved copiously and acetalyl sulfide was obtained as above, except in smaller yield. Curtius[2] describes the product of this latter reaction as mercaptoacetal.

Thiodiacetaldehyde and 3,5-Dihydroxythioxane.—Twenty-six grams of acetalyl sulfide was vigorously shaken with 100 cc. of 0.5% hydrochloric acid at a temperature of 40–50° until solution was practically complete. The material now gave a very strong, nearly blue color to Schiff's reagent. A small amount of norite was then added and the solution filtered. The filtrate was evaporated to a volume of 50 cc. *in vacuo* at room temperature and then cooled in an ice-bath. The material separated as white needles, a second crop bringing the yield to 11.8 g., or nearly the theoretical. For analysis the material was dried in a vacuum desiccator over sulfuric acid.

Anal. Calcd. for $C_4H_8O_3S$: S, 23.5. Found: S, 22.9.

3,5-Dihydroxythioxane melts at 73° and is soluble in water at room temperature. Its solution imparts a deep bluish purple color to Schiff's reagent, entirely different from the color given by other aldehydes. When placed on the skin it imparts a deep brown stain impossible to remove. It has a very characteristic odor. When its solution is treated with saturated salt solutions or a trace of alkali, or even when the solid is kept in the dry state, it polymerizes or condenses to a water insoluble material. Due to this property it was always used in dilute aqueous solution just after hydrolysis from the acetal.

When warmed with alcohol and a trace of hydrochloric acid, it is transformed quantitatively into 3,5-diethoxythioxane, VI.

The Amide of 3-Nitrilothiazane-5-carboxylic Acid.—Fifty-three grams of acetalyl sulfide was hydrolyzed as above with 300 cc. of 0.5% hydrochloric acid. After

(1) Fischer, *Ber.*, **42**, 1070 (1909).

(2) Curtius and Kyriacou, *J. prakt. Chem.*, [2] **95**, 370 (1917).

(3) Clarke and Smiles, *J. Chem. Soc.*, **95**, 992 (1909).

filtration of the hydrolysate it was concentrated *in vacuo* at room temperature to a volume of 100 cc. To the cooled concentrate was then added 11.2 g. of liquid hydrogen cyanide and the mixture was allowed to stand for ten minutes, after which an aqueous solution of 7.0 g. of ammonia was added slowly with stirring. The solution was then placed in the ice-box overnight. The reaction product was filtered off and recrystallized from 95% alcohol, in which it is sparingly soluble, to yield a crop of yellow needles. The yield is 17 g. or 50%. It melts with decomposition at 192°.

Anal. Calcd. for $C_6H_9ON_3S$: C, 42.1; H, 5.25; N, 24.5; S, 18.7. Found: (Schoeller) C, 42.2; H, 5.44; N, 23.5; S, 18.7.

This substance is insoluble in cold water and all organic solvents tried except boiling alcohol, but soluble in concentrated hydrochloric or sulfuric acid. When boiled with concentrated sodium hydroxide it gives off exactly two-thirds of its nitrogen as ammonia. When boiled with 0.05 *N* sodium hydroxide, one-third of the nitrogen appears as ammonia in twenty minutes. The second nitrogen is much slower to hydrolyze, only half of it appearing as ammonia in two hours. This behavior, coupled with its high insolubility, is interpreted as confirming the assigned structure.

Thiazane-3,5-dicarboxylic Acid.—Ten grams of the above nitriloamide was refluxed for three hours with concentrated hydrochloric acid. At the end of that time it was evaporated to dryness on a water-bath, taken up in water and made *just* alkaline to Congo red with ammonia, whereupon the thiazane-3,5-dicarboxylic acid came out in white needles which can be recrystallized from water and which contain one mole of water of crystallization. The yield was 6 g. or 56%. When heated it first decrepitates then melts with decomposition at 253–254°.

Anal. Calcd. for $C_6H_9O_4NS{\cdot}H_2O$: H_2O, 8.6; C, 34.5; H, 5.26; N, 6.7; S, 15.3. Found: (Schoeller) H_2O, 8.7; C, 34.4; H, 5.35; N, 6.3; S, 15.3.

Summary

A new application of the Strecker reaction, ring closure, has been used to enter the thiazane series.

Thiazane-3,5-dicarboxylic acid has been synthesized by means of this method. This substance can serve as a starting point for the synthesis of many new thiazane derivatives.

White Oak Holocellulose[2]

BY CARROLL D. BIRD AND GEO. J. RITTER

Holocellulose, the carbohydrate fraction in wood freed of its extraneous materials, has proved within the last three years a promising material for the study of the composition of wood.[3,4] It is similar in composition to the wood fraction, "skelettsubstanz,"[5] that is isolated by means of an aqueous solution of pyridine and chlorine dioxide.

Since the results on holocellulose from maple[3] and spruce[4] were published, others have been collected on the holocellulose from white oak. They are considered in the present paper.

Materials Used.—White oak sawdust (60–80 mesh) was used in this study. It was first extracted consecutively with alcohol, alcohol–benzene solution, and hot water to remove extraneous materials.

Alcohol–pyridine solution, consisting of 85 parts of 95% alcohol and 15 parts of pyridine (by volume), was used as the solvent.

A bleach solution was employed that was made by dissolving commercial chlorinated lime in distilled water. The supernatant liquor was removed from any undissolved residue by filtration and diluted so as to contain 1.6% of available chlorine. It was cooled to 10° and was made just acid to litmus by means of acetic acid immediately before using.

Isolation of Holocellulose.—The method developed by Ritter and Kurth[3] was employed for the isolation of holocellulose. Briefly, it consists of repeated alternate treatments of the wood with gaseous chlorine and alcohol–pyridine solution.

Four chlorinations were required to remove the maximum amount of lignin from the wood before carbohydrates began dissolving as was shown by determining[6] the lignin content of a control sample. In general, at this stage of delignification about 1.0% of lignin still remained in the residue. The residual lignin was removed by means of the bleaching solution at 10°.

Physical Properties of White Oak Holocellulose.—Unbleached white oak holocellulose is grayish tan in color; the bleached material is light-cream. It can be bleached

white but in doing so a small percentage of the acetyl groups is apt to be removed.

White oak holocellulose resembles the untreated wood structurally in that the fibers cling together. The clinging tendency of the fibers indicates the presence of carbohydrate material in the middle lamella and confirms findings by Bailey.[7] These physical properties are similar to those of maple and spruce holocellulose.[3,4]

Chemical Composition of Holocellulose.—The chemical composition of the holocellulose was determined by the following analyses: lignin was determined by the 72% sulfuric acid method,[6] methoxyl by the Zeisel method,[8] carbon dioxide by the 12% hydrochloric acid method,[9] acetyl by the toluene-sulfonic method[10] and pentosans by Tollens' method.[8]

The following three materials were analyzed by one or more of the foregoing methods: (1) white oak sawdust freed of its extraneous materials; (2) bleached holocellulose isolated from Material 1; (3) lignin isolated from Material 1 by means of the 72% sulfuric acid method. Table I shows the yields and composition of the three materials. Table II records the composition of the materials calculated on the basis of the extractive-free wood so as to reveal the proportion of the substituent groups in each of the three materials.

TABLE I

YIELDS AND RESULTS OF ANALYSIS OF EXTRACTIVE-FREE WOOD, HOLOCELLULOSE AND LIGNIN

Yields of materials based on oven-dry weight of extracted wood; results of analysis based on oven-dry weight of materials.

Material	Yields, %	Lignin 72% Sulfuric acid, %	Methoxyl, %	Carbon dioxide, %	Acetyl, %	Pentosans, %
Extracted white oak wood	100.0	23.40	6.44	1.20	2.37	18.70
White oak holocellulose	75.6	0.00	1.64	1.56	3.07	23.40
White oak lignin	23.4	...	22.44	..	..	...

White oak holocellulose is free from lignin (Table I). Its methoxyl content is about 25% of that of the extracted wood; it liberates considerably higher percentages of carbon dioxide than the wood; and it contains higher percentages of acetyl groups and pentosans than the wood. The carbon dioxide evolved from the holocellulose is believed to be a decarboxylation product of uronic acids. These acids and high percentages of pentosans render holocellulose especially prone to hydrate quickly in a pulp beater. As a result, it is converted to a stuff excellent for glassine paper by a sixty-minute processing treatment as compared with a ten-hour treatment for a refined pulp.

TABLE II

COMPOSITION OF EXTRACTED WOOD, HOLOCELLULOSE AND LIGNIN

Results based on oven-dry weight of extracted wood.

Material	Yields, %	Lignin 72% Sulfuric acid %	Methoxyl, %	Carbon dioxide, %	Acetyl, %	Pentosans, %
Extracted white oak wood	100.0	23.40	6.44	1.20	2.37	18.70
White oak holocellulose	75.6	0.00	1.23	1.18	2.32	17.70
White oak lignin	23.4	...	5.25	..	..	...

One per cent. of the holocellulose was lost during the isolation procedure (Table II), the sum of the holocellulose and the lignin being 99.0% (75.6 + 23.4 = 99.0). The loss occurs in pentosans as is shown in the last column. About 20.0% of the methoxyl groups are located in the holocellulose and 80.0% in the lignin. Within experimental error the results indicate that the carbon dioxide forming material and the acetyl groups of the wood are located in the holocellulose. These results on the location of the methoxyls, carboxyls and acetyls, are in agreement with those on maple and spruce holocellulose.[3,4]

Summary

White oak holocellulose has been isolated by means of alternate treatments with chlorine gas and alcohol–pyridine solution. It has physical properties similar to those of holocellulose from maple and spruce reported previously. Its substituent groups are also distributed similarly to those in maple and spruce; about 20% of the methoxyls and all the carboxyls and the acetyls are located in the white oak holocellulose.

The Enolizing Action of Methylmagnesium Iodide upon Hindered Ketones[1]

BY LEE IRVIN SMITH AND CYRUS GUSS[2]

The reaction between ketones and Grignard reagents most frequently consists in addition of the reagent to the carbonyl group. However, when the carbonyl group or the Grignard reagent is hindered by the accumulation of substituents near the functional group, speed of the addition reaction is reduced greatly, and under these circumstances time is available for other slower reactions to occur. The chief of these slower reactions are enolization, condensation and reduction.[3] Acetomesitylene has been studied rather extensively as an example of a hindered ketone in which the ordinary reactions involving addition to the carbonyl group are decreased in velocity to the point at which the slower, "abnormal" reactions make themselves felt. Thus the oxime cannot be made by the ordinary procedures;[4] the ketone is completely resistant to the action of alkalies, but is cleaved to the hydrocarbon (mesitylene) and acetic acid by the action of phosphoric acid,[5] in contrast to the behavior of acetophenone, which is cleaved to benzoic acid; and the ketone does not undergo the haloform reaction.[6]

Kohler, Stone and Fuson[7] using their "Grignard machine," found that acetomesitylene was completely enolized by methylmagnesium iodide, giving an iodomagnesium enolate together with an equivalent amount of methane, a result which was verified in a more extensive study of the reaction by Kohler and Baltzly.[4d] That enolization of ketones by Grignard reagents is primarily a function of hindrance in the ketone and that branching of the chain in the reagent is of relatively minor importance in this reaction, was shown by Kohler and Thompson.[8]

In order to extend and amplify the information on enolization of hindered ketones by Grignard reagents, the behavior of thirteen aceto- and diacetopolymethylbenzenes toward methylmagnesium iodide has been examined. The results are given in Table I.

The compounds were dissolved in xylene and analyses were made in a "machine" built essentially after the pattern of the one used by Kohler and his collaborators[7,9] and the procedure was essentially that used by them. The monoacetyl compounds were fairly easily handled, but the diacetyl compounds gave rise to complications due to the insolubility of the iodomagnesium derivative in the solvent. In such cases, the amount of xylene, as well as the time during which the reaction mixture was heated, had to be increased considerably before consistent results could be obtained. When water was added in the second part of the analysis it was also necessary to prolong the time of heating. Moreover, cautious shaking of the reaction chamber during both the first part of the analysis and the later decomposition by water was absolutely necessary. A correction factor, due to gas (nitrogen) dissolved in the reagent and to moisture which could not be removed from the apparatus, had to be introduced into the calculations. The correction, experimentally determined, amounted to 1.52 cc. Consistent values for the amount of

enolization were obtained readily, but values for the amount of addition varied, often by as much as 5% especially for the diaceto compounds. At least three analyses of each ketone were made; the figures given are average values. Acetophenone is included in the table for comparison.

The results given in Table I show that all of the monoketones having methyl groups in both ortho positions to the carbonyl group are 100% enolized by methylmagnesium iodide. When only one ortho position is substituted by a methyl group the extent of enolization apparently is affected by the number of methyl groups elsewhere in the ring as shown by aceto-*m*-xylene, acetopseudocumene and acetoprehnitene which are enolized to the extent of 5, 24 and 75%, respectively. Among the diaceto compounds, enolization does not reach 100%, and diaceto-*m*-xylene is only 8% (per carbonyl group) enolized. Because of this result, it was thought that this compound might possibly be 4,6-diaceto-*m*-xylene, although the arguments of Meyer and Pavia[10] as well as those of Klages and Lickroth[5] (p. 1562) indicate quite strongly that the substance is 2,4-diaceto-*m*-xylene. Diacetomesitylene shows the greatest amount of enolization (90% per carbonyl group) of any of the diketones. The other five diketones are 80–85% enolized by the reagent; the degree of enolization is apparently affected but little, if any, by the relative positions of the two acetyl groups.

The authors are greatly indebted to Dr. A. F. Thompson, Jr., for suggestions and criticisms with reference to the Grignard analyses.

Experimental Part[11]

The monoketones were prepared by the Friedel–Crafts synthesis from the hydrocarbons (1 mole), acetic anhydride (1.2 moles) and aluminum chloride (2.2 moles) in carbon bisulfide (400 cc.), according to the general procedure of Noller and Adams.[12] The products all distilled at nearly constant temperatures, except for small foreruns of hydrocarbons and some high boiling residues. The latter were worked up for diaceto compounds. The monoketones were all fractionated twice; in addition, acetodurene was crystallized from ether, and acetopentamethylbenzene from methyl alcohol.

For the diketones, the procedure was much the same, but using, per mole of hydrocarbon, 6 moles of aluminum chloride, 2.3 moles of acetic anhydride, and an amount of carbon disulfide sufficient to keep the reaction mixture fluid enough to stir well (200–500 cc.). The monoketones were removed from the products by fractionation and the residue was then distilled practically to dryness. The boiling points of the second fraction covered a wide range, but the distillate consisted almost entirely of the diketones which were crystallized from high boiling ligroin (A) or ether (B). Tables II and III show the physical constants and yields.

[g] A white solid (3 g.) melting at 164–174° was formed as a by-product in this preparation. It was diacetyldurene (m. p. 178°); mixed m. p. 170–178°. *Anal.* Calcd. for $C_{14}H_{18}O_2$: C, 77.07; H, 8.26. Found: C, 77.23, 77.08; H, 8.36, 8.12. This substance resulted from durene formed by action of aluminum chloride upon prehnitene during the prolonged, slow, diacetylation of prehnitene.

Summary

1. Thirteen aceto- and diacetopolymethylbenzenes, three of them new compounds, have been analyzed in the Grignard machine with regard to enolization by methylmagnesium iodide.

2. All of the diortho substituted monoketones were 100% enolized by the reagent.

3. The degree of enolization of the mono ortho substituted monoketones was increased by the presence of methyl groups in the meta and para positions.

---

(10) Meyer and Pavia, *Ber.*, **29**, 2566 (1896).

(11) Microanalyses by J. W. Opie.

(12) Noller and Adams, THIS JOURNAL, **46**, 1889 (1924).

4. The diketones were only 80–90% enolized by the reagent; the relative positions of the two acetyl groups had little effect on the degree of enolization.

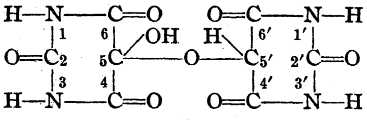
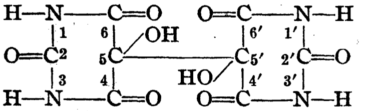
Studies in the Alloxantine Series[1]

BY DOROTHY NIGHTINGALE[2]

The formation and many of the reactions of alloxantine[3] can be explained by either the hemiacetal structure (I) of Piloty and of Slimmer and Stieglitz, or by the pinacol structure (II).



I



II

On the basis of the hemiacetal structure, it should be possible to prepare two isomeric methyl alloxantines and two unsymmetrical dimethyl alloxantines, namely, 1-methylalloxantine and 1′-methylalloxantine, and 1,3-dimethylalloxantine and 1′,3′-dimethylalloxantine. The first step, therefore, was to try to prepare the two possible monomethyl alloxantines, and then to determine by means of their hydrolytic products whether or not they maintained their identity. According to the pinacol formula they should be identical.

The 1-methylalloxantine can be prepared from methylalloxan and dialuric acid, and would be expected to yield these compounds on hydrolysis. Similarly, 1′-methylalloxantine should be formed by the union of alloxan and methyldialuric acid, and on hydrolysis should yield these same products. If the pinacol structure is correct, then either compound could yield a mixture of dialuric acid, methyldialuric acid, alloxan and methylalloxan. Tartar[4] concluded that the unsymmetrical dimethylalloxantines maintained their identity because the dimethyl murexides which he obtained from them gave dimethylalloxan and uramil, alloxan and dimethyluramil, respectively, when hydrolyzed with dilute hydrochloric acid. No further evidence was presented for their structures.

Alloxantine can be hydrolyzed with the following reagents and the hydrolytic products separated nearly quantitatively: (a) hydrochloric acid and the subsequent treatment of the solution with hydroxylamine hydrochloride, (b) hydroxylamine hydrochloride, (c) primary amines, (d) potassium acetate solution. When the mono or dimethyl alloxantines are used, however, this is no longer true. Solubilities are changed and yields lowered so that the hydrolytic products furnish little definite quantitative evidence as to probable structure.

Method (d) is useful for the isolation of only one hydrolytic product, namely, dialuric acid. According to Koech[5] freshly prepared potassium acetate solution hydrolyzes alloxantine to give alloxan and a quantitative yield of the slightly soluble potassium dialurate. The potassium salt of methyldialuric acid is very soluble in water, making this reaction of use only in detecting dialuric acid. A large excess of potassium acetate seems to be necessary for a quantitative yield of the potassium dialurate. With the theoretical amount, only a small quantity of potassium dialurate is precipitated. The reaction was applied to the methyl alloxantines with interesting results.

One rather unexpected result was observed, namely, the formation of potassium dialurate from 1′-methylalloxantine prepared from either 1-methyldialuric acid or its derivative 1-methyluramil. This result can be explained on the assumption that there is oxidation–reduction of methyldialuric acid by alloxan after hydrolysis.

According to Biilmann and Bentzon[6] alloxan-

---

[1] Abstract of a portion of a dissertation presented by the author in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the University of Chicago in 1928. The investigation was carried out under the supervision of the late Professor Julius Stieglitz.

[2] Present address, University of Missouri, Columbia, Missouri.

[3] For a bibliography and brief discussion of the possible structures of alloxantine, see Davidson and Epstein, *J. Org. Chem.*, **1**, 305 (1936).

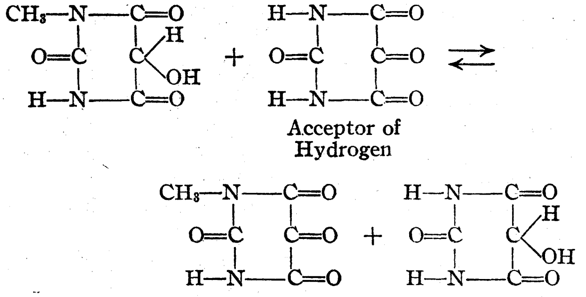
tine is 78% dissociated in saturated aqueous solution into dialuric acid and alloxan. The extent and rate of dissociation of 1′-methylalloxantine should be somewhat the same as for alloxantine, since the methyl radical of the ureide group should not affect the group of atoms which are involved in the hydrolysis. In an aqueous solution of 1′-methylalloxantine there would be the equilibrium

1′-methylalloxantine $\rightleftharpoons$ 1-methyldialuric acid + alloxan



When potassium acetate is added, it reacts to form the slightly soluble potassium dialurate, more dialuric acid is formed to satisfy the equilibrium, and thus the 1′-methylalloxantine is destroyed completely. This is indicated by the fact that the potassium dialurate is precipitated slowly, completion of the reaction requiring several hours, whereas potassium dialurate is precipitated in a few minutes in excellent yield when either alloxantine or 1-methylalloxantine is hydrolyzed under the same conditions. This interpretation is in accordance with the hemiacetal formula for the alloxantines.

The acetyl and benzoyl derivatives of alloxantine prepared by Friedrich[7] from the corresponding acyldialuric acid and alloxan are stable compounds which melt without decomposition and are soluble in alcohol as well as in water. These facts suggested the possibility of preparing isomeric acyl methyl alloxantines which might have different melting points. The benzoyl derivatives were chosen because they do not hydrolyze as readily in aqueous solution as do the acetyl derivatives.

Benzoyldialuric acid and methylalloxan or dimethylalloxan reacted readily to form the corresponding benzoyl methyl or dimethyl alloxantines, but there was no evidence of any reaction between benzoylmethyldialuric acid and the alloxans.

Experimental

1-Methylalloxantine.—The compound can be prepared by either of the following methods: (1) the reaction between dialuric acid and methylalloxan, first proposed by Andreasch,[8] and later more carefully developed by Biltz and Heyn,[9] yielding about 30%; and (2) the reaction of uramil and methylalloxan in dilute hydrochloric acid solution, an application of the method recently described by Davidson and Epstein[3] but first developed by Tartar[4] for the unsymmetrical dimethyl alloxantines. The yield is nearly quantitative; hence this method, described below, was used more frequently.

Uramil (2.8 g.) and an excess of methylalloxan (4 g.) were added to 25 cc. of water containing 2 cc. of concentrated hydrochloric acid. The mixture was kept at a temperature of 50° for three hours, with the addition of a little water from time to time to keep the volume constant. The mixture was cooled and the colorless crystals collected on a filter, washed with water, alcohol and ether, and dried in a vacuum desiccator; yield 5 g.

Anal. Calcd. for $C_9H_8N_4O_8 \cdot 3H_2O$: N, 15.82. Found: (Kjeldahl) N, 15.72.

1′-Methylalloxantine.—Freshly prepared methyluramil (2.5 g.) and alloxan monohydrate (2.5 g.) were added to 20 cc. of water containing 2 cc. of concentrated hydrochloric acid. The mixture was kept at a temperature of about 60° for two and one-half hours, following the procedure given above; yield 4 g.

Anal. Calcd. for $C_9H_8N_4O_8 \cdot 3H_2O$: N, 15.82. Found: (Kjeldahl) N, 16.00.

Both compounds when recrystallized melt with decomposition at 226°, and soon turn red when exposed to air, especially if at all moist. The dried samples were kept in well-stoppered bottles in a desiccator. In order to avoid as far as possible oxidation–reduction during solution, the methylalloxantines for the hydrolysis experiments were not recrystallized. The compounds were recrystallized for analysis.

Hydrolysis of 1-Methylalloxantine.—The 1-methylalloxantine (3 g.) was dissolved in hot boiled water (75 cc.) and to this solution was added a solution of potassium acetate prepared as follows: 1.2 g. of potassium hydroxide was dissolved in 10 cc. of water and glacial acetic acid added drop by drop until the solution was just acid to litmus. Crystals of potassium dialurate began to separate rapidly as soon as the potassium acetate solution was added to the solution of 1-methylalloxantine. The solution was kept hot but not boiling, to prevent the precipitation of the difficultly soluble methylalloxantine. The precipitation was complete in about fifteen minutes. The crystals of potassium dialurate were collected on a filter, washed with alcohol and ether and dried in a vacuum desiccator; yield 1.17 g., theoretical 1.54 g.

Anal. Calcd. for $C_4H_3N_2O_4K$: N, 15.38. Found: (Kjeldahl) N, 15.37.

Hydrolysis of 1′-Methylalloxantine.—The 1′-methylalloxantine (3 g.) was hydrolyzed under the same conditions as 1-methylalloxantine. After standing for about

[7] Friedrich, *Ann.*, **344**, 7 (1906).

[8] Andreasch, *Monatsh.*, **3**, 431 (1882).

[9] Biltz and Heyn, *Ber.*, **52**, 1310 (1919).

fifteen minutes, crystals of potassium dialurate began to form slowly. The precipitation required several hours for completion. As has already been pointed out, this relatively long interval is of theoretical significance. The yield of potassium dialurate was 1.35 g. The yield of salt possible if all of the 1′-methylalloxantine is converted into dialuric acid and methylalloxan is 1.54 g.

Anal. Calcd. for $C_4H_3N_2O_4K$: N, 15.38. Found: (Kjeldahl) N, 15.23.

The experiment was repeated several times, using 1′-methylalloxantine prepared by the Biltz–Andreasch directions as well as by Tartar's method, with the same results.

In support of the assumption that the formation of potassium dialurate from 1′-methylalloxantine is the result of intermolecular oxidation–reduction after hydrolysis, the following experiment was carried out. Methyldialuric acid (1.7 g.) was dissolved in hot water (60 cc.). To this solution was added the 10 cc. of potassium acetate solution prepared as described above. Alloxan monohydrate (1.6 g.) dissolved in water (15 cc.) was added at once. The solution was kept hot to prevent the precipitation of the methyldialuric acid. After a time, crystals began to separate and after several hours precipitation was complete. The crystals of potassium dialurate were collected on a filter and dried; yield 1.2 g., theoretical 1.8 g.

Anal. Calcd. for $C_4H_3N_2O_4K$: N, 15.38. Found: (Kjeldahl) N, 15.29.

Hydrolysis of the Unsymmetrical Dimethylalloxantines.—The unsymmetrical dimethylalloxantines were prepared in the same manner as the monomethyl alloxantines and were hydrolyzed with potassium acetate as described above. From 3 g. of 1,3-dimethylalloxantine an almost quantitative yield of 1.18 g. of potassium dialurate was obtained in a short time. A 2-g. sample of 1′,3′-dimethylalloxantine gave 0.65 g. of potassium dialurate, a 66% yield if all of the alloxan is reduced completely by dimethyldialuric acid to dialuric acid. This latter reaction proceeded slowly, as with 1′-methylalloxantine.

Benzoyl-1-methylalloxantine.—Friedrich's[7] directions were used to prepare benzoyldialuric acid. To a solution of the acid (1.5 g.) in 90 cc. of hot water, methylalloxan (1.5 g.) was added. Crystals separated when the solution was cooled and the beaker scratched. The benzoylmethyl alloxantine was collected on a filter, washed with water and finally with ether, and recrystallized from hot absolute alcohol. The yield was 0.72 g. of purified product which melted with decomposition at about 233°.

Anal. Calcd. for $C_{16}H_{12}N_4O_9$: N, 13.86. Found: (Kjeldahl) N, 13.93.

Benzoyl-1,3-dimethylalloxantine was prepared in the same manner from benzoyldialuric acid (1.5 g.) dissolved in 100 cc. of hot water and dimethylalloxan (1.7 g.). The yield was 1.3 g. The compound decomposed at 237°.

Anal. Calcd. for $C_{17}H_{14}N_4O_9$: N, 13.40. Found: (Kjeldahl) N, 13.41.

Benzoylmethyldialuric acid, a compound not described in the literature, was prepared as follows: 1-methyldialuric acid (5 g.) was added to 25 g. of benzoyl chloride and the mixture heated on an oil-bath for half an hour. A reaction began at about 120° with the evolution of hydrogen chloride. The methyldialuric acid went into solution at about 150°. Crystals separated when the mixture was cooled and the sides of the flask scratched. After standing for several hours, the crystals were collected on a Büchner funnel and as much of the benzoyl chloride as possible removed by suction. The compound was washed with ether until the odor of the acid chloride was no longer noticeable; yield 6 g., melting point 185–187°. Repeated recrystallization of the compound from hot water did not change its melting point.

Anal. Calcd. for $C_{12}H_{10}N_2O_5$: N, 10.68. Found: (Kjeldahl) N, 10.60.

The potassium salt of benzoylmethyldialuric acid was prepared from 2.5 g. of the acid dissolved in 70 cc. of 95% alcohol and a solution of 3.2 g. of potassium acetate in 30 cc. of alcohol. Colorless crystals separated rapidly when the two solutions were mixed. After standing some time, the crystals were collected on a filter, washed with alcohol and ether, and dried in a vacuum desiccator.

Anal. Calcd. for $C_{12}H_9N_2O_5K\cdot 1H_2O$: K, 12.30; N, 8.80. Found: K, 12.38; N, 8.83.

For the preparation of benzoyl-1′-methylalloxantine benzoylmethyldialuric acid (1.5 g.) was dissolved in 125 cc. of hot water and to this solution was added alloxan (0.5 g.). After several hours the crystals which separated (1.3 g.) were collected and dried. Their melting point was 185–187° and the melting point of a mixture of these crystals and benzoylmethyldialuric acid was also 185–187°.

Summary

1. The experimental evidence indicates that methylalloxantine may exist in the form of two isomers, as represented by the hemiacetal formula. In aqueous solution 1-methylalloxantine would dissociate into dialuric acid and methylalloxan, and when potassium acetate solution is added, potassium dialurate is precipitated rapidly. Similarly, 1′-methylalloxantine would yield methyldialuric acid and alloxan. The alloxan appears to be reduced slowly by the methyldialuric acid to dialuric acid, which is precipitated slowly as the difficultly soluble potassium dialurate. Similar results were obtained with 1,3-dimethylalloxantine and 1′,3′-dimethylalloxantine.

2. Methods are given for the preparation of the following compounds not described in the literature: benzoyl-1-methyldialuric acid, benzoyl-1-methylalloxantine, benzoyl-1,3-dimethylalloxantine.

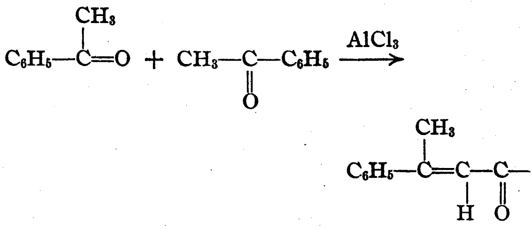
Reactions in the Presence of Metallic Halides. I. β-Unsaturated Ketone Formation as a Side Reaction in Friedel–Crafts Acylations

BY N. O. CALLOWAY[1] AND LOUIS D. GREEN

Often directions for the preparation of ketones by the Friedel–Crafts method from a hydrocarbon and an acid halide specify a reaction period of such length that hydrogen halide evolution ceases. These statements lead to ambiguous reaction conditions. A major difficulty is the problem of determining the point at which the hydrogen halide evolution stops. On the one hand, experience has shown that the reaction is seldom complete when there is no longer visible bubble formation at room temperature. On the other hand, it is not possible to discern bubble formation during reflux especially if low-boiling solvents are used.[2] Yet the ordinary test with ammonia shows *some* evolution of hydrogen halide *as long as the reaction mixture is refluxed.*

It has further been noted that prolonged reflux or extended reaction time actually decreases the yield of ketone beyond a certain period. This decrease in ketone is accompanied by an increase in the formation of high-boiling oxygen containing substances.

In an effort to find, if possible, a method that would minimize the loss of ketone by reaction subsequent to formation, it was observed in the synthesis of acetophenone that the residues consisted primarily of dypnone which had resulted from the condensation of two molecules of acetophenone.



$$C_6H_5-\overset{CH_3}{\overset{|}{C}}=O + CH_3-\underset{O}{\underset{\|}{C}}-C_6H_5 \xrightarrow{AlCl_3} C_6H_5-\overset{CH_3}{\overset{|}{C}}=\underset{H}{\underset{|}{C}}-\underset{O}{\underset{\|}{C}}-C_6H_5$$

Closer examination of this reaction revealed the fact that it is one that will take place to an extent approximating completeness only when the ketone is present in excess of molar quantities as compared with the aluminum chloride. Two moles of acetophenone per mole of aluminum chloride gave the highest yields (73%). Quantities of aluminum chloride in excess of 1 mole per mole of acetophenone were essentially without effect in bringing about the reaction. Any excess of simple ketone beyond 2 moles tended to produce high molecular weight, viscous gums, and to reduce markedly the yield of dypnone. At low temperatures the condensation proceeds quite slowly and the formation of the gummy residues which are always present in small quantities when the reaction takes place at room temperature is strongly inhibited. At 40–50° the time for the reaction is shortened and the residue is markedly increased. Stirring has little effect.

Although hydrogen chloride is evolved continually during any period of heating of acetophenone and aluminum chloride, the simple explanation that the condensation is promoted by hydrogen halide is not tenable. This general type of condensation may be promoted by hydrogen halides,[3] it is true, but also by alkalies,[4] heat,[5] radiation,[6] zinc alkyls,[7] organoaluminum halides,[8] acetic anhydride,[9] sulfuric acid,[9] sodium pyrosulfate,[10] sodamide,[11] and aluminum and alkyl halides.[12]

The fact that the three valences of aluminum in aluminum chloride are occupied by chlorine atoms seemed incidental to the process of condensation. Therefore, a substance such as triphenylaluminum, in which the three valences are occupied by non-haloid groups, should bring about this condensation.[13] It was found that triphenylaluminum did condense acetophenone to yield dypnone although a portion of the organometallic compound reacted with the car-

bonyl group. No methyldiphenylcarbinol was observed. There was isolated, however, a substance which gave every indication of being *as*-diphenylethylene. There was a residue of resinous material that undoubtedly resulted from further condensation of the β-unsaturated ketone.

$$C_6H_5COCH_3 \xrightarrow{(C_6H_5)_3Al} (C_6H_5)_2C(OH)CH_3 \xrightarrow{-H_2O} (C_6H_5)_2C{=}CH_2$$

From the general effectiveness of aluminum alcoholates as condensing agents, it may be that in both the case of aluminum chloride and of triphenylaluminum there was an intermediate formation of substances of the general type of R–O–Al–R_2 which actually promoted the condensation. Thus in the case of aluminum chloride, the aluminum salt may have been formed from the enol of acetophenone. From triphenylaluminum the salt may arise either by reaction with enolic acetophenone or more likely directly by reaction of triphenylaluminum with the acetophenone.

When benzaldehyde was substituted for one mole of the acetophenone and condensation was brought about by aluminum chloride, chalcone was isolated in excellent yields (91%). It is noteworthy here that the reaction proceeded more rapidly than when dypnone was formed.

Experimental Part

Dypnone from Ketone Synthesis.—To 13.3 g. (0.1 mole) of anhydrous aluminum chloride in 100 cc. of dry carbon disulfide in a 500-cc. three-necked balloon flask equipped with a mercury-sealed mechanical stirrer, a dropping funnel, and a reflux condenser closed by a tube of calcium chloride leading to a suitable trap, there was added dropwise 7.8 g. (0.1 mole) of redistilled acetyl chloride taking care that the temperature did not rise above 25°. After the resulting oily complex had stirred for fifteen minutes, there was added dropwise 7.8 g. (0.1 mole) of dry, thiophene-free benzene over a period of twenty minutes. The reaction was stirred for one hour, after which it was refluxed and stirred for twelve hours. Hydrogen chloride was evolved during this entire period, rapidly at first and more slowly toward the end of the reaction.

The dark brown, viscous reaction mixture was poured over 200 g. of crushed ice. The aqueous layer was separated and extracted with two 25-cc. portions of carbon disulfide. The washings were combined with the original carbon disulfide layer and washed with two portions of water and one of 10% sodium bicarbonate. After drying over sodium sulfate the solvent was removed on a water-bath.

Vacuum fractionation yielded 8.4 g. (70%) acetophenone, b. p. 106–109° (38–40 mm.), and 3 g. of dypnone, b. p. 160–165° (1 mm.). There was a gummy viscous residue of 1 g.

The dypnone was identified by the semicarbazone which melted at 150–151° and showed no depression when mixed with a sample of known material.[14]

In a duplicate run which was heated for only three hours, 10.1 g. of acetophenone was obtained (83%). There was no dypnone or residue.

Condensation of Acetophenone to Dypnone.—For all reactions involving stirring or refluxing the set-up described for the acylation above was used. Heat was applied to the appropriate reactants by means of a water-bath on a hot-plate. For all reactions not involving stirring or refluxing, the following set-up was used. A suitably sized Erlenmeyer flask was equipped with a rubber stopper fitted with a large straight calcium chloride tube completely filled with coarse calcium chloride.

In all cases the acetophenone was added slowly to the aluminum chloride in carbon disulfide. During this addition considerable heat was evolved. Reflux of the solvent was avoided by cooling with running water; 100 cc. of carbon disulfide was used for each tenth mole of aluminum chloride. *In every case hydrogen chloride was evolved throughout the reaction period.*

The products were isolated by the procedure given for the isolation of dypnone from the ketone synthesis above. Systematic variation of conditions showed that the best yields of dypnone were obtained when two moles of acetophenone were added to one mole of aluminum chloride at room temperature and allowed to stand for seven days, yield 73%.

The Synthesis of Chalcone.—Using essentially the same procedure as that outlined for dypnone chalcone was prepared by adding 12.1 g. (0.1 mole) of acetophenone to 13.3 g. (0.1 mole) of aluminum chloride in 100 cc. of carbon disulfide keeping the reaction cooled with tap water. After the resulting complex was formed, the reaction mixture was allowed to stand for thirty minutes with occasional shaking. There was then added slowly 10.6 g. (0.1 mole) of purified benzaldehyde. The flask was closed with a tube of calcium chloride and shaken occasionally during the first hour. It was then allowed to stand for four days. At the end of this time the liquid complex had solidified to definite yellow to brown crystals. The carbon disulfide was decanted and discarded. The crystals were washed with two portions of benzene and allowed to drain free of solvent by inverting the flask. Water was now added and the crystalline mass broken up with a stirring rod. When hydrolysis was complete the product was cooled in ice. The resulting yellow crystalline product was filtered off. After one crystallization from alcohol it melted at 54–56°, yield 19 g., 91% of theoretical. The m. p. of a sample mixed with an authentic specimen[4] was 55–56°.

Hydrolysis of the entire reaction mixture without decanting the carbon disulfide, as for dypnone, gave essentially the same results as obtained in the preceding chalcone run, when the product was distilled.

Reaction of Triphenylaluminum with Acetophenone.—Triphenylaluminum[15] was prepared in toluene solution from diphenylmercury[16] under nitrogen free from carbon dioxide, oxygen and moisture. To 190 cc. of a filtered solu-

tion of 7.7 g. (0.03 mole) of triphenylaluminum in a three-necked flask fitted with an inlet for nitrogen, a mechanical stirrer and a reflux condenser closed by a tube filled sufficiently with sulfuric acid to assure a positive nitrogen pressure, there was added 12 g. (0.1 mole) of acetophenone. No immediate reaction was perceptible. After thirty minutes a flocculent precipitate appeared. The mixture was now heated in an oil-bath at 100–115° for six hours after which it was allowed to stand for six hours at room temperature. The thick, pasty reaction mixture was poured into 100 cc. of water containing 2% nitric acid. The toluene layer was separated, washed with water and 10% sodium bicarbonate and dried over sodium sulfate. The solvent was removed by distillation and the residue was twice vacuum fractionated at 9 mm. Two fractions were obtained: (A) b. p. 108–120°, 3 g.; (B) b. p. 190–195°, 4 g.; residue, 3 g. that did not distill up to 270°. This residue set to a hard amber colored resin-like mass soluble in acetone but sparingly soluble in alcohol and ether.

Fraction B.—Dypnone by m. p. and mixed m. p. of oxime,[17] 133–134°.

Fraction A.—This material was shaken for fifteen hours with a saturated solution of sodium bisulfite to remove any ketone. The oil was then extracted with ether and dried over sodium sulfate. Distillation gave 2 g. of a product boiling at 272–277°; n^{14}D 1.6070; 0.1 g. of this material in dry chloroform immediately discharged the color of bromine[18] to form an addition product that evolved hydrogen bromide when the solvent was removed.

Oxidation[18] of 0.8 g. of this oil at 80° for five hours gave a product which when extracted from alkaline solution by ether would not crystallize at room temperature, but gave 1 g. of an oxime, melting[18] (p. 150) at 140–141° and showing no depression of m. p. when mixed with a known sample of benzophenone oxime. It was concluded that the substance was α,α-diphenylethylene.

In a run in which acetophenone was refluxed with sodium-dried toluene for thirty-six hours, no dypnone was found.

The authors are grateful to Mr. Thomas Campbell who kindly prepared some of the starting materials.

Summary

1. The evolution of hydrogen halide in the Friedel–Crafts ketone synthesis is not a satisfactory criterion for judging the optimum period of reaction.

2. Drastic and prolonged reaction conditions and especially the use of an insufficient proportion of aluminum chloride tend to encourage condensation of ketones primarily formed by acylation.

3. Aluminum chloride is capable of condensing acetophenone to form dypnone and a mixture of acetophenone and benzaldehyde to form chalcone.

4. Triphenylaluminum similarly will produce dypnone from acetophenone.

Oxidation of Ethyl Mercaptan and Ethyl Disulfide by Bromine in the Presence of Water

BY H. A. YOUNG

Dilute carbon tetrachloride solutions of ethyl mercaptan and ethyl disulfide are oxidized in a normal manner[1] to ethyl sulfonic acid by bromine water, as represented by the equations

$$RSH + 3Br_2 + 3H_2O = C_2H_5SO_3H + 6HBr \quad (1)$$

$$C_2H_5SSC_2H_5 + 5Br_2 + 6H_2O = 2C_2H_5SO_3H + 10HBr \quad (2)$$

Ethyl mercaptan is converted instantaneously and quantitatively to the disulfide in the absence of water, in accord with the results of Otto and Rossing.[2]

Experimental Part

Equivalents of Bromine Used per Mole of Sulfur Compound

Ethyl Mercaptan.—Carbon tetrachloride solutions of the mercaptan were prepared and analyzed just before use by the iodimetric method of Reid.[3] A measured volume of mercaptan solution (approximately 0.005 *M*) was introduced into a 250-cc. glass-stoppered flask containing 100 cc. of water and a measured volume of a known solution of bromine (excess) in carbon tetrachloride was added immediately. The flasks were then put in a shaker in a 25° thermostat, and after various times were withdrawn, 2 g. of solid potassium iodide added, and the liberated iodine was titrated with 0.1 *N* sodium thiosulfate solution. The results of a series of such experiments showed that 6.00 ± 0.03 equivalents of bromine were used per equivalent of

---

[1] It is well known that strong oxidizing agents convert mercaptans and disulfides to the corresponding sulfonic acids. Friedman [*Beitr. Chem. Physiol. Path.*, **3**, 25, 38 (1903)] has shown that bromine oxidizes cystine and cysteine to cysteic acid.

[2] Otto and Rossing, *Ber.*, **19**, 3136 (1886).

[3] Sampey and Reid, THIS JOURNAL, **54**, 3405 (1932).

mercaptan and that the reaction was complete in about twenty-four hours.

Ethyl Disulfide.—Since no method of analysis is known for disulfides, it was necessary to weigh a sample of ethyl disulfide for each experiment. This was done by introducing the disulfide from a dropping pipet with a long capillary into a weighed, thin-walled glass weighing ampoule. The ampoule was iced, sealed, dried and reweighed, after which it was dropped into a 250-cc. glass-stoppered flask containing a known excess amount of bromine in carbon tetrachloride and 100 cc. of water. The subsequent treatment was the same as with the mercaptan.

In these experiments it was found that the bromine used was almost always about 1% high. Blank experiments showed that this error was due to loss of bromine during the manipulations, probably chiefly during the introduction of the ampoule containing the ethyl disulfide. Table I gives two typical experiments.

TABLE I

Expt.	R_2S_2, g.	Eq. Br_2 per mole R_2S_2	Correction	Eq. Br_2 per mole R_2S_2 corr.
1	0.0776	10.11	0.15	9.96
2	.1324	10.14	.14	10.00

In view of the above data it seems safe to conclude that these measurements are good to about 1.5% in spite of the relatively high volatility of every substance involved, and that the main reactions are probably those suggested in equations 1 and 2.

Oxidation of Ethyl Mercaptan by Dry Bromine.—The amount of bromine used by ethyl mercaptan in the absence of water was measured by mixing dilute carbon tetrachloride solutions of a known amount of ethyl mercaptan with a known excessive amount of bromine. After various times, the solutions were shaken with aqueous solutions of potassium iodide and the resulting iodine titrated with sodium thiosulfate solution.

The amount of hydrogen ion produced in the reaction was measured in a similar fashion by using excess ethyl mercaptan. The carbon tetrachloride solutions were extracted and washed with water and the extract titrated with standard sodium hydroxide solution.

The results of a series of experiments in which the mercaptan concentration varied from 0.003 to 0.03 *M* showed that 1.00 ± 0.01 equivalents of bromine were used per mole of mercaptan; those of a second series in which the bromine concentration varied from 0.003 to 0.025 *M* indicated that 1.00 ± 0.03 moles of hydrogen ion were liberated per equivalent of bromine used.

These experiments also showed that the reaction was complete within forty-five seconds after mixing, and that no further reaction took place.

Identification of Ethyl Sulfonic Acid.—The oxidation reactions were allowed to go to completion in reaction mixtures containing 12 g. of the sulfur compound and 100 g. of bromine. The water layer was separated, concentrated by evaporation, neutralized with sodium hydroxide and evaporated to dryness. After drying at 120° for three hours, the sodium ethyl sulfonate was extracted by use of hot 95% ethyl alcohol. The sodium salt was then converted to the corresponding acid chloride by the method of Marvel, Helfrick and Belsley.[4] The acid chlorides obtained boiled at 177° which compares with a boiling point of 177.5° given by Carius.[5]

Summary

1. Ethyl mercaptan and ethyl disulfide are oxidized to ethylsulfonic acid by bromine water, the oxidation requiring 3 and 5 moles of bromine per mole of the sulfur compound, respectively.

2. Ethyl mercaptan is very rapidly oxidized to ethyl disulfide by dry bromine.

The Rate of Oxidation of Ethyl Disulfide by Bromine

BY H. A. YOUNG AND M. B. YOUNG

In the preceding paper,[1] it has been shown that bromine oxidizes ethyl disulfide to ethylsulfonic acid in the presence of water, and that under proper conditions five moles of bromine are used for each mole of disulfide oxidized. While performing the experiments described in the above paper, it was noted that immediately upon the addition of ethyl disulfide to a carbon tetrachloride solution of bromine, the color of the latter changed perceptibly, becoming lighter and a more pronounced yellow. Also when excess disulfide was added to bromine, distributed between water and carbon tetrachloride, the bromine was almost completely removed from the water layer.[2] These observations suggest the rapid formation of an addition compound between bromine and ethyl disulfide. That the formation of the addition compound is reversible is shown by the fact that a known amount of bromine which has been treated for several hours

---

(1) H. A. Young, THIS JOURNAL, **59**, 811 (1937).

(2) A similar effect is noticed with iodine. Excess ethyl disulfide in carbon tetrachloride will remove enough iodine from a water layer to prevent the formation of a blue color in the presence of starch, as first noted by Sampey and Reid, *ibid.*, **54**, 3405 (1932).

with ethyl disulfide in carbon tetrachloride solution (water absent) shows no loss in oxidizing power. The purpose of the present work is to investigate the addition compound by measuring the rate of disappearance of bromine during the oxidation of ethyl disulfide in the two-phase system consisting of bromine and disulfide dissolved in carbon tetrachloride as one phase and bromine in water as the second. Since the final products of the reaction are found in the water layer, the reaction steps involving water presumably take place either across the boundary of the carbon tetrachloride or in the carbon tetrachloride itself with subsequent diffusion. The authors undertook the investigation realizing the difficulties involved in the interpretation of rate measurements in such a heterogeneous system, as pointed out by Bell,[3] yet they believe the simplicity of the obtained initial rates is significant.

Experimental Part

The desired amount of ethyl disulfide for each experiment was weighed in a weighing ampoule, and the ampoule was broken in 100 cc. of carbon tetrachloride which was at the reaction temperature and which was contained in a 300-cc. glass-stoppered flask. A bromine solution for each experiment was prepared and analyzed iodimetrically after being brought to the reaction temperature.

An experiment was carried out as follows: 100 cc. of water at 25° and 50 cc. of bromine solution were introduced, respectively, into a 300-cc. glass-stoppered conical flask. Fifteen cc. of the disulfide solution was pipetted into the flask and the mixture was then placed in a shaker in a thermostat at 25.0 ± 0.1°. Zero time was taken when half the disulfide had run into the flask. In each experiment five such mixtures were prepared. At various intervals, the flasks were removed from the thermostat, 2 g. of solid potassium iodide was added and the liberated iodine titrated with sodium thiosulfate solution.

Experimental Results

The bromine concentrations for the carbon tetrachloride layer were calculated on the assumption that all of the bromine was in the carbon tetrachloride. This point will be referred to later. These bromine concentrations were plotted as abscissas against time in minutes as ordinates, and values of $-d(Br_2)/dt$ obtained by taking slopes of the tangents. After preliminary work indicated that the values of $-dBr_2/dt$ taken at zero time were reproducible to within 5% a series of fourteen experiments was made. There were occasional inexplicable erratic points which obviously lay off the bromine–time curves.

TABLE I

REPRESENTATIVE EXPERIMENTAL DATA

	Expt. 1 R_2S_2 = 0.0133		Expt. 2 R_2S_2 = 0.00542		Expt. 5 R_2S_2 = 0.0252	
	Concentrations

300	.0371	.0336	.0597	.0555	155	.00453

In only one experiment was there more than one such point, and in that case the experiment was discarded. Table I contains the complete data for three representative experiments; Fig. 1 is the bromine–time plot for the same experiments.

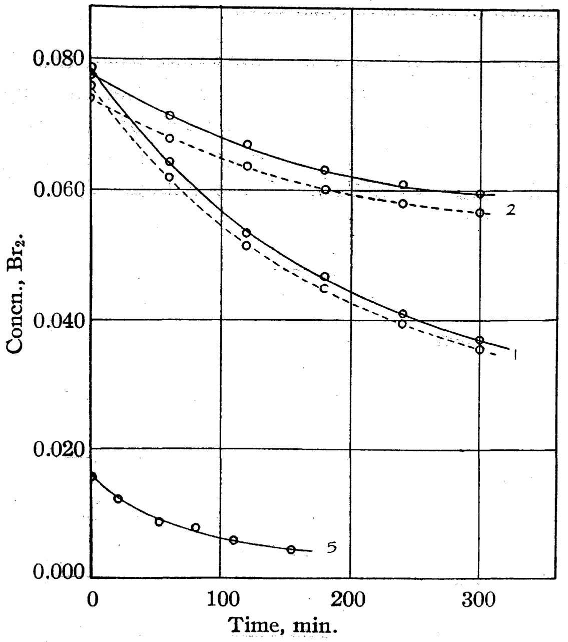

Fig. 1.—Plot of bromine concentration against time in minutes for Expts. 1, 2 and 5.

Table II contains a summary of the thirteen experiments. The initial concentrations of the reactants are given in columns two and three and the initial values of $-dBr_2/dt$ in column 4.

Discussion of Results

From the initial slopes in Expts. 1, 2 and 3, it is seen that when the concentration of bromine is high and that of disulfide low, the initial rate is independent of bromine concentration and may be expressed by the equation $-dBr_2/dt = k_1 (R_2S_2)$. The values given in column 5 of Table II indicate that k_1 has an average value of 0.020. Examination of the initial rates obtained in

[a] Expt. 12, original $H^+ = 0.10\ M$. [b] Expt. 13, shaker reduced to one-fourth usual speed.

Expts. 4, 5, 6 and 7 indicates that when the disulfide concentration is high and the bromine low, the initial rate is independent of the disulfide concentration, and may be expressed by $-dBr_2/dt = k_2(Br_2)$. From column 7, Table II, k_2 has an average value of 0.011.

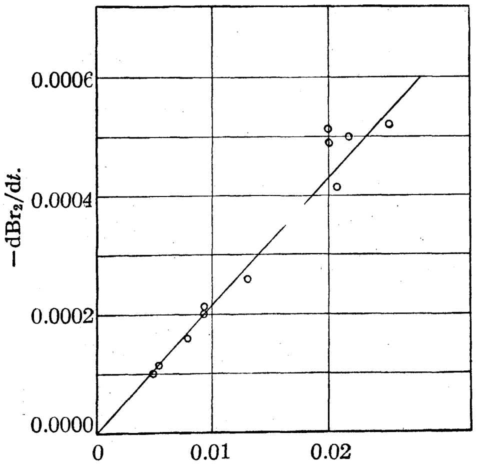

Fig. 2.—Initial rates of disappearance of bromine plotted against calculated concentration of intermediate.

The simplest explanation for the results of Expts. 1 to 7 is that the initial rate of using bromine is proportional to the concentration of a compound which is in equilibrium with one molecule of disulfide and two molecules of bromine, as represented by the equation

$$R_2S_2 + 2Br_2 \rightleftarrows R_2S_2(Br_2)_2$$

From the results of Expts. 8, 9, 10, 11 as shown in column 7 of Table II, it appears that within the limits of experimental error the formation of the addition compound is complete.

The original assumption that all the bromine is found in the carbon tetrachloride may now be seen to produce no appreciable error in the experiments in which the disulfide is in excess, for in this case all but the minute equilibrium quantity of the bromine is in the form of addition compound which is insoluble in water. With bromine in excess, however, an appreciable amount of it is in the water layer. Using 27 as the distribution ratio of bromine between carbon tetrachloride and water and assuming the concentration of the intermediate to be that of the disulfide, corrected values of bromine concentrations in the carbon tetrachloride layer were obtained and plotted against time as before for Expts. 1, 2 and 3. The corrected data for Expts. 1 and 2 are given in Table I, and the corrected plots are shown by broken curves in Fig. 1. In only Expt. 2, where the value of k_1 dropped from 0.021 to 0.020, was the corrected initial value of k_1 significantly different from the uncorrected value.

Concentrations of the addition compound, taken as one-half the bromine concentration when the disulfide is in excess and as the disulfide concentration when the bromine is in excess are listed in column 8 of Table II. These concentrations are plotted against the corresponding initial values of $-d(Br_2)/dt$ in Fig. 2. The points lie very close to a straight line of slope 0.021, so that within the limits of experimental error the initial rates are given by the expression $-d(Br_2)/dt = 0.021[R_2S_2(Br_2)_2]$. The two points which lie farthest from the line represent Expts. 10 and 11, in which the uncertainties in the slopes are probably greater than in any other of the experiments.

The rate measurements do not distinguish between intermediates of the types $R_2S_2(Br_2)_2$ and $RSBr_2$, although the existing independent evidence appears to favor the breaking of the sulfur–sulfur linkage by bromine. Zincke and Farr[4] have prepared mono-*o*-nitrophenyl sulfur bromide from the corresponding disulfide by treatment with bromine. Hunter and Sorenson[5] in their discussion of the mechanism of the reduction of sulfonyl bromides by phosphorus tribromide assumed an equilibrium of

---

[4] Zincke and Farr, *Ann.*, **391**, 67 (1912).

[5] Hunter and Sorenson, THIS JOURNAL, **54**, 3668 (1932).

the form $RSSR + Br_2 \rightleftarrows 2RSBr$. They were able to demonstrate that *o*-nitrophenyl sulfur bromide gave small amounts of *o*-nitrophenyl disulfide upon standing, but were unable to prepare the sulfur bromide from the disulfide and bromine. Zincke and Frohneburg[6] have studied the oxidation of dithiohydroquinone and thiocresol by chlorine and bromine in the presence of water and have postulated the first step to be the formation of a disulfide, followed by an intermediate of the type $RSBr_3$.

It seems probable, therefore, that the oxidation of ethyl disulfide by bromine in the presence of water takes place in steps, the first of which is a rapid reversible one of the type $2Br_2 + RSSR \rightleftarrows 2RSBr_2$. The second and rate determining step is probably the hydrolysis of the product of the first reaction, *i. e.*, $RSBr_2 + H_2O = RSO + 2HBr$. In view of the recent work of Johnson and Sprague[7] who isolated ethyl sulfonyl bromide from aqueous solutions when S-ethylisothiourea hydrogen bromide was oxidized by bromine at temperatures below 5°, and the work of Zincke and Frohneburg,[6] who showed that the ultimate oxidation product of both dithiohydroquinone and thiocresol by bromine in the presence of water was a sulfonyl bromide, it seems probable that another of the intermediate products in the system under consideration is ethyl sulfonyl bromide.

Effect of Hydrogen Ion and Rate of Shaking

The presence of hydrogen ion materially increases the initial rate as is indicated by Expt. 12. In this experiment the initial hydrogen ion concentration was 0.10 *N* and the value of k_2 obtained was 0.025 as contrasted with 0.011, the average value in the other experiments. The accelerating effect of hydrogen ion was not unexpected in view of the results of some measurements on the rate of oxidation of ethyl mercaptan by excess bromine in the presence of water. As shown in the preceding paper, the first step in the oxidation of the mercaptan is the rapid formation of ethyl disulfide with the liberation of hydrobromic acid, so that except for the presence of hydrogen ion the mercaptan experiments would be identical with those involving disulfide. The initial rates in the mercaptan experiments were found to be determined by the mercaptan concentrations, but were anomalously high. The effect of hydrogen ion upon the initial rate is being investigated further.

The effect of the rate of shaking upon the reaction rate is shown by Expt. 13 in which the speed of the shaker was reduced to one-fourth its usual value. The initial rate yielded a value of k_1 equal to 0.018, which is not far from the average value of 0.020. However, in the latter stages of this experiment the reaction rate was much slower than usual. This suggests that toward the end of the reaction the rate determining step is one of diffusion. If such is the case, the rate of using bromine in all of the experiments except number 13 might finally approach the same first order rate law. To test this hypothesis, values of $-dBr_2/dt$ at various times were plotted against calculated concentrations of the intermediate $[R_2S_2(Br_2)_2]$ (Fig. 3). The curves in that plot appear to approach a straight line of slope 0.014.

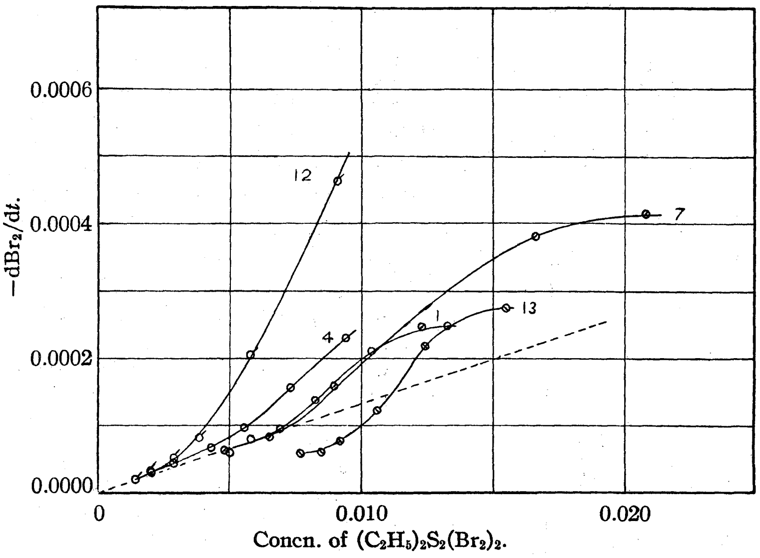

Fig. 3.—Rates of disappearance of bromine plotted against calculated concentration of intermediate.

Summary

1. The rate of the reaction between carbon tetrachloride solutions of bromine and ethyl disulfide in the presence of water has been measured at 25°.

---

[6] Zincke and Frohneburg, *Ber.*, **42**, 2721 (1909); **43**, 1348 (1916).

[7] Johnson and Sprague, THIS JOURNAL, **58**, 1348 (1936).

2. The initial rates have been shown to be represented by the equation $-dBr_2/dt = k \times [R_2S_2(Br_2)_2]$ where k is a function of the rate of shaking.

3. The first steps in the oxidation of ethyl disulfide by bromine in the presence of water are suggested as

$$R_2S_2 + 2Br_2 \rightleftarrows 2RSBr_2, \text{ and} \qquad (1)$$

$$RSBr_2 + H_2O = RSO + 2H^+ + 2Br^- \qquad (2)$$

Raman Spectra. II. Monomethoxy Derivatives of Ethyl Benzoate

BY DOROTHY D. THOMPSON

The Raman spectra of several derivatives of benzoyl chloride were determined[1] in an attempt to find a relationship between this property and the rates of esterification of the acid chlorides, and these spectra were compared with those of the corresponding ethyl esters.[2] Since, however, the spectra of the methoxy derivatives of ethyl benzoate had not been determined, it was thought advisable to prepare them and study their Raman spectra.

Experimental

Apparatus.—The same Hilger E-439 glass spectrograph,[3] system of filters, light source, Raman tube and photograph plates were employed as were described in a previous paper.[1] The frequencies of the lines were determined as before except that the deviation curves were made from the difference from linear dispersion in terms of wave numbers instead of wave lengths. The accuracy is about the same as before (±1 for the strong, sharp lines, but a greater error up to ±4 cm.$^{-1}$ for very weak diffuse lines).

Purification of Compounds.—The esters were prepared from the corresponding acid chloride and absolute alcohol or by the action of absolute alcohol saturated with hydrogen chloride on the corresponding acid (*o*-methoxybenzoic acid prepared by methylation of salicylic acid with dimethyl sulfate; *p*-methoxybenzoic acid was Eastman White Label). The esters were washed rapidly with ice-cold sodium carbonate and several times with cold water, then dried over calcium chloride. They were distilled *in vacuo* from an ordinary Claisen flask several times or until the index of refraction of the major portion remained constant. One distillation through a modified Vigreux[4] column showed that the boiling point range was in every case not greater than 0.2°. The densities were determined in the usual way with a pycnometer having a capacity of 5 ml. The average deviations of three to five independent determinations never exceeded one part in twenty thousand. The calculations were made in the usual way correcting for the buoyancy of air and for the expansion of glass. The indices of refraction were measured with an Abbé refractometer and the molecular refractions calculated from the equation of Lorenz and Lorentz.

Data

Explanation of Tables.—The values of the Raman spectra have been summarized in the usual way. The value for the Raman shift is followed by a number in parentheses indicating the relative intensity (estimated)—the large numbers indicating greater intensity, the letter "b" for broad and "d" for diffuse. This is followed by letters indicating the mercury exciting lines as follows: a = 24,705 cm.$^{-1}$, b = 24,516 cm.$^{-1}$, c = 23,039 cm.$^{-1}$, d = 22,995 cm.$^{-1}$ and e = 22,938 cm.$^{-1}$. Each compound was photographed four times—twice with "Greenish Nultra" filter only, with long and short exposure times, once with "Greenish Nultra" + quinine sulfate, and once with "Red-Purple Ultra" glass + sodium nitrite. Each Raman line occurred on at least two plates unless indicated with a *.

Ethyl *o*-Methoxybenzoate.—Boiling point 104.4–104.5° at 2 mm.; n^{20}_D 1.5224; d^{20}_4 1.1124; d^{25}_4 1.1077; R_M calcd. 48.40, obsd. 49.42.

Discussion

When the Raman spectra of these methoxy derivatives of ethyl benzoate are compared with the spectra of other esters which have substituents in corresponding positions, one striking difference appears. The number of weak lines of frequency difference of less than 600 cm.$^{-1}$ is much greater in each of these new spectra than in that of any other corresponding ester—even greater than in the spectrum of its acid chloride. Nor does this seem to be due to a shift toward lower frequencies of normally occurring higher frequencies since the correspondence of the rest of the spectra is almost perfect for all three position substitutions. The difference is probably not due to a difference in technique, for the comparison of the spectra of the acid chlorides determined by the author[1] shows no such disagreement with those of the same compounds determined by Kohlrausch, Pongratz and Stockmair.[5] Perhaps there is a relationship between this phenomenon and the optical exaltation to 1 ml. observed for ethyl *o*-methoxybenzoate of 2 ml. for the para derivative. Although no significant reason for this large number of low frequencies in the methoxy compounds can be advanced now, it was felt that the data should be published so that they will be available for interpretation when Raman spectra are better understood.

Summary

The Raman spectra of pure methoxy derivatives of ethyl benzoate have been determined and compared with the spectra of other derivatives of ethyl benzoate and of benzoyl chloride. The boiling points, densities, indices of refraction and molecular refractions for these compounds have, also, been determined and recorded.

The Infrared Absorption of Mixtures of Methyl Alcohol with Ethyl Formate and with Ethyl Acetate

BY DUDLEY WILLIAMS[1] AND WALTER GORDY[2]

Recently a series of experiments[3] has been made on the infrared absorption spectra of water, alcohol, and aniline in various solutions of other liquids. In every case when the solvent contained the strongly electronegative atoms, oxygen or nitrogen, having unshared electron pairs, pronounced changes were observed in the intensity and position of the vibrational OH band of alcohol and water, and in the NH band of aniline. In some cases certain changes were likewise observed in the spectrum of the solvent. For example, in mixtures of alcohol with acetone the vibrational band of the OH alcohol group was shifted to the shorter wave lengths, and its intensity was increased, while the CO band of acetone was shifted to the longer wave lengths and its intensity was increased correspondingly. It was suggested that these results indicate some type of interaction, possibly the formation of hydrogen bonds between the solute and solvent molecules. For the purpose of determining whether these results indicate some general type of interaction, the study has been continued, and in the present article results obtained from observations of the absorption spectra of different mixtures of methyl alcohol with ethyl formate and with ethyl acetate are discussed.

Experimental

The apparatus and experimental method were the same as those used in the previous investigations[3] and will not be described here. The methyl alcohol and ethyl acetate were Baker "Certified Products." The ethyl formate was prepared by the action of formic acid on absolute ethyl alcohol, the ethyl formate being fractionated off during the reaction.

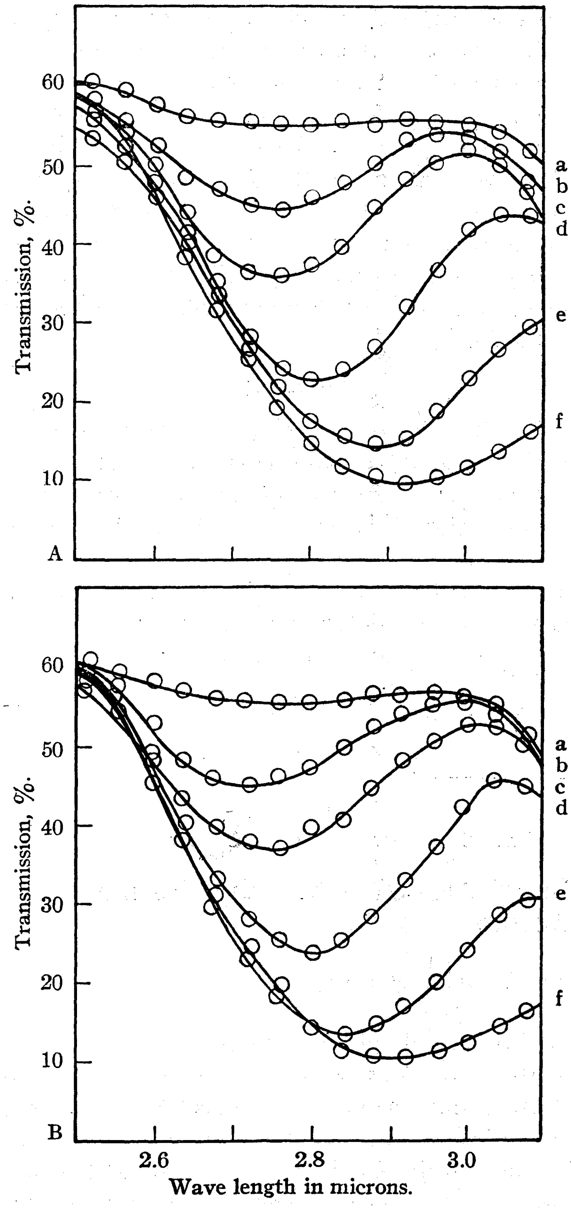

Fig. 1.—A. Transmission of methyl alcohol–ethyl formate mixtures: (a) pure ethyl formate; (b) 6.25% alcohol; (c) 12.5% alcohol; (d) 25% alcohol; (e) 50% alcohol; (f) pure alcohol. B.—Transmission of methyl alcohol–ethyl acetate mixtures: (a) pure ethyl acetate; (b) 6.25% alcohol; (c) 12.5% alcohol; (d) 25% alcohol; (e) 50% alcohol; (f) pure alcohol.

Results

The effects of ethyl acetate and of ethyl formate on the fundamental vibrational band of the OH alcohol group will be evident from Fig. 1. The center of the band in pure methyl alcohol appears at 2.9 μ. When the alcohol is mixed with either of the esters the band appears at shorter wave lengths, and the magnitude of the shift increases as the ester concentration in the mixture is increased. For alcohol concentrations as low as 12.5% in either ester the center of the band appears at about 2.74 μ. The intensity of the band does not decrease in proportion to the number of absorbers. This will be evident from a comparison of some of the experimental curves with theoretical ones for the same mixtures, computed on the assumption that neither component of the mixture influences in any way the spectrum of the other. In Fig. 2 the theoretical curves for mixtures of 12.5 and 6.25% methyl alcohol in ethyl acetate are shown with the experimental curves for the same mixtures. The method used in determining the theoretical transmission of a

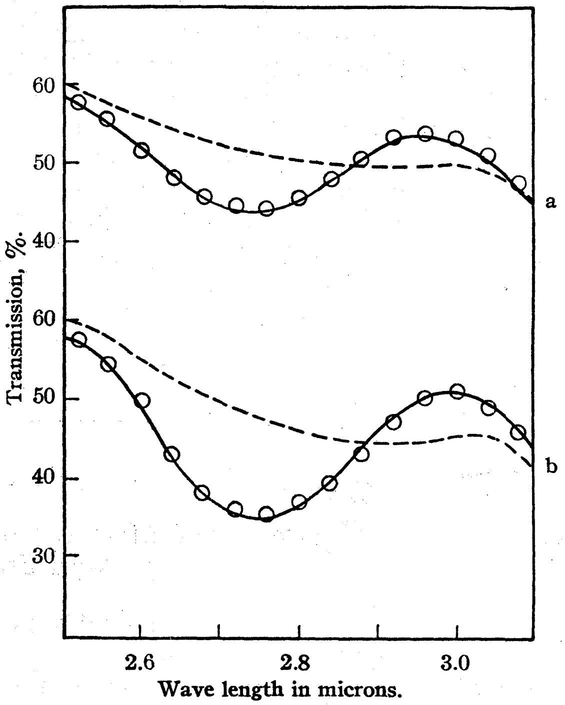

Fig. 2.—Comparison of theoretical with experimental transmission of some methyl alcohol–ethyl acetate mixtures: (a) 6.25% alcohol; (b) 12.5% alcohol.

mechanical mixture has been given in a previous paper[3c] and will not be repeated.

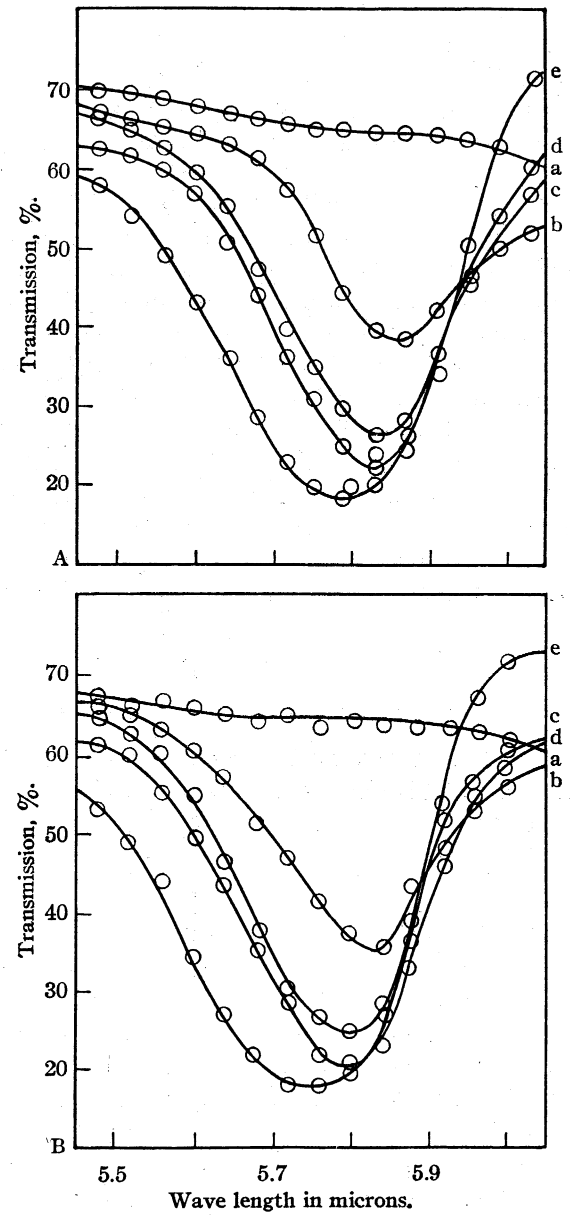

Fig. 3.—A. Transmission of methyl alcohol–ethyl formate: (a) pure alcohol; (b) 6.25% ethyl formate; (c) 12.5% ethyl formate; (d) 25% ethyl formate; (e) 50% ethyl formate; (f) pure ethyl formate. B.—Transmission of methyl alcohol–ethyl acetate mixtures: (a) pure alcohol; (b) 6.25% ethyl acetate; (c) 12.5% ethyl acetate; (d) 25% ethyl acetate; (e) 50% ethyl acetate; (f) pure ethyl acetate.

The vibrational band of the CO group in ethyl formate appears at about 5.79 μ, and in ethyl acetate it appears at about 5.75 μ. Figure 3 shows the effects of methyl alcohol on this band. In each of the esters the band is shifted to the longer wave lengths, and its intensity is increased by the methyl alcohol. The shift amounts to 0.08 μ for alcohol concentrations of 88.5%. Theoretical curves for two of the mixtures are given in Fig. 4. A study was also made of the effects of alcohol on the band appearing at about 8 μ in the two esters. No shifts in the position of the band could be detected. The curves for these mixtures are not shown. Due to the overlapping of bands of the two components it was not found practicable to study other bands appearing between 2.5 and 8.5 μ. The CO band of ethyl acetate was studied for various concentrations of ethyl acetate in isopropyl ether. The ether does not produce shifts and intensity changes in the band as does alcohol.

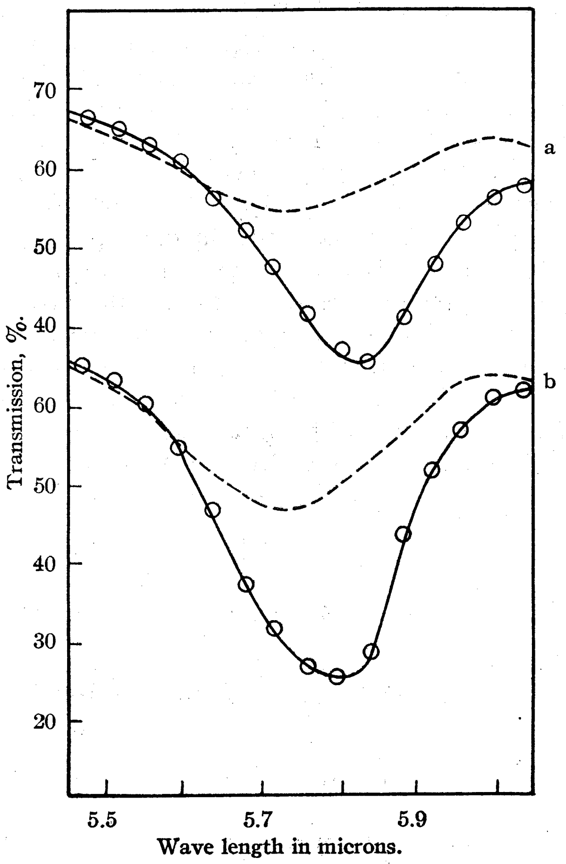

Fig. 4.—Comparison of theoretical with experimental transmission of some methyl alcohol–ethyl acetate mixtures: (a) 12.5% ethyl acetate; (b) 25% ethyl acetate.

Discussion

Since the discovery of the hydrogen bond[4] it has been generally believed that alcohols in

---

[4] W. M. Latimer and W. H. Rodebush, THIS JOURNAL, **42**, 1419 (1920).

the liquid state are associated through the formation of hydrogen bonds. The OH band appears at longer wave lengths and is much broader in the liquid than in the vapor state.[5] The changes in the character of this band as the alcohol passes from the vapor state to the liquid state are evidence that the OH group participates in the association process. Although in ethyl acetate and in ethyl formate the OH band is shifted to the shorter wave lengths, and this may indicate the breaking of hydrogen bonds between the alcohol molecules, the band does not become sharp, as it does for alcohol in the vapor state. It may be possible to interpret these results by assuming that as the ester content in the mixture is increased the polymerization of the alcohol is decreased and that the alcohol becomes associated to some degree with the ester through the formation of weak hydrogen bonds between the hydroxyl group of the alcohol and the carbonyl group of the ester. This would account for the shift to the longer wave lengths and the increase in intensity of the band associated with the carbonyl group, and it is in accord with the results of the previous investigations.[3]

The writers wish to express gratitude to Dr. E. K. Plyler for the use of his laboratory facilities.

Summary

Ethyl formate and ethyl acetate were found to shift the OH band of methyl alcohol to the shorter wave lengths and to increase its intensity. The CO band of the esters was shifted to the longer wave lengths by the alcohol, and its intensity was increased correspondingly. As a possible means of accounting for these results it was suggested that the esters may tend to decrease the polymerization of the alcohol, and to become associated with it, to some degree, through the formation of weak hydrogen bonds.

The Pinacol Rearrangement of *cis*- and *trans*-1,2-Dimethylcyclohexanediol-1,2 and the Relationship of the Walden Inversion to the Mechanism of Molecular Rearrangements

BY PAUL D. BARTLETT AND IRVING PÖCKEL

The course of a molecular rearrangement has been observed in some cases to depend upon the conditions of the rearrangement[1] and upon the configuration of the rearranging compound.[2] The dependence of the course of reaction upon configuration in the alicyclic series has been studied hitherto only for cases of *semi*-pinacolic rearrangements such as that of 1-methylcyclohexanediol-1,2. When the *cis*-isomer of this compound forms 2-methylcyclohexanone on dehydration, it is ascribed to a direct elimination of water, molecular rearrangement occurring to an important extent only in the *trans*-isomer, where ring contraction makes the rearrangement evident.

We have undertaken the study of an actual pinacol rearrangement, where vinyl dehydration is impossible, and where the results tell us directly the effect of configuration upon the relative ease of migration of two organic radicals. There is little doubt of the configurations of the 1,2-diols in the cyclohexane series. The ultimate criterion in this series is the resolution of the *trans*-cyclopentanediol and *trans*-cyclohexanediol into optical isomers.[3] A number of independent criteria, most of them due to Böeseken and his co-workers, support the generalization that where the two isomeric diols can be prepared, one by hydration of the corresponding epoxide and the other by aqueous permanganate oxidation of the corresponding cyclohexene, the former has the *trans* and the latter the *cis* configuration. The isomeric 1,2-dimethylcyclohexanediols-1,2 have been prepared by these methods, and hence although neither of them has been resolved, their configurations are known with a high degree of probability.

The *trans*-pinacol, m. p. 92–92.5°, prepared by hydrolysis of the oxide, was rearranged by Namet-

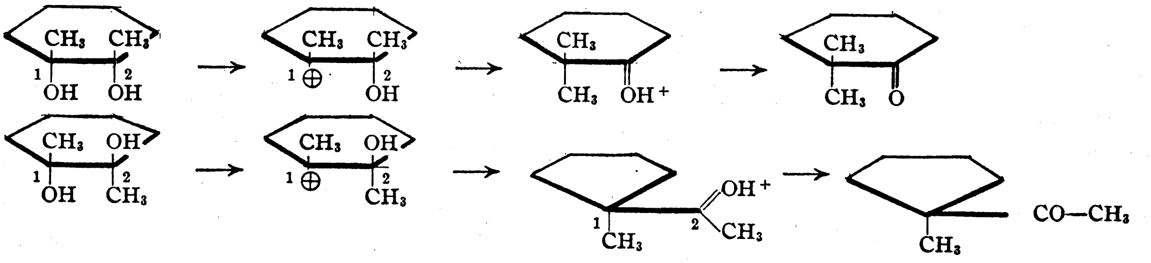
kin and Delektorsky[4] and found to give 1-methyl-1-acetylcyclopentane in 78% yield (semicarbazone, m. p. 140.5–141°). We repeated this experiment for the sake of standardizing our conditions and then, using the same procedure (boiling with 20% sulfuric acid), carried out the rearrangement of the *cis*-pinacol, m. p. 38.5–39.1°, prepared by the action of aqueous permanganate on 1,2-dimethylcyclohexene-1. The sole product of this rearrangement was 2,2-dimethylcyclohexanone, whose semicarbazone, m. p. 202–204° with decomposition, was isolated in 74% yield and unmixed with any of its lower melting isomer.

These observations have an important bearing on the mechanism of the pinacol rearrangement. This reaction is included by Whitmore among those rearrangements which proceed because a carbon atom exists with an "open sextet" of electrons,[5] which becomes completed by the migration of an organic radical with its electron pair. Despite the success of this theory in correlating facts and predicting the course of reactions, its users have been rather cautious not to speak literally of positive carbonium ions. Recently skepticism has been growing concerning the actual existence of such ions in metathetical reactions.[6]

In the present reaction we are dealing with the relative migration aptitudes of two groups, the methyl group and that group which is a part of the cyclohexane ring.



The space relations cannot be pictured exactly, since the cyclohexane ring is non-planar and the *cis* groups may be at any angle to each other within a range of angles determined by the mobility of the ring. However, the *average* positions of the groups, if the ring is mobile, are shown in the formulas. In the *cis*-pinacol, the ring carbon atom and the methyl group which migrates are about equally remote from the hydroxyl group which is eliminated in the reaction. In the *trans*-pinacol, the ring carbon atom which migrates is much more remote from the replaced hydroxyl group than the methyl. In other words, a group migrates by preference which is located in space near the ***opposite side*** of carbon atom No. 1 to that occupied by the hydroxyl group which is to be replaced. This is inconsistent with the idea that the hydroxyl group is actually removed before the migration occurs, for then the radical most accessible to the open spot on carbon No. 1 would surely be the one to migrate. The fact that different products result from the two stereoisomers also excludes the formation of a racemizable "open sextet," as do the pinacolic and semi-pinacolic deaminations of McKenzie,[7] which yield optically active products. There remains only the possibility that the migration of carbon and the expulsion of the hydroxyl are simultaneous processes. The preferred migration of the radical situated near the back side of the carbon atom No. 1 brings out a very strong resemblance between the pinacol rearrangement and those replacement reactions[8] in which it has been so elegantly shown that Walden inversion attends every act of replacement. Whether or not a Walden inversion mechanism is the only one by which a pinacol rearrangement occurs, this case in which the inversion mechanism is the preferred one seems to justify the modification of the "open sextet" theory as indicated in the scheme

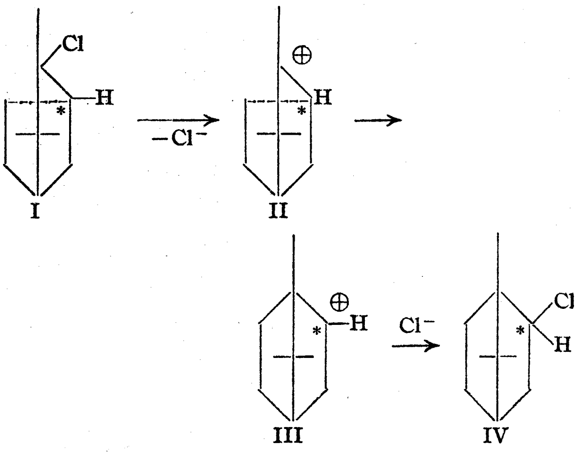
A similar mechanism was written by Wallis and Bowman[6] for the more complicated case of a dehydration by thionyl chloride.

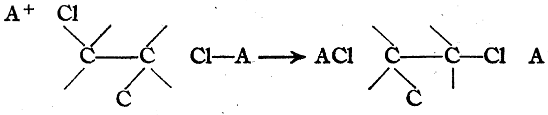
The "open sextet" theory has been of the greatest service in correlating the facts of the Wagner–Meerwein rearrangement. The extensive and careful work of Meerwein and van Emster[9] showed that the conversion of camphene hydrochloride (I) into isobornyl chloride (IV), which is promoted by solvents like sulfur dioxide, cresol, and nitromethane, and by such catalysts as hydrogen chloride, stannic and ferric chlorides, could be formulated as follows



From the standpoint of the existence of free ions, it is a most remarkable property of this rearrangement that of the two possible stereoisomeric chlorides, differing in the configuration of the starred carbon atom, only one—isobornyl chloride—is the direct product. Its isomer, bornyl chloride, is nevertheless the more favored at equilibrium, and is produced very slowly by the same reagents on long standing. The bond represented by the dotted line in the camphene formulas is, in space, behind the vertical bond which it crosses in the diagram. Therefore, if the simple ionization picture were correct, the only explanation for the formation of isobornyl chloride would be that the chloride ion caught the ion III with its open face still to the rear, in the place vacated by the migrating bond. This demands that isobornyl chloride should have the "endo" configuration, advocated by Lipp,[10] rather than the "exo" assignment of Vavon[11] and Hückel.[12] The recent work of Asahina, Ishidate and Sano[13] has shown that isoborneol in fact possesses the "exo" configuration.

It is not rigorously certain that isobornyl chloride is configuratively related to isoborneol, but all evidence points in this direction. This chloride is produced from borneol under conditions normally leading to Walden inversion.[14] Furthermore, the Wagner–Meerwein rearrangement can be duplicated with an acetate radical instead of the chlorine, by treating camphene with acetic and sulfuric acids (Bertram–Walbaum reaction), and the product in this case is isobornyl acetate, which can be hydrolyzed normally to isoborneol, almost certainly without change of configuration.

We can only conclude that the Wagner–Meerwein rearrangement involves complete Walden inversion at the starred carbon atom. This is incompatible with any reasonable deductions from the literal open sextet theory, and is equally incompatible with a series of steps involving solvated carbonium ions which undergo inversion at every reaction. It is completely compatible with a "push and pull" theory analogous to the one advanced by Lowry[15] for acid–base catalysis, in which donors and acceptors of protons are replaced by donors and acceptors of chloride ions, and a Walden inversion occurs at each replacement involving the halogen ion. Such a mechanism may be represented schematically thus



In this representation ACl is any compound capable of yielding a chloride ion, and the three carbon atoms are those three of the camphene-isobornyl system which actually participate in the rearrangement.

Meerwein and van Emster state that the rearrangement is a first order reaction, and this can of course not be literally true if the mechanism we have outlined is correct. Two observations of these authors show the way to the explanation. In the first place, hydrogen chloride is a powerful catalyst for the rearrangement;

[15] Lowry and Faulkner, *J. Chem. Soc.*, 2883 (1925); Lowry, *Chem. Rev.*, **4**, 231 (1927).

and in the second place, hydrogen chloride is always present in any solution of camphene hydrochloride, for this compound dissociates rapidly and reversibly into hydrogen chloride and camphene. In most of the solutions used by Meerwein the degree of dissociation was determined as being between 5 and 10%, and the dissociation equilibrium was established rapidly enough to be maintained throughout the reaction.

Now, either hydrogen chloride or the free chloride ion might act as a chloride donor, and either hydrogen chloride or solvated hydrogen ion might act as a chloride acceptor. The purpose of the present discussion is not to decide among these possibilities, but to present a recalculation of the kinetic data of Meerwein and van Emster, showing that two different kinetic formulations, based upon the "push and pull" theory, both fit these data better than the first order formulation used by the original investigators.

If x is the concentration of camphene hydrochloride, at equilibrium with a small concentration y of hydrogen chloride and of camphene, then at all times

$$y^2 = K^2x$$

where K^2 is the equilibrium constant of dissociation. In most of the solvents employed, it is proper to treat the hydrogen chloride thus as completely non-ionized, for they are solvents of far less basicity than water or the alcohols. We may now suppose two alternative kinetic situations, which are representative but do not exhaust the possibilities.

CASE I.—Suitable collision between the camphene hydrochloride and a single hydrogen chloride molecule, acting as either donor or acceptor (or a hydrogen and a chloride ion), is sufficient to bring about reaction. In this case

$$-\mathrm{d}x/\mathrm{d}t = kxy = kx \times K\sqrt{x} = kKx^{3/2}$$
$$\text{and} \qquad 1/\sqrt{x} - 1/\sqrt{x_0} = (1/2)kKt$$

where x_0 is the initial value of x.

CASE II.—The reaction is brought about by suitable collision between a camphene hydrochloride molecule and *two* hydrogen chloride molecules (one acting as donor and one as acceptor). Then

$$-\mathrm{d}x/\mathrm{d}t = kxy^2 = kK^2x^2, \qquad \text{and}$$
$$(1/x) - (1/x_0) = kK^2t$$

These assumptions lead, respectively, to 3/2-order and to second-order kinetic equations.

Meerwein and van Emster report the original data for reaction in ten solvents, of which one run, that with petroleum ether as solvent, was so slow that it was carried only to about 10% of total reaction. The other nine were followed to about 60% reaction. In order to make the fairest possible comparison between the first, three-halves, and second order formulations for these nine runs we have used the method of normal equations to pass the best straight line, in each of the twenty-seven cases, through the points which are supposed to lie on a straight line. The mean deviations of the points from the straight line have then been reduced to a common scale, with the slope of each line taken as the unit, so that the reduced mean deviations represent the fractional error in the value of k which would be made by computing k from two points an hour apart, one of which was in error by the mean deviation. This procedure eliminates the undue emphasis on the initial point of each curve which is inherent in the method used by Meerwein and van Emster.[15a] In each case the first value of k as determined by them is much lower than those determined from subsequent points. This is in accordance with the "push and pull" mechanism, which demands a short incubation period while the camphene hydrochloride is dissociating, but the least squares treatment shows that the second point is by no means so far off the curve as is suggested by the successive constants of Meerwein and van Emster.

As an example of this treatment we may show the fitting of a second order kinetic equation to the data on the rearrangement in benzene at 40°. The solution of the normal equations leads to the most probable straight line given by

$$1/x = 0.00995 + 0.0000496t$$

in which for convenience the unit of x is taken as one-hundredth of the initial concentration (Meerwein's results are tabulated in terms of per cent.). In the following table, the values in the "calculated" column are those obtained with the use of this equation.

The superiority of this formulation over the 3/2-order and first order is shown both by its lower reduced mean deviation (Table II) and by the

---

(15a) Even the method used by Meerwein and van Emster leads to the same conclusions with regard to the order of the reaction. We have also applied a more exact formulation taking into account the fact that not x, but $x + y$, is the quantity whose rate of change determines the order of the reaction. This formulation also produces no change in the conclusions, and makes such a minor correction in each case that for our present purpose the simpler formulation seems preferable.

TABLE I

RATE OF REARRANGEMENT OF CAMPHENE HYDROCHLORIDE IN BENZENE AT 40°

Hours	$1/x$ (obsd.)	$1/x$ (calcd.)	Deviation × 10^5
0	0.01000	0.00995	− 5
17	.01066	.01079	+13
42	.01205	.01203	− 2
66	.01310	.01322	+12
95	.01502	.01466	−36
143	.01696	.01704	+ 8
192	.01941	.01947	+ 6
		Average	12

Reduced mean deviation = 0.00012/0.0000496 = 2.36

fact (Table I) that the deviations alternate in sign, indicating that the points are without trend, while the signs of the deviations in the other two formulations clearly indicate a curvature.

Table II summarizes the results of the comparison of formulations for the nine solvents.

TABLE II

COMPARISON OF FIRST, THREE-HALVES AND SECOND-ORDER FORMULATIONS FOR THE WAGNER–MEERWEIN REARRANGEMENT IN VARIOUS SOLVENTS

		Reduced mean deviation for order of reaction		
Solvent	Temp., °C.	First	Three-halves	Second
Chlorobenzene	40	3.17	1.16	0.79
Benzene	40	6.69	3.81	2.36
Nitromethane	20	0.12	0.06	0.05
Ethyl bromide	40	3.08	1.89	.84
Acetonitrile	20	0.52	0.15	.08
Benzonitrile	20	.97	.51	.20
Nitrobenzene	20	.40	.17	.25
Anisole	40	1.45	.54	.73
Bromobenzene	40	1.36	.58	.67

It should be mentioned that as measures of precision the reduced mean deviations as we have taken them are only horizontally comparable; multiplication for each run by the total number of hours of the run would make them vertically comparable in the table, but would not affect the comparison between different methods of formulation.

It is seen that for the first six solvents in the table the second-order formulation is the best; for the last three solvents, the three-halves order formulation is the best; and in all cases the first-order is much the worst. Further experimental work, which is being undertaken in this Laboratory, will be necessary to decide specifically the mechanism of this process, and to sort out the various types of "pushes and pulls" which might lead to these or intermediate orders of reaction.[16] Meanwhile, we can only be impressed with the excellence of the pioneer experimental work of Meerwein, which after fifteen years of accumulated experience still throws new light on this difficult problem.

Experimental

cis-1,2-Cyclohexanediol-1,2 was prepared by the method of Wallach.[17] It was crystallized from hexane with the aid of solid carbon dioxide, and melted at 38.5–39.1°.

Rearrangement of the *cis*-Pinacol.—0.43 g. of the *cis*-pinacol was boiled with 20% sulfuric acid and the product, a ketone of peppermint-like odor, was removed by steam distillation. The semicarbazone was prepared directly by allowing the product to stand with 0.34 g. of semicarbazide hydrochloride and 0.40 g. of sodium acetate in 40 cc. of water. The semicarbazone was obtained in a yield of 0.41 g. (74.2% based on the pinacol) and melted at 202–204° (dec.). 2,2-Dimethylcyclohexanone-1 and its semicarbazone have been made by Meerwein,[18] and by Auwers and Lange.[19] The melting point given by Meerwein is 200–201°. The isomeric ketone from the rearrangement of the *trans*-pinacol yields a semicarbazone melting at 140.5–141°.[20]

Summary

1. The pinacol rearrangement of 1,2-dimethylcyclohexanediol-1,2 takes different courses for the *cis*- and *trans*-isomers, a carbon atom migrating in each case which is, on an average, remote in space from the adjacent hydroxyl group which it replaces.

2. An interpretation of the pinacol rearrangement as involving Walden inversion at the carbon atom where replacement occurs is derived from these facts.

3. The modification of the "open sextet" theory so introduced, if extended to the Wagner–Meerwein rearrangement of camphene hydrochloride into isobornyl chloride, is consistent with the configurations of borneol and isoborneol recently assigned by chemical methods, while a literal "open sextet" theory is not.

4. It now becomes necessary to regard this Wagner–Meerwein rearrangement, not as a spontaneous intramolecular process, but as one involving donors and acceptors of chloride ion, quite analogous to the acid–base catalysis of Lowry.

5. A thorough recalculation of the kinetic data of Meerwein and van Emster shows that

---

(16) A hydrogen ion as acceptor and a hydrogen chloride molecule as donor would lead to a reaction of the 7/4 order.

(17) Wallach, *Ann.*, **396**, 280 (1913).

(18) Meerwein, *ibid.*, **405**, 143 (1914).

either a three-halves order or a second order formulation of this rearrangement, derivable from the donor-acceptor theory, will fit the facts better than the first-order formulation used by these authors.

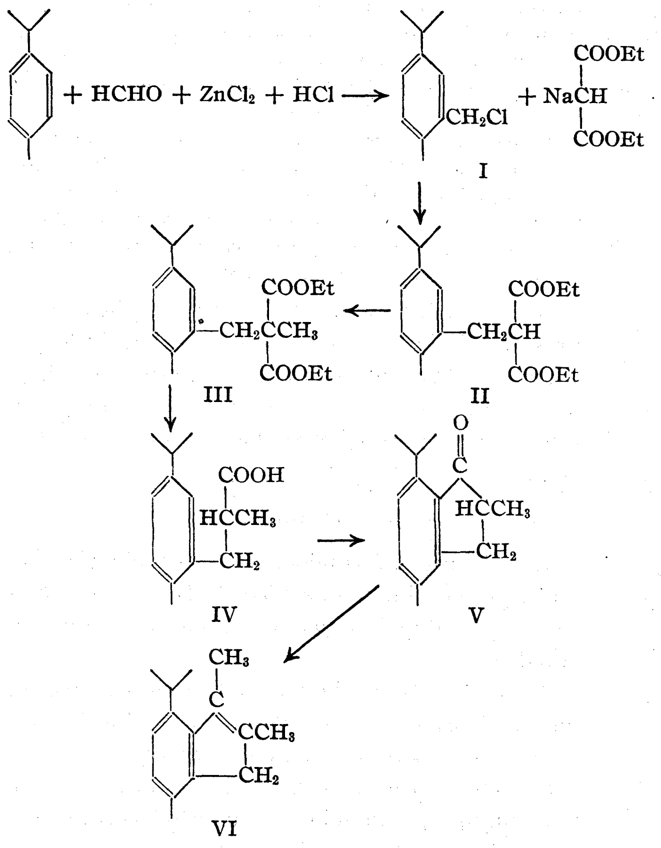
The Synthesis of 1,2,4-Trimethyl-7-isopropylindene

BY WALTER G. WHITTLESTON

The following equations represent the manner in which the synthesis of 1,2,4-trimethyl-7-isopropylindene was carried out



The synthesis was carried out with the object of producing a substance which on reduction and dehydrogenation would yield a compound of the structure .

Owing to shortage of materials and time, this was not completed.

The Introduction of the Chloromethyl Group into *p*-Cymene.—The first method attempted was that of Rapson and Short[1] in which *p*-cymene, anhydrous zinc chloride and paraformaldehyde were stirred into an emulsion and dry hydrogen chloride bubbled through the rapidly stirred mixture. This method was unsuccessful. It may be mentioned here that the yield obtained by the above authors, calculated on the basis of the amount of *p*-cymene taken at the start of the preparation, was 43%, and not the higher figure which they give.

The method due to Blanc[2] was finally employed, 40% aqueous formaldehyde being used in the place of paraformaldehyde. By employing apparatus in which the hydrogen chloride was distributed to the reaction mixture by a rapidly rotating hollow paddle stirrer, and keeping the temperature at 60° in a thermostatic bath, together with the use of nickel chloride as a catalyst, it was possible to get better yields than those of Blanc. The use of a small amount of nickel chloride reduced the production of tarry by-products in the reaction, and so made it much more efficient and convenient.

The preparation of diethyl methyl-(2-*p*-cymylmethyl)-malonate was carried out using the usual methods. This substance was saponified and decarboxylated. The acid chloride was prepared by the use of thionyl chloride, and after removal of the hydrogen chloride and sulfur dioxide by boiling, ring closure was effected by the addition of anhydrous aluminum chloride. The resultant ketone on treatment with methylmagnesium iodide gave 1,2,4,-trimethyl-7-isopropylindene.

Experimental

All temperatures are uncorrected. I. 2-*p*-Cymylmethyl Chloride.—Fifty grams of *p*-cymene, 20 g. of zinc chloride (anhyd.), 1 g. of nickel chloride and 40 g. of 40% formalde-

---

[1] Rapson and Short, *J. Chem. Soc.*, 128 (1933).

[2] Blanc, *ibid.*, Ai, 549 (1923).

hyde were stirred together, and hydrogen chloride passed through, a temperature of 60° being maintained. After eight hours, the reaction mixture was steam distilled.

It was found better to use the small quantities mentioned, and to carry out many preparations, rather than to use larger quantities. Automatic apparatus requiring little attention facilitated the use of long reaction times; yield, 47 g. (69%) of a colorless liquid; b. p. 123–124° (20 mm.). A Stepanov chlorine determination gave 19.8% chlorine ($C_{11}H_{15}Cl$ requires 19.5%).

II. Diethyl (2-*p*-Cymylmethyl)-malonate.—Six grams of sodium was dissolved in a benzene solution of 40 g. of malonic ester, and 44 g. of 2-*p*-cymylmethyl chloride added. After boiling until the sodio derivative had disappeared, the reaction mixture was treated with water, and the benzene layer separated, dried and distilled. The required ester had a b. p. of 190–195° (9 mm.); yield 55 g. (60%).

III. Diethyl Methyl-(2-*p*-cymylmethyl)-malonate.—Four grams of sodium was dissolved in a benzene solution of 40 g. of *p*-cymylmethylmalonic ester. When the sodium had dissolved, 24 g. of methyl iodide was added. After boiling for two hours, the mixture was treated as in II; yield 32 g. of material (76%); b. p. 182–187° (8.5 mm.).

IV. Methyl (2-*p*-Cymylmethyl)-malonic Acid.—Twelve and eight-tenths grams of sodium was dissolved in 256 cc. of rectified spirits, and 48 g. of methyl (2-*p*-cymylmethyl)-malonic ester was added. After refluxing for four hours, the mixture was diluted with water and the excess alcohol distilled off. The aqueous solution of the sodium salt was extracted with ether and then acidified with hydrochloric acid. The organic acid was separated by filtration and dried in a vacuum desiccator, yield 95%.

The dibasic acid, after careful heating over a gauze followed by distillation at 12 mm., gave an oily liquid of b. p. 189–190° (12 mm.).

2-*p*-Cymylpropionic acid was prepared in the same way as the above, but omitting the introduction of a methyl group (step III). The corresponding dibasic acid in this case was a solid of m. p. 165°. On decarboxylation, a crystalline monobasic acid of b. p. 190–195° (20 mm.), and m. p. 76.5° was obtained. Equivalent weight by titration 210; by silver salt analysis 205.7 ($C_{13}H_{18}O_2$ requires 206.0).

The 3-*p*-cymylpropionic acid obtained by Cook, *et al.*,[3] has a m. p. of 61–62°. This indicates that the chloromethyl group definitely enters position 2 as has been supposed, in the initial synthesis.

V. 2,4-Dimethyl-7-isopropylhydrindone.—2-*p*-Cymylisobutyryl chloride was prepared by treating 20 g. of the isobutyric derivative with 15 g. of thionyl chloride dissolved in petroleum ether free from aromatic hydrocarbons. After keeping at 60° for two to three hours, the temperature was raised, thus removing the sulfur dioxide and most of the hydrogen chloride formed.

The acid chloride was not isolated, but 12 g. of anhydrous aluminum chloride was added slowly. The product was heated on the water-bath for two to three hours, decomposed with dilute hydrochloric acid, and extracted with petroleum ether. Distillation yielded 15 g. of material, b. p. 147–150° (9 mm.). It was not found possible to crystallize the product which appeared to be contaminated with a highly colored impurity of similar boiling point.

VI. 1,2,4-Trimethyl-7-isopropylindene.—One and two-tenths grams of magnesium was dissolved in 6.0 g. of methyl iodide in anhydrous ether, and 8 g. of the ketone added. This reaction yielded 4 g. of a substance, which, on recrystallization from absolute ethanol, formed colorless, silky, acicular crystals with a high refractive index. The substance melted at 99.5°, and boiled with slight decomposition at 140–145° (10 mm.).

Analysis gave C, 89.7; H, 10.07. ($C_{15}H_{20}$ requires C, 90.0; H, 10.0.) This indicates that the elements of water have been lost, yielding the corresponding unsaturated indene derivative. The substance was found to absorb bromine readily, and to form a picrate consisting of fine, brick-red, acicular crystals, m. p. 88–89°.

Acknowledgments.—The author wishes to express his indebtedness to the late Dr. J. K. H. Inglis for his suggestions and kindly criticism. The work was carried out at Otago University during the tenure of a Sir George Grey Scholarship.

Summary

1. The use of formaldehyde, hydrochloric acid, and zinc chloride in the introduction of the chloromethyl group into *p*-cymene has been investigated.

2. It has been shown that with the use of nickel chloride as a catalyst, the yields in this reaction can be improved considerably.

3. The synthesis of 2-*p*-cymylisobutyric acid, 2-*p*-cymylpropionic acid, 2,4-dimethyl-7-isopropylhydrindone, and 1,2,4-trimethyl-7-isopropylindene has been carried out.

Photochemical Investigations. III. The Effect of Cell Size on the Quantum Yield for the Decomposition of Ammonia[1]

BY EDWIN O. WIIG

Recently suggested mechanisms[2-4] for the photolysis of ammonia are based on experimental data which apparently show the quantum yield independent of pressure. However, a later investigation[5] demonstrated that there is a change in the quantum efficiency with a change in the total ammonia pressure. This dependence might be due to a change in the character of the homogeneous gas reactions occurring after the primary dissociation brought about by light or to a change from a homogeneous reaction to a heterogeneous reaction taking place on the walls of the reaction cell. As the thermal decomposition of ammonia is known to be heterogeneous and probably involves hydrogen atoms and NH,[6] one might be inclined to be suspicious of the photo-reaction in the absence of evidence of homogeneity or heterogeneity. In view of this, no mechanism accounting for the pressure dependence of the yield was suggested in the previous paper.[5] The experiments reported here were carried out in a reaction cell of somewhat different size from that previously used in an attempt to settle this point.

Experimental Details

The light source, apparatus and materials were the same as used earlier,[5] except for the replacement of the previous cell by another. Both cells were cylindrical with plane parallel windows on the ends and all seams fused. The first cell (Cell 1) was 25 mm. in diameter by 50 mm. long with an area–volume ratio of 200 mm.$^{-1}$ while the new cell (Cell 2) was 40 mm. in diameter and 35 mm. long with an area–volume ratio of 157 mm.$^{-1}$. At the conclusion of the experiments with each cell the rear window was cut off and its transmission measured. Previous to removing the windows, hydrogen bromide was decomposed in the cells, using exactly the same procedure as in ammonia photolysis.

Results

In order to compare the photolyses in the two cells the quantum efficiency for the ammonia decomposition was determined, as in the earlier work, for the single Zn line λ 2100 Å. at ammonia pressures ranging from 4–886 mm. The results are shown in Table I. These yields were calculated on the assumption that the non-condensable gas remaining after freezing out the ammonia with liquid air consisted of 75% hydrogen and 25% nitrogen. The energy measurements upon which these quantum yields depend were checked by measuring the quantum efficiency for the decomposition of hydrogen bromide. Using the experimentally determined correction factors for the energy losses at the cell window, lens and

thermopile window, the average quantum yield found for the hydrogen bromide photolysis was 2.14. This is in good agreement with the value of 2.01 found by experiment in the previous investigation and with the accepted value of 2.0. The results with hydrogen bromide given in Table II have been corrected to make the average yield 2.00 and the data for ammonia in Table I have been corrected similarly. The correction is small and might have been neglected but it serves to refer the data in Cells 1 and 2 to the same standard. All the experiments performed have been listed in these two tables except runs B1–9 which were performed on old hydrogen bromide that had been stored in contact with phosphorus pentoxide for several months. The yields in these experiments were very erratic. The later experiments of Table II, as in the earlier work, were carried out with freshly prepared hydrogen bromide which, as may be seen, gave easily reproducible results.

From Table I it is apparent that the same sort of pressure dependence of the yield obtains as in the earlier cell. For convenience of comparison the data in Table I of the earlier work[5] and the present data have been plotted as shown in Fig. 1. The full curve is the curve in Fig. 2 of the preceding paper[5] and shows the variation of quantum yield with pressure in experiments performed with Cell 1. The vertical lines, which correspond in length to a quantum yield of 0.025 and whose mid-point is the actually determined value, represent the individual experiments in Cell 2 as given in Table I. Some measurements made with a third cell (Cell 3) of the same diameter as Cell 1 but 100 instead of 50 mm. long gave yields which fit the curve for Cell 1.

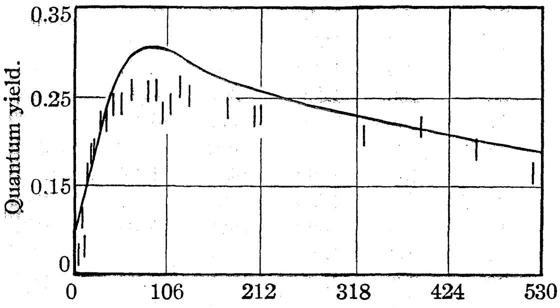

Fig. 1.—Quantum yield for the photo decomposition of ammonia as a function of pressure at λ 2100 Å.: full curve, cell 1; vertical lines, cell 2.

After the completion of this work there appeared a paper by Welge and Beckman[7] reporting an investigation of the photodecomposition of ammonia in the region of very minute amounts of decomposition. Their results show that in their apparatus at pressures of products of 0.05 mm. or greater the non-condensable gases consist of 75% hydrogen and 25% nitrogen, but when the amount of decomposition is decreased down to pressures less than 1 micron the gas contains about 95% hydrogen and approaches 100% as a limit. Based on the percentage of hydrogen and that the stoichiometric reactions involved are

$$2NH_3 = N_2 + 3H_2 \text{ and}$$
$$2NH_3 = N_2H_4 + H_2$$

Welge and Beckman find quantum yields approaching unity. They suggest that perhaps the low quantum yields obtained by others[2,3,5] are due in part to a change in composition of the gaseous products.

In the experiments of Wiig and Kistiakowsky the products were shown to be $3H_2 + N_2$ down to 8 μ pressure with the full light of the zinc spark and down to 16 μ with the monochromatic light and conditions used in the quantum yield determinations. The amount of decomposition in every experiment with λ 2090 Å. corresponded to a pressure of products of 19.7 μ or greater. The quantum yields of *ca.* 0.25 obtained are based, therefore, on a known composition of products and are real. In the present studies the products of the exposure of ammonia to the full light of the zinc spark were shown[5] to be 75% hydrogen and 25% nitrogen down to pressures of 22 μ. The pressures of the decomposition products in the data used here vary from about 0.6–12 μ.

Subsequently, the constancy of the composition of the products down to about 2 μ pressure has

---

(7) Welge and Beckman, THIS JOURNAL, 58, 2462 (1936).

been tested. If the non-condensable product at 1 μ is 100% hydrogen, the calculated quantum yield on the assumption of 75% hydrogen and 25% nitrogen would be[7] about 0.25. The maximum value of the yield (Fig. 1) comes at an ammonia pressure of about 100 mm. and has a value of about 0.30 in Cells 1 and 3 for λ 2100 Å. and *ca.* 12 μ of products. If this efficiency is for products containing $3H_2 + N_2$, then on reducing the time of exposure so as to obtain only 1 μ of products the calculated yield should approach 0.25 as the gas approaches 100% hydrogen. Cell 3, as it is the only one intact, was used for making the test. The cadmium line at λ 2144 Å. was chosen since decompositions up to 30 μ could be obtained readily with the higher intensity available. The results are given in Table III.

TABLE III

PHOTOLYSIS OF AMMONIA IN CELL 3

λ 2144 Å. P_{NH_3} = 105 mm. Vol. = 230 cc. Temp., 21–27°

Expt.	Exposure, sec.	Quanta absorbed, $\times 10^{-14}$	Pressure of products, microns	Quantum yield
C-135	2580	3236	29.96	0.354
136	2220	2320	21.81	.360
142	2100	976	8.44	.332
139	600	725	6.55	.344
143	1500	621	5.60	.349
140	360	454	4.12	.345
141	180	230	1.73	.288
138	180	185	1.30	.266
137	120	137	0.98	.274

These yields at λ 2144 Å. are slightly higher than those reported for λ 2100 Å. The data of Ogg, Leighton and Bergstrom show the same tendency to higher values at λ 2144 as compared with λ 2100 Å. Whether or not this difference is real is of no importance here. The yield, it will be observed from Table III, is about 0.345 for products varying from 30 μ, where the composition has been determined with certainty, down to 4 μ. At pressures of products less than 2 μ the yield falls sharply which, on the basis of Welge and Beckman's results, might indicate a change in composition. All the experiments indicated in Fig. 1 produced more than 4 μ of non-condensable gas except a few runs at low or high pressures where the yields are less than 0.20 (*e. g.*, *ca.* 0.10 in Expts. B-15, 31, 32). If the gas were 100% hydrogen in these few experiments, the yield should still be about 0.25, so that a change in composition cannot account for these low yields.[8] It seems, therefore, that the variation in quantum yield at ammonia pressures ranging from at least 30–700 mm. is real and not due to a change in composition of gaseous products. In the decomposition of ammonia by α-particles, Luyckx[9] likewise finds an increase in the yield per ion pair as the ammonia pressure is decreased to about 100 mm. and points out that earlier data[2,10] show the same tendency, although no such claim was made.

Discussion

The plot in Fig. 1 shows a small but very definite difference in the quantum yields in the two cells at about 60–300 mm. ammonia pressure. In this pressure range the reaction apparently becomes heterogeneous. The experiments of Welge and Beckman[7] also indicate that the reaction must be at least partly a wall reaction, since saturation of the walls with atomic hydrogen previous to photolysis results in a higher yield. By means of the effect of hydrogen atoms on the para- to ortho-hydrogen transformation Farkas and Harteck[4] have shown that the hydrogen atom concentration, [H], in ammonia undergoing photolysis, decreased with decrease in total pressure for total ammonia and hydrogen pressures less than 140 mm. When the surface was increased by filling the reaction cell with lengths of quartz tubing, [H] decreased. While these experiments were performed at 400 and 300°, respectively, and not at room temperatures, they nevertheless indicate the heterogeneous character of the reaction.

The dependence of the quantum yield on ammonia pressure is readily accounted for by making use of the following reactions. The individual reactions have been suggested at various times but not as presented here.

$$\begin{array}{rll}
NH_3 + h\nu \longrightarrow (NH_3)' & \longrightarrow NH_2 + H & (1) \\
H + H \text{ at wall} & \longrightarrow H_2 & (2) \\
NH_2 + H + M & \longrightarrow NH_3 + M & (3) \\
NH_2 + NH_2 + M & \longrightarrow N_2H_4 + M & (4) \\
NH_2 + NH_2 & \longrightarrow N_2 + 2H_2 & (5) \\
N_2H_4 + H & \longrightarrow NH_3 + NH_2 & (6)
\end{array}$$

---

(8) There is a striking difference in the intensities used in the experiments of Welge and Beckman and those in Fig. 1. In the latter the number of quanta absorbed varies from 300 to 1300 × 10^{14}, the smaller number coming at low ammonia pressures, where absorption is weak. The average is about 800 × 10^{14}. For approximately the same exposures, the number of quanta absorbed in the experiments of Welge and Beckman varies from 41–86 × 10^{14}, the average being 60 × 10^{14}. Whether or not this accounts for the difference in the composition of the products obtained in the two investigations is difficult to state.

(9) (a) Luyckx, *Bull. soc. chim. belg.*, **43**, 117 (1934); (b) Luyckx, Revue de Questions scientifiques, Nov., 1935, p. 441.

(10) Kuhn, *J. chim. phys.*, **23**, 521 (1926).

The evidence for reaction (1) is cited by numerous workers.[2–4,7] Farkas and Harteck, as well as Welge and Beckman, have suggested that the union of hydrogen atoms, (2), is a wall reaction. Reactions (3) and (4) followed by (6) account for the decrease in rate observed by Melville.[11] As pointed out by Taylor and Jungers,[12] reaction (3) (and also (4) followed by (6)) provides one reason for the low quantum yield in ammonia photolysis, and also accounts for the NH_2D and NHD_2 which they found in mixtures of ammonia, deuterium and mercury vapor exposed to a quartz mercury arc. The presence of hydrazine, as demanded by reaction (4), has been shown by various investigators.[7] The reaction between hydrazine and hydrogen atoms, (6), has been shown experimentally by Dixon[13] to proceed rapidly. The exact nature of this reaction is open to question,[2,3,9,14] but reaction (6) as given here appears to be probable.[3] The NH_2 formed in (6) disappears in (3), (4) or (5), and the equations may readily be combined to give the observed reaction products, $3H_2 + N_2$.

As the ammonia pressure is decreased from about one atmosphere down to about 100 mm. reactions (2) and (5) would be favored as against (3), (4) and (6) and the quantum yield should increase. At the maximum, as the different yields in the two cells indicate, the reaction becomes heterogeneous and regeneration of ammonia can now begin to occur at the walls. Thus, a rapid fall in yield is to be expected as the wall effect increases, which is in agreement with observation. The above mechanism leads to the rate equation

$$-\mathrm{d}(\mathrm{NH_3}) = \frac{I_{\mathrm{abs.}}\sqrt{k_2(k_5 - k_4M)}}{k_3M + k_5\sqrt{\dfrac{k_2}{k_5 - k_4M}}}$$

which should hold for pressures greater than about 100 mm.; below that the reaction is both homogeneous and heterogeneous, the proportions of each depending on the pressure. At high pressures k_2 would involve three-body collisions, at intermediate pressures three-body collisions and wall reaction. The rate, it will be observed, is proportional to the energy absorbed and the quantum yield independent of light intensity, which is in agreement with observation[2,4,15] for the intensities used. As the pressure is increased above 100 mm. the denominator in the above equation increases more rapidly than the numerator and the quantum yield falls. For moderately high pressures (1.2 to 8.5 atmospheres) as in the experiments of Ogg, Leighton and Bergstrom the quantum yield would probably change very little. When the value of M attains very large values as in liquid ammonia or aqueous solutions of ammonia, the rate approaches zero. This is in agreement with the observed facts as both liquid ammonia[16] and aqueous solutions of ammonia[17] undergo no appreciable photodecomposition. The suggested mechanism also explains the lower yield in the larger cell, Cell 2, since diffusion of hydrogen atoms to the walls would be slower.

From the proposed mechanism one would predict that the addition of an inert gas to ammonia at a pressure of about 100 mm. should result in a decreased quantum yield. Likewise, the addition to ammonia at pressures of 10–40 mm. of a foreign gas so as to make the total pressure about 100 mm. should give an increased yield. These effects would account for Warburg's constant quantum yield of 0.23 at total pressures of ammonia, nitrogen and hydrogen of 800–900 mm. The work is being continued with a view to testing these and other points.

Summary

The quantum efficiency for the photolysis of ammonia by λ 2100 Å. is found to depend upon the size of the reaction cell, being slightly, but definitely, smaller in a cell of larger diameter. The reaction appears to become heterogeneous at ammonia pressures less than about 300 mm. and may be partly heterogeneous at higher pressures. A mechanism for the photodecomposition is suggested and discussed.

Heats of Organic Reactions. V. Heats of Hydrogenation of Various Hydrocarbons

BY M. A. DOLLIVER, T. L. GRESHAM, G. B. KISTIAKOWSKY AND W. E. VAUGHAN

In the previous publications of this series[1] there have been reported the heats of hydrogenation of a considerable number of unsaturated hydrocarbons. These data, it has been shown, indicate some rather striking regularities, correlating molecular structure and this thermo quantity. In this paper we shall present some additional determinations and attempt to substantiate and to amplify some of our earlier generalizations. Our next paper will deal with hydrogenations of some oxygen-containing compounds.

Preparation of Materials

Inasmuch as the purity of the compounds is probably the factor limiting the accuracy of our calorimetric determinations, we shall follow our set precedent and report the preparations in some detail.

Ethylbenzene.—Ethylbenzene was prepared from acetophenone by the method of Clemmensen.[2] Fritche's acetophenone was distilled through Column B of Paper II at 100 mm. pressure. The major portion, which distilled at 132.4–132.7°, was used in this synthesis. The refractive indices of the fractions collected varied from $n^{17.5}_{\mathrm{D}}$ 1.5348 to 1.5350.[3]

The best yield of crude ethylbenzene on any one reduction was 50% of the theoretical; the over-all yield of crude material from 2280 g. of actophenone was 42.5%. The crude product was washed with potassium carbonate solution, dried over calcium chloride and let stand over sodium for fifteen hours. It was then distilled from the sodium, giving 769 g. of product which was fractionated in Column B; 686 g. of material was obtained which distilled at 136.80 ± 0.05° at 755 mm. This corresponds to a yield of 38% based on the weight of acetophenone used. Upon refractionation through Column A of Paper II a middle fraction of 114 g. distilled at 135.97° at 765 mm. The freezing point of this fraction was −94.7°[4] and n^{20}_{D} 1.4960.[4]

The total distillate of this fractionation (approximately 515 g.) distilled at 135.98 ± 0.02° at 765 mm.

***o*-Xylene.**—*o*-Xylene ("reinst"), as obtained from Dr. Frankel and Dr. Landau of Berlin, Germany, was fractionated through Column A. The fraction chosen for calorimetric measurements, No. 5, had the following constants: b. p. 144.07–0.08° at 765 mm.,[5] n^{20}_{D} 1.5055, f. p. −25.10°.

Fraction No. 5, 90 g., was the only fraction obtained with a flat boiling point; the other fractions were lower boiling and comprised about 66% of the charge of 500 g.

Mesitylene.—Eastman best grade of mesitylene was purified according to the method given in "Organic Syntheses";[6] 398 g. of mesitylene was recovered from 500 g. of starting material. This was distilled through Column B at 100 mm.; a middle fraction of 323 g. was obtained which distilled flatly at 99.3°; n^{20}_{D} 1.4995;[7] f. p. −51.4°.[8]

Styrene.—Styrene was prepared from phenylethyl alcohol by the method of Sabetay:[9] 2074 g. of phenylethyl alcohol in two and three molar runs was dehydrated by heating over a molten 50–50 mixture of sodium and potassium hydroxides (50 g. mixture per mole of alcohol) contained in a round-bottomed flask bearing a downward condenser. Heating was so regulated that the temperature of the distillate did not exceed 140°. The product was separated from the water layer, washed with saturated calcium chloride solution and dried over calcium chloride. Treatment with metallic sodium seemed to cause considerable polymerization, so this procedure was omitted after the first three runs. The yield of styrene to this point was 1627 g. or 92%. Fractionation of the crude material from a small amount of hydroquinone through Column B at 60 mm. gave 1008 g. of material distilling at 66.7 ± 0.05° corresponding to a yield of 57% based on the phenylethyl alcohol used. The refractive indices of the fractions obtained varied from $n^{17.2}_{\mathrm{D}}$ 1.5479 to 1.5483. This material was stored over hydroquinone in the dark and redistilled as needed for the calorimeter.

Sample No. 1, 173 g., distilled at 65.15° at 50 mm.; n^{20}_{D} 1.5470.[10] Sample No. 2 distilled at 65.6° at 50 mm.; n^{20}_{D} 1.5470; f. p. −30.5°.[11]

Indene and Hydrindene.—A pure grade of indene, obtained from Gesellschaft für Teerverwertung, was distilled through Column B; the middle fraction, consisting of Samples 2, 3 and 4, had a flat b. p. of 83.8° at 30.5 mm. The refractive index of the three samples was the same, $n^{19.8}_{\mathrm{D}}$ 1.5767.[12] Sample No. 2 had a f. p. of −1.67°.[13]

Part of this fraction was hydrogenated, using the Adams catalyst,[14] to hydrindene using no solvent. Hydrogen was taken up at the rate of about nine liters an hour when 1 g. of catalyst was used for 200 g. of indene. The absorption of hydrogen ceased immediately when the calculated

amount had been taken up. Practically all of the hydrindene distilled flatly in Column B at 79.0° and 29 mm.; $n^{20.7}_{\mathrm{D}}$ 1.5382;[15] f. p. −51.4°.

Cyclopentene.—Cyclopentanone was prepared from adipic acid by the method of Boedtker[16] with a 90% yield of crude product after it had been washed with potassium carbonate to remove any adipic acid and dried over anhydrous potassium carbonate. The cyclopentanone was fractionated carefully in Column B. The fractions used distilled from 130.2–130.3° at 756 mm.

Cyclopentanol was prepared from cyclopentanone by reduction with the Adams platinum catalyst. It was found that by promoting the catalyst with a small amount of iron[17] the ketone could be reduced very rapidly if the very pure ketone with no solvent was used in the Adams machine. The rate of absorption of hydrogen was about eight liters per hour. Five-tenths gram of catalyst was employed with each two-mole run. The cyclopentanol thus obtained was distilled in Column B giving a middle fraction boiling at 139.8–139.9° at 751 mm.

Cyclopentene was prepared by dehydrating the alcohol with anhydrous oxalic acid,[17a] washing the product with water and potassium carbonate solution, drying with calcium chloride and finally distilling from sodium metal. A yield of 83% based on alcohol dehydrated was obtained. The cyclopentene was then fractionated in Column A. The fraction used for measurement had the following physical constants: b. p. 44.17 ± 0.01° at 760 mm.; f. p. −134.6°; $n^{20.3}_{\mathrm{D}}$ 1.4223.[18]

α-Phellandrene.—The Hercules Powder Company through Dr. E. R. Littmann very kindly supplied us with approximately 250 cc. of α-phellandrene; the material was represented as being the best obtainable. This was purified, following the suggestions of Littmann, by distillation through a three-foot (91-cm.) jacketed, indented column under a pressure of 16 mm. The bulk of the material, about 200 cc., distilled at 62.5–66.5°. This was refluxed for one-half hour over clean metallic sodium and redistilled under 16 mm. pressure, giving a main fraction of b. p. 62.7–64.1°. A second distillation gave a main fraction of 75 cc., b. p. 64.7–65.7°; n^{20}_{D} 1.4746.[19]

α-Terpinene.—This compound, also supplied by the Hercules Powder Company, was purified in the same way as was α-phellandrene. The middle fraction from the distillation was taken for calorimetric measurement; it distilled at 81.5–82.0° under 30 mm. pressure; n^{20}_{D} 1.4757.[20]

Limonene.—Eastman best grade of limonene was distilled through Column B giving a middle fraction, Samples II, III and IV, with b. p. 74.7° at 24 mm. α-Phellandrene, α-terpinene and limonene all formed glasses when chilled in liquid air and no freezing points could be obtained. Sample II had a refractive index of n^{20}_{D} 1.4721 and for Sample IV n^{20}_{D} 1.4727 was found.[21]

Isopropylethylene.—The sample of isopropylethylene was kindly supplied by Dr. E. P. Carr of Mt. Holyoke College. The constants submitted with the sample were: b. p. 20.18–.21° at 760 mm. and n^{20}_{D} 1.3675.[22] No freezing point was obtained on this material as it formed a very viscous liquid in liquid air even after repeated warming and cooling; this agrees with the observation of Norris and Reuter.[22]

Neo-amylethylene.—This compound was prepared from the Grignard reagent of *t*-butyl chloride and allyl bromide according to the method of Whitmore and Homeyer.[23] The allyl bromide used was a flat cut at 69.75° and 753 mm. The *t*-butyl chloride was of the same grade as was used in making *t*-butylethylene. A 63% yield of the ethylene was obtained, boiling at 71.0–72.8°. This was converted into the dibromide[23] and distilled. The fractions with boiling range of 104.7–105.0° at 16 mm. were treated with zinc in ethyl alcohol to regenerate the hydrocarbon; this was recovered by distillation of the reaction mixture, washing with successive portions of water, and drying with calcium chloride, yield 68%. Systematic fractionation through Column A gave a middle fraction with b. p. 72.63 ± 0.01° at 765 mm., f. p. −136.5°, n^{20}_{D} 1.3919.[24]

Tertiary Butylethylene.—A good grade of commercial *t*-butyl alcohol was distilled in Column C; a fraction boiling over 0.2° was used for the preparation of *t*-butyl chloride.[25] A sample of *t*-butyl chloride boiling flatly at 50.7° (766 mm.) (Column C) was used to prepare the Grignard reagent according to Whitmore.[26] Pure acetaldehyde, freshly distilled, was added to this reagent, the reaction mixture broken down and the product recovered in the usual manner. A 58% yield of pinacolyl alcohol was obtained based on *t*-butyl chloride used. This alcohol was converted, after fractionation, to the acetate by treatment with 10% excess acetyl chloride; the chloride was added slowly with stirring and the reaction mixture allowed to stand overnight. The excess acid chloride was then distilled off and the ester fractionated in Column B; a 61% yield was obtained, distilling at 80.5–80.9° at 99 mm.; n^{23}_{D} 1.4020 to n^{23}_{D} 1.4023.

Acetic acid was split out by a method suggested by Dr. Paul L. Cramer of General Motors (private communication), who obtained better yields than found in the original work of Whitmore and Rothrock.[27] Pinacolyl acetate was converted into *t*-butylethylene and acetic acid by passage through a reaction tube packed with glass wool in a furnace maintained electrically at 400°. The reaction product was washed free from acetic acid and the *t*-butylethylene separated from unchanged pinacolyl acetate by fractionation. The unchanged pinacolyl acetate was recovered nearly quantitatively and repassed through the

furnace. The *t*-butylethylene thus obtained was then distilled from sodium and finally fractionated through Column A. The product used had the following physical constants: b. p. 41.18 ± 0.01° at 760 mm.; n^{20}_D 1.3765.[28]

2,4,4-Trimethylpentene-1 and 2,4,4-Trimethylpentene-2.—Technical diisobutylene was generously supplied us by Prof. George S. Parks of Stanford University. About 4 liters of this material was refluxed over sodium metal chips for one hour and then distilled. The resulting product, 2321 g., was fractionated in two distillations through Column A to give a rough separation of the two isomers. Each isomer was then carefully refractionated, giving the following data.

2,4,4-TRIMETHYLPENTENE-1[29] (LOW-BOILING ISOMER)
Charge 473 g., b. p. 101.51–.58°, 765 mm.

Fraction	B. p., °C. (765 mm.)	n^{20}_D	Wt., g.
DIB-27	101.22–.49	1.4075	110
DIB-28	101.49–.53	1.4082	60
DIB-29	101.53–.56	1.4087	77
DIB-30	101.56–.58	1.4089	122
DIB-31	101.58–.58	1.4089	28
Residues			46

2,4,4-TRIMETHYLPENTENE-2[29] (HIGH-BOILING ISOMER)
Charge 424 g. Residues from first fractionations

DIB-21	104.30–.74	1.4159	98
DIB-22	104.74–.84	1.4159	67
DIB-23	104.84–.83	1.4159	27
DIB-24	104.83–.85	1.4159	27
DIB-25	104.85–105.63	1.4160	80
DIB-26	105.63–106.56	1.4155	24
Residues			137

The structures of these isomers as assigned to them by Whitmore and Church[30] on the basis of ozonolysis were confirmed by the same method; we shall forego a discussion of the tedious details.

Pentadiene-1,3.—Crotonaldehyde from Carbide and Carbon Chemical Corporation was fractionated through Column B; the samples used distilled at 102.3–102.4° at 765 mm.

Methylmagnesium chloride Grignard reagent was made up in 5-molar lots in the usual way and crotonaldehyde, to which had been added about an equal volume of anhydrous ether, was added until a negative test for Grignard reagent was obtained with Michler's ketone. Grignard reagent from 25 moles of magnesium required 23.7 moles of crotonaldehyde. The reaction mixture was decomposed with water and an amount of 30% sulfuric acid added sufficient to neutralize the magnesium hydroxide formed. Upon working up the product, it was found to be not pentene-2-ol-4 but the ether from two moles of the pentenol as described by Baudringheim.[31]

The crude product was washed with saturated sodium bisulfite solution, and then water. The yield was 1290 g. (8.3 mole) corresponding to 70% based on crotonaldehyde. Fractionation in Column B gave 801 g. of product distilling at 158.5–158.9° at 770 mm., a yield of 44%.

The 801 g. of product was passed over freshly activated alumina for dehydration to pentadiene-1,3; better yields of olefin were obtained when the temperature of dehydration was 280–290°. The crude pentadiene was distilled through a three-foot (91-cm.) jacketed, indented column, giving 510 g. of material (72% yield) boiling at 35–45° and yielding a bromide upon saturating a small sample in carbon tetrachloride with bromine in the cold, that melted at 114–114.5°.[32] The once-distilled pentadiene was fractionated through Column B, giving 353 g. distilling at 41.2–42.6° at 770 mm. and this in turn was fractionated through Column A. Three samples totaling 70% of total charge were collected for use in the calorimeter:

Sample	B. p., °C. (760 mm.)[33]	n^{20}_D	F. p., °C.
P-2	41.85–.87	1.4304	−87.7
P-3	41.88–.90	1.4303	−88.1
P-4	41.91–.93	1.4304	−88.9

2,3-Dimethylbutadiene-1,3.—2,3-Dimethylbutadiene-1,3 was prepared by dehydrating pinacol over activated alumina.

The pinacol hydrate starting material was obtained from Professor L. F. Fieser of this Laboratory. To remove the water of hydration it was distilled at atmospheric pressure in Column C until the temperature of the distillate reached 122°. The residue from 3580 g. of hydrate amounted to 1475 g., a yield of 79%. The crude pinacol was subjected to distillation at 100 mm., giving 1226 g. (65% yield) of product; b. p. 117.4–117.5°; m. p. 43.2–43.4°.

Dehydration of the pinacol was accomplished by passing it through a tube 70 cm. long and 2.5 cm. in diameter filled with activated alumina at 450–500°. The product from 1179 g. of pinacol was distilled through Column B giving 585 g. (71.5% yield) of 2,3-dimethylbutadiene-1,3 distilling at 68.6–69.7° at 765 mm. This was fractionated through Column A; from 304 g. of olefin was obtained 153 g. distilling at 68.70 ± 0.01° at 765 mm.; f. p. −76.0° and n^{20}_D 1.4390.[34]

Data and Results

No important variations in calorimetric procedure have been adopted. With some of the higher boiling compounds, in order to obtain a workable rate of temperature rise, it was necessary to keep the device in which the hydrogen becomes saturated with the hydrocarbon at 100°; to ensure against condensation of reactant or product in the flow system, the operating temperature of the calorimeter was raised above the 82°

common to our earlier determinations. For purposes of comparison, all data have been reduced to 82° by use of ΔC_p values of −4 cal./deg. for addition of one H_2, −8 for $2H_2$, −12 for $3H_2$ and −16 for $4H_2$; errors resulting from this approximation are slight due to the small temperature ranges involved.[35]

Ethylbenzene + $3H_2$.—The table shows a high degree of precision, even with varied flow rates. The freezing point of the ethylbenzene was very sharp at −94.7°; addition of 0.5% benzene lowered the initial freezing point by 1.1° and the freezing curve dropped off steadily. A test for irreversible adsorption on the cobalt–nickel catalyst used was negative, as were tests designed to detect ethane and methane in the hydrogenated product. Unfortunately it proved impossible to freeze the product; even with prolonged chilling in liquid air the material remained glassy; n^{20}D 1.4333, to be compared with n^{20}D 1.4332[36] for ethylcyclohexane. We estimate the over-all accuracy of the determination as 100 cal./mole.

Run no.	Moles C_8H_{10}	Moles H_2 per min.	Moles C_8H_{10} per min.	$-\Delta H_{381}$ cal./mole
1	0.022190	0.0143	5.06 (10^{-4})	49,252
2	.022423	.0136	7.81 (10^{-4})	49,219
3	.022496	.0170	8.38 (10^{-4})	49,217
4	.022549	.0142	11.57 (10^{-4})	49,250
			Average	49,235 ± 17
			$-\Delta H_{355}$	48,920

o-**Xylene + $3H_2$.**—This hydrogenation over cobalt–nickel yields a mixture of isomers and no test of purity of the product by the freezing point method was possible; a glass resulted on chilling in Dry-Ice; n^{20}D 1.4321 to 1.4324.[37] The freezing "flat" of the *o*-xylene was not especially good, falling off 0.1° to 70% frozen material; however, addition of 0.5% of the lowest boiling fraction caused a freezing-point lowering of 0.2° and the curve fell off more rapidly than in the case of the pure material. Each run was tested chemically for completeness of hydrogenation by treating 1 cc. of the product with 7–10 small drops of concd. sulfuric acid for one and one-half minutes at 70°; blanks showed that 0.1% of *o*-xylene in the product caused the formation of a yellow tint. The test for irreversible adsorption was negative. The over-all accuracy is estimated at 200 cal./mole.

Run no.	Moles C_8H_{10}	Moles H_2 per min.	Moles C_8H_{10} per min.	$-\Delta H_{373}$ cal./mole
1	0.021830	0.01653	5.58 (10^{-4})	47,492
2	.021571	.01355	3.49 (10^{-4})	47,440
			Average	47,466 ± 26
			$-\Delta H_{355}$	47,250

Mesitylene + $3H_2$.—The freezing point of mesitylene was very sharp at −51.4°; addition of 0.8% benzene lowered the initial freezing point by 1.1° and the temperature dropped off steadily. A chemical test for completeness of reaction similar to that for *o*-xylene was used: 0.1% mesitylene in the product was detectable; all runs were complete. No freezing point of the hydrogenation product as a criterion of purity was possible, as a mixture of isomers results in this experiment; n^{20}D 1.4280.[38] Tests for the presence of methane in the effluent gases and for irreversible adsorption on the cobalt–nickel catalyst were both negative. The over-all accuracy is probably 200 cal./mole, which includes any uncertainty in the purity of the mesitylene. However, the average ΔH represents the formation of an unknown mixture of isomers and thus may have a not well-defined thermodynamic meaning. It would seem from the data of Eisenlohr and Gorr[38] that we are getting chiefly the *trans* isomer, but the agreement of the refractive indices may be fortuitous.

Run	Moles C_9H_{12}	Moles H_2 per min.	Moles C_9H_{12} per min.	$-\Delta H_{381}$ cal./mole

3	.020746	.0050	4.94 (10^{-4})	47,827
4	.011447	.0158	3.67 (10^{-4})	47,920
			Average	47,930 ± 57
			$-\Delta H_{355}$	47,620

Styrene + $4H_2$.—The data on this compound are quite consistent over a two-fold variation of hydrogen and styrene concentration. To ensure against polymerization the samples were stored in Dry-Ice and put into the clean saturating device just before the runs; this procedure was employed with all compounds for which polymerization was suspected. No methane or ethane was formed as concurrent side-reactions on the cobalt–nickel catalyst and no irreversible adsorption occurred. The styrene froze rather sharply at −30.5°; addition of 0.5% ethylbenzene lowered the initial freezing point by 0.2° and the "flat" was somewhat steeper. The hydrogenation product showed no definite freezing point, yielding a glass; n^{20}D 1.4333 (compare with product from ethylbenzene). The over-all accuracy is approximately 200 cal./mole.

Run	Sample	Moles C_8H_8	Moles H_2 per min.	Moles C_8H_8 per min.	$-\Delta H_{381}$ cal./mole
1	1	0.014153	0.0065	3.11 (10^{-4})	77,777
2	2	.013755	.0127	4.15 (10^{-4})	77,886

4	2	.013829	.0103	5.63 (10^{-4})	77,953
				Average	77,893 ± 61
				$-\Delta H_{355}$	77,480

Hydrindene + $3H_2$.—The tabulated data show fair consistency in the runs. The freezing point of the hydrindene was excellent at −51.4°; addition of 0.5% hydrogenation product lowered the initial freezing point by 0.3° and the temperature dropped off much more rapidly than with the pure material. A test for completeness of hydrogenation was devised: 1 cc. of the product + 10 small drops of concd. sulfuric acid at room temperature; blanks showed that as little as 0.1% of hydrindene in the product caused the formation of a definite brown color. The test was negative for all the reported runs, as was the test for ir-

---

(35) A determination of the heat of hydrogenation of benzene to cyclohexane as a test of the calorimeter one year after the reported values (see IV) gave ΔH = −50,021 at 101.6°; corrected to 82° with ΔC_p = −12 cal./deg., ΔH = −49,788; this is to be compared with the earlier average of −49,802.

				Average	70,199 ± 194
				$-\Delta H_{355}$	69,910

The table shows large variation in the calorimetric results. A plot of ΔH versus the reciprocal of the length of the run (or versus rate of flow of indene) shows an irregular increase of ΔH with increased contact time on the catalyst; however, the slowest run, 6, gives almost the same ΔH as the next two, Nos. 5 and 3. Incomplete reaction in the faster runs, as a possible explanation of this difficulty, must be ruled out for the following reasons. (1) Each run's product was tested for completeness by the sulfuric acid test used for hydrindene and gave negative results (blanks with indene proved the validity of the test). (2) The experimental molar refractivity, P, from the determined $n^{20}\mathrm{D}$ 1.4683 and d_{20} 0.8748 of the product from Run 3, is 39.46, and agrees well with the theoretical value, 39.37 calculated from Hückel's[40] figures for C_9H_{16}. (3) A comparison of the refractive indices of the product of "slow" Run 3 and of a non-calorimetric run faster than Run 4 was made by use of a Zeiss portable laboratory interferometer; this instrument had previously been calibrated with liquids of known index; the test showed the index of the product of the "fast" run only 0.00033 unit (23 scale divisions) higher than that of the "slow" run; this would correspond to about 0.3% incompleteness, while the maximum variation of the heats of hydrogenation is about 1%. (4) Comparison of the indices of the products from indene and hydrindene by means of the Zeiss interferometer shows that the latter is 0.00017 unit higher than the former. (5) Two cubic centimeters of the hydrogenation product from "slow" Run 3 in 30-cc. glacial acetic acid with 0.1 g. of platinum oxide and a trace of ferrous ion was treated in an Adams hydrogenation apparatus;[41] the test was negative as only the empirical amount of hydrogen for the catalyst was absorbed. Addition of 0.1 cc. of hydrindene resulted in the absorption of 60 cc. of hydrogen. This test for incompleteness was repeated with 4.4 cc. of product from a run faster than Run 4 and was likewise negative. Two cubic centimeters of indene was then hydrogenated in the Adams apparatus and approximately the theoretical amount of hydrogen was absorbed, corresponding to formation of octahydrindene.

In view of all this evidence we are completely puzzled and shall give only the over-all average ΔH. Compared with the fairly uniform data for hydrindene it seems entirely unlikely that varying amounts of the isomers of the hydrogenation product or that concurrent side-reactions, such as breakage of the five-membered ring, are causing the difficulty. As in the case of hydrindene, the hydrogenation product formed a glass and a freezing-point test of purity was impossible; $n^{20}\mathrm{D}$ 1.4683. The test for irreversible adsorption on the cobalt–nickel catalyst was negative. The freezing point of the pure indene was very sharp at −1.67°; an initial freezing-point lowering of 0.3° and a pronounced falling off in temperature resulted upon contamination of the indene with 0.5% hydrogenation product.

As a crude estimate of over-all accuracy we shall give 500 cal./mole.

Cyclopentene + H_2.—The freezing point of the cyclopentene was sharp at −134.6° and dropped off markedly on addition of 1% of hydrogenation product (initial f. p. −135.0°). The hydrogenation product froze at −93.4°,[42] 0.3° higher than that of the diene hydrogenation product (see IV, p. 151), but the trend of the freezing curve was the same as that of the diene. Each run was checked for completeness of hydrogenation by means of the bromine addition test (see II, p. 876). Tests for irreversible adsorption on the cobalt–nickel catalyst were negative; $n^{20}\mathrm{D}$ 1.4064.[43] The over-all accuracy is estimated as 60 cal./mole.

			Average	26,915 ± 5

α-Phellandrene[44] + $2H_2$.—The data on the three related compounds, α-phellandrene, α-terpinene, and limonene, have no claim to high accuracy as we have such weak data regarding the purity of reactant and product. It probably is fair to assign a variation of 300 cal./mole to each final figure, as even fairly high percentages of other terpenes would not greatly influence the hydrogenation value.

This hydrogenation over cobalt–nickel yielded a product which was a mixture of isomers and formed a glass when chilled; $n^{20}\mathrm{D}$ 1.4376 to 1.4380.[45]

---

[39] Hückel, Sachs, Yantschulewitsch and Nerdel, *Ann.*, **518**, 155 (1935), give for hydrindane (*cis*) $n^{20}\mathrm{D}$ 1.4713 to 1.4716.

[40] Hückel, "Theor. Grundlagen d. org. Chem.," Akad. Verlag., Leipzig, 2d ed., Vol. II, 1935, p. 86.

[41] We are indebted to Dr. E. B. Hershberg for his kindness in performing these experiments.

[42] "I. C. T.," Vol. I, p. 192, gives −93.3°.

[43] Compare with product from cyclopentadiene, $n^{20}\mathrm{D}$ 1.4065 (see IV); Landolt-Börnstein, Erg. IIb, p. 820, gives $n^{20}\mathrm{D}$ 1.40609 for cyclopentane.

[44] 2-Methyl-5-isopropylcyclohexadiene-1,3.

[45] "I. C. T.," Vol. I, p. 277, gives $n^{20}\mathrm{D}$ 1.437 for para-menthane; a vast variety of values may be found for this compound.

2	.018017	.0096	5.88 (10^{-4})	53,619
			Average	53,622 ± 3
			$-\Delta H_{355}$	53,410

α-**Terpinene**[46] **+ $2H_2$.**—Each run was tested chemically for completeness of reaction. The product of this hydrogenation over cobalt–nickel formed a glass when cooled in liquid air; n^{20}_{D} 1.4403. We cannot explain the variation of the indices of the three hydrogenation products of these related compounds; it may be due both to varying amounts of impurity and to varying amounts of the isomers of *p*-menthane.

Run	Moles $C_{10}H_{16}$	Moles H_2 per min.	Moles $C_{10}H_{16}$ per min.	$-\Delta H_{355}$ cal./mole

t-**Butylethylene + H_2.**—The freezing point determination of *t*-butylethylene was very unsatisfactory; even with carefully controlled cooling, the material would supercool, heat to an initial freezing point and the temperature would then gradually drop off at an almost linear rate. Even hydrocarbon subjected to two fractional recrystallizations in liquid air-baths behaved in this manner, and the initial freezing point was not appreciably changed. This material has been sent to Prof. Parks for his estimate of the situation.[52a] Likewise difficulty was experienced with the hydrogenation product: a glassy solid resulted even after many attempts. The test for irreversible adsorption on cobalt–nickel was negative, as were all the bromine addition tests for incompleteness of reaction; n^{20}_{D} product 1.3688.[53] We estimate the over-all accuracy as 150 cal./mole.

2,4,4-Trimethylpentene-2 + H_2.—Parks, Todd and Shomate[54] estimate the purity of this hydrocarbon, Samples DIB 23 + 24, as 98%; this lower purity was suspected by us in view of the distillation data (see Preparations). It seems likely that there exists another compound boiling only slightly above this isomer; this point is strongly supported by an examination of the distillation curves of Fenske, Quiggle and Tongberg.[57] The table shows that Run 1 on Sample DIB-25, from just above the "flat," gives a ΔH markedly different from those of Runs 2, 3 and 4 which are with Samples DIB-22 and -23 from the region of the "flat."[58]

$n^{20}D$ of product: from 1, 1.3932; from 2, 3, 4, 1.3918.[59] The usual tests for completeness of reaction and for irreversible adsorption on the cobalt–nickel catalyst were negative. The initial freezing point of the hydrogenation product was −108.2° (compare with 2,4,4-trimethylpentene-1) and the freezing curve had a pronounced downward trend. This freezing-point depression and dropping-off shows that the impurity present is not the low-boiling isomer, which should yield the same saturated hydrocarbon upon hydrogenation, but rather some other material. In view of this evidence it is difficult to estimate the over-all accuracy of this determination.

Crawford and Parks[60] have determined the heat of hydrogenation of the mixture of diisobutylenes in the liquid phase; $\Delta H_{298} = -28,580$ (±800) cal./mole. Assuming with Fenske, Quiggle and Tongberg[57] that the pentene-1 is four times as abundant as the pentene-2, our data give for the heat of hydrogenation in gas phase of the mixed isomers at 298°K. $\Delta H = -27,240$. The agreement is fair, considering neglect of heats of vaporization.

Pentadiene-1,3 + $2H_2$.—The small amount of material available prevented an attempt to separate the *cis–trans* isomers of this diene. However, several hydrogenations over copper were made on the three main samples; these are listed in the table. The trend is the same as found with the butenes-2, suggesting that the *cis*-isomer is the higher boiling one. The various samples represent far from pure materials as the freezing points given are initial ones and in each case the curve fell off rapidly; addition of 0.5% pentane to Sample P-2 lowered the freezing point to −87.8° but the trend of the curve was essentially unaltered. However, 15 cc. of the hydrogenation product from several samples of the diene gave an excellent freezing "flat" at −129.6°,[61] showing conclusively that the starting material can only consist of 5-C straight-chain compounds. Thus it is fairly certain that the diene is a mixture of pure isomers, as presence of a mono-olefin is eliminated by the preparation. The bromine titration was used to show completeness of reaction; no degradation, polymerization or irreversible adsorption on the copper catalyst occurred. We have struck an average of all the ΔH values and present it as we did the value for the mixture of pentenes-2. The over-all accuracy is approximately 150 cal./mole.

Discussion

In order to conserve space we shall not attempt here a comparison of our data with those obtained by the combustion method. It is, however, noteworthy that in general combustion data on the more easily purified compounds agree much better with the present determinations than those made on difficult substances. This suggests that one of the major sources of error in those measurements is the inadequate purification of the materials.

With the three newly added monosubstituted ethylenes, isopropyl, neo-amyl and *t*-butyl ethylenes, the number of representatives of this group of hydrocarbons has been increased to six. It will be noted that with the exception of the neo-amyl group, the rest agree well among themselves,

(59) Compare with product from low-boiling isomer.

(60) Crawford and Parks, THIS JOURNAL, **58**, 373 (1936).

(61) Parks and Huffman, *ibid.*, **52**, 4381 (1930), give −129.7° (143.4°K.) for *n*-pentane.

(62) Compare with indices of product from *unsym*-methylisopropylethylene, $n^{20}D$ 1.3746; product from tetramethylethylene, $n^{20}D$ 1.3747 (omitted from III); "I. C. T.," Vol. I, p. 276, gives $n^{20}D$ 1.3783 for 2,3-dimethylbutane.

averaging 30,200 ± 100 cal./mole. The neo-amyl group, however, gives a distinctly lower result but the suggestion in paper III that branched-chain substituents are generally more effective in lowering the heat of hydrogenation can no longer be supported. Instead it must be concluded that introduction of branched-chains near the double bond leads to heats of hydrogenation which cannot be so accurately represented by the simple rules postulated in paper III as is possible with straight-chain alkyls. This is shown very clearly by the isomeric diisobutylenes. The lower boiling, 2,4,4-trimethylpentene-1, agrees still quite well with predictions. Its heat of hydrogenation is some 800 to 1000 cal. lower than those of other unsymmetrical disubstituted ethylenes (see III), whereas neo-amylethylene has a value which is lower by 600 to 800 cal. than those of other monosubstituted compounds. The 2,4,4-trimethylpentene-2, however, is completely anomalous. The same rules would predict for it a value of some 27,000 cal. (as in trimethylethylene) and in any case a value lower than that of its isomer. Instead, 28,400 cal. is found. Two per cent. impurity found by Parks, Todd and Shomate[54] does not explain the discrepancy unless the impurity is supposed to be a diene, perhaps C_7H_{12}, formed by splitting out of methane in the process of manufacture, boiling at nearly the same temperature. This is admittedly not very probable, but the structure of this hydrocarbon has been determined reliably by ozonolysis. Because of the good applicability of the hydrogenation rules as tested heretofore with pure compounds of established structure the possibility of diene impurity cannot be ignored.

However, Samples DIB-23 and 24 were returned to us by Professor Parks for further tests. At his suggestion we tested for peroxides by means of potassium iodide–starch solutions with negative results. Also, thirty-two grams of this material was treated with 0.65 g. of maleic anhydride on a steam-bath at 50° for thirty minutes; the diisobutylene was distilled off under reduced pressure at 35°, washed with potassium carbonate solution and dried with potassium carbonate. It was then subjected to a fractional distillation in a small Podbielniak-type column at a 10:1 reflux ratio; from 30 g. of material there was obtained 25 g. boiling at 104.8° (760 mm.). A calorimetric run was made on this sample and its heat of hydrogenation found to be −28,337 cal./mole. Thus it seems that, if the discrepancy regarding this compound is to be attributed to a diene impurity, at least the diene present cannot be a conjugated one, capable of reacting with maleic anhydride.

With substituted conjugated dienes the introduction of alkyl groups also results in a lowering of the heat of hydrogenation, but the regularities are not very clear cut. Thus the change from butadiene to cyclohexadiene (equivalent to substitution on both ends of the chain) (see IV) lowers the heat by 1700 cal., butadiene to 1-methylbutadiene-1, 3 results in 3000 cal. change, and an introduction of two methyl groups in 2,3-positions causes 3100 cal. lowering. These apparent irregularities are probably connected with small changes of the conjugation resonance energy. If one assumes that precisely the same rules hold for substitution of alkyls in dienes as do in mono-olefins the resonance energies are found to vary from 4000 to 1800 cal.

The study of the terpenes was undertaken chiefly to verify the data on cyclohexadiene-1,3 in view of the importance of this compound in the light of a considerable disagreement with the older thermochemical data. The new results confirm the heat of hydrogenation of cyclohexadiene as well as can be expected considering the somewhat uncertain state of purity of the new substances. In α-phellandrene one of the double bonds receives an additional methyl substituent as compared with cyclohexadiene. Taking for this effect the value of 1500 cal. (difference between butene-2-*cis* and trimethylethylene), we calculate 53,800; obsd. 53,400. α-Terpinene has two new substituents on both double bonds; hence its heat of hydrogenation according to the same rule should be 52,300 whereas 50,700 is found. Limonene is not conjugated; to calculate its heat of hydrogenation we take the figure for methylisopropylethylene (28,000) and add to it monosubstituted cyclohexene (27,100) obtaining 55,100; found 54,100 for $-\Delta H$. Roth[62a] has stated, on the basis of the heats of combustion of α-phellandrene (1435 Cal.) and 1,3-dimethyl-5-ethenecyclohexene-3 (1455 Cal.), that a shift of a double bond from a side chain into the ring in a conjugated position liberates *ca.* 20 Cal. Our values for α-phellandrene and limonene do not confirm this. The discrepancy may well be attrib-

uted to the purity of the compounds used in the combustion measurements.

Benzene derivatives show a general lowering of their heats of hydrogenation as compared with parent substance. The lowering is rather small, being 900, 1300 and 700 cal. per substituent group in ethylbenzene, *o*-xylene and mesitylene, respectively. These figures are distinctly lower than those for the third substituent in aliphatic compounds, but the trend is in general the same. It is to be noted that the substituents on the benzene ring have little effect on the resonance energy. The heat of hydrogenation of the ethylenic group in styrene can be calculated readily by comparison with ethylbenzene and is found to be 28,560 cal. It is noteworthy that the conjugation energy with the benzene ring is quite small, amounting to only 1600 cal. This is a case where the use of thermochemical data has led to quite different results.[63] The heat of combustion, however, undoubtedly was falsified by the presence of polymerized material, which fortunately does not affect the present method as the high-boiling polymer is not carried by the passing gas stream into the calorimeter.

We now come to compounds containing five-membered carbon rings and it is desirable to consider them from a unified point of view. In paper IV the heat of hydrogenation of cyclopentadiene was reported as 50,865 cal., which is 4500 cal. lower than that of cyclohexadiene-1,3. This was interpreted as due to increased resonance energy but present measurements do not bear out this point of view. Indeed the heat of hydrogenation of cyclopentene, 26,915 cal., is 1680 cal. lower than that of cyclohexene and thus the resonance energies in the two cases are practically the same. The uniformly lower values in the five-membered ring systems, however, are very puzzling. If it is assumed tentatively that the entire difference between the six- and the five-membered series is due to strain and that the six-membered rings, whether saturated or unsaturated, are practically strainless,[64] then it follows that with increasing saturation of the five-membered rings the strain increases. Namely, to explain the lowered heat of hydrogenation one must suppose that in the process of hydrogenation part of the available energy is retained by the molecule as increased strain instead of being liberated as heat.

The reliability of these experimental findings receives independent support from the study of indene and hydrindene. Unfortunately at present there are no values of 1,2-dihydronaphthalene[65] to be compared with indene but we may use the data on styrene and correct them for substitution according to the rules previously developed. Correcting for orthosubstitution on the benzene ring of styrene (difference between ethylbenzene and *o*-xylene) and for second substitution on the side chain double bond, we arrive at 73,700 cal. The observed value for indene is 69,900 and while both may be rather considerably in error, the magnitude of the difference is much too large to be explained away on this basis.

Quite similar are the results obtained with hydrindene. It may be compared directly to *o*-xylene because, as we have found earlier, the change from methyl to longer chain radicals does not affect appreciably the heat of hydrogenation. Hence, if the five-membered ring acts in all respects as an aliphatic chain the two figures should be identical. Actually it is found that hydrindene has a 1400-cal. lower heat of hydrogenation. For the logical validity of this comparison it is not necessary to fix the double bonds in the benzene ring. The physical facts are that after hydrogenation we have a five-membered saturated (substituted) ring and that in the process of hydrogenation this system has been obtained from one which lacked two hydrogens in adjacent positions common to the benzene ring. By comparison with *o*-xylene we note that the introduction of these two hydrogens into the five-membered ring releases less heat than a similar process when the ring is not closed as in *o*-xylene. (We are supposing here that the other hydrogenated positions in the benzene ring are less affected by the five-membered ring than these particular two atoms; for this we have complete justification from all data on the heats of hydrogenation.)

It is seen thus that indene and hydrindene fall in line with cyclopentadiene and cyclopentene, namely, there is less heat evolution when these compounds take up hydrogen and become

---

[63] Pauling and Sherman, *J. Chem. Phys.*, **1**, 684 (1933), give 6900 cal. (calcd.); 6700 (obsd.).

[64] Cyclohexane and cyclohexene are entirely strainless on the basis of the tetrahedral carbon atom model if one allows non-planar rings. Cyclohexadiene, even when planar, is under a very slight strain, when accepted internuclear distances are used. Perhaps this explains the slightly lower magnitude of the resonance energy found by us for cyclohexadiene as compared with other conjugated dienes.

[65] Data on this and related compounds may soon be available from determinations of heats of hydrogenation in the liquid phase made by Dr. R. B. Williams of this Laboratory.

saturated five-membered rings than when the corresponding process occurs in open chains or six-membered rings.

The data on cyclopentene and cyclopentadiene can be summarized by stating that the former has a strain smaller by some 1600 cal. and the latter one smaller by *ca.* 4000 cal. than cyclopentane. And since the latter, as combustion data[66] indicate, is itself under a strain of about 4000-5000 cal., there appears to be no strain in cyclopentadiene and a very small one in cyclopentene.

These facts are quite difficult to reconcile with tetrahedral angle carbon atom models. Construction of diagrams of the five-membered rings readily shows that the strain in these rapidly increases with increasing unsaturation. The use of 1.53 Å. for the single bond and 1.36 Å. for the double bond distances, together with tetrahedral angles, reveals that in cyclopentane the formation of the planar pentagon produces a strain due to the closure of a gap of 0.16 Å. In cyclopentene the gap has increased to 1.34 Å. and in cyclopentadiene it is 2.06 Å. In this last case the gap is hardly larger than in the model of cyclobutane, which latter compound, as it is known, is under a severe strain. Indeed, on studying these models, one wonders how cyclopentadiene, if it has this theoretical stereochemical structure, could ever have been found in the distillation of coal.

The discrepancy can be, of course, formally ascribed to some other, as yet unstudied, competing effects which overshadow the strains. Such an attitude, however, is very unsatisfactory since the strain theory itself was introduced to explain the instability of certain atomic configurations in organic compounds and one rather must conclude that the magnitude of strains cannot be evaluated in some special cases, at least, on the basis of the tetrahedral angle model. The problem is one of great interest and further work on small, unsaturated rings, in particular on lactones and acid anhydrides, is planned.

Some comments concerning the fixation of double bonds in benzene rings are in order. From the conclusions as to the relative strains in the five-membered rings one cannot, of course, arrive at definite conclusions about the positions of double bonds in the attached benzene ring. One point is quite clear, however, if in the tetralin molecule the saturated ring does not prevent the free resonance between the two Kekulé formulas, in hydrindene such resonance cannot be hindered in favor of a single bond being made a part of the five-membered ring. This is evident because more heat is evolved when an unsaturated six-membered ring is converted into a saturated one than when this happens to a five-membered ring. The entropies of the two processes are unknown but one might surmise, with a considerable degree of certainty, that they are not far different from one another. Hence there will be less driving force for the five-membered ring in hydrindene to become saturated than for the six-membered one in tetralin. This is in decided disagreement with conclusions reached by Mills and Nixon,[67] Sidgwick and Springall[68] and Fieser and Lothrop[69] from their studies of other phenomena. As these phenomena are rather complex it is somewhat questionable whether their conclusions are the only plausible ones.

Acknowledgment.—It is a pleasant duty to thank Prof. E. P. Kohler and Dr. J. B. Conant for many helpful suggestions and criticisms which have aided materially the progress of this work, which was made possible by a grant from the Rockefeller Foundation.

ERRATA AND ADDENDA

(1) In III, p. 143, there should be recorded the n^{20}D of the product from tetramethylethylene = 1.3747.

(2) In IV, p. 150, 5% Pt-on-asbestos was the catalyst used in the hydrogenation of cyclopentadiene.

(3) Parks, Todd and Shomate[54] have given the following estimates of purity: in III, heptene-1, 99.85%; in III, tetramethylethylene, "probably of similar high order"; in IV, 1,4-pentadiene, 99.90%.

Summary

The heats of hydrogenation of the following substances have been determined:

---

[66] Hückel, "Theor. Grundlagen d. org. Chem." Akad. Verlag., Leipzig 2d ed., Vol. I, 1935, p. 60, gives 5000 cal. Consistent use of Swietoslawski's data on cyclopentane and cyclohexane [as given by Kharasch, *Bur. Standards J. Research*, **2**, 359 (1929)] and Rossini's very reliable data on the straight-chain compounds [*ibid.*, **13**, 21 (1934)] corrected from gas to liquid state, gives −13,200 and −9700 as the heats of formation of the straight-chain compounds from the cyclic ones; the strain in cyclopentane is thus 3500 cal.

1. The previously discussed rules correlating the heat of hydrogenation with the structure of unsaturated hydrocarbons have been extended. It has been found that branched-chain substituents do not follow the rules as well as do the straight chains.
2. The evidence of the heats of hydrogenation of the five-membered carbon ring systems points to a strain which decreases as unsaturation increases. This is quite contrary to conclusions which may be drawn from tetrahedral angle carbon atom models. The implications of these results are discussed.

Dibenzylideneglucose and Dibenzylideneglucuronic Acid from 6-Benzoyldiethylmercaptoglucose. Synthesis of Another Dibenzylideneglucose from 4,6-Benzylideneglucose

BY PHILIPPOS E. PAPADAKIS

It is known that acetals of aromatic aldehydes and sugars are obtainable in pure crystalline form. Benzylidene derivatives of sugars which have part of their hydroxyl groups blocked are convenient starting materials in synthetic work.[1] The application of catalytic hydrogenation to such acetals of aromatic aldehydes and sugars for the splitting of the benzylidene residue, wherever the acid hydrolysis is objectionable, constitutes another advantage in favor of their use.

The present author had occasion in the past to prepare 6-benzoyldiethylmercaptoglucose in pyridine solution at 0°. This was used as a starting material for the preparation of a dibenzylidene derivative of glucose. The method adopted was similar to that used by L. Zervas[1] in the preparation of 4,6-benzylideneglucose. In the course of the experimental work it was found that the ethyl mercaptal groups were split off and a monobenzoyl dibenzylidene derivative of glucose resulted which does not reduce Fehling's solution. It is thought that the compound may be 1,2,3,5-dibenzylidene-6-benzoyl-*α*-*d*-glucofuranose. If that be the case then by hydrolyzing the benzoyl group one may obtain 1,2,3,5-dibenzylidene-*α*-*d*-glucofuranose. The latter by subsequent oxidation should yield 1,2,3,5-dibenzylideneglucuronic acid which could be changed into glucuronic acid. The benzoyl residue of the monobenzoyldibenzylideneglucose was split off by means of either alcoholic potassium hydroxide solution and heat or by means of the calculated amount of sodium methoxide in chloroform at 0°. The resulting

[1] L. Zervas, *Ber.*, **64**, 2289 (1931); P. Brigl and R. Schinle, *ibid.*, **66**, 325–30 (1933); P. Brigl and H. Grüner, *ibid.*, **65**, 1428 (1932); P. Brigl and O. Widmaier, *ibid.*, **69**, 1219 (1936); P. A. Levene and G. M. Meyer, *J. Biol. Chem.*, **53**, 431 (1922); *ibid.*, **57**, 319 (1923).

dibenzylideneglucose does not reduce Fehling's solution. On oxidation it yielded dibenzylideneglucuronic acid, m. p. 175°. The oxidation under the conditions of the experiment described later was difficult because of the low solubility of the substance in the presence of water. Attempts to oxidize the substance with alkaline permanganate in acetone–water solution or in dioxane were given up temporarily because the permanganate was reduced by the solvents.

At this point it was thought that if part of the benzoylmercaptoglucose had its benzoyl group located on some other carbon than the sixth, then the benzylidene group would block carbon no. 6 and the resulting monobenzoyldibenzilideneglucose would not oxidize. Since Zervas obtained a 4,6-monobenzylideneglucose by treating glucose in the benzaldehyde with zinc chloride, it seemed plausible that if the hydroxyls of carbons 4 and 6 of the monobenzoylmercaptoglucose were free, then when the latter is treated with benzaldehyde and anhydrous zinc chloride the benzaldehyde group may go into acetal formation with them. In that case a 3-benzoyl-1,2,4,6-dibenzylideneglucose would be a possibility and hence a 1,2,4,6-dibenzylideneglucose would result from the hydrolysis of the benzoyl group. Zervas' work on 4,6-benzylideneglucose[1] and on 1,2-acetone-5,6-benzylidene-*α*-*d*-glucofuranose[2] suggests that by treating 4,6-benzylideneglucose with benzaldehyde in the presence of phosphorus pentoxide, one may obtain a 1,2,4,6-dibenzylideneglucose. As is shown later, a dibenzylideneglucose derivative was obtained by this method, m. p. 163°. Mixed melting points with this substance were tried with dibenzylideneglucose from the mercaptoglucose method before the oxidation to dibenzylideneglucuronic acid, and with the residue which had not oxidized. In both cases the melting point was depressed to the same extent. Further work is contemplated for the elucidation of the structure of these compounds.

Experimental

6-Benzoyldiethylmercaptoglucose.—The method used for the preparation of 6-benzoyldiethylmercaptoglucose is essentially the same as that of Lieser and Schweitzer[3] with some modifications.

Benzoyl chloride (1 mole) was added slowly with stirring to a saturated solution of diethylmercaptoglucose (1 mole) and anhydrous pyridine. The latter was cooled previously to 0°. The reaction mixture was kept at 0° for three hours; then the pyridine was extracted with petroleum ether and the residue was poured into ice water. Crystals of monobenzoyldiethylmercaptoglucose, m. p. 112°, were separated, washed with water, filtered and recrystallized by dissolving the crystals in boiling methanol and then cooling the solution to 0°. The compound melted at 114°; $[\alpha]^{23}\text{D} + 47.23°$ (0.4393 g. in 25 cc. of chloroform solution in a 1-dm. tube rotates 0.83° to the right). Lieser and Schweizer did not give specific rotation while Brigl and Grüner[3] reported m. p. 111–112° and $[\alpha]\text{D} + 45.82°$.

Anal. Calcd. for $C_{17}H_{26}O_6S_2$: C, 52.30; H, 6.66. Found: C, 52.23; H, 6.70.

The 6-benzoyldiethylmercaptoglucose prepared as above was dissolved in pyridine and boiled under a reflux condenser for three hours. Afterward it was reclaimed from pyridine and recrystallized as above. The specific rotation did not change.

6-Benzoyldibenzylideneglucose.—Anhydrous zinc chloride (6.5 g.) was added in small portions with shaking to a mixture of 4.9 g. of 6-benzoyldiethylmercaptoglucose and 30 cc. of benzaldehyde. The bottle containing the reaction mixture was kept in an ice-bath during the mixing period and later was placed on a shaking machine for fifteen minutes. The resulting solution was allowed to stand at room temperature for two hours. The benzaldehyde was extracted with petroleum ether and the glucose derivative with ethyl acetate. The latter solution was shaken with a saturated solution of sodium chloride and separated. From the ethyl acetate solution 2.2 g. of 6-benzoyldibenzylideneglucose, m. p. 156°, was obtained. It does not reduce Fehling's solution.

Anal. Calcd. for $C_{27}H_{24}O_7$: C, 70.40; H, 5.25. Found: C, 70.35; H, 5.21.

Dibenzylideneglucose.—6-Benzoyldibenzylideneglucose (2.5 g.) was boiled for three hours under a reflux condenser with an alcoholic solution of potassium hydroxide (1 g.). Then the solution was diluted to five times its volume with water. The crystals separating melted at 161°. They were recrystallized from ether and then from methanol, m. p. 163°; yield 1.5 g.

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 67.38; H, 5.66. Found: C, 67.07; H, 5.49. Calcd. for $C_{20}H_{20}O_6$: C, 67.38; H, 5.66. Found: C, 66.97; H, 5.68.

Dibenzylideneglucuronic Acid.—Twenty-five cc. of 2 *N* sodium hydroxide and 0.5 cc. of bromine were added with shaking to a solution of 1.4 g. of dibenzylideneglucose (m. p. 161°) and 20 cc. of pyridine at 0°. After five minutes the reaction mixture was placed on a shaking machine for fifteen hours. Only part of the substance dissolved and the remaining material was filtered off. The filtrate was cooled to 0° and titrated with concd. hydrochloric acid until Congo red paper changed to blue. Needle-like crystals were formed which were dissolved immediately in ethyl acetate. The ethyl acetate solution was shaken with potassium bicarbonate solution until it showed an alkaline reaction and was then separated from the water solution. The latter was cooled to 0° and titrated with concd. hydrochloric acid as before. The crystals were filtered off, redissolved in potassium bicarbonate, the solution cooled and

retitrated as before. This process was repeated three more times; 200 mg. of crystals was obtained. They were dissolved in alcohol and reprecipitated with distilled water, m. p. 175°.

Anal. Calcd. for $C_{20}H_{18}O_7$: C, 64.83; H, 4.9. Found: C, 64.93; H, 5.08.

Dibenzylideneglucose from 4,6-Benzylideneglucose.—4,6-Benzylideneglucose (2.1 g.) previously dried over phosphorus pentoxide was mixed with phosphorus pentoxide (2 g.) in a dry Erlenmeyer flask. All precautions were taken to avoid moisture. To this mixture was added freshly distilled benzaldehyde (7 cc.), previously cooled to 0°. The reaction flask was stoppered quickly and shaken in an ice-water-bath for ten minutes. Then it was taken out of the ice-bath and shaken twenty minutes at room temperature. Dry ether was added to extract the substance and the ether solution was washed with saturated sodium chloride solution made alkaline with a little ammonium hydroxide. The ether layer was separated and, after partially evaporating the ether, petroleum ether was added. The crystals formed were separated, boiled with water, filtered off from the hot water and then recrystallized from ether and finally from methanol, m. p. 163°. It does not reduce Fehling's solution. Mixed melting points of this substance were tried (a) with dibenzylideneglucose from the mercaptoglucose method before the oxidation to dibenzylideneglucuronic acid, m. p. 143–148°, and (b) with the residue which had not oxidized, m. p. 142–148°; mixed melting points of dibenzylideneglucose from (a) with residue from (b), m. p. 163°.

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 67.38; H, 5.66. Found: C, 67.39; H, 5.92.

The author wishes to express his appreciation to Dr. L. Zervas for the interest which he has shown in this work, and to Mr. D. Rigakos of the Rockefeller Institute for Medical Research for the microanalyses for carbon and hydrogen.

Summary

1. 6-Monobenzoyldibenzylideneglucose was prepared by treating 6-monobenzoyldiethylmercaptoglucose with benzaldehyde and anhydrous zinc chloride. It does not reduce Fehling's solution.

2. Dibenzylideneglucose was prepared from 6-monobenzoyldibenzylideneglucose. The compound does not reduce Fehling's solution.

3. Dibenzylidene glucose was oxidized to dibenzylideneglucuronic acid.

4. Dibenzylideneglucose was prepared from 4,6-benzylideneglucose. It does not reduce Fehling's solution. It was found to differ from the dibenzylideneglucose prepared from 6-benzoyldiethylmercaptoglucose.

On 1,2- and 1,4-Addition.[1] II. Nitrogen Tetroxide and Trimethylethylene

BY ARTHUR MICHAEL AND G. H. CARLSON

Probably no other reagents act so diversely upon ethylenic hydrocarbons as the higher oxides of nitrogen and the reactions, although repeatedly investigated, are still understood very incompletely. The relative negativity of the possible addenda components, formed by intramolecular fission of nitrogen tetroxide, should decrease in the order. $ONO_2 > ONO > NO_2 > NO$ and, correspondingly, the polarity differences between the paired addendum groups of the following combinations should decrease as follows: $ONO_2 + NO > ONO + NO_2$. Alkenes in which the polarities of the Δ-carbons differ considerably should, therefore, add the tetroxide to form the nitroso-nitrate and less of the nitro-nitrite. This relationship has not been realized experimentally with alkylenes owing, largely, to the protean chemical character of the addendum. It may function not only as the balanced system $2NO \rightleftarrows O_2N—O—NO$, but as a powerful oxidant upon the alkene; further, as a polymerizing reagent upon alkenes easily susceptible to that process and the polymers may be reacted upon by the tetroxide.

Schmidt[2] passed the gas formed by heating lead nitrate into a cooled, ether solution of trimethylethylene until "saturated" and obtained mainly a greenish-blue oil with a varying yield (maximum 25%) of crystalline trimethylethylene nitrosate.[3] This compound was shown

[2] Schmidt, *Ber.*, **35**, 2336 (1902). Guthrie [*J. Chem. Soc.*, **13**, 35, 129 (1861)] by the action of nitric acid, or of nitrogen tetroxide, upon trimethylethylene obtained, besides unidentified oily products, a colorless crystalline compound $C_5H_{10}N_2O_4$. This substance was prepared by Wallach [*Ann.*, **262**, 324 (1891)] by the action of nitric acid upon a solution of the alkene and isoamyl nitrite in acetic acid. From its chemical behavior, Wallach concluded the product is $C_5H_{10}(NO)(ONO_2)$ or $C_5H_9(=NOH)(ONO_2)$.

[3] The strongly oxidative, undried gas was used in a large excess and the solution stood at room temperature for a long time. Besides oxygen, nitrous and nitric acids were introduced into the reaction

by Schmidt to be dimeric in a cold, colorless solution, but to dissociate appreciably, at 30°, into the blue, monomeric form. When fused, the bis-nitrosate, in contrast to the bis-nitrosite,[4] could not be depolymerized, but completely decomposed; accordingly, only in a dilute solution is there any indication of the existence of the monomeric form. Yet, Schmidt concluded that the main reaction product, the greenish-blue oil, principally because of its color and because a small amount of the bis-nitrosate gradually separated from the oil, consisted, mainly, of the monomeric trimethylethylene nitrosate, notwithstanding that the oil could not be purified, did not analyse correctly, became discolored and decomposed on standing.

Schmidt believed that the polymerization of the mono- to the bis-nitrosate was a slow process, but Klingstedt[5] noticed that the separation of the bis-nitrosate was complete after two to four hours and concluded that the blue oil is not the monomeric nitrosate. In support of this view, he showed that the bis-nitrosate with aniline gave trimethylethylene nitrolamine, whereas the blue oil gave undefined products.

Previous work[2,6] has shown that reduction with metals, in acidic, basic or neutral media, is generally not a satisfactory method for establishing the structure of the nitrogen tetroxide addition products. Catalytic reduction, too, under varied conditions, gave us indefinite results; ammonia was formed invariably and amines were isolated in yields too low to permit of identification. Since potassium thiophenylate reacts with benzyl nitrate and yields potassium nitrate and benzyl phenyl sulfide quantitatively,[7] it seemed probable that the mercaptide might be used to characterize ester groups formed in the addition of nitrogen tetroxide to alkenes. Sodium thiophenylate and the ethyl mercaptide replace, quantitatively, the nitric ester radical in bis-trimethylethylene nitrosate to yield the corresponding thio ethers

$$[CH_3CH(NO)C(ONO_2)(CH_3)_2]_2 + 2RSNa \longrightarrow 2CH_3CH(NO)C(SR)(CH_3)_2 + 2NaNO_3$$

The thio ethers gave colorless solutions in hot benzene, but were partially associated in the freezing solvent, in this respect behaving like β-triazo-β-methylbutan-γ-oxime.[8] The thio ethers unite rapidly with phenyl isocyanate to form the corresponding urethan derivatives, but this reaction does not prove the presence of an isonitroso group in the original thio ether, for the isocyanate cannot differentiate with certainty between nitroso and isonitroso groups in compounds easily capable of tautomerization. A summary of the experimental details of this work is given in Table III. The mercaptide reaction, however, is not of general applicability; with some of the liquid, nitrogen tetroxide addition products, oxidative reactions occurred, resulting in formation of disulfides, as the main and sometimes the only product of reaction which could be identified.

Anhydrous, pure nitrogen tetroxide, distilled into cold ether solutions of trimethylethylene, in excess of equimolecular proportion, formed blue solutions from which bis-trimethylethylene nitrosate separated in varying yields. Typical results are given in Table I.

The maximum yield of bis-nitrosate (8.2%) appeared in experiment III, but under equally

---

mixture. Wieland [*Ber.*, **54**, 1782 (1921)] stated that nitrogen tetroxide acts upon ether with formation of nitrous and nitric ethyl esters; accordingly, at least six reactants were present in Schmidt's experiments, which cannot be considered, therefore, as representing the addition of nitrogen tetroxide to trimethylethylene.

favorable conditions (II) the yield was 2% lower and only a negligible amount was formed in experiment I. No general relation can be discerned between the yield of bis-nitrosate and the experimental conditions. The yield of bis-nitrosate was invariably higher (35.2–39.2%) when petrol was used as diluent (experiments IV and V). Since the bis-nitrosate is difficultly soluble in petrol and only slightly more so in ether, the large variation between yields of bis-nitrosate formed in the two solvents cannot depend solely upon the slight difference between the solubility in the respective solvents. Without solvent, the amount of bis-nitrosate formed at −80° (experiment VII) was 5.8% lower than that produced at −7° (experiment VI) and 4.4% less than that formed slightly above room temperature in a gas phase reaction (experiment VIII). In these experiments, again, no direct relation appears between the yield of bis-nitrosate and the experimental conditions. Since in the absence of a diluent a variation of temperature of about 100° alters the yield of solid product by only 4.4%, the actual yield fluctuating between 43.2–47.6%, whereas the maximum yield produced in ether solution was only 8.2%, evidently, the effect of solvent upon the course of addition of nitrogen tetroxide to alkenes is far greater than that of the reaction temperature.

A comparison of the results obtained in petrol solution with those obtained without solvent, or in the gas phase, shows unmistakably that the degree of dissociation of the addendum has no material influence upon the extent of the bis-nitrosate formation. At −7°, without solvent, conditions under which the addendum consisted almost entirely of O_2N—ONO, 49% of the bis-nitrosate appeared, while in the gas phase, where the tetroxide was considerably more dissociated, almost the same percentage of the bis-nitrosate was formed; even at −80°, the proportion of bis-nitrosate differed but slightly. From these, and results with other ethylenic hydrocarbons, it is evident that the course of the addition depends only slightly upon the relative proportions in which the components of the addendum appear in the equilibrium, $2NO_2 \rightleftharpoons O_2N\text{—}ONO$; apparently, the dominant chemical factor is the relative polarity of the Δ-carbons of the alkene. In no experiment with trimethylethylene did we succeed in isolating a dinitro addition product, nor a corresponding dinitrite.

The green oils formed in petrol solution decomposed so easily that purification by fractionation was impossible, nor could the oily products obtained from the crude oils by benzoylation, or treatment with acetic anhydride and sulfuric acid, be identified. According to Schaarschmidt and Hofmeier,[9] the action of nitrogen tetroxide upon alkenes is more complex and the products less stable, the lower the reaction temperature. However, on adding the tetroxide to reaction mixtures cooled only to 0°, the yield of bis-nitrosate (39.2%) obtained approximated that found (35.2%) at −15°: the liquid products slowly decomposed, even at 0°, liberating a colorless gas and depositing a small amount of ammonium nitrate. Although decomposing slowly, the liquid product in one experiment was subjected to distillation at the pressure of a mercury pump and the volatile as well as the non-volatile oil treated with sodium thiophenylate in alcoholic solution, but organic sulfur derivatives suggestive of the constitution of the original, green addition product could not be isolated. Likewise, in the absence of diluent, other than excess trimethylethylene, green, unstable oils were formed which could not be identified: the oils deposited ammonium nitrate, at 0°, and decomposed with evolution of nitrous fumes when subjected to steam distillation. The green liquid distilled at the pressure of the mercury pump and at 30° to give a blue distillate and a non-volatile, yellow oil, neither of which could be identified directly, nor through the reaction products formed with sodium thiophenylate. We were, therefore, unable to determine whether these oils contained the blue product and the nitro-nitrite formed in the presence of ether.

The blue oil, formed by interaction of nitrogen tetroxide and trimethylethylene in ether solution, is a mixture and may be separated by distillation into an easily volatile, blue and a less volatile, greenish oil. A summary of a typical fractionation is given in Table II. Although the refractive index of the blue oil, purified by repeated fractionation, indicated that the material was nearly pure after one fractionation, yet the empirical constitution (approximate formula, $C_4H_6NO_2$) could not be established from the values obtained on analysis. Molecular weight determinations in freezing benzene gave the values 120 and 112, which indicate that the blue oil is monomeric

---

[9] Schaarschmidt and Hofmeier, *Ber.*, **58**, 1047 (1925).

and of lower molecular weight than monomeric trimethylethylene nitrosate. The deep blue coloration is characteristic of monomeric nitroso derivatives, but, whereas the latter generally polymerize to crystalline solids, the purified, blue oils did not solidify at −80°. The catalyst and the experimental conditions were varied, but catalytic hydrogenation invariably stopped when relatively a small amount of hydrogen was absorbed and ammonia was the only reaction product identified; reduction with metals gave no better results. The blue oil is inert toward hot formic acid and 40% hydrobromic acid, did not react with phenyl isocyanate, nor with dimethylaniline. With phenylhydrazine and semicarbazide, oxidation occurred and the products could not be identified. Samples of blue oil separated from the reaction mixture by steam distillation had properties and gave results on analysis which compare favorably with those of preparations purified by low pressure distillation (Table II). In contrast, bis-trimethylethylene nitrosate is completely decomposed by steam distillation and under no conditions could it be depolymerized to a stable, blue oil. Attempts to convert the blue oil to a more stable product, by treatment with ozone, gave mixtures which could be separated only incompletely and could not be identified. Reduction of the blue oil with aqueous potassium hydrosulfide gave a complex mixture of products which could not be separated, nor could the nature of the main reaction product be established. The blue oil, isolated by methods which permit of semi-quantitative separation, constituted about 20–25% of the total reaction product.

By cooling the greenish-yellow oil, remaining as a residue after the liquid reaction product had been steam distilled, a crystalline, waxy solid (A), m. p. 60°, was obtained in low yield. The same material was subsequently isolated, in better yields, by cooling the greenish-yellow oil which was volatile with steam, or by diluting the original, liquid, reaction product with ether and cooling to −80°. The composition, $C_5H_{10}N_2O_4$, and the values (157 and 168) obtained in molecular weight determinations, together with the products, sodium nitrite and 3-nitro-2-methylbutanthiol-2-phenyl ether, quantitatively formed in the reaction with sodium thiophenylate, establish the structure of the waxy product as the nitrous ester of 3-nitro-2-methylbutanol-2. The quantitative details of the reactions which confirm the structure of the nitrous ester are given in Table III. Semi-quantitative isolation of the nitrous ester was not realized, but, based on the best separations, although steam distillation was employed entailing loss of about 15% of material, the minimum quantity produced in ether solution may be estimated as approximating 35% of the total reaction product.

The influence of a solvent upon the course of addition of hydrogen bromide to certain alkenes has long been known,[10] but in the above reaction the solvent exerts a decisive influence upon the chemical manner in which a reagent functions as an addendum. In petrol, or without solvent, the tetroxide functions with the component parts $—ONO_2 + NO$, yielding considerable amounts of the polymerized nitrosate; the oily by-products decomposed so easily that no pure compound could be isolated. On the other hand, the amount of bis-nitrosate formed in ether was relatively small, but the distillable oil contained up to 35% of the nitro-nitrite, formed by addition of the addendum components $—ONO + NO_2$ to the Δ-carbons.

Besides the blue oil and the nitrous ester, non-volatile, liquid products are formed constituting approximately 10% of the total reaction product. With sodium thiophenylate, no sulfur derivative indicative of the structure of the complex oil could be obtained. The molecular weight (208 and 307) of the non-volatile oil suggested that, in the presence of nitrogen tetroxide, trimethylethylene may have been polymerized to di- and triisoamylene and these acted upon by the tetroxide. Greenish-yellow oils were produced by the action of nitrogen tetroxide upon di- and triisoamylene, but, since no blue oils were formed, the products were not investigated. It is evident from the above results that the blue-green oil, formed by interaction of nitrogen tetroxide and trimethylethylene in ether, which Schmidt[2] believed to be the slightly impure monomeric nitrosate, is a complex product, from which as

yet only the isomeric, monomeric nitro-nitrite has been isolated in a perfectly pure condition.

Experimental

Nitrogen tetroxide was prepared by heating anhydrous lead nitrate, the evolved gas passed through a tube of phosphoric anhydride and condensed in a weighed ampoule.

Trimethylethylene was prepared by heating tertiary amyl alcohol with 10% hydrochloric acid, fractionating the distillate, removing the last traces of alcohol and water with sodium and refractionating.

Ether was dried with phosphoric anhydride and distilled. Petroleum ether (b. p. 20–40°) was washed, successively, with concentrated sulfuric and nitric acids, water, dried with phosphoric anhydride and distilled.

The reaction vessel, in all experiments excepting VII and VIII, consisted of a three-necked flask, provided with a stirrer, a calcium chloride tube and a tube suitably arranged so that connection could be made rapidly with the nitrogen tetroxide ampoule which, just previously, had been cooled to −30° and unsealed.

An all-glass arrangement of vertical, concentric tubes, shaped as nozzles,[11] was used in experiment VIII. The reaction chamber was 3 cm. long and 12 mm. in diameter and was sealed to 20 cm. of 10-mm. tubing, terminating in a 50-cc. bulb which, cooled to −30°, served as a condenser. By means of concentric nozzles suitably arranged, nitrogen tetroxide was diluted with dry nitrogen and entered the reaction chamber into which was simultaneously admitted a stream of nitrogen, previously passed through trimethylethylene contained in a Leyden flask cooled to 0°. Bis-trimethylethylene nitrosate collected in the vertical tube immediately below the reaction chamber and the green, oily product drained into the bulb condenser.

In experiment VII, nitrogen tetroxide was diluted with dry nitrogen, using the mixing apparatus described above, and then passed through an 8-mm. tube into the side neck of a two-necked flask, equipped with a stirrer and a calcium chloride tube.

With ether as solvent, the solid reaction product was filtered off, solvent removed at reduced pressure from the filtrate and the residual, blue oil steam-distilled, or distilled at the pressure of a mercury pump. With petroleum ether, the liquids were decanted from the bis-nitrosate, the solid triturated with ether, filtered off and the residual oil, recovered from the filtrate, combined with that decanted with the petrol solution. When no solvent was used the oily product was decanted, the solid washed with ether and the residual oil obtained from the filtrate combined with the decanted oil.

Separation of Liquid Products.—The liquids from two similar experiments were combined and the products separated by methods of which three typical examples are described. The low-pressure distillations were made in an all-glass apparatus, which was attached by a heavy rubber connector to a McLeod gage and a mercury vapor pump: distillation pressures were not recorded. A, B and C designate, respectively, the following compounds: the nitrous ester of 3-nitro-2-methylbutanol-2, 3-nitro-2-methylbutanthiol-2-phenyl ether and 3-nitro-2-methyl-2-phenylsulfone-butane.

Steam distillation of 55.6 g. of blue liquid gave (1) 25.8 g. of easily volatile, deep blue oil; (2) 13.9 g. of less volatile, greenish oil; and (3) 3.4 g. of residual oil. Distillate (1) was fractionated and gave 16.0 g. of deep blue distillate, b. p. 46–70° at 3 mm., leaving 6.8 g. of green, residual oil which, at −25°, deposited 1.5 g. of (A), m. p. 60°. *Anal.* Calcd. for $C_5H_{10}N_2O_4$: C, 37.05; H, 6.16; N, 17.3. Found: C, 37.23; H, 5.9; N, 16.6. The greenish oil (2) solidified at −25°, but only 3.2 g. of (A) could be isolated by filtration; the filtrate, diluted with ether and cooled to −80°, deposited 8 g. of crude (A), which was recrystallized from ether at −80° and gave 6 g. of pure product: mol. wt. calcd., 162. Found, in freezing benzene, (1) 157; (2) 168.

Low pressure distillation of 77 g. of blue oil yielded only 3.2 g. of blue distillate during three hours. The operation was discontinued, the residual, blue-green oil diluted with ether and cooled to −80° deposited 13.8 g. of (A). The oil (49.7 g.) from the filtrate was steam distilled and the oily distillate, cooled to −80°, gave 3 g. of (A). In another low pressure distillation, 71 g. of blue oil gave 24.0 g. of deep blue distillate, leaving 39.5 g. of greenish oily residue from which, after two recrystallizations at −80°, 6.7 g. of pure (A) was isolated. Three grams of (A) was added to a solution prepared from 0.8 g. of sodium, 20 cc. of methyl alcohol and 5 g. of thiophenol: the organic product (3.9 g.), insoluble in 10% alkali, distilled to give 3.2 g. of (B), b. p. 135° at 2 mm., which was treated with 3 g. of chromic anhydride in 10 cc. of glacial acetic acid and gave 3.1 g. of (C).

When steam distilled, the residual green oil (32.8 g.), from which the nitrous ester had been separated at −80°, gave (a) 20.8 g. of blue-green distillate and (b) 4.2 g. of viscous, yellow, residual oil. The blue-green oil (a) was fractionated: (1a) 3.3 g., of blue oil, b. p. 55–72° at 2 mm.; (2a) 16.2 g., nearly colorless oil, b. p. 80–100° (mostly at 87–100°) at 2 mm. Three grams of fraction (2a), treated with sodium thiophenylate as described above, gave, as the organic product, 3.7 g. of oil from which 3.5 g. of (B),

NOTES ON TABLE III

D and E represent the phenyl and ethyl ethers, respectively, of 3-nitroso-2-methylbutanthiol-2; for reasons stated above, these compounds may have the isonitroso structure. F designates bis-trimethylethylene nitrosate, A, B and C the same compounds as before.

I. A suspension of (F) was heated with alcoholic sodium thiophenylate, most of the solvent removed and sodium nitrate filtered off. An ether solution of the filtrate was washed with water, dried and the solvent removed. The residual thio ether (D) melted at 90°. *Anal.* Calcd. for $C_{11}H_{15}NOS$: C, 63.16; H, 7.18; N, 6.7; S, 15.3; mol. wt. 209. Found: C, 63.25; H, 7.5; N, 7.15; S, (1) 15.9; (2) 15.4; mol. wt. (in freezing benzene), (1) 273, (2) 308. In ether solution, 1 g. of (D) and 0.6 g. of (D) (1 g.) and 0.6 g. of phenyl isocyanate gave 1.6 g. of addition compound, m. p. 113–114°. *Anal.* Calcd. for $C_{18}H_{20}N_2O_2S$: C, 65.85; H, 6.1; N, 8.54. Found: C, 65.87; H, 5.87; N, 9.1.

II. Products treated as above. *Anal.* Calcd. for $NaNO_3$: Na, 27.05. Found: Na, 26.9.

III. A suspension of (F) in a solution prepared from 0.3 g. of sodium, 25 cc. of alcohol and 0.8 g. of ethylmercaptan was heated, solvent distilled and sodium nitrate collected. *Anal.* Calcd. for $NaNO_3$: Na, 27.05. Found: Na, 27.3. The filtrate, in ether solution, was washed with water, dried and the solvent removed. The thio ether (E) was purified by sublimation at reduced pressure. *Anal.* Calcd. for $C_7H_{15}NOS$: S, 19.9; mol. wt., 161. Found: S, 20.3; mol. wt. (in freezing benzene), 231. In ether solution, 0.5 g. of (E) and 0.4 g. of phenyl isocyanate gave 0.8 g. of addition compound, m. p. 122°. *Anal.* Calcd. for $C_{14}H_{20}N_2O_2S$: N, 10.1; S, 11.43. Found: N, 10.12; S, 11.49.

IV. Bis-trimethylethylene nitrosate was suspended in a solution prepared from 0.3 g. of sodium, 25 cc. of alcohol and 1 g. of ethyl mercaptan. *Anal.* Calcd. for $NaNO_3$: Na, 27.05. Found: Na (1) 27.90; (2) 27.95. Solvent was removed from the filtrate, the residue, in ether solution, washed with water, dried and the solvent removed. The residual product (E) solidified completely.

V. A methyl alcohol solution of (A) and sodium thiophenylate was heated on the water-bath, most of the alcohol distilled and the sodium nitrite filtered off. *Anal.* Calcd. for $NaNO_2$; Na, 33.35. Found: Na, 33.23. Solvent was removed from the filtrate and the residual thio ether (B) distilled at 1 mm. with the bath temperature at 170°.

VI. Sodium nitrite (0.5 g.) was filtered off: the alcoholic filtrate, after concentration, yielded 0.3 g. of sodium nitrite. Both portions were analyzed. *Anal.* Calcd. for $NaNO_2$: Na, 33.35. Found: Na (1) 33.3; (2) 33.25. The liquid thio ether (B), treated with 2.7 g. of 30% hydrogen peroxide in acetic acid, was recovered unchanged; oxidized with 2.7 g. of chromic anhydride in 10 cc. of hot acetic acid, gave the sulfone (C) (2.3 g.), m. p. 102–103°. *Anal.* Calcd. for $C_{11}H_{15}NO_4S$: C, 51.4; H, 5.84. Found: C, 51.25; H, 5.84.

b. p. 132° at 2 mm., was obtained, oxidation of (B) with chromic anhydride, after two treatments, yielding 1.9 g. of (C).

The oil, non-volatile with steam, gave the value 307 in a molecular weight determination in freezing benzene. Incomplete separation may account for the lower value (208), found for the residual oil remaining after the liquid product had been distilled at low pressure.

The easily volatile, deep blue oil, isolated by steam or low pressure distillation, was fractionally distilled, using a jacketed column of beads. A typical fractionation is give in Table II.

(B) Properties of Blue Oil Separated by Steam Distillation.—B. p. 43–47° at 2 mm.; $n^{9.5}_D$ 1.4512; d_{20} 1.044; mol. wt., 120. Analysis of three preparations gave the average results: C, 48.72; H, 7.25; N (one determination), 12.58.

Table III is a summary of the data obtained in the study of the action of sodium mercaptides upon bis-trimethylethylene nitrosate and the nitrous ester of 3-nitro-2-methylbutanol-2.

Summary

1. The action of nitrogen tetroxide upon trimethylethylene has been re-investigated. The course of the reaction varies slightly with the temperature but greatly with the solvent. In ether, comparatively little bis-trimethylethylene nitrosate is formed; the yield of the latter varied from 28–39% in petrol and without solvent from 42–49%, although the temperature varied from −80 to 30°. Since the proportion of NO_2 to O_2NONO in the system $2NO_2 \rightleftarrows O_2NONO$ increased considerably, the course of formation of bis-nitrosate is relatively independent of the degree of dissociation of the addendum.

2. The liquid reaction product formed in petrol solution, or without solvent, is unstable and decomposed on vacuum distillation. The chemical nature of the oil could not be established.

3. The blue-green liquid formed in ether solution, contrary to the conclusion of Schmidt, is

not, or to any appreciable extent, the monomeric trimethylethylene nitrosate. The blue coloration is caused by a distillable, blue liquid, constituting only 20–25% of the total reaction product, which could not be polymerized, nor solidified at −80°. Oxidation as well as addition apparently enters into its formation. The remainder of the liquid reaction product is composed of the nitrous ester of 3-nitro-2-methylbutanol-2, constituting at least 35% of the total reaction product, and high boiling, complex oils, representing 10% of the total product, which could not be characterized.

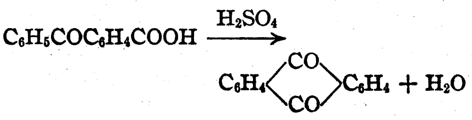
A Kinetic Study of the Sulfuric Acid Condensation of *o*-Benzoylbenzoic Acid[1]

BY CHARLES W. DEANE

Both for considerations of kinetic theory and for its practical interest as the principal step in the industrial synthesis of the dye intermediate, anthraquinone, an extension of the velocity measurements on the decomposition of *o*-benzoylbenzoic acid, particularly in fuming sulfuric acid concentrations, appears especially valuable.

The major historical points appeared in an earlier report[2] on this reaction



$$C_6H_5COC_6H_4COOH \xrightarrow{H_2SO_4} C_6H_4\genfrac{<}{>}{0pt}{}{CO}{CO}C_6H_4 + H_2O$$

Since 1929 Wiig,[3] also Hammett and his co-workers,[4,5] have used the data upon *o*-benzoylbenzoic acid in dealing, respectively, with Taylor's theory of negative catalysis and with correlations of the kinetics to the acidity function, H_0.

With reference to Fig. 1, a graphical analysis using the data of Gleason and Dougherty shows that rather than as reported to the contrary,[2] *o*-benzoylbenzoic acid is not exceptional, but is like oxalic acid in having the velocity constant k, as a logarithmic or exponential function of the water present. The extra dotted line shows the result of using Gleason and Dougherty's kinetic value obtained at a decomposition of but 4% which resulted from employing an inflexible four-hour period to measure the reaction rate.

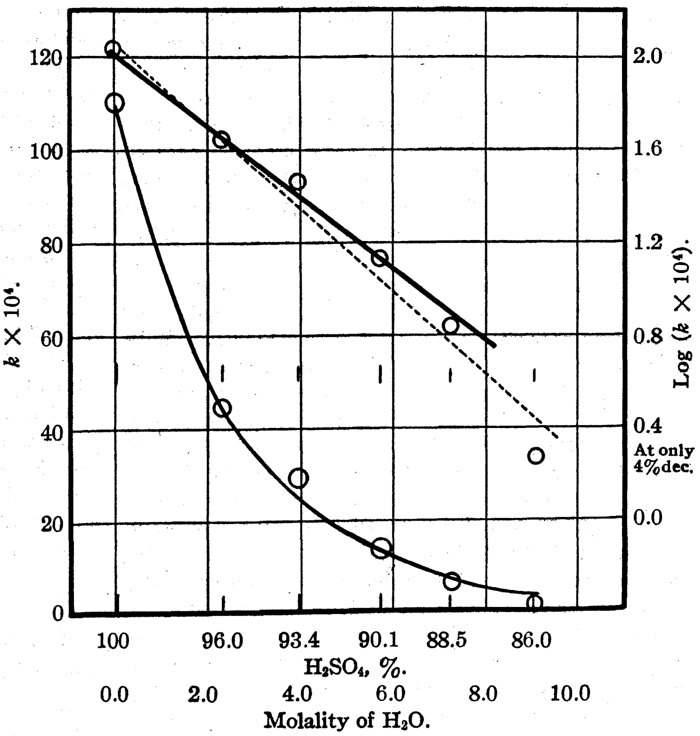


Fig. 1.—The velocity constant k for the condensation of *o*-benzoylbenzoic acid by sulfuric acid at 75°. Analysis of data obtained by Gleason and Dougherty.[2]

The main objectives in the present work have been to extend the data by certain basic improvements in the general method of Gleason and Dougherty,[2] and to obtain precise results at the far higher reaction speeds due to fuming sulfuric acid. This extension of data was undertaken to check general theoretical predictions of the kinetic effects[3] in the unexplored regions of fuming sulfuric acid.

Among the exceptional features and advantages afforded by this reaction for kinetic studies

are: a single reaction product, besides the equivalent of water, results; this is obtained instantaneously by a dilution of the reaction mixture, and accurate gravimetric measurements are possible; the reactants and products remain in the liquid phase; the substrate concentrations employed can be relatively very high; any slight side products of the reaction play in it a very negligible part.

Experimental Part

Preparation and Purification of Materials.—The following method of purifying *o*-benzoylbenzoic acid, similar to that used in the Eastman Synthetic Laboratories, is based on 500 g. of the original material. In a 1-liter wide-mouthed flask heat over a free flame to about 80° with mechanical stirring, 335 g. (5.55 moles) of glacial acetic acid (99.9%, m. p. 16.6°, sp. gr. 1.05). A current of air properly blown around the neck of the flask prevents any acetic acid vapors from flowing down around the flask to the heat source and igniting. With the temperature of the acetic acid at 80–85°, slowly add 500 g. (2.38 moles) of *o*-benzoylbenzoic acid, m. p. 127°. After continued stirring until this acid is dissolved, filter the mixture through flannel. While the filtrate is still hot pour it into a 2-liter flask and add cold water until the solution commences to become cloudy. Now add no more water until crystals of *o*-benzoylbenzoic acid begin to appear, which with mechanical stirring occurs within five minutes. At this point add slowly more cold water (if water is added too rapidly, undesirable large lumps of an *o*-benzoylbenzoic acid aggregate form) until the 2-liter flask is filled. With external cooling by a water jet, continue mechanical stirring until the mixture is cold. Filter the crystals by suction, and wash well to remove any remaining acetic acid. Accomplish the removal of the last water in a hot cabinet, drying the material at 105–110° on glass or porcelain.

The purified *o*-benzoylbenzoic acid when dry melted at 127.2–128.5° (corr.). Both Richter's "Lexikon" and the "International Critical Tables" give a m. p. of 127° for water-free material. Tests on the above purified material by twelve hours of drying at 110–115° showed a loss of weight of less than 0.2%. The water-absorbing power of this material on exposure to ordinary laboratory conditions of humidity was negligible (0.002%). Before purification, this material, upon heating for four hours in an oven at 110–115°, proved to be 3 to 5% volatile. Because the *o*-benzoylbenzoic acid furnished (Eastman product) became a deep brown on solution in sulfuric acid it was conjectured that, despite a sharp melting point, small aggregates of foreign materials might be causing coloration, or that possibly a breakdown and carbonization was occurring. Tests on the carefully purified materials, however, resulted in colored solutions both for anthraquinone and for *o*-benzoylbenzoic acid. This is in line with the basis of recent colorimetric determinations of acidity in the highly concentrated acids[4,5] in which slight concentrations of anthraquinone are used as indicators.

Three lots of sulfuric acid corresponding to 94.86, 100.42 (1.8% fuming), and 105.92% (26.2% fuming) were employed. Except for the first, these were prepared by mixing c. p. 95% sulfuric acid with Baker and Adamson reagent quality fuming sulfuric acid, 30%, in the calculated proportions for approximating the desired strengths. By precipitation as barium sulfate four samples of each were analyzed, due precautions being taken in weighing and manipulation to prevent either sulfur trioxide loss or moisture absorption. An independent and fuller check, as it included the calculating and mixing procedure universally employed in the experiments to obtain the sulfuric acid strengths used, was obtained by mixing in the calculated proportions 94.86 and 100.42% sulfuric acid for a 100% acid, and taking its melting point. By a triple determination this was 10.38°, or the acid thus proved to be within 0.1% of 100% by comparison with a plot of the data of Hantzsch[6] in which per cent. water concentration in the sulfuric acid was plotted against the melting point.

Apparatus and Procedure.—Solutions of *o*-benzoylbenzoic acid in sulfuric acid of the desired strength were prepared in 200-cc. round-bottomed flasks provided with propeller stirrers and adequately protected against the access of moisture from the air. In general 8.1021 g. of the ortho acid was added to 35 cc. of sulfuric acid solution at the reaction temperature and the stirring started. Independent tests showed that within six to nine minutes thereafter the temperature of the solutions came within one-tenth of a degree of that prevailing in the surrounding thermostat (constant within 0.1°), whereupon an initial sample was removed. Subsequent samples were removed by means of a 5-cc. pipet at 0.25, 0.40, 0.60, and 0.75 of the life period of the reaction, delivered into 100 cc. of water and analyzed according to the procedure of Gleason and Dougherty,[2] except that an asbestos mat in a Gooch crucible was employed for filtration.

The initial concentration, *a*, was ascertained in two ways; either by analysis after allowing the reaction to go to completion in triplicate samples, or by calculation from the original amounts of ortho acid added, correcting in each case for the expansions due to the temperature change and to the addition of the ortho acid. These corrections were at 75° 19.6 and 20.0%, and at 85° 20.1 and 20.4%, for 98.0 and 105.9% sulfuric acid, respectively.

Results

Completeness and Order of the Reaction.—Quantitative yields of anthraquinone from *o*-benzoylbenzoic acid have been reported.[2] In 8% fuming sulfuric acid, the author found the yields above 99%; however, at concentrations above 20% fuming acid, yields fell to 97–98%.

A set of typical kinetic measurements and the computed velocity constants, assuming a unimolecular reaction, appear in Table I.

As can be seen from the last column, the value of the constant decreases slightly as the reaction progresses, doubtless due to the water formed during the reaction. Further proof that the reaction is indeed unimolecular was obtained

by similar experiments at half the ortho acid concentration above, when values resulted whose average was 125.1.

The Effects of Water and of Sulfur Trioxide on the Reaction Rate.—Based on previous findings of sulfur trioxide and of water as negative inhibitors upon the oxalic, malic and the citric acid decompositions,[7–9] a maximum rate of decomposition would be expected with *o*-benzoylbenzoic acid. Tables II and III summarize the average velocity constants for each set of experiments at 75 and 85°. The mean deviation of the half-life average *k*'s is less than 0.4%, and at comparable points, the data agree well with the values of Gleason and Dougherty.[2] These determinations indicate that the ortho acid is really an exceptional case to the predicted maximum[3] based on Taylor's theory of negative catalysis.[10]

106.5		5.055	477.8	486.2	481

Figure 2 shows the relative effects of water and of sulfur trioxide upon the logarithm of the velocity constant, *k*. Up to the 100% point, the molality (moles per 1000 g. of solvent) of the inhibitor, water, plotted against the logarithm of *k* gives a straight line. Beyond the 100% point, the slope of the line lessens considerably, being nearly horizontal from 2% fuming acid to approximately the 14% point. Despite special experimental care, no peak was found at 14% sulfur trioxide, which point may possibly be the maximum for oxalic acid.[7] At 14% fuming acid and higher, the decomposition curve for *o*-benzoylbenzoic acid rises to assume a slope approximately one-fifth of the slope caused by a corresponding decrement in the molality of water below the 100% sulfuric acid point.

The Effect of Temperature on the Reaction Rate.—The development of a correlation of kinetic data with various postulated factors and mechanisms may be aided considerably by data on the temperature coefficient, and by a tabulation of *E*, the energy of activation. These values are given in Table IV for which the data of Tables II and III have been used to derive the values presented. The values of *E* were calculated from the following integrated form of the Arrhenius equation

$$E = \frac{1.98 \times T_2 \times T_1 \times \log k_2/k_1 \times 2.303}{T_2 - T_1}$$

The ratio of k_2/k_1 was evaluated by a large scale

plot of Fig. 2 on cross section paper. A computation of the data of Gleason and Dougherty yields temperature coefficients of 3.2 and 3.4, respectively, for the intervals 85–75° and 75–65° at 96% sulfuric acid. The results presented here indicate a temperature coefficient somewhat below three, as shown in Table IV, but the agreement is reasonably satisfactory. It is to be noted that the sulfur trioxide, *acting as a positive catalyst*, diminishes the temperature coefficient.

Discussion

Figure 3 compares the effects of corresponding molalities of water and of sulfur trioxide upon the rates of decomposition of three organic acids with sulfuric acid. Table V lists these acids and states the widely variant effects of the catalysts upon the decomposition velocities. The unusual feature for *o*-benzoylbenzoic acid is the behavior of sulfur trioxide, particularly in fuming acid concentrations above 14%, as a positive catalyst.

TABLE V

COMPARISON OF THE INHIBITING POWER OF WATER AND OF SULFUR TRIOXIDE UPON THE DECOMPOSITION OF ORGANIC ACIDS

Organic acid	Relative inhibiting power For water	For sulfur trioxide
Oxalic	++, very strong	o, weak, if at all
Malic	++, very strong	++, very strong
o-Benzoylbenzoic	o, +, quite weak	o, − not inhibition, but acceleration

Possible correlations on the basis of effective ionic and molecular concentrations to explain the sulfuric acid decompositions of the organic acids are now considered. Because organic oxygen compounds are highly ionized basically in strong sulfuric acid, it is possible that factors of acid–base catalysis are effective. Assuming that the hydrogen ion concentration is related to reaction velocity, then the kinetic data on *o*-benzoylbenzoic acid indicate an increasing acidity in fuming sulfuric acid. An interesting question is the validity of this correlation above 100% sulfuric acid. Thus, to test whether the hydrogen ion concentration in terms of the acidity function H_0,[5] is a prime variable, its measurement in fuming sulfuric acid is in order. Because of the variant kinetic features exhibited by the oxalic and malic acid decompositions (Fig. 3 and Table V) it definitely appears that other phenomena predominate, and that these reactions are *not* governed by simple ionic factors.

To consider the kinetics of *o*-benzoylbenzoic acid from the molecular standpoint up to 28.8% fuming sulfuric acid, also, the extent of the determinations is limited. Of the five organic acids[1,7,9,11,12] only the oxalic acid study[7] presents data over a sufficient range to permit general comparisons with the kinetics of the *o*-benzoylbenzoic acid.[13] In Fig. 3 it will be noted that the ortho acid rate remains nearly horizontal from approximately 2 to 14% fuming acid. This 14% point also appears the point of maximum decomposition velocity for oxalic acid. Above 14% sulfur trioxide, however, a marked difference is to be noted: the oxalic acid decomposition is probably very slightly inhibited, while that of *o*-benzoylbenzoic acid is definitely accelerated by additional sulfur trioxide.

To explain these phenomena molecularly, the oxalic acid behavior up to the 14% point is due

[13] However, it may be noted that in the cases for citric and malic acids, the reaction in fuming sulfuric acid at 14% sulfur trioxide approaches zero rate at room temperatures.

to the decreased water (a very strong inhibitor here) in the fuming sulfuric acid by the increase of sulfur trioxide. Above 14% sulfur trioxide the reaction is that of oxalic acid with sulfuric acid, slightly inhibited by the sulfur trioxide. This is in accord with Taylor's theory of negative catalysis.[10]

To rationalize the exceptional *o*-benzoylbenzoic acid, a new case may be postulated in that the predominant reaction above the 14% point is the decomposition caused by sulfur trioxide itself, or by pyrosulfuric acid. No inhibiting complex with sulfur trioxide is effective, so that Taylor's theory of negative catalysis does not here apply in fuming sulfuric acid above 14% sulfur trioxide.
