Below 14% sulfur trioxide the same mechanism may apply for *o*-benzoylbenzoic acid as for oxalic acid. By Fig. 3 and Table V water is shown a relatively weak inhibitor for *o*-benzoylbenzoic acid. An explanation, then, as to why its curve (Fig. 3) remains flat to about 14% sulfur trioxide follows: the inhibiting water is furnished by the equilibrium $H_2SO_4 \rightleftarrows SO_3 + H_2O$. Owing to a displacement of this to the right by temperatures of 75 and 85°, the experiments for *o*-benzoylbenzoic acid require a strength of about 14% sulfur trioxide to overcome the water resulting from the dissociation at these higher temperatures.

A mechanism for the decomposition of *o*-benzoylbenzoic acid by sulfuric acid has been proposed by Gleason and Dougherty.[2] Their velocity measurements upon which this was partly based, however, were not such as would disclose the slowing down of the reaction during its course because the reaction speed is relatively quite insensitive to the slight amount of water formed. Inasmuch as the decrease of *k* as shown in Table I consistently occurred in all these experiments, the fast reaction they postulated because of no falling off of the rate receives no support here. The proposed intermediate reaction may take place but probably is not instantaneous.

From the industrial angle, the kinetic data above reported deal directly with a principal step in the production of anthraquinone. By the data presented, comparisons can be made of the relative condensing powers of concentrated and fuming sulfuric acids.

The author wishes to express his heartfelt appreciation to Dr. Edwin O. Wiig for his helpful suggestions and sincere interest in the progress of this work.

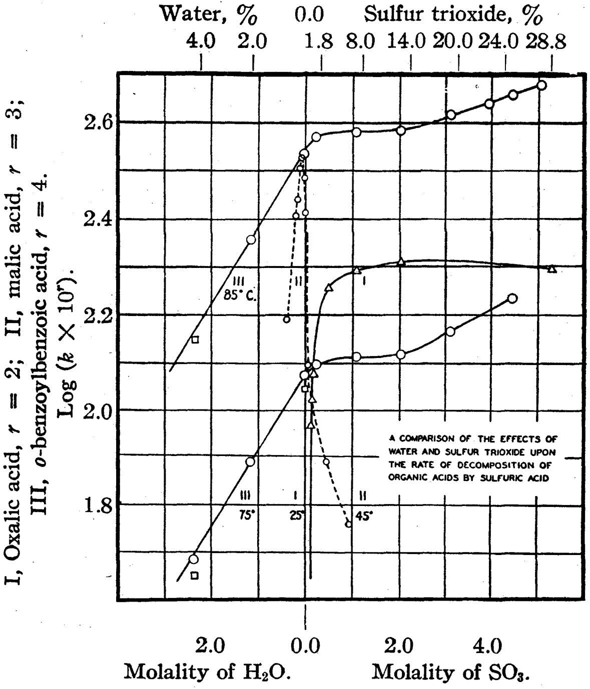

Fig. 3.—A comparison of the effects of water and of sulfur trioxide upon the rate of decomposition of organic acids by sulfuric acid.

Summary

This investigation of the decomposition velocity of *o*-benzoylbenzoic acid in concentrated and fuming sulfuric acid presents (1) an adequate method of determining the reaction rates in fuming sulfuric acid; (2) a suitable means of purifying *o*-benzoylbenzoic acid; (3) experimental evidence that the reaction follows the unimolecular law, and that yields are quantitative; (4) a check of earlier determined reaction rates and new reaction rate data, with energies of activation, for the decomposition of *o*-benzoylbenzoic acid in 98 to 106.5% sulfuric acid at 75° and 85°; (5) the discovery that, unlike other organic acids studied to date, *o*-benzoylbenzoic acid has no maximum decomposition velocity for a definite water or sulfuric trioxide concentration; and that sulfur trioxide at concentrations above 14% acts as a positive catalyst; (6) theories for the reaction mechanism briefly discussed and an explanation of the observed kinetics.

Condensations of Aromatic Amines with Formaldehyde in Media Containing Acid. VII. The Polymeric States and Structures of Some Anhydro-*p*-(alkylamino)-benzyl Alcohols

BY W. S. YOUNG AND E. C. WAGNER

Anhydro-*p*-alkylaminobenzyl alcohols of the type $\left[{}^{\text{R}}{>}\text{NC}_6\text{H}_4\text{CH}_2\text{—}\right]_n$, or their salts, have been reported from six alkylarylamines, *viz.*, methyl-, ethyl-, *n*-propyl-, *n*-butyl-, isoamyl- and benzyl anilines.[1-4] Only the methyl, ethyl and benzyl compounds have hitherto been isolated as bases,[2,4] and of these only the first has been well characterized. Friedländer[4] found for the methyl compound a molecular weight of 224, and reported it to be dimeric. He established its essential structure by reduction to methyl-*p*-toluidine. In like manner the salts of other bases of this type were shown[3] to have the same structure.

Knowledge of the anhydro-*p*-alkylaminobenzyl alcohols is so meager that a more careful characterization of the compounds mentioned was undertaken. The six bases were isolated in a state of purity from the purified hydrochlorides. Their essential structural identity was shown by reduction to the corresponding alkyl-*p*-toluidines. Molecular weight determinations in benzene, with precautions to minimize error due to moisture absorbed from the atmosphere, failed to confirm Friedländer's value for anhydro-*p*-methylaminobenzyl alcohol. This base, and all the others, were found to be trimeric, *viz.*, $\left[{}^{\text{R}}{>}\text{NC}_6\text{H}_4\text{CH}_2\text{—}\right]_3$. A cyclic structure is probable and would be strain-free.[5] Molecular weights determined in molten camphor were much higher, indicating further polymerization by heat. The bases, and to a less degree the hydrochlorides, are not very stable and on keeping acquire a yellow to orange color. Table I presents molecular weights, melting points and analytical values for the six bases. Results of the reduction experiments are mentioned in the experimental part.

The six bases were made also by the use of methylal instead of formaldehyde. A temperature of about 50° was necessary to disengage formaldehyde in the reaction mixtures, and as this temperature was favorable also to the formation of diphenylmethane bases[6] the method appeared to be without advantage.

Experimental

General.—The alkylanilines used were redistilled Eastman Kodak Company products; benzylaniline was a Kahlbaum specimen.

Boiling points of alkyl-*p*-toluidines obtained in the reduction experiments were determined by Siwoloboff's method.

Molecular weights in benzene were determined with a P. T. R. Beckmann thermometer in the presence of anhydrous barium perchlorate, as recommended by Rall and Smith,[7] and with an air-sealed mechanical stirrer to minimize interference by atmospheric moisture. The cryoscopic constant of the benzene was determined using pure naphthalene. Molecular weights in camphor were determined by the procedure of Rast, using a turpentine thermometer.

Preparation of Hydrochlorides of Anhydro-*p*-alkylaminobenzyl Alcohols.—The method described previously[3] was employed with slight changes as required in individual cases. Salts of the methyl-, ethyl-, *n*-propyl- and *n*-butyl compounds were made in water solution. To obtain the hydrochlorides of the isoamyl and benzyl bases it was found better to dissolve the alkylaniline in several parts of U. S. P. alcohol, add a slight excess of concd. hydrochloric acid, dilute with water and then add to the chilled mixture the required formalin. Benzylaniline separated at first as its hydrochloride, which dissolved progressively as the anhydro-*p*-benzylaminobenzyl alcohol hydrochloride formed and crystallized out.

The filtered anhydro-*p*-alkylaminobenzyl alcohol hydrochlorides were washed thoroughly with alcohol and then ether. This operation was found to be important, especially with the *n*-butyl and isoamyl compounds, whose salts were slimy as first obtained. The alcohol and ether removed resinous or oily impurities which otherwise later contaminated the isolated bases and impeded their crystallization. The salts so obtained were pure white, and unlike specimens prepared without effective washing,[3] approached analytical purity.

Preparation of the Anhydro-*p*-alkylaminobenzyl Alcohol Bases.—The washed and dried salt was suspended in about five parts of alcohol chilled in ice. The mixture was stirred mechanically and 20% aqueous sodium hydroxide solution was added slowly to alkalinity. Stirring and chilling were

[a] Averages of from two to five values. [b] Previously reported[2,3]: 210°, 205–210°. [c] Friedländer[4] found 224. [d] Previously reported[2,4]: 86°, 79–80°. [e] Previously reported[2]: 161°. [f] Semi-micro method. Analyses by Wm. McClellan. [g] Semi-micro Kjeldahl method. Analyses by F. W. Landau. [h] Micro Dumas method. Analyses by Edw. D'Ouville.

continued some minutes longer, and any lumps of base were broken up. The mixture was treated with several volumes of ice water, and the precipitated base was filtered off and washed with cold 50% alcohol. It was dried in a vacuum desiccator and then crystallized. The methyl compound was satisfactorily crystallizable from benzene, and the other compounds from ligroin (70–90°). The *n*-butyl and isoamyl compounds were very soluble in ligroin, and their recovery necessitated evaporation of part of the solvent; the isoamyl compound required considerable manipulation to induce crystallization.

The bases were crystalline and white, but became discolored on standing. Melting points were not in all cases sharp; it is possible that melting was accompanied by incipient decomposition or by change in polymeric state. The melting points of homologous bases showed "alternation."

Reduction of Anhydro-*p*-alkylaminobenzyl Alcohols to Alkyl-*p*-toluidines.—Reduction was effected using zinc dust and hot dilute sulfuric acid as previously described.[3] The alkyl-*p*-toluidines from new bases were identified by their boiling points and by melting points of their hydrochlorides. The values obtained were as follows: (1) *n*-propyl-*p*-toluidine, b. p. 237–240°; hydrochloride, m. p. 154–155°, (2) *n*-butyl-*p*-toluidine, b. p. 251–252°; hydrochloride, m. p. 148–149°, (3) isoamyl-*p*-toluidine, b. p. 266–267°; hydrochloride, m. p. 139–142°, (4) benzyl-*p*-toluidine, b. p. 318–320°; hydrochloride, m. p. 180–181°. The hydrochlorides of *n*-butyl- and isoamyl-*p*-toluidines were identified also by mixed melting point tests.

Summary

1. Three new bases of the anhydro-*p*-alkylaminobenzyl alcohol series have been prepared, and together with three bases previously known, have been characterized with respect to polymeric state and structure.

2. The six bases were found to be trimeric in benzene solution, a finding at variance with Friedländer's conclusion that anhydro-*p*-methylaminobenzyl alcohol is dimeric. In molten camphor polymerization was found to be extensive. Strong reduction split the bases into the corresponding alkyl-*p*-toluidines, showing them to have the structure $\left[{}^{R}\!\rangle NC_6H_4CH_2—\right]_3$.

Reactions of Alkenyl Esters Derived from Alkylacetylenes[1]

BY STEFAN J. SLANINA AND G. F. HENNION

Introduction

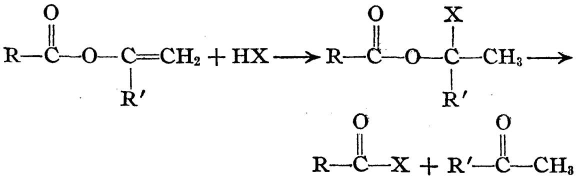
It was reported in a previous paper[2] that addition of bromine to the 2-acyloxy-1-alkenes derived from alkylacetylenes was followed by spontaneous cleavage yielding an acyl bromide and a monobromomethyl alkyl ketone. Further study has revealed that a number of other agents effect similar cleavage.

As in the case of bromination these esters react readily with hydrogen bromide and chloride. The addition compounds are unstable and cleave to yield the acyl halide and corresponding methyl alkyl ketone. The reactions may be represented as

---

(1) Paper XX on the chemistry of the alkylacetylenes and their addition compounds; previous paper, *J. Org. Chem.*, **1**, in press (1937).

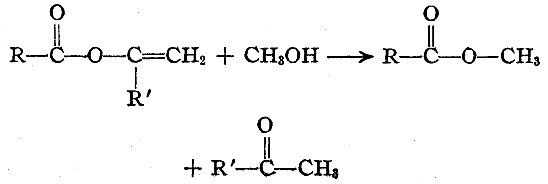
(2) Slanina, Hennion and Nieuwland, THIS JOURNAL, **58**, 891 (1936).



$$\mathrm{R{-}\overset{O}{\overset{\|}{C}}{-}O{-}\underset{R'}{\underset{|}{C}}{=}CH_2 + HX \longrightarrow R{-}\overset{O}{\overset{\|}{C}}{-}O{-}\underset{R'}{\underset{|}{\overset{X}{\overset{|}{C}}}}{-}CH_3 \longrightarrow R{-}\overset{O}{\overset{\|}{C}}{-}X + R'{-}\overset{O}{\overset{\|}{C}}{-}CH_3}$$

The intermediate halogen esters were not isolated. When hydrogen bromide was used, however, there was obtained, in addition to the two products indicated in the above equation, a small quantity of unidentified high-boiling material. Tests for bromine were negative. A corresponding substance was not obtained when 2-(chloroacetoxy)-1-hexene was treated with hydrogen chloride.

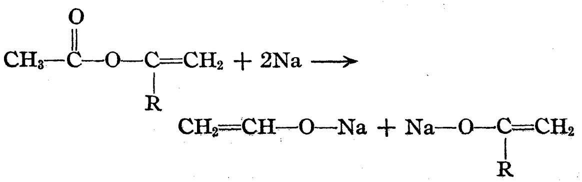
The alkenyl esters alcoholize readily when either *p*-toluene sulfonic acid or sodium methylate are employed as catalysts.



$$\mathrm{R{-}\overset{O}{\overset{\|}{C}}{-}O{-}\underset{R'}{\underset{|}{C}}{=}CH_2 + CH_3OH \longrightarrow R{-}\overset{O}{\overset{\|}{C}}{-}O{-}CH_3 + R'{-}\overset{O}{\overset{\|}{C}}{-}CH_3}$$

When such an ester and sodium methylate were mixed in molar proportions the reaction was extremely violent and apparently yielded the sodium ketone enol in addition to the methyl ester.

The 2-acetoxy-1-alkenes do not decompose when kept in contact with liquid ammonia at −34° for one hour. They do, however, react rapidly with sodium in liquid ammonia in the ratio of one mole of ester to two atoms of sodium, probably as follows



$$\mathrm{CH_3{-}\overset{O}{\overset{\|}{C}}{-}O{-}\underset{R}{\underset{|}{C}}{=}CH_2 + 2Na \longrightarrow CH_2{=}CH{-}O{-}Na + Na{-}O{-}\underset{R}{\underset{|}{C}}{=}CH_2}$$

Addition of 2-acetoxy-1-hexene to a solution of iodine in liquid ammonia also effected ester cleavage. Iodoform was the only identified product and the reaction was not further investigated.

Experimental

Reagents.—The alkenyl esters were prepared from the appropriate alkylacetylene and acid as previously described by Hennion and Nieuwland.[3] Hydrogen bromide was generated by the action of bromine on hot tetralin and was purified by passage over naphthalene followed by phosphorus pentoxide. Hydrogen chloride was obtained from sodium chloride and sulfuric acid and was dried by bubbling through sulfuric acid.

Action of Hydrogen Bromide on 2-Acetoxy-1-heptene.—A one-liter three-necked flask was equipped with a reflux condenser, a motor-driven mercury-sealed stirrer and a gas inlet tube extending to the bottom. Into the flask there was placed 117 g. (0.75 mole) of acetoxyheptene. The flask was cooled with ice and water and hydrogen bromide passed in with stirring until saturated which required about thirty minutes. The crude product was transferred to a 500-ml. round-bottomed flask provided with a 40-cm. Vigreux column and distilled. Three fractions were collected at atmospheric pressure: up to 100°, 100–140° and 140–160°. The pressure was then reduced to 23 mm. and a fraction boiling between 135–150° was collected. There was 14 g. of residue. Repeated distillation of the first three fractions yielded 38 g. (41% yield) of acetyl bromide, b. p. 80–81°, 10 g. of acetic acid, and 42 g. (49% yield) of methyl amyl ketone,[4] b. p. 145–150°. The vacuum distilled material was redistilled *in vacuo* and 15 g. of product collected between 140–150° at 23 mm. This unidentified material had the following characteristics: $n^{27}\mathrm{D}$ 1.4511; d^{27} 0.8421.

The identity of the acetyl bromide was confirmed by its action on anhydrous methanol. Methyl acetate was formed with rapid evolution of hydrogen bromide. The methyl amyl ketone yielded a semicarbazone, m. p. 122°.

Action of Hydrogen Bromide on 2-Acetoxy-1-hexene.—Hydrogen bromide was passed into 106.5 g. (0.75 mole) of acetoxyhexene at 30–32° as described above. Distillation gave 40 g. (43% yield) of acetyl bromide, 34 g. (45% yield) of methyl butyl ketone,[4] b. p. 124–127°, and 12 g. of a fraction, unidentified, b. p. 130–140° at 23 mm.; $n^{27}\mathrm{D}$ 1.4491; d^{27} 0.8465. There was 23 g. of non-distilled residue.

Action of Hydrogen Chloride on 2-(Chloroacetoxy)-1-hexene.—Hydrogen chloride was passed into 106 g. (0.6 mole) of chloroacetoxyhexene at approximately 10° as described above. Distillation to 124° at atmospheric pressure gave 40 g. of distillate. The pressure was then reduced to 20 mm. and distillation continued yielding 35 g. boiling to 90° and 35 g. boiling between 90–102°. The residue weighed 9 g. Repeated distillation yielded 25 g. of chloroacetyl chloride, b. p. 108–112°, 33 g. of methyl butyl ketone, b. p. 124–127° and 35 g. of recovered chloroacetoxyhexene, b. p. 97–102° at 20 mm.

Alcoholysis of 2-Acetoxy-1-heptene.—A solution of 0.5 g. of sodium in 12 g. of absolute methanol was treated with 47 g. (0.3 mole) of acetoxyheptene at 0°. The mixture was refluxed on a water-bath for thirty minutes and distilled. There was obtained 18 g. (81% yield) of methyl acetate, b. p. 54–57° and 28 g. (81% yield) of methyl amyl ketone, b. p. 148–155°.

A second sample of acetoxyheptene weighing 41 g. (0.263 mole) was treated with 40 g. of absolute methanol in which 1 g. of *p*-toluene sulfonic acid had been dissolved. The mixture was heated for three hours on the water-bath and distilled, yielding 15 g. of methyl acetate and 25 g. of methyl amyl ketone.

Cleavage of 2-Acetoxy-1-heptene with Sodium in Liquid Ammonia.—A mixture of 41 g. (0.263 mole) of acetoxy-

---

[3] Hennion and Nieuwland, THIS JOURNAL, **56**, 1802 (1934).

[4] The product darkened upon standing unless thoroughly washed with sodium carbonate and water prior to final distillation.

heptene in 200 ml. of liquid ammonia was treated with 11.5 g. (0.5 mole) of sodium dissolved in 200 ml. of liquid ammonia. It was necessary to add 1 ml. more of the ester to effect complete decolorization of sodium. The mixture was hydrolyzed by careful addition of 250 ml. of water. The organic layer was washed twice with water, dried over calcium chloride, and distilled. Distillation was complete between 146–151° to give 23 g. (77% yield) of methyl amyl ketone. The semicarbazone melted at 122°.

Summary

Cleavage of alkenyl esters R—COO—C(R)=CH_2 with hydrogen bromide, hydrogen chloride, methanol, sodium in liquid ammonia and iodine in liquid ammonia is reported and the products described.

Anthranol-beta-*d*-glucoside[1]

BY JOHN H. GARDNER[2] AND THOMAS F. MCDONNELL

In view of the suggestion of Hauser[3] that barbaloin is a *d*-arabinoside of aloe-emodin anthranol, since it yields aloe-emodin anthrone on hydrolysis with borax solution, we have prepared anthranol-β-*d*-glucoside as the most readily obtained analogous compound and have studied its hydrolysis under a variety of conditions by the methods used previously in the study of glycosides of various mono- and dihydroxyanthraquinones.[4] It was found that anthranol-β-*d*-glucoside is hydrolyzed completely by 0.05 *N* hydrochloric acid in one hour and by 0.05 *N* potassium hydroxide in thirty minutes. Hydrolysis was 62.4% complete in one hour with 9% borax. All hydrolyses were carried out at 100°. In the acid hydrolysis, pure anthrone was recovered, but with potassium hydroxide a part of the product was oxidized to dianthrone. The hydrolysis product formed with borax was not separated from unchanged glucoside and consequently was not identified.

These results differ markedly from the behavior of barbaloin in several ways. Notably, aloin is hydrolyzed extremely slowly by hydrochloric acid yielding chiefly a red, resinous material with a small amount of aloe-emodin, an anthraquinone derivative. No evidence of the formation of aloe-emodin anthrone under these conditions has ever been found. Reasoning by analogy, it seems extremely improbable that aloin could be an arabinoside of aloe-emodin anthranol.

Experimental

Anthranol-tetraacetyl-β-*d*-glucoside.—To a solution of 0.25 g. of potassium hydroxide in 50 cc. of acetone and 25 cc. of water there were added 0.8 g. of anthrone and 1.7 g. of acetobromoglucose. The flask was closed quickly with a stopper provided with a stopcock and evacuated until the solvent boiled. The evacuated flask was swirled vigorously until an orange solution had formed and it was then allowed to stand at room temperature for five hours with occasional shaking. During this time, the solution became lemon yellow and a magma of fine needles precipitated. The reaction mixture was then diluted to 150 cc. with water and filtered. The cream colored solid was stirred into 15 cc. of methyl alcohol and filtered, leaving 0.6 g. (28%) of nearly pure anthranol-tetraacetyl-β-*d*-glucoside. After recrystallizing four times from ethyl alcohol, it formed long colorless needles, m. p. 205–205.2°.

Anal. Calcd. for $C_{28}H_{28}O_{10}$: C, 64.1; H, 5.38. Found: C, 64.0, 64.4; H, 5.54, 5.33.

Anthranol-β-*d*-glucoside.—A suspension of 0.6 g. of anthranol-tetraacetyl-β-*d*-glucoside in 75 cc. of 50% ethyl alcohol was heated to 60° and treated with 1 g. of barium hydroxide in 20 cc. of water. The mixture was maintained at 60° for fifteen minutes, with mechanical stirring. It was then cooled in ice and made slightly acid with dilute sulfuric acid. The precipitated barium sulfate was filtered out and the filtrate was concentrated under reduced pressure to 20–25 cc. The cream colored solid which separated was filtered out, crystallized from 25% ethyl alcohol and dried over sulfuric acid in a vacuum; m. p. 204–206°. Mixed with an equal quantity of the tetraacetyl glucoside, it melted at 175–187°. Its solutions in alcohol and other common solvents showed a brilliant blue fluorescence.

Anal. Calcd. for $C_{20}H_{20}O_6{\cdot}H_2O$: C, 64.1; H, 5.92. Found: C, 63.7; H, 5.33.

A sample was dried in a Pregl microdesiccator for thirty minutes at 110° in a current of dry air.

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 67.4; H, 5.62. Found: C, 66.7; H, 5.41.

Hydrolysis Experiments.—As our supply of the glucoside was limited because of the poor yields, no attempt was

[1] Anthracene Series. XII.

[2] This investigation was made possible by a grant to the senior author from a fund given to Washington University by the Rockefeller Foundation for research in science.

[3] Hauser, *Pharm. Acta Helv.*, **6**, 79 (1931).

[4] Gardner, McDonnell and Wiegand, THIS JOURNAL, **57**, 1074 (1935); Foster and Gardner, *ibid.*, **58**, 597 (1936); Gardner and Demaree, *ibid.*, **58**, 757 (1936).

made to determine the extent of hydrolysis for varying periods of time. Instead, one experiment with each was carried out, using 0.05 *N* hydrochloric acid, 0.05 *N* potassium hydroxide and 9% borax at 100°. With hydrochloric acid, hydrolysis was complete in one hour and with potassium hydroxide, in thirty minutes. With borax, the glucoside was hydrolyzed 62.4% in one hour. The insoluble product of acid hydrolysis was quite pure anthrone (m. p. 154–155.5°), but with potassium hydroxide, some oxidation to dianthrone occurred. The insoluble product of borax hydrolysis was not obtained free from unchanged glucoside.

Summary

Anthranol-β-*d*-glucoside has been prepared and has been found to be hydrolyzed easily in acid and alkaline media.

The Chemistry of the Lipides of Tubercle Bacilli. XLVII. The Composition of the Avian Tubercle Bacillus Wax[1]

BY R. E. REEVES[2] AND R. J. ANDERSON

In paper X of this series Anderson and Roberts[3] described the extraction and fractionation of the lipides of the avian tubercle bacillus and it was found that the crude chloroform-soluble wax amounted to 70.7% of the total lipides and 10.79% of the dried bacterial mass. The present report deals with the properties and composition of the above mentioned wax. After the wax had been purified and saponified the cleavage products were found to consist of fatty acids, unsaponifiable matter and a water-soluble carbohydrate.

The fatty acids were a complex mixture of optically active hydroxy acids of very high molecular weight whose constitution we could not determine. None of the ordinary fatty acids could be found. The unsaponifiable matter consisted mainly of *d*-eicosanol-2 together with a small amount of *d*-octadecanol-2. The water-soluble carbohydrate was identified as trehalose.

The nature and kind of the cleavage products of the avian wax differentiate this material sharply from the previously examined wax of the human tubercle bacillus.[4] The latter product gave on saponification a mixture of fatty acids from which a hydroxy acid of high molecular weight, designated by the term "unsaponifiable wax," was isolated. The unsaponifiable matter contained the dihydric alcohol, phthiocerol, $C_{35}H_{72}O_3$,[5] while the water-soluble component was a specific polysaccharide which on hydrolysis yielded *d*-arabinose, galactose and other carbohydrates including inosite, mannose and glucosamine.

The avian wax shows considerable resemblance to the timothy bacillus wax which was recently analyzed by Pangborn and Anderson.[6] Both the avian and the timothy wax contain *d*-eicosanol-2, *d*-octadecanol-2 and trehalose together with new and previously unknown fatty acids of undetermined constitutions.

The object of the present investigation was not only to determine the chemical composition of the avian wax, which is quantitatively the most important fraction of the lipides of the avian tubercle bacillus, but also to provide sufficient quantities of the purified wax and of its cleavage products for physiological studies. The physiological experiments are being carried out by Dr. F. R. Sabin and collaborators of the Rockefeller Institute for Medical Research and will be reported independently.

Experimental Part

The crude wax isolated as described by Anderson and Roberts[3] was a non-crystalline powder of light yellow color. It was easily soluble in chloroform, ether, benzene, toluene, ligroin and ethyl acetate but it was insoluble in acetone, alcohol and methyl alcohol. The following constants were determined: m. p. 53–54°, iodine no. 7.8, saponification no. 77, $[\alpha]_D$ in $CHCl_3$ + 25.6°. A trace of phosphorus was present but sulfur, nitrogen and halogen were absent.

---

[1] An abstract of this paper was read before the Division of Organic Chemistry at the meeting of the American Chemical Society, Pittsburgh, Pa., September, 1936. The data are taken from the dissertation submitted by Richard E. Reeves to the Faculty of the Graduate School, Yale University, 1936, in partial fulfilment of the requirements for the degree of Doctor of Philosophy. The present report is a part of a coöperative investigation on tuberculosis; it has been supported partly by funds provided by the Research Committee of the National Tuberculosis Association.

Purification of the Wax.—For purification 170 g. of the wax was precipitated from solution in chloroform or ether by adding methyl alcohol and cooling. The wax separated as a white, granular powder. The optical rotation increased slowly during purification until the maximum value of +38.6° was attained after forty precipitations. The yield of the purified wax, designated Fraction I, was 69.6 g. The substance had the following properties, m. p. 54–55°, iodine no. 4.5, $[\alpha]_D$ in $CHCl_3$ +38.6°. It contained the merest trace of phosphorus. On combustion it gave C, 75.38, H, 12.14. When titrated in ether–alcohol solution the wax was found to be essentially neutral.

The material contained in the mother liquors was recovered as follows. (a) The mother liquors from the first ten precipitations were concentrated to dryness. The residue which contained most of the coloring matter of the original wax formed a yellowish solid and it weighed 35.1 g. This fraction was set aside and was not examined further. (b) The mother liquors from the subsequent precipitations were concentrated to dryness. The residue was dissolved in chloroform and precipitated by adding methyl alcohol and cooling. The nearly white powder which was obtained weighed 62.2 g. and was designated Fraction II. It had the following properties: m. p. 53–55°; iodine no. 8.7; $[\alpha]_D$ in $CHCl_3$ +17.7°. Except for a lower optical rotation and a somewhat greater solubility Fraction II was very similar to Fraction I.

Since neither fraction could be obtained in crystalline form they were saponified and the cleavage products were separated.

Saponification of the Wax.—The purified wax, Fraction I, was saponified in two lots; in each case 25 g. of the wax was refluxed for ten hours on a water-bath with 500 cc. of 1.6% alcoholic potassium hydroxide. Fraction II was also saponified in two lots using a corresponding quantity of alcoholic potassium hydroxide. The wax melted in the boiling alcohol and as the saponification proceeded the oil was replaced gradually by a brittle cake on the bottom of the flask. The material was never completely in solution.

Separation of the Cleavage Products. The Alcohol-Insoluble Fraction "A."—The hot alcoholic solution was decanted from the insoluble cake and the flask was rinsed several times with hot alcohol. The residue in the flask was extracted with hot benzene and the material obtained on evaporation of the solvent was added to the alcoholic solution. The alcohol and benzene insoluble fraction was soluble in water and was reserved for the isolation of trehalose as will be described later.

Alcohol-Insoluble Potassium Soaps. Fraction "B."—The alcoholic solution containing the potassium salts of fatty acids, unsaponifiable matter, etc., deposited on cooling a large amount of a white precipitate which was found to consist of the potassium salts of high molecular weight fatty acids. The precipitate was filtered off, washed with cold alcohol and dried.

Fatty Acids from the Alcohol-Soluble Potassium Soaps. Fraction "C."—The filtrate from the alcohol-insoluble potassium salts was freed from excess of potassium hydroxide by means of carbon dioxide. The potassium carbonate was filtered off, washed with alcohol and discarded. The filtrate and washings were concentrated to a volume of about 200 cc. and the hot solution was mixed with a hot alcoholic solution of lead acetate. The precipitate which separated on cooling was filtered off, washed with alcohol and decomposed in the usual manner, yielding a small amount of fatty acid.

The alcoholic filtrate from the lead salt was concentrated *in vacuo* to dryness and the residue was mixed with water and extracted with ether. The aqueous solution was reserved and examined for glycerol as will be described below.

The ethereal solution was washed first with dilute acetic acid for the removal of any lead which might be present, and then with water until the washings were neutral, after which it was twice extracted with dilute potassium hydroxide. The ethereal solution was reserved for the isolation of unsaponifiable or neutral material. The alkaline extract was acidified and extracted with ether. The ethereal extract yielded on evaporation a small amount of fatty acids which was combined with the acids obtained from the lead salts.

The Unsaponifiable or Neutral Material. Fraction "D."—The ethereal solution, after the alkaline extraction mentioned above, was washed with water, treated with norite, filtered and the ether was distilled off. The residue, which was a white crystalline solid, was found to consist of two optically active higher alcohols as will be described later.

Examination for Glycerol.—The aqueous solution which had been reserved for the examination for glycerol was evaporated to dryness *in vacuo*. The residue was extracted with warm pyridine, filtered and the pyridine was evaporated *in vacuo*. In no case was any weighable residue obtained and we conclude therefore that the wax did not contain any glycerol. Furthermore, no reducing sugar could be detected in the pyridine-insoluble salt residue.

A summary of the cleavage products of the wax fractions is presented in Table I.

TABLE I

CLEAVAGE PRODUCTS OF THE AVIAN WAX

	Purified wax		Wax fraction II
Wax saponified, g.	25.0	25.0	62.2
Carbohydrate, Fraction "A," %	11.3	13.3	5.6
Alcohol-insoluble soaps, Fraction "B," %	80.0	82.0	84.8
Acid from alcohol-soluble soaps, Fraction "C," %	2.2	2.6	6.8
Neutral material, Fraction "D," %	10.8	9.1	9.0
Glycerol	None	None	None

Examination of the Cleavage Products

Isolation and Identification of Trehalose.—The alcohol insoluble Fraction "A" was dissolved in water and the solution was neutralized with acetic acid. The solution was filtered from a slight amount of insoluble material, concentrated *in vacuo* to a small volume, and neutral lead acetate solution added until no further precipitate formed. The slight precipitate was filtered off and discarded. A carbohydrate was isolated from the filtrate by means of basic lead acetate and ammonia in the usual manner. The crude carbohydrate, which was obtained as a white powder, gave no pentose reactions and no reduction with Fehling's solution until after it had been boiled for some time with dilute acid.

One gram of the substance was acetylated and yielded 1.95 g. of the acetyl derivative. After two crystallizations as described by Pangborn and Anderson[6] the colorless, needle-shaped crystals weighed 1.2 g. and after being heated at 60° *in vacuo* for several hours melted at 97–98°. In chloroform solution $[\alpha]_D$ was +163.7°. On saponification 70.6% of acetic acid was liberated. Trehalose octaacetate requires 70.8% of acetic acid.

The acetyl derivative, 6.5 g., prepared as above, was saponified and the free trehalose was isolated and crystallized from 80% alcohol. Large, colorless, prismatic crystals were obtained which weighed 1.7 g. and melted at 98°, $[\alpha]_D$ in water +178°. On drying at 78° *in vacuo* the crystals lost 9.85% in weight. Calcd. for $C_{12}H_{22}O_{11}\cdot 2H_2O$: H_2O, 9.52.

These data complete the identification of the carbohydrate as trehalose.

Examination of the Acids from the Alcohol-Insoluble Potassium Salts. Fraction "B."—The alcohol-insoluble Fraction "B" was found to consist of potassium salts of fatty acids of high molecular weight. The separation of the free acids by fractional precipitation or by fractionation of the acetyl derivative was difficult and incomplete. A more rapid and satisfactory separation into two distinct fractions was effected by means of the difference in solubility of the potassium salts between ligroin and methyl alcohol. The potassium salts were easily soluble in ligroin and when the ligroin solution was shaken with methyl alcohol two layers separated. The alcoholic solution contained the salt of an acid having a molecular weight of about 500, Fraction BI, while the ligroin solution contained the salt of an acid having a molecular weight of about 1300, Fraction BII. By repeating the procedure several times with each fraction two acids were obtained in about equal amounts whose properties remained essentially unchanged by further attempts at purification. The potassium salt of the acid having the lower molecular weight although insoluble in pure methyl alcohol was easily soluble in methyl alcohol containing ligroin.

An adequate purification of these wax acids was impossible by present available methods. The acids do not crystallize but separate from solvents in the form of colorless, globular particles; hence criteria of purity are entirely lacking. The analytical values for carbon and hydrogen and the molecular weights as determined by titration do not correspond to any definite empirical formula. The reason may depend upon lactone formation.

The analyses of the acids and of their derivatives indicate that the acids contain more than 2 atoms of oxygen but we have been unable to demonstrate conclusively that a third oxygen atom is present as a hydroxyl group although the methyl esters show some active hydrogen[7] and the free acids on acetylation yield products which are partly acetylated. The ratio of C:H is somewhat less than 1:2 but the acids show a low iodine number and on treatment with bromine they yield anomalous bromine derivatives, bromine is absorbed and is also slowly substituted with liberation of hydrobromic acid.

The free acids were prepared from the potassium salts in the usual manner and purified by precipitation from ethereal solution by the addition of alcohol. The acids were easily soluble in ether, chloroform, ligroin and benzene but insoluble in alcohol or acetone. Dr. F. R. Sabin examined these acids and found that they were acid-fast.

In general the properties of the avian wax acids resemble those of the analogous acids encountered in the wax from human tubercle bacillus[4] and in the timothy bacillus wax[6] but they are not identical.

The complete elucidation of the composition and structure of these interesting but very complex wax acids must be left for future investigations. For the present we record the observed properties of the free acids and of some of their derivatives in Table II.

TABLE II

PROPERTIES OF THE AVIAN WAX ACIDS

	Fraction BI	Fraction BII
Free acid, m. p., °C.	69–70	60–61
$[\alpha]_D$ in $CHCl_3$	+5.6°	+5.5°
Analysis	C, 78.99; H, 12.78	C, 82.46; H, 13.49
Mol. wt. by titration	501–520	1280–1300
Approximate formula	$C_{38}H_{74}O_3$	$C_{88}H_{174}O_3$
Acetyl derivative, m. p., °C.	54–55	48–57
Methyl ester, m. p., °C.	54–55	49–50
Active hydrogen of ester,[7] %	0.92	0.82
Bromo derivative	m. p. 47–49° Br. 22.4%	m. p. 43–49° Br. 22.9%
Iodine number (Hanus)	6.5	5.5

Fraction C.—The acids obtained from Fraction C represented only a small percentage of the total acids. They were semi-solid, had low iodine numbers and were obviously a mixture from which no pure substance could be isolated, nor could any of the usual fatty acids be found.

The Neutral Material. Fraction D. Isolation of *d*-Eicosanol-2.—The neutral material was found to consist largely of *d*-eicosanol-2 but a small amount of *d*-octadecanol-2 was also present. The isolation of *d*-eicosanol-2 was accomplished readily by crystallization. After the crude neutral material had been crystallized three times from ethyl acetate and twice from methyl alcohol, colorless prismatic crystals were obtained which melted at 62–63° and gave no depression when mixed with an authentic specimen of *d*-eicosanol-2; $[\alpha]_D$ in ether +6.79°.

Anal. Calcd. for $C_{20}H_{42}O$(298): C, 80.55; H, 14.18. Found: C, 80.54; H, 14.25; mol. wt. (Rast), 294.

The 3,5-dinitrobenzoate was prepared and recrystallized from alcohol. Colorless, needle-shaped crystals were obtained which melted at 77.5–78°; $[\alpha]_D$ in $CHCl_3$ +23.4°.

Anal. Calcd. for $C_{27}H_{44}O_6N_2$(492): C, 65.82; H, 9.01. Found: C, 65.62; H, 8.91.

Oxidation of the alcohol by the procedure employed by Pangborn and Anderson[6] yielded eicosanone-2, colorless thin plates, m. p. 60–61°. The melting point was not depressed when the ketone was mixed with a sample of synthetic eicosanone-2.

Anal. Calcd. for $C_{20}H_{40}O$(296): C, 80.99; H, 13.61. Found: C, 80.73; H, 13.44.

The semicarbazone was prepared and crystallized from alcohol. Colorless, prismatic crystals were obtained which

---

(7) T. Zerewitinoff, *Ber.*, **40**, 2023 (1907).

melted at 130–131°. The melting point was not depressed when the semicarbazone was mixed with the semicarbazone of eicosanone-2.

Isolation of *d*-Octadecanol-2.—The material recovered from the mother liquor from *d*-eicosanol-2 yielded very small quantities of *d*-octadecanol-2. A portion of this material, 0.9 g., was converted into the phenylurethan. The latter after more than 100 recrystallizations yielded 60 mg. of needle-shaped crystals which had the correct melting point, 76–76.5°, of the phenylurethan of *d*-octadecanol-2. A mixed melting point with an authentic specimen gave no depression. However, this method of purification was too laborious and the yield too small.

Another portion of the crude material, 2.53 g., was first fractionated by distillation through a modified Widmer column into 3 fractions. The first fraction, 0.73 g., which distilled at 170–190° and 3 mm. pressure, was converted into the 3,5-dinitrobenzoate. The product, after treatment with norite, was recrystallized from alcohol until the melting point was constant at 71–72°. The colorless needle-shaped crystals weighed 0.45 g.; $[\alpha]_D$ in $CHCl_3$ $+25.3°$.

Anal. Calcd. for $C_{25}H_{40}O_6N_2$(464): C, 64.61; H, 8.68. Found: C, 64.78; H, 8.56.

The dinitrobenzoate, 392 mg., was saponified by refluxing with 4% alcoholic potassium hydroxide. After the alcohol had been isolated and recrystallized four times from methyl alcohol, 197 mg. of colorless needles was obtained. The crystals melted at 53–54° and there was no depression when mixed with *d*-octadecanol-2; $[\alpha]_D$ in $CHCl_3$ $+4.84°$.

Anal. Calcd. for $C_{18}H_{38}O$(270): C, 79.91; H, 14.17. Found: C, 80.15; H, 13.98; mol. wt. (Rast), 271.

The octadecanol-2, 88 mg., was oxidized to the ketone and the latter was recrystallized three times as described by Pangborn and Anderson.[6] The yield was 32 mg. of colorless, plate-shaped crystals. The ketone melted at 50–51° and there was no depression when mixed with a sample of synthetic octadecanone-2.

Summary

1. The chloroform-soluble wax of the avian tubercle bacillus has been purified, saponified and the cleavage products investigated.

2. The principal constituents of the wax are hydroxy fatty acids of very high molecular weight. The acids were acid-fast and were optically active. None of the usual fatty acids were found.

3. The unsaponifiable matter of the wax consisted of *d*-eicosanol-2, $C_{20}H_{42}O$, together with a small amount of *d*-octadecanol-2, $C_{18}H_{38}O$.

4. The water-soluble component of the wax liberated on saponification was identified as the disaccharide trehalose, $C_{12}H_{22}O_{11}$.

5. Glycerol could not be detected among the cleavage products.

The Oxidation of Substituted Phenols. The Effect of Iodine in the Ortho and Para Positions

BY G. H. WOOLLETT, F. M. DAVIS, C. N. JONES AND MARY NEILL

Upon oxidation 2,6-dimethoxyphenol is converted almost quantitatively into cedriret (3,5,3′,5′-tetramethoxydiphenoquinone-4,4′)[1] while similar phenols such as 2,6-dimethylphenol[2] and 2,6-diacetamidophenol[3] yield 70% or more of dinuclear quinones. These are highly colored conspicuously crystalline sparingly soluble compounds whose structure has been verified amply. The reaction is commonly cited as an example of steric hindrance. Carboxyl, chlorine, bromine,[4] hydroxyl, methoxyl[2] and methyl para to the hydroxyl prevent the reaction.

Another group of substances often confused with the true dinuclear quinones is the highly colored resinoids obtained by the action of iodine and alkali on phenols having ortho and para positions unsubstituted. One of these (Lautemann's Red), obtained from common phenol, was said to be 3,5,3′,5′-tetraiododiphenoquinone-4,4′, by Kammerer and Benzinger[5] shortly after the report on the structure of cedriret by Hoffman, the similarity in color no doubt being the cause of the mistake. The analogous product from thymol[5,6] (aristol) was also thought to be a dinuclear quinone. Later investigators[7–10] agree that Lautemann's Red and aristol are amorphous and have high molecular weights, although it has been sug-

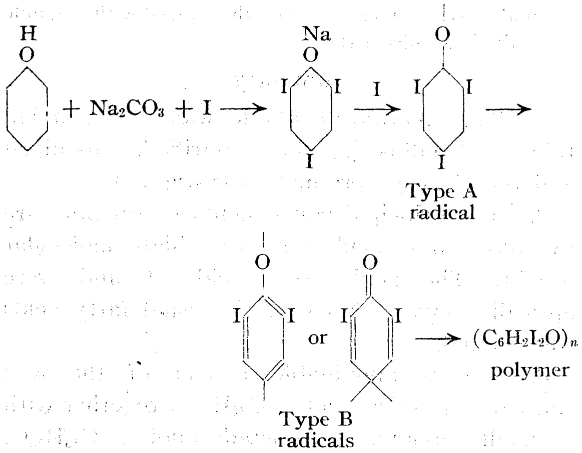
gested recently that aristol is a dimer of diiododithymoquinone.[11]

A mechanism suggested by Hunter[9,12] for the formation of Lautemann's Red is shown by the series of reactions



If this is correct some true dinuclear quinone should be formed, the amount depending upon the relative stability of the quinoid form of the type B radical. Showing that the formation of cedriret and the colored resinoids do, after all, have something in common, Hunter and Morse[13] have obtained a 5.6% yield of a true tetraiododiphenoquinone by rapid oxidation of potassium triiodophenolate, the remainder being largely Lautemann's Red. Additional work done in this Laboratory on the role of iodine in the two types of reactions is presented here.

The preparation of tetraiododiphenoquinone from triiodophenol has been repeated and confirmed. Since iodine in the para position in triiodophenol does not prevent the formation of dinuclear quinone, it would be expected that some of this quinone would be made during the preparation of Lautemann's Red in the usual way. This has been shown to occur to the extent of 2.1%.

The largest yield of the quinone would be expected to result from the oxidation of 2,6-diiodophenol. This has proved to be approximately 31%.

Thus the "pro" effect of iodine in the 2,6-position in causing the cedriret reaction may be represented by the figure 31 and the "con" effect of iodine in the para position by the decrease from 31 to 5.3 or 83%. The formation of tetraiododiphenoquinone from 2,6-diiodophenol also shows that the iodine atoms occupy the 3,5- and 3′,5′-positions relative to the bonds between the rings.

By way of checking the effect of iodine it was found that oxidation of 2,6-dibenzamidophenol and 2,6-dibenzamido-4-iodophenol yields 84 and 11.3% of 3,5,3′,5′-tetrabenzamidodiphenoquinone-4,4′, respectively, thus showing a "pro" figure of 80 for benzamido and a "con" of 86% (84 to 11.3) for para iodine.

As the diphenoquinones isolated are para quinones and as it has been shown previously[14] that either ortho or para iodine may be removed in the formation of resinoids but that the resinoids from para cresol[10d] and 2,4-dimethylphenol in which the iodine removed must be from the ortho position are practically colorless it seems probable that the ortho quinoid form of the diiodo type B radical  is not formed.

Experimental

2,6-Diiodo-4-nitrophenol.—Para nitrophenol was iodinated in hot sodium carbonate solution with an excess of iodine–potassium iodide solution. The conditions are not critical.

2,6-Diiodo-4-aminophenol.—A modification of the general method of Hodgson and Kershaw[15] was used. To a hot solution of 50 g. of diiodonitrophenol and 100 g. of sodium carbonate in 1200 cc. of water 80 g. of sodium hydrosulfite was added gradually during energetic stirring. Pure 2,6-diiodo-4-aminophenol, m. p. 170°, separated in 86% yield. Raiford, Taft and Lankelma[16] give 169–171°.

2,6-Diiodophenol.—A cooled solution of 10 g. of diiodoaminophenol in 250 cc. of alcohol and 5 cc. of sulfuric acid was treated gradually with the calculated amount (22 cc.) of *N* sodium nitrite, then refluxed for one hour, cooled, made slightly alkaline with ammonium hydroxide containing a little sodium bisulfite, water added and the phenol extracted with ether; yield 5 g. (52%). This was purified by steam distillation, precipitation from alcoholic solution by a large amount of ice water, and finally from hot glacial acetic acid; white needles, m. p. 67.2°.

Oxidation of 2,6-Diiodophenol and Isolation of 3,5,3′,5′-Tetraiodo-4,4′-dihydroxydiphenyl.—One gram of diiodophenol was dissolved in 10 cc. of water and 1.5 cc. of 2 *N* potassium hydroxide, cooled and poured into a cooled solution of 10 g. of chromium trioxide in 10 cc. of water. The mixture was shaken for ten minutes and filtered by suction. Average weight of red precipitate at this time was 0.775 g.

[15] Hodgson and Kershaw, *J. Chem. Soc.*, 2703 (1928).

[16] Raiford, Taft and Lankelma, This Journal, **46**, 2057 (1924).

The red mixture was wet with alcohol and treated with a solution of 1 g. of hydrazine sulfate in 20 cc. of 2 *N* potassium hydroxide, filtered, treated with Norite, refiltered, and precipitated with acetic acid: average yield of white microscopic needles, 0.308 g. (31%). After recrystallizing twice from hot acetone by adding glacial acetic acid it melted with decomposition at 284° if the melting point tubes were inserted in the bath after it had reached 250°. A lower melting point and more decomposition resulted from the usual treatment.

Anal. (Carius). Calcd. for $C_{12}H_6I_4O_2$: I, 73.61; mol. wt. 689.73. Found: I, 73.50, 73.43; mol. wt. (Rast), 662, 640.

Other products of oxidation of 2,6-diiodophenol as found in samples from 1 g. of phenol: by steam distillation, *m*-diiodoquinone, 0.06 g., yellow platelets from hot alcohol, m. p. 175–176°. Amorphous product, 0.067 g.: insoluble in alkali after reduction and when reoxidized by lead dioxide in carbon bisulfide and precipitated by heptane became a red powder. This is evidently Lautemann's Red. A sticky yellow substance soluble in alcohol, 0.338 g.

Tetraiododiphenol from Phenol.—Lautemann's Red was made from 15.7 g. of phenol by treating with sodium carbonate and iodine in the usual way.[5] After thorough washing the wet product was reduced by treating with 320 cc. of 2 *N* potassium hydroxide, 600 cc. of water and 11 g. of hydrazine sulfate. The bleached material was filtered and extracted twice with *N* potassium hydroxide and filtrate and washings acidified. The white precipitate weighed 1.928 g. and consisted mainly of triiodophenol and tetraiododiphenol. Triiodophenol was removed by treating this, dissolved in 3 cc. of 2 *N* potassium hydroxide and 40 cc. of water, with 14 g. of potassium ferricyanide in 60 cc. of water. The red precipitate was filtered, washed and reduced as before using 1.5 g. of hydrazine sulfate, 20 cc. of alkali and 50 cc. of water. The filtrate and washings from this, after warming with Norite, filtration and acidification, yielded 1.20 g. (2.1%) of white microscopic needles which, after recrystallizing twice from acetone and glacial acetic acid, melted at 283° and showed no change in m. p. when mixed with an equal quantity of tetraiododiphenol from 2,6-diiodophenol.

Tetraiododiphenol from Triiodophenol.—The preparation was made according to the directions of Hunter and Morse[13] except that it was crystallized from acetone–acetic acid, m. p. (pre-heated bath) 283°. When mixed with an equal quantity of the analogous product from 2,6-diiodophenol it also melted at 283°.

Oxidation of 3,5,3′,5′-Tetraiodo-4,4′-dihydroxydiphenyl.—Samples from the three sources were oxidized in glacial acetic acid or ethyl acetate by chromium trioxide or ferric chloride; however, oxidation in ethyl acetate by chromium trioxide gave best crystals. All samples behaved identically producing microscopic green needles with metallic luster and red streak and which decomposed without melting. The product apparently may be reduced and reoxidized indefinitely. No satisfactory solvent was found.

2,6-Dibenzamidophenyl Benzoate.—Forty-two grams of sodium hydrosulfite was added in 10-g. portions with energetic shaking to a hot solution of 2,6-dinitrophenol (5 g.) in 650 cc. of water. The faintly colored solution was cooled and 70 cc. of 40% sodium hydroxide added, followed by 25 cc. of benzoyl chloride. Eleven grams (93%) of the tribenzoyl compound separated and after recrystallization twice from glacial acetic acid melted at 220°.

2,6-Dibenzamidophenol.—Fromm and Ebert's[8] method was used, giving light yellow needles of m. p. 179–180°.

Oxidation of 2,6-Dibenzamidophenol.—Sodium nitrite, periodic acid and permanganate produced the quinone in glacial acetic acid. Nitrite, however, gave the cleanest product. Samples of 0.1 to 0.3 g. were dissolved in from 18 to 50 cc. of glacial acetic acid and treated with 0.3 cc. of 20% sodium nitrite solution per 0.1 g. of phenol. After fifteen minutes the quinone was filtered off, dissolved in 150 cc. of chloroform for each 0.1 g. of quinone and precipitated by adding 2.5 volumes of alcohol: average yield from 18 samples, 84% of 3,5,3′,5′-tetrabenzamidodiphenoquinone-4,4′; greenish black microscopic needles which decomposed without melting and which have metallic luster and purple streak. Chloroform solutions were deep permanganate color.

Anal. Calcd. for $C_{40}H_{28}N_4O_6$: N, 8.45; O, 4.84; mol. wt., 660. Calcd. for $C_{20}H_{14}N_2O_4$: N, 8.09; O, 9.25; mol. wt., 346. Found: N (Dumas), 8.79, 8.79; quinoid O (hydrazine) 4.74, 5.08, 4.87, 5.05; mol. wt. (Rast), 696, 557.

2,6-Dinitro-4-iodophenol.—This was made from isopicramic acid and also by iodination of 2,6-dinitrophenol in glacial acetic acid by iodine monochloride. Both melted at 113°.

2,6-Dibenzamido-4-iodophenylbenzoate.—Five grams of dinitroiodophenol and 10 g. of sodium bicarbonate were dissolved in 300 cc. of water to which 25 g. of sodium hydrosulfite was added in portions with energetic shaking. As ordinary Schotten–Baumann procedure removed iodine the mixture was made alkaline with sodium bicarbonate and the amine extracted with ether. The ether solution was filtered and to it added 10 cc. of pyridine and 6 cc. of benzoyl chloride. After the voluminous precipitate had formed 200 cc. of alcohol was added and 4.6 g. (50%) of the tribenzoyl compound filtered off. After recrystallization from hot glacial acetic acid colorless needles melting at 253–254° (dec.) were obtained.

Anal. (Carius). Calcd. for $C_{27}H_{19}N_2O_4I$: I, 22.59. Found: I, 22.75, 22.24.

2,6-Dibenzamido-4-iodophenol.—Four grams of the tribenzoyl compound was dissolved in a mixture of 320 cc. of alcohol and 13 cc. of 10% sodium hydroxide. The yellow solution was diluted with 500 cc. of water and acidified, yielding 3.3 g. (99%) of colorless microscopic needles which after recrystallization from hot acetic acid melted with decomposition at 232°.

Anal. (Carius). Calcd. for $C_{20}H_{15}N_2O_3I$: I, 27.75. Found: I, 27.83, 28.07, 27.64, 28.14.

Oxidation of 2,6-Dibenzamidophenol.—A solution made by mixing 10 cc. of 10% sodium hydroxide with 6 g. of the phenol and adding 1 liter of water was poured with vigorous stirring into a solution containing 40 g. of chromium trioxide and 1200 cc. of water. The red precipitate was digested with 800 cc. of alcohol to dissolve the main product of the reaction—presumably *m*-dibenzamidobenzoquinone. The portion insoluble in alcohol was dissolved in 500 cc. of chloroform and precipitated with 1000 cc. of alcohol. The yield was 0.485 g. (11.3%) of greenish black microscopic needle-shaped crystals having metallic luster and purple streak and which appeared to be identical with those obtained from 2,6-dibenzamidophenol.

Anal. (Kjeldahl). Calcd. for $C_{40}H_{28}N_4O_6$: N, 8.49; quinoid O, 4.84. Found: N, 8.31; quinoid O (hydrazine), 5.22, 5.24.

The alkali salt of the hydroquinone formed by reduction of quinone from either source by hydrazine is yellow. Its yellow solution on acidification yields the colorless hydroquinone which rapidly becomes purple in the air. Reoxidized quinone from the above preparation contained 8.92% N which indicates some saponification of benzamido groups has occurred.

Summary

1. Iodine in the 2,6-position in phenols is about 37% as efficient as benzamido in favoring the cedriret reaction.

2. Placing iodine in the 4-position in 2,6-diiodophenol or 2,6-dibenzamidophenol does not prevent the cedriret reaction but decreases the yield by 83–86%.

3. The positions of the iodine atoms in the tetraiododiphenoquinone have been determined and 2,6-dibenzamido-4-iodophenol and 3,5,3′,5′-tetrabenzamidodiphenoquinone-4,4′ have been prepared.

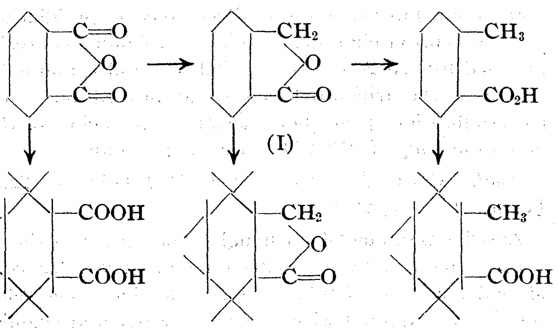
Phthalide. I. The Hydrogenation of Phthalic Anhydride

By Paul R. Austin, E. W. Bousquet and Wilbur A. Lazier

Phthalic anhydride has been hydrogenated over nickel[1] and platinum[2] catalysts by a number of investigators, all of whom note the formation of phthalide (I) accompanied by varying amounts of toluic acid as well as ring-hydrogenated derivatives of the components of the reaction mixture (Chart I).

Chart I

Hydrogenation of Phthalic Anhydride



The complexity of the reaction may be illustrated by the recent work of Adkins, Wojcik and Covert[1d] who carried out the hydrogenation with nickel and isolated about equal amounts of phthalide, *o*-toluic acid and hexahydro-*o*-toluic acid. It was thought worth while to investigate further the optimum conditions for the catalytic synthesis of phthalide. Since early trials showed the presence of a solvent to be essential to high conversions, this factor was given primary consideration.

With nickel-on-kieselguhr catalyst yields of phthalide above 80% of the theoretical were realized using ethanol as the reaction medium. This process was carried out at 150–160°, a temperature at which the phthalic anhydride is converted readily to ethyl hydrogen phthalate and one might expect that the hydrogenation of this aromatic ester would be limited to the nucleus[1d] or inhibited completely by the action of the acid on the nickel catalyst.[3] The formation of phthalide which occurs in the presence of alcohol, leads us to postulate the hydrogenation of the tautomeric form of ethyl hydrogen phthalate (II), the course of the reduction proceeding by hydrogenolysis[4] in accordance with the following scheme (Chart II).

Furthermore, the closely related ester, *pseudo*-ethyl phthalaldehydate (III), hydrogenated smoothly to phthalide and *o*-toluic acid as predicted by this hypothesis. It is interesting to note that ester solvents, such as ethyl acetate, ethyl butyrate and butyl acetate may be employed satisfactorily in this process.

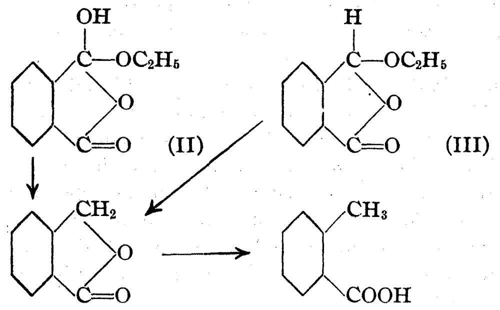
CHART II

HYDROGENATION OF ETHYL HYDROGEN PHTHALATE AND *pseudo*-ETHYL PHTHALALDEHYDATE



The use of Raney nickel catalyst in alcohol gave a relatively high conversion to phthalide and a low proportion of toluic acid, but the catalyst was found to promote considerable nuclear saturation. The effect of temperature on the distribution of the reaction products was rather marked. Hydrogenation in alcohol solution with nickel catalyst at 160° gave about 20% of toluic acid at the expense of a portion of the phthalide, while at 150° only 10% of toluic acid was obtained, and the yield of phthalide was above 80%. At 140° the hydrogen absorption was very slow. The conversion to hexahydrophthalide was little affected by the temperature in this range but, as indicated above, was largely dependent on the type of catalyst employed. Pressures varying from 700–2000 lb./sq. in. (47–133 atm.) were about equally satisfactory in all of the hydrogenations using nickel.

Nuclear saturation and relatively high conversions to *o*-toluic acid are inherent disadvantages in the hydrogenation of phthalic anhydride with nickel, and to obviate these factors other types of catalysts were investigated. Copper chromite was the most effective in accomplishing this purpose. Benzene was found to be a suitable solvent, and hydrogenation carried out at 270° under 3000 pounds per sq. in. (200 atm.) of hydrogen pressure gave phthalide in a yield of 82.5%, while the conversion to *o*-toluic acid was about 10%. Alcohols were not useful as solvents for hydrogenations with copper chromite; for example, copper–barium chromite catalyst with ethanol and phthalic anhydride gave toluene, xylene and diethyl phthalate, but no phthalide. In hydrogenating phthalic anhydride in the absence of a solvent, copper–barium chromite and copper chromite catalysts gave 10 and 56% of phthalide, respectively.

By applying the hydrogenation technique to phthalide and some of its derivatives, a series of interesting compounds has been prepared. Thus Raney nickel catalyst with phthalide itself gave hexahydro-phthalide (82.5% conversion), 5-nitrophthalide was reduced over nickel-on-

[a] About 3–4% of hexahydrophthalide also was obtained. [b] Seven per cent. of hexahydrophthalide was also isolated. [c] Phthalic acid 33.4% also was obtained. [d] Phthalic acid, 64.7%, predominated. [e] *pseudo*-Ethyl phthalaldehydate was prepared according to the procedure outlined by Meyer [*Monatsh.*, **25**, 491 (1904)]; it melted at 66°. [f] *o*-Toluic acid (1.0%) and hexahydro-*o*-toluic acid (6.0%) were also isolated. The hexahydrophthalide distilled at 103–105° (2 mm.). Einhorn [*Ann.*, **300**, 175 (1898)] gives the boiling range as 160–165° (60 mm.). [g] Nitrophthalide, m. p. 142°, was prepared as described by Teppema [*Rec. trav. chim.*, **42**, 30 (1933)]. 5-Aminophthalide was isolated by solution of the reaction mixture in dilute hydrochloric acid, filtration of the catalyst and precipitation of the free base with ammonium hydroxide. Crystallized from ethanol the aminophthalide melted at 182°. Tasman [*ibid.*, **46**, 661 (1927)] gives the melting point as 182°.

kieselguhr to 5-aminophthalide (85% conversion), and sodium-α-hydroxy-*o*-toluate (phthalide dissolved in aqueous sodium hydroxide) yielded *o*-toluic acid (80%) on hydrogenation over nickel-on-kieselguhr.

The hydrogenation of phthalic anhydride, pthalide and various phthalide derivatives is summarized in Table I.

Experimental Part

Apparatus.—The apparatus used in this work consisted of a shaking device, high pressure steel tubes connected to recording gages, electrical pyrometers for temperature control and a source of high pressure hydrogen. The tube capacity was approximately 400 cc. In operation, the material and catalyst were charged into the tube which was then made tight with a plug and a threaded nut. A thermocouple well extended through the plug into the inner space of the tube, and a hydrogen inlet line, valve and flexible line connected to the gas manifold completed the assembly. The tube was heated and agitated mechanically, and hydrogen absorption was measured by the pressure drop in the closed system. The time of reaction given in Table I was measured from the beginning of the hydrogenation to the conclusion of the run.

Catalysts.—Nickel-on-kieselguhr catalyst was prepared from the nitrate by precipitation of the carbonate followed by hydrogen reduction according to well-known methods[3] (p. 1651). Unsupported pyrophoric nickel was prepared according to the method of Raney,[5] and copper chromite and promoted copper chromite catalysts[6] were prepared according to the standard procedures.

Isolation of Products.—Water-soluble solvents were evaporated, replaced by benzene, and the acidic components extracted with aqueous sodium carbonate. The alkaline solution was separated and acidified to give *o*-toluic acid or hexahydro-*o*-toluic acid. Phthalide was obtained by evaporation of the organic solvent and may be further purified by crystallization from alcohol or benzene. Phthalic acid, when isolated, was found in the catalyst fraction and was recovered by solution and reprecipitation from sodium carbonate solution. All of the materials isolated were characterized by means of their melting points or boiling points and by comparison with authentic specimens.

Summary

Phthalide has been obtained in excellent yields by the hydrogenation of phthalic anhydride (a) with copper chromite in benzene, (b) with Raney catalyst in ethanol and (c) with nickel-on-kieselguhr in ester or alcohol solvents. The novel use of alcohol as a solvent for this reduction has been investigated and a mechanism for the hydrogenation has been proposed. Hexahydrophthalide, 5-aminophthalide and *o*-toluic acid have been obtained in high yields by further hydrogenation of phthalide or appropriate derivatives.

The Ternary Systems $KClO_3$–KBr–H_2O, $KClO_3$–KI–H_2O and KIO_3–KI–H_2O at 25°

BY JOHN E. RICCI

The solubility isotherms reported in this paper were studied during the course of more extensive investigations; while no complex formation, in the form either of double compounds or of solid solutions, was found in all three systems, the results are nevertheless presented as solubility determinations which may have some interest and value. In connection with the system KIO_3–KI–H_2O, it may be mentioned that although a double compound or complex of some sort of these two salts might have been expected on the basis of the compounds known to form between sodium iodate and sodium iodide,[1] the results show no tendency at all toward compound formation between the potassium salts at 25°.

The experimental procedure was that usually employed for similar measurements. Definite mixtures of the components were stirred in a bath thermostatically controlled at 25 to ±0.02°, sufficient time (at least two days) being allowed for the attainment of equilibrium. The method of analysis of the saturated solution varied for the different systems, as follows: for the first system, the potassium bromide was determined by titration with standard silver nitrate solution, using Mohr's method; the total solid was determined by evaporation at 100° followed by 250°; and the potassium chlorate was then calculated by difference. In the second system, the potassium iodide was likewise titrated argentometrically, by Fajans' method, using eosin as the

---

[1] Ricci, THIS JOURNAL, **56**, 295 (1934).

adsorption indicator, and titrating actually to the clear-point; the potassium chlorate was then calculated similarly by means of the total solid determination. In the third system, the titration of the iodide was avoided because of the insolubility of silver iodate; the potassium iodate was consequently determined directly by adding excess potassium iodide, acidifying, and titrating the liberated iodine with standard sodium thiosulfate; the determination of total solid then allowed the calculation of the original potassium iodide by difference.

The solid phases, already known in every case, were identified and verified by algebraic extrapolation of the tie-lines on the ternary diagrams, the average deviation of these extrapolations for all three systems being 0.26% from the composition of the pure solid phase. The densities reported were calculated from the weight delivered by a volumetric pipet calibrated for delivery.

The experimental results for the three systems are presented in Tables I, II and III. Figure 1 shows the isotherm for the system $KClO_3$–KBr–H_2O; the isotherms for the other two systems are very similar to this and need not be added here. The data and the plotted results show clearly that the only solid phases in the systems at this temperature are the anhydrous salts themselves, and that there is no evidence of any complex formation in the various pairs of salts.

Summary

Solubility measurements are given for the ternary systems $KClO_3$–KBr–H_2O, $KClO_3$–KI–H_2O and KIO_3–KI–H_2O at 25°. These salt pairs are found to form neither double compounds nor solid solutions at this temperature, the only solid phases being the respective anhydrous salts.

The Ternary Systems $NaNO_3$–NaBr–H_2O and $NaNO_3$–NaI–H_2O at 25°

BY JOHN E. RICCI, JOSEPH BUDISH AND NICHOLAS BORODULIA[1]

As part of the systematic phase rule investigation of ternary systems involving the alkali nitrates and halides, and for the purpose of obtaining solubility data, the ternary systems $NaNO_3$–NaBr–H_2O and $NaNO_3$–NaI–H_2O were studied at 25°. The results have shown the systems to be of the simple type at this temperature, with no complex formation, the only solid phases being the pure salts themselves, anhydrous or hydrated.

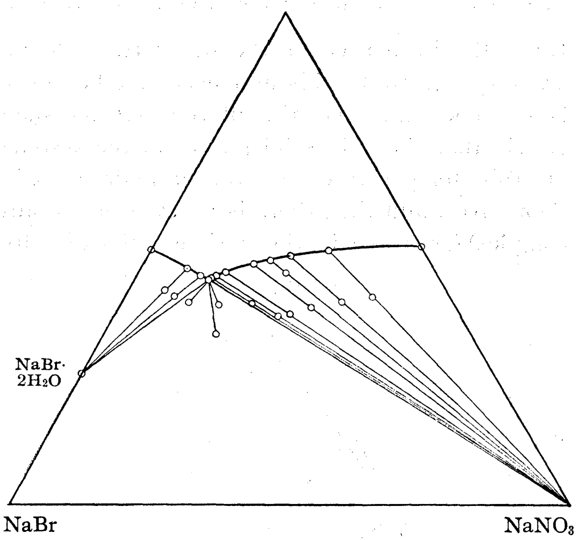

Fig. 1.—25° Isotherm: $NaNO_3$–NaBr–H_2O.

The experimental procedure was the familiar technique used in other similar investigations.[2] The salts used were recrystallized C. P. material. Weighed complexes of definite composition were brought to equilibrium by stirring in a thermostat at 25°, with the temperature constant to ±0.02°; the time allowed for equilibrium was at least two days in each case. The saturated solution was analyzed for bromide or iodide by titration with standard silver nitrate solution by means of Fajans' method, using fluorescein as the adsorption indicator, in the presence of some dextrin; this determination, combined with a determination of the total solids by proper evaporation, allowed the calculation of the sodium nitrate concentration by difference. Since no new solid phases were encountered, the phases of known composition were identified in every case by the algebraic extrapolation of the tie-lines joining the composition of the saturated solution and that of the original complex;[3] the error of these extrapolations then checks the accuracy of the analysis and the attainment of equilibrium. The average error, of extrapolation, in the $NaNO_3$–NaBr–H_2O system was 0.50%; in the $NaNO_3$–NaI–H_2O system, 0.38%.

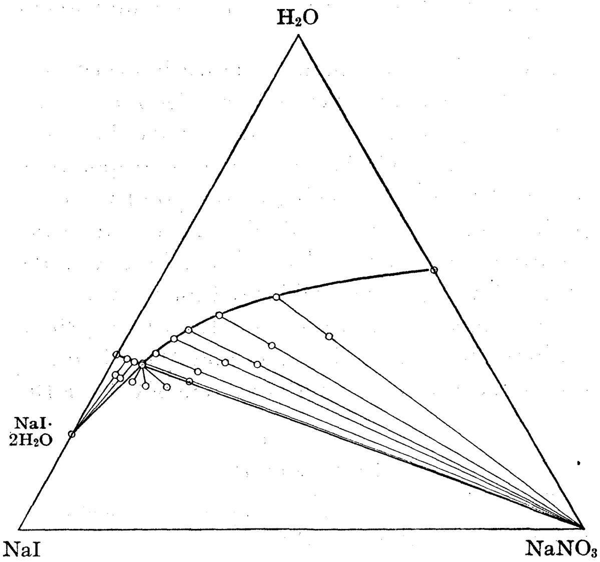

Fig. 2.—25° Isotherm: $NaNO_3$–NaI–H_2O.

Average (of 3)		5.48	61.13	$NaNO_3 + NaI \cdot 2H_2O$
2.97	66.35	3.93	62.06	$NaI \cdot 2H_2O$
2.05	67.08	2.57	63.12	$NaI \cdot 2H_2O$
0.00	...	0.00	64.71	$NaI \cdot 2H_2O$

The experimental results are presented in Tables I and II, and are shown graphically also in Figs. 1 and 2, which are self-explanatory. The solubility isotherms are seen to be of the simple two-branched type, with no evidence of any complex formation. The compositions of the isothermally invariant solutions for the two systems, are, respectively, as follows: for saturation with respect to both $NaNO_3$ and $NaBr \cdot 2H_2O$, 13.62% $NaNO_3$, 41.05% NaBr, 45.33% H_2O; for saturation with respect to $NaNO_3$ and $NaI \cdot 2H_2O$ simultaneously, 5.48% $NaNO_3$, 61.13% NaI and 33.39% H_2O. These values are in each case the averages of at least three determinations.

Summary

Solubility measurements are given for the two ternary systems $NaNO_3$–NaBr–H_2O and $NaNO_3$–NaI–H_2O at 25°; no complex formation is found, the solid phases being $NaNO_3$ and, respectively, $NaBr \cdot 2H_2O$ and $NaI \cdot 2H_2O$.

Abundance Ratio of the Isotopes of Potassium in Animal Tissues

BY A. KEITH BREWER

The utilization of the mass spectrograph in determining the isotope abundance ratio and the atomic weight of potassium in minerals, plants and ocean water has been discussed in recent publications.[1–3] The results indicate that the isotope ratio is not necessarily constant in nature, but in specific instances may deviate appreciably from the normal. In the present paper this investigation has been extended to a study of the potassium isotope ratio in various animal tissues.

Experimental Technique

The apparatus was essentially the same as that described previously,[1] although several improvements were incorporated. The position of the filament slit was made adjustable by means of a screw operated through a sylphon tube; this permitted a better focusing of the maximum ion beam on the filament slit. The evacuation channel was extended completely along the bottom and both sides of the pole pieces; the channel not only facilitated evacuation but served as a trap to prevent ions not in focus from being reflected into the collector slit. The entire spectrograph was heavily chromium plated and the pole pieces highly burnished; it was found that when the iron pole pieces were exposed a deposit of rust collected on the surface which, because of its poor conductivity, became charged and in consequence distorted the resolved ion beam.

The samples of tissue to be tested were washed in distilled water and then ashed in a platinum crucible. The ion source used was a small platinum disk of the type described previously. The platinum was impregnated with potassium by placing a piece of ash about the size of a pin head on the disk and moistening with distilled water. The entire filament assembly was placed in a separate evacuation system and the filament heated to just redness for about thirty minutes; during the heating process an appreciable quantity of alkali dissolves in the platinum. After heating the disk was scraped free of all visible deposit; in cases where the ash fused on heating it was necessary to remove the disk from the filament to free it from ash. The disk was then smoothed by lightly tapping between plates and rewelded in position.

Results

The abundance ratios for the two principal isotopes of potassium found in various animal sources are presented in Table I.

In the abundance ratio column limits are expressed for the apparent uncertainty for each sample. The ratios given are the averages of determinations made on several samples while the uncertainty factor represents the limits to

which the various readings deviated from the average. The atomic weights given are computed by assuming 1.00027 for the conversion factor from the physical to the chemical scale, and −7.0 for the packing fraction.

Discussion of the Method

The advantages of the mass spectrographic method in studying comparative atomic weights are: (1) the sensitivity is high, (2) no chemical purifications are necessary, (3) small quantities of material are required; the amount of potassium actually involved probably does not exceed 10^{-8} to 10^{-9} g. while the presence of far smaller quantities can be detected.

The possibility of error in mass spectrographic measurements may enter from two types of sources, general and functional. The general errors involve uncertainties in the isotope effect at the source, in the conversion factor from the physical to the chemical scale, and the packing fraction. None of these errors affects the relative values of the abundance ratios or the atomic weights.

Functional errors enter from an improperly operating apparatus and are not likely to affect all observations similarly. These errors have their source in some factor which gives rise to (1) a resolution of the primary ion beam between the source and the filament slit, (2) a general background which makes it difficult to measure the exact peak height, or (3) a broadening or scattering of the resolved ion beam. It is necessary to test for the presence of each of these factors in every sample to obtain comparable results. Ordinarily these difficulties are overcome by washing the filament slit free of any deposit, and by scraping all adhering ash from the disk source.

An accurate determination of the abundance ratio from measurements of the resolved ion currents necessitates that all the ions of the isotope in question which pass through the filament slit reach the collector. This was made possible in the present set-up by using filament and collector slits 0.22 mm. and 0.77 mm. in width, respectively; the width of the collector slit is thus appreciably greater than that of the resolved ion beam provided no scattering of the beam occurs. Under proper operating conditions the flat top of the K^{39} peak was one-fifth the width of the separation between the center of the K^{39} and K^{41} peaks. Since scattering tended to broaden the beam, it was discernible by a sharpening of the resolved peaks. It was found in practice that particles of ash which had not been removed from the disk and irregularities in the disk itself were responsible for most of the scattering.

Considering the various sources of error and nonuniformity in the results that are involved, it seems probable that the sixth significant figure in the comparative atomic weight calculations is accurate to within ±1 to ±5 depending on the sample. No such accuracy, however, can be claimed for the absolute value of the atomic weight. In this respect it should be pointed out that an abundance ratio of 14.20 gives 39.094 for the atomic weight using the most probable values for the packing fraction and the conversion factor, but since either of these quantities may be in error by as much as one part in 10,000, the atomic weight as computed may be inaccurate by as much as ±4 in the fifth significant figure. The calculated values in Table I, are included for comparative purposes only.

Significance

There are very few references in the literature relative to an isotope effect for potassium in the animal organisms. Potassium, nevertheless, is without doubt the most interesting of all the elements in this connection, since it is the only element necessary to the vital process that is radioactive, one of its isotopes emitting two hard β rays. Ernst[4] making use of this radioactivity reports that potassium from human and animal sources is more radioactive than normal. A. and M. Lasnitzki[5] observe some differentiation between mineral and biological potassium in the feeding of mice. A general review of the effect of natural processes on the isotope ratio has been given by Vernadsky.[6]

A survey of the data presented in Table I shows that the isotope abundance ratio for potassium in most animal tissues is close to 14.20; this is the same as that for sea water and the majority of plants and minerals. In only a few instances are any marked deviations from the normal to be found. The heart muscles and especially the lining of the right auricle as well as the membranes supporting the valves are inclined to be low in K^{41}. The heart was tested in parti-

cular since it has long been known that potassium in the blood is a factor in regulating heart beat, and since Zwaardemaker[7] and Loeb[8] have raised the question of the effect of the radioactive potassium isotope on beat stimulation. The results indicate that the lining of the auricle may contain less than the normal amount of the radioactive isotope. Some uncertainty still remains regarding which potassium isotopes are responsible for the radioactivity although the abundant isotope K^{39} is known to be non-radioactive. Recently Smyth and Hemmendinger[9] have shown that the exceedingly rare isotope K^{40} is responsible for part and possibly all of the radioactivity. Any process, however, that will concentrate K^{41} will doubtless concentrate K^{40}; in consequence an abundance ratio below 14.20 should represent a radioactivity above normal. The facts that this radioactivity is feeble and that the deviations in the abundance ratio recorded in Table I are small make it seem very doubtful whether the potassium from various tissues is distinguishable by radioactive measurements. The relative abundance of K^{40} has been measured by A. O. Nier[10] and by the writer[11] but measurements of the K^{39}/K^{40} ratio involve too much uncertainty for a comparison of various sources.

The most conspicuous concentration of K^{41} was observed in bone marrow. The data, while insufficient, indicate a possible dependence of the abundance ratio on the age of the animal; in all the cases examined the ratio was higher for young than for old animals. It should be mentioned that bone marrow was investigated in some detail, since Hoffmann[12] had shown that the potassium content appears to be associated with embryonic cell development, diminishing markedly at the conclusion of growth activity, and increasing again on the development of carcinoma. Unfortunately, it was not possible to make abundance ratio tests on any cancerous animals.

In conclusion it should be mentioned that while the deviations which have been reported for animal and plant tissues are small, they are nevertheless appreciable. Deviations of this magnitude are exceedingly difficult to produce in the laboratory; the writer has tried several times himself and has examined many samples prepared by eminent scientists but in no instance has a definite isotope shift been observed. While it is possible to conjecture concerning the mechanism of the isotope effect in nature, the data are still too meager to permit any definite conclusion to be drawn.

The writer is indebted to Mr. N. G. Barbella, of the Bureau of Animal Industry for furnishing many of the samples tested.

Summary

The abundance ratio of the two principal isotopes of potassium present in animal tissues have been measured with a mass spectrograph. The K^{39}/K^{41} ratio for most organs is close to 14.20, which is the same as that previously obtained for most plants and minerals and for ocean water. A few tissues, such as the lining of the auricle and the lining of the small intestine, appear to possess an abnormally high concentration of K^{39}, while bone marrow is high in K^{41}. The results with bone marrow are significant in that they indicate a possible relationship between the abundance ratio and the age of the animal, and hence with the development of embryonic cells within the organism.

The atomic weight of potassium has been calculated using the most probable values for the packing fraction and the conversion factor; the value thus obtained for most tissues is 39.094. Since all deviations from this normal value are small, it does not seem probable that the potassium in animal tissue could be distinguished from mineral potassium by radioactive measurements as has been suggested by some investigators.

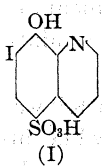
A Study of 7-Iodo-8-hydroxyquinoline-5-sulfonic Acid as a Reagent for the Colorimetric Determination of Ferric Iron[1]

BY JOHN H. YOE AND ROBERT T. HALL[2]

In 1932 Yoe[3] reported a method for the colorimetric determination of iron by means of 7-iodo-8-hydroxyquinoline-5-sulfonic acid (I).[4] It was found that this compound reacts instantaneously with ferric ions yielding green colored solutions, the color intensity varying with the iron concentration. The reaction is very sensitive and may be used to determine ferric iron in the presence of ferrous, since the latter produces no color with the reagent. Also, the color does not fade on standing, which is an advantage over the thiocyanate method as frequently carried out in acid solution.



(I)

In view of the advantages offered by this method, namely, the stability of the colored compound, the high sensitivity of the reaction, and its ability to distinguish between ferric and ferrous ions, it seemed desirable to investigate it in detail. In fact, the reagent appears to be specific for ferric ions, since no other ion has been found to yield a color reaction with Ferron.[3]

The following studies have been made on the reagent and its reaction with ferric ions: solubility in various solvents; nature of the color reaction; physical and chemical properties of Ferron; influence of various ions; sensitivity; Lambert–Beer law; effect of hydrogen-ion concentration; aging effect and the effect of temperature.

Reagents and Solutions.—The general technique and method of investigation has been described in a previous paper by Yoe and Wirsing.[5] 7-Iodo-8-hydroxyquinoline-5-sulfonic acid (Ferron) was first prepared by Claus.[6] The compound used in this investigation was a very pure product obtained from G. D. Searle and Co., Chicago, Ill. A saturated aqueous solution (approximately 0.2%) of Ferron makes a satisfactory reagent solution. For convenience in obtaining various molecular ratios between the Ferron and ferric iron, several other Ferron solutions of known concentration were prepared.

The standard iron solution was prepared from ferrous ammonium sulfate, $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$, reagent quality, 0.7020 g. of the salt being weighed out and dissolved in about 100 ml. of distilled water. Five milliliters of concentrated sulfuric acid (iron-free) was then added to the solution to prevent hydrolysis. Five to ten milliliters of saturated bromine water was added and the solution boiled until the iron was oxidized and the excess bromine expelled. The solution was then cooled and diluted to a liter in a volumetric flask. Its iron content was checked volumetrically by reducing (with the Jones reductor) the ferric sulfate solution and titrating immediately with a potassium permanganate solution which had been standardized against sodium oxalate obtained from the National Bureau of Standards. The average of three determinations in close agreement gave the iron concentration as 0.1005 g. per liter. This solution was used as a stock solution from which more dilute ones were conveniently prepared as needed.

Solutions of the salts used in studying the effects of various ions were prepared so that 1 ml. would contain 2 mg. of the desired ion, assuming complete dissociation. Chlorides, nitrates and sulfates were employed and, when necessary, they were recrystallized from conductivity water until iron-free.

The buffer solutions were prepared from various standard solutions according to the directions of Clark.[7]

Apparatus.—For the solubility measurements, a large thermostat equipped with an immersed, rotating wheel was used. Its temperature was maintained constant at 25 to ±0.1°. Standard types of apparatus and methods were employed in making the *p*H determinations. In making color comparisons, a daylight lamp and Duboscq colorimeter (Bausch and Lomb) were always used in fixed positions in a dark room. Also a set of twelve carefully matched 50-ml. Nessler tubes (210-mm.) was used. These were placed in a shielded Nessler tube rack.

All weights, pipets and volumetric flasks were calibrated. The reagents were measured out with pipets which were labelled so that a given pipet was always used for one solution only.

Composition of Ferron.—An ultimate analysis was made of the 7-iodo-8-hydroxyquinoline-5-sulfonic acid, using standard methods. The results of the analysis are summarized in Table I.

Table I

Constituent	Found	Calcd.
Carbon	30.68	30.76
Hydrogen	1.62	1.72
Oxygen[a]	18.43	18.27
Nitrogen	4.03	3.99
Sulfur[b]	9.04	9.11
Iodine[b]	36.06	36.15

[a] Obtained by difference.

[b] Average of three analyses.

Experimental

Solubility of Ferron.—The solubility of 7-iodo-8-hydroxyquinoline-5-sulfonic acid in several solvents and mixtures of solvents was determined at 25°. Into clean 100-ml. glass-stoppered Pyrex bottles was introduced 50 ml. of the solvent and sufficient of the Ferron so that after thorough agitation a few tenths of a gram of the solid settled out. The bottles were tightly stoppered, firmly attached to the thermostat wheel, rotated for twenty hours and then allowed to stand for sixteen hours. Without removing the bottles from the thermostat, 25 ml. of the clear supernatant liquid was withdrawn and introduced into dried weighed crucibles. The solutions were evaporated to dryness in vacuum desiccators and the crucibles plus their contents then weighed. The data are recorded in Table II.

Table II

Solubility of Ferron at 25 ±0.1°

Solvent	Solubility, g./100 ml. soln.
Acetone	0.0080
Glacial acetic acid	.0192
Alcohol (absolute)	.0304
Water	.2220
Water–alcohol (1:1 by vol.)	.3500
Water–alcohol (3:2 by vol.)	.5696
Water–acetone (1:1 by vol.)	.7200

It is interesting to note that the mixtures have a greater solvent action than the individual solvents. The presence of the sulfonic acid group in the compound probably causes it to have a greater solubility in water than in an organic solvent. If the compound did not contain the sulfonic acid group, it would be expected to be more soluble in an organic solvent than in water. Therefore it might be predicted that the maximum solubility would be attained in a mixture of water and an organic solvent. Such was found to be the case.

Physical and Chemical Properties of Ferron.—7-Iodo-8-hydroxyquinoline-5-sulfonic acid is a bright yellow crystalline solid. On slow heating it changes from a yellow color to a dark brown at 225°, and at 250° turns completely black, decomposition occurring without melting. On rapid heating it melts sharply at 285°, at the same time undergoing decomposition as is indicated by an evolution of iodine vapor. Boiling its aqueous solution causes a slow decomposition with the evolution of a trace of iodine, easily detected by its odor. Also, the aqueous solution on standing for several weeks takes on a slightly darker shade of yellow due to the presence of a little iodine liberated by the compound. However, such solutions are quite satisfactory for colorimetric work.

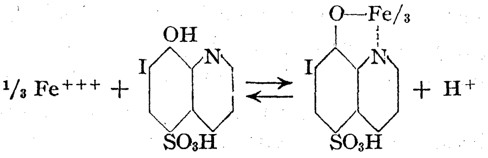
Nature of the Reaction.—The exact reaction that takes place between 7-iodo-8-hydroxy-

---

[7] Clark, "The Determination of Hydrogen Ions," 3d ed., Williams and Wilkins Co., Baltimore, Md., 1928.

quinoline-5-sulfonic acid and ferric ions is not known with certainty. In the first part of our work aqueous solutions of the reagent were prepared in such concentrations that when added to known amounts of ferric iron, there existed a definite molecular ratio between the iron and the reagent. By changing these molecular ratios both the color and the intensity could be varied. It was reasoned that if the molecular ratio in which the ferric ions and the reagent combine to give the optimum color formation could be determined, this might give some information as to the probable reaction. With this in view a number of solutions were prepared for observation in Nessler tubes and in the colorimeter. The molecular ratios of the reagent to ferric iron in these solutions were varied widely and covered the range from 0.5 mole of reagent : 1 mole of ferric iron to 6 moles of reagent : 1 mole of ferric iron. The reagent solutions were prepared in varying concentrations so that the same volume of reagent was added to the iron solution in each case, although different molecular ratios existed after final dilution. The amount of iron was constant throughout.

The color studies indicated that 1 mole of ferric iron requires at least 1 mole of reagent but not more than 3 moles. Color studies were made on the three molecular ratios, 1:1, 2:1 and 3:1. The evidence in all cases pointed to a 3:1 molecular reaction between Ferron and ferric iron, *i. e.*, one equivalent weight of ferric iron requires one mole of the reagent. The reaction may be expressed by



This reaction is in accord with the work of Berg[8] on the complex metal salts of *o*-hydroxyquinoline. Berg postulated that the hydrogen of the hydroxyl group, due to the position of this group relative to the quinoline nucleus, had its activity enhanced and that the compound reacting with metals formed an inner complex salt. However, it should be noted that our conclusions concerning this reaction are based purely on color formation and of course cannot be considered as a rigid proof. Attempts to obtain the colored compound in a crystalline form were unsuccessful. Slow evaporation at room temperature always yielded a dark green amorphous mass. In any case, in the preparation of a standard series, at least enough reagent should be added to use up all the iron on the basis of a 3:1 reaction, *i. e.*, 3 moles of Ferron to 1 gram-atom of iron.

Influence of Various Ions.—In the preliminary investigation Yoe[3] found that ferric ions are the only ions which give a color reaction with 7-iodo-8-hydroxyquinoline-5-sulfonic acid. He also pointed out that salts which hydrolyze easily, or yield colored ions, interfere with the color reaction. Therefore a quantitative study of the effect of various ions likely to be encountered in analyses was made. Aqueous solutions containing known amounts of ferric iron plus various other ions were prepared. The amount of iron in these solutions was then determined by comparison with standards. The procedure was as follows: measured quantities of the metallic salts were placed in Nessler tubes and to each tube was added a known amount of ferric iron. The acidity was adjusted to a *p*H of about 2.5 by adding hydrochloric acid–potassium acid phthalate buffer solution. The reagent was then added, the solutions diluted to the mark, thoroughly mixed and compared with a series of standards. The results are shown in Tables III and IV.

The data in Table III show that colored ions should not be present except to a limited extent. Aluminum may be present in an amount approximately five times that of ferric iron without causing marked interference. Colbalt and nickel may be present individually in proportions about twice as great as iron. Titanium should not be present in a concentration greater than a few tenths of a part per million. The chromium concentration should not exceed that of the iron. The effect of the above colored ions appears to be additive. It is of particular interest to note that ferrous iron may be present without causing the least difficulty in the determination of the ferric iron.

Table IV records the ions that cause the most difficulty. These ions must not be present in concentrations greater than a few tenths of a part per million. For precise work they should be removed totally. Cupric ions interfere when present to the extent of only 0.2 p. p. m. Salts that hydrolyze easily, such as those of tin and titanium, should be removed before an iron determination is made. It should also be pointed out that fluoride causes a partial bleaching of the color and must be absent. Relatively large amounts of phosphate may prevent the immediate formation of maximum green color intensity but on standing (five minutes to two hours) the maximum intensity develops.

Sulfate, nitrate and chloride ions do not interfere with the color reaction.

Sensitivity.—The sensitivity measurements were made according to the method described by Yoe and Wirsing.[5] The results are recorded in Table V.

In Table V column 1 gives the concentration stated as liters containing one gram-atom of iron.

Table V

V	B	Δ	S	B'	B/B'
7,977	0.3500	Too intense for observation			
15,954	.1750	0.0125	80	0.1875	0.933
21,476	.1300	.0075	133	.1375	.945
31,023	.0900	.0050	200	.0950	.947
50,950	.0548	.0037	266	.0585	.936
186,133	.0150	.0025	400	.0175	.857
310,230	.0090	.0020	500	.0110	.820
1,116,800	.0025	Barely distinguishable from blank			

In the second column B is the total milligrams of iron in 50 ml. of solution. Δ is the mg. of iron producing a perceptible difference in the color intensity of 50 ml. of solution. S is the sensitivity and is the reciprocal of the figures recorded in column 3. $B' = B + \Delta$.

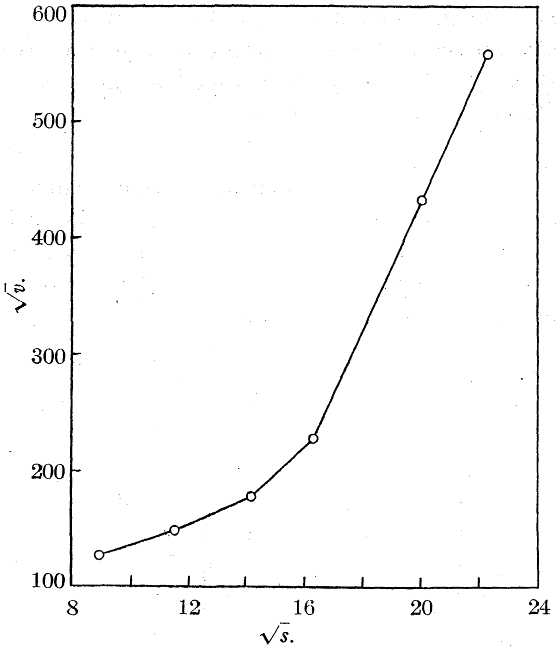

Fig. 1.

Figure 1 shows graphically how the sensitivity varies with the concentration. For convenience in plotting, the square roots of the volume and sensitivity were used. The sensitivity curve for iron is very similar to those obtained by Yoe and Hill[9] for aluminum and by Yoe and Wirsing[5] for nickel. The portion of the curve having the least slope is the range of maximum sensitivity. Except for this portion and at very dilute solutions the sensitivity is a straight line function of the concentration.

Horn[10] has suggested that the ratio B/B' is probably constant throughout colorimetry,

(9) Yoe and Hill, This Journal, **50**, 748 (1928).

(10) Horn, *Am. Chem. J.*, **35**, 253 (1906).

independent of the color examined. The data in Table VI are in agreement with this hypothesis.

TABLE VI

Ion	Method	Color	B/B' av.	Observer

Our experiments showed that the Ferron reagent will determine quantitatively as little as 0.1 mg. of iron in a liter of solution, that is, 1 part in 10 millions.

Lambert-Beer Law.—In the case of colored solutions, the absorption of light depends not only on the thickness of the layer traversed, but also on the molecular concentration in the layer. Beer (1852) therefore modified Lambert's law (1760) and expressed it as

$$I = I_0^{-kcl} \qquad (1)$$

in which k is the molecular absorption coefficient; c is the molecular concentration; I is the intensity of the light after passing through the thickness, l, of the medium and I_0 is the intensity of the incident light upon the medium.

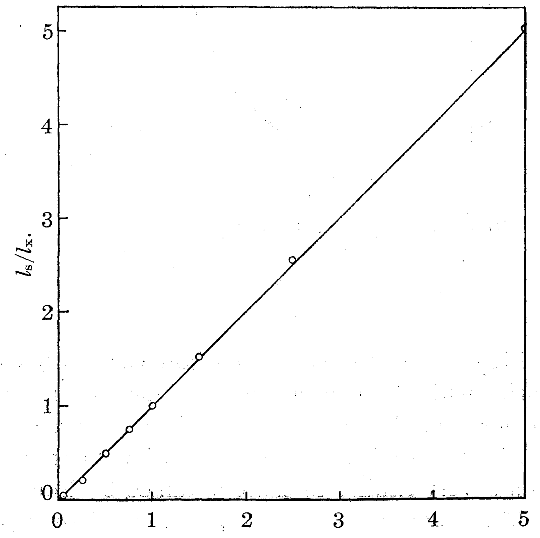

Fig. 2.

As applied to colorimetry, the Lambert-Beer law is generally expressed in the following more convenient form

$$c_x/c_s = l_s/l_x \qquad (2)$$

where c_s and c_x represent the concentrations of the standard and "unknown," respectively, and l_s and l_x are the readings of the heights of the standard and "unknown" solutions, respectively.

According to equation (2) when equal color intensity is obtained from different heights of two solutions, the concentrations are inversely proportional to the heights. In order for this relationship to hold, the color formation in the two solutions must be perfectly formed, or imperfectly formed to the same extent in both solutions. When this is not the case the difficulty must be overcome by the use of a calibration curve which can be prepared experimentally from solutions of known concentrations.

For the study of the Lambert-Beer law colored solutions of various concentrations were prepared from the stock (standard) iron solution and each solution was then matched against the standard colored solution in a B. and L. Duboscq colorimeter. The amount of Ferron added in each case was sufficient to satisfy a 3:1 molecular reaction. The pH of the solutions was kept constant at 2.6 by the use of hydrochloric acid-potassium acid phthalate buffer solution. The data are shown graphically in Fig. 2. According to the Lambert-Beer law a straight line would be obtained by plotting the ratio of heights against the inverse ratio of concentrations. An examination of Fig. 2 shows that the law is followed, within the experimental error, over the range of concentration examined.

Effect of Hydrogen-Ion Concentration.—The hydrogen-ion concentration has a pronounced influence on the reaction between ferric ions and Ferron. Yoe[3] reported that the reaction is best carried out in a solution acid to methyl orange paper, and that the color was completely destroyed by the addition of either strong acid or alkali. In this work a more extensive study of the effect of hydrogen-ion concentration was made and the optimum pH range for the color reaction was determined.

First of all, a study was made of the sensitivity of the reagent solution to hydrogen-ion concentration. It was found that below a pH of 1.2 and above a pH of 8.3 the reagent solution was completely decolorized. However, over the pH range from 2 to 3 there was only a slight change in the color intensity of the reagent solution.

Experiments with the colored iron solutions showed that once the color is formed it could exist with varying intensities over a fairly wide pH range (2 to 5 approximately). The color intensity of iron solutions of the same concentration shows no perceptible variation over a *p*H range from 2 to 3, but it was noted in all of this work that above *p*H 3.0 a very small change in hydrogen-ion concentration had a pronounced effect on the color intensity. Since in the *p*H range from 2 to 3 the color intensity is constant and reproducible, in practice, the hydrogen-ion concentration should be adjusted to a *p*H of approximately 2.5. It was found that this could be done with a precision of ±0.2 *p*H by the use of hydrochloric acid–potassium acid phthalate buffer. This buffer does not, in any respect, interfere with the color reaction.

Aging Effect.—In many colorimetric methods the color formed has the unfortunate property of fading rapidly on standing, thus making it necessary to make the color comparison at once. Moreover, the standard color solutions must be made up fresh for each determination, unless it be possible to obtain satisfactory permanent standards made from stable colored compounds. In this investigation a thorough study was made of the effect of aging on the green colored solution. Both Nessler tubes and a Bausch and Lomb Duboscq colorimeter were used in this study. It was found that a colored solution which had aged thirty-six days still matched a freshly prepared solution of the same concentration.

Effect of Temperature.—The temperatures of various colored solutions of the same iron concentration were fixed at different values, covering a range from 15 to 40° and observations were made on them in Nessler tubes. No color changes or changes in intensity could be detected. Hence, variations that occur within the range of laboratory temperatures have no effect on the color.

Optimum Experimental Conditions.—The results of the studies made on the various factors involved enabled the establishment of certain experimental conditions under which the color reaction should be carried out in order to obtain the most satisfactory results. Sufficient reagent solution should be added to react with all the ferric iron present on the basis of a 3:1 molecular ratio. However, for Nessler tube work it was found convenient to add a fixed amount of reagent over a whole range of iron concentration. For iron concentrations less than 1 p. p. m., prepare a solution free from any interfering ions, adjust the acidity to a *p*H of 2.5 by means of hydrochloric acid–potassium acid phthalate buffer and add 5 drops (0.25 ml.) of the Ferron reagent. The color develops at once. Dilute to the mark with distilled water and mix thoroughly.

For iron concentrations from 1.0 p.p.m. to 2.0 p. p. m., 1 ml. of the reagent solution is added and for concentrations above 2.0 p. p. m., add 2 ml. of reagent. Due to the great intensity of the green color formed, precise matching is impossible for concentrations greater than 4.0 p. p. m. of Fe^{+++}. In other words, with 50-ml. Nessler tubes (tall form), the range is from 0.005 to 0.2 mg. of ferric iron. Matching is much more easily made over the range from 0.0075 mg. iron per ml. to 0.05 mg. per ml.

In the analysis of unknowns it sometimes happens that a very large excess of reagent is used in preparing both the standard and the unknown. A Corning HR yellow filter No. 351 will be helpful in eliminating the effect of excess reagent.

It must be borne in mind that the use of a buffer solution alone to adjust the *p*H is governed by some practical considerations, the most important of which is that the amount of buffer solution used has a limited capacity to prevent appreciable changes in hydrogen-ion concentration. It is possible that an unknown might be so strongly acidic or basic that the buffer could not hold the *p*H within the required range. For this reason the sample solution should always be tested with an indicator paper (Congo red or methyl orange) and the *p*H approximately adjusted, if too acid or too alkaline.

Determination of Iron in Various Materials

The colorimetric method described in the preceding section has been used for the determination of iron in a large number of the National Bureau of Standards samples. The samples analyzed varied widely in their chemical nature and included such materials as bauxite, feldspar, glass sands, glasses, clays, limestones and alloys. Hence, it was possible to try out the method over a wide range of conditions.

The colorimetric part of these analyses was done by means of the standard series method using 50-ml. Nessler tubes (tall form). The sensitivity data showed that the concentration range from 1 to 2 p. p. m. of Fe^{+++} was within the range of greatest sensitivity. A difference in iron content of 5 γ could be detected. If the magnitude of the amount of iron in the sample was known, then the weight of sample to be taken for analysis could be calculated, so that the concentration of the solution finally analyzed fell within the range of maximum sensitivity. When the approximate iron content was unknown (to the analyst), a rough preliminary analysis was made to determine the correct size of sample to be taken. All samples were issued to one of us (R. T. H.) as unknowns.

In general, the procedures used in the analyses of the various samples followed closely those given in the National Bureau of Standards Certificates of Analyses. In many cases it was possible to simplify these considerably, since in this work only one constituent was sought. For convenience, the materials analyzed may be classified into three groups: glass sand and glass, rocks and alloys.

Methods of Analysis

After investigating several procedures, the following was found to be the most satisfactory for glass sand and glass.

Glass Sand and Glass.—A sample of about 0.25 g. was weighed out after the material had first been dried at 110°. The weight of sample to be taken was governed by certain considerations already pointed out. The sample was then fused to a clear melt in a platinum crucible, using sodium carbonate as a flux. The fusion, after cooling, was disintegrated and treated by the perchloric acid method[11] for the dehydration of silicic acid. The silica was filtered off, washed thoroughly with dilute hydrochloric acid and finally with water. The filtrate was received in a porcelain casserole and its acidity adjusted by the addition of concentrated ammonium hydroxide until it was just acid to Congo red paper. The solution was evaporated on the steam-bath to such volume that it could be introduced into a Nessler tube along with 10 ml. of buffer solution (pH 2.6) and 1 ml. of the Ferron reagent. This Nessler was then compared with a standard series, and a match obtained. In some cases, instead of evaporating the solution to a small volume, it was found convenient to dilute it to a known volume in a volumetric flask and then remove an aliquot for analysis. In all these analyses the pH of the standard and of the unknown was determined. In every case the pH was within the range of 2.6 ± 0.2, and usually did not vary more than 0.1 of a pH unit.

When aluminum was present in amounts relatively large in comparison with the amount of iron, as was the case in a few of the samples, it interfered to some extent with the determination. This difficulty was overcome either by adding a little aluminum salt to the standard in cases where the aluminum content was known or by separating the iron from the aluminum (by means of sodium hydroxide) in the manner given by Hillebrand and Lundell.[11] In some instances it was necessary also to remove the titanium. The iron was separated from both the aluminum and the titanium according to the National Bureau of Standards method.[12]

Rocks and Clays.—Included in this group were the following: bauxite, plastic clay, fluorspar, feldspar, dolomite and argillaceous limestone. The procedures used for these samples were for the most part based on the methods of the National Bureau of Standards. Aluminum and titanium were present throughout this whole group and in most instances it was necessary to remove these constituents in order to make a satisfactory determination of the iron. The methods used on bauxite and plastic clay were essentially the same as the one given by Lundell and Hoffman.[13] The fluorspar, feldspar, and limestones were analyzed according to standard methods and the iron determined colorimetrically by Ferron.

Alloys.—The iron content of the following alloys was determined colorimetrically by means of the Ferron reagent: sheet brass, cast bronze and zinc base die-casting alloy. The elements copper, tin and antimony were present in varying amounts in all of these materials and nickel was present in two of them. It had previously been found that all of these elements interfere with the Ferron method for iron. The separation of these elements from the relatively small amount of iron present in the samples was extremely difficult in some cases. The sheet brass and cast bronze were analyzed according to a procedure developed by Lundell and Scherrer.[14] Of the constituents in the zinc base die-casting alloy, only the copper and aluminum were present in amounts sufficient to make their elimination necessary.

The results of all analyses are summarized in Table VII.

TABLE VII

Material	B. of S. No.	Total iron as Fe_2O_3	
		B. of S. Av.	Found
Bauxite	69	5.66	5.72
Clay, plastic	98	2.05	2.00
Dolomite	88	0.084	0.092

(13) Lundell and Hoffman, *Bur. Standards J. Research*, **1**, 91 (1928).

(14) Lundell and Scherer, *Ind. Eng. Chem.*, **14**, 426 (1922).

An examination of the table shows that with one or two exceptions the results are in good agreement with those reported by the National Bureau of Standards. The low percentages obtained on the alloys undoubtedly were due to the experimental difficulties of separating small amounts of iron from relatively large amounts of elements such as tin and antimony. These low results can hardly be attributed to any inherent weakness of the colorimetric method since no tendency of this sort is apparent in the other results obtained. Also, it is of interest to note that in the two cases where the Bureau reports analyses by a colorimetric method, the results obtained by the Ferron method checked the latter closer than the average value reported by the Bureau.

Summary

A study has been made of 7-iodo-8-hydroxyquinoline-5-sulfonic acid and its reaction with ferric ions. The solubility of the reagent has been determined in water, alcohol, acetic acid and in mixtures of these solvents. The color reaction has been investigated and a probable mechanism for it has been postulated. Cupric ions and salts that hydrolyze easily, or yield colored ions, interfere with the reaction and should not be present except in very low concentration. The sensitivity of the reaction has been determined. The reagent will measure quantitatively one part of iron in ten million parts of solution, when the observation is made in 50-ml. Nessler tubes (tall form). The color has been found to obey the Lambert–Beer law over the range of concentration examined. The effect of hydrogen-ion concentration has been studied and the optimum *p*H range for the color reaction determined. Aging and temperature have been found to have no effect on the color reaction. The optimum experimental conditions for the determination of iron have been established.

The iron content of a wide variety of materials has been determined colorimetrically, using 7-iodo-8-hydroxyquinoline-5-sulfonic acid. With one or two exceptions, the results obtained are in good agreement with the values reported by the National Bureau of Standards.

Condensations of Aromatic Amines with Formaldehyde in Media Containing Acid. V. Substituted Dihydroquinazolines from *p*-Chloroaniline and *p*-Bromoaniline

BY E. C. WAGNER AND ABNER EISNER[1]

The condensations of *p*-substituted amines with formaldehyde in aqueous acid solution have been studied for *p*-toluidine by Maffei and by the writers,[2] for *p*-phenetidine and *p*-nitroaniline by Maffei,[3] and by Cairncross and Bogert for *p*-aminobenzoic acid and ester[4] and for *p*-bromoaniline.[5] The reported products included the corresponding 3,6-disubstituted-3,4-dihydroquinazolines except in the case of *p*-bromoaniline, from which Cairncross and Bogert[5] obtained as the main product (19%) a base of m. p. 257° identified as 3-(*p*-bromophenyl)-6-bromo-3,4-dihydroquinazolone-4, and smaller amounts of two other bases (m. p. 204° and 193–196°), neither examined further. At the time these results were published the writers had practically completed a study of the condensation of *p*-chloroaniline with formaldehyde in dilute hydrochloric acid solution. The principal product was the expected substituted quinazoline. These contrasting results with two compounds so similar led to extension of the work to include *p*-bromoaniline. Condensation of this amine with formaldehyde in dilute hydrochloric acid solution at or below room temperature gave as the main product (26%) a base of m. p. 205.8° (corr.), found to be 3-(*p*-bromophenyl)-6-bromo-3,4-dihydroquinazoline. No base of m. p. 257° was isolated. Comparison of the two sets of conditions which yielded these unlike results shows that Cairncross and Bogert used less acid, more water, and considerably higher temperature (70°); the separation and purification of the several products involved a laborious and lengthy procedure. In the writers' experiments the isolation of the quinazoline offered no difficulty.

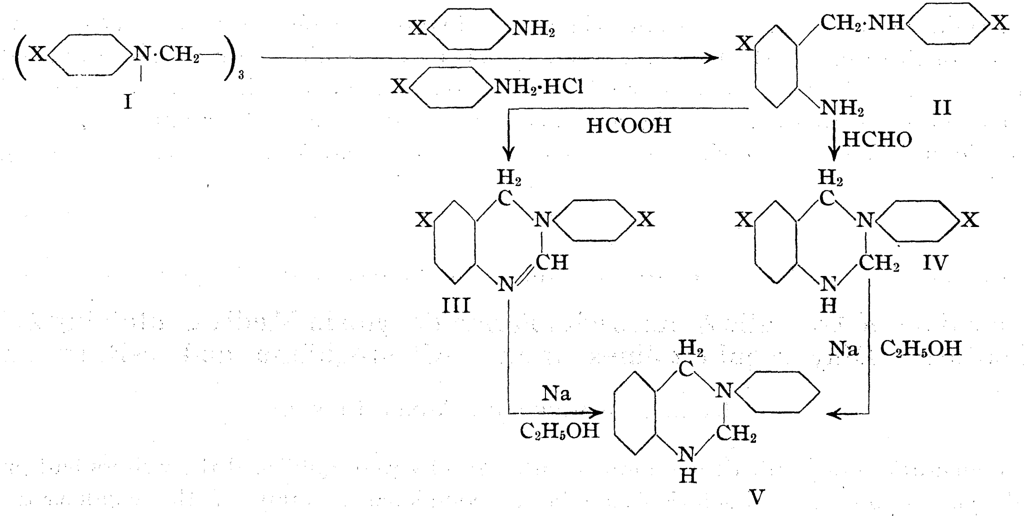
This paper describes the results of condensations of *p*-chloroaniline and of *p*-bromoaniline with formaldehyde in aqueous solutions containing hydrochloric acid, and the experiments by which the main reaction products were identified as the 3,6-disubstituted dihydroquinazolines. From both amines there were obtained also somewhat smaller amounts of lower-melting bases (135° and 134–135°, respectively), which have not been identified. The condensations were accompanied by methylation of part of the original amines, as has been reported also in the cases of *p*-toluidine and *p*-phenetidine.

The identifications of the substituted quinazolines were effected by the syntheses and transformations shown in the reaction scheme.



In the case of each starting compound (*p*-chloroaniline and *p*-bromoaniline) the trimeric Schiff base (I), prepared by the method of Miller,[6] was converted to the aminobenzylarylamine base (II) by the customary procedure,[7] and II was changed to the dihydroquinazoline (III) by ring-closure with formic acid.[7b] The dihydroquinazolines thus obtained were found to be identical with the main products of the condensations of the halogenated amines with formaldehyde. The structure of II, upon which the proof depends, may be inferred from the method of preparation used, and was supported by the characteristic behavior of the compound with formaldehyde to yield the tetrahydroquinazoline (IV), by the fact that II gave with benzaldehyde a monobenzal derivative from which benzaldehyde was split out by acid hydrolysis, and by the analytical values obtained for II, its benzal derivative, and IV. Hydrogenation of III to IV, apparently a simple way to establish the relationship of the two, was not effected,[8] but III was treated with excess sodium and alcohol under conditions which detached halogen quantitatively,[9] by which treatment both dihydroquinazolines yielded the same product (V), namely, 3-phenyl-1,2,3,4-tetrahydroquinazoline.[10] Further the tetrahydroquinazoline (IV) from *p*-bromoaniline was dehalogenated by sodium and alcohol yielding V, identical with the compound obtained from the two halogenated dihydroquinazolines (III). In the cases of the bromine compounds (III and IV) the bromine split off was recovered as silver bromide and weighed, with results close to the theoretical.

The foregoing evidence, together with analytical values, identify the two condensation products as 3-(*p*-chlorophenyl)-6-chloro-3,4-dihydroquinazoline (m. p. 192°, corr.) and 3-(*p*-bromophenyl)-6-bromo-3,4-dihydroquinazoline (m. p. 205.8°, corr.). Apparently both compounds have been obtained previously as unidentified reaction products, *viz.*, a base of m. p. 188° from *p*-chloroaniline, reported in a German patent,[11] and the

[8] No method came to hand by which the 1,2-double bond could be hydrogenated without cleavage of halogen. Alcohol and a moderate amount of sodium split off part of the halogen, as found also by Paal and Koch [*J. prakt. Chem.*, [2] **48**, 554 (1893)]. Hydrogen under 30 pounds (2 atm.) pressure and in presence of Raney nickel was found, in trials with other dihydroquinazolines, to be ineffective. Hydrogen in presence of palladized calcium carbonate [Busch and Stöve, *Ber.*, **49**, 1063 (1916); ref. 5] removes halogen without hydrogenating the double bond.

base of m. p. 204° obtained from *p*-bromoaniline by Cairncross and Bogert.[5]

Experimental

Condensation of *p*-Chloroaniline and *p*-Bromoaniline with Formaldehyde in Aqueous Acid Solution.—The amine (0.1 mole) was dissolved in 100 cc. of water and 18 cc. of concd. hydrochloric acid. To the cold solution was added 10 cc. of 37% formalin (0.12 mole), and the mixture was stirred. A white precipitate appeared after some minutes, and increased steadily, while the liquid and precipitate acquired a gradually deepening red color. The separated hydrochlorides were filtered off after several hours. The filtrate was allowed to stand at room temperature, with removal of the further precipitate when it had become considerable, and this was continued until the final precipitate was negligible (eight to eleven days). The combined crops of colored hydrochlorides were dissolved in boiling water, filtered hot, and while still hot (to prevent separation of hydrochloride) the solution was made alkaline. The precipitate of bases was stirred until well granulated, and was filtered cold and washed with water. The yield from *p*-chloroaniline was 9.9 g., and from *p*-bromoaniline 11.2 g. The crude product was crystallized from 95% alcohol. In each case there separated first a crystalline base only slightly soluble in cold alcohol. After recrystallization from alcohol the base from *p*-chloroaniline melted at 186–187°, obsd., and that from *p*-bromoaniline at 201°, obsd. These bases were the dihydroquinazolines. The mother liquors were diluted while hot, and on chilling gave a second product more soluble than the first. The base from *p*-chloroaniline, after recrystallization from dilute alcohol, melted at 135°, obsd., and that from *p*-bromoaniline at 134–135°, obsd. The yields from *p*-bromoaniline were 4.74 g. of the 201° base (25.9%) and 3.34 g. of the 134° base.

After removal of the crude hydrochlorides in an experiment with *p*-bromoaniline the final filtrate was made alkaline and was steam-distilled, yielding 1.38 g. of steam-volatile oil, which was examined by the Hinsberg–Kessler procedure. There were obtained 0.29 g. of primary amine derivative (m. p. 127°), 0.31 g. of secondary amine derivative (brown oil), and 0.27 g. of tertiary base (diazotization and coupling test negative) whose crystallization was not feasible, but which gave a picrate of m. p. 139°, found to be identical (mixed melting point test) with the picrate of dimethyl-*p*-bromoaniline.

3 - (*p* - Chlorophenyl) - 6 - chloro - 3,4 - dihydroquinazoline.—Colorless needles from alcohol slightly diluted; m. p. 187°, obsd., or 192°, corr.

Anal. Calcd. for $C_{14}H_{10}N_2Cl_2$: C, 60.67; H, 3.61; N, 10.11; Cl, 25.62; mol. wt., 277. Found: C, 60.71; H, 3.69; N, 9.96, 9.95; Cl, 25.47, 25.47; mol. wt. (benzene), 294, 295; (camphor), 268, 270. Picrate: small yellow needles from alcohol; m. p. 233°, obsd., or 239°, corr.

3 - (*p* - Bromophenyl) - 6 - bromo - 3,4 - dihydroquinazoline.—Small elongated prisms from slightly diluted alcohol; m. p. 201°, obsd., or 205.8°, corr.

Anal. Calcd. for $C_{14}H_{10}N_2Br_2$: C, 45.92; H, 2.73; N, 7.65; Br, 43.66; mol. wt., 366. Found: C, 46.11; H, 2.72; N, 7.60, 7.41, 7.44; Br, 43.59; mol. wt. (camphor), 380, 376. Picrate: small bright yellow needles from hot alcohol; m. p. 235°, obsd., or 242°, corr.

Trimeric Methylene-*p*-chloroaniline.—This compound was reported by Bischoff and Reinfeld,[12] who found the m. p. to be 157° and the molecular weight 437, but gave no analytical values. Specimens made for this work by the method of Miller,[6] and crystallized from ligroin, melted at 151°, obsd., a value not raised by another crystallization. This compound was examined further in order to make certain of its identity.

Anal. Calcd. for $(C_7H_6NCl)_3$: Cl, 25.44; mol. wt., 417.5. Found: Cl, 25.25, 25.22; mol. wt. (benzene), 422, 420.

Reduction by zinc dust and hot dilute sulfuric acid[6,13] split the compound into bases recognized by the Hinsberg–Kessler procedure to be primary, secondary and tertiary. The evidence given establishes the compound as the trimeric Schiff base, as claimed by Bischoff and Reinfeld.

In molten camphor this base gave molecular weight values of 287 and 290, indicating partial depolymerization at 175°, as with similar compounds studied previously.[6]

Trimeric Methylene-*p*-bromoaniline.—This compound, not previously reported, was prepared by the method of Miller.[6] The reaction mixture, at first kept in an ice-bath, deposited initially a solid product which soon became viscous, and on standing overnight set to an amorphous mass; 17.2 g. of *p*-bromoaniline gave 11.4 g. of crude product (61.7%). The base crystallized from ligroin or alcohol in long thin flexible needles clumped in loose bulky masses. The compound melted at 166° obsd., or 168.8°, corr., to a turbid liquid.

Anal. Calcd. for $(C_7H_6NBr)_3$: C, 45.68; H, 3.26; N, 7.61; mol. wt., 552. Found: C, 45.80; H, 3.38; N, 7.64, 7.54; mol. wt. (benzene), 563, 546. In molten camphor the molecular weight results were 378, 389 and 374, showing partial depolymerization at 175°.

Cleavage of 2.95 g. of the compound by reduction[6] gave 2.28 g. of steam-volatile oil, which by the Hinsberg procedure was shown to contain primary and secondary bases, and yielded also 0.48 g. of a solid tertiary base. This melted at 54–55°, and was found by mixed melting point test to be identical with dimethyl-*p*-bromoaniline (m. p. 54°). The picrates (m. p. 140–141°) also were identical.

N-(2-Amino-5-chlorobenzyl)-*p*-chloroaniline (II).—This aminobenzylarylamine was made[14] by heating a mixture of 10 g. of crude methylene-*p*-chloroaniline, 23 g. of *p*-chloroaniline hydrochloride, 50 g. of *p*-chloroaniline and 5 cc. of nitrobenzene for six hours at 80–90°. The mixture was made alkaline and all steam-volatile material was removed. The somewhat gluey residue in the flask was extracted with ligroin (70–90°), yielding a yellow granular product (8.9 g., or 46.5%). Several crystallizations from ligroin gave small imperfect prisms with a slight yellow tinge, and a good melting point of 92°, obsd., or 93°, corr.

[12] Bischoff and Reinfeld, *Ber.*, **36**, 47 (1903).

[13] Wagner, THIS JOURNAL, **54**, 660 (1932).

[14] The procedure used was based on German Patent 105,797 (ref. 7) and will be reported in a later paper.

Anal. Calcd. for $C_{13}H_{12}N_2Cl_2$: C, 58.45; H, 4.49; N, 10.49; mol. wt., 267. Found: C, 58.67, 58.74; H, 4.45, 4.57; N, 10.34, 10.45; mol. wt. (camphor), 272, 265.

N-(2-Amino-5-bromobenzyl)-*p*-bromoaniline (II).—A mixture of 10.0 g. of methylene-*p*-bromoaniline, 10 g. of *p*-bromoaniline hydrochloride and 100 g. of *p*-bromoaniline was heated in an oil-bath at 85° for four hours.[14] After removal of *p*-bromoaniline by steam distillation, the crude product in the flask solidified on cooling. It was partially dried, dissolved in hot alcohol, and recovered in several crops by progressive dilution with water. The crude yield was 10.7 g., or 55.3%. After two crystallizations from ligroin the substance was crystalline, though still yellowish, and melted well at 116°, obsd., or 117.6°, corr.

Anal. Calcd. for $C_{13}H_{12}N_2Br_2$: C, 43.84; H, 3.37; N, 7.87; mol. wt., 356. Found: C, 44.08, 44.12; H, 3.51, 3.63; N, 7.59, 7.58, 7.63; mol. wt. (camphor), 340, 348.

The resinous material obtained from the alcoholic mother liquors was worked up and yielded a small amount of the picrate of 3-(*p*-bromophenyl)-6-bromo-3,4-dihydroquinazoline (m. p. 232°; identified by mixed m. p. test), a normal by-product of the main reaction, as shown by Simons.[15]

N-(2-Benzalamino-5-chlorobenzyl)-*p*-chloroaniline.—To 0.50 g. of 2-amino-5-chlorobenzyl-*p*-chloroaniline in 10 cc. of hot alcohol was added 0.5 cc. of benzaldehyde. The liquid soon set to a mass of crystals. Alcohol was then added in portions to the heated mixture until the product just dissolved. On cooling the filtered solution there separated 0.48 g. of needle-shaped crystals, and from the filtrate after concentration 0.06 g. more, a total yield of 80.6%. The benzal derivative melted at 137°, obsd., or 139°, corr. Heated with dilute sulfuric acid it yielded benzaldehyde.

Anal. Calcd. for $C_{20}H_{15}N_2Cl_2$: N, 7.89. Found: N, 7.80, 7.84.

N-(2-Benzalamino-5-bromobenzyl)-*p*-bromoaniline.—Prepared by the method described for the corresponding chlorine compound this derivative was obtained in 86.6% yield. After recrystallization from alcohol it melted at 142°, obsd., or 144.6°, corr.

Anal. Calcd. for $C_{20}H_{15}N_2Br_2$: N, 6.31. Found: N, 6.37, 6.27.

Conversion of Aminobenzylarylamine Bases (II) to the Corresponding Tetrahydroquinazolines (IV)

Ring-closure by introduction of the methylene group was effected by formaldehyde in alcohol containing potassium hydroxide, as described previously.[2d,16]

3-(*p*-Chlorophenyl)-6-chloro-1,2,3,4-tetrahydroquinazoline.—This compound was obtained as small needles and in 72.7% yield. After crystallization from slightly diluted alcohol it melted at 155°, obsd., or 158° corr.

Anal. Calcd. for $C_{14}H_{12}N_2Cl_2$: N, 10.00. Found: N, 9.92, 10.03, 9.85.

3-(*p*-Bromophenyl)-6-bromo-1,2,3,4-tetrahydroquinazoline.—The yield of small plates was 92.9%; m. p. 170°, obsd., or 173°, corr. Recrystallization from hot alcohol appeared to deteriorate this compound both in appearance and melting point; better results were obtained when alcohol containing a small amount of potassium hydroxide was used.[17]

Anal. Calcd. for $C_{14}H_{12}N_2Br_2$: N, 7.61. Found: N, 7.67, 7.59.

Conversion of Aminobenzylarylamines (II) to the Corresponding Dihydroquinazolines (III)

Ring closure through =CH— was effected by heating the base with 90% formic acid on the water-bath.[7b] The mixture was made alkaline with sodium hydroxide, and steam-volatile material was removed. The residue was dried, and resins were dissolved by extraction with a little ether in a beaker, assisted by manipulation with a stirring rod with flattened end. The crystalline mass of nearly white dihydroquinazoline was filtered off, washed with a little chilled ether, and recrystallized from slightly diluted alcohol.

3-(*p*-Chlorophenyl)-6-chloro-3,4-dihydroquinazoline was thus obtained from aminochlorobenzyl-*p*-chloroaniline as fine needles; after crystallization from alcohol the base melted at 186–187°, obsd. Mixed with the base of m. p. 187°, obsd., obtained by the *p*-chloroaniline-formaldehyde condensation, the m. p. was 186–187°, obsd.

3-(*p*-Bromophenyl)-6-bromo-3,4-dihydroquinazoline was obtained, after crystallization from alcohol, as a yellow-tinted crystal meal of m. p. 200°, obsd. Mixed with the base of m. p. 202°, obsd., obtained from the condensation of *p*-bromoaniline and formaldehyde the compound melted at 201°, obsd.

Hydrogenation of the Halogenated Dihydroquinazolines

Saturation of the 1,2-double bond, and replacement of halogen by hydrogen, were effected in one operation by drastic reduction with sodium and absolute alcohol, using for 0.5 g. of the dihydroquinazoline about 2.5 g. of sodium and 25 cc. of alcohol. After the sodium had dissolved water was added and the alcohol was taken off under reduced pressure. The precipitated solid was crystallized from dilute alcohol. Both the chlorine and bromine compounds (III) gave the same product: colorless needles of m. p. 121–122°; a mixture of the two had the same melting point. In an experiment with 3-bromophenyl-6-bromodihydroquinazoline the bromine was recovered and weighed as AgBr: 0.50 g. of dihydroquinazoline gave 0.51 g. of silver bromide, corresponding to 43.4% bromine, that calculated being 43.7%. The product, 3-phenyl-3,4-dihydroquinazoline (V), made synthetically by Paal and Busch,[16,18] was reported to melt at 119°.

Anal. Calcd. for $C_{14}H_{14}N_2$: C, 80.00; H, 6.67; N, 13.33; mol. wt., 210. Found: C, 79.82; H, 6.64; N, 13.21, 13.36, 13.33; mol. wt. (camphor), 211, 218.

Debromination of 3-(*p*-Bromophenyl)-6-bromo-1,2,3,4-tetrahydroquinazoline.—Treatment with sodium and alcohol as outlined above gave from 0.50 g. of this compound

[17] The relative instability of the structural condition >N—CH_2—N< in acid media is familiar. A striking example is afforded by the conversion of bis-(*p*-anisyl)-methane to the trimeric Schiff base on crystallization from alcohol.[12]

[18] Paal and Busch, *Ber.*, **22**, 2693 (1889).

0.20 g. of fine needles of m. p. 118°, obsd. A mixture of the product with that obtained by similar treatment of the dihydroquinazoline (m. p. 121°) melted well at 120°. The bromine split out was weighed as silver bromide: 0.50 g., corresponding to 42.6% bromine, that calculated being 43.5%.

Grateful acknowledgment is made to the Faculty Research Committee of the University of Pennsylvania for a grant to aid this study, and to the following for most of the analytical results reported: W. S. Young (molecular weights), F. W. Landau (nitrogen), and Wm. McClellan (carbon and hydrogen).

Summary

Condensation of *p*-chloroaniline and of *p*-bromoaniline with formaldehyde in cold aqueous solution containing hydrochloric acid yielded as main products the corresponding 3-(halogenophenyl)-6-halogeno-3,4-dihydroquinazolines, of m. p. 192° (corr.) and m. p. 206° (corr.), respectively. The identities of these bases were experimentally established. Formation of these products was accompanied by that of unidentified bases and by methylation of part of the original amines.

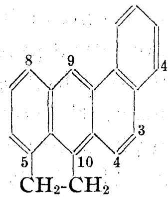
4,10-Ace-1,2-benzanthracene

By Louis F. Fieser and Arnold M. Seligman

The powerfully carcinogenic hydrocarbon cholanthrene[1,2] is the 5,10-ace- (or dimethylene-) derivative (I) of 1,2-benzanthracene and it is one of four possible ace- derivatives of this hydrocarbon. Two of the remaining isomers already have been synthesized and submitted to biological tests. The 8,9-ace- compound (8,9-dimethylene-1,2-benzanthracene[2]) has carcinogenic properties, but it produces tumors less than half as rapidly as cholanthrene.[3] The 3,4′-isomer (acenaphthanthracene[4]), in which both meso positions are unsubstituted, has given only negative results.[5] The synthesis of the fourth isomer, 4,10-ace-1,2-benzanthracene (VIII, below), is described in the present paper. The hydrocarbon is of particular interest because of the indications that substitution at the 10-position in the 1,2-benzanthracene molecule often is particularly favorable for the development of cancer-producing properties,[6] but tests with the new hydrocarbon which are being conducted by Dr. M. J. Shear are not yet complete. The compound produces severe ulceration in mice as rapidly as cholanthrene, but thus far no tumors have been obtained. It is interesting that the three isomeric ace-1,2-benzanthracenes in which the five-membered ring is joined to a meso position of the aromatic system all show some biological activity, while the 3,4′-isomer is completely inactive.



I

The initial step in the synthesis consisted in the condensation of hydrindene with succinic anhydride. As in other Friedel and Crafts reactions, substitution occurred exclusively in the β-position, giving β-(5-hydrindoyl)-propionic acid (II). Reduction to III, cyclization, and reduction to V all proceeded smoothly, and the structure of the tricyclic compounds was established by oxidation of the ketone IV to pyromellitic acid. The structure of the keto acid II follows from that of the ketone. The condensation of 6,7-cyclopentenotetralin (V) with benzoyl chloride gave a liquid product for which only the structure VI is possible, and dehydrogenation of the ketone with selenium gave a liquid of approximately the composition of 1-benzoyl-2,3-cyclopentenonaphthalene, VII. The final step in the synthesis consists in a modified Elbs condensation of the type employed for the preparation of methyl-

cholanthrene,[7] but since the ring closure in this case involves substitution in a phenyl, rather than a naphthyl, nucleus, it is not surprising that the hydrocarbon VIII, isolated as the picrate from the oily product of pyrolysis, was obtained in only 10% yield. No difficulty was experienced, however, in obtaining the 4,10-ace-1,2-benzanthracene in a pure condition. Confirmatory evidence of the structure was found in the oxidation of the hydrocarbon to an anthraquinone acetic acid corresponding in properties and analysis to formula IX.

The pyrolysis of the hydrogenated ketone VI also was investigated in order to determine if there is any preference for the participating of the five-membered or six-membered ring in the cyclization. One reaction product was obtained easily in a crystalline and highly pure condition on treating the oily distillate with ether, and a second compound was isolated from the mother liquor through the picrate. The latter compound is a hydrocarbon of the expected composition ($C_{20}H_{18}$), and, as it yielded 4,10-ace-1,2-benzanthracene (VIII) on dehydrogenation, it evidently is the normal product of a cyclization utilizing the cyclopenteno ring, and it can be assigned the formula X. The hydrocarbon which crystallizes from ether has two atoms of hydrogen less than X, or than the hypothetical pyrolysis product XI, and it is resistant to dehydrogenation with selenium. On oxidation, the compound was found to yield the known phenanthrene-8,9-dicarboxylic anhydride, XIII.[8] The hydrocarbon therefore is an 8,9-substituted phenanthrene derivative, and the most probable structure is that of formula XII. The exact location of the alicyclic double bond has not been established. The hydrocarbon evidently is formed as the result of an intramolecular cyclization involving a methylene group of the cyclohexeno ring of the ketone VI, but the anthracene derivative XI, which would result as the primary product of this condensation, does not appear to be stable at the temperature of the reaction. A stabilization possibly is achieved by the migration of one double bond into the angular six-membered ring, followed by the aromatization of this ring through a process of disproportionation, one of the double bonds in the originally aromatic ring remaining at the position between two bridge heads.

That the cyclodehydration proceeds in both possible directions is in keeping with a similar observation[9] concerning a ketone having available for the condensation both an adjacent cyclo-

penteno ring and an *o*-methyl group. The present results find a correlation also with observations concerning the pyrolysis of tetralyl naphthyl ketones,[10] for in two cases phenanthrene derivatives were obtained in place of the expected anthracenoid isomers, and in one instance a dehydro compound was isolated. The controlling factor doubtless is that the angular arrangement of three aromatic rings presents a more stable structure than the linear arrangement, and it is interesting that a readjustment of double bonds and hydrogen atoms occurs without the use of catalysts at the temperature of the pyrolysis.

We are indebted to Mr. Philip A. Shaffer, Jr., for able assistance in the preparative work.

Experimental Part[11]

β-(5-Hydrindoyl)-propionic Acid (II).—The hydrindene employed, b. p. 79.0° (29 mm.), was prepared and carefully fractionated in conjunction with Dr. T. L. Gresham. To a solution of 118 g. of the pure hydrocarbon and 110 g. of succinic anhydride in 500 cc. of tetrachloroethane and 200 cc. of nitrobenzene, cooled to 0°, 270 g. of aluminum chloride was added in portions. The mixture was cooled in an ice-bath for several hours, allowed to stand at room temperature for two days, and then poured onto ice and hydrochloric acid. After removing the solvents with steam, the product was taken into soda solution, and precipitated after clarification with Norite. The crude acid, m. p. 118–120°, uncorr., was satisfactory for use in the next step; yield, 211 g. (97%). After several crystallizations from dilute alcohol and from benzene, the substance was obtained as small needles, m. p. 125–125.5°.

Anal. Calcd. for $C_{13}H_{14}O_3$: C, 71.52; H, 6.47. Found: C, 71.70; H, 6.55.

γ-(5-Hydrindyl)-butyric Acid (III).—Following the general procedure of Martin,[12] a mixture of 211 g. of the acid II, 750 g. of amalgamated mossy zinc, 600 cc. of concentrated hydrochloric acid, 300 cc. of water, and 600 cc. of toluene was refluxed for fifty hours, with the addition of 500 cc. of concentrated acid at intervals. The toluene layer was washed, clarified and distilled, the product being collected as a colorless distillate, b. p. 202° (5 mm.), m. p. 55°; yield, 145 g. (73%). The acid crystallizes from alcohol as colorless needles melting at 54.9–55.2°.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.43; H, 7.90. Found: C, 76.50; H, 8.13.

6,7-Cylopenteno-1-tetralone (IV).—The acid III (145 g.) was refluxed with 200 cc. of thionyl chloride for several hours, and the acid chloride was obtained as a colorless liquid, b. p. 170° (10 mm.); yield, 143 g. (90%). A solution of this material in 250 cc. of carbon bisulfide was added during one hour to a stirred suspension of 130 g. of aluminum chloride in 2 liters of carbon bisulfide at 0°. After being stirred at 0° for one and one-half hours, the mixture was allowed to stand at room temperature for several hours and then decomposed with ice and acid. After removing the solvent with steam, the residual oil was extracted with ether, dried, and distilled. The ketone was obtained as a colorless liquid, b. p. 151–152° (2 mm.); yield, 110.5 g. (92%, based on the acid chloride used). The sample darkened on long standing.

Anal. Calcd. for $C_{13}H_{14}O$: C, 83.83; H, 7.58. Found: C, 83.27, 83.74; H, 7.47, 8.25.

In order to establish the structure, 5 g. of the ketone was heated with 1.5 cc. of concentrated nitric acid and 2.5 cc. of water at 190° for fourteen hours; 1.5 cc. of concentrated acid was added and the heating continued for twelve hours. On concentrating the solution, adding fuming nitric acid, and cooling, 0.7 g. of pyromellitic acid separated. The material was converted into the anhydride at 250°, and this was sublimed and crystallized from dioxane as in a previous experiment.[13] The anhydride melted at 282–283° and did not depress the melting point of an authentic sample.

[13] Fieser and Hershberg, *ibid.*, **57**, 2196 (1935).

6,7-Cyclopentenotetralin (V).—To a refluxing mixture of 350 cc. of water, 750 cc. of concentrated hydrochloric acid, 200 cc. of alcohol, and 1100 g. of granulated zinc (amalgamated by contact with a solution of 56 g. of mercuric chloride for five minutes), a solution of 109 g. of the tetralone IV in 300 cc. of alcohol was added over a period of three hours. After refluxing for an additional twelve-hour period, during which time 400 cc. of concentrated acid was added in portions, the mixture was cooled and diluted with an equal volume of water. The liquor was extracted twice with ether, and the bulk of the product was obtained by extraction of the zinc residue with ether. The collected hydrocarbon was steam distilled from a mixture with aqueous alkali, dried, and distilled; b. p. 104–106° (3 mm.); yield, 90 g. (89%). The hydrocarbon is a colorless, mobile liquid which does not alter on storage.

Anal. Calcd. for $C_{13}H_{16}$: C, 90.66; H, 9.37. Found: C, 91.12; H, 9.23.

5-Benzoyl-6,7-cyclopentenotetralin (VI).—A solution of 90 g. of V in 100 cc. of tetrachloroethane was added in the course of one-half hour to a stirred mixture of 80 g. of benzoyl chloride, 90 g. of aluminum chloride, 400 cc. of tetrachloroethane, and 100 cc. of nitrobenzene at 0°. After standing overnight, the mixture was decomposed with 1.5 kg. of ice and 150 cc. of concentrated hydrochloric acid, the solvent was removed with steam, and the residual oil was washed in ethereal solution with water and alkali, dried, and distilled. The ketone was obtained as a very viscous, pale yellow oil, b. p. 183–185° (0.5 mm.) or 215–217° (3.5 mm.); yield, 130 g. (90%).

Anal. Calcd. for $C_{20}H_{20}O$: C, 86.90; H, 7.30. Found: C, 87.04, 86.30; H, 7.76, 7.49.

1-Benzoyl-2,3-cyclopentenonaphthalene (VII).—The above ketone (20 g.) was heated with an equal weight of selenium in an atmosphere of nitrogen at 290° (bath) for twenty-four hours, adding 20 g. of fresh selenium in portions at eight-hour intervals. The material was extracted with benzene and the dark solution was filtered, shaken with a few drops of mercury, allowed to stand overnight, treated with Norite, filtered, and distilled. The product was a yellow, viscous oil, b. p. 215–220° (1.5 mm.); yield, 13.5 g. (69%). The analyses indicate that the material probably contained a small amount of the more highly hydrogenated ketone.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.92. Found: C, 88.32, 88.26; H, 6.89, 7.12.

Dehydrogenation of VI with sulfur was investigated without success.

4,10-Ace-1,2-benzanthracene (VIII).—The above oil (13.5 g.) was heated in a bath at 405° for forty-five minutes, and on distillation at 2 mm. pressure there was obtained a viscous yellow oil which failed to solidify or to yield crystals from ether. A hydrocarbon picrate was obtained without difficulty from benzene–ether solution; 5.5 g. of crystalline picrate was collected, and on purification the substance formed clusters of brown-black needles melting at 148–149°. The hydrocarbon recovered from the purified picrate crystallized from ether in the form of stout yellow needles melting at 138.5–140°; yield, 1.3 g. (10%). Further purification by passage through an adsorption tower of alumina and crystallization gave faintly yellow needles of the same melting point. The hydrocarbon gives a deep red solution in concentrated sulfuric acid, and on heating the color changes to violet and then to greenish-black.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.45; H, 5.55. Found: C, 94.17; H, 5.88. *Anal.* (picrate). Calcd. for $C_{20}H_{14}\cdot C_6H_3O_7N_3$: N, 8.69. Found: N, 8.80.

1,2-Benzanthraquinone-4-acetic Acid (IX).—A solution of 0.35 g. of the hydrocarbon VIII in 20 cc. of hot glacial acetic acid was cooled rapidly to give a fine suspension of the material, and on adding 1.8 g. of sodium dichromate and shaking at room temperature the hydrocarbon soon dissolved. The solution was refluxed for twenty minutes and on dilution with water a yellow oxidation product was precipitated. This was dissolved in hot, dilute soda solution and, after clarification and after redissolving some sodium salt which crystallized, reprecipitated. The quinone crystallized from xylene–benzene as small, yellow needles (0.2 g.) melting at 228–229.5° and giving an orange-red vat with alkaline hydrosulfite solution.

Anal. Calcd. for $C_{20}H_{12}O_4$: C, 75.92; H, 3.83. Found: C, 75.81; H. 3.80.

Pyrolysis of 5-Benzoyl-6,7-cyclopentenotetralin.—After heating 13.5 g. of the ketone for one hour at 410°, the residue was distilled in vacuum and the viscous oil obtained was warmed with ether. Before the bulk of the material had dissolved, a crystalline product began to separate, and this substance (A, see below) was easily obtained in a nearly pure condition, m. p. 140–141°, uncorr.; yield, 2.1–2.5 g. (17–21%). After removing this hydrocarbon as completely as possible, the oil recovered from the mother liquor was treated with picric acid in benzene–ether solution, and on standing there was obtained 2.5 g. of a crystalline picrate melting at about 110°. Further crystallization from benzene gave 1 g. (4%) of pure tetrahydro-4,10-ace-1,2-benzanthracene picrate, which formed small, dark red plates melting at 131–132°. The corresponding hydrocarbon is described below.

In one experiment 13.5 g. of ketone was heated as above except for the addition of 1.3 g. of zinc dust. There was little change in the yields, 1.8 g. of hydrocarbon and 3 g. of crude picrate being obtained.

Hydrocarbon A, Probably Δ^3-Dehydro-3,4-trimethylene-isobenzanthrene-2 (XII).—The pyrolysis product separating easily from ether was purified by further crystallization from this solvent and by chromatographic adsorption. It forms faintly yellow-green, fluorescent prisms melting at 144.5–145°. Its solution in sulfuric acid is red, changing to a darker red on heating without showing signs of decomposition. The picrate crystallizes from benzene–ether in the form of crimson needles melting at 136–137°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.68, 93.89; H, 6.34, 6.49. *Anal.* (picrate). Calcd. for $C_{20}H_{16}\cdot C_6H_3O_7N_3$: N, 8.95. Found: N, 9.12.

On attempting to dehydrogenate the hydrocarbon (0.6 g.) with selenium (2 g.) at 295° for twenty-four hours, considerable material was destroyed and the only product isolated was unchanged starting material (0.1 g.).

Oxidation was effected by refluxing a solution of 2 g. of the hydrocarbon and 16 g. of sodium dichromate in 50 cc.

of glacial acetic acid for one-half hour. Yellow needles of the reaction product began to separate from the boiling solution, and the precipitation was completed by the addition of water. The crude oxidation product was dissolved in dilute sodium hydroxide solution at the boiling point and the yellow solution was filtered from a dark sludge of suspended material. When refiltered through a pad of charcoal, the solution was nearly colorless, and on adding acid and boiling, the product separated as a pale yellow precipitate in a nearly pure condition; yield 0.5 g. The substance is insoluble in cold alkali. On crystallization from dioxane, in which it is readily soluble, the substance formed fan-shaped clusters of pale yellow needles, m. p. 280.5–281.5°.

Anal. Calcd. for $C_{16}H_8O_3$: C, 77.41; H, 3.25. Found: C, 77.71; H, 3.39.

The analysis and properties are those of phenanthrene-8,9-dicarboxylic anhydride, for which Pschorr[8] reports the corrected melting point 283–284°. No depression was observed in the melting point on admixture with a slightly less pure sample of the anhydride previously prepared in this Laboratory.[14]

1',2',3',4'-Tetrahydro-4,10-ace-1,2-benzanthracene (X).—This hydrocarbon was recovered from the purified picrate, m. p. 131–132°, described above, by distribution between ammonia water and ether. The compound crystallizes well when an ethereal solution is diluted with methanol and concentrated to the point of saturation. The sample for analysis was distilled in vacuum and recrystallized, forming silky, colorless needles melting at 106–107°. The solutions are beautifully fluorescent.

Anal. Calcd. for $C_{20}H_{18}$: C, 92.98; H, 7.02. Found: C, 92.69; H, 7.24. *Anal.* (picrate). Calcd. for $C_{20}H_{18} \cdot C_6H_3O_7N_3$: N, 8.62. Found: N, 8.78.

Dehydrogenation of the hydrocarbon with a large excess of selenium was conducted at 300–320° for twenty hours. The product was extracted with benzene, the solution was passed through a tower of alumina, and the recovered material on crystallization from methanol gave pale yellow needles melting at 135–137° and showing no depression when mixed with 4,10-ace-1,2-benzanthracene.

Summary

The synthesis of 4,10-ace-1,2-benzanthracene, an isomer of the carcinogenically active cholanthrene, has been accomplished by the use of the modified Elbs reaction. This pyrolytic reaction, applied in another case where both a five-membered and a six-membered ring are available for condensation, was found to proceed in both possible directions. Further evidence was found of the tendency of 1,9-trimethylene derivatives of anthracene to undergo transformation to phenanthrene derivatives in the course of the pyrolysis.

The Tautomerism of Certain Derivatives of Acetomesitylene

BY E. P. KOHLER AND R. B. THOMPSON

In a recent study of the structure of the magnesium derivatives of mono ketones[1] it was found that the derivative of benzhydryl acetomesitylene is an enolate and that the corresponding enol is sufficiently persistent in solution to be detectable as peroxide. This observation is important because at present the only reliable evidence that a substance obtained by adding a metallic derivative to an unsaturated ketone or ester is an enolate, is its conversion into an enol by a process which does not enolize the corresponding ketone or ester.

It was found, also, that in a series of related mono ketones the mode of acylation of the magnesium derivatives appeared to be associated with the relative persistence of the enolic modifications. At the time this observation was made it was not possible to study the behavior of these enolates in reactions involving alkylation because they failed to react with any of the alkylating agents that were available. Having found, in the meanwhile, that magnesium derivatives of this type react very readily with chloromethyl ether we have now compared the mode of alkylation of the enolates which differed most in the mode of acylation, namely, the magnesium derivatives of benzhydryl acetophenone and benzhydryl acetomesitylene. We have also compared the tautomerism of a number of other ketonic derivatives of mesitylene with that of the corresponding derivatives of benzene. The results are embodied in the present paper.

When the magnesium derivative of benzhydryl acetophenone reacts with chloromethyl ether the result is a mixture composed of 30% of the

---

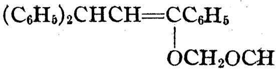
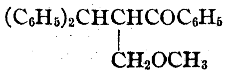
O-alkylation product I and 70% of the C-alkyl derivative II.



$(C_6H_5)_2CHCH{=}\underset{OCH_2OCH_3}{C}C_6H_5$

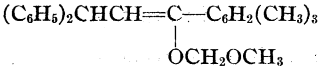
I



$(C_6H_5)_2CH\underset{CH_2OCH_3}{C}HCOC_6H_5$

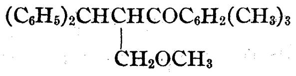
II

The magnesium derivative of benzhydryl acetomesitylene likewise yields both O- and C-alkyl derivatives but the relative amounts are almost completely reversed, at least 75% of the product being the O-alkyl derivative, III. In these two



$(C_6H_5)_2CHCH{=}\underset{OCH_2OCH_3}{C}{-}C_6H_2(CH_3)_3$

III

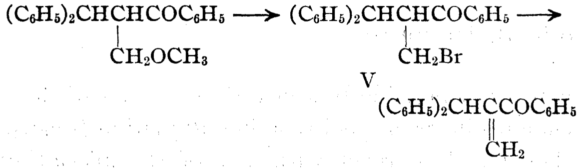


$(C_6H_5)_2CH\underset{CH_2OCH_3}{C}HCOC_6H_2(CH_3)_3$

IV

cases, therefore, alkylation and acylation follow the same course, both being associated in some manner with the persistence of the enolic form.

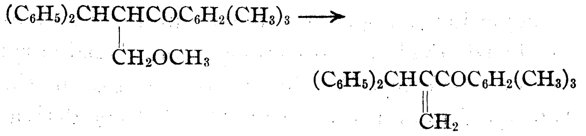
The O-alkylation products I and III are of little interest because their behavior is similar to that of all other acetals. The more interesting C-alkyl derivatives differ considerably in their chemical properties. Thus the benzene derivative II is insensitive both to bases and to dilute acids. In order to convert it into an unsaturated ketone it is necessary to replace the methoxyl group with bromine by prolonged heating with concentrated hydrobromic acid and then to eliminate hydrogen bromide from the bromo compound



$(C_6H_5)_2CH\underset{CH_2OCH_3}{C}HCOC_6H_5 \longrightarrow (C_6H_5)_2CH\underset{CH_2Br}{C}HCOC_6H_5 \longrightarrow (C_6H_5)_2CH\underset{CH_2}{\overset{}{C}}COC_6H_5$

V VI

In contrast both methyl alcoholic potassium hydroxide and acids convert the mesitylene derivative IV directly into the corresponding unsaturated ketone

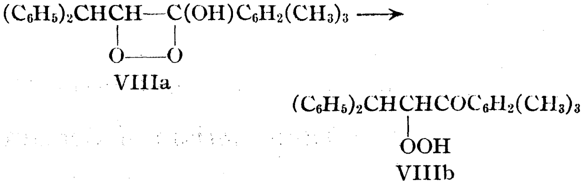


$(C_6H_5)_2CH\underset{CH_2OCH_3}{C}HCOC_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_2CH\underset{CH_2}{C}COC_6H_2(CH_3)_3$

VII

The properties of these C-alkylation products, like the behavior of the magnesium enolates toward acylating and alkylating agents, show that in ketones containing the group $—CHCOC_6H_2(CH_3)_3$ the mesitylene residue increases the activity of the α-hydrogen atoms, promotes enolization and enhances the stability of the enolic form. Although this form of benzhydryl acetomesitylene could not be isolated, we secured ample evidence of its presence and persistence in solutions obtained by acidifying its magnesium derivative. These solutions do not give a color reaction with ferric chloride—doubtless because the enol lacks the oxygen necessary for chelation[2]—but they decolorize bromine instantaneously and a titration by the Kurt Meyer method showed that they still contained about 90% of enol after several hours in a freezing mixture. They also absorb oxygen avidly, but when they are concentrated to the point of crystallization they deposit only the ketonic form which neither decolorizes bromine nor combines with oxygen.

As a result of autoxidation the enol is converted into a crystalline peroxide which differs, structurally, from all other substances of this type in that it has hydrogen in place of the usual hydrocarbon residue in the α position. In view of this peculiarity it is necessary to consider the possibility that the cyclic peroxide which would be expected may immediately undergo rearrangement to an open chained isomer



$(C_6H_5)_2CH\underset{O}{C}H{-}\underset{O}{C}(OH)C_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_2CH\underset{OOH}{C}HCOC_6H_2(CH_3)_3$

VIIIa VIIIb

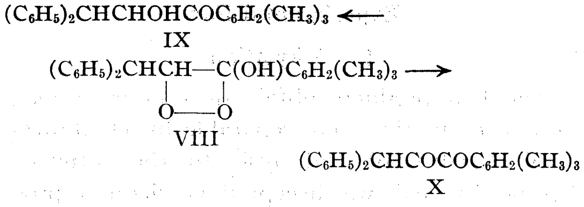
In thermal stability and chemical activity the peroxide does not differ materially from known peroxides which are undoubtedly cyclic in structure. When it is heated it decomposes, with a flash, into mesitylene carbonic acid and diphenyl acetaldehyde. It readily loses one atom of oxygen to hydrogen iodide and to platinum and hydrogen, being reduced to a hydroxy ketone instead of to the usual oxanol. Like the peroxides of known structure, also, it is attacked by aqueous alkalies, but instead of being cleaved it is dehydrated to an α-diketone. All of these properties and products can be reconciled with either of the two formulas, but the peroxide is neutral while all known derivatives of hydrogen peroxide, including the naphthalene derivative discovered by Hock and Susemihl,[3] are distinctly acidic. It seems probable, therefore, that the substance is

---

(2) Hantzsch, *Ann.*, **392**, 292 (1912).

(3) Hock and Susemihl, *Ber.*, **66**, 61 (1933).

a cyclic peroxide, that the divergent reduction product is due to the instability of the oxanol[4] and that aqueous alkali rearranges the cyclic to the open chained form which is then dehydrated to the diketone



$$(C_6H_5)_2CHCHOHCOC_6H_2(CH_3)_3 \longleftarrow$$

IX

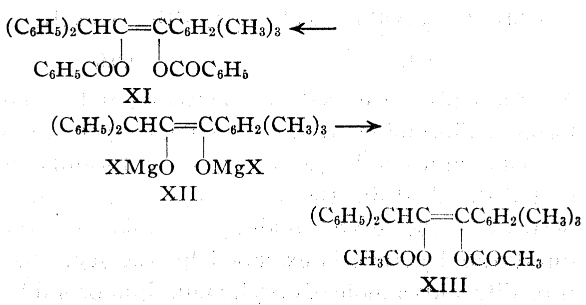
$$(C_6H_5)_2CH\underset{\underset{\textstyle O}{|}}{C}H-\underset{\underset{\textstyle O}{|}}{C}(OH)C_6H_2(CH_3)_3 \longrightarrow$$

VIII

$$(C_6H_5)_2CHCOCOC_6H_2(CH_3)_3$$

X

Although not perceptibly enolized in solution, the hydroxy ketone IX, like all other substances containing the group $CHCOC_6H_2(CH_3)_3$, is converted into an enolate by Grignard reagents. It liberates two moles of gas from methyl magnesium iodide and when the resulting magnesium compound is acylated the product is a di-ester



$$(C_6H_5)_2CH\underset{\underset{\textstyle C_6H_5COO}{|}}{C}=\underset{\underset{\textstyle OCOC_6H_5}{|}}{C}C_6H_2(CH_3)_3 \longleftarrow$$

XI

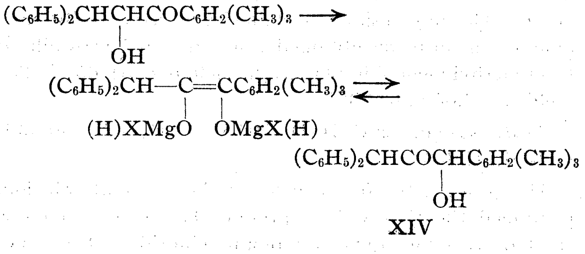
$$(C_6H_5)_2CH\underset{\underset{\textstyle XMgO}{|}}{C}=\underset{\underset{\textstyle OMgX}{|}}{C}C_6H_2(CH_3)_3 \longrightarrow$$

XII

$$(C_6H_5)_2CH\underset{\underset{\textstyle CH_3COO}{|}}{C}=\underset{\underset{\textstyle OCOCH_3}{|}}{C}C_6H_2(CH_3)_3$$

XIII

Evidently the magnesium derivative is a di-enolate which undergoes only O-acylation. The corresponding di-enol could not be isolated. Like the enol of benzhydryl acetomesitylene it is remarkably persistent in solution but when these solutions are concentrated they deposit only the isomeric hydroxy ketone



$$(C_6H_5)_2CH\underset{\underset{\textstyle OH}{|}}{C}HCOC_6H_2(CH_3)_3 \longrightarrow$$

$$(C_6H_5)_2CH-\underset{\underset{\textstyle (H)XMgO}{|}}{C}=\underset{\underset{\textstyle OMgX(H)}{|}}{C}C_6H_2(CH_3)_3 \rightleftarrows$$

$$(C_6H_5)_2CHCO\underset{\underset{\textstyle OH}{|}}{C}HC_6H_2(CH_3)_3$$

XIV

In this case, therefore, it is possible to follow, step by step, the isomerization of an hydroxy ketone by way of an intermediate di-enol. This same di-enol also serves as an intermediate in the interconversion of the hydroxy ketones and the α-diketone, X. It is an energetic reducing agent which decolorizes indophenol dyes as readily as do the well-known cyclic di-enols ascorbic acid and reductone. In contact with air it is oxidized rapidly to hydrogen peroxide and the α-diketone. The diketone, in turn, when it is reduced catalytically, yields colorless solutions that are indistinguishable from those which are obtained by acidifying the magnesium derivative of the di-enol. Here, clearly the di-enol is formed by 1,4-addition to the diketone.

In solution this diketone slowly enolizes, forming an equilibrium mixture which in alcohol is composed of approximately equal quantities of ketone and enol. As the system

$$(C_6H_5)_2CHCOCOC_6H_2(CH_3)_3 \rightleftarrows$$

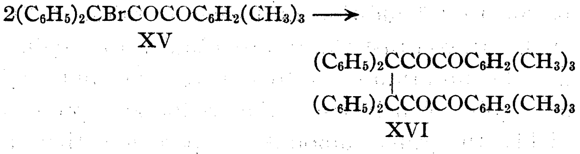
X (a)

$$(C_6H_5)_2C=C(OH)COC_6H_2(CH_3)_3$$

X (b)

is uncommonly sluggish both the ketonic and the enolic forms can be isolated without much difficulty.

The ketonic form is stable in the air, but like other α-diketones it is oxidized by alkaline hydrogen peroxide, the products being diphenyl acetic and mesitylene carbonic acids. It forms exceedingly reactive halogen compounds that lose the halogen when they are shaken with metals, leaving residues which couple to a highly phenylated tetraketone



$$2(C_6H_5)_2CBrCOCOC_6H_2(CH_3)_3 \longrightarrow$$

XV

$$\begin{array}{l}(C_6H_5)_2CCOCOC_6H_2(CH_3)_3\\ \quad\quad\quad\;|\\ (C_6H_5)_2CCOCOC_6H_2(CH_3)_3\end{array}$$

XVI

The enolic form is comparatively stable in the solid state but in solution it is oxidized rapidly by free oxygen, being cleaved thereby to benzophenone and trimethylphenyl glyoxylic acid. It is also oxidized by such mild oxidizing agents as ferric chloride but the result is synthesis instead of cleavage, the product being the same tetraketone that is formed by the removal of bromine from the bromo ketone.

As a consequence of the sluggishness of the keto–enol system the diketone and its enol do not, as might be expected, give the same products when they are treated with Grignard reagents. Both substances liberate approximately one mole of gas from methylmagnesium iodide but while the ketone is reduced to the di-enolate XII, the enol is converted into a magnesium derivative which on acidification yields only β-phenyl benzalacetomesitylene. All attempts to establish the struc-

---

ture of this magnesium derivative were unsuccessful but presumably it is an allenic compound

$$(C_6H_5)_2C{=}C(OH)COC_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_2C{=}C{=}C(OMgX)C_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_2C{=}CHCOC_6H_2(CH_3)_3$$

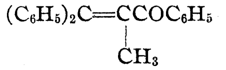
Having found that mesitylene derivatives can be employed for establishing the manner in which hydrogen adds to α-diketones, we undertook to utilize them also for ascertaining the mode of reduction of α,β-unsaturated ketones. To this end we reduced β-phenylbenzal acetomesitylene both catalytically and with zinc and acid. Some years ago Straus[5] inferred, from the nature of the products obtained from a series of unsaturated ketones, that in the catalytic reduction of these compounds 1,2- and 1,4-addition are competing reactions and that the outcome depends upon the same factors that control the mode of addition of Grignard reagents. Our experiments bring a measure of support to this inference. When phenylbenzal acetomesitylene was reduced with hydrogen and palladium on calcium carbonate the product was a mixture of approximately 88% of benzhydryl acetomesitylene and 12% of its enol. It is certain, therefore, that in this case at least 12% of the product is due to 1,4-addition of hydrogen but we were unable to determine whether the saturated ketone is due to 1,2-addition or to ketonization of the enol. In contrast the results obtained by reducing the unsaturated ketone with zinc and acid are quite conclusive; the reduction product yields the same amount of peroxide that is formed from the product obtained by adding phenylmagnesium bromide to benzalacetomesitylene. The reduction of α,β-unsaturated ketones with metal combinations, therefore, involves 1,4-addition to the conjugated system.

From the foregoing account it is evident that in every case in which it has been possible to establish the structure of a magnesium derivative resulting from the addition of a Grignard reagent to the conjugated system of an unsaturated ketone it has proved to be an enolate due to 1,4-addition. As the list now includes open chained and cyclic ketones, ketones with and without substituents in the α-position it is reasonable to assume a similar mode of addition to all systems of this type. It now seems clear, also, that the mode of alkylation and acylation of the enolates of mono ketones is associated in some manner with the stability of the corresponding enol, and it seems probable that the rate at which the enolic radical or ion is ketonized determines the relative amounts of C and O products that are formed.

Experimental Part

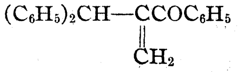
I. Alkylation

The two products obtained from each magnesium derivative were separable by crystallization. Facility of hydrolysis to the saturated ketones by acids was accepted as adequate proof of the O-alkyl derivatives. The formula of the C-alkyl derivative of benzhydryl acetophenone is based on the fact that the unsaturated ketone obtained by the indirect elimination of methyl alcohol is reducible to α-methyl-β,β-diphenyl propiophenone. For this unsaturated ketone, therefore, only two formulas are possible, namely



$(C_6H_5)_2C{=}C(CH_3)COC_6H_5$

and



$(C_6H_5)_2CH{-}C({=}CH_2)COC_6H_5$

As the substance reduces permanganate and forms a dibromide from which it is regenerated by potassium iodide the first of these formulas is excluded. And in the case of the mesitylene derivative the corresponding formula for the unsaturated ketone is excluded by the fact that it readily adds a mole of ethylmagnesium bromide.

Alkylation of Benzhydryl Acetophenone.—To an ethereal solution of phenylmagnesium bromide prepared from 2.5 g. of magnesium was added 10 g. of benzal acetophenone. The mixture was boiled for half an hour, treated with 8.5 g. of chloromethyl ether and boiled for two more hours. After cooling, the clear ethereal layer was decanted from the paste adhering to the walls of the vessel, treated with ammonia and ammonium chloride and distilled with steam. The distillate contained only diphenyl and benzyl methyl ether. The oily residue contained the acetal. By suitable treatment it was obtained as a solid which crystallized from methyl alcohol in plates and melted at 64–65°. The yield was 4.65 g. or 30%.

Anal. Calcd. for $C_{23}H_{22}O_2$: C, 83.6; H, 6.7. Found: C, 83.6; H, 6.8.

The paste, left after decanting the ethereal solution, contained the C-alkylation product II. It was likewise treated with ammonia–ammonium chloride. The ether was thus obtained as a solid which crystallized from methyl alcohol in prisms and melted at 131–132°. The yield was 11 g. or 70%.

Anal. Calcd. for $C_{23}H_{22}O_2$: C, 83.6; H, 6.7. Found: C, 83.3; H, 6.6.

α-Benzhydryl-β-bromo Propiophenone, V.—As the C-alkyl derivative was not affected by either dilute acids or bases it was heated in a sealed tube for ten hours with a large excess of 50% hydrobromic acid. The solid product

---

[5] Straus and Grindel, *Ann.*, **439**, 276 (1924).

crystallized from alcohol in fine needles melting at 163°. The yield was 91%.

Anal. Calcd. for $C_{22}H_{19}OBr$: C, 69.7; H, 5.1. Found: C, 69.9; H, 5.2.

α-Benzhydrylvinyl Phenyl Ketone, VI.—The bromo compound was converted into the unsaturated ketone by dissolving it in boiling alcoholic potassium hydroxide. The ketone crystallized from alcohol in coarse needles melting at 115°.

Anal. Calcd. for $C_{22}H_{18}O$: C, 88.6; H, 6.1. Found: C, 88.9; H, 6.3.

Unlike vinyl phenyl ketone itself this benzhydryl derivative shows no tendency to polymerize or undergo autoxidation. It is, however, readily oxidized by permanganate and in the presence of platinum it is rapidly reduced to α-methyl-β,β-diphenyl propiophenone.

The dibromide of the ketone crystallized from alcohol in prisms melting at 105°. It lost its bromine and regenerated the unsaturated ketone when it was boiled with methyl alcoholic potassium iodide.

Anal. Calcd. for $C_{22}H_{18}OBr_2$: C, 57.6; H, 4.0. Found: C, 57.7; H, 4.1.

α-Methyl-β,β-diphenylvinyl Phenyl Ketone, $(C_6H_5)_2C{=}C(CH_3)COC_6H_5$.—This isomeric unsaturated ketone was obtained in small quantities when the C-alkyl derivative was boiled with concentrated sodium ethylate. It crystallized from alcohol in prisms melting at 114°. Unlike its isomer it does not reduce permanganate.

Anal. Calcd. for $C_{22}H_{18}O$: C, 88.6; H, 6.1. Found: C, 88.5; H, 6.1.

Alkylation of Benzhydryl Acetomesitylene.—A solution of the magnesium derivative was prepared by adding 5 g. of the ketone to ethyl magnesium bromide formed from 0.6 g. of magnesium in 100 cc. of ether and 50 cc. of benzene, and boiling for half an hour. To this solution was added 2 g. of chloromethyl ether. The mixture was boiled for two hours, then decomposed with ammonia and ammonium chloride. The ethereal layer, on evaporation, deposited a mixture which was separated by extraction with low-boiling petroleum ether. The extract deposited the acetal III. It crystallized from methyl alcohol in needles melting at 92°. The yield was 77–80%.

Anal. Calcd. for $C_{26}H_{28}O_2$: C, 83.0; H, 7.6. Found: C, 82.8; H, 7.4.

The residue left after extraction with petroleum ether was recrystallized from methyl alcohol. It separated in prisms melting at 155°. The yield of the ether IV was 18–20%.

Anal. Calcd. for $C_{26}H_{28}O_2$: C, 83.0; H, 7.6. Found: C, 83.2; H, 7.7.

α-Benzhydrylvinyl Mesityl Ketone, VII.—The ether was heated to 100° with 50% hydrobromic acid and boiled for one and one-half hours with methyl alcoholic potassium hydroxide. In both cases the product was the unsaturated ketone. The ketone crystallizes from methyl alcohol in prisms melting at 109–110°. The yield was 90%. Like the corresponding benzene derivative it combines with bromine and reduces permanganate.

Anal. Calcd. for $C_{25}H_{24}O$: C, 88.2; H, 7.1. Found: C, 87.9; H, 7.4.

II. Acylation

The magnesium enolate of benzhydryl acetomesitylene was obtained either by adding phenylmagnesium bromide to benzalacetomesitylene or by boiling the ethereal solutions of the saturated ketone itself with a slight excess of ethylmagnesium bromide. For the purpose of getting solutions of the enol the enolate was decomposed with iced acid in the presence of ether, the ether solution washed with ice-water and rapidly dried with sodium sulfate. A titration with bromine showed that a solution prepared in this manner contained 90–95% of enol.

The Peroxide, VIII.—For the purpose of preparing the peroxide the ethereal solution obtained by acidifying the enolate was diluted with three or four times its volume of petroleum ether and then washed with ice-water. A rapid current of oxygen was passed through the moist solution for several hours to complete the precipitation of peroxide which began in about an hour. The peroxide was purified by solution in ether and reprecipitation with petroleum ether. It crystallized in small needles melting, with decomposition, at 116–117°. The yield was 90%.

Reduction. α-Hydroxy-β,β-diphenylpropionyl Mesitylene, IX.—The peroxide was reduced both with hydrogen in the presence of platinum and by shaking it for several hours at the ordinary temperature with potassium iodide and glacial acetic acid. In both cases the product was the hydroxy ketone. The second method was found to be the more convenient. By recrystallization from hexane the hydroxy ketone was obtained in prisms melting at 76°. The yield was about 77%.

Anal. Calcd. for $C_{24}H_{24}O_2$: C, 83.7; H, 7.0. Found: C, 83.6; H, 7.1.

The acetate of the hydroxy ketone, prepared by acetylation with acetyl chloride, is convenient for identification because it is less soluble than the hydroxyl compound and crystallizes well from alcohol in prisms melting at 89°.

Anal. Calcd. for $C_{26}H_{26}O_3$: C, 80.8; H, 6.8. Found: C, 80.7; H, 7.0.

The benzoate, formed when the hydroxy ketone is treated with benzoyl chloride in pyridine, crystallizes from alcohol in prisms melting at 114–115°.

Anal. Calcd. for $C_{31}H_{28}O_3$: C, 83.0; H, 6.3. Found: C, 82.7; H, 6.5.

Isomerization, IX–XIV.—As the di-enol that is formed by adding excess of a Grignard reagent to the hydroxy ketone and acidifying the product, undergoes autoxidation much more rapidly than ketonization, the ordinary methods of manipulating organic magnesium derivatives yield only oxidation products. In order to secure a hydroxy ketone it was necessary, therefore, either to promote ketonization by addition of a base like piperidine or to prevent oxidation by addition of a reducing agent. The best results were obtained by the following procedure. An ethereal solution of 4 g. of the hydroxy ketone was added to a solution of ethylmagnesium bromide containing slightly more than two moles of reagent. The mixture was boiled for an hour then treated with excess of zinc dust and acidified by cautious addition of cold dilute acetic acid. The acidified solution was left to itself for a week in a securely corked flask before the product was isolated in the usual manner. The result was the isomeric hydroxy ketone. It crystallized from alcohol in prisms and melted at 77–78°. The yield was 90%.

Anal. Calcd. for $C_{24}H_{24}O_2$: C, 83.7; H, 7.0. Found: C, 83.6; H, 6.9.

The Dibenzoate, XI.—The hydroxy ketone was converted into a magnesium derivative as described in the preceding experiment, slightly more than two equivalents of benzoyl chloride was added to the resulting solution and the mixture was boiled for four hours. The result was a solid which crystallized from alcohol in prisms and melted at 157°. The yield was 80–85%.

Anal. Calcd. for $C_{38}H_{32}O_4$: C, 82.6; H, 5.8. Found: C, 82.4; H, 6.0.

The Diacetate.—As the compositions of the mono- and di-benzoates are too similar for differentiation by analysis, the diacetate was prepared in the same manner. It was obtained in two forms, the one melting at 127–128° and the other at 149°. Both forms crystallize well from alcohol.

Anal. Calcd. for $C_{28}H_{28}O_4$: C, 78.5; H, 6.6. Found: (128°) C, 78.4; H, 6.4. (149°) C, 78.7; H, 6.7.

Benzhydryl Trimethylphenyl Diketone, X.—When the solution, obtained by converting either of the isomeric α-hydroxy ketones into the magnesium derivative in the manner described in the preceding experiments and acidifying, is handled in the usual manner it absorbs oxygen from the air and the principal product is the α-diketone. In addition to the diketone there is formed a small quantity (3–4%) of a high-melting hydrocarbon (212°) which presumably is an indene derivative.

The diketone is obtained more readily, however, by oxidization of the α-hydroxy ketone. For this purpose a warm solution of the crude hydroxy ketone in glacial acetic acid is treated with a solution of slightly more than the calculated quantity of chromic acid in 95% acetic acid. The mixture is kept at 50° for half an hour, then poured into water. The diketone is extracted with ether and crystallized from alcohol. It separates in yellow cubes melting at 74–75°.

Anal. Calcd. for $C_{24}H_{22}O_2$: C, 84.2; H, 6.4. Found: C, 84.2; H, 6.7.

In the solid state the diketone appears to be completely stable. In solution it enolizes in part but in the absence of bases the process is exceedingly slow; the enolic form absorbs oxygen rapidly but no measurable quantity of oxygen was absorbed when an alcoholic solution of the diketone was shaken with oxygen for three and one-half hours. In the presence of a trace of piperidine or sodium methylate, however, it enolizes more rapidly and in the course of fifteen minutes forms an equilibrium mixture composed of nearly equal quantities of enol and ketone.[6]

Reduction of the Diketone.—When a yellow solution of the diketone in methyl alcohol was shaken with hydrogen and platinum it rapidly absorbed hydrogen and became colorless. A drop of piperidine was added to promote the ketonization and the solution was then set aside for thirty-six hours, before it was filtered and concentrated. The product was the higher-melting hydroxy ketone and the yield was 95%. The reduction was repeated, but the colorless solution was filtered immediately and the filtrate was allowed to evaporate in contact with air. It turned yellow and deposited the α-diketone in a yield of 95%. The solution which had been oxidized in the air also contained a considerable quantity of hydrogen peroxide. As the hydroxy ketone is insensitive to oxygen, the formation of the diketone is proof that the reduction product is the di-enol.

Reaction with Ethylmagnesium Bromide.—An ethereal solution of 3 g. of the diketone was added to a solution of ethylmagnesium bromide containing slightly more than two equivalents of the reagent. A small quantity of benzene was added to prevent precipitation of magnesium compounds, the mixture was boiled and then treated with acetyl chloride in slight excess. The product was the higher-melting diacetate of the di-enol—proving that organic magnesium compounds reduce the diketone to the magnesium derivative of the di-enol.

The Enolic Form of the Diketone, Xb.—The diketone was converted into the enol by dissolving it in a slight excess of 2% methyl alcoholic potassium hydroxide and pouring the red solution of the resulting enolate into excess of 2 *N* hydrochloric acid. It usually separated as an oil that soon solidified. The solid was washed with water and crystallized from methyl alcohol or low-boiling petroleum ether. It separated in pale yellow prisms melting at 117°. The yield was quantitative.

Anal. Calcd. for $C_{24}H_{22}O_2$: C, 84.2; H, 6.4. Found: C, 83.8; H, 6.6.

The Phenyl Urethan.—The enol can be identified by converting it into the phenyl urethan which is perfectly stable. It crystallizes well from ether and petroleum ether in pale yellow needles melting at 148°.

Anal. Calcd. for $C_{31}H_{27}O_3N$: C, 80.6; H, 5.9; N, 3.0. Found: C, 80.4; H, 6.2; N, 3.3.

Autoxidation.—In the absence of air the pure solid enol is fairly stable but all samples ultimately liquefy. Its solutions slowly absorb oxygen, the enol being oxidized to benzophenone, mesityl glyoxalic acid and mesitylene carbonic acid. When it is acylated it forms only O-acyl derivatives, the structure of the acylation products being definitely established by the fact that when they were reduced with zinc and acetic acid they formed the corresponding acyl derivatives of α-hydroxy benzhydryl acetomesitylene.

The acetate, formed by heating the enol with acetyl chloride on a steam-bath for ten hours, crystallized from petroleum ether in pale yellow prisms melting at 86–87°.

Anal. Calcd. for $C_{26}H_{24}O_3$: C, 81.2; H, 6.3. Found: C, 81.3; H, 6.4.

The benzoate, formed by benzoylation in pyridine, crystallizes from alcohol in pale yellow prisms melting at 124°. The yield was 90%.

Anal. Calcd. for $C_{31}H_{26}O_3$: C, 83.4; H, 5.9. Found: C, 83.3; H, 5.9.

Halogenation.—The halides that are formed by the addition of chlorine or bromine to the enol immediately lose halogen acid and form the halogen substitution products of the α-diketone. As the action of free chlorine involves

---

(6) The statement of Kohler and Weiner [This Journal, 56, 434 (1934)] that benzhydryl phenyl diketone does not enolize is incorrect. A sample, equilibrated in methyl alcohol with a trace of piperidine, was titrated with bromine by H. E. Schroeder who found 15.5% enol.

substitution in the mesitylene group, the pure chloro compound is most readily made by employing a calculated quantity of sulfuryl chloride. The pure bromo compound can be made by operating with free bromine in chloroform at low temperatures. These halogen compounds are interesting because they are as reactive as the halogen derivatives of triaryl methanes. The constants of the chloro and bromo compounds as well as those of the corresponding ethers are shown in the following table.

	Calcd.		Found			M. p.,
	C	H	C	H	Form	°C.
$C_{24}H_{21}O_2 \cdot Cl$	76.5	5.6	76.4	5.9	Yellow plates	134
$C_{24}H_{21}O_2 \cdot Br$	68.4	5.0	68.1	5.4	Yellow plates	152
$C_{24}H_{21}O_2 \cdot OC_2H_5$	80.8	6.8	80.8	7.1	Prisms	121
$C_{24}H_{21}O_2 \cdot OCH_3$	80.6	6.5	80.6	6.8	Prisms	68

Coupling. The Tetraketone, XVI.—The enolic form of the α-diketone develops a brown color in alcoholic solutions of ferric chloride but the color soon fades. When the reaction was carried out with larger quantities the product was a sparingly soluble compound which crystallized from ether–petroleum ether in deep yellow prisms and which melted at 194°. The structure of this product was established by a synthesis from the bromo compound of the diketone. For this purpose a solution of 3 g. of the bromo compound in 50 cc. of dry benzene was shaken for twelve hours with 20 g. of mercury. The result was the same compound that had been obtained from the enol. The yield was 80–85%.

Anal. Calcd. for $C_{48}H_{42}O_4$: C, 84.4; H, 6.2; mol. wt., 682. Found: C, 84.1; H, 6.6; mol. wt., 685.

Catalytic Reduction of β-Phenylbenzal Acetomesitylene.—Preliminary experiments showed that the unsaturated ketone is reduced more rapidly by palladium on calcium carbonate than by platinum and hydrogen. Accordingly solutions of 4 g. of the ketone in ethyl acetate and in ether were shaken with hydrogen in the presence of 2 g. of the palladium catalyst until the calculated volume of hydrogen had been absorbed. The rate was the same in both solvents, the time required being an hour and three quarters. The suspensions were filtered, the filtrate was diluted with five times its volume of petroleum ether and saturated with oxygen. As the principal product was the saturated ketone, it was impossible to isolate pure peroxide but a crude estimate based on oxidation of acidified potassium iodide and on conversion to the enol of the diketone indicated that the mixture contained 10–12% of peroxide.

Reduction with Zinc and Acetic Acid.—A solution of 3 g. of the unsaturated ketone in 20 cc. of glacial acetic acid, 20 cc. of ether and 0.5 cc. of water was cooled in a freezing mixture and treated in the course of three minutes with 2.5 g. of zinc dust. The mixture was shaken in the freezing mixture for another three minutes, then poured in a mixture of 10 cc. of ether and 40 cc. of petroleum ether and washed rapidly with ice water until free from zinc and from most of the acetic acid. From the resulting ether–petroleum ether solution oxygen precipitated 3 g. of peroxide—a yield of 90%.

Summary

The paper presents evidence that the system $C{=}C(OH)C_6H_2(CH_3)_3$ is unusually persistent in solution. By utilizing this peculiarity it was possible to prove that the catalytic reduction of α-diketones proceeds by 1,4-addition to the oxygen atoms, that the reduction of α,β-unsaturated ketones with palladium on calcium carbonate and hydrogen proceeds at least in part by 1,4-addition to the conjugated system and that the reduction of α,β-unsaturated ketones by zinc and acid proceeds wholly by 1,4-addition.

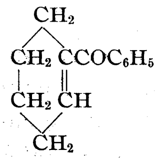
The Application of the Principle of Vinylogy to Unsaturated Ketones

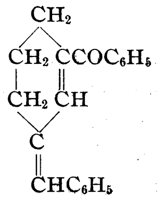
BY R. E. CHRIST[1] AND REYNOLD C. FUSON

A methyl group, separated from a carbonyl group by one vinylene unit, exhibits properties that are similar to those which it possesses when it is attached directly to the carbonyl group.[2] The present paper is an extension of this principle to ketones in which the vinylene group forms a part of a six-membered ring.

Tetrahydrobenzophenone (I) was prepared from benzoyl chloride and cyclohexene by use of the Friedel–Crafts synthesis. This compound was of particular interest, inasmuch as it offered the possibility of testing whether the activating influence of a carbonyl group outside the ring could be exerted on a methylene group which was a member of the ring. The ketone was found to react with benzaldehyde in an alcoholic solution, sodium ethoxide being used as a condensing agent. The product isolated was the expected ketone (II).



I



II

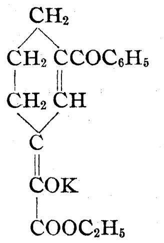
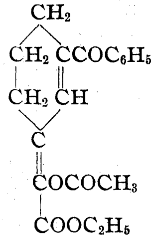
[1] Du Pont Post-doctorate Fellow.

[2] Fuson, Christ and Whitman, THIS JOURNAL, **58**, 2450 (1936).

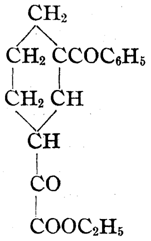
Tetrahydrobenzophenone was also condensed with ethyl oxalate in ether solution, potassium ethoxide being employed as a catalyst. The reaction led to the formation of the potassium salt (III). When treated with acetyl chloride, the salt was converted into the acetate (IV). The free keto ester (V) was produced by dissolving the potassium salt in water and acidifying with dilute hydrochloric acid.



III

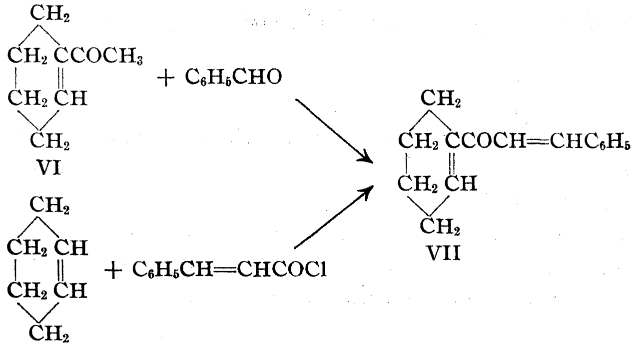


IV

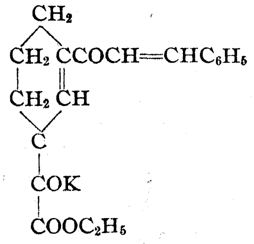


V

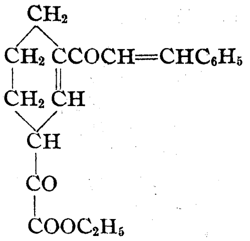
Tetrahydroacetophenone (VI) was chosen as a compound suitable for determining the relative reactivity of a methyl group adjacent to the carbonyl group and that of a methylene group separated from the carbonyl group by a linkage of the type —C=C—. The ketone was condensed with benzaldehyde in an alcoholic solution, sodium ethoxide being employed as a catalyst. The reaction product failed to give a positive iodoform test. This, along with its analysis, indicated that one molecule of aldehyde condensed with the methyl group in preference to the methylene group in the ring, giving the unsaturated ketone (VII). The identity of this compound was proved by its preparation from cinnamyl chloride and cyclohexene by means of the Friedel–Crafts method.



Benzaltetrahydroacetophenone (VII) in ether solution reacted with ethyl oxalate in the presence of potassium ethoxide to give the potassium salt (VIII). The free keto ester (IX) was produced by dissolving the salt in water and acidifying with dilute acid.

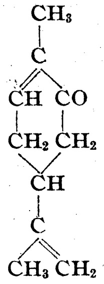


VIII

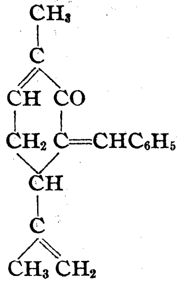


IX

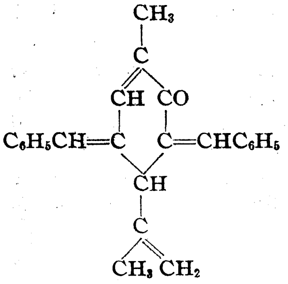
Müller[3] reported that carvone (X) condensed readily with benzaldehyde in the presence of alkali to yield two different forms of benzylidenecarvone (XI). Wallach,[4] on the other hand, had reported the formation of an amorphous material.



X



XI



XII

The principle of vinylogy suggests the possibility of the formation of dibenzylidenecarvone (XII). For this reason, the reaction of carvone with benzaldehyde was restudied. The ketone and aldehyde were condensed in alcoholic solution, in the presence of sodium ethoxide, to give benzylidenecarvone. No attempt was made to separate the two forms. Instead, the mixture was condensed with benzaldehyde again, and a product was obtained whose composition was that of the expected dibenzylidenecarvone (XII). However, it could not be crystallized from ordinary solvents.

This is analogous to the condensation of one molecule of menthenone (XIII) with two mole-

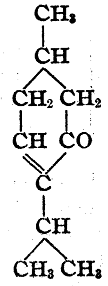
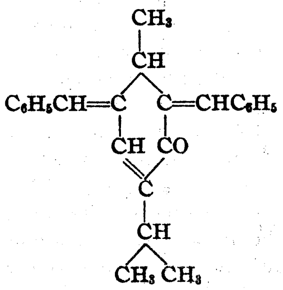
(4) Wallach, *Ann.*, **305**, 274 (1899).

cules of benzaldehyde to produce dibenzylidenementhenone (XIV), as reported by Wallach.[5]



XIII



XIV

Experimental

Tetrahydrobenzophenone.—This substance was prepared by a modification of the method of Wieland and Beltog.[6]

One mole of benzoyl chloride, 86 g. of cyclohexene and 600 cc. of carbon disulfide were placed in a 2-liter, three-necked flask to which were attached a stirrer, reflux condenser and an inlet for aluminum chloride. The flask was cooled with an ice-bath and 133 g. of aluminum chloride was added cautiously while the solution was agitated vigorously. Afterward it was stirred for an additional six hours. The mixture was treated with iced hydrochloric acid, and the carbon disulfide layer was separated and dried with calcium chloride.

The solvent was removed, and 56 g. of potassium hydroxide, dissolved in 200 cc. of ethyl alcohol, was added. After three hours of refluxing, the alcohol was distilled. The residue was washed several times with water, and dissolved in ether. The solution was dried over calcium chloride and, after removal of the solvent, was distilled under reduced pressure. Two fractions were collected: (1) 74 g., b. p. 147° (8 mm.); n^{22}_{D} 1.5595; d^{22}_{4} 1.070; (2) 9 g., b. p. 174° (8 mm.).

Fraction (2) solidified upon cooling. Recrystallization from alcohol yielded colorless, well-developed needles melting at 110°. These were not studied further.

Fraction (1) was the desired tetrahydrobenzophenone, and represented a yield of 40% of the theoretical amount. It absorbed bromine readily, showing unsaturation.

Anal. Calcd. for $C_{13}H_{14}O$: C, 83.82; H, 7.58. Found: (semi-micro) C, 83.59; H, 7.75.

Condensation of Tetrahydrobenzophenone with Benzaldehyde.—To a solution of 6.2 g. of tetrahydrobenzophenone and 3.5 g. of benzaldehyde in 15 cc. of absolute alcohol maintained at 0° was added, with shaking, a solution of 1 g. of sodium in 10 cc. of absolute alcohol. The mixture soon assumed a gelatinous appearance, and gradually developed a reddish-brown color. It was allowed to stand for twelve hours in a stoppered flask. When it was diluted with water, a heavy yellow precipitate formed. Two crystallizations from alcohol gave faintly yellow crystals; m. p. 115°.

Anal. Calcd. for $C_{20}H_{18}O$: C, 87.55; H, 6.61. Found: (semi-micro) C, 87.70; H, 6.67.

Condensation of Tetrahydrobenzophenone with Ethyl Oxalate.—A total of 7.8 g. of finely cut potassium was converted to potassium ethoxide by dissolving in 35 cc. of absolute alcohol. Two hundred cubic centimeters of dry ether was added, and the mixture was cooled to 0°.

To the ether solution was then added 18.6 g. of tetrahydrobenzophenone and 14.6 g. of ethyl oxalate dissolved in 50 cc. of ether. The mixture was allowed to stand for a period of twenty hours in an ice box; a heavy layer of orange crystals of the potassium salt (III) settled out.

The mixture was filtered rapidly, and the potassium salt was then washed several times with dry ether, and finally dried in a desiccator under reduced pressure. The weight of the final product was 29 g.; yield 89%.

The keto ester (V) was prepared by dissolving 19 g. of the potassium salt in 100 cc. of cold water and neutralizing with an excess of dilute hydrochloric acid solution. The ester was thrown out of solution as a yellow, semicrystalline mass. Two crystallizations from alcohol gave beautiful, faintly yellow needles. This compound begins to assume a deeper color at 85°, and finally melts at 92°. It dissolves in alkali, giving a light yellow solution.

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.29; H, 6.34. Found: (semi-micro) C, 71.00; H, 6.32.

Reaction of the Potassium Salt (III) with Acetyl Chloride.—Ten grams of the salt was mixed with 5 g. of acetyl chloride dissolved in 75 cc. of ether and allowed to stand for a period of twenty hours at room temperature.

Water was added, and the insoluble ether layer was separated and washed several times. The solvent was then evaporated, leaving a yellow crystalline mass of the acetyl derivative (IV). Two crystallizations from alcohol gave 4.5 g. of almost colorless needles; m. p. 92°.

Anal. Calcd. for $C_{19}H_{20}O_5$: C, 69.47; H, 6.14. Found: (semi-micro) C, 69.53; H, 6.36.

Preparation of Tetrahydroacetophenone.—This compound was made by a modification of the directions of Darzens.[7]

A mixture of 158 g. of acetyl chloride, 172 g. of cyclohexene and 1 liter of carbon disulfide was placed in a 3-liter, three-necked flask to which was attached a stirrer, reflux condenser and an inlet for aluminum chloride. The flask was cooled to 0°, and 266 g. of aluminum chloride was added, with stirring. Afterward, the mixture was stirred for two hours at room temperature. It was then treated with iced hydrochloric acid. The carbon disulfide layer was separated and dried with calcium chloride.

The solvent was removed, and the residue was distilled twice at reduced pressure from an excess of sodium carbonate to eliminate hydrogen chloride. The fraction, having a boiling point of 195–200°, was collected as the tetrahydroacetophenone. The yield was 155 g., or 62% of the theoretical amount.

The semicarbazone, a known compound,[7] melted at 220–221°.

Condensation of Tetrahydroacetophenone with Benzaldehyde.—A solution of 24.8 g. of tetrahydroacetophenone and 21.2 g. of benzaldehyde in 100 cc. of 95% alcohol was cooled to 0°. Two grams of sodium dissolved in 40 cc. of absolute alcohol was added slowly, with shaking. The solution assumed a reddish color and took on a gelatinous appearance. The mixture was allowed to stand in a stop-

pered flask for four days. Steam was then led through to remove the alcohol, and the residual material was dissolved in ether. The solution was dried over calcium chloride and distilled under reduced pressure. A total of 1.7 g. of unchanged reactants was recovered.

In addition, there was obtained 16.6 g. of a light yellow oil having a boiling point of 160–165° (4 mm.). When allowed to stand in a refrigerator for a short time, it solidified. Crystallization from alcohol gave almost colorless crystals; m. p. 68°. This substance was benzaltetrahydroacetophenone; it absorbed bromine readily, showing unsaturation. It failed to give an iodoform reaction.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.85; H, 7.60. Found: (semi-micro) C, 84.62; H, 7.79.

Benzaltetrahydroacetophenone.—This compound was prepared for comparison from cinnamyl chloride and cyclohexene by means of the Friedel–Crafts method.

One hundred twenty grams of cinnamyl chloride and 59.5 g. of cyclohexene were dissolved in 100 cc. of carbon disulfide. The solution was added dropwise to a mixture of 106.5 g. of aluminum chloride and 400 cc. of carbon disulfide maintained at a temperature of 0°. Stirring was continued for an additional two hours at room temperature. The mixture was hydrolyzed with iced hydrochloric acid. The carbon disulfide layer was separated and dried with calcium chloride.

The solvent was removed, and the remainder was distilled at reduced pressure from an excess of sodium carbonate to remove hydrogen chloride. Two fractions were collected: (1) Four grams, b. p. 80–130° (4 mm.). This fraction was not studied further. (2) Fifty grams, b. p. 160–165° (4 mm.). This fraction solidified upon cooling. Crystallization from alcohol gave almost colorless crystals; m. p. 68°. A mixed melting point with the benzaltetrahydroacetophenone described previously showed no depression.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.85; H, 7.60. Found: (semi-micro) C, 84.69; H, 7.77.

Condensation of Benzaltetrahydroacetophenone with Ethyl Oxalate.—To a solution of 4.9 g. of potassium in 22 cc. of absolute alcohol was added 150 cc. of dry ether, and the mixture was cooled in an ice-bath. To the solution was added a solution of 13.2 g. of the ketone and 9.1 g. of ethyl oxalate in 50 cc. of ether. The mixture was allowed to stand for a period of twenty-four hours in an ice box; a heavy layer of brilliant red crystals of the potassium salt (VIII) settled out.

The mixture was filtered, washed several times with dry ether, and then dried under reduced pressure. The weight of the final product was 19.2 g.; yield, 88% of the theoretical amount.

The keto ester (IX) was prepared almost quantitatively by dissolving the salt in cold water and neutralizing with dilute hydrochloric acid. The ester was thrown out of solution as a yellow, viscous mass. Two crystallizations from alcohol gave yellow crystals; m. p. 131–132°.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.03; H, 6.46. Found: (semi-micro) C, 72.91; H, 6.58.

Condensation of Benzaldehyde with Carvone.—A solution of 75 g. of the ketone and 53 g. of the aldehyde in 200 cc. of absolute alcohol was cooled to 0°, and 10 g. of sodium dissolved in 75 cc. of absolute alcohol was added gradually, with shaking. The solution soon acquired a reddish-brown color and a gelatinous appearance. It was allowed to stand for an additional forty-eight hours at room temperature. The alcohol was removed by steam distillation, and the viscous residue was dissolved in ether. The solution was washed with dilute acid, dried over calcium chloride and then distilled under reduced pressure. There was recovered 15.3 g. of unchanged reactants. In addition, two other fractions were obtained:

(1) Forty grams, b. p. 153° (3 mm.), a faintly yellow color; $n^{24.5}D$ 1.6040. The analysis corresponded to benzylidenecarvone, which was found by Müller[3] to exist in two different forms. No attempt was made here to separate them, however, as the fraction was to be further treated with benzaldehyde to see if a dibenzylidenecarvone could be prepared.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.66; H, 7.62. Found: (semi-micro) C, 85.65; H, 7.64.

(2) Twenty-two grams of higher-boiling, yellow, viscous liquid whose range of boiling point varied from 180 to 225° at 3 mm. pressure. Most of the material distilled in the vicinity of 210° (3 mm.). When cooled, it formed a glassy solid which could be crushed to an amorphous powder. The properties were very similar to those of dibenzylidenecarvone described in the next paragraph.

Condensation of Benzylidenecarvone with Benzaldehyde.—To a solution of 20 g. of ketone, 9 g. of benzaldehyde and 50 cc. of absolute alcohol, cooled to 0°, was added slowly, with shaking, 2 g. of sodium dissolved in 25 cc. of alcohol. The solution changed to a brownish-red gelatinous mass after a short time. It was allowed to stand an additional forty-eight hours at room temperature, and was finally warmed for an hour on a steam-bath. The alcohol was then removed by steam distillation, and the residual viscous material was washed with dilute acid, extracted with ether, dried over calcium chloride and distilled under reduced pressure. Two fractions were obtained: (1) Two and five-tenths grams, having a b. p. of 153° (3 mm.). This was unchanged benzylidenecarvone.

(2) Fifteen and five-tenths grams, having a b. p. of 210° (3 mm.). This was a very viscous yellow liquid which, when cooled, formed a glassy solid that could be crushed to an amorphous powder, but which could not be crystallized from ordinary solvents. This was undoubtedly the amorphous material prepared by Wallach, but not analyzed or investigated further. The composition corresponds to dibenzylidenecarvone which would be the product formed by the condensation of two molecules of benzaldehyde with one of carvone.

Anal. Calcd. for $C_{24}H_{22}O$: C, 88.30; H, 6.80. Found: (semi-micro) C, 88.15; H, 6.94.

Summary

Tetrahydrobenzophenone (I) has been prepared from benzoyl chloride and cyclohexene by use of the Friedel–Crafts synthesis. The ketone was found to react with benzaldehyde and ethyl oxalate, due to the reactivity of hydrogen atoms on the γ-carbon atom.

Tetrahydroacetophenone (VI) has been pre-

pared in an analogous manner. It, likewise, was condensed with benzaldehyde, producing benzaltetrahydroacetophenone (VII), which, in turn, was condensed with ethyl oxalate to form the keto ester (IX).

Carvone (X) was condensed with two molecules of benzaldehyde to yield an amorphous product whose composition was that of dibenzylidenecarvone (XII).

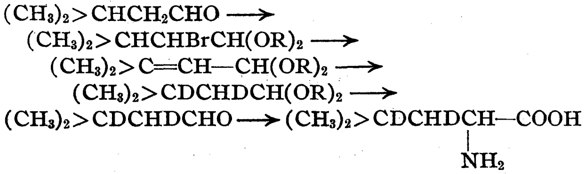
Dideuteriovaline and Dideuterioleucine

BY C. R. KINNEY AND ROGER ADAMS[1]

Analogs of two of the essential amino acids, valine and leucine, have been prepared in which two hydrogen atoms have been substituted by deuterium atoms. These new products are being tested in growth experiments to determine whether they may replace valine and leucine.

It is desirable, if not essential, for the deuterium to be introduced into such positions that during the reactions involved in the synthesis or in the animal body before metabolism actually starts, it will not be replaced by hydrogen. Thus, the deuterium atoms must not be substituted on the amino or carboxyl groups. Moreover, deuterium on a carbon atom from which rearrangement of the deuterium to oxygen or other similar atoms might take place, must be avoided.

The preparation of α-aminoisovaleric-β,γ-d_2 acid (dideuteriovaline) and of α-aminoisohexanoic-β,γ-d_2 acid (dideuterioleucine) from isobutyraldehyde and isovaleraldehyde, respectively, was carried out as illustrated by the following series of reactions for dideuterioleucine



$$\begin{array}{l} \mathrm{(CH_3)_2{>}CHCH_2CHO} \longrightarrow \\ \quad \mathrm{(CH_3)_2{>}CHCHBrCH(OR)_2} \longrightarrow \\ \qquad \mathrm{(CH_3)_2{>}C{=}CH{-}CH(OR)_2} \longrightarrow \\ \qquad\quad \mathrm{(CH_3)_2{>}CDCHDCH(OR)_2} \longrightarrow \\ \mathrm{(CH_3)_2{>}CDCHDCHO} \longrightarrow \mathrm{(CH_3)_2{>}CDCHD}\underset{\mathrm{NH_2}}{\underset{|}{\mathrm{C}}}\mathrm{H{-}COOH} \end{array}$$

It is obvious that in the intermediates isopentanal-β,γ-d_2 and isobutanal-β,γ-d_2, a deuterium on the carbon atom α to the aldehyde group exists; secondary in the former, tertiary in the latter. Both aldehydes theoretically are capable of enolization and thus it is possible that one of the deuterium atoms might be replaced at the intermediate aldehyde stage. A greater tendency to enolization would be expected in the molecule with the tertiary deuterium.

Analyses of the amino acids for deuterium indicated that the dideuteriovaline from the isobutanal-β,γ-d_2 contained about 25% less deuterium and the dideuterioleucine from the isopentanal-β,γ-d_2 6.5% less deuterium than the calculated amount. It is probable that an error of the magnitude of the latter might be introduced in the preparation of the isopentanal-β,γ-d_2 so that any appreciable loss of deuterium through enolization and hydrolysis is not indicated. On the other hand, the error of 25% in the dideuteriovaline probably is due in part to the purity of the isobutanal-β,γ-d_2, but principally to the replacement of deuterium by hydrogen during the transformation of the isobutanal-β,γ-d_2-diethylacetal through the aldehyde to the amino acid. In connection with these operations, it is significant that the deuterium in the intermediates, in spite of rather vigorous conditions in the presence of water and acids, is removed only where enolization may occur and then merely to a minor degree.

The authors desire to express their thanks to Dr. David Rittenberg of the Department of Biochemistry of Columbia University Medical School for his kindness in carrying out the deuterium analyses on the amino acids.

Experimental

α-Bromoisobutyraldehyde Diethylacetal.—Isobutyraldehyde was brominated according to the method[2] used for the preparation of α-bromoisovaleraldehyde diethylacetal. The crude product was fractionated carefully and the product, b. p. 78–82° (28 mm.), used for the subsequent reaction; yield 88%. Completely purified material boils at 80° (28 mm.).

Isobutanal Diethylacetal.—This was prepared according to directions[2] for making isovaleraldehyde diethylacetal except that it was found advantageous after treatment with molten potassium hydroxide to drop water slowly into the hot mixture until sufficient had been added to dissolve

---

(1) For the last paper in this field see Leffler and Adams, THIS JOURNAL, 58, 1555 (1936).

(2) Fischer, Ertel and Loewenberg, *Ber.*, **64B**, 30 (1931); Dworak and Prodinger, *Monatsh.*, **53**, 590 (1929).

all the potassium bromide. The acetal was then separated, dried over solid potassium hydroxide and distilled; b. p. 136–139° (748 mm.); yield 71%.

Anal. Calcd. for $C_6H_{16}O_2$: C, 66.66; H, 11.11. Found: C, 66.52; H, 11.31.

Isobutanal-α,β-d_2 Diethylacetal.—Isobutenal diethylacetal was treated with pure deuterium as described in previous papers[1] using platinum oxide as a catalyst and ethyl acetate as a solvent. A large cell was employed so that the deuterium could be generated rapidly. The pure material which gave no permanganate reaction had a boiling point of 133–135° (747 mm.); d^{20}_{4} 0.8368; n^{20}_{D} 1.3938.

Anal. Calcd. for $C_8H_{16}D_2O_2$: C, 64.86; H + D, 12.31. Found: C, 64.60; H + D, 11.90.

Isobutanal Diethylacetal.—This was prepared by the reduction of the unsaturated acetal with hydrogen. It had the following constants: b. p. 135–136° (745 mm.); d^{20}_{4} 0.8295; n^{20}_{D} 1.3885. Oeconomides[3] reported the b. p., 134–136°; d^{12}_{4} 0.9957.

The calculated value for the density of isobutanal-α,β-d_2 diethylacetal on the assumption of the same molecular volume for deuterium and hydrogen[4] is 0.8408 as compared with the found value of 0.8368.

Dideuteriovaline (α-Aminoisovaleric-β,γ-d_2 Acid).—A mixture of 35 g. of isobutanal-α,β-d_2 diethylacetal (which did not react with potassium permanganate solution in three to four minutes), 125 cc. of water and 15 drops of concentrated sulfuric acid was stirred or shaken for thirty minutes. The reaction product was distilled slowly into a flask cooled in ice, containing 100 cc. of methanol and 35 g. each of ammonium chloride and potassium cyanide. When all of the aldehyde had distilled, the receiver was connected to a reflux condenser and refluxed for two hours. After cooling, 100 cc. of ether was added and the precipitated salt filtered and washed with ether. To the alcohol–ether solution 100 cc. of 40% aqueous hydrogen bromide and 25 cc. of water was added, and the mixture allowed to stand for two hours. It was heated under an air reflux until the alcohol and ether were removed. Some water was added to replace that lost by evaporation. The air reflux was replaced by a water-cooled one and the mixture refluxed for a total of twelve hours.

The solution was carefully evaporated to dryness, the final stages being carried out under reduced pressure. The solid was dissolved in about 200 cc. of water, the solution cooled in ice and well-washed silver oxide was added (from 50 g. of silver nitrate) in small lots. When an excess of silver oxide had been added, the solution was filtered and the precipitate well washed. Hydrogen sulfide was passed into the solution until no more silver sulfide precipitated. After filtering, the solution was evaporated until the amino acid began to crystallize out. Methyl alcohol was added and the solution cooled in ice; yield 12.2 g. (43.4%). The acid was recrystallized from water, using norite to remove a faint yellow color. If heated slowly, the melting point in a sealed tube was 273° with decomposition. The substance consistently melted 1.5–2° lower than pure *dl*-valine when both were melted in the same bath.

Anal. Calcd. for $C_5H_9D_2O_2N$: N, 11.76; D, 18.8 atom per cent. Found: N, 11.54, 11.44; D, 13.2 atom per cent. (±0.7).

Isopentanal-α,β-d_2 Diethylacetal.—Isopentenal diethylacetal was prepared[2] from isovaleraldehyde made from synthetic isoamyl alcohol. Difficulty was encountered in its reduction with deuterium. The best method was found to be by the use of dioxane (distilled from sodium) as a solvent, freshly distilled isopentenal acetal and Raney nickel as a catalyst. The product after fractionation gave a b. p., 164–165° (740 mm.); n^{20}_{D} 1.4025; d^{20}_{4} 0.8423.

Anal. Calcd. for $C_9H_{18}D_2O_2$: C, 66.66; H + D, 13.57. Found: C, 66.21; H + D, 12.59.

Isopentanal Diethylacetal.—This was prepared by reduction of the unsaturated acetal with hydrogen. It had the following constants: b. p. 167–168° (750 mm.); n^{20}_{D} 1.4040; d^{20}_{4} 0.8356. Alsberg[5] reported b. p. 168.2°; d^{12}_{4} 0.835.

The calculated value for the density of isopentanal-α,β-d_2 diethylacetal on the assumption of the same molecular volume for deuterium and hydrogen is 0.8464 as compared with the found value of 0.8423.

Dideuterioleucine (α-Aminoisohexanoic-β,γ-d_2 Acid).—The isopentanal-α,β-d_2 diethylacetal (which did not react with potassium permanganate solution in three to four minutes) was converted to dideuterioleucine following the procedure outlined for the valine derivative. The yield of acid recrystallized from water, using norite to remove color, was about 30% of the weight of the acetal. The melting point taken slowly in a sealed tube was 271° with decomposition. *dl*-Leucine in the same bath melted consistently 2° higher.

Anal. Calcd. for $C_6H_{11}D_2O_2N$: N, 10.52; D, 15.4 atom per cent. Found: N, 10.31; D, 13.7 atom per cent. (±0.7).

Summary

Dideuteriovaline (α-aminoisovaleric-β,γ-d_2 acid) and dideuterioleucine (α-aminoisohexanoic-β,γ-d_2 acid) have been prepared for comparison with valine and leucine in growth experiments.

The Migration of Alkyl Radicals. I. Transfer of Some Tertiary Alkyl Radicals from Phenols to Hydrocarbons

BY RICHARD A. SMITH

In a study of alkyl phenyl ether rearrangement it was found that the migrating alkyl group can be introduced into a different molecule instead of merely rearranging to another part of the same molecule.[1] In this report the migration has been extended to apply to the change of position from the phenol nucleus to the benzene nucleus. As with the migration quoted, the reaction offers a means of preparation of alkylated benzenes. In some studies of rearrangements performed in this Laboratory by Niederl and the author, which have not been reported, it has been observed that alkyl groups in the phenolic ring can be made to change ring position under the influence of rearranging agents such as are used to effect phenyl ether isomerizations. It was thought that this migration might be intermolecular, in which case it should be possible to effect the migration to a foreign nucleus. Para substituted tertiary alkyl phenols were chosen as being very likely to undergo migration with the least possible side reactions. The action of aluminum chloride in the presence of benzene at room temperature and at reflux temperature upon *p*-*t*-butylphenol, *p*-*t*-amylphenol and 4-(1,1,3,3-tetramethobutyl)-phenol has been studied. The products are phenol and corresponding alkylbenzenes. With the butylphenol a good yield of *t*-butylbenzene was obtained; the reaction was carried out at the reflux temperature. The migration of the amylphenol was performed at room temperature. The migration of the octylphenol was performed at both room temperature and at the reflux temperature. There was no fundamental change in the reaction. The products identified were free phenol and *t*-butylbenzene. It will be noticed that the octyl group underwent scission. This is not unexpected as a Friedel–Crafts reaction between diisobutylene and benzene yields *t*-butyl substituted benzenes.[2] If this migration is bimolecular, the results may be interpreted as additional evidence for the para position of the octyl group in 4-(1,1,3,3-tetramethobutyl)-phenol.[3]

Procedure

I. The Action of Aluminum Chloride upon *p*-*t*-Butylphenol.—A half mole of the phenol, two-thirds of a mole of technical anhydrous aluminum chloride, and 150 cc. of benzene were refluxed for eight hours. The whole was then poured upon ice, the organic layer separated and water washed. The aqueous layers were extracted with ether, the ether layer dried with anhydrous sodium sulfate, the ether evaporated on a steam-bath, and the residual liquid purified by distillation and identified as phenol. The organic layer was washed with Claisen solution, water and then dried with anhydrous sodium sulfate. The product was purified by fractional distillation. A small Hempel column was found useful.

t-Butylbenzene, b. p. 167–168°; $n^{24}\text{D}$ 1.4958; d^{24} 0.868; yield 70%. *Anal.* Calcd. for $C_{10}H_{14}$: C, 89.6; H, 10.4. Found: C, 89.3; H, 10.1.

II. The Action of Aluminum Chloride upon *p*-*t*-Amylphenol.—A half molar quantity of the phenol and corresponding quantities of aluminum chloride and benzene as in (I) were allowed to stand at room temperature for twelve days. The whole was then worked up as in (I). Phenol was again obtained. The other product was purified by fractional distillation using appropriate sized columns.

t-Amylbenzene, b. p. 188–190°, $n^{24}\text{D}$ 1.5032; d^{24} 0.864; yield 25%.

III. The Action of Aluminum Chloride upon 4-(1,1,3,3-Tetramethobutyl)-phenol.—A six molar quantity of the phenol was treated with equivalent amounts of aluminum chloride and benzene at room temperature as in (II). A half molar quantity was treated at the reflux temperature as in (I). The products soluble in Claisen solution, in addition to phenol, are still under investigation.

t-Butylbenzene.—Yield in the cold (a) 50%; in the hot (b) 70%. Calcd. for $C_{10}H_{14}$: C, 89.6; H, 10.4. Found: (a) C, 89.9, 89.2; H, 10.4, 10.1.

The author wishes to acknowledge the help of Jack Rosen who performed a part of this work in connection with research for the degree of B.S. He wishes also to thank Miss R. T. Roth for the micro-analyses performed.

Summary

1. The migration of alkyl groups from a phenol nucleus to a benzene nucleus has been demonstrated.

2. The above migration has been performed

at room temperature and at the reflux temperature.

3. The scission of the octyl group of 4-(1,1,3,3-tetramethobutyl)-phenol has been demonstrated.

4. *t*-Butylbenzene has been prepared from 4-*t*-butylphenol and from 4-(1,1,3,3-tetramethobutyl)-phenol. *t*-Amylbenzene has been prepared from 4-*t*-amylphenol.

5. Further studies of this type of migration are being made. Systems now under investigation include migrations from phenol nuclei of different types of alkyl groups to simple and substituted (phenol, phenyl ether and naphthol) aromatic nuclei.

Equilibria of the Reactions between Acetylene and Heavy Water at 0 and 100° and the Heats of Reaction[1]

BY L. H. REYERSON AND BRUCE GILLESPIE

In a previous communication[2] the equilibrium constants for the reactions between acetylene and heavy water at 25° were given. At equilibrium six different molecular species were involved in seven possible reactions and the constants for five of them were calculated from the experimental results. The experimental technique involved the accurate determination of the deuterium content of the heavy water before and after exchange. This investigation has been extended and the equilibria of the reactions have been determined at 0 and 100°.

The experimental methods with some small refinements remained much the same as in the previously reported study, except that a heavily insulated constant temperature air thermostat was substituted for the water-bath used in the earlier investigations. At 100° the normal alkaline solutions attacked the Pyrex glass bulbs so strongly that several of them broke during the time required for equilibrium. As a result quarter normal solutions of sodium hydroxide were used in the experiments run at 100° and half normal solutions were used at 0°. Because of the high partial pressure of water vapor at 100° the partial pressure of the acetylene was kept at about half an atmosphere to reduce the hazard of explosions. In all cases the bulbs containing the acetylene and heavy water solutions were made up and run at room temperature for several days, after which they were run at either 100 or 0° for from forty-eight to sixty hours. At the conclusion of a given run the heavy water was recovered from the bulbs and its density determined in the same manner as previously reported.[2] From the changes in the density of the heavy water solutions and a knowledge of the equilibrium constants K_6 for the reaction $D_2O + H_2O \rightleftharpoons 2HDO$ and K_7 for the reaction $C_2D_2 + C_2H_2 \rightleftharpoons 2C_2HD$ it was possible to calculate the number of moles of each of the six reacting molecules at equilibrium. According to Topley and Eyring[3] K_6 has a value of 3.118 at 0° and 3.374 at 100°. Glockler and Morrell[4] gave the value of K_7 at 0° as 1.373 and at 100° as 1.584. Tables I and II give the results of these calculations at 0 and 100°.

Using the values given in Tables I and II the equilibrium constants for the following exchange reactions were calculated.

$$C_2H_2 + HDO \rightleftharpoons C_2HD + H_2O \quad (1)$$
$$C_2HD + HDO \rightleftharpoons C_2D_2 + H_2O \quad (2)$$
$$C_2H_2 + D_2O \rightleftharpoons C_2HD + HDO \quad (3)$$
$$C_2HD + D_2O \rightleftharpoons C_2D_2 + HDO \quad (4)$$
$$C_2H_2 + D_2O \rightleftharpoons C_2D_2 + H_2O \quad (5)$$

Table III gives the equilibrium constants for the exchanges at 0° and Table IV gives the values at 100°. The equilibrium constants at 100° are all higher than those previously reported at 25° and the values at 0° are all lower than at 25°.

It is of interest to note that Hiroto and Okamoto[5] calculated the equilibrium constant K_1 at 25° from spectroscopic data. They obtained a value of 0.59 where our experimentally determined value was 0.599. The agreement is excellent and

offers additional confirmation of the fact that equilibrium was reached by our method of investigation.

The values reported in Tables III and IV are given just as they came out in the calculation. No significance is attached to any figure beyond the second decimal place and it may not be correct. Taking the average value to two decimal places we have for the constants at 0° $K_1 = 0.57$, $K_2 = 0.42$, $K_3 = 1.78$, $K_4 = 1.30$ and $K_5 = 0.74$. At 100° the values would be $K_1 = 0.67$, $K_2 = 0.43$, $K_3 = 2.27$, $K_4 = 1.44$ and $K_5 = 0.97$.

Using these values together with those previously reported[2] it is possible to determine the heats of reaction for these isotopic exchanges. From the well-known equation of van't Hoff it is evident that the heats of reaction, ΔH, may be determined by plotting $-R \ln K$ (equilibrium constant) against $1/T$ (T in absolute temperature). The slopes of the curves so obtained give the values of ΔH. In Fig. 1 the values of log K are plotted against $1/T$. The resulting curves are practically straight lines. Using the slope of these curves and multiplying by -4.5787 to convert to $-R \ln K$ the values of ΔH in calories are obtained.

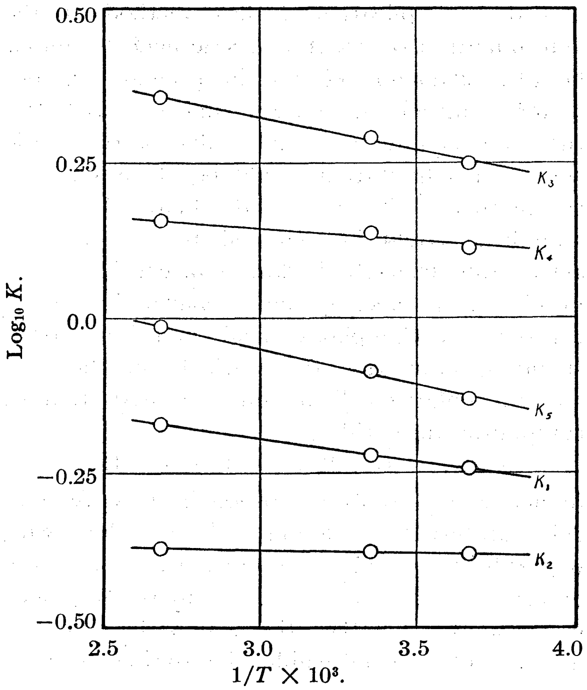

Fig. 1.—Variation of exchange equilibrium constants with temperature.

These values are given in Table V together with all of the equilibrium constants for the five reactions. As might well be expected the heats of reaction for these isotopic exchanges are very small.

TABLE V

Reactions	Equilibrium Constants 0°	25°	100°	ΔH
1	0.57	0.60	0.67	275
2	.42	.42	.43	35
3	1.78	1.95	2.27	480
4	1.30	1.37	1.44	175
5	0.74	0.82	0.97	530

Summary

1. The equilibrium constants for the reactions between H_2O, HDO, D_2O, C_2H_2, C_2HD and C_2D_2 have been determined experimentally at 0 and 100°.

2. From a knowledge of the change of the equilibrium constants of isotopic exchange reactions with the temperature (in the range 0 to 100°), the heats of reaction of these exchanges have been calculated.

A Polarimetric Method for the Determination of Water in Acetic Acid[1]

BY GERRIT TOENNIES AND MARGARET ELLIOTT

Some recently proposed methods for the determination of water in organic media are based on the acidimetric determination of acetic acid formed from acetyl chloride[2] or from acetic anhydride.[3] Application of these methods to the determination of water in acetic acid or similar liquids, although possible in principle, is obviously limited in accuracy and sensitivity by the large acidimetric blank value of the acetic acid. This limitation would be abolished if in the method of Toennies and Elliott[3] the acetic anhydride could be replaced by an optically active anhydride the hydration of which is measurable by an accompanying change in optical rotation. *d*-Camphoric acid and the corresponding anhydride differ widely in their effect on polarized light, but the hydration of camphoric anhydride

$$C_8H_{14}(CO)_2O + H_2O \longrightarrow C_8H_{14}(COOH)_2 \quad (1)$$

in acetic acid solution, although susceptible to acid catalysis,[4] was found to be too slow, with tolerably low acid concentrations (in presence of 0.1 M $HClO_4$ $k_{25} \cong 10^{-3}$), to be of practical promise. On the other hand, the complete absence of a conceivable[5] interfering reaction

$$C_8H_{14}(CO)_2O + 2CH_3COOH \longrightarrow C_8H_{14}(COOH)_2 + (CH_3CO)_2O \quad (2)$$

—in spite of the large excess of one of the potential reactants (CH_3COOH)—suggested the probability of a strong thermodynamic tendency for the opposite of reaction (2)

$$(CH_3CO)_2O + C_8H_{14}(COOH)_2 \longrightarrow 2CH_3COOH + C_8H_{14}(CO)_2O \quad (3)$$

This was found to exist: the bimolecular constant[6] of this reaction in acetic acid is directly proportional to the amount of strong acid present[7] and is, in the presence of 0.001 M perchloric acid and at about 25°, of the order of 10^{-1}; *i. e.*, with equal amounts of catalyst, reaction (3) is estimated to be 10^4 times as fast as reaction (1). Therefore, and since the acid-catalyzed reaction of acetic anhydride with moderate amounts of water in acetic acid is even more rapid than reaction (3), the following principle for the determination of water in glacial acetic acid suggests itself.

In the presence of a suitable small concentration of a strong acid (perchloric acid) the acetic acid solution of water is allowed to react with a measured quantity of acetic anhydride, and the unused amount of acetic anhydride is determined by the decrease in optical rotation coincident with its reaction with a measured amount of *d*-camphoric acid.

The experimental investigation of the method has been confined to a demonstration of its practicability and its minimum accuracy, while it has not been extended either to a quantitative study of various factors that might add to its refinement (such as temperature, concentration or mutual effects on the specific rotations of *d*-camphoric acid and *d*-camphoric anhydride) nor to a consideration of possible interfering substances (such as might conceivably be formic acid or

acetone[3]), nor to an exploration of its applicability to other acid or non-acid media.

Experimental

Reagents: Perchloric Acid Solution.—By dissolving a weighed amount of standardized concentrated perchloric acid in acetic acid[8] a solution of 1.00 *M* perchloric acid and 2.70 *M* water (exclusive of the water content of the acetic acid) was prepared. Repeated titration with an acetic acid solution of piperidine, with crystal violet as the indicator,[9] showed complete stability.

Acetic Anhydride.—The percentage of acetic anhydride (x) in a concentrated preparation was calculated from the average equivalent weight (e. w.) obtained by methylate titration[10,3] of a suitable aliquot dissolved in acetonitrile

$$\frac{x}{102.05} + \frac{100 - x}{60.03} = \frac{100}{\text{e. w.}}$$

The preparation used (Merck Reagent) showed 95.4 ± 0.2% acetic anhydride.

***d*-Camphoric Acid and *d*-Camphoric Anhydride.**—The camphoric acid used (Eastman) had a melting point of 187.5°, corr. (Beilstein 187°, corr.), and an equivalent weight, by methylate titration,[10,3] of 100.1 (calcd. 100.1). Determinations of the specific rotation[11] in acetic acid gave $[\alpha]_{\text{Hg}}^{27\pm1}$ + 53.9 ± 0.1° in 0.25 *M* solution, and $[\alpha]_{\text{Hg}}^{27\pm1}$ +54.25 ± 0.1° in 0.05 *M* solution, while *d*-camphoric anhydride in 0.25 *M* solution showed $[\alpha]_{\text{Hg}}$ −0.8 ± 0.2°. Ten cc. of acetic acid was found to dissolve at room temperature more than 0.5 but less than 0.6 g. of *d*-camphoric anhydride.

Reaction Velocities.—The velocity of the acid-catalyzed reaction between camphoric anhydride and water is illustrated by the experiment recorded in Table I. The bimolecular constant, calculated over the range of 25 to 89% conversion of the anhydride, shows a uniformly increasing trend which tends to disappear when it is assumed that the velocity is inversely proportional to the water content of the medium (Table I, column 4). This assumption may be justified as an approximation in view of the fact that H_2O, due to its basic properties in acetic acid,[12,9] will lower the acid potential of the catalyst

$$HClO_4 \begin{cases} +CH_3COOH \rightleftarrows CH_3COOH_2^+ + ClO_4^- \\ +H_2O \rightleftarrows H_3O^+ + ClO_4^- \end{cases}$$

In another experiment with initial concentrations in acetic acid, of 0.334 *M* H_2O, 0.550 *M* $(CH_3CO)_2O$, 0.219 *M* $C_8H_{14}(CO)_2O$ and 0.10 *M* $HClO_4$, the rotation (2-dm. tube, α_{Hg}) remained −0.03 ± 0.02° over a period of ten days, indicating that the water had reacted completely with the acetic anhydride and that reaction (2) does not take place. This, in conjunction with the following experiments showing the ease and completeness of the opposite reaction (3), seems sufficient evidence for the conclusion that under the experimental conditions a reaction between camphoric anhydride and acetic acid is thermodynamically impossible.

TABLE I

REACTION BETWEEN *d*-CAMPHORIC ANHYDRIDE AND WATER

Initial concentration of camphoric anhydride, b = 0.270 *M;* of water, estimated from water content of acetic acid, as determined (*v. infr.*), and from water introduced by 0.25 cc. of 10.9 *M* $HClO_4$, a = 0.362 *M*. Medium: acetic acid. Catalyst: 0.11 *M* $HClO_4$. Temperature: 24.0 ± 1.5°. $\alpha = \alpha_{\text{Hg}}$ measured in a 2-dm. tube. The values of the third column have been obtained by integrations over the successive intervals of time, and those of the fourth column by multiplying each value of the third with the mean value of the water concentration for each interval. In a control tube, without catalyst, (b = 0.273 *M*, a = 0.068 *M*) the rotation remained, over a period of seven days, α = −0.07 ± 0.02°.

Hours	α	$k \times 10^3$	$k(a - x) \times 10^3$
19.5	+1.41	0.75	2.47
43.5	+2.92	1.13	2.96
67.5	+3.99	1.59	3.21
90.0	+4.71	2.29	3.68
115.5	+5.20	2.73	3.63

The velocity of the reaction between camphoric acid and acetic anhydride (3) was investigated in the following experiments. A solution of the initial concentrations 0.067 *M* H_2O, 0.688 *M* $(CH_3CO)_2O$, 0.216 *M* $C_8H_{14}(COOH)_2$ and 0.001 *M* $HClO_4$ showed in the 2-dm. tube the following rotations:

Minutes	7	10	12	14	16	20	25	32
α_{Hg}	2.73°	2.22°	1.91°	1.60°	1.40°	0.90°	0.60°	0.32°

The temperature was 25–26°. Calculation of the bimolecular constants for the points of 20, 40, 60 and 80% conversion of the camphoric acid, obtained from the plotted curve and from the calculated initial and final rotations +4.67 and −0.06°, gives k = 0.135 ± 0.007, the assumption being made that the water present is eliminated at once by reacting with the equivalent amount of acetic anhydride. A similar solution containing 0.01 *M* perchloric acid showed after ten minutes the calculated value for camphoric anhydride. In the presence of 0.0001 *M* perchloric acid, on the other hand, the same reaction was 50% complete after twenty-five hours, while in the absence of any added catalyst a corresponding half time of ninety hours was found. No quantitative conclusions should be drawn from the latter two data, as without special precautions interference by contamination with minute amounts of either acid or basic material must be considered possible. However, on the basis of these experiments 1 to 5 × 10^{-3} *M* perchloric acid was selected as a catalytic agent suitable to ensure sufficiently rapid completion of the reaction of camphoric acid with acetic anhydride in the presence of an adequate excess of the latter.

Determination of Water Present in Glacial Acetic Acid.—The first experiment was based on the tentative assumption that the water content of the glacial acetic acid at hand ("assay 99.5% CH_3COOH") would be be-

---

[8] Glacial Acetic Acid "Merck Reagent" was used throughout this work.

[11] For the polarimeter and light source used *cf. J. Biol. Chem.*, **89**, 155 (1930).

[12] N. F. Hall and J. B. Conant, THIS JOURNAL, **49**, 3055 (1927).

tween 0.3 and 0.7% (0.16–0.40 *M* water). An acetic acid solution containing 8.822 g. of 95.4% acetic anhydride (=8.5 cc.) per 100 cc. was used. To 6.44 mml. of camphoric acid in a 25-cc. flask 12.5 cc. of the acetic anhydride solution (10.31 mml. $(CH_3CO)_2O$) and 1.25 cc. of 0.1 *M* perchloric acid in acetic acid (=0.125 mml. $HClO_4$ with 0.34 mml. H_2O) were added, and the solution was completed to 25 cc. with acetic acid. The contribution of camphoric acid to the total volume under the conditions of these experiments was determined as approximately 0.845 cc. per gram. Accordingly the amount of acetic acid present is, with sufficient accuracy, 25.00−1.06 (acetic anhydride) − 1.09 (camphoric acid) = 22.85 cc. This solution showed after one hour a constant rotation of $\alpha_{Hg} = -0.08°$ (2-dm. tube), indicating complete conversion of camphoric acid into the anhydride. If the assumption is correct that acetic anhydride reacts much more rapidly with water than with camphoric acid this result shows that the acetic acid cannot have contained more than 10.31 (= total $(CH_3CO)_2O$) − 6.44 (= $C_8H_{14}(COOH)_2$) −0.34 (= H_2O introduced with $HClO_4$) = 3.53 mml. H_2O, *i. e.*, the water content was less than 3.53/22.85 = 0.154 *M* (0.278 g. per 100 cc.).

Accordingly the following two solutions were made, using the same stock solutions as in the preceding experiment: (A) 6.45 mml. $C_8H_{14}(COOH)_2$, 4.12 mml. $(CH_3CO)_2O$ and 0.12 mml. $HClO_4$ + 0.33 mml. H_2O and (B) 6.50 mml. $C_8H_{14}(COOH)_2$, 6.60 mml. $(CH_3CO)_2O$ and 0.125 mml. $HClO_4$ + 0.34 mml. H_2O, both completed to 25 cc. with acetic acid. After two hours the rotation (α_{Hg}, 2 dm.) was found to be stationary in both solutions, solution (A) showing +3.71 ± 0.005° and (B), +1.565 ± 0.015°. These values correspond to 33.0 and 71.2% conversion of camphoric acid into anhydride (obtained by using the values of +54.0 and −0.8° for the specific rotations of the two forms); *i. e.*, 2.13 and 4.63 mml. camphoric acid, respectively, have reacted with an equivalent amount of acetic anhydride. This leaves 4.12 − 2.13 = 1.99 and 6.60 − 4.63 = 1.97 mml. of acetic anhydride which must have reacted with equivalent amounts of water. 0.33 and 0.34 mml., respectively, are accounted for by the water introduced with the perchloric acid, leaving 1.66 and 1.63 mml. of water, which must have been present in the acetic acid. The amounts of the latter used were 25.00 − 1.09 (volume of camphoric acid) − 0.43 (volume of acetic anhydride) = 23.48 cc. and similarly 25.00 − 1.10 − 0.68 = 23.22 cc. so that 1.66/23.48 = 0.0707 *M* and 1.63/23.22 = 0.0702 *M* are the values obtained in two separate experiments for the water concentration, equal to 0.127 ± 0.0005% by volume.

Although the close agreement between the results of two determinations—in which the amounts (relative and absolute) of acetic anhydride used differed in the ratio of 5:8—seemed sufficient evidence for the validity of the method, this was verified by a set of determinations in which a known amount of water was added to the acetic acid. An additional purpose of this experiment was to see whether the time allowed for the reaction between acetic anhydride and water previous to the addition of camphoric acid could have any influence on the result, or, stated differently, if in the competition between camphoric acid and water for acetic anhydride the latter could be used up before all of the water had reacted. If this were possible the remaining water would react extremely slowly with camphoric anhydride (*cf.* under Reaction Velocities). 15.00 cc. of an acetic acid solution containing 52.16 mml. of $(CH_3CO)_2O$ (= 5.14 cc. 95.4% acetic anhydride), 0.520 cc. of H_2O (= 28.9 mml.) and 0.10 mml. of $HClO_4$ together with 0.27 mml. of H_2O were made up to approximately 100 cc. with acetic acid. The solution weighed 104.62 g. and contained the following amounts of water.

(100.00 − 5.14 − 0.52) 0.0705	= 6.65 mml.	(water content of the acetic acid, based on the preceding determination)
0.520/0.018	= 28.86 mml.	(added water)
	0.27 mml.	(introduced with $HClO_4$)
	35.78 mml.	

or 0.3420 mml. of H_2O per gram of solution.

25-cc. flasks, containing weighed amounts of camphoric acid, were filled to volume with the described solution, the exact amount of solution used being determined by weighing. Table II summarizes the results of this experiment.

TABLE II

DETERMINATION OF A KNOWN AMOUNT OF WATER IN ACETIC ACID SOLUTION

This table should be read in the light of the preceding text. The following notes, referring to the horizontal columns, will assist in its interpretation: $d = \frac{c \times 52.16}{104.62}$, $g = \frac{54.0 \times 2 \times e \times 0.2001}{f}$, $i = \frac{(g - h)100}{g + 0.075}$, $k = \frac{e \times i}{100}$, $l = d - k$, $m = l/c$.

(a)	Time between adding catalyst to the acetic anhydride-acetic acid–water mixture and combining the resulting solution (b) with camphoric acid, min.	6	12	120
(c)	Amount of solution (b) used, g.	24.97	24.79	24.95
(d)	Amount of acetic anhydride present, mml.	12.45	12.36	12.44
(e)	Amount of camphoric acid, mml.	6.50	6.72	6.49
(f)	Volume, cc.	25.05	25.00	25.10
(g)	Calculated initial rotation (2-dm. tube), α_{Hg}	5.61°	5.805°	5.59°
(h)	Final rotation, determined after 4 and 20 hours, α^{27}_{Hg}	2.265°	2.50°	2.285°
(i)	Fraction of camphoric acid converted into anhydride, according to (h), %	58.8	56.2	58.3
(k)	Acetic anhydride consumed by reaction with camphoric acid, mml.	3.815	3.775	3.78
(l)	Acetic anhydride consumed by reaction with water, mml.	8.635	8.585	8.66
(m)	Water initially present, per gram of solution (b), mml.	0.346	0.346	0.347

The amount of water found lies within approximately 1% of the calculated value and appears independent of the time allowed for the separate reaction between acetic anhydride and water, indicating that this reaction is much faster than the one between acetic anhydride and camphoric acid. This is in agreement with the data of Orton and Jones (*cf.* footnote 4) and is also evident from the observation, in this last experiment, of a considerable evolution of heat as soon as the catalyst was added even though its concentration was only 0.001 *M*.

Outline of a Practical Method.—The specific rotation of *d*-camphoric acid to be used is determined in about 0.25 *M* solution in glacial acetic acid. About 6.5 mml. of *d*-camphoric acid is weighed accurately in a 25-cc. volumetric flask, a definite amount of standardized acetic anhydride—the amount to be used is chosen so that after reaction with the expected amount of water 3.25 ± 3 mml. of $(CH_3CO)_2O$ remain for reaction with camphoric acid—is added and the flask is filled up to the mark with the acetic acid to be tested, including in the total volume 0.125 mml. of perchloric acid of known water content (*e. g.*, 0.125 cc. of a 1.00 *M* $HClO_4$ solution in acetic acid made from 70.0% aqueous perchloric acid would contain 0.299 mml. of H_2O). The amount of acetic acid employed is obtained by deducting the known volumes of the other ingredients from the total volume, using 0.845 as the partial specific volume of *d*-camphoric acid or, more accurately, by weighing. From the resulting solution a 2-dm. polarimeter tube is filled and polarimetric readings are taken until the optical rotation has become stationary. If the stationary value corresponds to the specific rotation of *d*-camphoric acid or to that of *d*-camphoric anhydride ($[\alpha]_{Hg} = -0.8°$) a new experiment with a larger or smaller amount, respectively, of acetic anhydride is started. The difference between the initial amount of acetic anhydride and the polarimetrically determined amount of camphoric anhydride formed is equivalent to the amount of water present. For confirmation of the result the determination should be repeated with a different amount of acetic anhydride.

Discussion

The amount of water present per gram of solution, expressed in the terms used in Table II, is

$$m = \frac{d}{c} - \frac{e(2 \times 0.2001 \times [\alpha]_1 \times e - fh)}{c(2 \times 0.2001 \times [\alpha]_1 \times e + 2 \times 0.1821 \times [\alpha]_2 \times e)}$$

where $[\alpha]_1$ and $[\alpha]_2$ are the specific rotations of camphoric acid and camphoric anhydride, respectively. By means of the probability theorems relating to the probable errors of arithmetically combined measurements,[13] the probable error of *m* may be calculated in algebraic terms. On the basis of the analytical experience of the present study the following estimated probable errors may be tentatively assigned:

Amount of acetic anhydride	d/c	±0.2%
Specific rotation of camphoric acid	$[\alpha]_1$	±0.3%
Specific rotation of camphoric anhydride	$[\alpha]_2$	±15%
Final rotation	h	±0.4%
Amount of camphoric acid	e/c	±0.2%

Application of these probable errors to the data results in a probable error, for the *single* determination, of ±1.8% in the most unfavorable case of determination *B* (p. 904 and of ±0.5% for each single determination of Table II. These computations, together with the actual results, point to a precision and probable accuracy of the method of at least ±1% for water concentrations of 0.1 to 1%. Undoubtedly this figure could be appreciably improved by more refined measurements.

A comparison of the analytical results with those obtainable by other methods has not been attempted as the limitations of available methods seemed to preclude the possibility of yielding results of comparable accuracy. Since the literature values[14] for the absolute freezing point of acetic acid vary at least between 16.62 and 16.67° an attempt to determine the freezing point of the acid used in the present work with an accuracy of 0.002°, corresponding to a variation in the water content of 0.001%, would appear futile. An alternative physical method based on critical solution temperatures,[15] although of about six times higher temperature sensitivity than the freezing point method, is also limited by the lack of absolute standard data. The chemical method of K. Fischer,[16] which is based on the fact that iodine is reduced by sulfur dioxide only in the presence of water, and which in regard to sensitivity is comparable with the present method, has not been applied by its author to acetic acid and may not be applicable without considerable additional research.

Summary

The amount of water present in acetic acid can be determined by allowing it to react with a known amount of acetic anhydride and by determining the excess of acetic anhydride by the decrease in optical rotation caused by its reaction with *d*-camphoric acid, by which the latter is converted into *d*-camphoric anhydride. Both reactions involved are strongly catalyzed by low concentrations of strong acids. The accuracy

of the method is characterized by determinations of 0.1 and 0.6% of water, within limits of ±0.001 and ±0.008% respectively.

Chemical and X-ray Investigation of Barium Sulfate Contaminated with Permanganic Acid[1]

BY PHILIP R. AVERELL AND GEORGE H. WALDEN, JR.

Introduction

A recent article by Walden and Cohen[2] reported the results of an investigation of barium sulfate precipitates contaminated with nitrate. The results of this work indicated the necessity of a similar investigation using a contaminating ion of different configuration, such as permanganate ion. Several investigators, notably Grimm and Wagner[3] have reported on the precipitation of barium sulfate in the presence of potassium permanganate.

The present investigation deals with (1) the precipitation of barium sulfate in the presence of permanganate ion, hydrogen ion being the only other foreign ion present; (2) the establishment, by chemical analysis, of the complete constitution of these contaminated precipitates, thereby identifying the cation which balances the charge of the coprecipitated permanganate ion; (3) investigation of the character of the precipitates by means of X-ray powder photographs.

It developed that the method of precipitation used by Walden and Cohen,[2] which for them produced beautifully coarse crystalline precipitates contaminated with nitrate ion, yielded for us precipitates so fine as to appear amorphous even when examined between crossed nicols under an oil-immersion objective, and which gave only a vague trace of an X-ray diffraction pattern. The method of precipitation used by Grimm and Wagner,[3b] adapted to the new conditions, proved to be apparently the only one which would yield precipitates of the desired coarseness.

Complete analyses of samples prepared by both methods showed that barium and sulfate ions exist in the precipitates always in a mole ratio of 1:1, which shows that the ion accompanying the permanganate ion is not barium, and therefore must be hydrogen or a hydrated hydrogen ion.

X-ray powder photographs showed a definite and fairly regular expansion of the lattice parameters with increased contamination, a conclusive evidence of the existence of solid solution.

Method of Preparation.—The method of precipitation used by Walden and Cohen, adapted to the study of permanganate contamination, consists of the slow addition of a sulfuric–permanganic acid solution to a barium permanganate–permanganic acid solution, the concentrations being so adjusted that the permanganate concentration is the same in both solutions; the sulfuric acid added is sufficient to precipitate less than half of the barium ion. The method of Grimm and Wagner, adapted to the present investigation, is to mix rapidly two solutions containing respectively equimolar quantities of barium permanganate and sulfuric acid. Each solution contains in addition permanganic acid in such amount that the permanganate ion concentrations are equal.

Since the unpreventable spontaneous decomposition of permanganic acid made it impossible to keep the system free of manganese dioxide, it was necessary to use all solutions as quickly after preparation as possible, and to use some means of removing manganese dioxide from the precipitate before final filtration, washing and drying. Accordingly, after the mother liquor was removed, the precipitate was given one washing with either sulfur dioxide solution or dilute hydrogen peroxide acidified slightly with hydrochloric acid, followed by water. All washings were made more effective by centrifugal drainage. As the slow drying of water-wet precipitates also caused decomposition with formation of manganese dioxide, this difficulty was obviated—again using Grimm's procedure—by washing with acetone four or five times, the last washings being colorless, then with anhydrous ether, before drying in air or over concentrated sulfuric acid.

The product thus prepared is a beautiful rose-colored precipitate, showing no traces of manganese dioxide, either to the unaided eye or under a microscope. As in the case of the precipitates described by Grimm, the co-precipitated permanganate ion is chemically very inert. The color is not noticeably bleached by contact with strong reducing solutions even after standing for several days. Heating at 110° for twenty to forty hours produces decomposition only in insufficiently washed precipitates, and in

those of highest contamination; in general, such heating causes not even a detectable loss in weight. One sample, after several hours ignition at 700–800°, showed the presence of undecomposed permanganate when dissolved in concentrated sulfuric acid.

Chemical Analysis

Two methods were used to decompose the barium sulfate precipitates for analysis: (1) fusion with anhydrous sodium carbonate; and (2) solution in concentrated sulfuric acid. In method (1), the melt was decomposed with a small amount of water, and a few drops of hydrogen peroxide added to reduce all the manganese to manganese dioxide. After filtration, the residue of barium carbonate and manganese dioxide was dissolved in dilute hydrochloric acid plus hydrogen peroxide; the barium was precipitated as the sulfate and weighed, while the manganese could be determined in the filtrate. The original filtrate, consisting of sodium sulfate and sodium carbonate, was made acid with hydrochloric acid, diluted to 400 cc., and the sulfate precipitated with barium chloride. In method (2), the coprecipitated permanganate was reduced to manganous ion by passing sulfur dioxide over the surface of the sulfuric acid during solution of the barium sulfate; the latter was then reprecipitated by adding water, washed, filtered, ignited and weighed; the filtrate was analyzed for manganese by the bismuthate method as modified and described by Park;[4] in place of potassium permanganate as a standard solution, ceric sulfate was used in conjunction with phenanthroline-ferrous ion indicator.[5] Samples of 0.5–1.5 g. required a titer of 5–10 cc. of 0.1 *N* ferrous sulfate; considering the accuracy of the bismuthate method, as well as the relatively small amount of permanganate ion in such a sample, these small titers yielded adequate precision in the calculations.

X-ray Analysis

Powder photographs were taken with the same apparatus used by Walden and Cohen[2] with a few mechanical improvements. The lattice parameters were calculated from film measurements by the least squares treatment developed by Cohen.[6]

Data and Interpretation

The equivalence of barium and sulfate ions in the precipitates was established by analyses of several precipitates by the sodium carbonate fusion method; representative precipitates prepared by both methods were analyzed. Table I shows the weights of barium sulfate obtained from the barium ion in the original precipitates (denoted by $\textit{Ba}\mathrm{SO}_4$ in the table, and from the sulfate ion (denoted by $\mathrm{Ba}\textit{SO}_4$). The upper group consists of precipitates in which the manganese dioxide was dissolved out with sulfur dioxide before the final washings with acetone and ether.

TABLE I

Ppt. no.	G. sample	G. $\textit{Ba}\mathrm{SO}_4$	G. $\mathrm{Ba}\textit{SO}_4$	Ratio Ba/SO$_4$
20	0.7486	0.6944	0.7056	0.984
22	1.0998	1.0429	1.0531	.990
24	0.9221	0.8798	0.8872	.992
42	.5545	.5357	.5418	.988
32	.9208	.8950	.8943	1.001
36	.8339	.7243	.7210	1.005
44	.5141	.4955	.4947	1.002
45	.3838	.3690	.3694	0.999
48	.5192	.4904	.4905	1.000

It will be noted that in these precipitates, the sulfate exceeds the barium by an amount distinctly outside the experimental error. Apparently washing with sulfur dioxide results in added contamination of the precipitate with excess sulfate ion formed on oxidation of the wash solution by manganese dioxide. When hydrogen peroxide solution was substituted for sulfur dioxide, this difference disappeared, as can be seen in the lower group, in which hydrogen peroxide was used to remove manganese dioxide.

As has been indicated above, the charge on the co-precipitated permanganate ion could conceivably be balanced in only three ways: (1) by barium ion, (2) by hydrogen ion or (3) by both barium and hydrogen ion. Since barium and sulfate ions are equivalent in the contaminated precipitates, alternatives (1) and (3) are thus ruled out; the permanganate ions must then be balanced wholly by equivalent hydrogen ions.

The demonstration of the equivalence of barium and sulfate also made it possible to use exclusively the sulfuric acid solution method of analysis, which actually measures only the barium content.

If the precipitates are considered to contain only barium sulfate plus permanganic acid, an appreciable portion of the weight of the original sample is left unaccounted for; that is, the weight of barium sulfate reprecipitated after solution in sulfuric acid, plus the weight of permanganic acid calculated from the manganese found by analysis, does not add up to the weight of sample used. The obvious explanation of this discrepancy is that the precipitates must contain water. Since permanganic acid is a strong acid, it would be present in the precipitating solution as oxonium and permanganate ions rather than anhydrous undissociated hydrogen permanganate molecules, and would be expected to enter the barium sulfate crystals in that form. As a matter of fact, our

analyses, so interpreted, indicate a variable proportion of water, but in only one instance does the determined ratio of moles of water to moles of permanganic acid fall below unity.

The composition of the contaminated precipitates may then be expressed as barium sulfate plus permanganic acid and water in varying proportions. Table II shows the numerical results of analyses of precipitates which were properly prepared, using hydrogen peroxide to clear up manganese dioxide, and which showed no traces of manganese dioxide. Precipitates in which sulfur dioxide was used are omitted.

50	96.26	2.269	1.47	4.39

Since the weight of water was calculated by difference, it was considered advisable to confirm the actual presence of water in the calculated proportion by some other method. Accordingly, weighed samples of different precipitates were given thirty minutes ignition at 700°. The ignited precipitates were weighed, then treated with 18 *M* sulfuric acid, the barium sulfate going into solution, and the residual manganese oxides remaining in suspension. After dilution with water to the proper volume, the barium sulfate being reprecipitated, a measured excess of standard ferrous sulfate solution was added and let stand until the manganese oxides were completely dissolved; the excess of ferrous sulfate was then titrated with standard ceric sulfate. Since the percentage of manganese in each sample was known already, and hence the weight of manganese present, the analysis after ignition yielded the average composition of the manganese oxides in the ignited precipitates. The observed weight loss during the ignition should then consist of the excess water, the water of constitution from permanganic acid, and oxygen from manganese heptoxide to the oxide of the determined average composition. From these data, the actual loss of water may be determined, and compared with the weight of water calculated by difference from the original analyses (see Table II). Since the oxygen and water of constitution of the permanganic acid amount to only a third of the total observed loss in weight, the remainder cannot be explained by experimental error. The only possible conclusion seems to be that the residual loss must be water, and this residual loss checks very well with the weight of water calculated by difference. The results are shown in Table III.

Table III

Ppt. no.	G. sample	H_2O by diff., g.	H_2O by ignition, g.
32a	1.1584	0.0096	0.0101
32b	1.1778	.0097	.0098
44	0.8989	.0088	.0083
47	.6363	.0077	.0073

This water is held tightly by the crystal lattice as shown by the fact that neither vacuum desiccation over concentrated sulfuric acid for four months, nor heating at 110° for a week caused any appreciable loss in weight. On the basis of this confirmation by a different method of attack, we may say with reasonable assurance that the precipitates definitely contain water.

In order to correlate our observations on permanganate contamination with those of Walden and Cohen on nitrate contamination, it was necessary to have complete analyses of their precipitates, which they had analyzed only for weight per cent. of nitrate ion. Two of the precipitates prepared by Walden and Cohen were selected and fused with anhydrous sodium carbonate to determine the ratio of barium to sulfate ion. As is shown in Table IV (nomenclature the same as in Table I), the difference between the barium and sulfate precipitates is in both cases about 6% of the sample weight, which is decidedly greater than any possible experimental error. However, the excess of barium does not account for the total nitrate content of the precipitates as given by the analyses of Walden and Cohen. Moreover, the remainder of the nitrate, when calculated to nitric acid, still does not account for the total sample weight, which indicates the

Table IV

Ppt. no.	G. sample	G. $\mathit{Ba}SO_4$	G. $Ba\mathit{SO}_4$	Ratio Ba/SO_4
12	0.6269	0.6072	0.5703	1.065
14	.4670	.4516	.4243	1.064

possibility that there may be water taken in as part of the contaminant. Although the data are too meager to warrant any definite statement as to the precise constitution of these precipitates, what does seem to be definite is that the ratio of barium to sulfate is greater than unity, and therefore that at least part of the co-precipitated nitrate has its charge balanced by excess barium ions. In this respect, the nitrate contaminated precipitates differ from those containing permanganate.

X-ray Data and Interpretation

The lattice parameters of the crystalline contaminated precipitates are given in graphical form in Figs. 1 and 2. In Fig. 1 the parameters a_0, b_0, and c_0 in Ångström units, and the volume of the unit cell, $a_0b_0c_0$, are plotted against weight per cent. of permanganic acid. In Fig. 2, the abscissa is the weight per cent. of total contaminant, or $100 - \%$ $BaSO_4$. The radii of the circles around the experimental points are the probable errors as determined by the least squares analysis of the films.[6] It is apparent from the two sets of curves that the lattice parameters vary more regularly with the percentage of total contaminant than with the percentage of permanganic acid alone. A reasonable interpretation of these results seems to be that the lattice is expanded by the entry of both permanganic acid and water, but not to the same degree. Since, as has been pointed out, the ratio of water to permanganic acid varies in different precipitates, it is not to be expected that the points will lie closely on a smooth curve, as should be the case if the expanding effects were the same, weight for weight. The fact that the lattice parameters vary with increasing percentage of contaminant demonstrates the solid solution character of the precipitates.

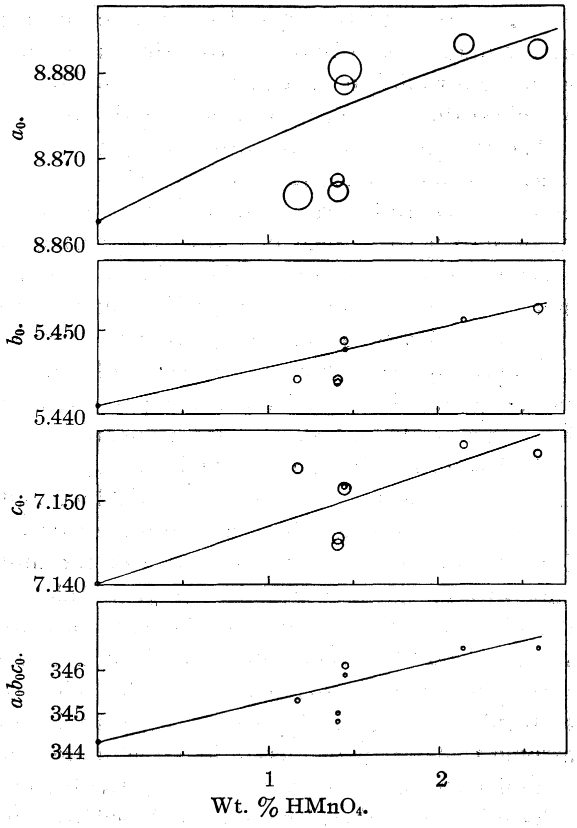

Fig. 1.

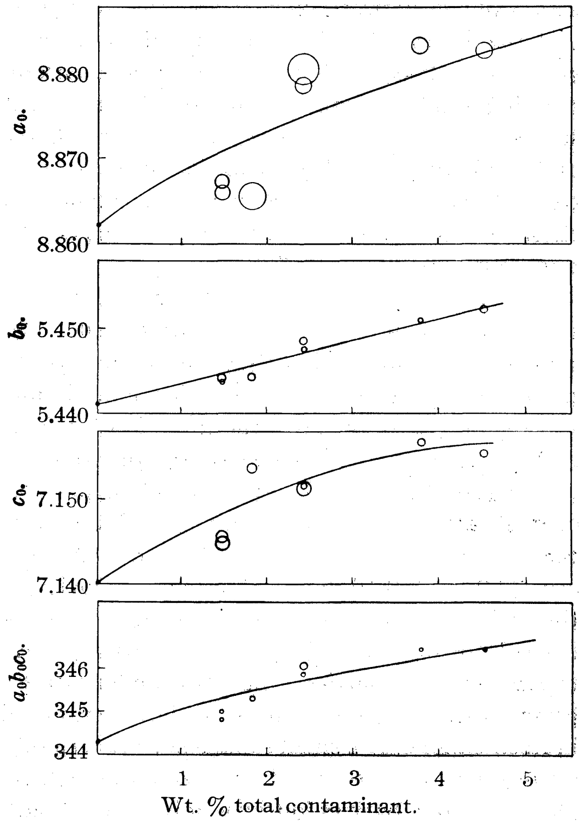

Fig. 2.

Discussion

It might be well at the outset to deal briefly with attacks[7] which have been made on the assumption of solid solution formation in precipitation systems on the ground that phase-rule studies of such systems show that no solid solution is found to exist in equilibrium with the mother liquor. It should be noted that there is no indication that any precipitate encountered in

---

(7) Benrath and Schackmann, *Z. anorg. allgem. Chem.*, **218**, 139 (1934).

analytical practice involving coprecipitation of a foreign ion is in actual equilibrium with its mother liquor. Rather it has been observed that such equilibrium is approached exceedingly slowly during prolonged digestion.[8] Undoubtedly the precipitates investigated by the authors, as well as those of Grimm and Wagner and of Walden and Cohen, are not the results of heterogeneous equilibria, but of kinetic processes localized at the surfaces of the growing crystals.

The data just presented suggest that some of our present ideas with regard to the limitations under which solid solutions may be formed must be revised. The question of crystallographic isomorphism between solvent and solute appears to have as little bearing here as it does in metal systems.[9] Since large lattice expansions accompanying solid solution are not to be expected, it seems reasonable to suppose that the size, charge and configuration of the entering ions are controlling factors. The possible importance of these factors has already been discussed by numerous investigators.[3b,10]

This idea appears to be quite consistent with the experimental data just presented. The radius of a complex ion may be defined as the radius of the smallest sphere which can be circumscribed about the whole structure. Both sulfate and permanganate ions consist of four oxygens in regular tetrahedral arrangement about the central atom; the ionic radii, calculated from dimensions given by Wyckoff[11] and Pauling,[12] are 3.00 and 3.16 Å., respectively. Obviously the substitution of two permanganate ions for one sulfate ion could take place only with excessive expansion of the lattice. Substitution of a single permanganate ion for a sulfate ion, however, would in itself cause only a small expansion. Such a substitution would necessitate the simultaneous replacement of a barium ion by a univalent cation,[13] which would likewise cause no large expansion if there were a corresponding similarity of radii.

Although precise values of the radius of an oxonium ion are at present lacking, Volmer's[14] X-ray measurements of ammonium perchlorate and oxonium perchlorate (usually written $HClO_4 \cdot H_2O$) indicate rather definitely that oxonium ion is about the same size as ammonium ion, or slightly larger than barium or potassium ion. The ionic radii given by Wyckoff[11] are $NH_4^+ = 1.50$, $Ba^{++} = 1.38$ and $K^+ = 1.33$ Å. Peters[15] was able to prepare barium sulfate precipitates contaminated with as much as 12% of ammonium permanganate, and on the basis of his results predicted that oxonium permanganate should likewise form solid solutions in barium sulfate. Our experimental data fulfil this prediction. Whether the additional water molecules which the precipitates were found to contain are associated with the oxonium ions or are distributed elsewhere through the crystal cannot be decided by the data at our disposal. In either case, they would contribute to the expansion of the lattice, as indeed the experimental evidence indicates.

The nitrate ion has its three oxygens at the apices of an equilateral triangle, close-packed about the central nitrogen atom and planar with it, or nearly so. Since in nitrate-contaminated precipitates a barium ion is balanced by either one sulfate ion or two nitrate ions, it is necessary to have some idea as to what orientation two nitrate ions may assume with respect to each other in replacing a single ion. Such an idea may be obtained by a study of the lattice of barium nitrate.

Barium nitrate has a cubic lattice in which distinct pairs of nitrate ions lie symmetrically about alternate lattice points like the sulfurs in pyrites. The two nitrogens lie on a diagonal of the unit cube with the plane of both ions perpendicular to the diagonal; the oxygens of the two ions are staggered so that their projections on a plane perpendicular to the diagonal are at the apices of a regular hexagon. It seems permissible to assume that a pair of nitrate ions might present a similar configuration when entering the barium sulfate lattice in the place of a single sulfate ion. The radius of the nitrate pair in the barium nitrate lattice is 3.42 Å. These nitrate ions are not close-packed; if they were, the radius would be about 3.1 Å. There is no way to predict how closely the ions would pack if substitution occurred in this manner; however, either value is sufficiently close to the radius of a sulfate ion to suggest that such a substitution would cause no large expansion of the barium sulfate lattice.

[15] Peters, Dissertation, Würzburg, 1930.

The correlation of these two cases of contamination involving different analytical results gives strong support to the assumption that size as well as charge and configuration of the ions concerned are very important factors controlling the formation of solid solutions in precipitation systems. The fact that, so far as is known, barium sulfate has only an orthorhombic form, while barium nitrate has only a cubic form, shows that for cases of partial miscibility isomorphism or structural similarity between any two component ion-pairs of the contaminated precipitate is immaterial to the process. Either cation or anion or both can be replaced independently.

Summary

1. Several samples of permanganate-contaminated barium sulfate were prepared in the absence of all foreign ions except permanganate and hydrogen ions, using the procedure employed by Grimm and Wagner.[3b]

2. Chemical analysis of the rose-colored precipitates shows that the total contaminant consists of hydrogen and permanganate ions in equivalent quantity, and a variable amount of water.

3. The lattice parameters of these precipitates, obtained by X-ray powder photographs, are all greater than those of pure barium sulfate, and when these are plotted against the weight per cent. of total contaminant present, a reasonably smooth, rising curve is obtained. The precipitates are, therefore, solid solutions.

4. Chemical analysis of nitrate-contaminated barium sulfate prepared by Walden and Cohen[2] shows that the mole ratio of barium to sulfate is greater than unity, and therefore that the coprecipitated nitrate ions are balanced, at least partially, by barium ions.

5. Comparison of permanganate contamination with nitrate contamination of barium sulfate shows that primary factors controlling the formation of solid solutions in precipitation systems are the size, charge and configuration of the ions entering the lattice. Crystallographic isomorphism and similarity of ionic structure are proved to be unnecessary conditions for cases of limited miscibility.

The Vapor Pressure of Phosphorus Pentoxide

BY J. C. SOUTHARD AND R. A. NELSON

Introduction

The vapor pressure of phosphorus pentoxide has been subject to some uncertainty. The disagreement in existing data has already been pointed out by Kelley.[1] The uncertainty, however, is not so much one of magnitude as of reproducibility. Smits and co-workers[2] obtained measurements which varied from sample to sample. They believed this variation to be due to the presence of two forms of phosphorus pentoxide which could be partially separated by fractional distillation. It necessarily follows that these two postulated forms should be not readily transformable one into the other, and that true equilibrium between them could not have existed at the time the vapor pressure measurements were made. Entirely reproducible results were obtained by Hoeflake and Scheffer[3] but they point out that their distillations were carried out under fairly uniform conditions. Hence, their measurements were not necessarily at variance with those of Smits.

The present investigation was undertaken with the hope of determining definitely whether this phenomenon of Smits exists. The results are interpreted as showing that it does not and that the measurements of Hoeflake and Scheffer are substantially correct.

Description of Apparatus

The Jackson[4] type gage was used by both Smits and Hoeflake and Scheffer. It consists essentially of a thin-

walled glass bulb collapsed on one side in such a manner that it is distorted easily by a difference in internal and external pressure. One end of the bulb is attached by a ring seal to an enveloping glass jacket and the other end to a long glass pointer. In practice the gage is used as a null instrument and the pressure in the external jacket is determined with a conventional mercury manometer. Hoeflake and Scheffer used such gages made of "fusible" glass, Jena glass and "verre dur"; Smits and Rutgers used gages made of high melting Jena glass and quartz while Smits and Deinum used quartz. The first measurements in this work were accordingly made with Jackson type gages constructed by Pyrex glass, Jena supremax glass and transparent silica glass (quartz).

The sensitivity of the gages used in this work was such that a difference in pressure between the inside bulb and the enveloping jacket of less than one millimeter of mercury could be detected. This was accomplished by observing the motion of the 35-cm. long glass pointer relative to a fine pointed tungsten reference needle through a ten-power reading telescope.

The pressure in the enveloping glass jacket was determined with an 8-mm. bore, two-meter long mercury manometer. The height of the mercury column was read with the unaided eye on a mirror backed scale which had been tested at the National Bureau of Standards. The readings were reduced to 0° and a gravity correction of 0.04 cm. per atmosphere ((980.091/980.665) × 76) applied.

The temperature of the gage was measured with a platinum–platinum–rhodium (10% rhodium) thermocouple. The noble metals of this couple were silver-soldered to copper wire and the junctions thus formed inserted in oil-filled glass protective tubes which in turn were immersed in a Dewar flask filled with crushed ice and distilled water. The e. m. f. developed by this couple was measured with a White potentiometer. Both the thermocouple and the potentiometer had been calibrated by the National Bureau of Standards.

Several furnaces were used, but all were provided with auxiliary heaters which permitted the temperature in the region surrounding the bulb to be maintained isothermal to ±0.2°, as shown by difference thermocouples located at various points.

At the higher temperatures these glass gages were attacked by the phosphorus pentoxide. In order to remove this objection and to escape errors which might have been inherent in the Jackson gage, it seemed advisable to make some measurements with an entirely different type of vapor pressure gage, preferably one which could be made of platinum and one which did not depend on diaphragm distortion. A gage which meets these requirements, but made of glass or quartz, has been used by Maier[5] in studying the vapor pressure of chlorides. This has been called the bulb type gage.

In this work it comprised a bulb of about 25-cc. volume connected by an approximately 30-cm. long, 1-mm. bore capillary to a glass U filled with mercury. The mercury in the capillary side of the U was kept at a reference mark by balancing an external pressure against it. In addition to the phosphorus pentoxide sample the bulb contained an inert gas (dry nitrogen) at a pressure of 15 to 20 cm. of mercury. This gas served as a means for transmitting the pressure in the bulb to the U-trap outside of the furnace, while such gaseous phosphorus pentoxide as diffused up the capillary was condensed on the walls. The pressure observed was thus approximately equal to the sum of the vapor pressure of the phosphorus pentoxide in the bulb and the pressure exerted by the inert gas. The latter was determined by extrapolation of pressure readings taken at temperatures where the vapor pressure was negligible. Three such gages were used, two made of Pyrex glass and one of platinum.

The disadvantages of this type of gage are due principally to the necessary presence of the inert gas. (1) Measurements are made with the substance under a pressure higher than its equilibrium vapor pressure. Under the conditions of these measurements the correction may possibly amount to as much as 0.1% but it has been neglected for lack of necessary data. (2) Equilibrium measurements are dependent on the rate of evaporation and diffusion of the substance in the bulb being faster than its rate of diffusion up and condensation in the capillary. (3) During vapor pressure measurements the pressure in the system is higher than during the simple inert gas pressure measurements. This results in an excess of inert gas in external or "obnoxious" volume of system over that prevailing during the blank measurements and in a corresponding decrease in the inert-gas pressure in the bulb. Correction for this is made as follows

$$P_{\text{corr.}} = (P_2 - P_1)(1 + (T_B V_A / T_A V_B))$$

where $P_{\text{corr.}}$ is the corrected vapor pressure, P_2 is the observed total pressure of inert gas and substance, P_1 is the pressure of inert gas and T_A, V_A, T_B, V_B the temperatures and volumes of the external and internal volumes, respectively. In our work this correction amounted to more than 2% at the higher temperatures.

The temperature–pressure measurements made and the furnaces used with the bulb type gages were the same as in the experiments with the Jackson type gages.

Measurements with the Jackson Type Gages

C. P. phosphorus pentoxide was distilled in a stream of oxygen at 800° in an iron tube furnace as described by Finch and Fraser.[6] This gave a product which showed a negative test for lower oxides with silver nitrate.[7] This distilled phosphorus pentoxide was loaded in a "dry box" into a tube which was immediately sealed onto a vacuum system comprising the vapor pressure gage with from one to three intermediate distillation bulbs, and the conventional trap, McLeod gage and mercury diffusion pump. After the system had been evacuated to less than 10^{-5} mm., the pentoxide was distilled first into the intermediate bulb or bulbs, and then into the gage. After the final distillation, the gage was sealed off and placed in the furnace after the system was shown to have no leaks.

The measurements obtained with the Pyrex glass gage are presented in Table I and Fig. 1. This gage without exception gave a reproducible zero position for the pointer on cooling down. Measurements in it on the vapor pressure of mercury gave results varying less than 0.2 cm. from the

values given in the "International Critical Tables." It was also subject to less attack by the phosphorus pentoxide than the gages made of either supremax or transparent silica glass. Readings were taken only when the temperature of the furnace was practically constant. As a rule check readings were made after a lapse of ten to fifteen minutes, and following a decrease as well as an increase in temperature. The data obtained with the Pyrex glass gage must accordingly be considered the most reliable of all those obtained by us with gages of the Jackson type. They differ but slightly from those obtained by Hoeflake and Scheffer. They show a metastable form (curve a, Fig. 1) existing below about 400°, a transient form (curve b, Fig. 1) and a stable form (curve c). The vapor pressure of the volatile form was entirely reproducible from day to day so long as the temperature did not exceed 360°. At 370° the rate of transition was such that satisfactory measurements could not be made. The transient form was considered by Hoeflake and Scheffer to be identical with that formed by supercooling the liquid. It could be obtained but once with the Pyrex gage. The curve c representing the stable form deviates from that of Hoeflake and Scheffer by an amount corresponding to about three degrees, which is not surely outside their limit of error. No satisfactory measurements on the vapor pressure of liquid phosphorus pentoxide could be obtained since the melting point lay above the workable range of a Pyrex gage.

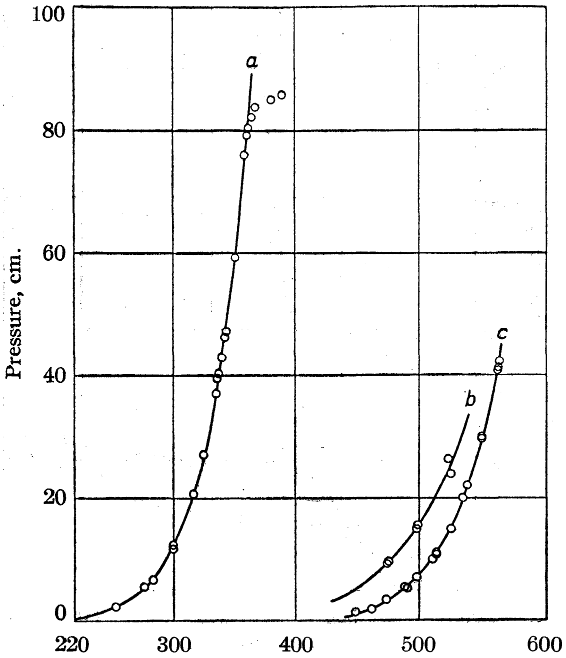

Fig. 1.—Vapor pressure of phosphorus pentoxide in Pyrex Jackson gage.

A gage was constructed from transparent quartz glass in an effort to obtain data on liquid phosphorus pentoxide. Also, it was thought desirable to duplicate Smits' working conditions as exactly as possible. Data obtained with this gage are given in Fig. 2. This gage showed a tendency for the position of the pointer to shift. At times this shift was equivalent to 5 cm. pressure. In most cases a suitable correction could be applied, but even then the measurements may be in doubt by more than a centimeter of mercury pressure.

The greatest fault of the quartz gage is the ease with which it is attacked by phosphorus pentoxide. Fairly reproducible measurements were obtainable at temperatures near 300°, but on maintaining the furnace at 350° overnight the pressure fell from about 50 to 18 cm. That this was not due to a transition to a more stable form is shown by the fact that a vapor pressure curve differing but slightly from the first measurements was obtained as soon as the temperature was lowered to a point where the gaseous phase was saturated. Furthermore, on three separate days (curves b, c, d, Fig. 2) measurements were obtained which were characteristic of a saturated vapor at the lower pressures and of a gas at the higher pressures. On each succeeding day not only was the temperature lower at which this break in the curve took place, but the pressure curves were lower. This could be explained by assuming that the phosphorus pentoxide was reacting with the walls of the gage. This assumption proved warranted as the gage was later found to be badly etched. In fact when the apparatus was inspected at the end of the series of runs, no phosphorus pentoxide at all was visible.

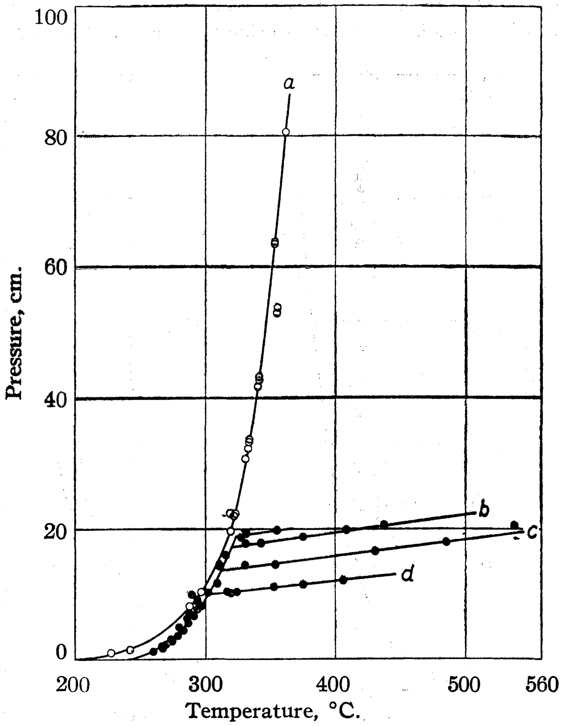

Fig. 2.—Vapor pressure of phosphorus pentoxide in transparent quartz Jackson gage.

Below 350°, however, some data were taken on the volatile form which do not differ by more than a centimeter or two from those obtained in the Pyrex glass gage. They were in general lower, as would be expected should contamination of the phosphorus pentoxide with silica have been occurring.

The Jena supremax glass gage was not entirely satisfactory either. In spite of its higher than Pyrex softening point its pointer was subject to some variation in zero position. The phosphorus pentoxide also finally disappeared into the glass walls although not so rapidly as in the quartz gage. The data obtained with this gage are shown in Fig. 3. No measurements could be obtained on the stable high temperature form. Curve b, Fig. 3, is almost identical with that of the amorphous form of Hoeflake and Scheffer. A reasonable explanation is that the phosphorus pentoxide suffered sufficient contamination by the supremax glass to prevent crystallization into the stable form.

Regardless of the glass used, the results obtained were not entirely above suspicion because some reaction with the walls occurred in all cases. This made measurements in a platinum system highly desirable.

Measurements with the Bulb Type Gage

Before building a gage from platinum, a series of measurements was made with the Pyrex bulb gages. This not only afforded an opportunity to study the reliability of the method, but offered an opportunity for comparing results obtained in the two types of gages made of the same material (Pyrex glass). There seems to be no systematic deviation between the observations obtained on the low temperature form with the two types. From necessity data on the bulb type gages had to be taken "on the fly" because if they were extended over too long a period the capillary tube would plug. The temperature of the furnace was consequently changing at a rate of about one to two degrees a minute during most readings. As a result the curves representing data taken during an increase in temperature will in general lie a degree or so higher than those representing the data taken during cooling. The mean, though, checks with the more static experiments of the Jackson gage.

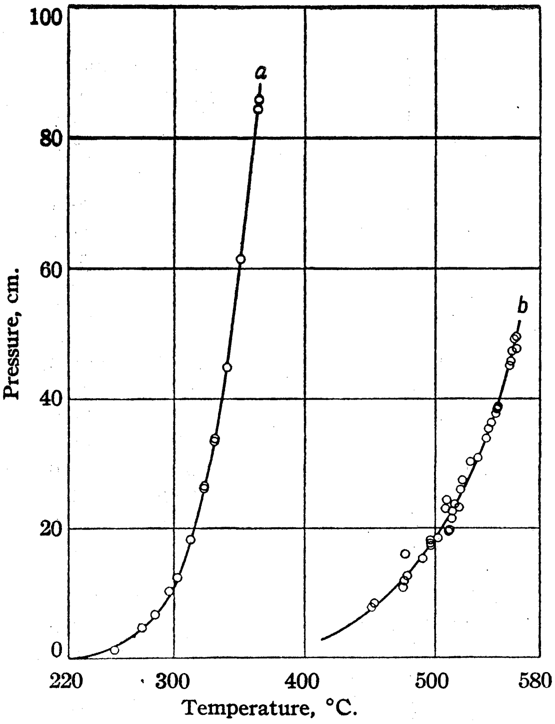

Fig. 3.—Vapor pressure of phosphorus pentoxide in supremax glass Jackson gage.

The platinum bulb gage presented a special problem in filling and sealing off, since dry phosphorus pentoxide cannot be handled in the open air. The upper end of the bulb was attached to a high vacuum system through the 30-cm. long platinum capillary tubes. The lower end of the bulb was provided with a short 1-mm. bore, gold lined, platinum capillary tube. To this was sealed a soft glass distillation apparatus which consisted of a bulb loaded with the pentoxide and but one intermediate bulb. The phosphorus pentoxide was first distilled under high vacuum into the intermediate bulb, the original container sealed off, and the phosphorus pentoxide finally distilled into the platinum bulb. These distillations were performed with the aid of an electrically heated tubular furnace at a temperature of about 300°. After the distillation, dry nitrogen was admitted to the system, the short platinum capillary was pinched shut and then sealed with gold. The bulb was then again evacuated to test for leaks and filled with dry nitrogen to a pressure of 15 to 20 cm.

The data obtained with the platinum bulb gage are presented in Fig. 4. They agree with the results obtained with the Pyrex Jackson gage on the two forms and in addition include five points which follow a curve assigned to the liquid phase by Hoeflake and Scheffer. The higher temperature measurements of August 20, 1936, obviously do not represent equilibrium since at one point the pressure rose from 90 to 110 cm. while holding the furnace temperature constant. This phenomenon took place in the course of about one hour. The possibility of such a pressure increase being due to a transition to another form having a higher vapor pressure is thermodynamically inconceivable. These data (of August 20) are included as being illustrative of the relative difficulty of obtaining equilibrium vapor pressure measurements on the high temperature form. Smits and Deinum (pp. 347, 348) experienced a similar difficulty and believed it to be due to lack of "internal equilibrium" between the postulated co-existent forms. If this had actually been the case it seems more reasonable that the pressure would have decreased rather than increased.

Results

The data obtained in this investigation together with those of previous workers are interpreted as showing that phosphorus pentoxide exists in two crystalline modifications. These are designated as the low temperature and high temperature forms, respectively.

The low temperature form has a vapor pressure which may be represented by equation (1)

$$\log_{10} p_{\text{cm.}} = -(5000/T) + 9.792 \qquad (1)$$

the high temperature form by equation (2)

$$\log_{10} p_{\text{cm.}} = -(7930/T) + 11.113 \qquad (2)$$

and the liquid by equation (3)

$$\log_{10} p_{\text{cm.}} = -(4320/T) + 6.809 \qquad (3)$$

Equation (1) gives 358.9° as the atmospheric sublimation temperature for the low temperature form. A temperature of 359.0° has been calculated from Hoeflake and Scheffer's[3] work by Frandsen.[8] Similarly the data of Smits and Deinum[2] give the three values 356.6, 362.0, 370.5° and the data of Smits and Rutgers 354.9 and 346.1°. The mean of these values based on the work of earlier investigators was thus estimated by Frandsen to be 358 ± 7°, which compares favorably with the value obtained here.

A solution of equations (2) and (3) determines the triple point between the liquid, high temperature solid form and gas as being at a pressure of 45.6 cm. and a temperature of 565.6°. The triple point pressure and temperature were found by Smits and Rutgers to be 0.59 atm. (44.8 cm.) and 563°; by Hoeflake and Scheffer to be 46 cm. and 569°; and by Smits and Deinum to be 55 cm. and 580°.

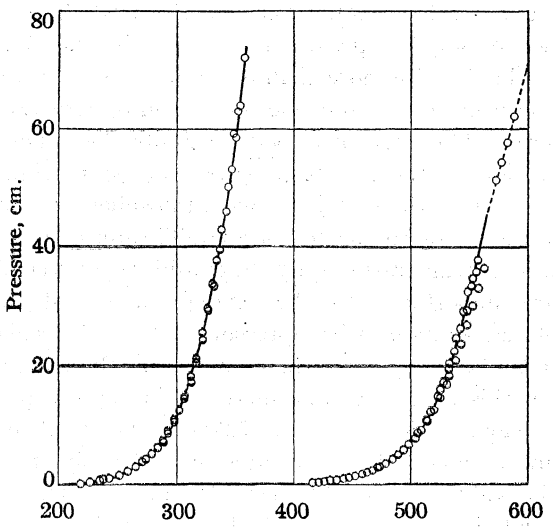

Fig. 4.—Vapor pressure of phosphorus pentoxide in platinum bulb gage: ———, vapor pressure of solid; - - - - - -, vapor pressure of liquid.

The heats of vaporization per gram molecule are determined from eq. (1) and (3) as 22,800, 36,200, 19,700 calories for the low temperature form, high temperature form and liquid, respectively. The heat of fusion is thus 16,500 cal. The only available calorimetric heat of vaporization work is that of Frandsen[8] on the low temperature form. He obtained the value 8800 ±1300 cal. per gram formula weight of phosphorus pentoxide.

To compare this calorimetric value with that calculated from the vapor pressure data it is necessary to have some knowledge of the molecular weight of the vapor. Vapor density determinations by West[9] at 1400° indicate a molecular weight of about 300, while measurements by Tilden and Barnett[10] at about 1000° range from 307 to 370. The molecular formula most nearly approaching these values is P_4O_{10} with a gram molecular weight of 284. The errors inherent in the vapor density determinations are such that they cannot definitely be said to disagree with this formula. However, the possibility

(10) Tilden and Barnett, *ibid.*, **69**, 154 (1896).

that the vapor is an equilibrium mixture of several forms must be considered. The composition of such a mixture would necessarily depend on the pressure, which in this case is the vapor pressure. Any wide variation in this composition would be reflected in the heat of vaporization, which would result in abnormal curvature of a log p *vs.* $1/T$ plot. The experimental data do not reasonably permit a variation in the slope of this line by more than a few per cent. between one atmosphere and one-tenth atmosphere pressure. This lack of curvature limits the concentration of the lowest polymer (P_8O_{20}) to something less than 5% at one atmosphere, if the variation of the association equilibrium constant in this temperature range be considered of secondary importance to the change of the degree of association with pressure. The molecular formula P_4O_{10} must therefore be nearly correct. On this basis the calorimetric value of the heat of vaporization becomes 17,600 ± 2,600 cal. per gram mole. This deviates considerably from the value 22,800 obtained here and 22,600 calculated from the data of Hoeflake and Scheffer.

Considerable importance is attached to the fact that phosphorus pentoxide vapor will condense only as the low temperature form. This indicates, at least, that the transition occurs only through the solid phase.

Acknowledgments.—The authors are indebted to P. H. Emmett, S. B. Hendricks, R. T. Milner and P. H. Royster for their advice and encouragement. Special mention should be made of the skillful glassblowing of Leonardo Testa in the construction of the Jackson type gages.

Summary

1. The vapor pressure of phosphorus pentoxide has been found to be entirely reproducible and independent of the rate of distillation of the sample.

2. The data are interpreted to show that phosphorus pentoxide exists in a low temperature and a high temperature crystalline form and as a liquid. The atmospheric sublimation temperature of the low temperature form was found to be 358.9°. The triple point between the high temperature crystalline form, the gas and the liquid was found to be at a pressure of 45.6 cm. of mercury and at a temperature of 565.6°. The rate of transition from the low to the high temperature form is undetectable below 360°.

Aging of Fresh Precipitates. XII. The Equilibrium between Mixed Crystals of Silver Chloride and Bromide and Solutions

BY H. C. YUTZY[1] AND I. M. KOLTHOFF

It is well known[2] that solid silver chloride and bromide form a complete series of mixed crystals. Küster,[3] preparing the mixed crystals by precipitation from solutions at 19°, was the first to study the equilibrium conditions existing between solid and solution. Various studies, more or less related to the subject, are found in the literature.[4–6] In connection with a study of the aging of precipitated silver chloride it was desirable to know the equilibrium conditions of distribution at 27 and 98°.

The relation between the distribution constant K and the composition of the liquid and the solid phase is found from the following considerations.

$$\mathrm{Cl}^- \text{ (crystal)} + \mathrm{Br}^- \text{ (solution)} \rightleftarrows \mathrm{Br}^- \text{ (crystal)} + \mathrm{Cl}^- \text{ (solution)}$$

in which Cl (crystal) and Br (crystal) denote the chloride and bromide in the mixed crystals. At equilibrium it is found that

$$K' = \left(\frac{a\ \mathrm{Br}^-}{a\ \mathrm{Cl}^-}\right)_{\text{crystal}} \left(\frac{a\ \mathrm{Cl}^-}{a\ \mathrm{Br}^-}\right)_{\text{solution}} = \left(\frac{f_{\mathrm{Br}^-}\ N_{\mathrm{Br}^-}}{f_{\mathrm{Cl}^-}\ N_{\mathrm{Cl}^-}}\right)_{\text{crystal}} \left(\frac{f_{\mathrm{Cl}^-}\ N_{\mathrm{Cl}^-}}{f_{\mathrm{Br}^-}\ N_{\mathrm{Br}^-}}\right)_{\text{solution}} \qquad (1)$$

in which a represents the activity of the particular component, f the activity coefficient, N the mole fraction. With the justifiable assumption that $f_{\mathrm{Cl}^-} = f_{\mathrm{Br}^-}$ in the solution (or that their ratio is constant over a wide range of ionic strengths) expression (1) can be written as

$$\left(\frac{\text{moles Br}^-}{\text{moles Cl}^-}\right)_{\text{crystal}} \left(\frac{\text{moles Cl}^-}{\text{moles Br}^-}\right)_{\text{solution}} = K' \left(\frac{f_{\text{Cl}^-}}{f_{\text{Br}^-}}\right)_{\text{crystal}} = K \quad (2)$$

K being called the distribution coefficient.

The value of K calculated by Küster[3] from his experiments was found to vary continuously with the composition of the precipitate. On the basis of equation (2) this variation is attributed to deviations from the ideal state in the solid as exemplified by a variation of the ratio of $(f_{\text{Cl}^-}/f_{\text{Br}^-})$ solid.

The above expressions and the method of approach which are given in the thesis[1] are almost identical with those described by Flood[7a] and Flood and Bruun.[7b] In addition, the latter authors concluded that K is equal to the ratio of the solubility products and equal to K' at a mole ratio of chloride to bromide in the solid of 1.

Experimental

In previous work, mainly that of Küster, analysis of the system was made by filtering off the mixed crystals, and analyzing them by use of the classical indirect gravimetric method—one admittedly inaccurate when the ratio of chloride to bromide is very large or very small. In our experiments, the residual bromide in the aqueous solution was determined by the method of D'Ans and Höfer,[8] with slight modifications.[9] Since the amounts of the various constituents which had been added were known, this allowed the calculation of the compositions of the two phases. This procedure enabled us to analyze with fair accuracy systems in which the gravimetric method would be extremely inaccurate. The reagents used were all reagent grade, ground and dried. The solutions were made up in distilled water and analyzed; the silver nitrate and chloride solutions gravimetrically, the bromide solutions by the above volumetric method. Application of the latter method to the sodium chloride showed that this salt contained less than 0.003% NaBr.[9]

Quite generally the experiments were performed by adding a measured volume of standard silver nitrate to a mixture of a chloride and bromide solution of known composition. After precipitation the solution was made up with water to a known volume and the suspensions shaken for various periods of time. After a given time the bromide content of the solution was determined in the centrifugate. Changes in the order of addition of the reagents have been made in order to see whether the same equilibrium was found when starting under different conditions.

Since Küster[3] did not make sure that he had reached equilibrium (in some experiments he stirred for only two and one-half hours) his experiment number 11 was repeated, adhering closely to his directions but extending the time of shaking from two and one-half hours to one week and analyzing for bromide by our method. Over this period of time the final bromide concentration remained constant (3.6×10^{-3} M), indicating that in this particular case equilibrium was reached within two and one-half hours of shaking. From the results a value of $K = 488$ (19°) was calculated, whereas Küster reported $K = 469$, a satisfactory agreement.

Küster always used a total volume of 1000 ml., whereas in our later work a volume of 100 or 225 ml. of suspension was used. Therefore it was thought desirable to make a few experiments at 19° using a volume of 100 ml. of suspension. After precipitation the suspension was shaken for three days and an aliquot part of the supernatant liquid analyzed for bromide. As an example of the calculations, the composition of the solutions and the derived values are given in Table I. In these cases 25 ml. of 0.2791 M silver nitrate was added to the chloride–bromide mixture.

TABLE I

EQUILIBRIUM AT 19°. TOTAL VOLUME 100 ML.

2 M NaCl, taken, ml.	0.1 M KBr taken, ml.	Millimoles at equilibrium Cl^- in soln.	 Cl^- in ppt.	 Br^- in soln.	 Br^- in ppt.	Mole fraction AgBr in solid	K
25	35	46.4	3.58	0.103	3.40	0.487	428
10	55	18.4	1.60	.115	5.38	.772	538

The corresponding values of K, interpolated from Küster's data, are 410 and 525, respectively. Apparently, there is no appreciable effect of volume changes upon the value of K. A tenfold change in volume resulted in values agreeing within the experimental error. This agreement justifies our assumptions that the variation of K is not to be attributed to a change of the ratio of the activity coefficients of chloride and bromide in solutions but to a change of the ratio in the solid, when the composition of the latter is altered.

Equilibrium at 27 ± 1°

In the first set of experiments a measured volume of 0.2791 M sodium chloride was introduced into a 250-ml. brown glass bottle, then equal volumes of water and of 0.2791 M silver nitrate were added, the latter as the solution was stirred vigorously. After stirring for two minutes, measured volumes of more concentrated sodium chloride and of potassium bromide were added and, if necessary, water to make the volume up to 225 ml. The glass stopper was put in place, sealed in with paraffin and the bottle shaken violently for a given period of time at 27 ± 1°. The bromide concentration in the centrifugate was determined by the volumetric method. For the sake of brevity, only the mole percentages of bromide in the solid, the final bromide concentration in the solution and the values of K after various periods of shaking are reported in Table II. For details about the composition of the original suspension and the analyses the reader is referred to the thesis of the junior author.[1] In all cases equilibrium was established within twenty-four hours of shaking. It should be noted that a small error in the determination of the final bromide concentration has a relatively large effect upon the value of K. This is especially true when the final bromide concentration is extremely small as in series IV where it was of the order of 3×10^{-6} M. At this small concentration the analytical determination is accurate

[a] In Series III and VI the solubility of the small amount of precipitate in the strong sodium chloride solution has been considered. Estimated from the data of Forbes and Cole[10] the solubility of silver chloride in 0.88 *M* sodium chloride is about 7×10^{-5} *M*. Application of a corresponding correction resulted in a change in K of only 3 to 4%. The solubility of the mixed crystals is smaller than that of silver chloride; since the above calculation yielded only a small correction for K it was not necessary to consider the solubility of the mixed crystals instead of that of silver chloride.

to only 10%. With a final bromide concentration of 2×10^{-5} *M* the method is accurate to 1%. Series I was repeated in the presence of nitric acid, the concentration of the acid in the suspension being 0.04 *M*, the same as used by Küster. The time–distribution curve of the bromide was practically identical with that in series IV, the final mole fraction of silver bromide in the solid being 0.00707 and K equal to 227.

Series I was repeated but instead of starting with a fresh precipitate of pure silver chloride the silver nitrate was added to a mixture of 25 ml. 0.2791 *M* sodium chloride, 50 ml. of 0.01 *M* potassium bromide and 25 ml. of water. After precipitation the conditions were made identical with those of series I. The time–distribution curve became practically identical with that of Series I after twenty-four hours; the final mole fraction of silver bromide in the solid being 0.0635 and K equal to 240. Series IV was also repeated in this way—precipitating together the mixture of chloride and bromide. Again, the time–distribution curve was practically identical with that of Series IV, the final mole fraction of silver bromide in the solid being 0.00707 and the final bromide concentration in the solution 2.8×10^{-6} *M* and K equal to 227. From these experiments it is evident that in all cases a true state of equilibrium was reached as the same final values were found, whether the original solid phase was pure silver chloride or a mixed crystal containing virtually all the bromide in the system.

The results of the determination of K at higher mole fractions of silver bromide are reported in Table III. In all cases 25 ml. of 0.2791 *M* silver nitrate corresponding to 1 g. of silver chloride was used as precipitating agent. After mixing of the reagents and making up to the indicated volume with water, the suspensions were shaken for one week at 27 ± 1°, centrifuged and the supernatant solutions analyzed for bromide. Equilibrium was approached from two sides, starting either with fresh silver bromide (a) or silver chloride (b). In all cases, except in the last sets in which the final mole fraction of bromide was very large (0.925), the true state of equilibrium was practically reached after a week of shaking.

With the high mole fraction of bromide in the precipitate true equilibrium was not reached after a month of shaking, although it seems to have been approached closely after one week when starting with silver bromide. In the latter case inhomogeneous mixed crystals too rich in chloride are formed during the early stages of aging as a result of recrystallization. Upon further aging these inhomogeneous crystals recrystallize faster than those formed in the reverse precipitation which soon become too rich in bromide and have a smaller solubility than the mixed crys-

[a] Silver nitrate added to the bromide, then chloride added. [b] Silver nitrate added to the chloride, then bromide added. [c] Shaken for one month instead of one week. [d] Not at equilibrium.

tals containing more chloride. Moreover, freshly precipitated silver bromide has a larger surface than a similar precipitate of silver chloride, the larger surface of the former favoring more rapid recrystallization. It may be noticed that in the last four cases reported in Table III the mole fractions of silver bromide in the solid are practically the same. Thus the same value of K would have been found in these four cases, if the analyses had been made according to the indirect method of Küster;[3] evidently the amount of bromide left in the solution is a much more sensitive indicator of the state of equilibrium. In order to ascertain that equilibrium had been reached in most of the experiments previously reported, a series of experiments was run by precipitating the bromide first and performing the shaking for one week in a medium 1 M in ammonia. The latter is a fair solvent for silver halides and hence should promote recrystallization. In the final analyses the amount of dissolved silver was determined by precipitation and weighing as silver iodide and was taken into account in the calculation of the composition of the solid. For the sake of brevity the details[1] are not reported separately, but the results are included in Table IV, the latter giving a summary of all the data found. From the good agreement it may be concluded that the figures reported in Table III and obtained by the method of precipitation "a" (Tables II, III and IV) correspond to the state of true equilibrium and that ammonium does not affect the value of K.

TABLE IV

EQUILIBRIUM VALUES OF K AT 27 ± 1°

Mole fr. of AgBr	0.00707	0.0362	0.0635	0.0674	0.0768
K	204	224	235	252	239
Mole fr. of AgBr	0.102	0.338	0.483	0.697	0.768
K	257[x]	327	354	395[x]	426
Mole fr. of AgBr	0.770	0.913	0.917	0.925	0.923
K	441	476[y]	466[z]	457[y]	473[y,z]

[x] In 1 M ammonia. [y] Silver bromide precipitated first, one week of shaking. [z] One month of shaking.

In Fig. 1 the values of K are plotted against the mole fraction of silver bromide in the solid. Within the experimental error K is found to increase linearly with the mole fraction N_{AgBr} of silver bromide in the solid. The values of K calculated from Küster's data at 19° have also been plotted in a similar way.

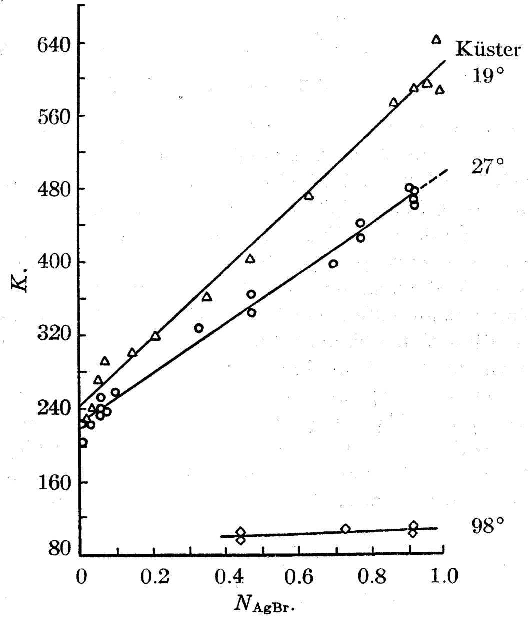

Fig. 1.—Value of K as function of N_{AgBr} at 19 (Küster), 27 and 98°.

The Value of K at 98°.—The experiments were carried out in a similar way to that reported in Table III. Immediately after precipitation and making up to volume, the bottles were heated in a water-bath to 100° (five to ten minutes), stoppered with collodion coated corks and placed in a rotator in an oven held at 98 ± 2° for a week. Then the bottles were cooled, centrifuged and samples taken for analysis for bromide. The results are given in Table V and also plotted in Fig. 1.

TABLE V

EQUILIBRIUM VALUES OF K AT 98 ± 2°. TOTAL VOLUME, 100 ML.

Order of pptn.	Total halide in system Cl⁻, mm.	Total halide in system Br⁻, mm.	Final amt. of bromide in soln. in millimoles	Mole fraction of AgBr in solid	K	$K_{\text{av.}}$
a	50	3.5	0.382	0.447	98	100
b	50	3.5	.367	.448	103	
a	20	5.5	.447	.724	106	106
b	20	5.5	(.397)	(.730)	(124)	
a	2.0	6.5	.139	.913	102	106
b	2.0	6.5	.132	.914	110	

[a] Silver nitrate added to bromide, then chloride added.
[b] Silver nitrate added to chloride, then bromide added.

Evidently, practically the same values were obtained independent of the manner of precipitation, indicating that distribution equilibrium had been obtained in all cases. At mole fractions of silver bromide between 0.45 and 0.91 a constant value of K of 104 ± 4 was found within the experimental error.

TABLE VI

COMPARISON OF K WITH RATIO OF SOLUBILITY PRODUCTS AND SOLUBILITIES OF SILVER CHLORIDE AND BROMIDE

Medium	t, °C.	S. P. AgCl	S. P. AgBr	sol. $\frac{\text{AgCl}}{\text{AgBr}}$	$\frac{\text{S. P. AgCl}}{\text{S. P. AgBr}}$	K	N_{AgBr}
Water	25	1.70×10^{-10}(12,13)	6.4×10^{-13}(12)	16.3	265	374[a]	0.5
						265[a]	.15
Water	100	2.10×10^{-8}(14)	3.25×10^{-10}	8	65	104	.45–0.9
Ethanol	25	1.16×10^{-14}(15)	1.06×10^{-16}				
		0.92×10^{-14}(16)	0.76×10^{-16}	10.8	116	110	.069

[a] Estimated from our data at 27°.

Experiments in Ethanol at 27 ± 2°.—A few experiments were made in absolute ethanol instead of in water as a liquid medium. Silver chloride was precipitated from aqueous medium at 27°, washed with water and then with absolute ethanol. After air had been drawn through to remove most of the adhering liquor the precipitate was divided among several bottles containing 210 ml. of a solution in absolute ethanol, 0.00237 M in sodium bromide and 0.466 M in lithium chloride. The bottles were shaken for various periods of time at 27° and centrifuged. The bromide was determined in the solution and silver in the precipitate. The values of K calculated from the results after various periods of shaking were 27.9 after two hours, 64.4 after a day and 109.5 after nine weeks. The mole fraction of silver bromide in the precipitate after nine weeks was 0.069.

Discussion

1. From the results reported in Table II it is seen that upon shaking of freshly precipitated silver chloride with an aqueous solution containing chloride and bromide a maximum is found in the amount of bromide in the precipitate after a certain period. During the early stages of aging, heterogeneous mixed crystals too rich in bromide are formed which eventually become homogeneous after repeated recrystallizations upon subsequent shaking. Qualitatively, the phenomenon is comparable to the heterogeneous distribution of thorium B through lead sulfate during the early stages of aging of the latter,[11] although in the latter case no maximum was found.

2. If silver chloride and bromide would form an ideal system of solid solutions it is easily derived (compare Flood and Bruun[7]) that under equilibrium conditions

$$\left(\frac{a\ \text{Cl}^-}{a\ \text{Br}^-}\right)_{\text{solution}} \left(\frac{N\ \text{Br}^-}{N\ \text{Cl}^-}\right)_{\text{solid}} = \frac{\text{S. P. AgCl}}{\text{S. P. AgBr}} = K'$$

(compare eq. 1 and 2)

In this equation mole fractions have been written instead of activities in the solid state, whereas S. P. denotes the solubility (activity) product. Actually it is seen from Fig. 1 that at 19 and 27° K increases with increasing mole fraction of bromide in the solid, the slope of the line being less at 27° than at 19°. It appears that the system approaches an ideal one with increasing temperature and it seems to behave as such at 98°.

In Table VI are given the ratios of the solubilities and of the solubility products of silver chloride and bromide in water at 25 and 100° and in ethanol at 25°. In water at 100° and in ethanol at 25° ($N_{\text{AgBr}} = 0.069$) the agreement between K and the ratio of the solubility products is within the experimental error. In water at 27° K is a linear function of the mole fraction of silver bromide in the solid, the value of K found being equal to the ratio of the solubility products at $N_{\text{AgBr}} = 0.15$.

3. Although according to Hildebrand's[17] own statement it is doubtful whether the system silver chloride–bromide can be considered as a "regular solution,"[18] this concept was applied by Flood and Bruun[7] to this particular case. On this basis it was inferred by the latter authors that log K should be a linear function of N_{AgBr}. They plotted log K *versus* $(2N_{\text{AgBr}} - 1)$ for Küster's data and actually found the relation $\log K = 0.19\ (2N_{\text{AgBr}} - 1)$ to hold within the experimental error. Our own data at 27° give a slope of 0.17, although our experimental data fit better the simple relation $K = K_0 + aN$, as plotted in Fig. 1.

Using the equations given by Hildebrand[18] (pp. 69, 70) in describing a regular solution, we may calculate the slope, approximately, in the following way. According to Hildebrand

$$RT \ln a_2/N_2 = bN_1^2 = RT \ln \gamma_2 \qquad (3)$$

$$\overline{H}_1 = bN_2^2;\ \overline{H}_2 = bN_1^2 \qquad (4)$$

in which γ is the activity coefficient, $\overline{H}$ partial

molal heat of mixing, b a constant, N the mole fraction in the mixed crystal.

From the above relations and the conventional between partial molal quantities it is found that

$$b = H/N_1N_2 \qquad (5)$$

in which H is the heat of mixing per mole.

From equation (2) in the present paper it is found that

$$\log K = \log K' + \log (f_{\text{Cl}}/f_{\text{Br}})_{\text{crystal}} \qquad (6)$$

From Hildebrand's expressions it follows that

$$RT \ln f_{\text{Cl}} = bN^2_{\text{Br}}$$
$$RT \ln f_{\text{Br}} = bN^2_{\text{Cl}}$$

and

$$\log_{10}\left(\frac{f_{\text{Cl}}}{f_{\text{Br}}}\right) = \frac{0.4343b}{RT}(2N_{\text{Br}} - 1) \qquad (7)$$

Combination of equations (6) and (7) leads to

$$\log K = \log K' + \frac{0.434b}{RT}(2N_{\text{Br}} - 1) \qquad (8)$$

Hence, if log K is plotted as a function of $(2N_{\text{AgBr}} - 1)$, the slope of the line should be

$$\frac{0.4343b}{RT} = \frac{0.4343}{RT}\,\frac{H}{N_1N_2}$$

Eastman and Milner[6] give the change in heat content in the formation of one mole of a mixed crystal, in which $N_{\text{AgBr}} = 0.728$ and $N_{\text{AgCl}} = 0.272$ as 81 ± 10 calories.

Taking this as the heat of mixing the calculated slope is

$$\frac{0.4343}{1.99 \times 298} \times \frac{81}{0.728 \times .272} = 0.30 \pm 0.04$$

The calculated value deviates from the experimentally found slope (0.19 Küster, 18°; 0.17 Yutzy and Kolthoff, 27°) by more than the estimated error. Thus the consideration of the solid phase as a "regular solution" seems questionable.

Summary

1. The distribution coefficient K of bromide between solution and mixed crystals of silver chloride and bromide has been determined at 27 and 98° in aqueous medium and at one mole fraction of silver bromide in ethanol at 27°.

2. At 27° K changes as a linear function of the mole fraction of silver bromide in the solid. Evidence has been given that the mixed crystals cannot be considered as "regular solutions." At 98° the value of K becomes practically independent of N_{AgBr}, and the solid approaches the behavior of an ideal solution.

3. The value of K is approximately equal to the ratio of the solubility products as pointed out by Flood and Bruun[7] and not to the ratio of the solubilities of the components.

MINNEAPOLIS, MINN. RECEIVED FEBRUARY 1, 1937

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF CALIFORNIA]

The Heat Capacity of Silver Nitrite from 15 to 300°K. The Heat of Solution at 298°K. of Silver Nitrite, Barium Nitrate and Thallous Nitrate. The Entropy of Silver Nitrite, Thallous Ion, Nitrate Ion and Nitrite Ion

BY OLIVER L. I. BROWN, WENDELL V. SMITH AND WENDELL M. LATIMER

The determination of the entropy of silver nitrite enables a calculation to be made of the entropies of both nitrate and nitrite ions. The entropy of nitrate ion can also be obtained by three other independent methods, making use of existing data on sodium nitrate, potassium nitrate and barium nitrate, combined with a value of the heat of solution obtained in this investigation. In the present paper we shall also present two methods of calculating the entropy of thallous ion.

Material.—The silver nitrite was a C. P. sample prepared in this Laboratory. It was recrystallized from distilled water and the product dried in a vacuum desiccator for several days. The final product was analyzed for nitrite by titration with permanganate solution, and for silver by thermal decomposition. Calcd. Ag, 70.10; nitrite, 29.90. Found: Ag, 69.89, 69.95, 69.90, 69.96; nitrite, 29.79, 29.74. The barium nitrate was a Mallinckrodt reagent grade sample, which was dried and used without further purification. The thallous nitrate was the same as that used by Latimer and Ahlberg.[1]

Heat Capacity Measurements.—The experimental method followed the general procedure described by Latimer and Greensfelder.[2] Specific

heat measurements were made on a sample weighing 103.893 g. *in vacuo* (0.67511 mole). One calorie was taken equal to 4.1833 int. joules. The heat capacities near the melting point of water showed the presence of 0.12% of water in the sample, in spite of the precautions taken to exclude it. The final heat capacities were corrected for this amount of water, even though the correction was small.[3] The results are summarized in Table I, and shown graphically in Fig. 1.

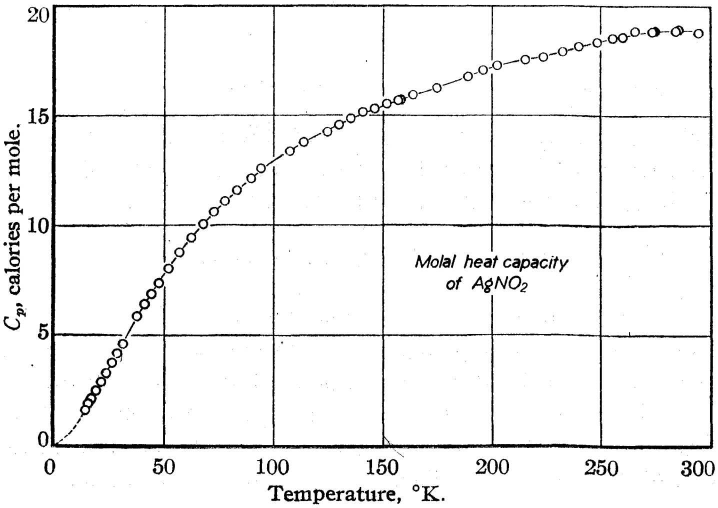

Fig. 1.—Molal heat capacity of silver nitrite.

Entropy of Silver Nitrite.—The entropy of silver nitrite at 298.1°K. was evaluated by graphical integration of the heat capacity data, combined with an analytical integration between 0° and 14.36° using the Debye specific heat equation. The result is summarized in Table II.

Table II

Molal Entropy of Silver Nitrite

0–14.36°K.	Debye extrapolation	0.55
14.36–298.1°K.	Graphical from data	30.07 ± 0.1
	Entropy at 298.1°K.	30.62 e. u.

Heat of Solution of Silver Nitrite.—We wish to acknowledge our indebtedness to Mr. Kenneth S. Pitzer whose work has enabled us to obtain an accurate value for this heat of solution. The work of Abegg and Pick[4] indicates that silver nitrite is not completely dissociated even in dilute solution so that a direct determination of the heat of solution does not give the quantity desired because of the very large uncertainty in the heat of dissociation and dilution. However, the heat of solution at infinite dilution can be obtained from the following three heats: (1) the heat of solution of silver nitrite in a dilute ammonia solution, (2) the heat of solution of silver nitrate in the dilute ammonia solution, and (3) the heat of solution of silver nitrate in an infinite amount of water. Adding (1) and (3) and subtracting (2) gives the heat of solution of silver nitrite in an infinite amount of water if one assumes that the heat effect going from nitrite ion in dilute ammonia solution to nitrite ion in an infinite amount of water is the same as that for nitrate ion. The heat of solution of silver nitrite in 0.14 *M* ammonia to form a 0.01 *M* solution was found to be −8020 ± 60 cal. Combining this with the heats for the other reactions[5] the heat of solution of silver nitrite at infinite dilution is found to be 10,070 ± 100 cal.

Entropy of Nitrite Ion.—Abegg and Pick[4] determined the solubility of silver nitrite at 298.1°K. and found a value of 2.0×10^{-4} for the equilibrium constant, from which $\Delta F^\circ_{298.1}$ of solution is 5050 cal. The entropy of solution is, therefore, $\Delta S^\circ = (10{,}070 - 5050)/298.1 = 16.8$ e. u. The entropy of silver ion[6] is 18.4, so that the entropy of nitrite ion is $S^\circ = 30.6 + 16.8 - 18.4 = 29.0$ e. u.

Heat of Solution of Barium Nitrate and Thallous Nitrate.—The integral heat of solution of

---

barium nitrate in 614 moles of water at 298.1°K. was determined using the calorimeter previously described.[7] Two determinations gave 9256 and 9236 cal. per mole. Combining the average value with the known heat of dilution,[8] the heat of solution at infinite dilution was found to be 9496 cal. per mole. We are greatly indebted to Mr. Kenneth S. Pitzer who has measured the heat of solution of thallous nitrate in 5000 moles of water at 298.1°K. and found a value of 10,050 ± 50 cal. per mole. Combining this value with an estimated heat of dilution we find the heat of solution at infinite dilution to be 10,020 cal. per mole.

Entropy of Nitrate Ion.—The reaction

$$2AgNO_2(s) = Ag^+ + NO_3^- + Ag(s) + NO(g) \quad (1)$$

has been studied by Abegg and Pick[4] and by Lewis and Adams.[9] The free energy change in this reaction at 298.1°K. has been fairly well established by these workers, but the $\Delta H°$ of the reaction which is necessary in computing the entropy change was not known with sufficient accuracy. Consequently, Randall, Manov and Brown[10] have studied the equilibrium reaction (2) and from the

$$2AgNO_2(s) = Ag(s) + AgNO_3(s) + NO(g) \quad (2)$$

change of equilibrium pressure with temperature have determined the $\Delta H^\circ_{298.1}$ of reaction (2) to be 14,040 cal. Combining this with the heat of solution of silver nitrate in an infinite amount of water[5] 5360 ± 50 cal./mole we find $\Delta H^\circ_{298.1}$ for reaction (1) to be 19,400 cal./mole. An extrapolation of the equilibrium measurements of Lewis and Adams and Abegg and Pick yields an average $\Delta F^\circ_{298.1} = 3600$. The entropies of nitric oxide,[11] silver,[12] and silver ion[6] are 50.4, 10.2 and 18.4 e. u., respectively, so that the entropy change of the reaction, and the entropy of nitrate ion are given by the expressions

$$\Delta S^\circ = (\Delta H^\circ - \Delta F^\circ)/T = (19{,}400 - 3600)/298.1 = 53.0 \text{ e. u.}$$

$$S^\circ_{NO_3^-} = \Delta S^\circ + 2S^\circ_{AgNO_2} - S^\circ_{Ag} - S^\circ_{Ag^+} - S^\circ_{NO(g)} = 35.2$$

Latimer and Ahlberg[13] determined the entropy of barium nitrate and calculated the entropy of nitrate ion. The principal uncertainties in their calculation were the entropy of barium ion, and the heat of solution of barium nitrate. The entropy of barium ion has recently been more accurately evaluated,[7] and with the heat of solution determined as described above, permits an accurate calculation of the entropy of nitrate ion. The entropy of solution and the entropy of nitrate ion are given by the expressions

$$\Delta S^\circ = (\Delta H^\circ - \Delta F^\circ)/T = (9496 - 3200)/298.1 = 21.1 \text{ e. u.}$$

$$S^\circ_{NO_3^-} = {}^1/_2(\Delta S^\circ + S^\circ_{Ba(NO_3)_2} - S^\circ_{Ba^{++}}) = {}^1/_2(21.1 + 51.1 - 2.2) = 35.0 \text{ e. u.}$$

The entropy of nitrate ion can be determined by a third independent method. The entropy of sodium nitrate[14] is 27.87 ± 0.08 e. u. The activity coefficient of sodium nitrate[15] at saturation (10.83 *M*) and a temperature of 298.1°K. is 0.355. The free energy of solution is then $\Delta F^\circ_{298.1} = -1363.8 \log (10.83 \times 0.355)^2 = -1596$ cal./mole. The heat of solution of sodium nitrate in an infinite amount of water at 291.1°K. is given by Bichowsky and Rossini[16] as 5051 cal./mole. Correcting this value to 298.1, using Rossini's[17] value for the partial molal heat capacity of sodium nitrate, we obtain $\Delta H^\circ_{298.1} = 4810$ cal./mole. The entropy of sodium ion[6] is 14.7 e. u., so that the entropy of solution and the entropy of nitrate ion are given by the expressions

$$\Delta S^\circ = (\Delta H^\circ - \Delta F^\circ)/T = (4870 + 1596)/298.1 = 21.5$$

$$S^\circ_{NO_3} = \Delta S^\circ + S^\circ_{NaNO_3} - S^\circ_{Na^+} = 21.7 + 27.9 - 14.7 = 34.7 \text{ e. u.}$$

The entropy of nitrate ion can be determined by still another method, which is independent of the three already described. The entropy of potassium nitrate[14] is 31.77 ± 0.10 e. u. The solubility in water[18] at 298.1°K. is 3.74 *M*, while the activity coefficient[19] at saturation is 0.233. The free energy of solution is then $\Delta F^\circ_{298.1} = 163$ cal./mole. The heat of solution in an infinite amount of water[16] at 291.1°K. is 8633 cal./mole. Correcting this value to 298.1°K., using Rossini's[17] value for the partial molal heat capacity of potassium nitrate, we obtain $\Delta H^\circ_{298.1} = 8341$ cal./mole. The entropy of potassium ion[3] is 24.2 e. u., so that the entropy of solution and the entropy of nitrate ion are given by the expressions

$$\Delta S^\circ = (\Delta H^\circ - \Delta F^\circ)/T = (8341 - 163)/298.1 = 27.4$$

$$S_{NO_3^-} = \Delta S^\circ + S^\circ_{KNO_3} - S^\circ_{K^+} = 27.4 + 31.8 - 24.2 = 35.0 \text{ e. u.}$$

The average value of $S^\circ_{NO_3^-}$ is then 35.0 ± 0.1 e. u.

The Entropy of Thallium Ion.—Latimer and Ahlberg[20] determined the entropy of thallous nitrate and calculated a value for nitrate ion. Since the entropy of nitrate ion is now known with greater exactness than the entropy of thallous ion, and particularly since any large uncertainty in the heat of solution of thallous nitrate has been removed by the measurements of Mr. K. S. Pitzer referred to above, we believe it preferable to calculate a value for the entropy of thallous ion. The entropy of solution of thallous nitrate and the entropy of thallous ion are given by the expressions

$$\Delta S^\circ = (\Delta H^\circ - \Delta F^\circ)/T = (10{,}020 - 1790)/298.1 = 27.6 \text{ e. u.}$$

$$S^\circ_{Tl^+} = \Delta S^\circ + S^\circ_{TlNO_3} - S^\circ_{NO_3^-} = 27.6 + 38.1 - 35.0 = 30.7$$

Another value for the entropy of thallous ion can be calculated from the electromotive force measurements of Cowperthwaite, La Mer and Barksdale.[21] These authors find for the reaction

$$\text{Tl(s)} + \text{AgCl(s)} = \text{Ag(s)} + \text{Tl}^+ + \text{Cl}^-,\ \Delta F^\circ_{298.1} = -12{,}877 \text{ cal.},\ \Delta H^\circ_{298.1} = -8307 \text{ cal.}$$

The entropies of Tl(s),[12] AgCl(s),[12] Ag(s),[12] and Cl$^-$[6] are, respectively, 15.5 ± 0.1, 23.0 ± 0.1, 10.2 ± 0.1 and 13.5 ± 0.1 e. u. The entropy change of the reaction and the entropy of thallous ion are given by the expressions

$$\Delta S^\circ = (\Delta H^\circ - \Delta F^\circ)/T = (-8307 + 12{,}877)/298.1 = 15.3$$

$$S^\circ_{Tl^+} = \Delta S^\circ + S^\circ_{Tl(s)} + S^\circ_{AgCl(s)} - S^\circ_{Ag(s)} - S^\circ_{Cl^-} = 15.3 + 15.5 + 23.0 - 10.2 - 13.5 = 30.1 \text{ e. u.}$$

The values previously calculated for thallous ion[6] have involved considerably greater uncertainties in the entropy and heat of reaction data than the two values calculated here. We therefore recommend the average value $S^\circ_{Tl^+} = 30.4$ e. u.

The Free Energy of Nitrate Ion.—Since the heat of formation of nitrate ion has been determined with considerable accuracy,[22] it can be combined with the entropy of formation to obtain a reliable value for the free energy of formation. Becker and Roth obtain −49,020 ± 80 cal. for the heat of formation from the elements at 293°K. of one mole of nitric acid in 1079 moles of water. Correcting this to infinite dilution and 25° gives $\Delta H^\circ_{298.1} = -49{,}290$ cal. for the heat of formation of nitrate ion. The entropy of formation of nitric acid at 25° is

$$\Delta S^\circ = S_{H^+} + S_{NO_3^-} - \frac{1}{2} S_{N_2} - \frac{3}{2} S_{O_2} - \frac{1}{2} S_{H_2} =$$

$$0 + 35.0 - \frac{1}{2}\,45.79^{23} - \frac{3}{2}\,49.03^{24} - \frac{1}{2}\,31.23^{25} = -77.1$$

Thus, the free energy of formation of nitrate ion from its elements is $\Delta F^\circ_{298.1} = -26{,}310 \pm 90$ cal. The value given by Lewis and Randall[26] is −26,500 cal., which agrees with our value within the limits of accuracy of their calculation.

Summary

The heat capacity of silver nitrite has been determined from 15 to 300°K. The entropy of silver nitrite has been calculated at 298.1°K. The entropy of nitrite ion has been determined as 29.0 e. u. The entropy of nitrate ion has been calculated by four independent methods and the values 35.2, 35.0, 34.7 and 35.0 e. u. obtained. The entropy of thallous ion has been calculated by two independent methods and the values 30.7 and 30.1 e. u. obtained. The heats of solution of silver nitrite, barium nitrate and thallous nitrate at 298.1°K. have been determined. The free energy of formation of nitrate ion at 298.1°K. has been calculated to be −26,310 cal.

Diarsyls. IX. Tetra-(3-amino-4-hydroxyphenyl)-diarsyl

BY F. F. BLICKE, J. F. ONETO[1] AND G. L. WEBSTER[2]

The preparation and properties of tetra-(3-amino-4-hydroxyphenyl)-diarsyl $[(H_2N)(HO)C_6H_3]_2As—As[C_6H_3(OH)(NH_2)]_2$ are of special interest because of the structural analogy of this compound with salvarsan $(H_2N)(HO)C_6H_3As{=}AsC_6H_3(OH)(NH_2)$. Fargher[3] isolated and analyzed the diarsyl dihydrochloride and this substance is mentioned also by Christiansen.[4] This paper deals with a study of the diarsyl base, the preparation of the corresponding arsinic acid and several related acids.

Tetra-(3-amino-4-hydroxyphenyl)-diarsyl is insoluble in many of the common organic solvents but is soluble in alkali and acids. In the solid state the diarsyl is quite stable toward oxygen but an alkaline solution of the compound absorbs the gas quite rapidly.

Through the courtesy of Parke, Davis and Company the compounds mentioned below were tested for general toxicity by intravenous injection in white rats and for trypanocidal action against the common *T. equiperdum.*

3,3′-Diamino-4,4′-dihydroxydiphenylarsinic acid (I) failed to kill rats in doses as large as 1500 mg. per kilo body weight, hence it is a relatively non-toxic substance. The corresponding oxide, tetra-(3-amino-4-hydroxyphenyl)-arsyl oxide (II), is much more toxic. Neither compound seemed to be of any value as a trypanocide.

As far as tetra-(3-amino-4-hydroxyphenyl) diarsyl tetrahydrochloride (III), methyl-3-amino-4-hydroxyphenylarsinic acid,[5] methyl-3-amino-4-hydroxyphenylchloroarsine hydrochloride[6] and dimethyl-di-(3-amino-4-hydroxyphenyl)-diarsyl dihydrochloride[7] are concerned only the first mentioned compound exhibited any appreciable activity as a curative agent against *T. equiperdum* in white rats.

The well-known therapeutic agents 3-acetylamino-4-hydroxyphenylarsonic acid (stovarsol), 3-amino-4-hydroxyphenylarsine oxide hydrochloride (mapharsen) and 3,3′-diamino-4,4′-dihydroxyarsenobenzene (salvarsan) are the *mono* aryl analogs of compounds I, II and III, respectively. In view of the data obtained it seems that no improvement is made, as far as trypanocidal action is concerned, by the attachment of a second aminohydroxyphenyl nucleus to the arsenic atom.

No thorough pharmacological study of any of the compounds was made nor were they tested against spirochetes since the preliminary investigation indicated that they would be of little practical value.

Experimental Part

4,4′-Dihydroxydiphenylarsinic Acid.—This acid, which melted at 246–247° with effervescence,[8] dissolved in hot acetic acid, is decomposed by bromine with the formation of tribromophenol; suspended in acetic acid the arsinic acid is converted quantitatively into arsenic triiodide upon the addition of hydriodic acid.

Anal. Calcd. for $C_{12}H_{11}O_4As$: As, 25.48. Found: As, 25.34.

Di-(3-nitro-4-hydroxyphenyl)-chloro- and -bromoarsine.—Two grams of 3,3′-dinitro-4,4′-dihydroxydiphenyl arsinic acid, prepared by nitration[9] of 4,4′-dihydroxydiphenylarsinic acid, was dissolved in a mixture of 10 cc. of acetic acid, 25 cc. of hydrochloric acid and a drop of hydriodic acid and treated with sulfur dioxide. The gummy precipitate soon solidified; yield 2.1 g. After recrystallization from acetic acid the yellow crystals melted at 142–143°. The product dissolved in dilute sodium hydroxide to yield a red solution.

Anal. Calcd. for $C_{12}H_8O_6N_2AsCl$: As, 19.38; Cl, 9.17. Found: As, 19.46; Cl, 8.67.

The yellow, crystalline bromoarsine, prepared from 1 g. of the arsinic acid, 5 cc. of acetic acid, 11 cc. of hydrobromic acid, a drop of hydriodic acid and sulfur dioxide, melted at 131–132° after recrystallization from acetic acid.

Anal. Calcd. for $C_{12}H_8O_6N_2AsBr$: As, 17.39; Br, 18.55. Found: As, 17.43; Br, 18.65.

3,3′-Diamino-4,4′-dihydroxydiphenylarsinic Acid.—A solution of 200 g. of flake sodium hydroxide in 300 cc. of water was added to 170 g. of ferrous sulfate, dissolved in 500 cc. of water. After the mixture had been shaken thoroughly and cooled, there was added 20 g. of 3,3′-dinitro-4,4′-dihydroxydiphenylarsinic acid, dissolved in

100 cc. of water and 9 g. of flake sodium hydroxide. The mixture was shaken again and after one hour was filtered. Hydrochloric acid (about 260 cc.) was added to the filtrate until the latter was slightly acid toward litmus, the precipitated impurities removed by filtration, the light brown filtrate treated with hydrochloric acid, drop by drop, to precipitate the last traces of colored by-products, charcoal added and the mixture filtered again. The filtrate should now be slightly yellow and if the arsinic acid does not begin to precipitate after a short time, a few more drops of acid should be added; yield 9–11 g. of light brown, glistening crystals. When heated the acid darkens about 210° and decomposes at 218°.[10] About 100 cc. of boiling water is required to recrystallize 1 g. of the arsinic acid.

Anal. Calcd. for $C_{12}H_{13}O_4N_2As$: As, 23.12. Found: As, 23.29.

Di-(3-amino-4-hydroxyphenyl)-chlorarsine Dihydrochloride.—A solution prepared from 2.5 g. of 3,3′-diamino-4,4′-dihydroxydiphenylarsinic acid, 6 cc. of water, 20 cc. of hydrochloric acid and a drop of hydriodic acid, was treated with sulfur dioxide. The precipitated chloride dihydrochloride was filtered through a Jena filter, dissolved in the least possible amount of warm water, shaken with charcoal, filtered, the colorless filtrate cooled with ice and the dihydrochloride precipitated by the addition of fuming hydrochloric acid. The pearly flakes weighed 1.9 g.; m. p. 214–215°.[11]

Anal. Calcd. for $C_{12}H_{14}O_2N_2AsCl_3$: As, 18.76; Cl, 26.62. Found: As, 18.65; Cl, 26.61.

Tetra-(3-amino-4-hydroxyphenyl)-arsyl Oxide.—To 5 g. of the above-mentioned dihydrochloride, dissolved in 35 cc. of water, there was added, slowly, 5 g. of sodium hydroxide, dissolved in 15 cc. of water. The clear, alkaline solution was then treated, gradually, with just enough acetic acid (about 3.3 cc.) to precipitate the arsyl oxide. The crystalline oxide is soluble in 0.5 *N* hydrochloric acid, 0.5 *N* sodium hydroxide, alcohol, somewhat soluble in water and insoluble in ether; m. p. 152–155° with decomposition.

Anal. Calcd. for $C_{24}H_{24}O_5N_4As_2$: As, 25.06. Found: As, 24.75.

Tetra-(3-amino-4-hydroxyphenyl)-diarsyl.—Three grams of either 3,3′-diamino-4,4′-dihydroxydiphenylarsinic acid or tetra-(3-amino-4-hydroxyphenyl)-arsyl oxide was dissolved in 30 cc. of 50% hypophosphorous acid, a drop of hydriodic acid added and the solution heated in a modified radical apparatus[12] for one hour at 60°. Upon the addition of 38 cc. of 20% sodium hydroxide solution a copious, crystalline precipitate formed; during the addition of the alkali the mixture should be allowed to become hot, otherwise the precipitate tends to separate in a flocculent state. After the addition of 100 cc. of water the product was filtered and washed three times with 100-cc. portions of water and then several times with acetone; when heated in a sealed tube filled with nitrogen the material turns brown at about 200° and melts suddenly, with decomposition, at 202°. This compound seems to be a tetrahypophosphite of the diarsyl.

Anal. Calcd. for $C_{24}H_{24}O_4N_4As_2 \cdot 4H_3PO_2$: As, 17.71. Found: As, 17.83.

In order to obtain the free diarsyl the salt mentioned above was dissolved in 15 cc. of hot, 20% sodium hydroxide solution; upon the addition of 25% acetic acid until the mixture was acidic toward phenolphthalein the diarsyl precipitated. The liquid was decanted and the diarsyl washed with acetone; yield 1.9 g.; m. p. 193–194° in a sealed tube filled with nitrogen.

Anal. Calcd. for $C_{24}H_{24}O_4N_4As_2$: As, 25.74. Found: As, 25.51.

The diarsyl is insoluble or only slightly soluble in benzene, ether, acetone, alcohol, chloroform, bromobenzene, acetophenone, ethylene bromide, nitrobenzene, tetralin and acetic acid; it is soluble in pyridine, 50% acetic acid, dilute sodium hydroxide and dilute hydrochloric acid.

The tetrahydrochloride of the diarsyl was prepared in the following manner. The diarsyl obtained from 5.0 g. of 3,3′-diamino-4,4′dihydroxydiphenylarsinic acid was dissolved, while still moist, in a mixture of 3 cc. of concd. hydrochloric acid and 5 cc. of water. After the addition of 100 cc. of alcohol the solvents were removed at 35° under diminished pressure. To the moist, gelatinous salt, dissolved in 17 cc. of absolute alcohol, there was added 40 cc. of ether whereupon the hydrochloride separated in the form of granular crystals. The alcohol and ether were removed under diminished pressure and the residue washed three times with 40 cc. of ether; after the salt had been dried and isolated in a carbon dioxide atmosphere it melted at 170–172°[13] in a sealed tube filled with nitrogen.

Anal. Calcd. for $C_{24}H_{28}O_4N_4Cl_4As_2$: As, 20.58. Found: As, 20.13.

Dissolved in 20 cc. of water 0.5884 g. of the diarsyl tetrahydrochloride absorbed little or no oxygen in ten minutes. When sufficient 0.5 *N* sodium hydroxide solution (14 cc.) was added to form the tetra salt of the diarsyl, 10 cc. (N. T. P.) of the gas was absorbed in two minutes and after thirty-five minutes 37 cc. of oxygen had been absorbed.

4,4′-Dimethoxydiphenylarsinic Acid.—To a hot, aqueous suspension of 1 g. of 4,4′-dimethoxydiphenylbromoarsine,[14] stirred vigorously, there was added an aqueous solution of potassium permanganate until the latter was no longer decolorized; any excess of permanganate was reduced with alcohol. The mixture was filtered and the filtrate acidified to congo red; yield 0.7 g. of dimethoxy acid, m. p. 190–191° after recrystallization from acetic acid or water.

Anal. Calcd. for $C_{14}H_{15}O_4As$: As, 23.26. Found: As, 23.28.

In a second procedure the bromoarsine was suspended in hot 10% sodium hydroxide solution and treated with superoxol. After some time the material all dissolved. The arsinic acid precipitated when the solution was acidified.

When 1 g. of the arsinic acid, 4 cc. of acetic acid, 8 cc. of hydrobromic acid (48%) and a drop of hydriodic acid

---

[10] Fargher[3] prepared the diamino acid by reduction of the dinitroarsinic acid with sodium hyposulfite but did not report a melting point.

[11] Fargher,[3] who prepared this compound in low yield by another method, reported the melting point to be 215° (corr.).

[12] Blicke and Webster, This Journal, **59**, 538 (1937).

[13] Fargher did not report the melting point of his hydrochloride which he prepared by another method.

[14] Blicke and Smith, *ibid.*, **51**, 1565 (1929).

was treated with sulfur dioxide the bromoarsine formed melted at 63–64°[15] after recrystallization from absolute alcohol. The bromoarsine was converted into tetra-(4-methoxyphenyl)-arsyl oxide when it was warmed for a short time with ammonia water; the oxide melted at 132–134°[16] after recrystallization from petroleum ether (90–100°).

3,3′ - Dinitro - 4,4′ - dimethoxydiphenylarsinic Acid.—Twelve grams of 4,4′-dimethoxydiphenylarsinic acid was nitrated in the same manner as the corresponding dihydroxy acid; yield 12.6 g. of the dinitro acid. The compound was recrystallized from acetic acid; when heated it softened about 220° and melted at 231° with decomposition.

Anal. Calcd. for $C_{14}H_{13}O_6N_2As$: As, 18.18. Found: As, 17.73.

3,3′ - Diamino - 4,4′ - dimethoxydiphenylarsinic Acid.—Ferrous hydroxide was prepared by the addition of 9.5 g. of 70% sodium hydroxide, dissolved in 36 cc. of water, to 23 g. of ferrous sulfate, dissolved in 66 cc. of water; 2 g. of the dinitro acid, dissolved in 20 cc. of water and 1.6 g. of sodium hydroxide, was added. After several hours the mixture was filtered, the filtrate shaken with charcoal, filtered and the filtrate acidified with acetic acid; yield 1.4 g.; the glistening crystals melted at 183–184° with decomposition after recrystallization from water.

Anal. Calcd. for $C_{14}H_{17}O_4N_2As$: As, 21.28. Found: As, 21.27.

Summary

A detailed study has been made of tetra-(3-amino-4-hydroxyphenyl)-diarsyl.

The preparation of 4,4′-dimethoxydiphenylarsinic acid and of 3,3′-diamino-4,4′-dihydroxydiphenylarsinic acid and some of their derivatives has been described.

ANN ARBOR, MICHIGAN RECEIVED MARCH 2, 1937

---

[15] Prepared by a different method Blicke and Smith[14] found the melting point to be 60–62°.

[16] Michaelis and Weitz [*Ber.*, **20**, 50 (1887)] obtained the oxide by a different procedure and recorded the melting point as 130°.

Quassin. I. The Preparation and Purification of Quassin and Neoquassin, with Information Concerning their Molecular Formulas

BY E. P. CLARK

The bitter and presumably the physiologically active constituent of quassia wood or Surinam wood (*Quassia amara*) is known as quassin. This material was first obtained in crystalline form by Winckler[1] in 1835. Although it has since been investigated by others, little information of value concerning its nature has emerged; in fact, instead of clarifying the problem, these investigations have tended to confuse it.

The principal contributions to the subject have been made by Wiggers,[2] Christensen,[3] Oliveri and Denaro,[4] Oliveri,[5] and Massute.[6] As Christensen and Massute give comprehensive reviews of the subject, the present discussion will present only a résumé of the essential claims concerning the material.

Wiggers, the first to analyze quassin, found it to have 65.8% carbon and 6.94% hydrogen (recalculated on the basis of present atomic weight values). Christensen, who undoubtedly had a pure material, recorded its melting point as 205°, $[\alpha]^{18}\text{D}$ as +37.8° (*C*, 4.22 in chloroform), and its analysis according to the average of three combustions as 66.9% carbon and 7.44% hydrogen. He proposed the molecular formula $C_{31}H_{42}O_9$ for the material, and showed conclusively that it was not a glucoside. Finally, by boiling quassin for twelve hours with 3% sulfuric acid, he obtained a product which melted at 237° and gave upon combustion 66.87% carbon and 6.72% hydrogen.

Oliveri and Denaro had a material that melted at 210–211°, but in view of information which will be presented later they obviously had a mixture of several crystalline substances. They proposed the molecular formula $C_{32}H_{42}O_{10}$ or $C_{16}H_{22}O_5$ for their quassin, and claimed the formation of several anhydrides as the result of the action of dilute sulfuric acid and of acetic anhydride and sodium acetate upon their material. By heating quassin with concentrated hydrochloric acid in a sealed tube, they obtained methyl chloride and a crystalline material to which they assigned the formula $C_{28}H_{38}O_6(COOH)_2$, and which they called quassic acid. On the basis

(6) F. Massute, *Arch. Pharm.*, **228**, 147 (1890).

of these findings and some incomplete work, they stated that quassin had four hydroxyl groups, two carboxymethyl groups and two ketonic groups, and that the molecule had an anthraquinone skeleton.

Massute separated his crude quassin into several fractions having different melting points and assumed them to be homologs differing by various multiples of CH_2, as $C_{32}H_4O_1(CH_2)_3$ and $C_{32}H_4O_1(CH_2)_5$. He made no molecular weight determinations, although methods were then available. He repeated some of the work previously reported, but none of the results were helpful.

On the basis of the foregoing work the chemical information concerning quassin may be summarized as follows: (1) it is an extremely bitter, neutral substance or mixture of substances composed of carbon, hydrogen and oxygen, which contains methoxyl groups; (2) it is not a glucoside; and (3) in general, derivatives are not easily obtained from it.

The work to be reported here is concerned with (1) a practical method for the preparation of quassin, (2) the purification of the crude product, which has been shown to be essentially a mixture of two isomers, and (3) the determination of the molecular formula of these materials.

Of the two main fractions, the one corresponding to Christensen's quassin has been further studied, and some derivatives of it have been prepared and their properties recorded. The information thus obtained is as follows: crude quassin consists essentially of two isomeric compounds having the formula $C_{22}H_{30}O_6$. One melts at 205–206° and is undoubtedly the material studied by Christensen. The other isomer melts at 225–226° and has properties other than its melting point which distinguish it from the first. It is proposed to retain the name "quassin" for the first isomer and call the second "neoquassin." Both compounds have two methoxyl groups.

When treated with boiling 3.5% hydrochloric acid, quassin loses one methoxyl group and yields a compound, $C_{21}H_{28}O_6$, which is insoluble in carbonates and bicarbonates but is freely soluble in alkali hydroxides and in many organic solvents. If, however, constant-boiling hydrochloric or hydrobromic acid is used, the quassin loses two methoxyl groups and two hydrogen atoms and yields a compound, $C_{2}H_{24}O_6$, which is freely soluble in alkalies but relatively insoluble in methanol or ethanol. This material melts at 263° with decomposition. Doubtless the substance is that called quasside or quassic acid by earlier workers. It is proposed to designate this compound as "quassinol." Acetylation of quassinol yields a monoacetyl derivative.

The action of acetic anhydride and sodium acetate upon quassin itself produces at least three substances. One is an anhydro compound, $C_{22}H_{28}O_5$, m. p. 196°, which represents a loss of a molecule of water from quassin; the second is a dehydro compound, $C_{22}H_{28}O_6$, m. p. 256°, containing two less hydrogen atoms than the starting material; and the third is an isomer of quassin, m. p. 214–215°, which is identical with a substance that has been isolated from the wood of *Picraena excelsa*. This is probably one of the picrasmins reported by Massute.[6] Work upon this phase of the problem is in progress and will be reported separately.

The action of chromic acid upon quassin is unusual. When an acetic acid solution of sodium dichromate is allowed to act upon quassin, a slow reaction occurs, and at the end of a week the dichromate is completely reduced. From this mixture is obtained about a 50% yield of a white crystalline material, m. p. 221°, which is isomeric with the starting material.

Attempts to obtain the material by allowing an acetic acid solution of quassin to stand, as in the chromic acid experiment, failed, and only the original material was obtained.

The reactions that have been discussed are represented diagrammatically in the accompanying chart.

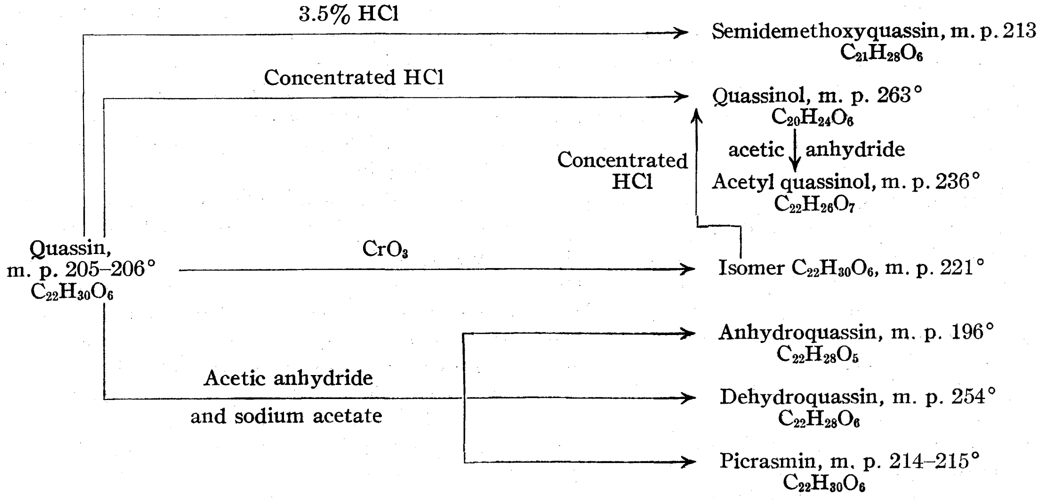
Experimental

Preparation of Quassin.—Quassia chips (20 kg.) were extracted by allowing them to stand in hot water for three hours. The decoction was decanted, and the process was repeated three times. Approximately 70 liters of extract was obtained from each treatment. Each extract was treated with a solution of normal lead acetate until further addition failed to give a precipitate; then, without removal of the separated material, sufficient activated carbon (Carbex) was added to adsorb the quassin. Complete adsorption was determined by the absence of a bitter taste in a filtered test portion.

The quantities of lead acetate and carbon necessary for each of the four extracts were

Extract no.	Carbon, g.	Lead acetate, g.
1	600	150
2	400	100
3	200	50
4	150	50

Reactions of quassin upon which a report has been made



The carbon was removed from each of the extracts and air-dried. It was then mixed, divided into two portions, and each portion was thoroughly percolated with chloroform. Each chloroform extract (representing 10 kg. of quassia chips) was concentrated to dryness under reduced pressure and then dissolved in 150 cc. of methanol. To this solution 950 cc. of hot water (*ca.* 60°) was added, and the turbid liquid was filtered through a thin layer of norit on a Büchner funnel.

Crystallization of crude quassin usually began at once and was completed within two days. Upon concentration, the mother liquors from the crystals gave an additional quantity of crystals. The yield from a number of experiments ranged from 0.15 to 0.18% with an average of 0.16%.

The crude material consisted principally of two isomeric compounds. One was in the form of thin, colorless plates which melted at 205–206°. The other separated from dilute methanol as dense, colorless prisms with a melting point of 225–226°.

The separation of these two isomers was accomplished in essentially the following manner.

One gram of the crude material was dissolved in 10 cc. of boiling methanol and diluted with an equal volume of hot water. The solution was then filtered through a thin layer of norit and allowed to crystallize. The substance obtained, which was approximately 50% of the starting material, consisted largely of quassin (m. p. 205–206°), with some neoquassin. The mother liquors were heated to dissolve any crystalline material, two volumes of water were added and this solution was allowed to crystallize. The crystals, which began to sinter at 205° but did not melt clear until 222°, were mainly neoquassin.

The mother liquors were then concentrated under reduced pressure, and the separated materials were removed from time to time. These fractions were shown by microscopic examination and melting point determinations to consist of both substances, but one or the other usually predominated. The fractions that consisted dominantly of quassin were combined, and the dominantly neoquassin fractions were united. Each was then dissolved in hot methanol and recrystallized by adding two volumes of water. The mother liquors were concentrated as outlined above, and the process was repeated until quassin and neoquassin with sharp melting points and uniform crystalline habit were obtained. The proportion of quassin to neoquassin was estimated to be approximately 2 to 1.

Small quantities of lower and higher melting products were also obtained, but as difficulty was experienced in purifying them, their analysis will be reserved until sufficient material is accumulated to make their characterization certain.

Quassin.—Quassin separates from dilute methanol as thin, colorless rods and micaceous plates which melt at 205–206°. In parallel polarized light (crossed nicols) the rods have straight extinction and positive elongation. In convergent polarized light (crossed nicols) the plates invariably extinguish sharply, indicating that η_β is more or less perpendicular to the broad base, precluding interference figures. The indices of refraction of the material are η_α 1.575; η_γ 1.590.[7]

A solution of 122.8 mg. of quassin in 2.28 cc. of chloroform (*C*, 5.38), when placed in a 96-mm. tube at 20°, rotated the plane of polarized light 2.06° to the right. Therefore, $[\alpha]^{20}\text{D}$ is +39.8°. This value and those to be given subsequently were all obtained with small quantities and microapparatus. They are therefore given, not as precision measurements, but rather to indicate their order of magnitude. A duplication determination with the above sample gave a value of $[\alpha]^{20}\text{D}$ +41°. Active hydrogen determined by the Tschugaeff–Zerewitinoff method gave a value equivalent to one atom.

Anal. Calcd. for $C_{22}H_{30}O_6$: C, 67.67; H, 7.75; OCH_3 (2), 15.9; mol. wt., 390.3; active H (1), 0.26. Found: C, 67.7, 67.8; H, 7.74, 7.73; OCH_3, 15.84; mol. wt. (Rast), 399; active H, 0.28.

Neoquassin.—Neoquassin separates from dilute methanol as dense, colorless six-sided prisms and quadrilateral plates which melt at 225–226°. $[\alpha]^{20}\text{D}$ is +46.6°; *C*, 4.92 in chloroform solution. In parallel polarized light

---

[7] The optical crystallographic data reported here were determined by George L. Keenan, of the Food and Drug Administration, U. S. Department of Agriculture. The values of the refractive indices are all ±0.003.

(crossed nicols) many fragments remain bright upon rotation of the microscope stage, while others extinguish sharply. In convergent polarized light (crossed nicols) partial biaxial interference figures are common. The refractive indices are η_α 1.575; η_β 1.600; η_γ 1.626.

Anal. Calcd. for $C_{22}H_{30}O_6$: C, 67.67; H, 7.75; OCH_3 (2), 15.9; mol. wt., 390.3. Found: C, 67.8; H, 7.8; OCH_3, 15.5; mol. wt. (Rast), 387.

Semidemethoxyquassin.—A suspension of 1 g. of quassin in 20 cc. of 10% hydrochloric acid and 40 cc. of water was boiled one and a half hours. After the resulting solution cooled somewhat, it was treated with potassium hydroxide until it remained just acid to Congo red. After three days approximately 0.6 g. of crystalline material had separated. This was dissolved in ethyl acetate, filtered, concentrated to a small volume and allowed to crystallize. A poor yield (160 mg.) of dense colorless prisms, tending to be six-sided, which began to sinter at 195° and flowed at 209–211°, was obtained. A second recrystallization from ethyl acetate brought the material to a constant melting point of 213°.

In parallel polarized light (crossed nicols) the extinction is straight and the elongation negative. No interference figures were observable in convergent polarized light (crossed nicols). The refractive indices of the crystals are η_α 1.517 (common lengthwise); η_β 1.585; η_γ 1.613.

Anal. Calcd. for $C_{21}H_{28}O_6$: C, 67.0; H, 7.5; OCH_3 (1), 8.25. Found: C, 67.1; H, 7.6; OCH_3, 8.2.

The crystals obtained from ethyl acetate may be recrystallized conveniently by dissolving them in water made slightly alkaline with potassium hydroxide and then acidifying the solution with hydrochloric acid. The resulting crystals, after thorough drying, begin to sinter at 195° and flow at 207°. This material gave the following analysis: C, 67.0; H, 7.6; OCH_3, 8.2.

Quassinol.—The action of constant-boiling hydrobromic or hydrochloric acid upon quassin yields quassinol, but the procedure that gave the best yields and the cleanest product is as follows. One gram of quassin dissolved in a solution of 10 cc. of acetic acid and 3 cc. of concentrated hydrochloric acid was heated in a boiling water-bath for one and one-half hours. The dark solution was diluted with four volumes of water, and the hydrochloric acid was neutralized with the calculated quantity of potassium hydroxide. The liquid was cooled with ice and allowed to crystallize. The mother liquors from the crystals were evaporated to dryness under reduced pressure, the salt was dissolved in water and the resulting mixture extracted with chloroform. The extract was dried, concentrated to a sirup and treated with a little hot methanol. Crystallization began at once. The crystalline material filtered from the original aqueous acetic acid reaction mixture was digested with hot methanol, and the resulting quassinol was added to that obtained from the chloroform extract of the mother liquors. In all 1 g. of quassin yielded 0.3 g. of quassinol, m. p. 262°. It was recrystallized by dissolving in boiling chloroform, filtering its solution through norit, concentrating the filtrate until crystallization began and then adding about five volumes of methanol. Thus obtained, it consisted of colorless rods which melted at 263° with decomposition. A solution of 114.9 mg. in 10 cc. of chloroform and observed in a 2-dm. tube at 20° rotated the plane of polarized light 1.44° to the right $[\alpha]^{20}D$ is therefore +62.6°. In parallel polarized light (crossed nicols) the extinction is straight and the elongation is positive. In convergent polarized light (crossed nicols) only faint biaxial interference figures characteristic of sections perpendicular to the acute bisectrix, are shown: η_α 1.518 (crosswise); η_β 1.543 (crosswise); η_γ >1.733 (lengthwise).

Anal. Calcd. for $C_{20}H_{24}O_6$: C, 66.6; H, 6.7; mol. wt., 360.3. Found: C, 66.8; H, 6.8; mol. wt. (Rast), 373.

Acetylquassinol.—A solution of 300 mg. of quassinol in 3 cc. of pyridine and 1.5 cc. of acetic anhydride was allowed to stand overnight. Upon dilution of the mixture with water, 300 mg. of crystalline material, m. p. 232°, separated. It was recrystallized from boiling 95% ethanol. The yield was 240 mg. and its melting point was 236° with evolution of gas.

Anal. Calcd. for $C_{22}H_{26}O_7$: C, 65.6; H, 6.5; acetyl (1), 10.7; mol. wt., 402.3. Found: C, 65.6; H, 6.6; acetyl, 11.2; mol. wt. (Rast), 422.

Action of Acetic Anhydride and Sodium Acetate upon Quassin.—One gram of quassin, 0.25 g. of dry sodium acetate, and 8 cc. of acetic anhydride were refluxed for one and one-half hours. The greater part of the acetic anhydride was then removed by distillation, and about 35 cc. of water was added to the mixture. Upon being stirred, the reaction product gradually crystallized, yielding 0.8 g. of material which melted between 160–170°. This was dissolved in hot methanol and an equal volume of water added. Crystallization began at once and yielded 390 mg. of a substance which melted at 190°. A second recrystallization in the same manner sufficed to yield a pure product, m. p. 196°. This was an anhydroquassin formed by the elimination of 1 mole of water from a mole of quassin.

Anal. Calcd. for $C_{22}H_{28}O_5$: C, 70.9; H, 7.6; OCH_3 (2), 16.7. Found: C, 70.7; H, 7.6; OCH_3, 16.8.

The mother liquor from the first recrystallization of the crude acetylation product was diluted with three volumes of water and allowed to crystallize for a day. A small quantity of material which melted unsharply at about 235° was obtained. This was twice recrystallized from its solution in acetic anhydride by adding three volumes of *n*-butyl ether. Thus obtained, the material was pure and separated as boat-shaped crystals tending to be long hexagonal plates. Its melting point was 254°. Analysis indicated it to be a dehydroquassin.

Anal. Calcd. for $C_{22}H_{28}O_6$: C, 68.0; H, 7.3; OCH_3 (2), 16.0; mol. wt., 388.3. Found: C, 67.6; H, 7.4; OCH_3, 15.6; mol. wt. (Rast), 403.

The mother liquors from the dehydro compound were concentrated under reduced pressure to a small volume, which caused a crystalline material to separate. Its melting point was 205–210°. Upon recrystallization from 25% methanol, it consisted of long rectangular plates melting at 214°. When mixed with picrasmin, m. p. 215–216°, there was no depression of the melting point.

Anal. Calcd. for $C_{22}H_{30}O_6$: C, 67.67; H, 7.75; OCH_3 (2), 15.9. Found: C, 67.5; H, 7.7; OCH_3, 15.9.

Action of Chromic Acid upon Quassin.—Ten cubic centimeters of a 10% acetic acid solution of crystalline sodium dichromate was added to a solution of 1 g. of quassin in 5 cc. of hot acetic acid. After a week two volumes of water was added to the solution and the mixture was concentrated under reduced pressure almost to dryness. Water was then added and the resulting crystals were collected. The yield was 0.5 g. and the material melted at 217°. One recrystallization from dilute methanol gave a pure product, m. p. 221°. It consisted of colorless rectangular rods and plates, which had optical crystallographic properties very similar to the starting material. In parallel polarized light (crossed nicols) the extinction is straight and the elongation is positive. Most of the crystals extinguish sharply (crossed nicols), although plates occasionally extinguish in a hazy, indefinite manner. In convergent polarized light (crossed nicols) these plates show a dim biaxial interference figure with both of the isogyres in the field (section perpendicular to the acute bisectrix). Owing to the dimness of the figure, the magnitude of the axial angle could not be determined definitely, but it appeared to be small. The refractive indices are: η_α 1.575 (common crosswise); η_γ 1.585 (common lengthwise); η_β could not be determined with certainty. Its specific rotation in chloroform solution (C, 5.22) was found to be $[\alpha]^{20}\text{D}$ +35.1°.

Anal. Calcd. for $C_{22}H_{30}O_6$: C, 67.67; H, 7.75; OCH_3 (2), 15.9. Found: C, 67.8; H, 7.4; OCH_3, 15.9.

Treatment of this material with acetic and hydrochloric acids as outlined for the preparation of quassinol gave just twice the yield of quassinol that was obtained from quassin itself. The identity of the quassinol was proved by its melting point, mixed melting point and optical properties.

Summary

A convenient method has been developed for the preparation of crude quassin. This material has been shown to consist essentially of two isomeric substances of the formula $C_{22}H_{30}O_6$, each containing two methoxyl groups. These have been separated, and directions are recorded for doing this. It is proposed to retain the name "quassin" for the isomer melting at 205–206° and designate the other isomer, m. p. 225–226°, as "neoquassin." A summary of the relationships between quassin and several derivatives is shown diagrammatically.

Washington, D. C. Received March 18, 1937

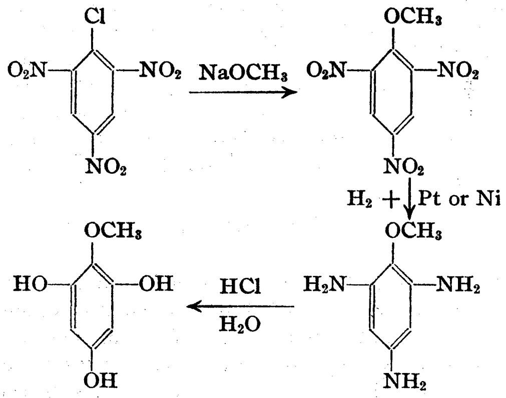
[Contribution from the Chemical Laboratory of the University of Illinois]

A Synthesis of Iretol

By R. E. Damschroder and R. L. Shriner

Iretol was first isolated by de Laire and Tiemann[1] as a degradation product of a glucoside obtained from *Iris florentina*. It is produced by alkaline degradation of tectorigenin[2] and of wogonin.[3] The structure of iretol as 2,4,6-trihydroxyanisole was established by conversion to phloroglucinol by de Laire and Tiemann,[1] and by a synthesis by Kohner,[4] who reduced 2,4,6-trinitroanisole with tin and hydrochloric acid to a diaminohydroxyanisole, which was then hydrolyzed to iretol. When this method was used for the preparation of iretol, it was found that the yields were very low, and that the presence of the large amounts of tin salts at the last step rendered the isolation of the product very difficult. Any procedures used for the preparation of this polyhydroxybenzene must be simple and require as short a time as possible, because aqueous solutions of the intermediate amino compound, as well as the final product, are very sensitive to oxygen of the air, and readily undergo oxidation to highly colored compounds.

A modified synthesis has been developed, using the reactions



The catalytic reduction of 2,4,6-trinitroanisole must be carried out rapidly, using a very active catalyst. A high ratio of catalyst to compound must be used. Yields of the 2,4,6-triaminoanisole as high as 81% were obtained, provided the product was isolated with the exclusion of oxygen. The final hydrolysis was accomplished with hydrochloric acid alone, no stannous chloride being necessary. Isolation of the iretol must be accomplished in a carbon

dioxide atmosphere, the final purification by a vacuum sublimation. The yields varied from 40 to 75%.

Experimental Part

Picryl Chloride.—Nitration of 2,4-dinitrochlorobenzene according to the directions of Frankland and Garner[5] gave 80% yields of picryl chloride, melting at 79–82°.

2,4,6-Trinitroanisole.—A solution of 50 g. of picryl chloride in 300 cc. of hot methanol is added slowly, with stirring, to a cold solution of sodium methoxide prepared by adding 13 g. of sodium to 200 cc. of methanol. The deep red solution is cooled in an ice-bath for two hours, and the red crystalline precipitate removed by filtration. This precipitate, a double compound of 2,4,6-trinitroanisole and sodium methoxide,[6] is suspended in 500 cc. of water, and the mixture made distinctly acid with concentrated hydrochloric acid. The mixture is filtered, and the precipitate dissolved in hot methanol. Rapid cooling of this solution gave an 82% yield of yellow prisms, which melted at 58–59°.

2,4,6-Trinitroanisole is peculiar in that it exists in several crystalline forms which melt at different temperatures. By very slow crystallization of the compound from dilute methanol solutions, four distinct types of crystals were obtained.

Crystal form	M. p., °C.
Square plates	50–51
Hexagonal plates	56–57
Prisms	58–59
Needles	68–69

The needles melting at 68–69° correspond to the form described by Meisenheimer,[7] but other investigators[6,8] have obtained forms melting from 58 to 65°.

The lower-melting forms, after standing in stoppered tubes for four months, melted at 68°, indicating that this form is the stable one, and that a gradual transition to the higher-melting form had occurred. In fact, once the higher-melting form had been obtained, it was then impossible again to secure crystals of the three lower-melting forms. The compound was analyzed to check its composition.

Anal. Calcd. for $C_7H_5O_7N_3$: N, 17.28. Found: N, 17.37.

2,4,6-Triaminoanisole.—A solution of 7.5 g. of 2,4,6-trinitroanisole in 170 cc. of absolute ethanol was reduced with hydrogen at a pressure of 2 to 3 atmospheres in the presence of a catalyst. If platinum oxide (0.2 g.) is used as the catalyst,[9] it is important that the catalyst be active enough to cause complete reduction in ten minutes or less. An 80% yield of the triamine may then be obtained. The cause of variations in activity of the catalyst appeared to be associated with the quality of platinum chloride. Catalyst prepared from platinum chloride, purified by precipitation as ammonium chloroplatinate, gave excellent results, as did chloroplatinic acid purchased from Mallinckrodt Chemical Works. With inactive catalysts, the yield of amine drops markedly. One batch of catalyst, prepared from a commercial platinum chloride, required two hours for absorption of the theoretical amount of hydrogen. Only highly colored condensation products were formed, and no triamine could be isolated.

Raney nickel[10] also was found to be a very effective catalyst, provided a 1:1 ratio of catalyst to compound was used, so that the reduction was completed in fifteen to thirty minutes. The yield of amine using this catalyst ranged from 68 to 78%. The results were more consistent with different batches of catalyst than was the case with platinum.

This reduction of the trinitro compound is exothermic and because of the rapid rate of reduction which is necessary, the container heats up considerably. It is desirable to place a safety glass shield between the operator and the reduction apparatus.

After the theoretical amount of hydrogen had been absorbed, the reduction mixture was filtered quickly, and the solvent removed with a water pump, at the same time passing in a slow current of carbon dioxide through the solution. The triamine started to precipitate when the volume reached about 20 cc. The mixture was then cooled in an ice-bath, and the product removed by filtration and washed with small amounts of cold absolute ethanol. The crude product varies from a light tan to a dark brown in color, and melts at 105 to 110°. It is purified by recrystallization from hot absolute ethanol with the aid of norite. The pure compound melted at 116.5–117.5° (corr.).

Anal. Calcd. for $C_7H_{11}ON_3$: N, 27.44; methoxyl, 20.26. Found: N, 27.42; methoxyl (Zeisel), 20.80.

2,4,6-Trihydroxyanisole (Iretol).—A solution of 6.12 g. of the crude triaminoanisole in 280 cc. of air-free water containing 9 cc. of concentrated hydrochloric acid was refluxed for twenty hours in an atmosphere of carbon dioxide. The brown solution was cooled, and a slight amount of brown, insoluble material removed by filtration. The water was removed by vacuum distillation, passing a stream of carbon dioxide through the capillary. The solution has a tendency to foam, and must be carefully watched. Bumping occurs near the end of the distillation, due to the precipitation of ammonium chloride. The dry residue is then thoroughly extracted with two 350-cc. portions and one 150-cc. portion of ether. The residue should be entirely free of any oily matter.

The combined ether extracts are dried over magnesium sulfate for one hour, and the ether is then removed by distillation.

If the triaminoanisole was exceptionally pure, the iretol may crystallize as the ether is removed. If the product is oily, it can be caused to solidify by adding a few cubic centimeters of dry ether and warming on a steam-bath for several minutes. The crude iretol is extracted with a small amount of dry ether and dried by warming for thirty minutes on a steam-bath in a carbon dioxide atmosphere. The crude product is tan colored, and melts at 165–175°. The iretol is most easily purified by sublimation at 150–

160° under 2 mm. pressure against a tube cooled with acetone and dry ice. Clear, feathery needles were obtained which melted at 187.5–188.5° (corr.). The poorest yield of sublimed iretol was 40%, and the best was 75% of the theoretical amount.

Anal. Calcd. for $C_7H_8O_4$: C, 53.83; H, 5.17; methoxyl, 19.87. Found: C, 54.10; H, 5.38; methoxyl (Zeisel), 19.60.

Iretol is stable when pure and dry, but readily turns dark if exposed to moisture and oxygen.

Summary

2,4,6-Trinitroanisole may be satisfactorily reduced catalytically to give 68 to 81% yields of 2,4,6-triaminoanisole, provided the reduction is carried out rapidly. The triamine may be hydrolyzed to 2,4,6-trihydroxyanisole (iretol) in 40 to 75% yields by means of hydrochloric acid.

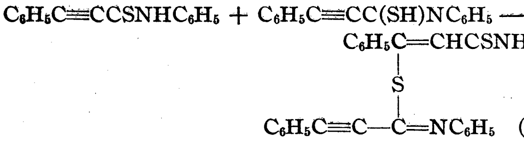
The Action of Hydroxylamine and Hydrazine on Acetylenic Thioamides

BY DAVID E. WORRALL

It has been shown previously that sodium phenylacetylene forms addition products with aromatic isothiocyanates.[1] Since the resulting thioamides contain an acetylenic group, they behave in a characteristic manner with certain reagents. These reactions have been investigated in the present communication.

Phenylpropiol thioanilide[1] obtained from phenyl isothiocyanate is destroyed easily by heat or acids; consequently the addition of water to the acetylenic group is yet to be observed. Like any thioamide it is soluble in aqueous alkali. On warming it polymerizes, a change that has been assumed to result from the interaction of I with its enol

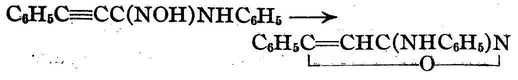


$$C_6H_5C{\equiv}CCSNHC_6H_5 + C_6H_5C{\equiv}CC(SH)NC_6H_5 \longrightarrow \begin{array}{l} C_6H_5C{=}CHCSNHC_6H_5 \\ \quad | \\ \quad S \\ \quad | \\ C_6H_5C{\equiv}C{-}C{=}NC_6H_5 \end{array}$$

(II)

The product is a highly colored dimer, still soluble in alkali, which reacts with hydroxylamine through hydrogen sulfide elimination. With bromine, part of the molecule is converted into the dibromide of I. The other portion changes into an intractable tar, precisely the effect of bromine on I, accompanied by the formation of hydrogen bromide.

I also reacts in a characteristic manner with hydroxylamine, the first formed oxime rearranging into an isoxazole.



$$C_6H_5C{\equiv}CC(NOH)NHC_6H_5 \longrightarrow \underbrace{C_6H_5C{=}CHC(NHC_6H_5)N}_{O}$$

(III)

III reacts smoothly with nitric acid and with bromine, forming products in which substitution has taken place in the aniline group, evidenced by the production of benzoic acid on oxidation. In a similar manner hydrazine and phenylhydrazine lead to substituted pyrazoles. The pyrazole obtained from hydrazine is of such a nature that the aniline group present is capable of reacting with three equivalents of bromine or nitric acid.

A small amount of by-product is usually present in the preparation of III, the analysis of which indicates that the original substance has taken on one equivalent of oxygen. Since the aromatic thioamides are readily converted into thiazoles under mild oxidizing conditions, the substance[2] may be regarded as phenacyl benzothiazole, $C_6H_5COCH_2\underbrace{C{=}NC_6H_4}_{S}$. It results perhaps from the addition of hydroxylamine to the acetylenic group followed by oxidation and hydrolysis under the influence of the organic base.

Experimental

Phenylpropiol Thioanilide.—To 0.5 gram mole of phenylacetylene converted into the sodium derivative and suspended in dry ether was added the equivalent of phenyl isothiocyanate. The bulky product after several hours was filtered and washed with ether. The residue was decomposed immediately in small lots (unchanged sodium present) with a well-stirred mixture of ice and water. An excess of dilute acid was used to complete the reaction after which the product, following thorough washing with dilute alcohol, was suspended in chloroform. Petroleum ether in excess was then added; final yield 70 g. Because of destructive decomposition, heating must be avoided. It separated from warm chloroform–petroleum ether mixtures as tiny yellow needles, decomposing at 113–114°. *Anal.* Calcd. for $C_{15}H_{11}NS$: C, 75.9; H, 4.6; S, 13.5. Found: C, 75.5; H, 4.6; S, 13.7. It changes into a glossy black resin if heated to 100° for a few minutes. The thio-

(2) Jacobsen, *Ber.*, **21**, 2629 (1888).

anilide is soluble in aqueous alkali, precipitating out unchanged on neutralization with acid, but polymerizing on the application of heat. A similar change takes place more slowly on heating an alcoholic solution of the substance in the absence of alkali accompanied by considerable decomposition into hydrogen sulfide and an intractable black tar. Destructive decomposition occurs slowly at room temperature if an acid is added to the alcoholic solution. All attempts to obtain a ketone by hydration of the acetylenic group failed. Mercuric salts decompose the substance. Bromine reacts instantly with blackening of the solution and subsequent elimination of hydrogen bromide fumes. An odor similar to sulfur chloride was noticed in the tarry residue.

Bis-phenylpropiolthioanilide was obtained by heating I with alcohol under a reflux condenser for several hours. The lustrous bronze colored plates produced were filtered while hot and thoroughly washed with warm alcohol; yield approximately 40%. *Anal.* Calcd. for $(C_{15}H_{11}NS)_2$: C, 75.9; H, 4.6. Found: C, 75.8; H, 4.6. A molecular weight determination using bromoform as a solvent indicated a dimer. It sinters at about 250°, decomposing indefinitely. Hydrogen sulfide was eliminated slowly by the action of hydroxylamine. The tarry residue on examination was found to contain sulfur, although no definite substance was isolated.

Phenylpropiolthioanilide Dibromide.—An equal weight of bromine mixed with II suspended in chloroform caused crystal formation in a few minutes. On standing, copious evolution of hydrogen bromide fumes occurred, but the amount of solid material did not change noticeably. Most of the products of the reaction remained in solution and were discarded, as tars separated on evaporation. The crystalline material separated from a large volume of glacial acetic acid in small yellow plates, decomposing at 226–227°. *Anal.*[3] Calcd. for $C_{15}H_{11}NSBr_2$: C, 45.3; H, 2.8; Br, 40.3. Found: C, 45.5; H, 2.7; Br, 40.2.

3-Anilino-5-phenylisoxazole.—An alcohol solution containing three equivalents of hydroxylamine was mixed with 10 g. of I and slowly heated to the boiling point. Heating was continued under a reflux condenser until no further hydrogen sulfide evolution occurred. The red solution, filtered if necessary, was poured into water. The product was crystallized repeatedly from alcohol to remove colored impurities, finally separating as sparkling plates, m. p. 142–143°; yield approx. 2 g. *Anal.* Calcd. for $C_{15}H_{12}ON_2$: C, 76.2; H, 5.1. Found: C, 76.1; H, 5.2. It is unchanged after long heating with either acid or alkali, but readily reduces permanganate solutions.

I-Phenacyl Benzothiazole.—A substance insoluble in alcohol was obtained with the isoxazole if concentrated solutions were used; yield 0.4 g. It was crystallized from glacial acetic acid in the form of deep yellow needles decomposing at 190–191°. *Anal.* Calcd. for $C_{15}H_{11}ONS$: C, 71.1; H, 4.3; S, 12.6. Found: C, 70.8; H, 4.4; S, 12.5. It is soluble in alcoholic potash, from which it is precipitated unchanged by acid or dilution with water. Hot alcoholic potash decomposes it into a tar. A small amount of an oil soluble in acid and with a pyridine-like odor was obtained on long heating with hydrochloric acid.

3-*p*-Bromoanilino-5-phenylisoxazole.—The isoxazole was brominated in chloroform and crystallized from alcohol, separating as plates, m. p. 158°. *Anal.* Calcd. for $C_{15}H_{11}ON_2Br$: Br, 25.4. Found: Br, 25.5. On oxidation with permanganate, benzoic acid was isolated from the material insoluble in acetone.

3-[2,4-Dinitroanilino]-5-phenylisoxazole.—The isoxazole dissolved readily in concd. nitric acid. Water throws out of solution the product which separated from glacial acetic acid as glittering yellow plates, m. p. 245–246°. *Anal.* Calcd. for $C_{15}H_9O_5N_4$: C, 55.5; H, 2.8. Found: C, 55.9; H, 2.8.

3-Anilino-5-phenylpyrazole.—I (10 g.) was heated with two equivalents of hydrazine, the excess being necessary to avoid the formation of II. Nearly colorless needles, m. p. 151–152°, were obtained eventually by repeated crystallization of the crude product; yield 3–4 g. The hydrochloric acid salt, prepared by adding a few drops of concd. acid to the alcohol solution, m. p. 166–167°, was used for analysis. *Anal.* Calcd. for $C_{15}H_{13}N_3 \cdot HCl$: C, 66.3; H, 5.2. Found: C, 66.5; H, 5.2. The base is sparingly soluble in hot water and unaffected by hot acid or alkali.

3-[2,4,6-Tribromoanilino]-5-phenylpyrazole.—The tribromo derivative, obtained as before, separated as a salt that hydrolyzed in the presence of alcohol or water. It was crystallized from a large volume of alcohol, forming needles decomposing at 206–207°. *Anal.* Calcd. for $C_{15}H_{10}N_3Br_3$: C, 38.1; H, 2.1. Found: C, 38.4; H, 2.3. On extraction with hot water of the acetone-insoluble material obtained by oxidation with permanganate, two products were found, benzoic acid and a yellow bromine-containing substance that was not examined further.

3-[2,4,6-Trinitroanilino]-5-phenylpyrazole.—Nitric acid dissolved the pyrazole, yielding a product that was crystallized from glacial acetic acid. It forms lustrous yellow needles decomposing at 266°. *Anal.* Calcd. for $C_{15}H_{10}N_6O_6$: C, 48.6; H, 2.7. Found: C, 48.3; H, 3.1.

1-Phenyl-3-anilino-5-phenylpyrazole.—Obtained from two equivalents of phenylhydrazine with 10 g. of I as pointed prisms, m. p. 153–154°, yield 4 g. *Anal.* Calcd. for $C_{21}H_{17}N_3$: C, 81.0; H, 5.5. Found: C, 81.4; H, 5.4. The dibromo derivative, needles, m. p. 181°, and the trinitro, tiny yellow plates, m. p. 197–198°, were prepared and analyzed.

Summary

Phenyl isothiocyanate forms an unsaturated thioanilide with phenylacetylene, a substance easily destroyed by acids, free halogens or heat. It is polymerized by alkali and reacts with hydroxylamine, hydrazine and phenylhydrazine, forming heterocyclic compounds from which bromo and nitro derivatives have been prepared.

MEDFORD, MASS.

RECEIVED MARCH 5, 1937

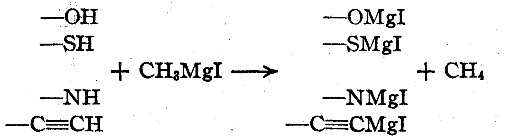
Relative Reactivities of Organometallic Compounds. XVI. Detection of the —SH Group

BY HENRY GILMAN AND JOSEPH F. NELSON

The Tschugaeff–Zerewitinoff[1] analysis makes it possible to determine, qualitatively and quantitatively, active or acidic hydrogens by measurement of the volume of methane evolved when a weighed amount of sample is treated with an excess of methylmagnesium iodide.



$$\begin{array}{c} -OH \\ -SH \\ -NH \\ -C{\equiv}CH \end{array} + CH_3MgI \longrightarrow \begin{array}{c} -OMgI \\ -SMgI \\ -NMgI \\ -C{\equiv}CMgI \end{array} + CH_4$$

A study of other organometallic compounds indicates that it may be possible, by use of appropriate organometallic compounds, to effect selective or preferential reactions with specific active hydrogen types. We are reporting at this time the use of triethylbismuth and tetraethyllead for detecting the —SH group.

Experimental Part

Materials.—A convenient method for the preparation of triethylbismuth is one patterned after the procedure of Schaefer and Hein[2] for the preparation of trimethylbismuth. To an ethylmagnesium bromide solution prepared from 1.4 moles of ethyl bromide in 400 cc. of ether, was added slowly and with rapid stirring 200 g. of an ether solution containing 0.4 mole of bismuth chloride. Because of the inflammability of triethylbismuth all operations were carried out in a nitrogen atmosphere. Heat was applied until the reaction was complete, and a large quantity of gray precipitate formed.

Most of the ether was then removed by fractionation through an efficient column, a hot water-bath being used. Triethylbismuth, like some other organometallic compounds, undergoes a ready ether distillation, and a fractionating column reduces the carry-over of triethylbismuth. The remaining ether and triethylbismuth were then distilled off at 4 mm. pressure into a 250-cc. modified Claisen flask cooled by an ether–dry ice mixture. In this distillation an oil-bath was used, and the external temperature was raised gradually to 170° near the end of the distillation. Abrupt and excessive heating should be avoided.

The ether was finally distilled from the distillate, and the triethylbismuth then collected at about 123° (150 mm.). The yield was 88%.

The tetraethyllead and the several compounds studied were purified by customary procedures.

Procedure.—The usual Zerewitinoff apparatus and technique were used, 5 cc. of *n*-butyl ether or of 1,4-dioxane being added to the 0.2–0.4 g. sample. After flushing out the side-bulb with nitrogen, 5 cc. of a 25% (by volume) solution of triethylbismuth in *n*-butyl ether was run into the side-bulb through a bent pipet provided with a stopcock. The main bulb was then flushed with nitrogen and attached to the gas buret.[3] The bulb was then immersed for a few minutes in a water-bath kept at 25°, and the system closed to the atmosphere. A water-bath containing boiling water was then applied and the water kept boiling for a definite time (see Table I), after which the contents of the bulb were cooled quickly and the original water-bath applied to bring the temperature to 25°. Temperature, volume and pressure readings were made fifteen minutes after heating was discontinued. Blanks, averaging 0.3 cc., were made, and this volume was deducted from the total volume measured. The same procedure was used in the tetraethyllead studies. All experiments were checked. The results given in Table I are averages, and the numerical values represent the fractional amount of the active hydrogen that reacted in the time given.

Tetraethyllead and Thiophenol.—In order to determine the number of ethyl groups that can be cleaved, 2 g. (0.018 mole) of thiophenol in 5 cc. of *n*-butyl ether was added to 0.629 g. (0.00194 mole) of tetraethyllead in 5 cc. of *n*-butyl ether, and the solution kept at 100° for six hours with occasional shaking. Gas was evolved quite rapidly at first, and of the 132.8 cc. finally collected only about 10 cc. was evolved in the last three hours. In a check experiment, 126.4 cc. of gas was collected, and these two volumes correspond to 3.07 and 3.20 ethyl groups, respectively.

The sulfur containing organometallic products obtained from the several compounds will be reported later.

The gas obtained from tetraethyllead and *p*-thiocresol was analyzed and shown to be ethane.

Discussion of Results

Organometallic compounds of lesser reactivity than the Grignard reagent almost always give low values in active hydrogen analyses. This applies not only to diethylzinc[4] but to organometallic compounds containing cadmium, mercury, boron, aluminum and tin. However, even though the results obtained with the lesser reactive RM types are only partially quantitative, they are of definite diagnostic value. Furthermore, when there is selective substitution of hydrogen by

(3) All traces of air are not removed by this procedure. As a consequence, the reagent becomes cloudy, but this appears to be without effect on the result. The ready clouding of triethylbismuth by oxygen suggests the use of triethylbismuth as a delicate test for traces of oxygen. Fortunately, for the purposes of such a test, triethylbismuth is unaffected by moisture.

[a] Dioxane was used as a solvent for these compounds. In all other cases, di-*n*-butyl ether was used. [b] An 87–90% solution of formic acid was used. The gas evolved with tetraethyllead was shown to be ethane. Also the gas from trichloroacetic acid and tetraethyllead was practically pure ethane. [c] Heating for sixty minutes gave 0.13 active hydrogen. [d] Heating for sixty minutes gave 0.03 active hydrogen. [e] Heating for one hundred and twenty minutes gave 0.14 active hydrogen. [f] Heating for ninety minutes gave no active hydrogen.

metal it appears reasonable to expect preferential replacement reactions with the intermediate metallic compounds. For example, acylation and alkylation of a compound containing both —SH and —NH groups may be largely confined to the —SH group after the compound is first treated with triethylbismuth or tetraethyllead.

There is a broad correlation between acidities of weakly acid organic compounds and relative reactivities of organometallic compounds. For example, the weakly acidic hydrogen in benzene is replaced by a metal when the highly reactive alkyl-alkali compounds are used, but not when the moderately reactive Grignard reagents are used. The reaction of —SH but not generally of —OH with triethylbismuth or tetraethyllead appears as a particularly striking exception, for some of the —OH compounds (Table I) which do not react are definitely more acidic than the —SH compounds which undergo substitution of hydrogen by metal. Acidities do play some part even in the substitutions considered, and one illustration from the results reported is the increase in rate of reaction observed with acetic and the chloroacetic acids.[5] For example, with triethylbismuth the number of active hydrogens observed after heating at 100° for two hours is: acetic acid, 0.11; chloroacetic acid, 0.22; dichloroacetic acid, 0.61; and trichloroacetic acid, 0.74. Incidental to the reaction of carboxylic acids with tetraethyllead it should be stated that silica gel is an effective catalyst for replacing one ethyl group to give $(C_2H_5)_3PbOCOR$ compounds,[6] and that three ethyl groups may be removed as ethane by the action of acetic acid at high temperature (250–260°).[7] In the Experimental Part we have reported the replacement of more than three ethyl groups from tetraethyllead by heating with thiophenol at 100°. Historically it is interesting to note that long years ago Dünhaupt[8] obtained bismuth sulfide from triethylbismuth and hydrogen sulfide.

Azo and nitro goups interfere with active hydrogen determinations by the Grignard re-

---

(5) If acidities play a significant role one might predict that tellurophenol will cleave organotin and possibly organogermanium compounds.

(6) Browne and Reid, THIS JOURNAL, **49**, 830 (1927).

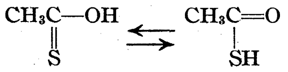
agent.[9] Triethylbismuth and tetraethyllead, however, do not evolve gas with such groups. The small volume of gas evolved from triethylbismuth and 1,3,5-trinitrobenzene is just about the experimental limit of accuracy.

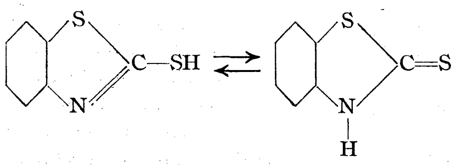
On general grounds triethylbismuth may be preferred to tetraethyllead because it not only gives high values for —SH groups but also is less interfered with by —OH groups. The inflammability and lesser accessibility of triethylbismuth is to be contrasted with the toxicity and accessibility of tetraethyllead.

Some of the results are interesting from the point of view of tautomerism. The replacement of hydrogen by metal noted with thioacetic acid establishes the presence of an —SH group, but throws no light on the equilibrium



$$\underset{\substack{\| \\ S}}{CH_3C}—OH \rightleftarrows \underset{\substack{| \\ SH}}{CH_3C}=O$$

Thioenolization is probably affected by the RM compounds used to establish the presence of active hydrogen groups. What may be a pertinent illustration are the results with 1-mercaptobenzothiazole.



Both triethylbismuth and tetraethyllead show the presence of an —SH group. However, tri-*n*-propylboron which reacts with —SH groups but not with the —NH group, gives no reaction with 1-mercaptobenzothiazole. Slight thioenolization is shown by *s*-diphenylthiourea but not by thiourea.

Some solvents may have special enolizing effects.[10]

Summary

Triethylbismuth and tetraethyllead can be used for the detection of the —SH group. These organometallic compounds do not react with the hydrogens in —NH and —C≡CH groups; they do not react with simple —OH groups, although some strong carboxylic acids undergo generally limited reactions; and there is no interference by azo or nitro groups.

The RM compounds may be useful to establish the existence of thioenolization in compounds like thioacetic acid.

The Passivity of Iron in Chromic Acid Solutions[1]

BY W. H. CONE AND H. V. TARTAR

In a previous paper[2] the authors described some experiments which showed that iron could be made active in chromic acid solutions if a sufficiently reduced pressure were maintained at the time of placing the iron in the solution. Subsequent experiments have shown that this effect of reduced pressure was associated with the presence of some sulfate ion in the solution. Experiments on iron in chromic acid solutions with and without phosphate or sulfate ion under varying conditions of temperature and pressure are described in this paper. Pertinent data on the adsorption of oxygen by iron are also given.

Materials and Apparatus.—Pure chromium trioxide (CrO_3) was prepared from potassium dichromate and sulfuric acid. The crystals were washed with concentrated nitric acid until free of sulfate and then dried at 80° to remove the nitric acid.

The data reported in this paper were obtained using No. 30 iron wire, for standardizing, Fe 99.84%. Some experiments were made with iron of varying purity without any appreciable effect on the results.

Preliminary tests showed that a reduction of pressure after the iron was placed in the chromic acid solution did not produce activity. Consequently in finding the pressure at which the iron became active, it was necessary to use a fresh piece of the metal each time the pressure was changed. To facilitate changing the sample of iron without changing the pressure, a special apparatus was constructed, Fig. 1. When the pressure in the system had been adjusted to the desired value a sample of iron wire was fed from the spool into the electrode vessel by means of the motor-driven feed rolls. The potential of the wire was determined by connecting to a potentiometer through a saturated calomel half cell. A nearly saturated potassium

[2] Cone and Tartar, THIS JOURNAL, **56**, 48 (1934).

nitrate solution was used as a bridge to connect the calomel cell with the electrode vessel. After measuring the potential of the iron against the chromic acid solution, the wire was cut and the piece removed by closing the circuit activating the electromagnet. The pressure in the system was then changed and the process repeated until a pressure was found at which there was a sudden change in the potential of the iron.

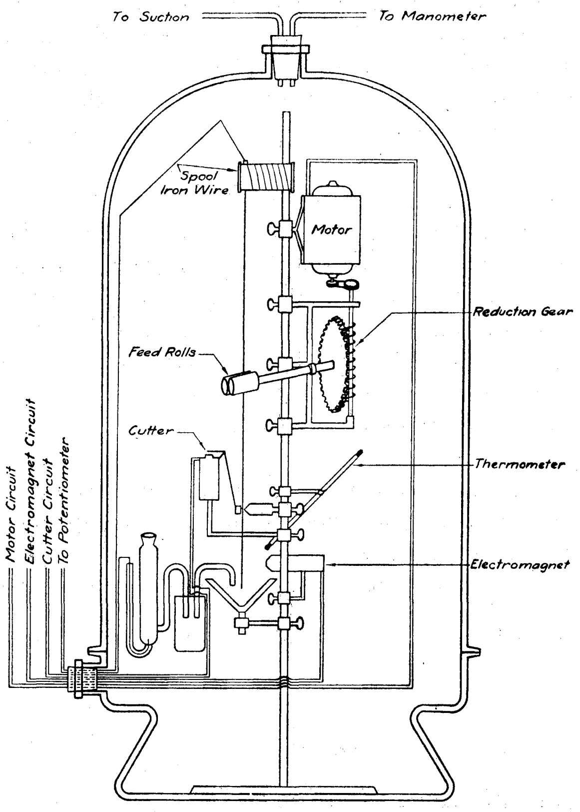

Fig. 1.—Apparatus for studying passivity at reduced pressures.

Experiments with Iron in Chromic Acid Solutions

When iron was placed under reduced pressure and then immersed in a solution of pure chromic acid, of concentrations varying from saturated to quite dilute, it did not become active even when the pressure was reduced to that of the vapor pressure of the solution. Solutions of chromic acid which contained a small amount of sulfuric acid or other activating electrolytes dissolved iron readily if the pressure was sufficiently reduced before placing the iron into the acid. The iron remained passive, however, if introduced into the solution when the pressure was above a given value which is here designated as the transition pressure.

The transition pressures could be determined either by reducing the pressure until the iron was active and then admitting air or oxygen until a sample tested passive or by decreasing the pressure slowly until a sample tested active. The results were the same within 10 mm. Since each test was made on a different piece of the wire, the surface of which varied from test to test, that was about the limit of experimental accuracy although many results did show better agreement.

The transition pressures rose rapidly with rise in temperature. This large temperature coefficient was doubtless due to two factors: changes in the adsorbed layer, and an increased activity of the ions of the activating electrolyte in the chromic acid solution.

Solutions having a high concentration of chromic acid were found to be most suitable. They were less sensitive to changes in the amount of activating electrolyte and the transition pressures occur in a measurable range at ordinary temperatures. The transition pressures were determined for several temperatures using a solution having the composition: CrO_3, 50.5%; H_2SO_4, 6.5%; H_2O, 43.0%. This was designated as solution No. 1. The data obtained with this solution are reported in Table I and Fig. 2.

When iron was suspended in an atmosphere of hydrogen for a few minutes and then lowered into a chromic acid–electrolyte solution, it was active. To show that this effect was not due to hydrogen dissolved in the chromic acid–electrolyte solution a piece of wire was covered completely with the solution which was then saturated with hydrogen. The iron remained passive. If, however, the iron was raised above the solution into the hydrogen atmosphere and allowed to drain thoroughly it became and remained active when again immersed in the solution. Iron which had been in a hydrogen atmosphere did not become active in solutions of pure chromic acid.

Some experiments were made to determine whether or not a coating of iron oxide would make the iron passive in a suitable chromic acid–electrolyte solution. Iron which was permitted to rust until covered with ferric oxide or heated in air and oxidized to give a bluish color was, after exposure to air, placed in solution No. 1 and also in a 50% solution of pure chromic acid. The oxide readily dissolved in both solutions leaving passive metal with a bright clean surface. When oxidized iron was put under reduced pressure (20 mm.) and then solution No. 1 admitted, the iron oxide dissolved, the metal was active and underwent total dissolution. These results indicate that the cause of passivity of iron in these chromic acid solutions is not an oxide film.

Solutions of chromic acid containing phosphoric acid or sodium sulfate show the same behavior as those containing sulfuric acid. For example, a solution containing 50.7% CrO_3, 8.6% Na_2SO_4, 40.7% H_2O had a transition pressure in air of 70 mm. at 28.7° while a solution containing CrO_3, 50.5%; H_3PO_4, 6.5%; H_2O, 43.0% gave under similar conditions a transition pressure of 150 mm. at 26°.

That this phenomenon of activation by reduced pressure extends over a wide range of concentration of chromic acid is illustrated by a solution having the composition CrO_3, 24.0%; H_2SO_4, 8.0%; H_2O, 68%. The transition pressure in air was 460 mm. at 22°.

To make sure that the results were not influenced by the electromagnetic fields in the apparatus a few points were checked in an apparatus free from all electrical circuits. The method was slow and laborious but sufficient data were obtained to show that the electric and magnetic fields produced no noticeable effect.

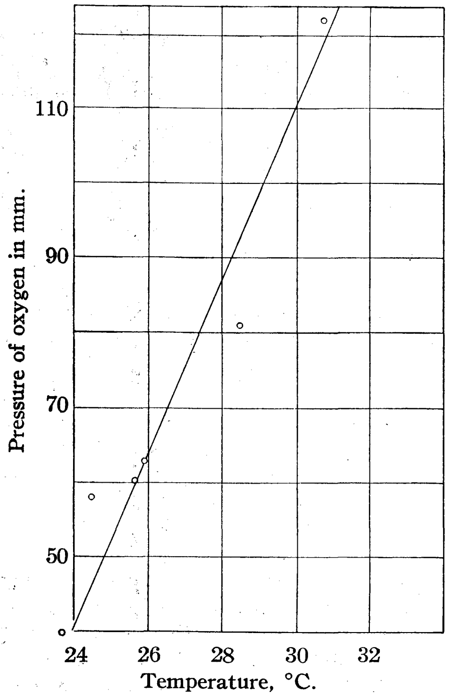

Fig. 4.—Passivifying pressures of oxygen for solution No. 1 at various temperatures.

Adsorption of Oxygen by Iron

Since the experiments described above show that oxygen plays a dominant role in the production of passivity in the chromic acid-electrolyte solutions, it was deemed advisable to determine the extent and reversibility of the adsorption of oxygen on an iron surface of the type under consideration. The apparatus was patterned after that used by Benton and White.[3] Provision was made for the collection and measurement of the gas as it came from a Töpler pump.

---

(3) Benton and White, THIS JOURNAL, **52**, 2325 (1930).

The oxygen was prepared by decomposing potassium chlorate. The gas was washed thoroughly and dried before it was admitted to the adsorption chamber.

Nitrogen of excellent commercial grade, which had been passed over copper at 400° to remove traces of oxygen, was used to determine the free space in the apparatus.

The iron sample was prepared by cutting 50 g. of the No. 30 iron wire into very short lengths. This was cleaned thoroughly and then heated *in vacuo* for seventy-two hours under a reduced pressure of 10^{-2} mm. No provision was made for the reduction of any invisible oxide that may have been formed by the brief contact with air because the desire was to have a surface similar to that which had been used in the previously described experiments. It is also somewhat doubtful whether the iron was completely outgassed under these conditions. The complete removal of oxygen was hardly necessitated, however, because the object was the determination of measurable adsorption in the region of transition pressures. The results of a typical run are shown in Table IV.

Table IV

Adsorption of Oxygen by 50 Grams of Iron at 25°

Pressure, mm.	Cc. adsorbed (standard conditions)	Pressure, mm.	Cc. adsorbed (standard conditions)
4.0	0.07	313.5	0.21
11.0	.13	411.7	.23
51.5	.17	515.0	.29
107.3	.18	639.0	.42
195.1	.15	682.0	.49
252.3	.17		

No high degree of accuracy is claimed in the low pressure region, but above 200 mm. very concordant results were obtained. The adsorption was found to be reversible. All of the oxygen entering the apparatus could be recovered at the end of a run within the limits of the reading of the buret. There were no visible signs of oxide formation even after repeated runs on the same sample of iron. Calculations made indicated that the adsorbed layer might be several molecules deep.

A few experiments were made to determine the effect of reduced pressure on iron in nitric acid. If the pressure in a small vessel containing a piece of iron wire was reduced to about 2 mm. and then concentrated nitric acid (sp. gr. 1.42) allowed to flow in around the wire, the iron became active and dissolved completely provided the capacity of the pump was great enough to pump off the gases as fast as they were formed.

These results agree with the work of Freundlich, Patscheke and Zocher[4] in which they found that slow filling of evacuated vessels, containing iron mirrors, with nitric acid caused greater activity than when they were filled rapidly.

The differences which they observed between the "vacuum mirrors" and the "air mirrors" were probably due to the oxygen remaining on the iron which can only be removed by heating to about 300° under pressures of 10^{-2} mm.

Discussion of Results

These experiments show that iron is passive in solutions of chromic acid at all concentrations. No evidence was found of periodic passivity which occurs in certain concentrations of nitric acid. If the chromic acid contains a sufficient concentration of activating ions the concentration of the oxygen surrounding the iron is the factor which determines whether it will be active or passive when placed in solution. That this effect of oxygen is due to adsorption is indicated by the adsorption data. It should be noted, however, that while the adsorption apparatus was as dry as it was possible to make it, water vapor was necessarily present in the other apparatus. To what extent this water vapor affects the adsorption of oxygen is not known.

From this and the previous work the writers have gradually come to the belief that the primary condition for the passivification of iron is the formation on the surface of an adsorbed layer of oxygen or of a "two dimensional compound" of oxygen and iron.[5] Definite oxides may be formed subsequently, particularly in the case of anodic passivation. Such oxides are readily soluble, however, in the acidic solutions used by the authors. Evans[6] has succeeded in isolating these films of oxide from iron which had been treated with various passivifying agents but his experiments fail to prove that these films were the primary cause of passivity. The fact that an oxide-covered iron wire may be made active or passive in chromic acid–electrolyte solutions by merely changing the pressure on the iron before immersion in the liquid makes it appear doubtful whether the oxide layer is an essential factor for passivification in these media.

Summary

1. Iron under reduced pressure becomes active when placed in solutions of chromic acid containing sulfuric acid or other activating electrolytes. In pure chromic acid solutions iron does not become activated by reduction of pressure.

2. The pressure of air or oxygen required to produce passivity increases rapidly with rise in temperature.

3. An atmosphere of hydrogen causes iron to be active in a chromic acid–electrolyte solution.

Organic Reagents[1] in Qualitative Analysis. III. The Analysis of the Common Metals of the Alkaline Earth Group and Magnesium Using 8-Hydroxyquinoline

BY LEO LEHRMAN, M. MANES AND J. KRAMER

In the field of qualitative analysis the detection of the alkaline earth metals, especially in small amounts, is one of the most difficult of all. Though a number of organic reagents have been suggested for this purpose, most of them have certain disadvantages which prevent their use in a scheme of analysis. Either they are not specific, or the presence of some other normally occurring metal interferes or else the reagent cannot be employed for separations. However, one organic substance, 8-hydroxyquinoline (oxin, 8-quinolinol), which has already been used as a precipitant for metals,[2] was found to be excellent reagent in the analysis of the group.

In this work a method of analysis of the alkaline earth metals and magnesium, using 8-hydroxyquinoline, has been developed which makes it possible to detect small amounts. In brief Ca^{++} and Mg^{++} are precipitated by the organic reagent in an ammoniacal solution containing ammonium salts. The Ca^{++} is then separated from Mg^{++} in acetic acid as the oxalate and the Mg^{++} reprecipitated as the 8-hydroxyquinoline salt by making the solution alkaline with ammonia. A distinct advantage of the use of 8-hydroxyquinoline is that any excess in the filtrate can be removed easily by evaporation, as it is apparently volatile with steam. The solution is then analyzed for Ba^{++} and Sr^{++} by one of the usual methods.

Together with the scheme of analysis a test has been worked out using tannic acid in an alkaline solution,[3] which gives a preliminary indication of the alkaline earth metals.

Experimental

1. Reaction of Alkaline Earth and Alkali Metals with Tannic Acid in Alkaline Solution.—To varying amounts from 1–500 mg. of the metals, separately, 1 ml. of 2% tannic acid solution was added and then made alkaline with 6 *M* sodium hydroxide solution. Ba^{++}, Sr^{++} and Ca^{++} gave blue-green solutions or precipitates while the others were tan colored; 1 mg. of Ba^{++}, Sr^{++} or Ca^{++} in the presence of 500 mg. of the others, except NH_4^+ gave the same result. When ammonium salts are present the solution is made distinctly alkaline with sodium hydroxide, carefully warmed until all the ammonia is volatilized and then the test is carried out. Thus 1 mg. of Ba^{++}, Sr^{++} and Ca^{++} in the presence of 500 mg. NH_4^+ gave a positive result.

2. Reaction of Ba^{++}, Sr^{++}, Ca^{++} and Mg^{++} with 8-Hydroxyquinoline.—Varying amounts from 1–500 mg. of each of the above, separately, were mixed with 5–30 ml. of saturated ammonium chloride solution, made alkaline with ammonia and 15% solution of 8-hydroxyquinoline in 6 *M* acetic acid[4] added, keeping the solution alkaline with concentrated ammonia, until no further precipitation took place. This is indicated by a yellow supernatant liquid. In order to distinguish a precipitate of a metal 8-hydroxyquinoline compound from that of the reagent itself, at first the solution was kept above the melting point, 73–74°, of the 8-hydroxyquinoline. However, it was found that the calcium salt is appreciably soluble in the hot solution. So, instead, a preliminary test was made using a saturated solution of the reagent in concentrated ammonia. The results of these experiments showed that Ca^{++} and Mg^{++} are completely precipitated while Ba^{++} and Sr^{++} are not precipitated at all.

Using the same procedure and various combinations of the metals, it was found that 1 mg. or more of Ca^{++} and Mg^{++} could be separated completely from 500 mg. of Ba^{++} or Sr^{++} or any combination of both. Similar results were obtained using Na^+ and K^+ instead of Ba^{++} and Sr^{++}.

However, when large amounts of Ca^{++} and Mg^{++} were precipitated in the presence of large amounts of Ba^{++} and Sr^{++}, as much as 5 mg. of Ba^{++} and Sr^{++} was adsorbed by the precipitate. Furthermore, in the presence of 500

---

[1] Most of the organic reagents are made by the Eastman Kodak Co., Rochester, N. Y.

[2] "Organic Reagents for Metals," Hopkin & Williams, Ltd., London, Eng., p. 51.

[3] L. Rosenthaler, *Mikrochemie*, **14**, 363–368 (1934); G. Ammer and H. Schmitz, *Wasser*, **8**, II, 161–168 (1934).

[4] This solution was chosen in preference to alcohol and diluted acetic acid solutions as a result of experiments showing less volume of the precipitant would be necessary.

mg. of Ca^{++} or Mg^{++} or combination of both, only 2 mg. of Ba^{++} or 3 mg. of Sr^{++} in the original solution could be detected after the precipitation.[5]

3. **Separation of Ca^{++} and Mg^{++}.**—Various combinations of Ca^{++} and Mg^{++} from 1–500 mg. in a saturated ammonium chloride solution were precipitated with 8-hydroxyquinoline, keeping the solution alkaline with ammonia, filtered with suction and then dissolved with hot 3 *M* acetic acid. While still hot 0.25 *M* ammonium oxalate solution was added slowly with stirring until no further precipitation of the Ca^{++} took place. The mixture was filtered, the filtrate concentrated to 10 ml. by evaporation and divided in half. One half was tested for Mg^{++} with *p*-nitrobenzene–azoresorcinol and sodium hydroxide[6] and the other half by making alkaline with ammonia and adding a small volume of 8-hydroxyquinoline solution. The experiments showed that 1 mg. of either metal could be detected in the presence of 500 mg. of the other.

4. **Separation of Ba^{++} and Sr^{++}.**—Though this method is a standard one, experiments were carried out to determine how much of each could be detected. Different mixtures containing 1–500 mg. of each were precipitated with 2 *M* ammonium carbonate, filtered and dissolved in 1 *M* acetic acid. The solution was warmed and 0.5 *M* potassium chromate solution added slowly with stirring until no further precipitation occurred. After filtering, washing and concentrating the filtrate, it was tested for Sr^{++} with ammonium oxalate solution. The results showed that 1 mg. of either metal could be detected in the presence of 500 mg. of the other.

On the basis of the above experiments a method of analysis was worked out and various combinations of the four metals from 1–500 mg. analyzed. The results confirmed those found above, *viz.*, that 1 mg. of Ca^{++} and Mg^{++} could be detected in the presence of 500 mg. of any other or combination of others; that 2 mg. of Ba^{++} and 3 mg. of Sr^{++} are detectable in the presence of 500 mg. of Ca^{++} or Mg^{++} or combination of both.

5. **Method of Analysis.**—The filtrate from the ammonium sulfide group, after acidification with acetic acid and removal of hydrogen sulfide, is evaporated to 25 ml. and filtered, if necessary. A small portion, 5 ml., is made alkaline with concentrated ammonia and a saturated solution of 8-hydroxyquinoline in ammonia added to test for the presence of Ca^{++} and Mg^{++}. If present, the test portion is combined with the main solution, made alkaline with concentrated ammonia and 15% solution of 8-hydroxyquinoline in 6 *M* acetic acid slowly added, keeping the solution alkaline with concentrated ammonia, until no further precipitation occurs. This is indicated by a yellow supernatant liquid. The mixture is filtered using suction and the precipitate washed twice with dilute ammonia, the washings being combined with the filtrate (filtrate B).

Residue.—The precipitate is dissolved in the smallest volume of hot 3 *M* acetic acid. While still hot, 1 *M* ammonium sulfate solution is added slowly with stirring to precipitate any Ba^{++} and Sr^{++} that had been adsorbed,[7] the solution filtered, the residue washed and then discarded. The filtrate is heated and 0.5 *M* ammonium oxalate solution slowly added with stirring until no further precipitation, showing the presence of Ca^{++}, takes place, filtered and washed (filtrate A).

Filtrate A.—A small portion is first tested for magnesium with *p*-nitrobenzene-azoresorcinol and sodium hydroxide. If positive, the remainder of the solution is made alkaline with ammonia and a small volume of the 8-hydroxyquinoline solution added, keeping the solution alkaline with ammonia. A yellow precipitate indicates Mg^{++}.

Filtrate B.—The solution is evaporated to dryness and the ammonium salts volatilized by continual heating. After cooling, the residue is treated with a small amount of dilute hydrochloric acid and then a small volume of water is added. The solution is filtered, if necessary, and the filter paper washed. The solution is made alkaline with concentrated ammonia and ammonium carbonate added until no further precipitation occurs, filtered and washed (filtrate contains alkali group).

Residue.—Dissolve with 1 *M* acetic acid and test a small portion for Ba^{++} with 0.5 *M* potassium chromate solution.[8] If present, warm the solution and add the potassium chromate solution slowly until no further precipitation takes place. Filter and wash. The filtrate is evaporated to 10 ml. and 0.5 *M* ammonium oxalate solution added, a white precipitate indicating Sr^{++}.

Summary

A preliminary test, using tannic acid, has been worked out, which can indicate 1 mg. of the alkaline earth metals even in the presence of large amounts of ammonium salts.

A method of analysis of the alkaline earth metals and magnesium, using 8-hydroxyquinoline, has been developed so that 1 mg. of Ca^{++} and Mg^{++}, 2 mg. of Ba^{++} and 3 mg. of Sr^{++} can be detected in the presence of 500 mg. of any other metal of this group or combination of others.

In the method of analysis Ca^{++} and Mg^{++} are separated from Ba^{++} and Sr^{++} by precipitating with 8-hydroxyquinoline in an ammoniacal solution. The Ca^{++} is separated from Mg^{++} as oxalate in acetic acid and the magnesium reprecipitated as the 8-hydroxyquinoline salt by making alkaline with ammonia. Ba^{++} and Sr^{++} are analyzed by one of the usual accepted methods.

NEW YORK, N. Y. RECEIVED FEBRUARY 13, 1937

---

[5] If the Ca^{++} and Mg^{++} 8-hydroxyquinoline precipitates are dissolved in acetic acid and reprecipitated with ammonia all the adsorbed Ba^{++} and Sr^{++} can be removed.

[6] (a) K. Suitzu and K. Okuma, *J. Soc. Chem. Ind., Japan*, **29**, 132 (1926); (b) Feigl, "Qualitative Analyse mit Hilfe von Tüpfel-Reaktionen," Akademische Verlagsgesellschaft, Leipzig, Germany, 1935, 2d ed., p. 262.

[7] As the largest amount of Ba^{++} and Sr^{++} adsorbed does not exceed 5 mg., only a small volume of ammonium sulfate solution is necessary and practically no Ca^{++} is precipitated. If very small amounts of Ba^{++} and Sr^{++} are to be detected, the 8-hydroxyquinoline precipitate should be dissolved in acetic acid and reprecipitated with ammonia.

[8] If Ba^{++} is absent, a sensitive test for Sr^{++} can be immediately performed by treating with a saturated water solution of tetrahydroxyquinone, a reddish-brown precipitate indicating its presence [G. Gutzeit, *Helv. Chim. Acta*, **12**, 728 (1929)].

The Dielectric Properties of Acetylenic Compounds. VII. Alkyl- and Arylpropiolnitriles. Resonance in the Acetylene Triple Bond

BY B. C. CURRAN AND H. H. WENZKE

The low moments of the halogenoacetylenes in comparison to those of the alkyl halides point to a probable resonance of the classical structures with the form $R—C^{-}=C=X^{+}$. Resonance of the —C≡C— group could be established more definitely by the examination of a class of compounds wherein the effect would be to increase the moment. The acetylenic nitriles offer a good test for this resonance in that the two forms contributing to the molecule would be R—C≡C—CN and $R—C^{+}=C=C=N^{-}$. That the comparison of the moments of acetylenic halides and nitriles is further opposite is evident from an analysis of the data of Table I. In these compounds the polarity of which is influenced only by induction, the increase in moments from the acids to the substituted butanes is seen to be roughly parallel. The inductomeric polarizabilities of the —CN and —Cl groups are thus very nearly the same.

TABLE I

Preparation of Compounds.—The butyl-, amyl- and phenylpropiolnitriles were prepared by the reactions of the corresponding acetylene magnesium bromides with cyanogen chloride.[2] The *p*-tolyl propiolnitrile was prepared by the following method. *p*-Tolylaldehyde was converted into *p*-methyl ethyl cinnamate by the action of ethyl acetate in the presence of sodium.[3] The cinnamate was brominated in the cold, dehydrohalogenated with alcoholic potassium hydroxide, acidified with hydrochloric acid, and the resulting *p*-tolylpropiolic acid esterified with methyl alcohol. The ester was dissolved in excess alcoholic ammonium hydroxide and allowed to stand in a stoppered flask for one month. The alcohol was then removed by distillation, and the amide was first dried and then converted into the nitrile by the action of phosphorus pentoxide.[4] The phenyl- and *p*-tolylpropiolnitriles were purified by repeated crystallizations from petroleum ether in a bath of liquid ammonia, and dried for a few hours by a current of dry air before being placed in a desiccator over calcium chloride. The polarizations at infinite dilution were obtained by the method of Hedestrand.[5] The value of the electronic polarization of phenylpropiolnitrile was obtained from the literature, and from this the value for *p*-tolylpropiolnitrile was calculated.

Phenylchloroacetylene[8]	1.10	Phenylpropiolnitrile	4.50

Discussion

The large moments found for the acetylenic nitriles reveal the existence of resonance in these compounds as well as in the halogenoacetylenes. From Table V it can be seen that butylchloroacetylene has a lower moment than chlorobenzene, while butylpropiolnitrile has a higher moment than benzonitrile. These comparisons indicate that the forms $R-C^{-}=C=Cl^{+}$ and $R-C^{+}=C=C=N^{-}$ contribute to a greater extent to their respective molecules than do the forms $^{-}C_6H_5=Cl^{+}$ and $^{+}C_6H_5=C=N^{-}$. The electromeric polarizability of the acetylene triple bond is therefore greater than that of the phenyl group. A pronounced increase in moment is obtained by replacing a phenyl group for an alkyl group in the acetylenic nitriles despite the fact that the alkylacetylenes have higher moments than phenylacetylene. While this increase is due partly to the fact that the form $^{+}C_6H_5=C=C=C=N^{-}$ is more polar than $R-C^{+}=C=C=N^{-}$ it is also evidence of the strong resonance in phenylpropiolnitrile.

Summary

1. Electric moments have been determined for butyl-, amyl-, phenyl- and *p*-tolylpropiolnitriles.

2. The values obtained for these moments prove the existence of resonance in these molecules as well as in the alkyl and aryl halogenoacetylenes.

3. The electromeric polarizability of the acetylene triple bond is shown to be greater than that of the phenyl group.

NOTES

Photosynthesis and the Absorption of Radiation by Plants

BY G. RICHARD BURNS

In the course of investigations on the amount of photosynthesis by white pine seedlings in different portions of the spectrum, a rather interesting correlation was found between the amount of photosynthesis and the color of the plant.

In an attempt to arrive at some value for the radiation absorbed by the plant the reflection of the plant was assumed to be the reflection of the needles to light of 45° incidence and the absorption, the absorption of the plant pigments in acetone solution with the concentration the same as in the plant. The absorption spectrum obtained from these two values might be called the "primary absorption spectrum" of the plant, defining the difference between this and the true absorption as the "secondary absorption." The values for the secondary absorption would be high where the primary is low due to reflection within the needle. Also the absorption of the pigments is shifted toward the blue when in solution. In determining the absorption and reflection values, each spectrometer reading covered a wide band of wave lengths and the front slit was 0.75 mm. wide so that the spectrum was rather blurred.

Graph I gives the percentage primary absorption for two types of seedlings, B for those grown in blue light and R for those grown in red. The stepwise curves indicate, approximately, the range of wave lengths covered at each reading. Assuming constant quantum efficiency and that only light thus primarily absorbed is effective in photosynthesis it is possible to calculate the relative amounts of photosynthesis in any two portions of the spectrum. These values calculated from the rough physical measurements agree within a few per cent. with the experimentally determined values in all cases. Thus these primary absorption curves may be considered as representing the relative amounts of photosynthesis at equal incident quantum intensity.

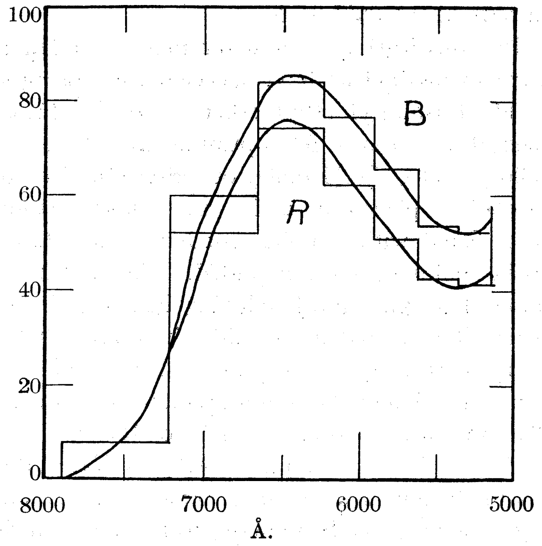

Fig. 1.

The fact that the amount of photosynthesis depends on the primary absorption spectrum seems fairly well established since the relationship holds for a large number of experiments with different ranges of wave lengths and different colors of trees as well as with experiments with semi-monochromatic radiation from filtered sodium and mercury sources. It offers a quantitative explanation of all our experimental results, published in botanical journals from 1933 on.

Just why the amount of photosynthesis should agree with this arbitrary value rather than with the true absorption is still a matter of speculation.

Diazo Coupling of 5-Hydroxy-6-methylhydrindene

By Louis F. Fieser and Warren C. Lothrop

In a previous report [This Journal, **58,** 2050 (1936)] we stated that the above compound (I) failed to couple with diazotized *p*-nitroaniline in alkaline solution, whereas in parallel tests 5-hydroxy-4,7-dimethylhydrindene and 6-hydroxy-5,8-dimethyltetralin coupled readily under the same conditions. On preparing a further quantity of I in order to investigate its behavior with other coupling agents, we first tried to effect a coupling with diazotized *p*-nitroaniline under other conditions and found that this indeed can be accomplished. Each of seven solutions containing 0.1 g. of I in 10.5- to 20-cc. portions of sodium hydroxide solutions of concentrations varying from 0.119 to 2.49 *N* was treated at 0° with 2.5 cc. of an aqueous solution containing approximately one equivalent of the diazo compound and 0.000021 mole of hydrochloric acid, and after ten minutes the mixtures were boiled and the precipitate collected. The crude *p*-nitrobenzeneazo derivative of I (m. p. 210–215°) was obtained in yields decreasing steadily from 36% in the most weakly alkaline medium to a negligible amount (*ca.* 1%) in the most alkaline solution. The purified azo compound formed brown-red needles, m. p. 230–232° (calcd.: C, 64.63; H, 5.08. Found: C, 64.32; H, 5.34). Similar results were obtained even with aniline, the benzeneazo compound forming red needles, m. p. 141–143° (calcd.: C, 76.16; H, 6.39. Found: C, 75.97; H, 6.60).

We are investigating the conditions of the couplings more fully and making a further comparison with related compounds; but it seems desirable to correct at once the impression given in the earlier report that the hydrindene derivative I departs entirely from the behavior characteristic of a phenol having a free ortho position.

Allomucic Acid

By Fred L. Humoller and Wm. F. McManus

Recently we published a paper on the preparation of new derivatives of *l*-allonic and *l*-altronic acids. While we were mainly concerned in this paper with the interesting behavior of allonic acid and its lactones, we also described briefly several new compounds related to the above two acids, among them allomucic acid. Dr. Th. Posternak has been kind enough to point out to us that in 1935 he had published an account of the preparation of allomucic acid from *d*-allonolactone. Unfortunately we had overlooked this publication[1] and the statement in our publication, "Posternak did not report, however, the preparation of allomucic acid," does a grave injustice to Dr. Posternak. After having read his paper no one can doubt Dr. Posternak's claim of priority of the preparation of allomucic acid.

Hydrogen-Deuterium Exchange in Acetate Solution

BY SYLVESTER LIOTTA AND VICTOR K. LA MER

In the course of a study of acetate-ion catalyzed reactions in heavy water, it became necessary to determine the extent of the exchange between the hydrogens of the methyl group and the deuterium of the solvent. From the results of early investigations[1,2,3] little or no exchange was to be expected, while from later work[4,5] varying degrees of exchange could be expected, depending upon temperature and time of contact.

Heavy water (d^{25}_{25} 1.1000, approximately 93% D) was purified by distillation *in vacuo* to remove possible catalysts. Anhydrous sodium acetate was added to produce a 10% solution. After standing for two weeks in a Pyrex vessel at 25–30°, the solvent was recovered by distillation *in vacuo*. The density was redetermined by filling the same pycnometer. Sodium acetate and acetic anhydride were then added to make a final concentration of 10% and 1%, respectively. After two weeks at 25–30°, the solution was neutralized with caustic soda and the same procedure repeated.

Solvent before addn. of sodium acetate, g.	10.5417
Solvent after first distn., g.	10.5413
Solvent after second distn., g.	10.5420

If any exchange occurs either in slightly acid or slightly alkaline solution at room temperature it is exceedingly slow.

An Improved Method for Synthesizing Isobutyl Ethyl Ether

BY E. M. MARKS, DAVID LIPKIN AND BERNARD BETTMAN

According to Cerchez[1] aliphatic ethers can be synthesized from alkyl sulfates and magnesium alcoholates. In several instances he obtained yields of 60–70%. In preparing isobutyl ethyl ether by this method from diethyl sulfate and magnesium isobutylate, we obtained the product in only about 30% yield.

By substituting sodium for magnesium in the Cerchez method we have succeeded in raising the yield of isobutyl ethyl ether to 70%. Experimental conditions for optimum results are as follows: 93 g. (1.25 mole) of anhydrous isobutyl alcohol is placed in a 500-ml. round-bottomed flask fitted with a reflux condenser and 12.5 g. (0.54 mole) of sodium added. The mixture is allowed to react until refluxing has ceased, after which it is heated in an oil-bath at 120–130° for two and three-quarters hours. At the end of this time a portion of the sodium remains undissolved. The mixture is then cooled to 105–115° and 77.1 g. (0.5 mole) of pure diethyl sulfate added gradually during a two-hour period. Reaction is vigorous and steady refluxing takes place during addition of the sulfate. After all has been added, refluxing is continued for two hours. The reaction mixture is then permitted to cool to room temperature (overnight) after which an equal weight of crushed ice is added, followed by a slight excess of dilute sulfuric acid. The ether is then steam-distilled out of the flask, separated from the aqueous portion of the distillate, given three equal-volume washes of 30% sulfuric acid, to remove most of the unreacted isobutyl alcohol, washed twice with water and dried over anhydrous potassium carbonate. The dried product is then refluxed over sodium ribbon for three hours to remove all traces of alcohol and finally is distilled through a precision fractionating column of the type recommended by Podbielniak.[2] The yield of isobutyl ethyl ether was 70%, based on diethyl sulfate. The boiling point, density and refractive index of our ether agreed with the recorded values[3] within the experimental error.

Several variables in this synthesis have been studied. (1) If the isobutyl alcohol is not dried rigorously, the yield of ether is reduced to

[3] Norris and Rigby, THIS JOURNAL, **54**, 2088 (1932).

67%. (2) Increasing the quantity of alcohol to 1.5 mole, in an attempt to dissolve more of the sodium, has no appreciable effect on the yield. (3) Prolonged heating of alcohol with sodium (eight hours) results in a darker colored crude product and also a reduction in yield to 65%. It is unnecessary that all of the sodium be dissolved before the diethyl sulfate is added. Apparently as the sodium isobutylate is used up in the reaction, more sodium goes into solution until all is dissolved. (4) A temperature range of 105–140° is permissible during reaction with the diethyl sulfate. If the temperature is kept lower (95°), the yield of ether is reduced (58%). (5) If only the theoretical amount of sodium (0.5 mole) is used, the yield of ether amounts to 65%. (6) Isobutyl alcohol, diethyl sulfate and solid potassium hydroxide react to form isobutyl ethyl ether in 22.5% yield. If the solid alkali is replaced by a 50% aqueous solution, no ether is formed.

It is possible also to synthesize *s*-butyl ethyl ether by this method, using sodium *s*-butylate and diethyl sulfate. Our data at this time are rather incomplete, but indications point to a maximum yield about 48%.

The Solubility of Lithium and Sodium Fluorides

BY JOHN H. PAYNE

In view of the discordancy in the data for the solubility of lithium and sodium fluorides in water,[1] we have conducted careful determinations of these data at 0, 25 and 35°.

Lithium sulfate made from Kahlbaum pure lithium carbonate was recrystallized until the reaction was neutral, and the fluoride precipitated by means of Merck "Zur Analyse" ammonium fluoride. Sodium fluoride was prepared from Kahlbaum pure sodium carbonate and hydrofluoric acid by the method of McAdams and Smith.[2] Both preparations were conducted entirely in platinum. Analysis by conversion to the sulfate gave an average of 99.94% purity. The purity of the fluorides was also checked by a spectroscopic examination. The solubility vessels, coated internally with several layers of a specially purified high-melting paraffin wax, were immersed completely in a thermostat with delivery tubes, also paraffined, to permit the removal of samples without removing the vessels from the thermostat. The samples were rotated for from forty-four to seventy-two hours until equilibrium was reached, then filtered into a 50-cc. pycnometer, also immersed in the thermostat. After weighing, the entire contents of the pycnometer were washed into a platinum vessel, evaporated to dryness, and weighed. All determinations were made in triplicate and equilibrium was approached from both directions in each case. The average deviation of the triplicates was 0.13% and the maximum deviation 0.38%. The thermostat was regulated to within 0.02°.

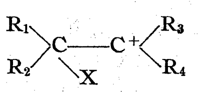
The Halogenation of Ethylenes

BY IRVING ROBERTS AND GEORGE E. KIMBALL

Recent work by Bartlett and Tarbell[1,2] has shown that the first step in the reaction of halogen molecules with the ethylene linkage leads to the formation of a negative halide ion and a positively charged organic ion. This ion has been postulated by Robinson[3] to have the structure



(1)

Some doubt has been cast on this mechanism[4] because of the presumption that there should be free rotation about the C–C single bond, which would lead to a mixture of equal amounts of the *cis* and *trans* halogenation products. In those cases in which the halogenation is homogeneous and not photochemical it is observed that either the *cis* or *trans* halogenation reaction predominates, forming at least 80% of the product.[5] It

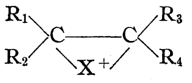
(5) *Cf.* Freudenberg, "Stereochemie," Verlag Franz Deuticke Vienna, 1933, p. 520. Some of the reactions listed here are photochemical or complicated by side reactions.

has, therefore, been postulated that the second step of the reaction (the addition of halide ion to the positive organic ion) takes place so rapidly that there is not sufficient time for rotation about the single bond to take place.

We would like to point out that free rotation about the C–C bond is *not* to be expected. If this structure is assumed, one of the orbitals of the C^+ must be completely empty. The X atom on the other hand has three orbitals occupied by pairs of electrons. This arrangement is such that a coördinate link will almost certainly be formed by the sharing of one of the pairs of electrons of the halogen with the unoccupied orbital of the carbon. Another possible structure of the ion is one in which the positive charge is on the halogen. The X^+, being isoelectronic with a member of the oxygen family, should show a valence of two, *i. e.*, it should form a structure of the ethylene oxide type



(2)

From an electronic viewpoint structures (1) and (2) are identical. The difference between the ionization potential of carbon (11.22 volts) and that of a halogen (*e. g.*, 11.80 volts for bromine) is so small that the actual structure of the ion is undoubtedly intermediate between (1) and (2). Since the two carbons in either structure are joined by a single bond and by a halogen bridge, free rotation is not to be expected.

If, however, R_1 and R_3 (or R_2 and R_4) are similarly charged groups (*e. g.*, COO^-) there may be sufficient repulsion between them to overcome the restraining force of the double linkage, and rotation to the opposite configuration may take place before the second step of the reaction occurs.

This second step, which may be the addition of either a halogen ion X^- or some other atom or molecule, is probably a simple "three-atom" reaction of the type proposed by London,[6] and developed by Polanyi[7] and Olson.[8] In this case the new atom will approach one of the carbon atoms from the side opposite to the X atom already present. A bond to this carbon will be formed while the bond from the original X to the carbon is broken, with simultaneous neutralization of the charge of the ion. This process will always lead to *trans* addition, except in the previously mentioned case in which there are two like charged groups initially in the *cis* position.

With this modification the mechanism suggested by Robinson and by Bartlett and Tarbell explains all the existing data on the reactions of the halogens with ethylene linkages. The additions of bromine and chlorine to maleic and fumaric acids are very largely *trans*,[9] as the theory predicts. The additions of bromine and chlorine to fumarate ion are again predominantly *trans*, but the addition of bromine or chlorine to maleate ion, with its two negatively charged *cis*-carboxylate ions, is almost entirely *cis*.[10]

The difficulty of explaining the maintenance of configuration in the bromination of stilbene and isostilbene, which yield different methoxybromides and different dibromides[1] no longer exists if this structure of the intermediate ion is postulated. This is also true of the formation of the halo-beta-lactones from dimethylmaleic and dimethylfumaric acids.[2]

The authors wish to thank Prof. L. P. Hammett for his helpful discussions of this problem.

A Fermentation Test for Vitamin B_1

BY ALFRED SCHULTZ, LAWRENCE ATKIN AND CHARLES N. FREY

Vitamin B_1 (Merck's natural-crystalline) exerts a powerful action on the rate of alcoholic fermentation. In the presence of a suitable sugar–salt buffer mixture as little as one gamma (0.000001 g.) of the vitamin may be detected.

Table I gives the results of a typical test.

TABLE I

Total volume in each case, 100 cc. (distilled water). Yeast for each, 1 g. commercial bakers' yeast (Fleischmann). Sugar, 3 grams Merck C. P. Dextrose, plus synthetic salt mixture and buffer. Temperature, 30°. Oscillations, 100 per minute.

Natural crystalline vit. B_1 mg.	Cc. of gas in 3 hours
None	185
0.001	215
.005	305
.010	350
.040	395
.100	405

It is natural to suppose that this phenomenon could be employed for vitamin B_1 assay. This has been done and when compared with assay by rat growth test the results so far have shown a very satisfactory concordance. We have been enabled to test synthetic vitamin B_1 (Merck "Betabion") through the courtesy of Merck & Co. The Betabion gives results scarcely distinguishable from the natural crystalline product.

Debromination of Mono and Dibromocholestanone

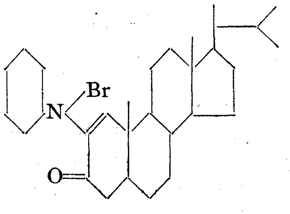
By E. Schwenk and B. Whitman

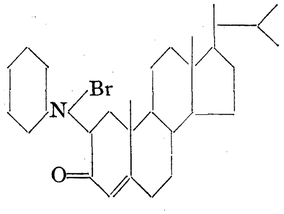
We have been studying for some time the debromination of various sterol bromides, particularly those compounds in which the reaction would lead to unsaturation in the first ring. The appearance of several articles[1] dealing with this subject makes it seem desirable to publish some of our results now.

We have found that the nature of the reagent used to remove hydrogen bromide from bromo sterols has considerable influence on the course of reaction. It is thus possible to obtain several different reaction products from the same bromo compound.

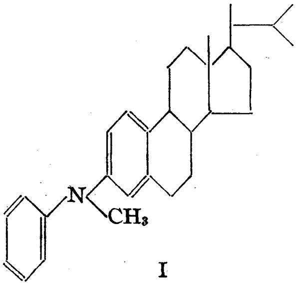
Experiments with mono- and dibromocholestanone are illustrative of this point. From monobromocholestanone, by refluxing with pyridine, we obtained the same pyridinium compound that Butenandt and Wolff[2] reported. However, with dimethylaniline, monobromocholestanone yields mainly cholestanone. In this case the bromine has been replaced by hydrogen. This is the only example of such a reaction of which we are aware.

With dibromocholestanone pyridine yields an unsaturated pyridinium salt, arising very probably by splitting one bromine atom as hydrobromic acid and forming a salt with the other. For the dibromocholestanone, the 2,2,[1b] as well as the 2,4,[1c] position for the bromine atoms has been discussed. Accordingly, the new pyridinium compound derived from dibromocholestanone would have one of the structures

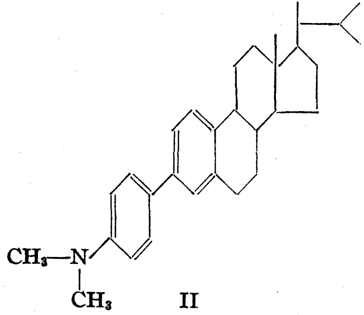




On refluxing dibromocholestanone with dimethylaniline, a substance was obtained which by analysis was found to contain only carbon, nitrogen and hydrogen, but no oxygen. The presence of nitrogen and absence of oxygen suggests that some condensation involving the keto group and the benzene ring has taken place. That such is the case is supported by the fact that this substance gives a beautiful wine-red coupling reaction with nitrodiazobenzene. This acid coupling is typical of an amine. The analytical results point to the substance being either $C_{33}H_{47}N$(I) or $C_{34}H_{49}N$(II) rather than $C_{35}H_{53}N$(III). In our opinion, formula II is the most probable. This would mean that ring A of the cholesterol has become aromatic.



I



II

on addition of *p*-nitrodiazobenzene solution, giving a beautiful wine-red coloration.[3]

Experimental

I. Five grams of monobromocholestanone is dissolved in 50 cc. of dimethylaniline and heated for eight hours so that the solution boils gently. The reaction mixture is poured into iced hydrochloric acid and the half solid precipitate taken up with ether. The ether solution is washed thoroughly with hydrochloric acid, water, soda solution and again water, dried and evaporated. A brown oil which partly crystallizes is obtained. By dissolving in acetone and chilling crystals are obtained which, by several recrystallizations, become white. They melt at 125–126°. With phenylhydrazine the tetrahydrocarbazol derivative described by Doré and Petrow[4] is obtained, melting point 167–182°. The mixed melting point with the tetrahydrocarbazol derivative m. p. 165.5–181° (Doré and Petrow 180–181°) prepared from pure cholestanone was found to be 168–182.5°. From the tetrahydrocarbazol derivative the picrate was prepared which melted at 208–209.5° (Doré and Petrow 209–210°).

II. Five grams of dibromocholestanone is heated with 50 cc. of pyridine. After a short time (twenty to thirty minutes) the precipitation of white crystals begins and soon the flask is filled with them, so that the mixture starts to bump. It is now cooled, filtered and the crystals washed with alcohol. After one recrystallization from alcohol, in which they are difficultly soluble, white shining needles are obtained which show decomposition above 280°, but no melting point. By pouring alkali on the crystals, they take up a beautiful orange coloration, characteristic of pyridinium compounds. Analysis showed them to contain bromine and nitrogen: calcd. for $C_{32}H_{49}ONBr$: N, 2.58; Br, 14.76. Found: N, 2.49; Br, 14.98.

III. Five grams of dibromocholestanone is heated with 50 cc. of dimethylaniline for five hours. The reaction mixture is treated as in Expt. I. After evaporation of the ether, a dark-brown colored oil remains to which was added a small amount of alcohol. By standing for several days in the ice-box, a small amount of crystals came out, the main part being a brown oil. As it was too difficult to separate the crystals, the mixture was taken up with ethyl acetate and alcohol added. Light brown flakes precipitated which were filtered and recrystallized four times from ethyl acetate and alcohol, finally from ethyl acetate: 50 mg. of white needles was obtained, melting point 230–232°.

Calcd. for $C_{33}H_{47}N$: C, 86.65; H, 10.27; N, 3.08. $C_{34}H_{49}N$: C, 86.63; H, 10.40; N, 2.97. $C_{35}H_{53}N$: C, 86.24; H, 10.87; N, 2.87. Found: C, 86.63; H, 10.37; N, 3.13.

A small amount of the substance was dissolved in alcohol and several drops of acetic acid added. After further addition of a solution of *p*-nitrodiazobenzene a deep wine-red coloration was obtained.

[3] We have also carried out experiments in which potassium acetate was used for the removal of the bromine. These experiments were made in acetic acid, ethyl alcohol, butyl alcohol and dioxane as solvents. Our results agree only partly with Butenandt *et al.*[1c] so that further investigation of these reactions seems necessary. Potassium phenolate gave a substance which coupled with *p*-nitrodiazobenzene in alkaline solution to give a deep bluish-red. This substance may also be a derivative of a diphenyl-like combination of the phenol with the cholestanone.

Synthesis of *d,l*-Alanine in Improved Yield from α-Bromopropionic Acid and Aqueous Ammonia

BY WALTER C. TOBIE AND GILBERT B. AYRES

After having synthesized *d,l*-alanine by the excellent but tedious method of Kendall and McKenzie,[1] we decided to try to adapt the method of Orten and Hill[2] for glycine to making *d,l*-alanine from α-bromopropionic acid and aqueous ammonia.

The following method has been worked out and is giving satisfactory results. Pour slowly and with stirring, 100 g. (0.65 mole) of cold (1–4°) α-bromopropionic acid (Eastman No. 981) into 3 liters (44.5 moles) of cold (1–4°) concentrated aqueous ammonia (sp. gr. 0.90) in a glass-stoppered bottle. Allow the mixture to stand at room temperature (below 40°) for at least four days. Evaporate under reduced pressure on a steam-bath to about 300 cc. Filter and evaporate to about 200 cc., cool, add 1 liter of methanol and cool overnight at 1–4°. Filter off the crystals of *d,l*-alanine and wash with methanol and ether; yield 42–46 g., 72–79% of theoretical. Recrystallize the crude product by dissolving in 200 cc. of hot water and by adding 1 liter of methanol, cooling and washing as before; yield 38–40 g., 65–68% of theoretical. This product is bromide free and contains only small amounts of ammonia which may be removed by using Permutit on the second crystallization or recrystallizing a third time. The purified product has a melting point of 194–195° dec., and contains 15.79% nitrogen (same as theoretical).

Other syntheses were carried out in the cold (1–4°) but this did not affect the yield. A temperature above 40° reduced the yield. A reaction time of less than four days cut down the yield, whereas a time of more than four days did not increase the yield. α-Chloropropionic acid gave poorer yields (43–46% of the theoretical) than the α-bromo acid.

REACTIONS OF CYCLOHEXANONE WITH DIAZOETHANE

Sir:

It has been shown by Mosettig and Burger [This Journal, **52,** 3456 (1930)] and by Meerwein (German Patent 579,309) that cyclohexanone reacts with diazomethane to form cycloheptanone and cycloöctanone as main products. The reaction takes place slowly even in the presence of a catalyst. Mosettig and Burger have suggested the possibility of replacing diazomethane by diazoethane and its homologs in this reaction.

In an investigation of the reactions of cyclic ketones with diazomethane and similar compounds which is under way in this Laboratory, the reaction of cyclohexanone with diazoethane has been carried out and the product obtained proved to be α-methylcycloheptanone. It was identified as the semicarbazone, m. p. 128–129°. Isolation of the product was brought about by removing the unattacked cyclohexanone with bisulfite solution, methylcycloheptanone being unaffected by this reagent. In contrast to the reaction with diazomethane, diazoethane requires no catalytic influence and the reaction is completed in a much shorter period of time. The reaction with diazomethane requires several days for completion while that with diazoethane takes less than twenty-four hours.

It is interesting further to record that while diazomethane reacts readily with cyclohexanone to form both cycloheptanone and cycloöctanone, according to the conditions of the reaction, it is without effect on cycloheptanone and reacts to a slight extent only with cyclopentanone, the products being mainly cycloheptanone together with a small amount of cyclohexanone.

In order to obtain information on the behavior of substituted cyclic ketones toward diazomethane and diazoethane reactions have been carried out with α-chlorocyclohexanone. Diazomethane gave practically a quantitative yield of α-chlorocycloheptanone while diazoethane gave methylchlorocycloheptanone as the main product.

These reactions were carried out in ether solution. The ketone was added to the ethereal solution of diazomethane or diazoethane and if evolution of nitrogen did not occur immediately methyl alcohol was added to catalyze the reaction. Completion of the reaction was indicated by disappearance of the yellow color in the solution.

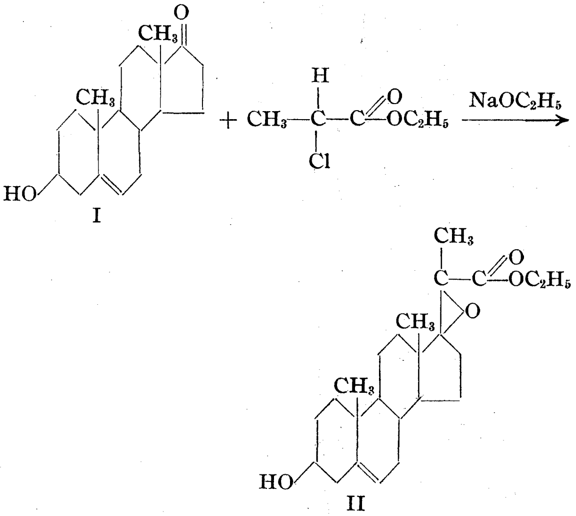
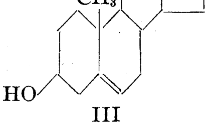
THE CONDENSATION OF DEHYDROANDROSTERONE WITH ETHYL α-CHLOROPROPIONATE

Sir:

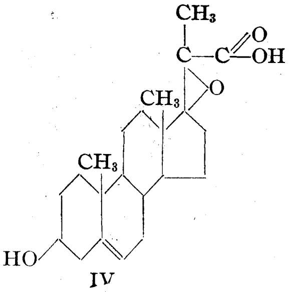
In the course of certain studies on the chemical properties of dehydroandrosterone, I, we have observed that under suitable conditions, in the presence of sodium ethylate, it is possible to effect a condensation of the Darzens type [*Compt. rend.*, **141,** 766 (1906)] between this hormone and ethyl α-chloropropionate according to the scheme



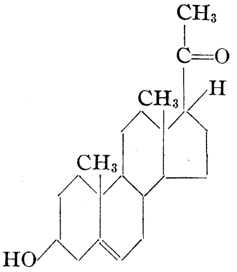
Some androstenediol-(3,17), III, is also formed during the reaction by the reducing action of the sodium ethylate. We have also found that hydrolysis of the ester oxide, II, with sodium hy-



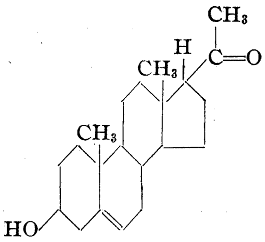
III



IV



V



VI

droxide yields two products: (a) an acid which forms an insoluble sodium salt, and presumably has the formula IV; and (b) a mixture of ketones formed by a rearrangement process having properties of Δ^5-pregnenolone, V, and Δ^5-*iso*-pregnenolone, VI, previously prepared from stigmasterol and pregnanediol by Fernholz [*Ber.*, **67,** 1855, 2027 (1934)] and by Butenandt and his co-workers [*Ber.*, **67,** 1611, 1901 (1934); **70,** 96 (1937)]. The exact proportions of the two ketones in the mixture are now being investigated, and experimental studies on the rearrangement of the acid, IV, into the corresponding ketones are in progress. The details of our experimental results will be published in a forthcoming paper. We hope that this announcement may serve as a reservation of this research project.

Alchemy and Other Chemical Achievements of the Ancient Orient. The Civilization of Japan and China in Early Times as Seen from the Chemical Point of View. By Dr. MASUMI CHIKASHIGE, Emeritus Professor of Kyoto Imperial University. Rokakuho Uchida, Tokyo, Japan, 1936. 102 pp. 17 plates. 12.7 × 18.8 cm. Price, 1.50 Yen.

This is an English translation of a book which appeared in the Japanese language in 1929 under a title which may properly be translated "Metallurgic Arts in the Orient." The Japanese version contained a discussion of European alchemy which is omitted from the present translation. The work is divided into three parts which deal, respectively, with Chinese alchemy, with Chinese bronze and with Japanese steel swords.

The author considers that many alchemical books can be enumerated, but that "in the final analysis, only two works, *Pao-p'u-tzu* (written by *Ko Hung,* fourth century A.D.) and *Pên Ts'ao Ching*" (a treatise on materia medica published toward the end of the *Han* dynasty) "remain as the authentic sources of information on the earlier Chinese alchemy." Biographical accounts of *Ko Hung* and *T'ao Hung-ching* are given, and many interesting quotations from the second (*Lun Hsien,* "Essay on the Immortals"), the fourth (*Chin Tan,* "Gold Medicine"), the eleventh (*Hsien Yao,* "Medicines of the Immortals") and the sixteenth (*Huang Pao,* "The Yellow and the White") of the Inner Chapters of "*Pao-p'u-tzŭ.*" Chikashige discusses the identity of some of the materials which *Ko Hung* used, and concludes that some of the processes may actually have yielded real gold because of the gold which existed in small amounts in the reagents.

The discussion of ancient Chinese bronzes centers around the "Six Recipes of *Chin*" which are set down in the *Chou Li K'ao Kung Chi* (Artificers' Record, the sixth part of the *Chou* ritual) which was published during the *Chou* dynasty in the tenth century B.C. The author concludes that these recipes, except the last one, are reasonable. He discusses the properties of the several kinds of bronze which correspond to them, and finally reports chemical analyses of ancient bronzes in which the proportions of copper to tin agree with those laid down in certain of the recipes. He has wisely made his analyses upon the uncleaned bronze objects, determining the total amount of each metal present in the combined mass of metal and oxidized material.

"As to the method of forging swords in extreme antiquity, no history nor tradition has been handed down; but some of the straight swords excavated by archeologists were once submitted to investigation from which it may be concluded with some justice that they belong to the class of forged swords. For they showed some signs of having been forged by 'folding,' or even by 'combining' different sorts of iron. The art of forging made great progress when in the days of the Prince Regent *Shōtoku* (573–621) it was taught by some naturalized smiths at Oshinumi and later when Emperor *Gotoba* (1180–1239) gave directions to the noted smiths of the various provinces and made them forge at the court. All this concerns the method of forging the so-called *kotō* (old swords) but this method was lost during the age of civil wars toward the end of the *Ashikaga* Period. *Shintō* (new swords) made their first appearance toward the beginning of the *Tokugawa* Period and during the *Anei* (1772–1780) era or thereabouts *shinshintō* (new new swords) began to be turned out. A sword-smith, named *Suishinshi* is said to have been the originator of the *shinshintō* school. He was a diligent investigator of the oldest school of sword forging, and thus the once obscured method became clear again; but it did not live long as such, for *Suishinshi* improved it further and gave birth to a new school. The doctrine of the school of *shinshintō* still survives among the sword-smiths of the last days of the *Tokugawa* Period."

Chikashige describes the methods of the *shinshintō* school, having procured his information from the notes of two who were instructed by master sword-smiths. The descriptions are clearly illustrated by diagrams, and the effect of the process upon the structure of the metal is made evident by micrographs of cross sections. Micrographs of cross sections of ancient Japanese swords and of inferior swords from Java and Formosa show plainly the manner in which they were forged.

TENNEY L. DAVIS

Boden und Pflanze. (**Soil and Plant**). By Sir E. JOHN RUSSELL. Second edition. Translated from the 6th English edition by Dr. K. W. MÜLLER, Zurich. Foreword by Prof. Dr. GEORG WIEGNER. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1936. xiii + 446 pp. 60 figs. 16 × 24 cm. Price, RM. 30; bound, RM. 32.

The contributions of Sir John Russell rank high in international soil science and this German translation of the sixth edition of his Soil Conditions and Plant Growth is especially interesting at this time. The first German edition appeared in 1914 and was by Hans Brehm. This second edition is by K. W. Müller of Zurich, and the late Prof. G. Wiegner has supplied the book with an appreciative preface. This new German edition meets all expectations and has in contrast with the first many changes to show, the contents having risen from 243 to 446 pages, and also the arrangement of the material has been considerably altered. The translation is well handled with a fine appreciation of technical accuracy. The following chapter headings give a good idea of the scope of the book: historical introduction; the influence of the soil on the growth of plants; the composition of the soil; the soil in nature; the changes in its mineral composition; the changes in organic matter; the micro flora of the soil and its relation to plant growth; the biological relationships in the soil; soil and plant; method of evaluating soil; methods of soil analysis. The author has handled the material in a different manner from that customary in most soil books. The soil itself and its relation to the plant receives the most detailed and thorough consideration. Even the first edition of the book received much praise in Germany and this second edition is considered as a most welcome corollary to German textbooks on Soil Science, as the name of its distinguished author is a guarantee of its value to soil science internationally everywhere.

OSWALD SCHREINER

Essential Principles of Organic Chemistry. By CHARLES S. GIBSON, O.B.E., M.A., Sc.D., F.R.S., Professor of Chemistry in the University of London, at Guy's Hospital Medical School. Cambridge University Press; The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1936. viii + 548 pp. 14.5 × 22.5 cm. Price, $5.00.

This text is designed for use in teaching organic chemistry to students who expect to specialize in the subject, and others for whom a thorough understanding of the principles of the science is essential. An examination of the contents leaves no doubt that the book is well suited to the group for which it is intended.

The first two pages form a very attractive introduction involving the presentation of the "carbon skeletons" of many compounds; ethyl ether, isoquinoline, diphenylmercury and trimethylamine are some of the examples. Then follows a description of analytical methods. While this latter material provides the logical and classical approach to the subject, it will seem to some a trifle old-fashioned compared with the introductory subject matter of the better American texts.

The first chapter deals with the aliphatic hydrocarbons, and the second with aromatic hydrocarbons. From this point, aliphatic and aromatic compounds are treated together. The result is very satisfactory. The presentation is excellent throughout.

The only serious adverse criticism of the book would be that many of the recent important developments are ignored. Synthetic plastics, polymerization, the synthesis of alcohols from olefins, ethylene glycol and its derivatives, the formation of phenol and aniline directly from chlorobenzene, dyes and terpenes are topics which are treated very briefly or omitted entirely.

The sections devoted to carbohydrates, purines, the Beckmann rearrangement and crystal structure are particularly satisfactory.

The book is well printed, is plentifully supplied with clear, attractive formulas and has very few typographical errors. It is to be highly recommended to teachers, with the reservation that the material needs to be supplemented with reference to certain of the newer developments.

REYNOLD C. FUSON

Die chromatographische Adsorptionsmethode, Grundlagen, Methodik, Anwendung. (**The Chromatographic Adsorption Method: Principles, Procedures and Applications.**) By Dr. L. ZECHMEISTER, Professor, and Dr. L. v. CHOLNOKY, Lecturer, at the Chemical Institute of the University of Pécs (Ungarn). Verlag von Julius Springer, Schottengasse 4, Wien I, Austria, 1937. xi + 231 pp. 45 figs. 14 × 21 cm. Price, RM. 14.40.

This carefully printed publication is an excellent compendium of the improvements and applications of the Tswett chromatographic adsorption method. The various uses of this columnar adsorption method for the detection, separation, isolation, purification and identification of chemical compounds are discussed. Consideration is given to the relation between the chemical structure and the adsorbability of organic compounds. Descriptions of the adsorbents and of the solvents required for the adsorption and elution of the compounds are included. The preparation of the adsorption columns is described, and methods for following the separation of colorless substances upon the columns are illustrated. The greater part of the volume (pp. 76–191) is devoted to the description of the separation of specific substances which are classified according to groups: (a) natural pigments, such as chlorophylls and derivatives, bile pigments, carotenoids and derivatives, naphthoquinone and anthraquinone pigments, flavines, pterine, anthrocyanins and other pigments; (b) synthetic dyes; (c) colorless substances, such as aliphatic and aromatic hydrocarbons and derivatives, polycyclic compounds, sterols, alkaloids, enzymes, vitamins, hormones, tannins and drugs. Photographs illustrating the separation of pigments by adsorption upon columns are reproduced. A comprehensive bibliography (all titles in German) and author and subject indexes are appended.

Everyone who is concerned with the isolation and identification of chemical compounds should find many helpful suggestions in this publication. Experience has shown, however, that the adsorptive properties of different preparations of the same adsorbent may vary more than is indicated; hence, familiarity with the properties of the adsorbents becomes an important factor in the application of the chromatographic adsorption technique.

Photochemical Investigations. IV. The Photochemical Decomposition of Deutero-ammonia[1]

BY EDWIN O. WIIG

The photochemical decomposition of deutero-ammonia is of interest since it can be investigated at wave lengths which, although near one another in wave length, show different types of absorption. Both ammonia and deutero-ammonia show absorption beginning at about λ 2300 Å. and extending to shorter wave lengths.[2] In ammonia the bands are diffuse, but in the case of deutero-ammonia the principal band at λ 2136–39 Å. is discrete, while at about λ 2105–22 and λ 2065–80 Å. there are exclusively diffuse bands.[3] The latter ND_3 bands correspond to predissociation and the primary process should presumably be the same as in the similar ammonia bands, a dissociation into ND_2 and D. Absorption of light in the discrete band should result in the formation of an electronically excited molecule. The photochemical decomposition of deutero-ammonia in the bands at about λ 2136–39 and 2105–22 Å. might, therefore, proceed differently, although the energies involved are almost identical.

This paper presents the results of a study of the photolysis of deutero-ammonia by the zinc spark lines at λλ 2138 and 2100 Å., in the discrete and diffuse bands, respectively. In order to compare these results with those for ammonia, measurements of the quantum yield for the latter at λ 2100 Å. were also made in the same cell.

Experimental Details

The light source and apparatus were the same as those used in previous investigations dealing with ammonia.[4] As the two earlier cells were not available, use was made of a third cylindrical cell, Cell 3, 25 mm. in diameter and 100 mm. long, with plane parallel windows fused on the ends. The materials used, with the exception of the deutero-ammonia, were prepared as before. The corrections for the energy loss at the rear cell window at the two wave lengths investigated were obtained from photolysis of hydrogen bromide under conditions identical with those prevailing in the ammonia or deutero-ammonia decompositions. The data for the hydrogen bromide decompositions have been omitted since they are similar to earlier data.[4]

Results

The quantum efficiencies obtained in the decomposition of deutero-ammonia at λλ 2100 and 2138 Å. and of ammonia at λ 2100 Å. in Cell 3 at room temperatures (23–29°) are shown in Tables I, II and III, respectively. For purposes of comparison these data are plotted in Figs. 1 and 2. In the calculation of the quantum yields it was assumed that the products are $N_2 + 3D_2$ from analogy with the ammonia photodecomposition. The question of a change in composition of the gaseous products as their pressure is decreased has already been discussed.[4] In a number of preliminary experiments with deutero-ammonia good checks could not be obtained.

---

[1] The results of this investigation were presented at the Rochester, N. Y., Intersectional meeting of the American Chemical Society, June 16–18, 1936.

[2] Dixon, *Phys. Rev.*, **43**, 711 (1933); Duncan, *ibid.*, **47**, 822, 886 (1935); **50**, 700 (1936).

[3] The present experiments were undertaken at the suggestion of Professor Hugh S. Taylor of Princeton University. The author is greatly indebted to Professor Taylor and Dr. W. S. Benedict for communicating to him the results of their study of the absorption spectrum of deutero-ammonia and for supplying a sample of pure ND_3.

[4] Wiig, THIS JOURNAL, **57**, 1559 (1935); **59**, 827 (1937).

This effect was eliminated by the following procedure. Deutero-ammonia at high pressure (500 mm.) was admitted to the cell (previously heated and evacuated, and cooled), the pressure reduced to 410 mm. and the quantum yield, ϕ, determined for λ 2100 and then λ 2138 Å. The pressure was again reduced to the next desired pressure, followed by a determination of ϕ for λ 2138 and then λ 2100 Å., and this procedure continued down to low pressures. Four samples of deutero-ammonia were used in this fashion in the experiments in Tables I and II. Exclusive of the preliminary runs, a total of 81 experiments, including checking the apparatus against hydrogen bromide, were performed. Of these only two have been omitted from the tables, both being rejected because of experimental difficulties.

Discussion

It will be seen from Fig. 1 that, at the same wave length (λ 2100 Å.) and for the same type of absorption, the decomposition proceeds about 1.3–1.5 times as rapidly with ammonia as with deutero-ammonia. This is apparently in disagreement with the results of Melville,[5] who reports NH_3 to ND_3 ratios of 2.6, 2.3 and 2.6 to 1. These ratios were obtained with 2.0 cm. length of ammonia and of deutero-ammonia, respectively, at pressures of 100 mm. exposed to a quartz mercury arc. The mercury lines around λ 2100 Å. were effective in these experiments,

---

(5) Melville, *Proc. Roy. Soc.* (London), **A152**, 325 (1935).

since absorption by NH_3 and ND_3 increases with decrease in wave length. Under his condition, Melville states, the absorption by NH_3 is about 96% for light around λ 2100 Å. and, presumably, absorption by ND_3 would differ only slightly from this. Calculations from actual measurements made in this Laboratory on 3.5 cm. of NH_3 at 100 mm. pressure indicate for a 2.0 cm. path 88% absorption with monochromatic light of λ 2100 Å., in fair agreement with the above 96%. But absorption by ND_3 of λ 2100 Å. is considerably weaker. From measurements on 10.0 cm. of ND_3 at 100 mm. pressure the absorption for a length of 2.0 cm. is calculated to be only 40% instead of the 88% obtained with NH_3. Thus Melville's ratios are much too high and the disagreement vanishes when allowance is made for the different absorptions.

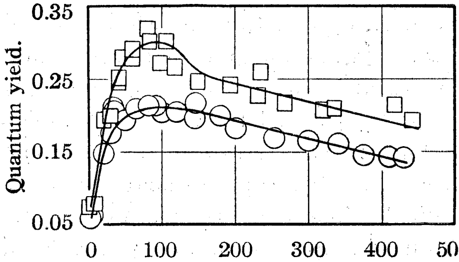

Fig. 1.—A comparison of the quantum yields for ammonia, □; and deutero-ammonia, ○, at λ 2100 Å.

The same sort of pressure dependence of the quantum yield as has previously been found[4] for ammonia is shown by deutero-ammonia (Fig. 1). This indicates that the mechanisms of the reactions following the primary process are similar. At λ 2100 Å. ND_3 and NH_3 show the same type of absorption,[3] so that the mechanism suggested for NH_3 should be applicable to ND_3. Melville[5] has shown that NH_3 and ND_3 are inhibited about equally by both hydrogen and deuterium atoms. It follows from the reactions suggested for the NH_3 decomposition[4] that the smaller yields with ND_3 are due to the reaction

$$ND_2 + ND_2 \longrightarrow N_2 + 2D_2$$

being slower than the corresponding one involving hydrogen. This suggestion has already been made by Melville and, as he points out, this is in keeping with previous experience in the kinetics of hydrogen and deuterium compounds.

The greater quantum yield for ND_3 with λ 2138 Å. as compared with λ 2100 Å. (Fig. 2) is rather puzzling. Offhand, most investigators would probably guess just the opposite, although a similar result has been found by West and Ginsburg[6] in the photolysis of gaseous ethyl iodide in the regions of continuous and banded absorption. In the photodecomposition of acetaldehyde Leighton and Blacet[7] found a higher yield in the region of fine structured bands as compared with the diffuse bands but they were able to show that the mercury line absorbed in the former region fell directly between two band maxima and the absorption was really due to the underlying continuum. In the case of deutero-ammonia there is no such underlying continuum, λ 2138 Å. falling in the discrete band at λ 2136–39 Å. The similarity in the pressure dependence of the yields at λλ 2138 and 2100 Å. indicates a

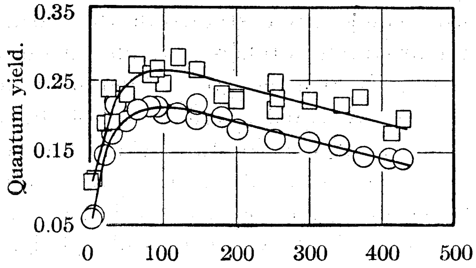

Fig. 2.—A comparison of the quantum yields for deutero-ammonia at λ 2138 Å., □; and λ 2100 Å., ○.

similarity in the mechanisms and suggests that at λ 2138 Å. we have

$$ND_3 + h\nu \longrightarrow ND_3' \qquad (1)$$

$$ND_3' + ND_3 \longrightarrow ND_2 + D + ND_3 \qquad (2)$$

The greater yield at λ 2138 Å. can then readily be accounted for by supposing that a small proportion of the collisions of electronically excited molecules, ND_3', with normal molecules, reaction (2), results in

$$ND_3' + ND_3 \longrightarrow N_2 + 3D_2 \qquad (3)$$

This would lead to a constant difference in the yields down to pressures where the reaction becomes heterogeneous,[4] in agreement with experiment. A somewhat similar suggestion has been made by West and Ginsburg and by Rollefson.[8] The homogeneous bimolecular decomposition of ammonia would probably require an activation energy greater than about 80 kcal.,[9] which is

considerably less than the 135 kcal. supplied by one einstein at λ 2138 Å.

Summary

The photodecomposition of ammonia is found to proceed about 1.3–1.5 times as rapidly as that of deutero-ammonia in the predissociation bands at λ 2100 Å. Approximately the same ratio holds for the rate of decomposition of deutero-ammonia at λ 2138 Å. in a discrete band to that at λ 2100 Å. in a diffuse band. These differences in rates are discussed and explanations to account for them suggested.

The Chemical Composition of the Active Principle of Tuberculin. XX. Comparative Study of the Yield, Potency, Specificity and Acid–Base-Combining Capacities of the Proteins from Five Human Tubercle Bacilli Culture Filtrates and other Acid-Fast Bacilli

BY FLORENCE B. SEIBERT[1]

During comparative studies of the chemistry of different strains of tubercle bacilli, the question has arisen whether as great differences might not occur on repeated examinations of the same strain. It is also a question whether constant differences can be established between tubercle bacilli and other members of the large group of acid fast bacteria, to which the tubercle bacillus belongs. In addition to the well-known method of differentiating the human, bovine and avian types of tubercle bacilli by means of their respective virulences for different animals, the distinctions made by Wilson[2] on the basis of agglutination and by Furth[3] on the basis of complement fixation and absorption experiments, it has recently been possible to differentiate them by means of the serological precipitin reaction,[4] using the purified proteins isolated from the bacillary culture filtrates as antigens. Furthermore, the proteins from these three types of tubercle bacilli, as well as from the acid-fast bacillus found on timothy grass, differed quantitatively in potency when equal doses were injected in the skin of tuberculous animals,[5] whereas no difference whatever could be distinguished between the potencies of proteins prepared from three different strains of the human type tubercle bacilli which differed widely in their virulence.

Chemical differences in the lipide contents of the different types of tubercle bacilli, human, bovine, avian, and the acid-fast timothy bacillus have been reported by Anderson[6] and his coworkers, and Chargaff and Dieryck.[7] Anderson noted especially the presence of an optically active liquid saturated fatty acid, phthioic acid, in the human H37 strain, whereas analogous acids from the other types of acid-fast organisms were optically inactive. He has made a further report[8] on the lipide contents of the bacilli of four different cultures of tubercle bacilli, recently isolated from human cases of tuberculosis, in comparison with results obtained on a freshly grown lot of the human type H37 bacillus.

The following paper is a comparative study of the proteins isolated from the culture filtrates of the same five batches of human tubercle bacilli used in Anderson's[8] studies. The results will be compared with similar studies on comparable proteins prepared from the bovine and avian tubercle bacilli and leprosy and timothy grass acid-fast organisms.

Experimental

History of Strains of Human Tubercle Bacilli Used.—

Strain A10—isolated May, 1932, on guinea pig passage from retroperitoneal lymph glands of patient (25435). Pathogenic for guinea pigs and only very slightly for rabbits. Recent test showed no pathogenicity for rabbits.

Strain A12—isolated November, 1932, from the sputum of patient (38135). Pathogenic for guinea pigs; nonpathogenic for rabbits.

Strain A13—isolated December, 1932, from the sputum of

patient (21443). Mildly pathogenic for guinea pigs; non-pathogenic for rabbits.

Strain A14—isolated January, 1933, from the sputum of patient (38502). Pathogenic for guinea pigs; non-pathogenic for rabbits.

H37—(Saranac Lake strain isolated in 1910.)[9] Non-pathogenic for rabbits when recently tested.

The first four strains were isolated at the Henry Phipps Institute by J. D. Aronson and H. J. Henderson.

Isolation of Proteins.—Approximately 300 cultures of each strain were grown in 1-liter Pyrex bottles under identical conditions on Long's synthetic medium[10] for eight weeks during 1934, by Mr. John Glenn of the Mulford Biological Laboratories, Sharp and Dohme, Glenolden, Pa. The bacterial masses were then filtered off on Büchner funnels and subsequently used by Dr. Anderson. The filtrates were preserved with 0.5% phenol, later filtered free of bacteria on Mandler filters, and sent to our laboratory in 8-liter Pyrex bottles. The quantities of raw tuberculin so prepared varied from 32 to 44 liters per strain, representing from 53 to 60 liters of original medium.

The proteins were isolated from these filtrates by a method described in 1932.[11] Briefly it was as follows. The unheated culture filtrates were concentrated by means of ultrafiltration through alundum filters impregnated with 13% guncotton, and then washed free of filtrable substances by repeated additions of 0.5% phenol. The non-filtrable residue representing approximately a 100 times concentration of the original solution, was filtered through the Seitz filter and then precipitated with 10% trichloroacetic acid, washed on the centrifuge five to six times with trichloroacetic acid, partially dried *in vacuo* at room temperature and finally thoroughly extracted and dried to a powder, by grinding with anhydrous ether.

Analyses and Potency of the Proteins.—These powders designated as TPT-H37, TPT-A10, TPT-A12, TPT-A13 and TPT-A14, were then analyzed for ash and volatile substances at 110° by the micro methods described by Pregl[12] and for nitrogen by the Parnas–Wagner modification of the micro-kjeldahl method,[12] using selenium[13] instead of copper sulfate as the oxidizing agent.

The potencies of the products were compared by making six simultaneous injections, each of 0.1-cc. saline solution containing 0.005 mg. protein, in eleven tuberculous guinea pigs inoculated six weeks previously with 0.1 mg. of H37 bacilli. The five proteins were compared with an equal dose of Purified Protein Derivative[14] which is the standard purified tuberculin adopted by the National Tuberculosis Association.

The results of the analyses and potency tests are recorded in Table I. The constancy in the yield of protein from the five strains is remarkable, when consideration is given to the fact that the A13 strain grew sparsely and was found by Anderson[8] to have yielded the lowest bacterial mass per culture. The A10 protein proved to be much less soluble than any of the other proteins and consequently there was an obvious loss in the product during its isolation. There was comparatively little difference in the potencies of the five proteins, although the A10 and H37 were slightly less potent than the other three. All were less potent than the standard Purified Protein Derivative.

TABLE I

TPT made from strain of human tubercle bacillus	Yield, g. TPT per liter original medium	Moisture, %	Ash, %	Nitrogen (ash-free dry wt.), %	Potency, av. size skin reaction with 0.005 mg. tested simultaneously on 11 tuberculous guinea pigs, 48 hrs.
H37	0.30[a]	14.6		15.9	
	.26	9.5	1.3	15.2	14 × 16 × 2.7
A10	.18	4.7	0.9	14.2	13 × 15 × 2.9
A12	.24	9.0	.5	14.0	16 × 19 × 3.6
A13	.17	10.7	.4	13.9	16 × 18 × 3.2
A14	.24	8.8	.9	14.1	17 × 19 × 3.1

[a] This product was made in 1932 from the same H37 strain.

Serological Specificity of the Proteins.—Since no significant differences between the proteins were obtained by means of the preliminary analyses reported above, the very delicate serological precipitin reaction was employed. It has been shown by many investigators, but especially by Landsteiner,[15] that very small differences in chemical structure of proteins and even polypeptides can be detected by this method. Since earlier work[4] showed that proteins made similarly from different types of tubercle bacilli, human, bovine, avian and timothy grass, could be differentiated by means of the precipitin reaction, it was advisable to determine whether serological differences could also be detected between these five strains, all of the human type tubercle bacillus.

Five per cent. solutions of the different antigens were prepared by putting the powders into solution with the minimal amount of normal sodium hydroxide, neutralizing to litmus with 0.1 normal hydrochloric acid, and diluting to standard volume with saline containing 0.5% phenol.

Two rabbits were injected intracutaneously with 10 mg. of each antigen ten times at approximately weekly intervals. The increasing degree of sensitiveness of the animals was followed by observing the Arthus reactions which occurred, and seven days after the tenth injection the rabbits were bled to death. The precipitin tests were performed by adding to 12 tubes containing 0.1 cc. each of serum 0.1 cc. of varying dilutions of 1% antigen solutions, varying from 1:200 to 1:2,000,000. They were shaken and kept in the ice box for forty-eight hours and then the amount of precipitate in each tube was noted. A control tube with saline was negative in all cases.

Table II shows the results of these tests. No differences in serological specificity could be detected between the five human strains, H37, A10, A12, A13 and A14, either in the end titer or in the amount of precipitate in any of the tubes. On the other hand, differences could be detected between these human strain proteins and the proteins of

bovine or timothy bacilli. While the bovine antigen gave in all cases some precipitate with the five human type antisera and even in several cases, as high a titer, the amount of precipitate produced was always obviously less, and in many cases there was zoning effect. On the other hand, the bovine antisera gave as high titers and as heavy precipitates with the five human type antigens as with itself. The sparseness of precipitate was very conspicuous in the case of the timothy antisera precipitated with the human type antigens as well as with the different human type antisera precipitated with timothy antigen. Therefore, the timothy protein showed a high degree of specificity, as noted earlier,[4] the bovine protein some degree of specificity and the human proteins only a type specificity. While the similarities and differences here described were plainly seen on observing the tubes, there is no doubt that it will be possible to record such differences more nearly quantitatively when Heidelberger's[16] quantitative precipitin method is perfected so that it can be applied to bacterial proteins as well as to such proteins as have been already studied by him.

Tests were made in order to determine whether the presence of so small an amount of polysaccharide as 0.5% or less, which is the usual content of reducing substances in these TPT products, may be responsible for the precipitin reactions obtained. A polysaccharide, prepared as described in an earlier publication[17] from the culture filtrate of the H37 tubercle bacillus, was serially diluted in the same way as the protein antigens and added to all the antisera. No precipitation occurred with any of the antisera in any of the dilutions, as recorded in Table II.

When relatively small quantities of proteins are available, possibly more information concerning their chemical character and reactivity can be obtained by studying the titration capacities with acid and alkali than in almost any other way, except possibly by migration velocity determinations. Studies of the latter will be reported in the future. At present, however, only electrometric titration data will be considered. So far no significant differences had been detected between the five human strain proteins, even by means of the delicate immunological precipitin reaction. Nevertheless, it was obvious that the solubility of, for example, TPT-A10 was much less than that of any of the other proteins and, therefore, physico-chemical methods may be of value in finding differences indistinguishable in any other way.

Base Combining Capacity and Titration Curves of the Proteins.—Because of the small quantities of material available in the cases of certain fractions required for comparative analyses the following method of performing the titration was chosen. In all cases 250 mg. of the product was put into solution with the minimal amount of 0.1 *N* sodium hydroxide and the volume was made up to 25 cc. with freshly distilled water. The hydrogen ion activity of the solution was then determined by means of two hydrogen electrodes immersed in the solution, so that every reading could be checked. Hydrogen gas washed through water, potassium hydroxide and pyrogallic acid, was bubbled through the solution at a rapid rate, without discontinuing the flow of gas during the entire titration. The hydrogen electrodes, freshly platinized before each titration, were referred to a saturated calomel half cell through a saturated potassium chloride agar bridge. After the bridge was introduced into the system no difficulty with poisoning of the electrodes was experienced, and there was no difficulty in obtaining a potential which remained practically constant for an indefinite period of time. The two electrodes usually gave identical potentials. Otherwise the maximum variation between them was 0.0015 volt or a difference of 0.035 *p*H.

The foaming of the protein solutions was controlled by the addition of ether in the experiments recorded in this paper. In later experiments caprylic alcohol was used. The ether had the disadvantage of reducing the temperature to the neighborhood of 10°, but the temperature of the solution was recorded with each determination and the proper *p*H obtained with the use of Leeds and Northrup conversion tables. When the temperature was not 10° the *p*H was corrected to 10° by multiplying by a factor,

(pKw at 10°)/(pKw at t°) = 14.375. This pKw value was obtained from data given by Michaelis.[18]

After the potential was determined aliquots of 0.1 N sodium hydroxide (0.1 to 0.5 cc.) were added, determining the potential after each addition, until a pH of 11 to 12 was reached, and then aliquots of 0.1 N hydrochloric acid were added in a similar way until a pH of 2 to 3 was reached.

Calculation of the Combining Capacities.—The system was checked before and after each titration by means of 0.1 N hydrochloric acid, made from constant boiling hydrochloric acid, and pH 1.087 was used as the standard value at 20°. Adequate corrections were made, in the same manner as by Simms,[19] for errors inherent in the entire system and for those due to variations in ionic strength of the solutions titrated, such as the activity coefficients. Accordingly, a blank titration with hydrochloric acid in water at 10° (obtained by the use of ether) was made and from the data a table was constructed of corrections to be applied to the hydrogen ion concentration at each $\sqrt{\mu}$ (μ = ionic strength = the concentration of hydrochloric acid). The limiting values of μ for base or acid in all of the experiments here reported were from 0.0001 to 0.025 M. Similarly a blank titration with sodium hydroxide in water was made at 10° (obtained by the use of ether) and a curve constructed from the data by plotting $\sqrt{\mu}$ (μ = ionic strength = the concentration of sodium hydroxide) against pH-log oh. In the equation pH-log $oh = pKw + \log f_{OH}$, f_{OH} is the activity coefficient of the hydroxyl ion. In this way, a table was constructed of the proper values for pH-log oh at every $\sqrt{\mu}$. From these pH-log oh values the pH determined for the solution under test was subtracted, giving the pOH. In the titrations of protein solutions as here recorded, μ was equal to b until a exceeded b and then it was equal to $b + (b-a)$.

The equivalents of base minus acid combined per kilogram of substance, were then calculated by means of the equation used by Simms,[19] $b' = (b-a)/c + (h-oh)/c$ in which b = concentration of strong base, a = concentration of strong acid, h = concentration of hydrogen ions, oh = concentration of hydroxyl ions, and c = concentration of protein. Since the molecular weight of none of the proteins studied was accurately known, all concentrations were expressed as kilograms of protein per liter. This would represent the molar concentration if the molecular weight were 1000.

The volume was changing throughout the titration, due to the repeated additions of alkali or acid, and, therefore, in the final calculation proper correction was made in a, b and c for each determination. A set of calculations, typical of those used for all of the curves in the paper, is given in Table III. In the curves, pH (activities) were plotted as abscissas against the corrected equivalents of base minus acid per kilo-

gram of protein (b') found by the above equation.

Discussion of Results

Since all the proteins were insoluble in water and for solution required sufficient hydroxide to result in a high *p*H value, the curves plotted begin with the values obtained when the *p*H was most alkaline and extend to the most acid *p*H. In order that the corrections due to this procedure might not be too large, the *p*H was never carried beyond 11.5.

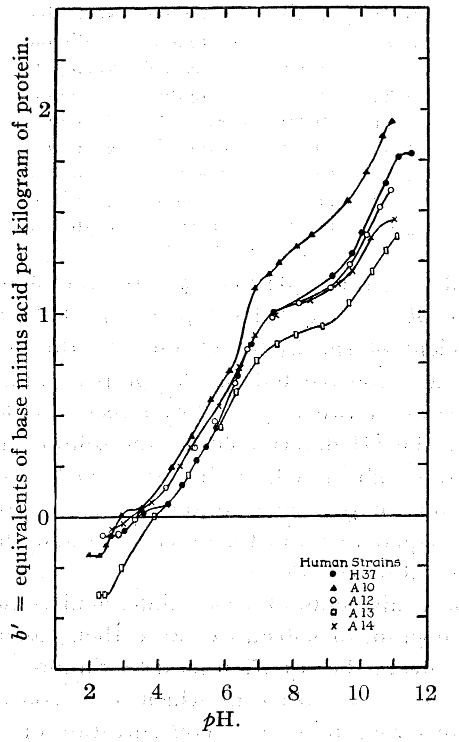

Fig. 1.

Figure 1 shows that the curves of the five human strain TPT's were similar. They were almost identical in the region between *p*H 2 and 6, and these similarities would exist regardless of what the real isoelectric points of the products might be. The curves of the TPT's from the bacillary strains H37, A12 and A14 are almost identical throughout; that of TPT-A13 shows a slightly less acidic substance, while that of TPT-A10 is more acidic. These similarities indicate a close correspondence in *p*K values for the different proteins and, therefore, presumably a similar amino acid structure. This probably explains why the precipitin tests showed identical crossing between all five proteins made from the human strain tubercle bacilli.

On the other hand, the curves of these human strains are quite different, in parts at least, from those of the TPT's made from acid-fast bacilli of other types (Fig. 2). The curves of the five human TPT proteins (represented by TPT-H-37 in Fig. 2) resemble that of the bovine TPT protein more than any of the others, especially in the portion of the curves more alkaline than *p*H 7.5, where the tyrosine, lysine and arginine groups are titrated. It is interesting to speculate on the bearing this may have on the fact that more immunological relationship was demonstrated, by means of the precipitin reaction, between these human TPT and the bovine TPT proteins than between the proteins of other type bacilli. It will be recalled that the bovine TPT antiserum crossed with the human TPT antigens almost as well as it did with itself, whereas the crossing, while real, was not as marked between the human TPT antisera and bovine TPT antigen. On the other hand, no crossing whatever occurred between the timothy and bovine TPT's. Furthermore, it has been shown by Henderson[20] that there is no immunological relationship between the *M. leprae* no. 1 TPT and the *M. leprae* no. 112 TPT, but that there is some crossing

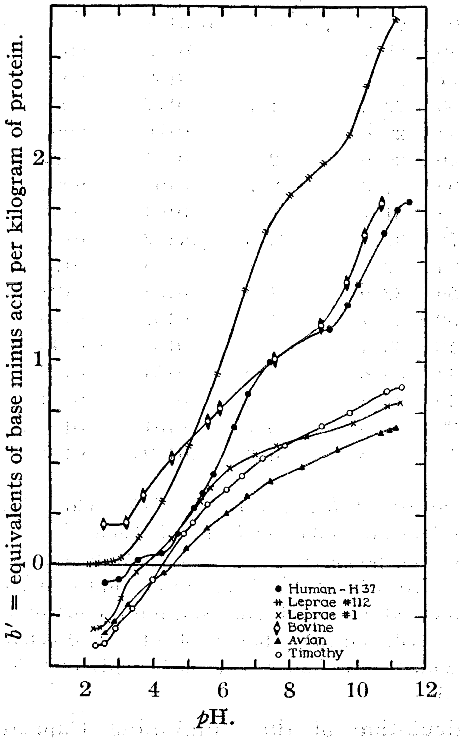

Fig. 2.

---

[20] H. Henderson, in press.

between the Human-H37-TPT and the *M. leprae* no. 1 TPT and that the crossing between timothy and *M. leprae* no. 1 TPT's was very marked, facts which also correspond with the titration curves. These results indicate that further work along this line may be fruitful. Discussion as to the significance of different parts of the curves in relation to the nature of the products will be reserved for another paper.

I wish to express my appreciation to Dr. H. S. Simons for his advice in calculation of the base-binding capacities.

Summary

A comparative study of the proteins isolated from five different strains of human type tubercle bacillus culture filtrates, grown under identical conditions, yielded the following results:

The yields of protein were very much alike, *viz.*, about 0.2 g. per liter of original medium.

The nitrogen content of four of them was 14% and of the fifth 15.2%.

The tuberculin potency, determined by means of the skin test in tuberculous guinea pigs, showed some variation, but this was not marked. All five proteins were potent tuberculins.

All five proteins proved to be identical serologically, when compared by the precipitin reaction. They were type specific, in that they could be distinguished easily by this method from proteins made similarly from other acid-fast bacilli, as had been shown in earlier work. The protein from the bovine type tubercle bacillus, while distinctive, was related to some extent to the human type proteins. Polysaccharide was not responsible for the immunological reactions, since it gave no cross reactions with any of the antisera.

Acid–base-combining capacity curves throughout the range of *p*H 2 to 11, as determined by electrometric titration, using the hydrogen electrode, showed a much closer correspondence between the five proteins from human type tubercle bacilli than between them and proteins made similarly from other types of acid-fast bacilli.

Hydnocarpic and Chaulmoogric Acids and Ethyl Esters

BY HOWARD IRVING COLE AND HUMBERTO CARDOSO

In making quantitative analyses of various chaulmoogra oils, it was necessary for us to know accurately the optical rotation and the boiling or melting points of pure hydnocarpic and chaulmoogric acids and their ethyl esters. The published data were not only incomplete but varied so widely that we found it necessary to prepare these substances in the pure state and redetermine their constants before proceeding with our analyses. Undoubtedly most of the errors found in the literature were due to impurities, since hydnocarpic acid is completely separated from chaulmoogric acid and from palmitic acid only with extreme difficulty. Hydnocarpic and chaulmoogric acids are optically active. They contain a double bond in the pentene ring and are classed theoretically as unsaturated acids as they absorb iodine or bromine in the theoretical amounts. On the other hand, being solid acids they behave physically more like the solid saturated acids, hence standard methods of separating unsaturated from saturated acids cannot be used for their isolation.

Methods of Separation

Pure chaulmoogric acid can best be obtained from the oil of *Oncoba echinata* or *Hydnocarpus alcalae* as these oils do not contain hydnocarpic acid. Analyses of chaulmoogra oils to date show no oil which contains hydnocarpic but not chaulmoogric acid, hence to obtain the former it must be separated from chaulmoogric acid. This was first accomplished qualitatively in 1905 by Power and his co-workers by fractional precipitation of their barium salts.[1] Other workers have used fractional crystallization of the free fatty acids or their salts, fractional distillation of the acids or methyl or ethyl esters, or some combination of these methods. Even so, complete purification is extremely difficult. For the preparation of pure hydnocarpic acid, *H. Wightiana* oil is recommended, as it does not contain palmitic acid whose physical properties are so close to those of hydnocarpic acid as to make complete separation of the latter next to impossible.

We have been able to separate completely hydnocarpic from chaulmoogric acids by employing a combination of

---

[1] F. B. Power and M. Barrowcliff, *J. Chem. Soc.*, **87**, 888, 896 (1905).

fractional vacuum distillation of their ethyl esters in a Podbielniak high temperature fractionating apparatus[2] and fractional crystallization of the free fatty acids made from these esters. The free fatty acids of *Hydnocarpus Wightiana* oil were prepared by saponifying it and liberating the acids with sulfuric acid in the usual manner. They were washed free of mineral acid and glycerol with hot water, solidified and remelted to free them from water. The acids were esterified by dissolving them in five times their weight of 99% ethyl alcohol, then slowly mixing in one part by weight of concentrated sulfuric acid and allowing the mixture to stand overnight. An equal volume of water was then added and the ester extracted with ethyl ether, washed, and free acids removed by a 10% solution of sodium carbonate. The ethereal solution was washed several times with water, then dried with lumps of calcium chloride, filtered and the ether removed. The ethyl esters so prepared were distilled at 10-mm. pressure in a model B Podbielniak high temperature fractionating apparatus. One fractionation separated the ethyl hydnocarpate from the chaulmoograte though not from the other solid and liquid acids present. The fractions were saponified by adding twice their volume of 95% alcohol and 10% excess of potassium hydroxide dissolved in as little water as possible. Complete saponification results after five minutes of boiling. After dilution with 3 or 4 parts of hot water an excess of 15% sulfuric acid was added. The fatty acids rise and solidify on cooling. They were washed four times with hot water and then crystallized to constant melting point and optical rotation from 80% alcohol. Usually two crystallizations were sufficient. It was observed that the melting point was not an accurate criterion of the purity of the compound. The optical rotation, which is very high, was a more sensitive indication of purity as was also the appearance of the crystals. The crystals of pure hydnocarpic and of pure chaulmoogric acid both grow upward in branching forms from the melted acid, as it solidifies. Even a small amount of impurities inhibits this very characteristic growth, yielding instead a flat upper surface. As far as we know this peculiarity has not been reported before.

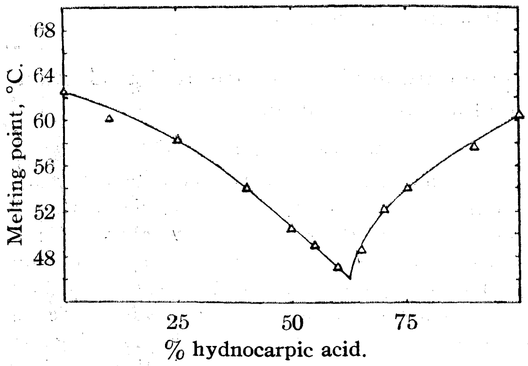

Fig. 1.—Melting point curve of palmitic and hydnocarpic acid mixtures.

The pure ethyl esters were prepared from these pure acids as outlined above and these were then redistilled in the Podbielniak apparatus. After taking the constants of these esters they were again changed to acids and crystallized two or more times. These acids showed no change in their constants from those first prepared. Ethyl esters from these acids when distilled gave the same boiling points, refractive indices and optical rotations as the preceding ones. Chaulmoogric acid and ethyl chaulmoograte prepared from *Oncoba echinata* oil gave the same constants as those from *H. Wightiana* oil. The constants of the pure acids and ethyl esters are given in Tables I and II.

TABLE I

CONSTANTS OF HYDNOCARPIC AND CHAULMOOGRIC ACIDS

Acid	Hydnocarpic	Chaulmoogric
Melting point, °C.	60.5	68.5
Specific rotation, $[\alpha]^{25}_D$	69.3	60.3
Iodine number (Hanus)	100.7	90.5
Neut. equivalent	251.8	280.9

Remarks: both the acids when pure grow upward in branching crystals from the melted acid as it solidifies.

TABLE II

CONSTANTS OF ETHYL HYDNOCARPATE AND CHAULMOOGRATE

Ester, ethyl		Hydnocarpate	Chaulmoograte
B. p. (10 mm.), °C.		184	206
Sp. rotation, $[\alpha]^{25}_D$		61.94	55.42
Specific gravity at	20/4	0.911	0.904
	25/4	.907	.901
	30/4	.904	.898
Refractive index at	20°	1.4597	1.4610
	25°	1.4578	1.4592
	30°	1.4558	1.4573

Melting Point Curves

It was noticed that even a small percentage of palmitic acid lowered the melting point of hydnocarpic acid to a surprising degree. The melting point curve of mixtures of these two acids was determined.

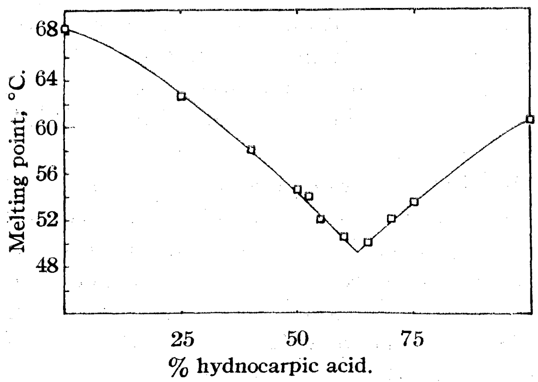

Fig. 2.—Melting point curve of chaulmoogric and hydnocarpic acid mixtures.

Power and Barrowcliff in their original work on hydnocarpic acid reported that systematic

---

(2) W. J. Podbielniak, *Ind. Eng. Chem., Anal. Ed.*, **3**, 181 (1931); **5**, 119 (1933).

fractional crystallization of the free fatty acids of *H. Wightiana*, *H. anthelmintica* or *T. Kurzii* oils always yielded mixtures which melted at 48–50°C.[1] They concluded that they were dealing with a molecular mixture of chaulmoogric acid and its homolog, hydnocarpic acid. By making up mixtures of these two pure acids and plotting the melting point curve, it was found that the lowest melting mixture was not at the point of a molecular mixture. Mixtures of the two acids do show, however, a very sharp drop in melting point and a loss of the characteristic crystalline formation of the pure acids (Fig. 2).

Optical Rotation

Because of the very high specific optical rotations of hydnocarpic and chaulmoogric acids (69.3 and 60.3°, respectively), the determination of this value is a very convenient means of ascertaining the purity of the acid. Especially is this so when one is able to employ, as we have done, an electric sodium lamp in conjunction with a precision polarimeter. Two different observers have been able to check readings with each other within ±0.02°.

The specific optical rotation of chaulmoogric acid often has been reported too high because there has been mixed with it a small amount of the more optically active hydnocarpic acid. Thus Stanley and Adams[3] report +61.9°, Power and Barrowcliff[1], +62.1° and Hinegardner and Johnson,[4] +62.2°. Goulding and Akers[5] report +60.0° while we obtain +60.3°.

In the case of hydnocarpic acid most of the optical rotation values given in the literature are too low due to the presence of palmitic or even chaulmoogric acid. We, however, closely check the value given by Stanley and Adams,[6] +69.4°, although their value for ethyl hydnocarpate, +70.5°, evidently is in error.

CALCULATIONS FOR SPECIFIC OPTICAL ROTATION

Compound	Source, oil of	Grams	$CHCl_3$, cc.	Ang. rotn., 100-mm. tube	$[\alpha]^{25}_D$
Chaulmoogric acid	*H. Wightiana*	2.5526	25	+6.16°	+60.3°
Chaulmoogric acid	*O. echinata*	3.2175	25	+7.77°	+60.3°
Ethyl chaulmoograte	*O. echinata*	2.6479	25	+5.87°	+55.42°
Hydnocarpic acid	*H. Wightiana*	4.9422	50	+6.86°	+69.3°
Ethyl hydnocarpate	*H. Wightiana*	1.9978	25	+4.95°	+61.94°

Summary

The published data on the physical constants of hydnocarpic and chaulmoogric acids and ethyl esters are incomplete and inaccurate. Methods of preparation of the pure acids and ethyl esters are described and their physical constants have been determined. The melting point curves for mixtures of hydnocarpic and palmitic and of hydnocarpic and chaulmoogric acids have been determined.

Some Reactions of Dihydroxyfluoboric Acid

BY J. W. KROEGER, F. J. SOWA AND J. A. NIEUWLAND[1]

A previous paper[2] from this Laboratory described the preparation and some of the properties of dihydroxyfluoboric acid and advanced a tentative structure for this compound. The present work was undertaken in order to throw some light on the structure of this acid and to present certain peculiar reactions which it undergoes.

The literature on the various acids of boron and fluorine has been reviewed by Meerwein and Pannwitz[3] and by the authors.[2] Meerwein describes a compound which he calls boron fluoride-dihydrate which is striking in its similarity to dihydroxyfluoboric acid. They have similar boiling and melting points, their indices of refraction and densities agree rather closely and the melting points of their dioxane derivatives are practically the same.

Dihydroxyfluoboric acid may be written in any of three ways

---

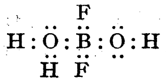
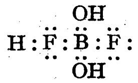
I



II



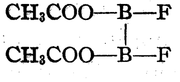
III

The first structure is the formal representation for this type of acid. The major part of the acid probably exists in the form of the second structure with the hydrogen ion coördinating with one of the hydroxyl groups. This is supported by the fact that dihydroxyfluoboric acid will combine with only one mole of boron trifluoride, probably through coördination with the second hydroxyl group. However, the possibility of the hydrogen ion coördinating with one of the fluorine atoms must also be admitted.

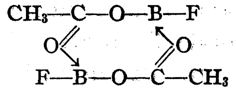
One hydrogen atom, as is represented in formula I, is available for salt formation. The others are alcoholic in their reactivity, or more properly, they resemble the hydrogen atoms in orthoboric acid. Sodium chloride reacts mole for mole with dihydroxyfluoboric acid with evolution of hydrogen chloride. The nickel salt crystallizes with three molecules of acid of crystallization as $Ni(H_2BO_2F_2)_2 \cdot 3H_3BO_2F_2$, but the unsolvated salt cannot be well characterized.

Dihydroxyfluoboric acid, in spite of the fact that it contains only two atoms of fluorine, forms boron trifluoride when it reacts. This is shown by the reaction with acetyl chloride and acetic anhydride, with oxygen compounds and with benzenediazonium chloride.

The hydrogen atoms of the two hydroxyl groups may be acetylated either with acetic anhydride or with acetyl chloride but, as yet, a stoichiometric equation cannot be written for the reaction. The products in the latter case are hydrogen chloride, acetic acid, acetic acid-boron fluoride [$(CH_3COOH)_2 \cdot BF_3$] and an acetoxy boron fluoride having the formula $(CH_3COOBF)_2$. This compound must be written in either of two ways

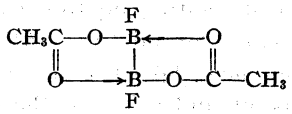


I



II

Acetoxyboron fluoride is a crystalline compound melting at 206–207° which sublimes with some decomposition *in vacuo*, is decomposed by water and most organic compounds containing oxygen (with the exception of acetyl chloride and acetic anhydride) and which has no reducing properties. Formula II is extremely unlikely since a seven electron shell about a boron atom is highly improbable. Formula I is more probable from a structural point of view. However, it is difficult to see how a boron-to-boron linkage could be formed from dihydroxyfluoboric acid. A third structure, a combination of the two previous, is somewhat more likely



III

if the formation of a boron-to-boron link is admitted to be possible.

Experimental and Discussion

Preparation of Dihydroxyfluoboric Acid.—The preparation of this acid has been somewhat modified for the sake of speed and convenience.

Seven hundred and seventy grams of liquid hydrogen fluoride were run into a 1000-ml. copper beaker cooled in an ice-bath. After the hydrogen fluoride had cooled to approximately the temperature of the bath, 500 g. of boric oxide was added slowly. A rather violent reaction took place immediately and was accompanied by evolution of boron trifluoride. When about half the boric oxide had been added it was found necessary to run in 300 g. more hydrogen fluoride because of loss from evaporation. The reaction time for these amounts of reagents was two hours.

The copper beaker and contents were then heated to 80° for a half hour to drive off dissolved gases, after which the reaction mixture was poured into a Claisen flask. The liquid at this point weighed 1014 g. and since the theoretically possible quantity of acid is 903 g. it was concluded that the mixture still contained a large amount of dissolved gases. After two distillations in vacuum, 890 g. of pure dihydroxyfluoboric acid was obtained, b. p. 159–160° (745 mm.), 93–95° (25 mm.), 84–86° (16 mm.); m. p. 4.0–4.5°; n^{25}_{D} 1.3323; d^{25}_{4} 1.6560.

The molecular refraction of this acid could be calculated using the following linkage values: HO—B—OH[4] 7.05, H—F[5] 1.9 and B—F[6] 2.0. These values show the calculated molecular refraction of dihydroxyfluoboric acid to be 10.95. A carefully fractionated sample had the constants n^{30}_{D} 1.3414, d^{30}_{4} 1.6539. From these constants the observed molecular refraction is 10.68.

Conductivity of Dihydroxyfluoboric Acid.—The conductivity of the acid was determined with the usual Kohl-

---

(4) Otto, unpublished work, University of Notre Dame. This value was calculated from the molecular refraction of orthoboric acid in dioxane (10.57).

(5) Smyth, "Dielectric Constant and Molecular Structure," A. C. S. Monograph, 1931, p. 149.

(6) Klemm, *Z. anorg. allgem. Chem.*, **213**, 115 (1933). Klemm found the molecular refraction of boron trifluoride to be 6.0.

rausch assembly at 25°. The resistance was 2867 ohms, cell constant 56.052, specific conductivity 0.0195 mhos, molal conductivity 0.988 mhos.

Dioxane Derivative.—Five grams of dihydroxyfluoboric acid was treated with 5.9 g. of dioxane in 15 ml. of petroleum ether. The solid which separated was recrystallized from a mixture of dioxane and petroleum ether. The large, brittle, apparently non-hygroscopic crystals were powdered and found to melt at 139.5–140.5°. Calcd. for $C_4H_8O_2{\cdot}H_3BO_2F_2$ (%): boron, 6.28; fluorine, 22.1. Found: boron, 6.27; fluorine, 22.1.

Acetylation of Dihydroxyfluoboric Acid.—Approximately one-half mole (46.1 g.) of dihydroxyfluoboric acid was weighed into a flask cooled in an ice-bath. One and one-half moles of acetyl chloride (120 g.) was dropped in over a period of two hours. Hydrogen chloride came off immediately and was passed through a trap cooled in ice into a solution of sodium hydroxide. The evolution of hydrogen chloride practically ceased when about 85 ml. of acetyl chloride had been added; however, the remainder was run in in order to decrease the solubility of acetoxyboron fluoride in the reaction mixture. The flask was then warmed to about 40° and swept out with dry air to remove the remaining hydrogen chloride. It was found that the weight of the absorber had increased 42.8 g. Back-titration of the remaining sodium hydroxide indicated that 40.2 g. of hydrogen chloride had been absorbed. The discrepancy between this value, which is very near the calculated figure (40.1 g.), and the actual weight was probably due to some entrainment of acetyl chloride.

The reaction mixture was let stand overnight to permit crystallization of the acetoxyboron fluoride. The liquid was then decanted and the crystals were washed with a small amount of acetyl chloride. When crystallization did not take place the liquid reaction mixture was distilled directly and the residue was recrystallized from acetyl chloride from which it separated in long needles. The following are the results obtained from the experiment described above.

TABLE I

Product	B. p., °C.	Yield, g.	$n^{25}D$
HCl	.....	40.2	....
CH_3COOH	116–117	11.9	1.3730
$(CH_3COOH)_2{\cdot}BF_3$	64–66 (15 mm.)	51.5	1.3735
$(CH_3COOBF)_2$	M. p. 206–207°	19.3	....

Acetoxyboron fluoride was analyzed for boron and fluorine according to the procedure of Pflaum and Wenzke,[7] modified by decomposing the sample with sodium in liquid ammonia as described by Vaughn and Nieuwland.[8]

The acetyl determination was carried out in the following manner. Accurately weighed samples of acetoxyboron fluoride, usually about 1.5 g., were dissolved in 10 to 15 g. of absolute ethyl alcohol and refluxed for two hours. The mixture was then distilled until the temperature reached 85°, the distillate being collected in 250 ml. of 0.1 *N* sodium hydroxide. To the residue was added 15 g. of absolute alcohol and, after refluxing and distilling as before, the residue was again treated with absolute alcohol and the procedure repeated. All parts of the apparatus except the actual reaction flask were then rinsed with absolute alcohol which was added to the flask containing the distillate and 0.1 *N* sodium hydroxide. This was allowed to stand overnight and was then titrated with 0.1 *N* hydrochloric acid using phenolphthalein as an indicator. From this, the amount of ethyl acetate in the distillate could be found and consequently the percentage of acetyl in the original compound. It was found that the distillate contained only traces of boron and no fluorine. Two treatments with absolute alcohol, as described above, were sufficient to remove all the acetoxy but the third was always included to ensure certainty in the results. Eight to twelve hours was found to be ample for the saponification of the ethyl acetate. The results obtained were, calcd.: acetoxy, 66.46; boron, 12.16; fluorine, 21.39; total 100.0. Found: acetoxy, 65.4; boron, 12.16; fluorine, 21.09; total 98.7. A qualitative test for chlorine was found to be negative.

The molecular weight of acetoxyboron fluoride was determined ebullioscopically in acetyl chloride. Mathews and Fehlandt[9] give a value for the heat of vaporization of acetyl chloride at 50.4° equal to 87.14 ± 0.09 cal./g. The ebullioscopic constant calculated from this value was found to be 2.38 degrees per mole per kilogram. This constant was checked experimentally using pure naphthalene, which gave a value of 2.21. A series of ten determinations of the molecular weight of acetoxyboron fluoride gave an average value of 175.5 ± 3.1. This value is approximately twice the formula weight of 88.8 so the formula of the compound must be $(CH_3COOBF)_2$.

Although acetoxyboron fluoride is rather insoluble in acetyl chloride, this solvent appears to be the only one in which there is no possibility of decomposition. It was thought that some light might be thrown upon the structure of this compound by a determination of the molecular refraction. The constants given below were all determined at 25°. Those for the pure solvent, acetyl chloride, were: d_4 1.0958, nD 1.38613, *MR*D calcd. 16.314, *MR*D obs. 16.827. The values for the solution were d_4 1.1009, nD 1.38646, c_2 0.0072116 moles/mole. These data give a value for the molecular refraction of 29.029. The calculated value, omitting the third valency of the boron atoms, is 30.268. This omission causes the calculated value to be low by at least one or two units; however, considering the extreme dilution of the solution and the lack of knowledge concerning the disposition of the third boron linkages, these values are in surprisingly good agreement.

Acetoxyboron fluoride is insoluble in most organic solvents and is decomposed by water and those containing oxygen. It may be crystallized from trimethyl borate if done quickly but on standing in contact with the solvent for more than a day it is decomposed.

---

(7) Pflaum and Wenzke, *Ind. Eng. Chem., Anal. Ed.*, **4**, 392 (1932).

(8) Vaughn and Nieuwland, *ibid.*, **3**, 274 (1931).

(9) Mathews and Fehlandt, THIS JOURNAL, **53**, 3212 (1931).

Referring to Table I it may be seen that, on the basis of one mole of dihydroxyfluoboric acid reacting, there are found in the products 0.984 atom of boron, 2.08 atoms of fluorine, 1.93 atoms of non-carbonyl oxygen but 3.594 atoms of hydrogen. The empirical formula for dihydroxyfluoboric acid is $H_3BO_2F_2$ and since the above value for hydrogen is definitely beyond the experimental error of the determination it is difficult to explain this discrepancy. Actual determinations of hydrogen by combustion methods gave a value of 3.37% as compared to the calculated value of 3.61%. In addition, when dihydroxyfluoboric acid is treated with sodium chloride exactly one mole of hydrogen chloride is given off.

One-third mole of dihydroxyfluoboric acid (28 g.) was dissolved in 200 g. of redistilled ether-boron fluoride b. p. 121–122° and 40 g. (excess) of powdered C. P. sodium chloride was added. The mixture was refluxed for three days and the hydrogen chloride which came off was dissolved in sodium hydroxide solution. Back-titration showed that 11.1 g. of hydrogen chloride had been absorbed. The calculated value, assuming only one hydrogen in dihydroxyfluoboric acid to be replaced, is 12.2 g. The reaction was very slow and probably did not go to completion.

Nickel Salts.—Since the nickel salt of dihydroxyfluoboric acid is quite readily prepared it was decided to utilize this as an additional method for characterizing the acid. This salt may be prepared without difficulty by dissolving nickelous carbonate or chloride in the acid but the oxides and hydroxide apparently do not react.

Slightly less than the calculated quantity of nickelous carbonate was dissolved in dihydroxyfluoboric acid by warming. The product, which solidified on cooling, was recrystallized from a small amount of pure acid. The resulting dark-green crystals were filtered with suction in a closed Gooch crucible and were quickly pressed dry on filter paper, then were analyzed for nickel using dimethylglyoxime. Calcd. for $Ni(H_2BO_2F_2)_2 \cdot 3H_3BO_2F_2$: Ni, 12.3. Found: Ni, 11.9, 12.1. This salt melted at 120°.

The salt was heated carefully and intermittently at 155–160° and 12 mm. pressure for a total period of twelve hours. Samples were removed at intervals of two to three hours and analyzed and in this way a material was obtained which corresponded to nickel dihydroxyfluoborate. Calcd. for $Ni(H_2BO_2F_2)_2$: Ni, 26.1. Found: Ni, 26.2, 26.2. This material, light green in color, is readily converted by heating for two to three hours at 200° and 12 mm. pressure to a creamy, fluffy powder. Calcd. for $Ni(HBO_2F)_2$, 31.8% Ni and for $Ni(BF_2O)_2$, 31.1% Ni; found, 31.0% Ni. The first salt might be formed by loss of hydrogen fluoride from the original material and the second by loss of water. The latter possibility was found to be the case since a small amount of water actually was collected during the second period of heating, that at 200°.

The cream colored salt was ignited in air at 900° for ten hours. The resulting greenish-black powder contained 60.1% Ni. After an additional ten hours of heating the percentage of nickel had risen to 61.7%. This material contained boron but no fluorine and was apparently a mixture of nickelous oxide and metaborate. Beginning with the original dark green crystalline salt, the solubility in water of the various compounds became smaller as heating progressed. The cream colored salt was only slightly soluble in water but soluble in dilute acids. The final oxide–metaborate mixture was insoluble in water and acids and in order to analyze for nickel the samples had first to be fused with sodium pyrosulfate. The remaining compounds were quite soluble in water.

Formation of Orthoboric Acid.—Dihydroxyfluoboric acid is decomposed by low-molecular weight acids, alcohols, esters, ketones, aldehydes and ethers, with the exception of dioxane, to form orthoboric acid and boron fluoride. This decomposition is apparently regulated by the ease of formation of the boron fluoride complex of the second reactant. Thus trichloroacetic acid, the boron fluoride complex of which is stable only at low temperatures, will not react with dihydroxyfluoboric acid even when melted, whereas acetic acid, which forms a stable addition compound boiling at 141–142°, reacts almost immediately.

The reaction always involves one mole of dihydroxyfluoboric acid and two moles of the second reactant. While the actual decomposition may be represented by the following scheme

$$3H_3BO_2F_2 \longrightarrow 2BF_3 + H_3BO_3 + 3H_2O$$

where the boron fluoride then forms a complex with the second reactant, it is difficult to understand why the additional amount of the oxygen compound is necessary. That is, three moles of the acid actually require six moles of the second reactant.[10] Two moles of an ether are required to combine with the boron fluoride liberated and either two or four moles of an acid or an alcohol ($ROH \cdot BF_3$ and $RCOOH \cdot BF_3$ or the more stable $(ROH)_2 \cdot BF_3$ and $(RCOOH)_2 \cdot BF_3$). In either case the amount is less than the six moles actually required. The boron fluoride and the orthoboric acid cannot be estimated accurately since the water formed in the reaction causes a secondary decomposition.

The boric acid from these decompositions, when filtered and pressed dry on filter paper,

---

(10) This was determined by preparing tubes containing identical amounts of dihydroxyfluoboric acid and varying amounts of the reactant, centrifuging and weighing the orthoboric acid formed. The boron fluoride was also estimated where the second reactant formed a complex, stable to distillation, as in the case of ether, acetic acid and methyl and ethyl acetates.

contained from 6 to 10% fluorine, and 16.7 to 17.0% boron (calcd. for H_3BO_3, 17.5% B). The melting point was always about 148–149° and since pure boric acid melts at 175–176° it was thought that there must be some other compound present. When thoroughly washed with the secondary reactant the material contained no fluorine, the melting point rose to 175–176° and the percentage of boron rose to the calculated value, 17.5%. The same thing could be accomplished by drying in a vacuum over potassium hydroxide for two weeks. After drying for twelve hours at 110° the material contained no fluorine and was found to be metaboric acid, m. p. 175–176°, 24.6% B, calcd., 24.6%.[11]

Samples of pure orthoboric acid were moistened with ether–boron fluoride, acetic acid–boron fluoride and methyl acetate–boron fluoride and after filtering and pressing dry on filter paper, were found to have melting points between 149 and 151° and contained considerable amounts of fluorine. Apparently this was the explanation for the low melting points.

Orthoboric acid is also formed by the action of water on dihydroxyfluoboric acid, m. p. 175°, calcd. % B 17.5; found, 17.4.

Preparation of Fluorobenzene.[12]—The best results were obtained using a ratio of two moles of dihydroxyfluoboric acid to one of the diazonium salt. One-quarter mole of benzenediazonium chloride was prepared to which was added one-half mole (42 g.) of dihydroxyfluoboric acid while cooling to below 10°. The mixture was stirred for forty-five minutes, then filtered and the light-green precipitate was washed with small amounts of alcohol and ether: yield of salt, 43 g.; decomposition point, 84°. This salt was decomposed by warming and formed 11.8 g. of fluorobenzene, b. p. 84–85°. If this salt were $C_6H_5N_2BF_2(OH)_2$ the yield of fluorobenzene was 25%, whereas if the compound were $C_6H_5N_2BF_4$ the yield was 50%.

The purest salt was obtained by using a ratio of one mole of dihydroxyfluoboric acid to one of the diazonium compound. The yield was extremely poor but the salt decomposed at 85°. One-half gram of this material, accurately weighed, was decomposed by heating and the evolved gas was analyzed. The volumes were corrected for pressure, temperature and the vapor tension of water. A total of 115 ml. of gas was collected over mercury. After washing with water 56 ml. of nitrogen remained. Calculated: total, 116.8 ml.; BF_3, 58.4 ml.; N_2, 58.4 ml. These results indicate that the salt was benzenediazonium fluoborate $C_6H_5N_2BF_4$ and that it was about 95% pure.

Acknowledgment.—The authors are indebted to Dr. R. R. Vogt for valuable advice and criticism and to Dr. M. M. Otto, Messrs. V. P. Osweiler, C. R. Montgomery and F. J. Froning for assistance in various parts of this work.

Summary

1. Dihydroxyfluoboric acid has been shown to contain one strongly acidic and two non-acidic hydrogen atoms.

2. Several reactions of dihydroxyfluoboric acid have been discussed and their products identified.

3. Acetoxyboron fluoride has been prepared by acetylation of dihydroxyfluoboric acid and a proposed structure has been advanced.

[11] It was thought that the presence of another compound might appear in a determination of molecular weight. Trimethyl borate was chosen as a solvent. The melting point was found to be −29.4 ± 0.1° and the cryoscopic constant, determined experimentally using naphthalene, was 4.68 ± 0.1° per mole per kilogram. However, it was found that the boric acids dissociated in this solvent. Thus, metaboric acid had an apparent molecular weight of 29.5.

The Steady-State Rate of a Chain Reaction for the Case of Chain Destruction at Walls of Varying Efficiencies[1]

BY GUENTHER VON ELBE[2] AND BERNARD LEWIS[3]

Bursian and Sorokin's[4] treatment of the rate of a chain reaction with destruction of the chain carriers at the wall considers only the case that every chain carrier striking the surface is destroyed. It is, however, well known that walls possess different efficiencies, as is shown, for example, by experiments with hydrogen atoms. The efficiencies may range from the order of 100% to <0.001%. Recently, Kassel and Storch[5] have treated the problem for a spherical vessel with varying efficiencies of the chain-breaking process. For the average concentration of chain carriers $\bar{n}$, transcendental equations are obtained. The reaction rate is equal to $Kc\bar{n}$, where c is the concentration of the gas with which the chain carrier undergoes reaction and K is the velocity coefficient.

In the present paper, the consequences of the theory for the experimental study of an unknown reaction are discussed. In particular, the influence of vessel diameter on the rate is described quantitatively by tabulation, since this can be done without knowledge of the reaction mechanism and since it serves adequately to explore regions of special kinetic interest. It is also shown that the exact transcendental equations can be replaced with good approximation by simple equations of the type customarily employed in kinetic work. This will serve to show the extent to which former treatments are valid.

It has often been assumed[6,7] that, in a quiescent mixture where chain carriers reach the wall by diffusion only, the concentration of chain carriers may be determined from the equation

$$\bar{n} = n_0 \Big/ \left(\frac{\text{const.}}{pd^2} - \alpha\right) \qquad (1)$$

in which n_0 is the rate of chain initiation per unit volume, $\alpha\bar{n}$ is the net rate of chain branching (α being the difference between the velocity coefficients of the rate of chain branching and the rate of chain destruction in the volume if such exists), p is the pressure, and d is a linear dimension of the reaction vessel. The term $(const./pd^2)\bar{n}$ would then be the rate of chain destruction at the wall, the constant being in some way dependent on the efficiency of chain destruction. The limitations of equation 1 do not seem always to have been fully appreciated. As will be seen later, the equation is approximately correct only for chain initiation in the gas phase, for relatively high efficiencies of chain destruction, and for vessel diameters and pressures that are not small compared with those necessary to induce explosion under the same conditions.

The two cases of chain initiation at the wall and in the gas phase will now be considered. For both cases chains are assumed to branch in the gas phase and to break principally at the wall.

Chain Initiation at the Wall

The concentration of chain carriers, n, at any distance, a, from the center of the spherical vessel of radius, r, is found by integrating the differential equation expressing that the change of concentration with time due to diffusion and net rate of branching is zero and introducing the boundary condition that the net rate of branching throughout the volume is equal to the rate of surface destruction of chains minus the rate of production of new chains at the surface. The rate of destruction of chains at the surface is ϵ times the rate at which the chain carriers strike it, ϵ being the efficiency of chain destruction with values ranging from 0 to 1.

The introduction of the boundary condition to determine the integration constant A in the expression n = f (a) (equation 4 of Kassel and Storch[5]) requires the determination of the total number of chain carriers in the volume, that is, solution of $\int_0^r 4\pi a^2 n da$. Substituting for A

equation 15[8] of Kassel and Storch, and solving for the average concentration of chain carriers, one obtains

$$\bar{n} = \frac{\gamma m_0}{\left[\frac{\epsilon r}{\lambda}\frac{1 - \sqrt{\alpha/\mathrm{D}}\,\lambda\,\mathit{ctn}\,\sqrt{\alpha/D}\,r}{1 - \sqrt{\alpha/D}\,r\,\mathit{ctn}\,\sqrt{\alpha/D}\,r} - 1\right]\alpha} = \frac{\gamma m_0}{\left[\frac{\epsilon r}{\lambda}\frac{1-\lambda/r}{1 - \sqrt{\alpha/D}\,r\,\mathit{ctn}\,\sqrt{\alpha/D}\,r} + \epsilon - 1\right]\alpha} \qquad (2)$$

m_0 is the rate of chain initiation per unit area and γ is the ratio of surface to volume and is equal to $3/r$. Therefore, γm_0 is the volume equivalent of the rate of chain initiation. D is the diffusion coefficient and λ is the mean free path.

$\bar{n}$ can have only positive values. The condition $\bar{n} = \infty$ marks the limit of the steady state where the reaction becomes explosive. Beyond this limit, that is, within the explosive region, equation 2 would give negative values for $\bar{n}$. It follows by inspection of equation 2 that for $\bar{n}$ to be positive $\sqrt{\alpha/D}\,r$ must not exceed π and as $\sqrt{\alpha/D}\,r$ approaches π, ϵ must approach 1.

Important deductions regarding the influence of experimental conditions on $\bar{n}$ may be made from the power series expansion of equation 2 for the limiting condition that $\sqrt{\alpha/D}\,r$ is close to zero. The term $1 - \sqrt{\alpha/D}\,r\,\mathit{ctn}\,\sqrt{\alpha/D}\,r$ reduces to $\frac{1}{3}\frac{\alpha r^2}{D}$. If $D = \frac{\bar{v}\lambda}{4}$[9] ($\bar{v}$ being the average molecular velocity) and $\lambda/r \ll 1$, equation 2 becomes

$$\bar{n} = \frac{\gamma m_0}{\left(\frac{\epsilon r}{\lambda}\frac{3D}{\alpha r^2} + \epsilon - 1\right)\alpha} = \frac{\gamma m_0}{{}^3/_4\frac{\epsilon\bar{v}}{r} - (1 - \epsilon)\,\alpha} \qquad (3)$$

For small values of ϵ the positive term in the denominator becomes identical with the coefficient of the rate of chain destruction. In contradistinction to the corresponding term in equation 1, it is inversely proportional to the radius and independent of pressure if ϵ is independent of pressure. The functional dependence of ϵ is determined by the mechanism of the chain-destroying reaction in which will enter the natures of the surface and the chain carrier and possibly pressure, temperature and mixture composition. If ${}^3/_4\frac{\epsilon\bar{v}}{r}\left(= \frac{\epsilon\bar{v}}{4}\gamma\right) \gg (1 - \epsilon)\,\alpha$, $\bar{n}$ becomes independent of vessel size and dependent on pressure, temperature and mixture composition only to the extent that $m_0/\epsilon\bar{v}$ is dependent on these factors. Experimentally, this region is of particular interest, since it allows a direct kinetic investigation of the ratio of the chain-initiating reaction to the efficiency of chain destruction. This much-needed separation of variables finds its counterpart in the independent kinetic investigation of α from the determination of the explosion regions in a diagram of any two of the variables pressure, temperature, mixture composition, vessel size.

The condition ${}^3/_4\frac{\epsilon\bar{v}}{r} \gg (1 - \epsilon)\,\alpha$ can be approached by making r small or by decreasing α in a manner that does not simultaneously decrease ϵ to the same or to a greater degree. This would demand that the functional dependence of ϵ on any variable shall be a milder one than the dependence of α on that variable. As far as pressure and mixture composition are concerned this limitation would seem to be the usual case. α may be made small by reducing the pressure of the reactants involved in the branching reaction. Frequently, α can be made small by decreasing the temperature but here one often encounters very complex functional dependencies of both α and ϵ. This is illustrated by the reaction between oxygen and higher hydrocarbons.[10]

Whenever the rate of a chain reaction is found to be independent of diameter there exist only two alternatives. Either the above-discussed case applies or chains are both initiated and destroyed in the gas phase. In the latter case, however, the rate will remain independent of diameter for all diameters, whereas in case chains are initiated and destroyed at the wall, branching causes the rate eventually to increase with increasing diameter. No such well-defined criterion for distinguishing these two cases is obtained by varying the pressure, temperature or mixture composition.

It has usually been found difficult to determine with accuracy the dependence of the reaction rate on diameter. There may be various reasons for this, the most obvious being the difficulty of controlling, experimentally, properties of the surface on which m_0 and ϵ depend. Often, it has only been possible to state that a reaction rate is either independent of or roughly dependent on some power of the diameter. In the light of the

---

[8] More exactly, the term $\frac{\epsilon\bar{v}r}{4}\sin\sqrt{\alpha/D}\,r$ in their equation 15 should be replaced by $\frac{\epsilon\bar{v}r}{4}\sin\sqrt{\alpha/D}\,(r - \lambda)$.

[9] The difference between this value of D and the usual value $\bar{v}\lambda/3$ arises from the assumption that all free paths are equal as has been done in Kassel and Storch's[5] treatment.

above results and others to be presented later, even such comparatively rough experimental data may provide considerable knowledge concerning the reaction mechanism.

The dependence of the reaction rate on diameter will now be investigated quantitatively. For given values of ϵ, λ, D and α there exists a vessel radius r_0 at which the rate becomes explosive, that is, $\bar{n} = \infty$. For radii $r < r_0$ the slow steady-state rate will be established, that is, $\bar{n}$ is finite and positive.

From equation 2 and $\lambda/r \ll 1$

$$\frac{\epsilon r}{\lambda} = (1 - \sqrt{\alpha/D}\,r_0\,ctn\,\sqrt{\alpha/D}\,r_0)\frac{r}{r_0}(1 - \epsilon) \qquad (4)$$

ϵ is small compared with 1 unless $\sqrt{\alpha/D}\,r_0$ is very close to π. If, for example, λ/r is of the order 10^{-3} corresponding to low pressures (a few mm. mercury) and ordinary vessel dimensions, ϵ is greater than the order of 0.1 only when $\sqrt{\alpha/D}\,r_0$ exceeds 0.99 π. For higher pressures, $\sqrt{\alpha/D}\,r_0$ must approach even closer to π before ϵ reaches this value.

Combining equations 2 and 4, the exact equation becomes

$$\frac{\alpha\bar{n}}{\gamma m_0} = \frac{1}{(1 - \epsilon)\left(\frac{1 - \sqrt{\alpha/D}\,r_0\,ctn\,\sqrt{\alpha/D}\,r_0}{1 - \sqrt{\alpha/D}\,r\,ctn\,\sqrt{\alpha/D}\,r}\frac{r}{r_0} - 1\right)} \qquad (5)$$

If $\bar{n}$ is independent of diameter the function $\alpha\bar{n}r_0/\gamma m_0 r$ must be constant. Values of this function calculated from equation 5 for $\sqrt{\alpha/D}\,r_0$ from 0 to π and r/r_0 from 0 to 1 are given in Table I. The corresponding values of $\frac{\epsilon r_0}{\lambda}\frac{1}{1 - \epsilon}$ are given in the second horizontal line. It is seen that the range of diameters within which the reaction rate is reasonably independent of diameter widens for increasing values of $\frac{\epsilon r_0}{\lambda}\frac{1}{1 - \epsilon}$. Thus, for $\epsilon r_0/\lambda = 0$, about a 10% increase in the value of the function occurs between $r/r_0 = 0$ and 0.1, whereas for $\epsilon r_0/\lambda = r_0/\lambda$ the same increase occurs between $r/r_0 = 0$ and 0.4. It is plain that for otherwise identical conditions the replacement of a vessel with a wall of high chain-breaking efficiency by one with low chain-breaking efficiency should markedly increase the dependence of the reaction rate on vessel diameter.

The following considerations give some idea of the magnitude of ϵ for a given value of $\frac{\epsilon r_0}{\lambda}\frac{1}{1 - \epsilon}$.

In the usual experiments the pressure may be between a few millimeters and 1 atmosphere, for which λ is of the order 10^{-2} to 10^{-4} cm., respectively. Values of the explosion radius r_0 depend on a number of conditions. In actual experiments it will probably not be less than the order of 10 cm. Thus, when $\frac{\epsilon r_0}{\lambda}\frac{1}{1 - \epsilon} =$ 14.80, ϵ would not be larger than 0.01 to 0.0001, depending on the above pressure range. This example illustrates that the effect of ϵ on the dependence of the rate on diameter becomes noticeable only in vessels with walls having extremely small chain-breaking efficiencies.

The influence of ϵ on the reaction rate itself is very pronounced over the whole range of values from 0 to 1, the rates decreasing with increasing ϵ.

Previously, non-transcendental equations were obtained for $\bar{n}$ on the basis of Bursian and Sorokin's treatment, which strictly apply only to the case of large efficiency of chain destruction (ϵ close to 1) and to the neighborhood of the explosion limit.[6] It will now be shown that for this condition, namely, $\sqrt{\alpha/D}\,r$ close to π, equation 2 can be reduced to a non-transcendental equation that describes with good approximation all the essential features of the theory. The term $1 - \sqrt{\alpha/D}\, r \, ctn \sqrt{\alpha/D}\, r$ now reduces, in the limit, to $1 \Big/ \left(\frac{\pi}{r}\sqrt{\alpha/D} - 1\right)$ or the general form $2^x/(y^{2^x} - 1)$ where $x = 0, 1, 2, 3 \ldots$ and $y = (\pi/r)\text{-}\sqrt{\alpha/D}$. The desired reduction is obtained for $x = 1$. If $\lambda/r \ll 1$ equation 2 becomes

$$\bar{n} = \frac{\gamma m_0}{\left[\frac{\epsilon r}{2\lambda}\left(\frac{\pi^2 D}{\alpha r^2} - 1\right) + \epsilon - 1\right]\alpha} \qquad (6)$$

To compare equation 6 with equation 2 for the influence of diameter, $\epsilon r/\lambda$ must be expressed as a function of r_0. This expression is obtained readily from equation 4, since $\sqrt{\alpha/D}\, r_0$ is also close to π. Thus

$$\frac{\epsilon r}{\lambda} = \frac{2}{\frac{\pi^2 D}{\alpha r_0^2} - 1}\,\frac{r}{r_0}\,(1 - \epsilon) \qquad (7)$$

Combining equations 6 and 7

$$\frac{\alpha\bar{n}}{\gamma m_0} = \frac{1}{(1 - \epsilon)\left(\frac{\frac{\pi^2 D}{\alpha r^2} - 1}{\frac{\pi^2 D}{\alpha r_0^2} - 1}\,\frac{r}{r_0} - 1\right)} \qquad (8)$$

A direct comparison of equations 8 and 5 is furnished by the tabulation of the ratio $\bar{n}_8/\bar{n}_5$ for the entire range of $\sqrt{\alpha/D}\, r_0$ and r/r_0. This is given in Table I. It is seen that equation 8 follows the trend of equation 5 over practically the entire range. Even in the columns toward the right of Table I it represents the region in which the rate is independent of vessel size over much the same range of r/r_0 as equation 5. The gradual improvement of the numerical agreement toward the left of Table I is accompanied by an increasing but always unimportant discrepancy in $\frac{\epsilon r}{\lambda}\frac{1}{1 - \epsilon}$ introduced through equation 7. Thus by the approximate treatment reaction vessels possess apparent chain-breaking efficiencies that are smaller than the actual ones. Ratios of such apparent to actual efficiencies calculated from equations 7 and 4 are listed in the third horizontal line in Table I.

The comparison of equations 2 and 6 will now be made in a perfectly general way, to include variations not only in diameter but in any physical condition such as pressure, temperature and mixture composition. According to equation 2, the condition for explosion may be written

$$1 - (\sqrt{\alpha/D}\, r)_0 \, ctn \, (\sqrt{\alpha/D}\, r)_0 = \left(\frac{\epsilon r}{\lambda}\frac{1}{1 - \epsilon}\right)_0 \qquad (9)$$

and according to equation 6

$$\frac{2}{\left(\frac{\pi^2 D}{\alpha r^2}\right)_0 - 1} = \left(\frac{\epsilon r}{\lambda}\frac{1}{1 - \epsilon}\right)_0 \qquad (10)$$

If $(\sqrt{\alpha/D}\, r)_0$ is close to 0, the left-hand sides of equations 9 and 10 become $\frac{1}{3}\left(\frac{\alpha r^2}{D}\right)_0$ and $\frac{2}{\pi^2}\left(\frac{\alpha r^2}{D}\right)_0$, respectively. Since $\sqrt{\alpha/D}\, r$ is ordinarily also close to 0, both equations 2 and 6 after substituting equations 9 and 10, respectively, become identical, namely

$$\frac{\alpha\bar{n}}{\gamma m_0} = \frac{1}{1 - \epsilon\left(\frac{(\alpha r^2/D)_0}{\alpha r^2/D} - 1\right)} \qquad (11)$$

It is now clear why $\bar{n}_8/\bar{n}_5$ should have been found equal to 1 for $\frac{\epsilon r}{\lambda}\frac{1}{1 - \epsilon}$ equal to 0 (Table I).

Let us now consider $\sqrt{\alpha/D}\, r \ll (\sqrt{\alpha/D}\, r)_0$ for any value of the latter between 0 and π. The more complete expansion of $1 - \sqrt{\alpha/D}\, r \, ctn \sqrt{\alpha/D}\, r$ is given by $\frac{1}{3}\frac{\alpha r^2}{D} + \frac{1}{45}\frac{\alpha^2 r^4}{D^2} + \ldots$, whence $\frac{1}{1 - \sqrt{\alpha/D}\, r \, ctn \sqrt{\alpha/D}\, r} = \frac{3D}{\alpha r^2}\frac{1}{1 + \frac{1}{15}\frac{\alpha r^2}{D} + \ldots}$. The corresponding term in equation 6, $\frac{1}{2}\left(\frac{\pi^2 D}{\alpha r^2} - 1\right) = \frac{\pi^2 D}{2\alpha r^2}\left(1 - \frac{1}{\pi^2}\frac{\alpha r^2}{D}\right)$ becomes, for small values of $\sqrt{\alpha/D}\, r$, equal to $\frac{\pi^2}{2}\frac{D}{\alpha r^2}\frac{1}{1 + \frac{1}{\pi^2}\frac{\alpha r^2}{D}}$. As $\sqrt{\alpha/D}\, r$ becomes small the two denominators, namely, $1 + \frac{1}{15}\frac{\alpha r^2}{D}$ and $1 + \frac{1}{\pi^2}\frac{\alpha r^2}{D}$ approach 1 almost simultaneously. Thus, both equations 2 and 6 approach an identical form almost simultaneously (apart from an unimportant numerical factor). This explains why the range over which the rate may be considered independent of diameter should have been found almost equally well described by equation 8 (Table I).

It has now been demonstrated that the approximate treatment (equation 6) is satisfactory for small chain-breaking efficiencies from slow reaction to explosion and for any chain-breaking efficiency in the region where the reaction rate is reasonably independent of diameter. The equation applies strictly to the range for which it was derived, namely, large chain-breaking efficiencies and reaction rates close to explosion. There remains the intermediate range in which discrepancies between approximate and exact treatments would be greatest. This range cannot be investigated in a general way because the functional dependencies of ϵ, α, D and λ vary for different reactions. Only for changes in vessel size is a comparison possible. Judging from the rather satisfactory agreement (Table I) it may be expected that for most kinetic purposes with emphasis placed on trend rather on exact numerical agreement, the approximate treatment will be found satisfactory.

Chain Initiation in the Gas Phase

In this case the concentration of chain carriers at any distance from the center of the spherical vessel is found by integrating the differential equation expressing the fact that the change of concentration with time due to diffusion, net rate of branching and initiation is zero and introducing the boundary condition that the net rate of branching plus the rate of chain initiation throughout the volume is ϵ times the rate at which chain carriers strike the surface. Using the same treatment as before, except that now $n = f(a)$ and the integration constant A are given by equations 13 and 14,[11] respectively, of Kassel and Storch,[5] one obtains

$$\bar{n} = \frac{n_0}{\alpha}\,\frac{\frac{3D}{\alpha r^2}(1 - \lambda/r)}{\frac{1 - \lambda/r}{1 - \sqrt{\alpha/D}\,r\,\mathrm{ctn}\,\sqrt{\alpha/D}\,r} - \frac{\lambda}{\epsilon r}(1 - \epsilon)} - 1 \quad (12)$$

where n_0 is the rate of chain initiation per unit volume.

As before, in order that $\bar{n}$ be positive $\sqrt{\alpha/D}\,r$ must not exceed π and as $\sqrt{\alpha/D}\,r$ approaches π, ϵ approaches 1.

For $\sqrt{\alpha/D}\,r$ close to 0, the series expansion

$$\frac{{}^1/_3\,\frac{\alpha r^2}{D}}{1 - \sqrt{\alpha/D}\,r\,\mathrm{ctn}\,\sqrt{\alpha/D}\,r} = \frac{1}{1 + \frac{1}{15}\frac{\alpha r^2}{D} + \ldots}$$

becomes equal to $1 - \frac{1}{15}\frac{\alpha r^2}{D}$ and equation 12 reduces to, for $\lambda/r \ll 1$

$$\bar{n} = \frac{n_0}{\frac{15D}{r^2}\,\frac{1}{1 + \frac{5\lambda}{\epsilon r}(1 - \epsilon)} - \alpha} \quad (13)$$

It is seen that if $\frac{5\lambda}{\epsilon r}(1 - \epsilon) \ll 1$ the rate of chain destruction is inversely proportional both to the pressure and to the square of the diameter. If, in addition, $15D/r^2 \gg \alpha$, the reaction rate is proportional to the square of the diameter. If $\frac{5\lambda}{\epsilon r}(1 - \epsilon) \gg 1$, equation 13 becomes

$$\bar{n} = \frac{n_0}{{}^3/_4\,\frac{\epsilon \bar{v}}{r} - \alpha} \quad (14)$$

and the rate of chain destruction is now inversely as the diameter. In this case, if $3/4\ \epsilon\bar{v}/r \gg \alpha$ the reaction rate is proportional to the first power of the diameter.

It immediately becomes apparent that for the case of chain initiation in the volume, the region in which the reaction rate is proportional to the first or second power of the diameter acquires similar importance for the study of reaction kinetics as the region of independence of diameter in the case of wall initiation. In the region of strict diameter-squared proportionality, $\bar{n}$ is proportional to n_0/D, whereas in the region of diameter to the first-power proportionality it is proportional to $n_0/\epsilon\bar{v}$. The separate investigation of α can be made by a study of the explosion regions as mentioned before.

Equation 12 will now be investigated for the dependence of reaction rate on diameter. $\epsilon r/\lambda$ is again given by equation 4. Combining equations 4 and 12, one obtains

$$\frac{\alpha\bar{n}}{n_0} = \frac{1}{{}^1/_3\,\frac{\alpha r^2}{D}\left(\frac{1}{1 - \sqrt{\alpha/D}\,r\,\mathrm{ctn}\,\sqrt{\alpha/D}\,r} - \frac{r_0/r}{1 - \sqrt{\alpha/D}\,r_0\,\mathrm{ctn}\,\sqrt{\alpha/D}\,r_0}\right)} - 1 \quad (15)$$

Table II contains values of the functions $\frac{\alpha\bar{n}}{n_0}\frac{r_0}{r}$ and $\frac{\alpha\bar{n}}{n_0}\frac{r^2_0}{r^2}$ calculated from equation 15 for $\sqrt{\alpha/D}\,r_0$ from 0 to π and r/r_0 from 0 to 1. Wherever these functions can be considered constant with respect to r/r_0, the rate is proportional to the first or second power, respectively, of the diameter. It is seen that the range of diameters within which the reaction rate is reasonably proportional to the first power of the diameter decreases as $\frac{\epsilon r_0}{\lambda}\frac{1}{1 - \epsilon}$ increases and that even in the most favorable case ($\epsilon r_0/\lambda = 0$) it does not begin until small fractions of the explosion diameter. For $\epsilon r_0/\lambda = r_0/\lambda$ there is no range over which the diameter to the first-power proportionality holds. In the latter case there is a large range of diameters over which the reaction rate is proportional to the square of the diameter. This range is considerably decreased and is shifted toward larger ratios of r/r_0 as $\frac{\epsilon r_0}{\lambda}\frac{1}{1 - \epsilon}$ decreases. It is seen that most of this narrowing and shifting of the range occurs for large values of $\frac{\epsilon r_0}{\lambda}\frac{1}{1 - \epsilon}$. There is very little additional change below 14.80.

---

[11] Strictly, a factor of $1 - \lambda/r_0$ should be inserted in the numerator of equation 14 of Kassel and Storch.

The influence of ϵ on the reaction rate itself varies with $\frac{\epsilon r_0}{\lambda}\frac{1}{1-\epsilon}$ and r/r_0. It is largest for small values of these functions and becomes rather negligible for large values.

Again, the essential features of the theory can be expressed with good approximation by a non-transcendental equation derived from equation 12 for the condition that $\sqrt{\alpha/D}\,r$ is close to π. Using the series expansion given earlier in connection with equation 6, equation 12 for $\lambda/r \ll 1$ reduces to

$$\bar{n} = \frac{(6/\pi^2)\,n_0}{\left[\frac{\pi^2 D}{\alpha r^2} - 1 - \frac{2\lambda}{\epsilon r}(1-\epsilon)\right]\alpha} - 1$$

Since $\frac{\pi^2 D}{\alpha r^2} - 1$ and $\frac{2\lambda}{\epsilon r}(1-\epsilon)$ become vanishingly small for $\sqrt{\alpha/D}\,r$ close to π, the reduction may be carried further to

$$\bar{n} = \frac{(6/\pi^2)\,n_0}{\frac{\pi^2 D}{r^2}\,\frac{1}{1+\frac{2\lambda}{\epsilon r}(1-\epsilon)} - \alpha} \qquad (16)$$

It can again be demonstrated that equation 16 is for most kinetic purposes a satisfactory substitute for equation 12, as was shown earlier for equation 6. This will be perhaps sufficiently evident from the similarity of equations 13 and 16, which were derived for opposite extremes. It is demonstrated in Table II specifically for the case of diameter dependence by the columns ($\bar{n}_{16}/\bar{n}_{12}$).

Summary

The steady-state treatment of chain reactions in which chains are broken at walls of varying efficiencies is discussed. Two cases are considered, namely, chain initiation at the wall and in the gas phase. It is shown that under conditions of negligible branching there exist characteristic relations between rate and vessel diameter. This may be used for a kinetic study of the unbranched reaction, whereas the branching reaction may be studied from explosion limits. The influence of vessel diameter on the rate has been described quantitatively for varying chain-breaking efficiencies. It is also shown that the exact transcendental equations may be replaced with good approximation by simple non-transcendental equations.

The Combustion of Paraffin Hydrocarbons[1]

BY GUENTHER VON ELBE[2] AND BERNARD LEWIS[3]

Norrish[4] has proposed a chain mechanism of the oxidation of hydrocarbons which describes the slow and explosive reaction of methane in agreement with a number of observations; it does not describe the phenomenon of the low-temperature explosion peninsula and other associated effects ("cool" flames, maximum in the reaction rate found in the neighborhood of 350° for all paraffin hydrocarbons above methane); it also does not explain the formation of methyl alcohol in large quantities in the oxidation of rich mixtures of propane[5] at low temperatures, a fact which, according to Pease, can best be explained by a chain mechanism involving monovalent (alkyl and alkoxyl) radicals. Pease's mechanism applies exclusively to this observation and does not describe the experimental facts accounted for by Norrish's scheme. A more extensive mechanism was proposed by Ubbelohde[6] but was not treated kinetically.

In the present paper a mechanism of the oxidation of paraffin hydrocarbons is proposed which is believed to allow a more comprehensive interpretation of chemical and kinetic facts.

Chemistry of the Oxidation

It is generally recognized that the oxidation of hydrocarbons passes through the aldehyde stage to the ultimate products carbon monoxide, carbon dioxide and water. Since aldehyde added in small amounts to a hydrocarbon-oxygen mixture very markedly decreases the induction period,[7] the latter is interpreted as the period during which the aldehyde gradually accumulates.[4,8] Its presence appears to be necessary for the creation of chain centers responsible for the subsequent chain reactions in the gas phase. Thus, the chemistry of hydrocarbon and aldehyde oxidation being intimately related, it is advantageous to consider first the aldehyde oxidation.

Oxidation of Aldehydes.—Two oxidation reactions of aldehydes have been reported.

One is a catalytic surface reaction[9] which is particularly pronounced at low temperatures (not much above room temperature) but decreases toward higher temperatures. This reaction passes through a peracid stage to carbon dioxide as the chief oxide of carbon, the process being strongly accelerated by coating the surface with potassium chloride.[9b]

The other reaction is a gas-phase reaction unquestionably of the chain type;[9,10] it proceeds through a step-wise degradation to lower aldehydes[10a] by the intermediate formation of peracids,[9,10d] carbon monoxide being the only oxide of carbon formed. Formaldehyde cannot degrade further but is oxidized to carbon monoxide and water. The chain character of the gas-phase reaction is demonstrated by the inhibitory action of packing the vessel and by the large quantum yield in the photochemical oxidation of acetaldehyde.[11]

The primary products in the photochemical reaction consist largely of monovalent radicals arising from the photodissociation[12]

$$CH_3CHO + h\nu = CH_3 + HCO \qquad (1)$$

In the absence of oxygen this would be followed by[12a]

$$CH_3 + CH_3CHO = CH_4 + CH_3CO \qquad (2)$$

In the presence of oxygen it is plausible that O_2 adds directly to the CH_3CO forming a peroxidic radical. This radical is assumed to react further with acetaldehyde in a manner analogous to reaction (2). Since the only radicals regenerated

are CH_3CO and $CH_3CO(OO)$ the chain would then be carried on essentially by the reactions

$$\mathrm{CH_3CO(OO) + CH_3CHO = CH_3CO + CH_3CO(OOH)} \qquad (3)$$

$$\mathrm{CH_3CO + O_2 = CH_3CO(OO)} \qquad (4)$$

At low temperatures the reaction stops at the peracid stage, the latter compound being formed in large amounts. If it is now assumed that chains are broken in the gas phase by

$$\mathrm{2CH_3CO(OO) = CH_3COOOOCCH_3 + O_2} \qquad (5)$$

a kinetic consideration shows that the reaction rate should be proportional to the square root of the light intensity and to the first power of the aldehyde concentration but independent of the oxygen concentration, as is found experimentally.[11]

At higher temperatures the reaction does not stop at the peracid stage and is assumed to lead to degradation reactions in rapid succession. This may be represented by

$$\begin{array}{r}\mathrm{RCH_2CO \xrightarrow{O_2} CO + H_2O + RCO \xrightarrow{O_2} \ldots\ CO + H_2O + CH_3CO} \\ \big\downarrow \mathrm{O_2} \quad (6) \\ \mathrm{HCHO^* + CO + OH}\end{array}$$

It is not entirely justified to exclude the formation of intermediate aldehydes as has been done here. However, intermediate aldehyde stages seem to be traversed rapidly to formaldehyde. The approximate formulation (6) possesses kinetic advantages. The formation of formaldehyde in the last step of reaction (6) is accompanied by the evolution of approximately 110 kcal. which is adequate to excite the observed luminescence ("cool" flames).[6]

Comparison of the chain length in thermal decomposition and oxidation of aldehydes shows that the latter is far more rapid than the former.[10a,11,13]

Chain Mechanism in Hydrocarbon Oxidation.—Once aldehyde has been formed by some mechanism which will be discussed later, it partly oxidizes catalytically to peracid, the latter being destroyed to form carbon dioxide or, as may be supposed, sometimes dissociating into two monovalent radicals, a fraction of which enters the gas phase to give rise to chains. The carbon dioxide-forming reaction being catalyzed by potassium chloride, the production of chain carriers and therefore the rate of hydrocarbon oxidation should be slowed down in a potassium chloride-coated vessel as is found experimentally.[14]

The mechanism for the oxidation of methane exclusive of branching reactions may be visualized as follows:

Chain initiation

$$\mathrm{HCHO + O_2 \xrightarrow{Surface} HCO(OOH) \xrightarrow{Surface} HCOO + OH} \qquad \mathrm{I}$$

Methane oxidation chain

$$\mathrm{OH + CH_4 = CH_3 + H_2O} \qquad \mathrm{II}$$

$$\mathrm{CH_3 + O_2 = HCHO + OH} \qquad \mathrm{III}$$

Aldehyde oxidation chain

$$\mathrm{OH + HCHO = HCO + H_2O} \qquad \mathrm{IV}$$

$$\mathrm{HCO + O_2 = HO_2 + CO} \qquad \mathrm{V}$$

$$\mathrm{HO_2 + HCHO = CO + H_2O + OH} \qquad \mathrm{VI}$$

Chain breaking

$$\mathrm{OH \xrightarrow{Surface} destruction} \qquad \mathrm{VII}$$

Direct association of oxygen in reaction V in binary collisions would seem to be very improbable. Reaction VI conforms to the fact that the ultimate products of the chain oxidation of formaldehyde in the gas phase are carbon monoxide and water.[10b]

While most of the formaldehyde is oxidized in the gas phase, some of it diffuses to the wall and reacts there to form more radicals according to (I). Many of these radicals remain adsorbed on the wall and eventually recombine to form saturated products. Some diffuse into the gas phase and generate new reaction chains. Thus, the process accelerates slowly from an unnoticeable to a measurable reaction during which the formaldehyde increases to a concentration easily detectable analytically.[15] In agreement with this are the experiments of Bone and Gardner,[8] who found a pronounced auto-accelerating curve for the increase of formaldehyde concentration with time.[16]

For the oxidation of higher hydrocarbons the mechanism is analogous. The radical CH_3 now becomes RCH_2, etc. Such large radicals presumably can add O_2 directly in a binary collision forming RCH_2OO, thus allowing an explanation of the formation of methyl alcohol in mixtures

(16) The exponential character of the curve does not seem to justify the opinion of these authors "that the formation of formaldehyde probably did not begin until after half way through the induction period."

containing a large excess of hydrocarbon. On analogy with Pease's[5a] mechanism we may write

$$RCH_2CH_2 + O_2 = RCH_2CH_2OO \longrightarrow RCHO + CH_3O \quad (7)$$

$$CH_3O + RCH_2CH_3 = CH_3OH + RCH_2CH_2 \quad (8)$$

The decomposition of the alkyl peroxide radical is in agreement with the similar behavior of saturated alkyl peroxides.[17] Now, the experimental data show that less alcohol is formed as the oxygen content of the mixture is increased[5a] and that finally the alcohol yield becomes negligible. Thus, in mixtures of 1 part of octane with 11 to 13 parts of oxygen, no alcohols are found.[10a] This fact may be accounted for by the destruction of methoxyl according to

$$CH_3O + O_2 = CO + H_2O + OH \quad (9)$$

It is evident that in very rich mixtures methyl alcohol and aldehydes should appear in approximately equal amounts, a fact borne out by experiment.[5a]

A further refinement of the proposed mechanism and enhancement of its chemical plausibility is obtained from experiments on the slow oxidation of rich mixtures of methane and ethane at high pressures.[18] In the case of methane, methyl alcohol is formed, the yield increasing with decrease in the oxygen content. It is only in mixtures containing a few per cent. of oxygen that the yield becomes large. The other products are carbon monoxide, carbon dioxide and water and a small amount of formaldehyde. In the case of ethane, both ethyl and methyl alcohols appear besides carbon monoxide, carbon dioxide and water. There are appreciable amounts of acetaldehyde, acetic acid and also methane. Increasing the oxygen content causes a decrease in the yields of the oxygenated organic compounds, but it is noted that the ethyl alcohol yield decreases very much more than the methyl alcohol.[18d]

To harmonize these facts, the following reaction will be assumed

$$CH_3 + O_2 + CH_4 = CH_3OOH + CH_3 \quad (10)$$

This reaction is favored by high pressures and rich mixtures. Concerning a direct proof of methyl peroxide formation, it is noted that this substance, as indeed others representative of this group, is highly unstable[17] and that there is no hope of isolating it from the reacting mixture, as has indeed been the experience.[7a,b,15,18b,c,d]

Methyl peroxide possesses a strong tendency to condense with aldehydes. With formaldehyde, oxydimethyl peroxide, $CH_3OOCH_2(OH)$, is formed.[17] The latter compound seems to possess a particular ability to dissociate at the peroxidic bond. This is evident by comparison of its behavior with that of the related compound dioxydimethyl peroxide, $CH_2(OH)O-OCH_2(OH)$, in alkaline solution. The latter decomposes into molecular hydrogen and formic acid* and the former partly into atomic hydrogen[17] and formic acid, indicating that the oxydimethyl peroxide undergoes primary dissociation into the radicals CH_3O and $CH_2(OH)O$.

It may be assumed, therefore, that in the high-pressure oxidation of methane, methyl peroxide and formaldehyde condense to oxydimethyl peroxide, which decomposes into radicals. A methyl alcohol chain then becomes possible involving reactions 8 (the hydrocarbon being methane), 10 and the last discussed condensation–dissociation reaction. The products carbon monoxide and formaldehyde would arise from reactions 9 and III. The mechanism thus accounts for the decreasing yield of methyl alcohol with increasing oxygen content. For the formation of carbon dioxide it is possible to propose other reactions such as the heterogeneous decomposition of oxydimethyl peroxide.[17]

If the same scheme is applied to the high-pressure oxidation of ethane, that is, starting correspondingly with ethyl peroxide and acetaldehyde, it is evident that methyl alcohol should appear as an oxidation product instead of water. The experimental facts concerning the total yields of oxygenated compounds and the ratio of the methyl and ethyl alcohol yields are also readily accounted for. Acetic acid probably arises from another decomposition reaction of oxydiethyl peroxide yielding also ethyl alcohol. Methane may arise from a side reaction conceivably involving the destruction of acetaldehyde.

It may be assumed that alkyl peroxide radicals condense similarly with aldehydes and dissociate at the peroxidic bond as postulated above. This would constitute a branching reaction (to be called peroxide branching) since two new free

valences are thus created. Evidently the probability of this reaction would depend on the lifetime of the R-OO radical (reaction 7) and thus is favored by lower temperatures. This would explain the pronounced reactivity[14a,19] and explosivity[20] particularly of normal paraffins in the neighborhood of 350°, and the accompanying phenomenon of "cool" flames[10a,14a,20,21] (see Fig. 1). If the hydrocarbon contains side groups then, as first pointed out by Pope, Dykstra and Edgar,[22] the degradation reaction 6 on reaching the tertiary carbon atom would leave a ketone instead of an aldehyde. The ketone cannot be expected to undergo condensation with peroxide and thus the fact can be explained that isoparaffins exhibit the low temperature phenomena to a lesser and lesser degree as the structure of the molecule is more condensed.[20b,22]

The radicals arising from the peroxide branching reaction are expected to oxidize further. Judging from the reaction energy involved in the oxidation, other bonds may be broken and assuming OH to be the favored radical, as many as five OH may result.

If one assumes with Norrish that the explosion at higher temperatures is predominantly of the branched chain type, another branching reaction with a positive temperature coefficient must be advanced. Expressions suitable for the description of explosion limits and other facts are obtained by assuming that branching occurs in ternary collisions of the radical HO_2 with aldehyde and oxygen. The reaction may be supposed to involve the primary oxidation of the aldehyde to peracid and subsequent dissociation of the latter. From an energy point of view the reaction is plausible. It will be referred to as the peracid branching reaction. Altogether three free valences appear, yielding on further oxidation three OH. The reaction may be written

Peracid branching

$$HO_2 + O_2 + HCHO \text{ or } RCHO \longrightarrow 3OH \qquad \text{VIII}$$

In order to account for the influence of mixture composition on the ignition temperature, a reaction competing with reaction V will be assumed, namely

Formaldehyde condensation

$$HCO + HCHO \longrightarrow (CH(OH)CHO) \xrightarrow{O_2} 2CO + H_2O + OH \qquad \text{IX}$$

That such an assumption is not improbable, particularly if one of the reactants is a radical, is shown by the fact that condensation products of formaldehyde, polyoxymethylenes, are known, which at 240° in the gas phase retain molecular weights amounting to 6 to 8 fold HCHO.[23]

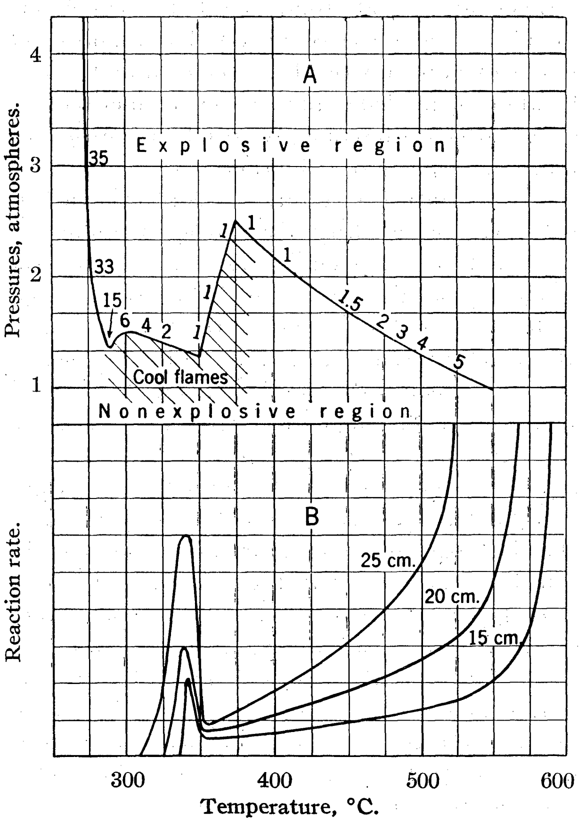

Fig. 1.—*Curve A:* Ignition region of 3.1% hexane in air mixture. Region of "cool flames" marked by shaded area. Induction periods in seconds indicated by numbers along curve (Townend, Cohen and Mandlekar reference 20b). *Curve B:* Reaction rates of 11.1% pentane in oxygen mixture at different pressures (Neumann and Aivazov reference 19a).

No crucial experiments seem to be available to rule out the possibility that methane explosions are thermal in nature in which case the peracid branching reaction VII could be dispensed with. However, the branched chain theory is adequate to describe the experimental results cited below.

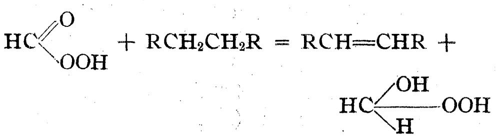
Primary Reactions.—For the kinetic treatment, the only specific assumption concerning the primary reaction between hydrocarbon and oxygen that need be made is that it is, as mentioned above, an aldehyde producing reaction. It is difficult to obtain experimental facts pertaining to this reaction because it is obscured by the ensuing chain reaction. However, it appears to the authors that the most probable assumption is a catalytic reaction. If, for example, a mixture of methane and oxygen is passed through a porous porcelain filter at atmospheric pressure and 440°, formaldehyde and some methyl alcohol are found.[24] The presence of the latter substance is explained readily on the basis of catalytic combination of methane and oxygen to methyl peroxide, which subsequently reacts as explained under high pressure oxidation.

A possibility for a direct gas-phase reaction with oxygen, at least for higher paraffins, is suggested by Stephens'[25a] experiments on the oxidation of alkyl-substituted benzenes. That higher paraffin hydrocarbons react with oxygen at temperatures as low as 130° to form explosive peroxides among other products, is well known.[25b]

At very high temperatures one may also consider the primary reaction to involve atoms or radicals originating from thermal dissociation.

Secondary Reactions.—Before leaving the chemical part of this paper, attention may be called to the fact that there are a number of secondary reactions of the non-chain type. Some of those which lead to oxygen-ring compounds have been studied by Ubbelohde.[26] A particularly common type is one that gives rise to the simultaneous appearance of olefins and oxyalkyl peroxides.[5b] This reaction can best be understood as the interaction of a newly formed peracid molecule with a hydrocarbon molecule.



(11)

$$\mathrm{HC(=O)OOH + RCH_2CH_2R = RCH{=}CHR + HC(OH)(H)OOH} \quad (11)$$

Mono-oxyalkyl peroxides are surprisingly non-explosive,[17] which accounts for the fact that they can be isolated at the high temperatures of the oxidation. They have been observed in the oxidation of hydrocarbons from ethane[7a] upward only, which is understandable in view of the fact that peracid cannot react with methane, as in reaction 11. By condensation with aldehydes they give rise to more complicated products.[27]

Kinetics of the Oxidation

Methane.—In the following, the symbols k_1, k_2, etc., are the velocity coefficients for the corresponding reactions in the mechanism I to IX. Concentrations in the gas phase are indicated by brackets. By assuming weak adsorption the rate of reaction I becomes on the basis of the Langmuir isotherm

$$(k_1/d)\,[\mathrm{HCHO}][\mathrm{O_2}] \qquad (12)$$

where d is diameter of the vessel.

It has been shown[28] that for the case of chain initiation at the wall the following equation obtain

$$\frac{2\lambda}{\epsilon r}\,\gamma m_0 + \alpha\bar{n} = \frac{\pi^2 D}{r^2}\,\bar{n} \qquad (13)$$

$\bar{n}$ is the average concentration of chain carriers, λ is the mean free path, r the radius of a spherical reaction vessel, ϵ the chain breaking efficiency of the wall, γ the ratio of surface to volume of the vessel, m_0 the rate of chain initiation per unit surface, α the velocity coefficient of chain branching and D the diffusion coefficient. This equation is a good approximation of the exact diffusion equation for the steady state and for the usual case that $\lambda/\epsilon r \ll 1$.[28]

$\pi^2 D/r^2$ will be replaced by $k_7/[M]d^2$ and $2\lambda/\epsilon r$ will be replaced by $k/[M]d$ where $[M]$ is the total concentration.

The concentration of formaldehyde in the gas phase reaches a maximum determined from the relative rates of aldehyde forming and destroying reactions. It is given by

$$[\mathrm{HCHO}]_{\mathrm{max.}} = \frac{k_2}{2k_4}\,[\mathrm{CH_4}] \qquad (14)$$

From equation (13) and the reaction mechanism I to IX

$$\frac{kk_1}{[\mathrm{M}]d^2}\,[\mathrm{HCHO}]_{\mathrm{max.}}[\mathrm{O_2}] + \frac{k_4k_5k_8[\mathrm{HCHO}]_{\mathrm{max.}}[\mathrm{O_2}]^2}{k_6(k_5[\mathrm{O_2}] + k_9[\mathrm{HCHO}]_{\mathrm{max.}})}\,[\mathrm{OH}] = \frac{k_7}{[M]d^2}\,[\mathrm{OH}] \qquad (15)$$

whence, for $k_9[\mathrm{HCHO}]_{\mathrm{max.}} \ll k_5[\mathrm{O_2}]$, the rate of methane oxidation for the steady state is given by

$$-\frac{\mathrm{d}[\mathrm{CH_4}]}{\mathrm{d}t} = \frac{k_1k_2{}^2k}{2k_4}\,\frac{[\mathrm{CH_4}]^2[\mathrm{O_2}]}{k_7 - (k_2k_8/2k_6)[\mathrm{CH_4}][\mathrm{O_2}][M]d^2} \qquad (16)$$

(27) This accounts for the peroxides isolated by Mondain-Monval, and Quanquin [*Ann. Chim.*, **15**, 309 (1931)] and others.

(28) Von Elbe and Lewis, THIS JOURNAL, **59**, 970 (1937).

Equation (16) shows that if the negative term in the denominator is small compared with k_7 the rate should be independent of the diameter of the vessel. This has been reported[29] for ethane–oxygen mixtures at low pressures (a few mm.) and at about 600° in silica vessels etched with hydrofluoric acid, the latter apparently having the effect of producing a surface of more or less uniform and also enhanced catalytic activity.[29,30] It appears that under these conditions the negative term, which is strongly dependent on pressure, is small. On the other hand, experiments on methane at 650° and at much higher pressures (atmospheric) show a decrease of the reaction rate on decreasing the dimensions of the vessel (packing).[14a] This is consistent with equation (16).

If, in a given vessel at constant temperature and pressure, the mixture composition is changed, equation (16) indicates a maximum reaction rate for a mixture containing between 50 and 66.7% methane in oxygen, the former percentage corresponding to a minimum of the denominator and the latter percentage to a maximum of the numerator. At atmospheric pressure and 447°, Bone and Allum[7b] found that a mixture containing 66.7% methane reacts faster than mixtures containing 50 or 75% methane. Intermediate points were not recorded.

Equation (16) shows that the reaction rate depends on a power of the methane concentration exceeding 2 and on a power of the oxygen concentration exceeding 1, depending on the magnitude of the negative term in the denominator compared with k_7. This is borne out by the experiments of Fort and Hinshelwood[10b] at 467° and pressures ranging from 300 to 600 mm.

The nature of the surface enters into the coefficients k_1 and k. Since the surface is likely to undergo imperceptible changes during the reaction, the rate should be erratic and unpredictable as is the general experience in untreated vessels.[31]

Concerning the explosive reaction it would be inconsistent to follow Semenoff's[32] suggestion of "degenerate" explosions for hydrocarbons since his suggestion becomes plausible only if an active intermediate of long lifetime were formed, reacting independently of the main chain reaction. No compelling reason for the suggestion is seen in the apparently continuous acceleration of the rate curves up to the inflection point since the steady-state treatment given in this paper would give the same type of curve on considering the consumption of the reactants. The condition for explosion is found to be

$$\frac{k_4k_5k_8[O_2]^2[HCHO]_{\text{max.}}}{k_6(k_5[O_2] + k_9[HCHO]_{\text{max.}})} = k_7/[M]d^2 \qquad (17)$$

It may be surmised that the actually observed explosion limit is somewhat affected by the rate of heat liberation, that is, the reaction rate. This would explain why the explosion limits depend somewhat upon the nature of the surface[20c,33] which enters into the coefficients k and k_1.

The sum of the energies of activation of reactions II and VIII is most probably larger than the energy of activation of reaction VI; the sum of the energies of reactions II and IX is larger than the sum for reactions IV and V. $[M]$ is equal to the sum of the concentrations $[CH_4] + [O_2] + [X]$, where $[X]$ is the concentration of any foreign gas. Combining equations (14) and (17) and substituting temperature functions, one obtains

$$([CH_4] + [O_2] + [X])\frac{[CH_4][O_2]^2}{[O_2] + K'e^{-A'/T}[CH_4]} = \frac{K}{d^2}e^{A/T} \qquad (18)$$

The ignition temperature should increase with decreasing vessel dimensions. This has been confirmed by experiments at 1 atmosphere pressure.[33,34]

Equation (18) reduces approximately to

$$\log P = (A/T) + B \qquad (19)$$

A and B being constants; the experimental curves have often been expressed by equations of this type.[14c,31]

If foreign gas, such as argon, is added to the mixture without affecting the concentrations of CH_4 and O_2 (that is, total pressure is increased), the ignition temperature should decrease. This has been found experimentally.[35] If part of the combustible mixture is replaced by foreign gas leaving the sum of the concentrations the same, the ignition temperature should increase. This also has been observed.[36] Moreover, if helium is substituted for argon, the ignition temperature is higher,[36] corresponding to the larger

value of the diffusion coefficient which enters into k_7 and, therefore, K.

If the ratio of methane to oxygen is changed, leaving the sum of the concentrations constant, the ignition temperature should pass through a minimum for a mixture ratio $CH_4:O_2 < 1:1$. Only if the term $K'e^{-A'/T}[CH_4]$ in the denominator of (18) were negligible would this minimum occur at a ratio 1:1. The larger this term is the more the minimum is shifted to leaner mixtures. Since the term becomes larger toward higher temperatures, mixtures diluted with foreign gas should exhibit a shift of the minimum ignition temperature to smaller ratios of $CH_4:O_2$ than is found in the undiluted mixture. In fact, at 1 atmosphere total pressure the minimum ignition temperature for undiluted mixtures has been found at a ratio of about 1:2, whereas using argon as diluent (O_2:A the same as $O_2:N_2$ in air) the minimum is at a ratio 1:3.6.[36] If the ignition temperature is increased still further by replacing argon by helium, the minimum is at a ratio 1:4.[36]

If the size of the vessel is decreased, thus increasing the ignition temperature, the minimum again shifts toward leaner mixtures.[36]

If the total pressure is increased, thus lowering the ignition temperature, the minimum shifts toward richer mixtures.[20c]

According to equation (17), it should be possible to induce explosions by the addition of formaldehyde in excess of $[HCHO]_{max}$. Smaller amounts should not lower the ignition temperature although they should decrease the induction period. Actually, formaldehyde added in amounts of 1 to 2% substantially lowers the ignition temperature;[20c] in amounts of about 0.027% practically no lowering is observed, but the induction period is markedly shortened.[36] That $[HCHO]_{max.}$ is smaller than 1% appears from the fact that in the non-explosive oxidation of CH_4, formaldehyde is found only in traces.[7b]

Higher Hydrocarbons.—The mechanism of the oxidation of higher hydrocarbons consists of the following reactions and the former reactions IV to IX.

Initiation

$$RCHO + O_2 \xrightarrow{\text{surface}} RCO(OOH) \xrightarrow{\text{surface}} RCOO + OH \qquad \text{I}$$

Hydrocarbon oxidation chain

$$OH + RCH_3 = RCH_2 + H_2O \qquad \text{II}$$

$$RCH_2 + O_2 = RCH_2OO \qquad \text{III}$$

$$RCH_2OO = R'CHO + CH_3O \xrightarrow{O_2} CO + H_2O + OH \qquad \text{X}$$

Peroxide branching

$$RCH_2OO + RCHO = (RCH_2O - OC(OH)R) \xrightarrow{O_2} 5OH \qquad \text{XI}$$

Degradation reaction

$$RCHO + OH = H_2O + RCO \xrightarrow{O_2} CO + H_2O + R'CO \xrightarrow{O_2} \ldots$$

$$CO + H_2O + CH_3CO \xrightarrow{O_2} HCHO^* + CO + OH \qquad \text{XII}$$

The condition for explosion is now found to be

$$\underbrace{\frac{k_2k_{11}}{k_{10}}[RCH_3][Ad]_{max.}}_{\text{Peroxide branching}} + \underbrace{\frac{k_4k_5k_8[O_2]^2[Ad]_{max.}}{k_6(k_5[O_2] + k_9[HCHO]_{max.})}}_{\text{Peracid branching}} = k_7/[M]d^2 \qquad (20)$$

where $[Ad]_{max.}$ is now the total maximum aldehyde concentration and equals

$$[Ad]_{max.} = \left(\frac{2k_4}{k_{12}} - 1\right)[HCHO]_{max.} = \frac{k_2}{2k_4}\left(\frac{2k_4}{k_{12}} - 1\right)[RCH_3] \qquad (21)$$

As before, the nature of the surface has been found to influence somewhat the explosion limits.[14c,20]

Since the peracid branching term is small at low temperatures and moderate pressures, the peroxide branching term must be large in order to fulfill the explosive condition (20). Since the radical R-OO is considered to have a long lifetime at low temperatures, the peroxide branching term is largely dominated by reaction X and is proportional to $Te^{A/T}[RCH_3]^2$. This term increases with decreasing temperature, tending toward infinity, thus accounting for the pronounced explosivity toward lower temperatures. The reason the reaction becomes non-explosive again at still lower temperature may be due to the greater stability toward oxidation of the condensation product in reaction XI and a gas phase chain breaking process involving the combination of two R-OO radicals. That the reaction becomes non-explosive at low pressures can be seen from equation (20). Thus, in a qualitative way, the peninsula shape of the explosion region and the maximum in the reaction rate may be accounted for.

It is reasonable to assume that the activation energies of the reactions in question are more or less independent of the length of the paraffin molecule so that the temperature limit of the peninsula is approximately the same for all higher paraffins.

Equation (20) in combination with (21) shows that for richer mixtures the explosion limit should be shifted toward lower pressures, which has been observed.[20] Decreasing the vessel diameter narrows the explosion region;[14c,20] if this is carried to the extreme by packing, the reaction, explosive or non-explosive, is entirely suppressed.[14a] Since, due to the intensity of peroxide branching, the concentration of excited formaldehyde becomes rather high, it is understandable that the luminescence should become pronounced ("cool" flames). Simultaneously the induction periods become very short[20] (see Fig. 1). If aldehyde is added to the mixture, branching becomes large immediately. In ethane, where the peninsula is weakly developed, addition of 1 to 2% of acetaldehyde brings out the peninsula phenomenon sharply and reduces the induction period prior to explosion from hours to seconds.[20c]

If the aldehyde added exceeds $[\mathrm{Ad}]_{\mathrm{max.}}$, the explosion region should widen progressively with increasing amounts. Also, the nature of the aldehyde should make little difference. These facts have been observed.[20]

If the energy of activation of reaction II exceeds that of reaction IV the value of $[\mathrm{Ad}]_{\mathrm{max.}}$ should increase toward higher temperatures. This explains the decreased effect of aldehyde on the position of the explosion limits toward higher temperatures.[20,37]

At higher temperatures the peracid branching term becomes predominant, and the ignition characteristics of higher hydrocarbons approach those of methane. The limits are generally lower, which is consistent with the larger $[\mathrm{Ad}]_{\mathrm{max.}}$ as compared with $[\mathrm{HCHO}]_{\mathrm{max.}}$ Comparing the explosion regions of methane[20c] and also isobutane[20b] with those of normal paraffins, it may be estimated that peroxide branching predominates up to about 400° whereas peracid branching predominates above about 500°.

That addition of foreign gas without altering the concentrations of the reactants produces the same effect as it does in methane, namely, lowers the ignition temperature, is shown in hexane–air and hexane–oxygen explosions.[20b] Likewise, if a part of the mixture is replaced by foreign gas, the ignition temperature is increased.[20b]

Experiments are available on the effect of mixture composition on the minimum ignition pressure in the region of predominant peracid branching as defined above. According to equation (20) toward lower temperatures the minimum should again shift from a mixture ratio of less than 1:1 to 1:1. At about 680° a minimum ignition pressure was found for a pentane–oxygen mixture having a ratio about 1:2.[31] At a considerably lower temperature, 480–520°, a minimum was found for an ethane–oxygen mixture having a ratio 1:1.[14c]

Studies of reaction rates are not apt to lead to simple relationships since branching of one type or another appears over the whole temperature range. As long as peroxide branching is predominant the equation for the reaction rate (same as equation (16) with peroxide branching term replacing peracid branching term) indicates that the most reactive mixture should be far on the rich side, >2:1. Measurements show that the rate is still increasing for a 2:1 mixture.[7a]

Summary

It is pointed out that there are certain shortcomings in existing theories which are overcome in the proposed theory. The concept of chain initiation *via* aldehyde is seen to require discussion of aldehyde oxidation. A chain mechanism consistent with experimental facts and chemical plausibility is described. The chain mechanisms of aldehyde and hydrocarbon oxidation are linked to each other and combined with a modified form of Pease's mechanism for higher hydrocarbons. Plausible relations between the high pressure oxidation of methane and ethane and the chemistry of peroxides are discussed. From this, a branching reaction involving alkyl peroxides and aldehydes which is operative predominantly at low temperatures is shown to be plausible chemically. It is called "peroxide branching" to distinguish it from "peracid branching" operative predominantly at high temperatures. The mechanisms of primary aldehyde forming reactions and secondary non-chain reactions are discussed. It is shown that kinetic facts concerning the slow reaction and explosion limits of methane are consistent with the scheme; that certain phenomena exhibited by higher hydrocarbons at relatively low temperatures (ex-

---

(37) This also explains why in ethane–oxygen mixtures, Bone and Hill[7a] observed an explosion induced by 1% acetaldehyde, whereas Steacie and Plewes[7c] did not. The former worked at 316° and the latter at 452° (*cf.* Townend and Chamberlain).[20c]

plosion peninsula, maximum in the reaction rate, "cool" flames) can be described by peroxide branching; and that peracid branching can describe the explosion limits of higher hydrocarbons at high temperatures.

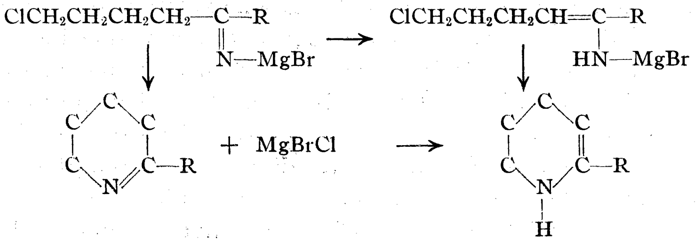
Synthesis of Some New Alpha-Substituted Tetrahydropyridines and Piperidines[1]

BY RICHARD SALATHIEL, J. MARVIN BURCH AND R. M. HIXON

A general method for the preparation of α-substituted tetrahydropyridines has been developed, a preliminary report of which was presented by Starr and Hixon,[2] who reported the preparation of α-phenyltetrahydropyridine. This preparation followed the general plan of the method used by Craig, Bulbrook and Hixon,[3] who reported the preparation of α-substituted pyrrolines by a modification of Cloke's reaction.[4] This paper extends this synthesis to the preparation of other compounds in this series, and to the preparation of the corresponding piperidines.

The reactions involved are first the reaction of a Grignard reagent with δ-chlorovaleronitrile to form the mixed magnesium bromide salt of a δ-chlorobutylketimine, $Cl(CH_2)_4CM + RMgBr \longrightarrow ClCH_2CH_2CH_2CH_2{-}CR{=}NMgBr$, and second the closing of the ring which is accomplished by replacing the ether in the reaction mixture with xylene and raising the temperature. Expressing this reaction by equations completely analogous to those proposed by Craig, Bulbrook and Hixon,[3] two possible mechanisms are shown.



Experimental Part

δ-Chlorovaleronitrile, b. p. 118–121° (25 mm.), was prepared as described by Starr and Hixon.[2]

α-Phenyltetrahydropyridine.—A Grignard reagent was prepared from 4.86 g. of magnesium, 34.5 g. of bromobenzene and 160 cc. of ether. A solution of 23.5 g. of δ-chlorovaleronitrile in 25 cc. of ether was added dropwise, as the reaction mixture was stirred and refluxed. The addition product, a heavy viscous colorless liquid, separated from the solvent. The ether was removed by distillation from an oil-bath, the volume in the flask being kept constant by the addition of xylene. When the temperature in the flask reached 130–135°, the liquid addition product quickly changed to a solid, semi-crystalline, yellow mass. Heating just sufficient to reflux the xylene was continued for an hour. The material was cooled and hydrolyzed, using 130 cc. of hydrochloric acid (sp. gr. 1.10). The xylene layer was separated and extracted again with hydrochloric acid. The acid solution was extracted with 20 cc. of petroleum ether to remove residual xylene, then made strongly basic with sodium hydroxide and extracted with ether. The ether extract was dried and fractionated. There was collected at 142–150° (20 mm.) 21 g. of a nearly colorless oil, which turns brown quickly on exposure to air. The yield is 66% of the theoretical.

The hydrochloride, precipitated from aqueous acetone, melted at 86–87° as reported by Gabriel[5] but when dried in a current of warm air the melting point becomes 152–153°. Other derivatives, the picrate, m. p. 181.5°, and the mercuric chloride–hydrochloride double salt, m. p. 165–166°, were prepared.

α-(*p*-Chlorophenyl)-tetrahydropyridine.—A Grignard reagent prepared from 2.43 g. of magnesium, 21.1 g. of *p*-chlorobromobenzene and 125 cc. of ether, was added to a solution of 11.8 g. of δ-chlorovaleronitrile. A procedure similar to that for α-phenyltetrahydropyridine yielded 9.5 g. of a colorless base boiling at 165° (13 mm.) which crystallized in the receiver, m. p. 54°. The yield is 49% of the theoretical.

A picrate, m. p. 177–178°, was crystallized from an alcohol solution. A mercuric chloride–hydrochloride double salt, m. p. 133–135°, a chloroplatinate, m. p. 192°, and a hydrochloride, m. p. 215–217°, were prepared from aqueous solutions.

Anal. Calcd. for $C_{11}H_{12}ClN{\cdot}HCl$: N, 6.09. Found: N, 6.19, 6.15.

α-(*p*-Tolyl)-tetrahydropyridine.—A Grignard reagent prepared from 2.5 g. of magnesium turnings, 21 g. of *p*-bromotoluene and 120 cc. of ether was treated with 11.7 g. of δ-chlorovaleronitrile. The product was obtained by a procedure similar to that for α-phenyltetrahydropyridine. The major portion of the 9 g. of the product distilled over at 145° (13 mm.). The yield is 52% of the theoretical.

The following derivatives were prepared: chloroplati-

nate, yellow needles from water, m. p. 186–187°; mercuric chloride–hydrochloride double salt, crystallized from water, m. p. 119.5°; picrate, yellow needles from alcohol, m. p. 178–179°; hydrochloride, crystallized from water solution, m. p. 137–137.5°.

Anal. Calcd. for $C_{12}H_{15}N \cdot HCl \cdot H_2O$: N, 6.15. Found: N, 6.10, 6.15.

In an oven at 100° the hydrochloride salt loses water and the melting point changes to 175–177°.

Anal. Calcd. for $C_{12}H_{15}N \cdot HCl$: N, 6.68. Found: N, 6.56, 6.61.

α-Cyclohexyltetrahydropyridine.—A Grignard reagent was prepared from 6 g. of magnesium turnings, 33 g. of chlorocyclohexane and 200 cc. of ether. A solution of 21.5 g. of δ-chlorovaleronitrile was added dropwise to the reagent and a viscous heavy liquid precipitated out. Following the usual procedure 7 g. of a light yellow oil, which darkens on exposure to air, boiling at 118–125° (17 mm.) was separated. The yield is 23% of the theoretical.

Anal. Calcd. for $C_{11}H_{19}N$: N, 8.48. Found: N, 8.50.

The hydrochloride, m. p. 222–224°, was prepared by passing hydrogen chloride gas into the free base and washing the resulting crystals with acetone. It loses hydrogen chloride slowly on standing in air.

α-(*n*-Butyl)-tetrahydropyridine.—To a Grignard reagent prepared from 4 g. of magnesium, 22 g. of *n*-butyl bromide and 170 cc. of ether, 15 g. of δ-chlorovaleronitrile was added dropwise. A liquid addition product separated out. The ether was replaced by xylene, the temperature raised and the resulting product hydrolyzed as in the α-phenyl preparation. The acid solution was made basic with sodium hydroxide and steam distilled. The distillate was made acid and concentrated by vacuum distillation, and then made basic with sodium hydroxide and extracted with ether. The dried ether extract was fractionated. The yield of a light yellow oil, boiling at 195–200°, which darkens quickly in contact with air, was 4 g. (22% of the theoretical).

Anal. Calcd. for $C_9H_{17}N$: N, 10.07. Found: N, 10.18, 10.00.

The hydrochloride decomposes easily, losing hydrogen chloride in air. The yellow crystalline chloroplatinate, m. p. 156°, was prepared from water solutions.

Anal. Calcd. for $(C_9H_{17}N)_2H_2PtCl_6$: C, 31.38; H, 5.27; Pt, 28.49. Found: C, 31.8; H, 5.32; Pt, 28.3.

α-Phenylpiperidine, in 6.5 g. yield, was prepared as described by Gabriel[5] by reduction of 9 g. of α-phenyltetrahydropyridine with tin and hydrochloric acid. It was characterized by the crystalline hydrate, m. p. 60–61°, and the hydrochloride, m. p. 200–201°.

α-(*p*-Chlorophenyl)-piperidine.—α-(*p*-Chlorophenyl)-tetrahydropyridine, 7 g., was reduced by refluxing with 60 cc. of hydrochloric acid (sp. gr. 1.10) and an excess of granulated tin for three hours. The reaction mixture was made basic with sodium hydroxide and steam distilled. The distillate was made acid with hydrochloric acid and concentrated by vacuum distillation. The hydrochloride salt crystallized out, and after recrystallization the yield was 5.3 g., m. p. 259–260°.

Anal. Calcd. for $C_{11}H_{14}ClN \cdot HCl$: N, 6.04. Found: N, 6.09, 6.02.

The base was freed from 4.7 g. of the hydrochloride with sodium hydroxide solution, extracted with ether and dried over sodium sulfate. The ether solution was fractionated, yielding 3.8 g. of a nearly colorless oil, boiling at 145° (8 mm.), which crystallized, on cooling in an ice-bath, m. p. 16°.

The chloroplatinate melted at 221° with decomposition.

α-(*p*-Tolyl)-piperidine.—A 6-g. portion of the α-(*p*-tolyl)-tetrahydropyridine was hydrogenated by refluxing for three hours with 80 cc. of hydrochloric acid (sp. gr. 1.10) and an excess of granulated tin. The reaction mixture was made basic, using a large excess of sodium hydroxide, and steam distilled. The distillate was made just acid with hydrochloric acid and concentrated by vacuum distillation to 50 cc. From this the base was set free with sodium hydroxide and extracted with ether. The dried ether extract was fractionated, yielding 5 g. of a nearly colorless oil boiling at 135° (8 mm.).

The hydrochloride, m. p. 209–210°, was prepared by passing hydrogen chloride gas into the free base and washing the resulting crystals with acetone.

Anal. Calcd. for $C_{12}H_{17}N \cdot HCl$: N, 6.62. Found: N, 6.71, 6.58.

α-Cyclohexylpiperidine.—A solution of 2.5 g. of α-cyclohexyltetrahydropyridine in 40 cc. of hydrochloric acid (sp. gr. 1.10) was refluxed with an excess of granulated tin for four hours. A separation procedure similar to that used for α-(*p*-tolyl)-piperidine yielded 1.5 g. of a pale yellow oil boiling at 135° (35 mm.).

The hydrochloride, prepared by passing hydrogen chloride gas over the base and washing the resulting crystals with acetone, melted sharply but not quite completely at 197–198°. It was apparent that there was a higher melting product present. Repeated crystallization from water of a rather large amount of the salt yielded a small amount melting at 250°. These two bodies are probably position isomers.

Anal. Calcd. for $C_{11}H_{21}N \cdot HCl$: N, 6.88. Found: N, (product melting at 197–198°) 6.90, (product melting at 250°) 6.91.

α-*n*-Butylpiperidine.—A solution of 1.8 g. of α-(*n*-butyl)-tetrahydropyridine in 20 cc. of hydrochloric acid (sp. gr. 1.10) was refluxed with an excess of granulated tin for three hours. By a separation procedure similar to that for α-(*p*-tolyl)-piperidine 1.5 g. of product, b. p. 185–192°, was obtained.

The hydrochloride, crystallized from water, melted at 185–186°. Löffler and Plöcker[6] reported 181–182° for this constant.

However, Winterfeld and Holschneider[7] reported 186–187°.

Anal. Calcd. for $C_9H_{19}N \cdot HCl$: N, 7.89. Found: N, 7.89, 7.84.

Summary

A satisfactory and convenient method for preparation of α-substituted tetrahydropyridines has been demonstrated.

The yields of the aromatic substituted com-

---

[7] Winterfeld and Holschneider, *Ann.*, **499**, 109 (1932).

pounds are notably superior to those of the aliphatic and cycloparaffinic substituted compounds prepared.

The α-substituted tetrahydropyridines can be reduced easily to the corresponding piperidines with tin and hydrochloric acid.

The following new compounds have been prepared and suitable derivatives reported: α-*n*-butyltetrahydropyridine, α-cyclohexyltetrahydropyridine, α-cyclohexylpiperidine, α-(*p*-tolyl)-tetrahydropyridine, α-(*p*-tolyl)-piperidine, α-(*p*-chlorophenyl)-tetrahydropyridine and α-(*p*-chlorophenyl)-piperidine.

The Preparation and Cracking of High Molecular Weight Nitriles

By A. W. Ralston, H. J. Harwood and W. O. Pool

Introduction

The present work was undertaken with the object of producing from high molecular weight fatty acids, straight chain aliphatic compounds containing less than thirteen carbon atoms per molecule. It was thought that a mixture of compounds containing only straight chains might be obtained if a fatty acid derivative which contained no oxygen were subjected to a cracking process similar to that used in the petroleum industry. The present paper is a report of the preparation and cracking of high molecular weight aliphatic nitriles and the partial identification and separation of the resulting compounds.

In undertaking a study of the cracking of high molecular weight nitriles a satisfactory method was essential for preparing such nitriles in considerable quantities from acids. The ordinary method of amide dehydration by means of agents such as phosphorus pentoxide or phosphorus oxychloride was not to be considered because of the expense of the reagents.

The pyrolysis of amides to produce nitriles in varying yields has been reported by several authors.[1] Weidel and Ciamician[2] obtained capronitrile by passing a mixture of ammonia and caproic acid vapor over red hot pumice. Mitchell and Reid[3] noted the formation of small amounts of nitriles incidental to the preparation of amides by passing ammonia through acids at 160–190°. These authors state that no amide was obtained from either palmitic or stearic acid and very little from lauric acid under their conditions.

Since lower amides are partially converted to nitriles upon distillation it seemed probable that stearamide with a high boiling point might be completely converted to nitrile in this manner. Accordingly, stearamide was distilled at atmospheric pressure. The distillate was found to consist of a mixture of stearonitrile and stearic acid together with some unchanged amide. Evidently the water formed by the dehydration of one molecule of amide had served to hydrolyze a second molecule. The ammonium stearate thus formed decomposed at the temperature of the distillation to ammonia and acid. The condition may be expressed by the following equilibria

$$\mathrm{RCOOH} + \mathrm{NH_3} \overset{\text{I}}{\rightleftarrows}$$

$$\mathrm{RCOONH_4} \underset{+\mathrm{H_2O}}{\overset{\overset{\text{II}}{-\mathrm{H_2O}}}{\rightleftarrows}} \mathrm{RCONH_2} \underset{+\mathrm{H_2O}}{\overset{\overset{\text{III}}{-\mathrm{H_2O}}}{\rightleftarrows}} \mathrm{RCN}$$

In view of the above result, it seemed probable that stearonitrile could be prepared from stearic acid by heating the acid to a sufficiently high temperature in a stream of ammonia. The ammonia would serve to force reaction I to the right and also to sweep out water as it was formed in reactions II and III. This procedure was carried out and was found to produce stearonitrile in excellent yields.

Two methods were used for the cracking of nitriles. The first consisted in passing the nitrile vapors through a glass tube packed with various catalysts maintained at temperatures of 450 to 600°. The second method was to heat the material in a closed vessel to a temperature of approximately 420°. This procedure gave higher yields than the first method and for this

reason was used to produce most of the "cracked fractions" dealt with in this paper. There was no qualitative difference between the products obtained by the two methods.

A study of cracked material boiling from 100 to 275° showed that it consisted of straight chain nitriles and hydrocarbons, both saturated and unsaturated.

In separating the nitriles from the hydrocarbons two general methods were used; the first depended on chemically altering one or the other of the two classes of compounds, the second employed only the difference in physical properties as a basis of separation. It is apparent that the second method, in which both the nitriles and hydrocarbons are separated and recovered in an unchanged condition, is the more desirable of the two. Two obvious ways of separating nitriles from hydrocarbons consist in hydrolyzing the nitriles to alkali soluble acids or in hydrogenating them to acid soluble amines. Separation by hydrolysis has been accomplished satisfactorily, while work on separation by hydrogenation is in progress. Attempts to separate nitriles from hydrocarbons without chemical reactions of the compounds have thus far depended on the differences in solubilities in various solvents and on differences in adsorption of the nitriles and hydrocarbons on silica gel.

Experimental

The Distillation of Stearamide.—Twenty grams of stearamide (m. p. 108–109°) was distilled from an ordinary distilling flask at atmospheric pressure. The temperature of the vapor was 340°. The fumes were alkaline to moist litmus paper. From the distillate, which weighed 17 g., there were isolated 7.5 g. of stearic acid of m. p. 65.5–68°, 6.1 g. of stearonitrile of m. p. 41.5–42.5° and 1.0 g. of stearamide of m. p. 105–106.5°.

The Preparation of Stearonitrile.—The apparatus is shown in Fig. 1. The reaction flask A was constructed from a 500-cc. Claisen flask. The length of the catalyst D was 30 cm. The total length of the catalyst tube was 70 cm. Stearic acid was placed in A and heated to the desired temperature by means of an electric heater. A stream of ammonia was passed through B. The mixture was so heated that the vapor did not rise above point C, about 15 cm. above the level of the liquid. Excess ammonia, together with water vapor and small amounts of acid, passed up through the catalyst which was maintained at a temperature of approximately 400° by means of the furnace E. The fused aluminum oxide catalyst (6 mesh)[4] used served only to convert into nitrile the small amount of acid carried over by the gas stream. Without the catalyst this acid condensed in the cooler portions of the system in the form of the ammonium salt, thereby plugging the tubes. Temperatures were read with thermocouples J and K. The water was condensed in F and collected in G. Exhaust gases were removed through I.

The apparatus was charged with 284 g. of stearic acid (m. p. 68–69°) and heating was started. When the temperature reached about 150° the ammonia was passed in. By means of the heater the temperature was increased to 330° at which point it was maintained during the course of the experiment. Heating was continued for a total of six hours. The ammonia rate was such that an excess was always present. The crude material in flask A weighed 261 g. and contained 2.2% of stearic acid as determined by titration. The receiver G contained 8.5 g. of mixed amide and nitrile which was discarded.

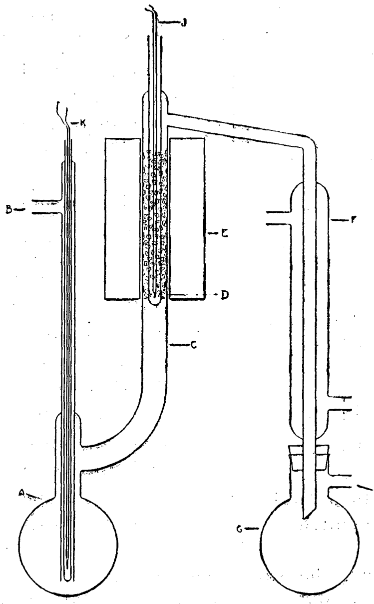

Fig. 1.—Apparatus for preparation of nitriles.

The nitrile was distilled at atmospheric pressure through a 50-cm. Vigreux column. The column was insulated and had an external heater. The nitrile had a boiling range of 352–360°, with about 75% distilling at 356–358°. The distillate weighed 234 g. and contained 3.8% of acid. This corresponds to a yield of 85%. To purify the nitrile further, it was washed with a hot, dilute solution of potassium hydroxide in 50% alcohol, then with hot water until neutral to phenolphthalein. After one crystallization from slightly dilute alcohol, the stearonitrile weighed 206 g., m. p. 41–42°. Pure stearonitrile melts at 42.5–43.0° (corr.).

Vapor Phase Cracking of Nitriles.—The apparatus used was a glass tube (2.5 cm. in diameter) packed with a catalyst and heated by an electric furnace. Temperatures were measured by a thermocouple imbedded in the catalyst. Nitriles of acids obtained from lard were vaporized at a uniform rate and passed over the catalyst in a stream of nitrogen or ammonia gas. The vapors were then con-

---

[4] Obtained from the Aluminum Ore Company, East St. Louis, Illinois.

densed and the percentage of material boiling below 275° was determined by distillation. The catalysts used were glass, pumice, aluminum oxide on charcoal, fused aluminum oxide, copper on fused aluminum oxide, and iron on fused aluminum oxide. No evidence was obtained that runs using any one catalyst led to the formation of compounds not present in products obtained when other catalysts were used. Under the same conditions, the yield of cracked material, as measured by the percentage of the total product which boiled below 275°, varied with the nature and age of the catalyst. Fused aluminum oxide gave the highest yield. The uncondensed gases consisted of about half unsaturates, the remainder being saturated hydrocarbons and hydrogen.

Liquid Phase Cracking of Nitriles.—Mixed nitriles, boiling above 275° (1846 g.), made from acids (neutral equivalent of 290.0) obtained from garbage grease were placed in the steel pressure vessel B shown in Fig. 2. The pressure vessel was then heated by a gas flame. When the temperature of the nitriles had reached 330°, as measured by a thermocouple inserted in well C, the valves D and E were closed. After nineteen minutes, the pressure, which was indicated by gage F, was 90 pounds (6 atm.) and the temperature was 415°. Heating was discontinued and the temperature was allowed to drop below 275°. Then the valve E was opened gradually until the pressure had dropped to zero. Heat was applied and all cracked material having a boiling point below 275° was distilled through the water-cooled condenser G. Then valve E was closed and the cycle was repeated. From time to time, additional nitriles were introduced into the pressure vessel through the inlet A until a total of 5538 g. of nitriles had been used. After twenty cracking cycles had been completed, the distillate amounted to 4412 g. (79.7%). The residue in the cracking vessel was a thick, black oil. This residue weighed 550 g. (9.9%). The loss due to uncondensed gases was 576 g. (10.4%) by difference. The distillate was washed with a silver nitrate solution to remove hydrogen cyanide which was always formed. Some of the lower nitriles were removed by this procedure, and the remaining material weighed 4180 g.

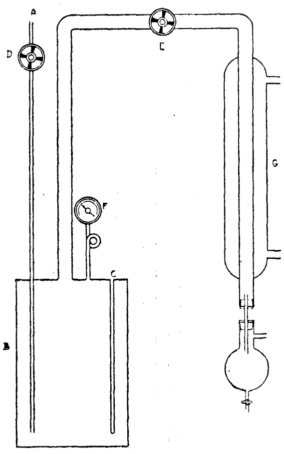

Fig. 2.—Apparatus for cracking nitriles.

Table I

Distillation of Cracked Fraction

Fraction	Weight	Boiling range, °C.	% of total	Nitrogen, %
1	405	30–105	9.7	..
2	609	105–150	14.6	3.54
3	957	150–200	22.9	4.06
4	1019	200–250	24.4	3.65
5	431	250–275	10.3	2.82
Residue	759	>275	18.1	..

The results obtained upon distillation of the 4180 g. of cracked material are shown in Table I.

Identification of Acids Obtained by Hydrolysis of Cracked Fraction.—A sample of miscellaneous cracked fraction (boiling range 100–275°) obtained by the vapor phase cracking of nitriles of acids obtained from lard over various catalysts was hydrolyzed by means of alcoholic potassium hydroxide. The acids obtained were converted into ethyl esters, hydrogenated using platinum catalyst and fractionated.[5] The curve for the second distillation is given in Fig. 3. The S-shaped curves are due to incomplete hydrogenation. The unsaturated esters have higher refractive indices but slightly lower boiling points than the corresponding saturated esters. Hence, an "S" occurs on the distillation curve instead of the usual plateau, due to a slight fractionation of the unsaturated compound from the saturated. Fraction 9 had an iodine number of 5.1.

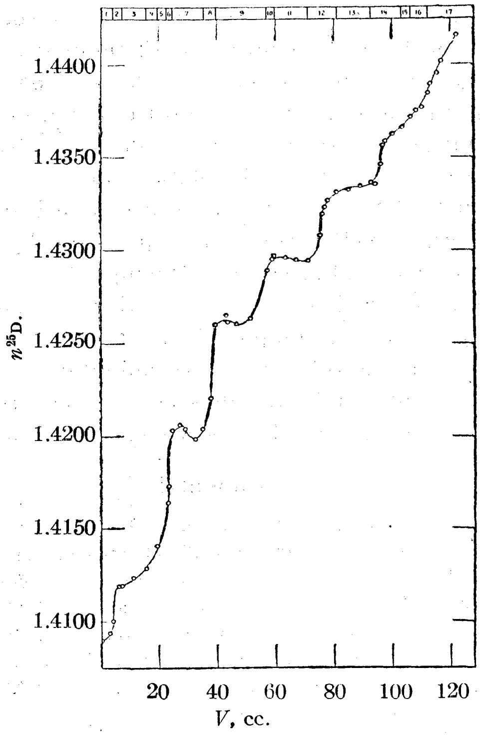

Fig. 3.—Distillation of ethyl esters. Fractions indicated at top.

A 3 to 4 g. sample from each of fractions 1, 3, 7, 9, 11, 13, and 15, Fig. 3, was saponified. The acids obtained were converted into 2-alkylbenzimidazoles according to the procedure of Pool, Harwood and Ralston.[6] The melting points of these derivatives and mixed melting points with derivatives of known acids are given in Table II

Estimation of the Amounts of Nitriles in Cracked Fractions.—The amounts of nitriles present in several cracked fractions were approximated by hydrolyzing the nitriles and weighing the resulting acids. Fifteen grams of acids

was obtained from 100 g. of a 30–130° fraction; similarly, 35 g. from a 100–220° fraction; and 37 g. from 100 g. each of 140–160° or 100–275° fraction.

Fractionation of the Hydrocarbons Obtained from Cracked Fraction.—Distillation curves for hydrocarbons obtained from a cracked fraction are given in Figs. 4 and 5. The curve shown in Fig. 4 was obtained by the distillation of a sample of hydrocarbons boiling below 125°. These hydrocarbons were obtained by cracking nitriles of acids obtained from cottonseed oil in a steel vessel under pressure and without a catalyst. The hydrocarbons were purified by washing with water,[7] passing over silica gel, and finally drying with sodium wire. The hydrocarbons were fractionated three times. The fractions were treated with sodium wire after each distillation in order to completely remove traces of nitriles.

The curve shown in Fig. 5 was obtained by the distillation of hydrocarbons from a sample of miscellaneous cracked fractions (boiling range 100–275°). These cracked fractions were prepared by the vapor phase cracking of nitriles of acids obtained from lard over various catalysts. The nitriles were removed from the hydrocarbons by hydrolysis to alkali soluble acids. The hydrocarbons (iodine number 135) were hydrogenated in the vapor phase to an iodine number of 6.8 using a nickel–chromium catalyst. The curve is for the third fractionation. Here, also, the S curves were due to incomplete hydrogenation.

In Table III are given iodine numbers and percentages of unsaturated hydrocarbons for various fractions of the distillation shown in Fig. 4. One double bond per molecule was assumed in calculating these percentages. Qualitative tests for acetylenic linkages were negative.

TABLE III

Fraction	B. p., °C.	Iodine No.	% unsatd. hydrocarbon
1	<37	102.8	28.3% Pentene
4	60–63	154.5	51.1% Hexene
5	63–66	142.3	47.1% Hexene
6	66–69	103.7	34.2% Hexene
7	69–72	89.5	29.6% Hexene
11	93–96	130.3	50.4% Heptene
12	96–99	100.6	38.8% Heptene

Separation of Nitriles from Hydrocarbons by Hydrolysis.—A cracked fraction (2500 g.) having a boiling range of 100–220°, together with 1600 g. of water and 400 g. of sodium hydroxide, was placed in a rocking autoclave and heated to 200°. The time required to attain this temperature was thirty minutes. The heat was then turned off, but the rocking was allowed to continue for an additional ninety minutes during which time the temperature dropped to 100°. The bomb was cooled, the contents were transferred to a separatory funnel, and the lower aqueous layer was drawn off after settling for one hour. The alkaline salt solution was steam distilled for several hours in order to remove a few grams of hydrocarbons which had remained suspended in the aqueous layer. The clear solution was then acidified with concentrated hydrochloric acid, and the resulting upper layer of fatty acids was separated and distilled. The acids weighed 890 g. and had a boiling range of 190° at 760 mm. pressure to 140°

(7) Acetonitrile, b. p. 79–81.5°, was isolated from the water washings.

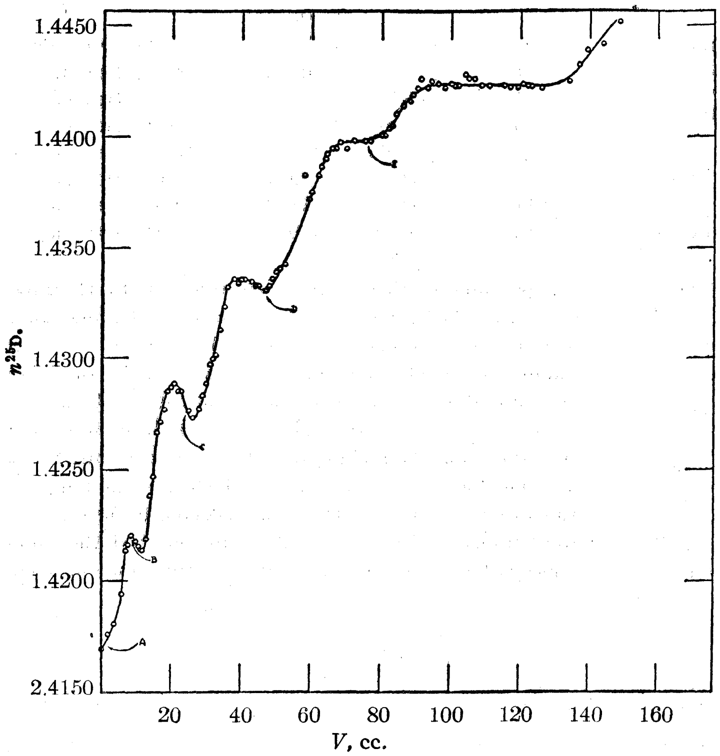

Fig. 5.—Distillation of hydrocarbons: A corresponds to 125° − b. p. of *n*-octane; B to 151° − b. p. of *n*-nonane; C to 174° − b. p. of *n*-decane; D to 195° − b. p. of *n*-undecane; E to 214° − b. p. of *n*-dodecane.

at 5 mm. pressure. The last few drops of the distillate had a molecular weight of 178.

Separation of Nitriles from Hydrocarbons by Solvents.—A sample of cracked fraction having a boiling range of 140–160° was washed three times with concentrated hydrochloric acid, then with water, and finally with dilute potassium hydroxide solution. The cracked fraction was then distilled under vacuum over phosphorus pentoxide. The distillate contained 0.04% fatty acid calculated as caproic and had a nitrogen content of 0.942 g. per 25 cc. The separation of the nitriles from the hydrocarbons by the use of different solvents was studied by the following method: 25 cc. of the cracked fraction was pipetted into a glass-stoppered 50-cc. graduated cylinder. Twenty-five cubic centimeters of the solvent to be tested was added. After thorough shaking, the mixture was allowed to separate into layers at room temperature and the volume of each layer was recorded. An aliquot from each layer was taken with a capillary pipet and the amount of nitrogen was determined. Some typical results are given in Table IV.

TABLE IV

SEPARATION OF NITRILES FROM HYDROCARBONS BY SOLVENTS

Solvent	Upper layer Vol., cc.	Upper layer N. g.,	Lower layer Vol., cc.	Lower layer N, g.
100.0% MeOH[a]	13.3	0.049	36.7	0.884
93.8% MeOH[a]	14.8	.088	35.2	.856
93.8% MeOH	9.5	.083	40.5	.860
70.6% MeOH	20.7	.457	29.3	.478
65.2% MeOH[b]	18.0	.239	82.0	.703
70.4% EtOH	19.7	.379	30.3	.563
95.6% Phenol[c]	9.5	.002	42.0	.939

[a] Separation of layers occurred at −77°. [b] Three volumes of solvent were used to one volume of cracked material. [c] Separation occurred at 4°. The volume of the phenol solution used was 26.5 cc.

Adsorption of Nitriles by Silica Gel.—The apparatus used is shown in Fig. 6. Solutions of nitriles were introduced at A and were forced downward through the column of silica gel[8] by nitrogen gas under a pressure of 8 cm. The nitrogen entered the system at B. In some cases the adsorbed material was removed by heat supplied by the electric furnace C. The temperature was ascertained by means of thermocouple D enclosed in a glass tube extending to the bottom of the silica gel. A solution of Eastman valeronitrile in petroleum ether (boiling range 33–50°), containing 24.40 g. of nitrile in a liter of solution, was passed through 16.5 g. of silica gel and the effluent liquid was received in fractions. Results are given in Table V.

A solution of lauronitrile in petroleum ether, containing 16.742 g. of nitrile in a liter of solution, was passed through 18.5 g. of silica gel. Results are given in Table VI.

Separation of the Nitriles from the Hydrocarbons in Cracked Fractions by Adsorption in Silica Gel.—Twenty-five cubic centimeters of cracked fraction similar to that used in the experiments on separation by solvents, was allowed to flow onto a column of silica gel weighing 58 g. The entire 25 cc. was adsorbed or held by capillarity.

TABLE V

ADSORPTION OF VALERONITRILE BY SILICA GEL

[8] The silica gel was the "Intermediate Activated" grade of the Silica Gel Corporation, Baltimore, Md.

Forty-five cubic centimeters of petroleum ether (boiling range 33–50°) was allowed to flow over the silica gel in order to wash off the hydrocarbons from the cracked fraction. The effluent liquid was received in a Kjeldahl flask, and the petroleum ether was removed by evaporation on a steam-bath. The hydrocarbons remaining in the flask had an approximate volume of 20 cc. and contained 0.0004 g. of nitrogen. Ammonia gas was then passed over the silica gel, which became warm and the temperature of the column was further increased by heat from the surrounding furnace until a final temperature of 400° had been attained. The heat caused a displacement of 2.0 cc. of water and 6.1 cc. of nitriles. The nitriles were washed thoroughly with hydrochloric acid to remove ammonia preparatory to analysis for nitrogen. The 6.1 cc. contained 0.861 g. of nitrogen.

Discussion

While the pyrolytic decomposition of amides to yield nitriles and water is well known, the simultaneous dehydration and hydration to yield nitriles and acids has not been reported previously. Apparently, in the case of stearamide, the nitrile and acid are formed in equimolecular amounts. Experiments not reported indicate that a similar reaction occurs in the case of lauramide.

The method described here for the preparation of nitriles is distinguished from older methods in that it is carried out in the liquid phase and in the absence of catalysts and produces almost theoretical yields of nitriles. The method has been applied to a variety of higher fatty acids and has been carried out on a very much larger scale in iron vessels.

Sufficient evidence has been presented to indicate the composition of the material produced by the cracking of high molecular weight nitriles. Certain conclusions in regard to the total composition of the cracked material are based on data obtained from restricted fractions. The cracked material consisted of a mixture of nitriles and hydrocarbons. Saturated and unsaturated compounds were present in approximately equal amounts in certain hydrocarbon fractions. That the mixture contained only straight chains is indicated by the occurrence of definite plateaus or breaks in the distillation curves of the hydrocarbons and of esters derived from the nitriles (Figs. 3, 4 and 5). In the volume–refractive index curves (Figs. 3 and 5) the breaks are accentuated by the presence of small amounts of unsaturated compounds. In the case of the hydrocarbons these breaks occur at points corresponding to the boiling points of the straight chain compounds. This would not be the case if branched chains had been present in other than very small amounts. The fractionated esters were further identified by means of derivatives. These derivatives showed the presence of straight chain nitriles containing from six to twelve carbon atoms in the particular fraction of cracked material which was used. Since hydrogen cyanide and acetonitrile were identified, it is reasonable to assume that nitriles and hydrocarbons containing from one to seventeen carbon atoms are produced by the cracking process. There was no indication that any particular chain length was predominant.

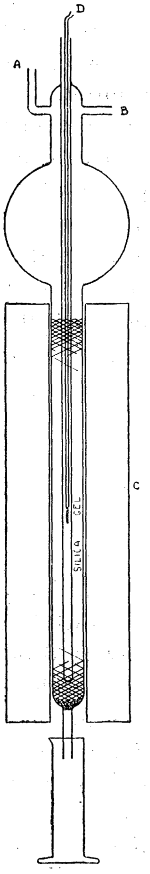

Fig. 6.—Adsorption apparatus.

Because of the similarity in physical properties of nitriles and hydrocarbons, considerable difficulty was experienced in attempting to separate them. Separation by fractional distillation was out of the question as the boiling point of any certain nitrile would have practically coincided with the boiling point of some hydrocarbon of greater chain length. Separation was possible by the preferential solubility of the nitriles in certain solvents from which the nitriles could be recovered unchanged. In Table IV, it is seen that the addition of 25 cc. of 93.8% methyl alcohol to 25 cc. of cracked fraction caused the formation of two layers having volumes of 9.5 cc. and 40.5 cc. Since the smaller layer does not decrease appreciably upon being washed with water, the solvent accounts for 25 cc. of the larger layer. If the solvent were removed by washing with water, 15.5 cc. of cracked fraction containing 0.860 g. of nitrogen would remain. By solvents it is thus possible to separate the cracked fraction into two parts, one of which has a nitrogen percentage 6.3 times as great as that of the other. Such a process would never yield pure nitriles and pure hydrocarbons in one operation, but repeated extractions could be made to give nitriles or hydrocarbons of almost any desired purity. Separation by adsorption appears to be preferable to separation by solvents. From

Table V, fractions 1 and 2 (130 cc.) contained only 0.004 g. of valeronitrile. The original nitrile solution contained 3.172 g. of valeronitrile in 130 cc. Therefore, 16.5 g. of silica gel adsorbed 3.168 g. of nitrile before adsorption ceased to be complete. This amount is equivalent to 19% of the weight of the silica gel. The nitrile can be displaced from the silica gel by means of hot water. By use of the data in Table VI it can be shown that silica gel will adsorb 18% of its weight of lauronitrile from a hydrocarbon solution before small amounts of nitrile appear in the effluent liquid. In the last of the adsorption experiments it is shown possible to remove practically all of the nitriles from a cracked fraction and to recover it after adsorption by heating the silica gel. The original 25 cc. of cracked material contained 0.942 g. of nitrogen, of which 0.861 g. was accounted for in the material removed from the silica gel by heating. Less than 1% of the nitriles was not adsorbed.

Summary

1. The decomposition of high molecular weight amides by heat has been shown to cause a simultaneous hydration and dehydration which leads to the formation of almost equal amounts of acids and nitriles.
2. A non-catalytic method has been developed for preparation of high molecular weight nitriles from fatty acids and ammonia.
3. High molecular weight nitriles have been cracked in the liquid and vapor phases to yield straight chain hydrocarbons and nitriles.
4. Methods have been described which permit the separation of nitriles from hydrocarbons.

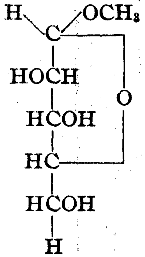
Crystalline Alpha-Methyl-*d*-arabinofuranoside[1]

By Edna M. Montgomery and C. S. Hudson

A new crystalline methyl *d*-arabinoside, which is shown in the accompanying article by Jackson and Hudson to be the alpha form of *d*-arabinofuranoside,[2] has been isolated from the mixture of substances that is obtained by the reaction of *d*-arabinose and methyl alcohol containing hydrochloric acid under mild conditions of glycoside formation. This reaction is accompanied by a double reversal of the sign of optical rotation, as has been reported by previous investigators.[3] The authors were able to crystallize the new furanoside, the rotation[4] of which (+123 in water) is opposite in sign to that of the sugar itself (−105) and to those of its alpha (−17) and beta (−245) methyl pyranosides, by stopping the reaction at its point of highest positive rotation. The substance crystallizes in well formed, clear prisms and the yield is about 9%. Its fast rate of hydrolysis in aqueous acid conforms with the behavior of known furanosides of aldoses. From the present knowledge of the rotation of this alpha form it appears safe to conclude that the rotation of beta-methyl-*d*-arabinofuranoside, a substance now unknown, will be found to be strongly in the levo direction.



Alpha-methyl-*d*-arabinofuranoside, $[\alpha]^{20}_{D}$ +123

Experimental

The removal of solvents and the drying of sirups and crystals were carried out at 25–27° in desiccators supplied with calcium chloride and soda lime and evacuated by a pump. When constant weights were desired the higher vacuum of an oil pump was used for final dryings. The hygroscopic character of the furanoside crystals and the high humidity of the summer atmosphere during the work made it advisable to perform many of the manipulations in dry air. We used a cabinet of 55 × 39 × 43 cm. dimen-

(4) Throughout this article the rotations are specific rotations at 20° for sodium light.

sions constructed of copper with a glass top and a removable end with strip felt closure, the other end being provided with two openings of 13 cm. diameter into which long rubber gloves[5] were fitted with adhesive tape.

Crystallization of α-Methyl-*d*-arabinofuranoside.—One hundred grams of finely powdered and sieved *d*-arabinose, rotation −105 in water, was agitated at 20° with 4 liters of anhydrous methyl alcohol containing 29.2 g. of hydrochloric acid (0.2 normal). Complete solution was obtained after thirty minutes and the observed rotation was strongly to the left, −65. On standing at 20° the solution became non-reducing after four and one-half hours and its specific rotation was then +24. On further standing the rotation increased in the dextro direction, reached a maximum of +45 after seventeen hours, and then receded until after forty-two hours it had reversed its sign and become −17. The new furanoside was obtained in greatest yield if the reaction was stopped when the rotation reached its maximum positive value. The acid was removed with silver oxide, the excess silver with hydrogen sulfide, the solution was concentrated *in vacuo* to 200 cc. (bath at 40°), transferred to a liter bottle, further concentrated to a thick sirup and finally dried overnight in an evacuated desiccator. The sirup was extracted six times at room temperature (25°) with 400-cc. portions of anhydrous ether, using a shaking machine for forty-five minutes for each extraction. At this point extraction with warm ether dissolved a relatively small amount of material, the rotation of which was much lower than that of the readily soluble portion. The ether was removed at the pump from the combined cold extractions (bath at 35°) leaving a sirup weighing about 23 g. of specific rotation +100 to +105, as tested on samples dried to constant weight. An ethyl acetate solution of this sirup which was kept at 5° crystallized spontaneously after two months. In later preparations the seeded sirup crystallized to a cake in two days. It was stirred with 25 cc. of ethyl acetate and filtered to remove sirupy material. The crystalline glycoside, dried under reduced pressure for several hours, weighed 11.5 g. and rotated +118 in water. It was recrystallized from 50 cc. of warm ethyl acetate by slowly cooling to 5° over a period of four to five hours. After three recrystallizations a crop of well formed, transparent prisms was obtained which was dried to a constant weight of 6.1 g., rotation +123 in water ($c = 1.20$). Recrystallization did not change this value. An additional 3.8 g. of pure material was obtained from the mother liquors; total yield, 9%. It did not reduce Fehling's solution but was readily hydrolyzed by acids to give a reducing solution. It melted at 65–67° in a closed tube, solidifying to colorless crystals on cooling. By warming 1.0 g. of the furanoside in 200 cc. of ether, which had been dried with sodium, a solution of about 0.80 g. was obtained which deposited crystals after two days at 5°. These were dried to a constant weight of 0.35 g. and showed a rotation of +123 ($c = 1.24$) in water, m. p. 65–67°. The glycoside was not difficult to prepare in pure anhydrous condition in small quantities, *i. e.*, 0.5 to 1.0 g. It is quite hygroscopic and is extremely soluble in water, methyl, ethyl, propyl and amyl alcohols, soluble in ethyl acetate and slightly soluble in ether.

Anal. Calcd. for $C_5H_9O_4(OCH_3)$: C, 43.88; H, 7.38; OCH_3, 18.91. Found: C, 44.08; H, 7.50; OCH_3, 18.63.

Rates of Hydrolysis of the Three Methyl-*d*-arabinosides.—The rates were measured on 2% solutions of the glycosides at 98° by polarimetric observations after rapid cooling to 20°, using 0.05 *N* aqueous hydrochloric acid with each pyranoside, and 0.01 *N* acid with the furanoside, which is more readily hydrolyzed. The reactions follow the unimolecular course and the coefficient $k = 1/t \log ((r_0 - r_\infty)/(r - r_\infty))$, expressed in minutes and decimal logarithms, has the following values: α-methyl-*d*-arabinopyranoside, 0.0032; β-methyl-*d*-arabinopyranoside, 0.0032; α-methyl-*d*-arabinofuranoside, 0.0068. Assuming the rate to be proportional to the acidity, the coefficient is about 0.00064 for the pyranosides in 0.01 *N* acid and it is seen that the furanoside is hydrolyzed about ten times faster than the pyranosides.

The authors are indebted to Dr. R. M. Hann and Dr. W. T. Haskins for the carbon, hydrogen and methoxyl determinations and to Dr. O. E. May of the Bureau of Chemistry and Soils, U. S. Department of Agriculture, for the supply of calcium gluconate from which the *d*-arabinose was prepared.

Summary

A new crystalline arabinoside, alpha-methyl-*d*-arabinofuranoside, specific rotation in water +123, m. p. 65–67°, has been isolated. Its rate of hydrolysis in aqueous acid is about ten times that of either alpha- or beta-methyl-*d*-arabinopyranoside.

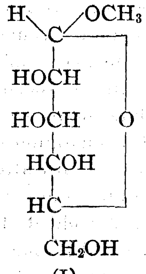
Studies on the Cleavage of the Carbon Chain of Glycosides by Oxidation. A New Method for Determining Ring Structures and Alpha and Beta Configurations of Glycosides[1]

BY ERNEST L. JACKSON AND C. S. HUDSON

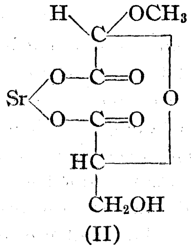
The oxidation of alpha-methyl-*d*-mannopyranoside (I) with barium hypobromite has been shown by us[2] to remove carbon atom 3 and to oxidize the alcohol groups at carbon atoms 2 and 4 to carboxyl groups, producing a dibasic acid which was isolated as the crystalline strontium salt (II). This salt could be prepared also through oxidation of the mannoside with periodic acid followed by oxidation of the product, the dialdehyde (III), with bromine water kept neutral with strontium carbonate. Inasmuch as this cleavage type of oxidation should be applicable to a large number of glycosides, it offered a new method for the proof of ring structures, provided the products from the various glycosides could be obtained in crystalline condition suitable for structural studies. The present article reports our progress in the development of the method as pertains to the methylaldohexosides and the methylaldopentosides.

The method consists in the oxidation of the glycoside with periodic acid in aqueous solution at 20° followed by the oxidation of the dialdehyde, after isolation, with bromine water in the presence of a metallic carbonate selected to yield a crystalline salt of the dibasic acid, the proof of the structure of which, in the case of the glycosides here studied, discloses the ring structure of the parent glycoside.[3] Important confirmatory evidence in the case of some structures is obtained by the measurement of the quantity of periodic acid consumed, as will be illustrated later.



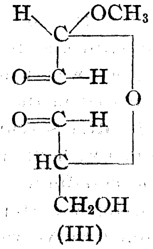
(I)

α-Methyl-*d*-manno-pyranoside



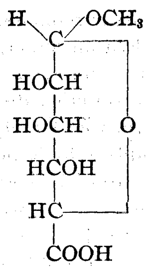
(II)

Strontium D′-methoxy-D-hydroxymethyl-diglycolate



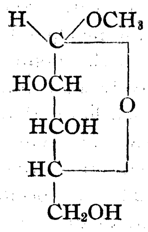
(III)

D′-methoxy-D-hydroxy-methyl-diglycolic aldehyde



(IV)

α-Methyl-*d*-mannuronide(1,5)



(V)

α-Methyl-*d*-arabino-furanoside

Inspection of the formulas shows that the same dialdehyde (III) and strontium salt (II) should be expected from all the eight possible alpha-methyl-*d*-aldohexopyranosides. The production of the same dialdehyde in the oxidation of four of these (the alpha-methyl-pyranosides of *d*-mannose, *d*-galactose, *d*-glucose and *d*-gulose) is apparent from the rotations recorded in Table I and the curves shown in Fig. 1. The dialdehyde from each of the four sources, isolated as a sirup and oxidized in the usual way, produced in yields of 65–70% the same crystalline strontium salt (II). The structure[4] of the strontium salt, particularly the presence of the *d*-glyceric acid moiety in the molecule, limits the ring of each of the four alpha-methyl-*d*-hexosides to the pyranoside(1,5) or septanoside(1,6) structure. In addition to the usually accepted evidence, two independent proofs, which exclude the septanoside ring structure and thereby

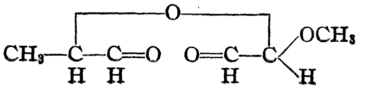
[3] The proof of the structure might be accomplished also through the dialdehyde or a suitable derivative. By the periodic acid oxidation of alpha-methyl-*l*-rhamnoside of specific rotation −62.8° we have obtained, at the dialdehyde stage, a crystalline compound melting at 101–102° and showing $[\alpha]^{20}_{D}$ −143° in water. Analyses for carbon, hydrogen and methoxyl show its empirical formula to be $C_6H_{12}O_6$, corresponding to the monohydrate of the expected dialdehyde



$$CH_3-\underset{H}{C}-\underset{H}{C}{=}O\quad O{=}\underset{H}{C}-C\begin{smallmatrix}OCH_3\\H\end{smallmatrix}$$

[4] The experimental details, omitted in ref. 2, for the preparation of oxalic and *d*-glyceric acids from the strontium salt are given in the experimental part of this article.

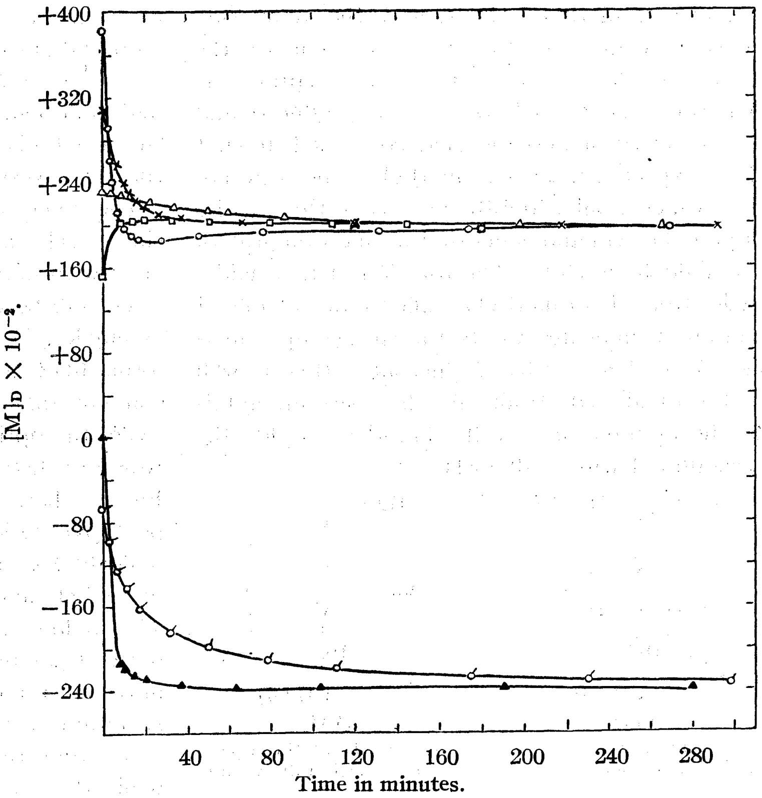


Fig. 1.—Rotatory changes during the oxidation of the methyl hexosides: ○, α-methyl-*d*-galactoside; ×, α-methyl-*d*-glucoside; △, α-methyl-*d*-guloside; □, α-methyl-*d*-mannoside; ♂, β-methyl-*d*-glucoside; ▲, β-methyl-*d*-galactoside.

limit the ring to that of a pyranoside, are provided by the present investigation. From the products of the oxidation of alpha-methyl-*d*-mannopyranoside with barium hypobromite we have prepared a crystalline brucine salt (m. p. 232°) which has been proved to be the brucine salt of alpha-methyl-*d*-mannuronide (IV). The formation of the methyl *d*-mannuronide through the oxidation of the primary alcohol group at carbon atom 6 to a carboxyl group obviously is incompatible with the 1,6-ring structure. The second proof is furnished by the preparation, through the usual oxidation reactions, of the strontium salt (II) from a new crystalline methyl-*d*-arabinofuranoside[5] (V); this proof will be presented when the oxidation of the methyl pentosides is discussed. The conclusion that the strontium salt (II) has the indicated structure is further supported by the known reactions of periodic acid;[6] the septanoside structure for an alpha-methyl-*d*-aldohexoside would be expected to consume three moles of periodic acid and yield the dialdehyde (X) (a substance which we have obtained from the alpha-methyl-*d*-pentopyranosides), whereas the alpha-methyl-*d*-aldohexosides that have been studied consume two moles of periodic acid and yield the dialdehyde (III).

The beta-methyl-*d*-aldohexopyranosides react with periodic acid in the same manner as the alpha forms, but the product (VI) is of course different since the dialdehydes from an alpha-beta pair retain the difference in configuration of carbon atom 1 that existed in the parent glycosides. Although the strontium salt in the beta series was not a crystalline compound, the barium salt (VII) crystallized quite readily and in high yield when prepared from beta-methyl-*d*-glucoside. By the same reactions as applied to the strontium salt from alpha-methyl-*d*-mannopyranoside, oxalic and *d*-glyceric acids were prepared from the barium salt; this limits the

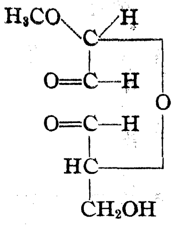
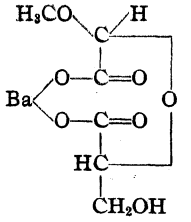
ring of beta-methyl-*d*-glucoside to the pyranoside or septanoside structure. In addition to the known evidence to exclude the septanoside structure, the dialdehyde that is produced and the quantity of periodic acid consumed are not those expected from beta-methyl-*d*-glucoseptanoside, which would doubtless consume three moles of periodic acid and generate the enantiomorph of the dialdehyde (X). The rotation of the dialdehyde from beta-methyl-*d*-galactoside (Table I and Fig. 1) indicates it to be the same compound as (VI) from beta-methyl-*d*-glucoside; this as well as the dialdehyde from all other beta-methyl-*d*-aldohexopyranosides will doubtless yield the crystalline barium salt (VII).



(VI)

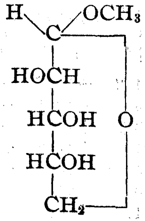
L′-methoxy-D-hydroxymethyl-diglycolic aldehyde



(VII)

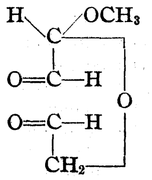
Barium L′-methoxy-D-hydroxymethyl-diglycolate

The oxidation products are named as derivatives of diglycolic aldehyde or acid; the prefixes D′ and L′ distinguish the configurations of carbon atom 1 in the products from the alpha- and beta-methyl glycosides, D′ signifying the configuration of carbon atom 1 as in alpha-methyl-*d*-mannopyranoside. The dibasic acid of specific rotation +26° from the alpha-methyl-*d*-aldohexopyranosides is named D′-methoxy-D-hydroxymethyl-diglycolic acid and that from beta-methyl-*d*-glucopyranoside, of specific rotation +45°, is named L′-methoxy-D-hydroxymethyl-diglycolic acid. The D and L symbols conform to the usual Fischer nomenclature for carbon 5 of the aldohexosides.



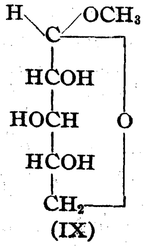
(VIII)

α-Methyl-*d*-arabinopyranoside



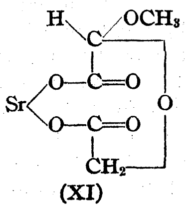
(X)

D′-methoxy-diglycolic aldehyde



(IX)

α-Methyl-*d*-xylopyranoside



(XI)

Strontium D′-methoxy-diglycolate

The oxidation of alpha-methyl-*d*-arabinopyranoside (VIII) and alpha-methyl-*d*-xylopyranoside (IX) with periodic acid should yield one and the same substance, namely, D′-methoxy-diglycolic aldehyde (X), and a similar oxidation of the beta forms likewise should be expected to produce a common dialdehyde, L′-methoxy-diglycolic aldehyde, the optical antipode of (X). The specific rotations listed in Table I and the curves in Fig. 2 show that the two pairs of methyl-*d*-pentopyranosides do indeed produce antipodal dialdehydes, the one from the alpha forms rotating +124° and that from the beta forms −124°. The dialdehyde from each of the four *d*-pentopyranosides produced, upon oxidation with bromine water and strontium carbonate, a crystalline strontium salt in about 80% yield; the salt (XI) from the two alpha forms rotated −56° while the salt from the two beta forms rotated +56°; these two salts are thus enantiomorphic forms. The methoxy-diglycolic acids from the methyl pentopyranosides, like the methoxy-D-hydroxymethyl-diglycolic acids from the methyl-aldohexopyranosides, are hydrolyzed readily in aqueous solution because of their acetal structure. The acid from the strontium salt (strontium L′-methoxy-diglycolate) prepared from beta-methyl-*d*-arabinopyranoside, when hydrolyzed and oxidized with bromine water yielded oxalic and glycolic acids, the latter identified through three crystalline derivatives (calcium glycolate, S-benzylthiuronium glycolate and *p*-bromophenacyl glycolate). Since glycolic acid contains only one alcoholic hydroxyl group, the oxygen linkage in the strontium salt must be as indicated, which proves the four parent methylpentosides to be of the pyranoside type and correlates the alpha and beta forms. Since the application of the usual oxidation reactions to a third crystalline methyl-*d*-arabinoside[5] (V) of specific rotation +123° yields a different strontium salt (II) (the one from the alpha-methyl-*d*-aldohexopyranosides, containing the *d*-glyceric acid grouping), the third methyl-*d*-arabinoside must have the furanoside structure (V) and be of the alpha configuration for carbon 1. This is the second proof, mentioned previously, for the structure of (II), (III) and (I). One observes that these oxidation results correlate the configuration of a pentofuranoside (V) and a hexopyranoside (I).

The ring structures which have been shown by these oxidation results confirm the pyranoside structures that are now accepted from methylation data; in the case of alpha-methyl-*d*-gulopyranoside and alpha-methyl-*d*-arabinofuranoside, where methylation data are lacking, the new method supplies conclusive proof for ring structures and alpha classification.

The preparation of *d*-glyceric acid from the methyl *d*-aldohexosides through either strontium D′-methoxy-D-hydroxymethyl-diglycolate or barium L′-methoxy-D-hydroxymethyl-diglycolate provides the most direct correlation of the configuration of the sugars with glyceric acid.[7] The present type of oxidation offers the possibility of improved methods for the preparation in pure condition of stereoisomers, such as *d*- and *l*-glyceric and lactic aldehydes and the corresponding acids, and of many mixed acetals for which no methods of synthesis have been known. These oxidation reactions, with periodic acid as the oxidant, appear to proceed practically quantitatively according to the following typical equations, the first of which has been proposed by Hérissey, Fleury and Joly.[6]

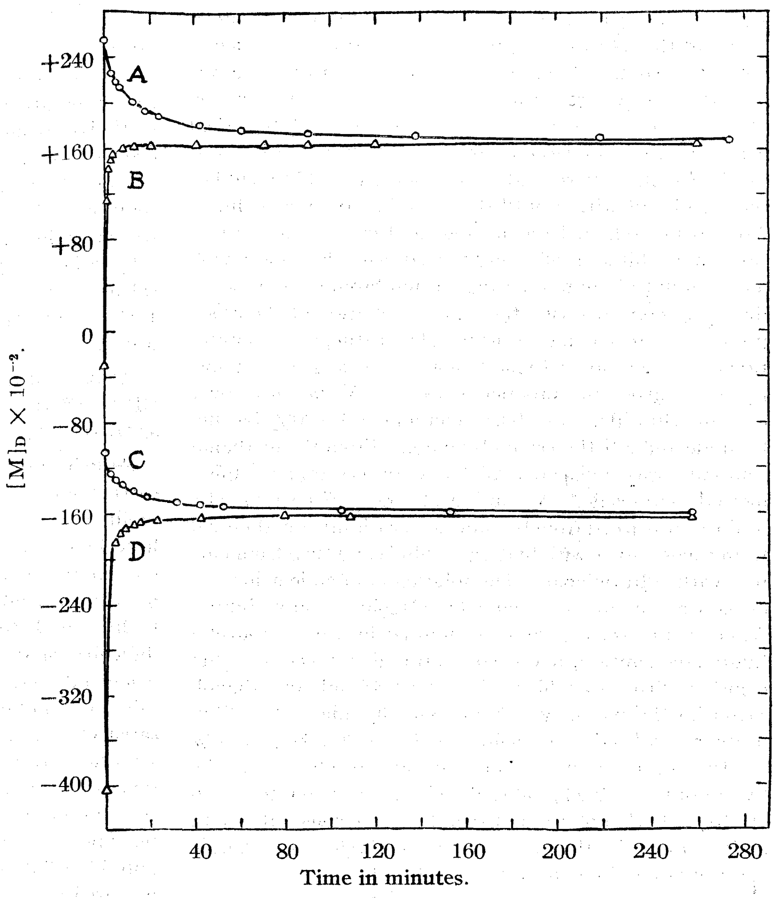


Fig. 2.—Rotatory changes during the oxidation of the methyl-pentopyranosides: (A), α-methyl-*d*-xylopyranoside; (B), α-methyl-*d*-arabinopyranoside; (C), β-methyl-*d*-xylopyranoside; (D), β-methyl-*d*-arabinopyranoside.

Experimental

Oxidation of Alpha-Methyl-*d*-mannopyranoside with Barium Hypobromite.—To a solution of 420 g. of barium hydroxide octahydrate and 166 g. of bromine in 12 liters of distilled water at 3° was added 100 g. of pure alpha-methyl-*d*-mannopyranoside. The solution, kept in the dark at 3–7° with occasional shaking, was free from hypobromite after eight to ten days as shown by starch–potassium iodide paper. The reaction of a second portion of the same amounts of barium hydroxide and bromine was complete after about eight days. The insoluble material (70–

---

[7] *Cf.* Wohl and Momber, *Ber.*, **47**, 3346 (1914); **50**, 455 (1917); Wohl and Schellenberg, *ibid.*, **55**, 1404 (1922); Freudenberg and Brauns, *ibid.*, **55**, 1339 (1922).

75 g.), apparently barium carbonate, was removed by filtration and the neutral solution was concentrated *in vacuo* to 500 ml. About 325 g. of crystalline barium bromide was separated in two crops through filtration and concentration of the filtrate *in vacuo* to 250–300 ml. The solution then was evaporated *in vacuo* to dryness; a solution of the residue in 75 ml. of warm water was poured into 2 liters of hot methanol and stirred until the precipitated gum solidified. After being refluxed for an hour and cooled, the barium salts were filtered off and washed with hot methanol. The amount of contaminating barium bromide may be reduced by concentrating the aqueous solution of the crude product *in vacuo* to a thin sirup and repeating the precipitation and extraction with methanol. The yield of the amorphous, hygroscopic product, dried at 25° *in vacuo* over calcium chloride, was 100 g. containing 15–20% barium bromide and a little barium bromate. From the methanol solutions was recovered 25–30 g. of crystalline alpha-methyl-mannoside. A solution of 250 g. of barium salts in water was freed from bromine ions with silver carbonate, from excess silver with hydrogen sulfide and then from barium with sulfuric acid. The solution of organic acids was dextrorotatory and reduced Fehling's solution only slightly. After neutralization to phenolphthalein with strontium hydroxide solution, it was concentrated *in vacuo* to a thin colorless sirup to which was added 15 ml. of ethanol. Strontium D′-methoxy-D-hydroxymethyl-diglycolate dihydrate crystallized at 5° as fine needles; yield, 80 g. or 25% on the alpha-methyl-mannoside that reacted with the hypobromite. Recrystallized twice from water to which 10–15% of ethanol was added and dried to constant weight at 105° *in vacuo*, the pure anhydrous salt showed a specific rotation[8] of −53.0° in water (*c*, 0.6).

Anal. Calcd. for $C_6H_8O_7Sr$: C, 25.74; H, 2.88; OCH_3, 11.1; Sr, 31.33. Found:[9] C, 25.74, 25.54; H, 2.93, 3.04; OCH_3, 10.9, 10.8; Sr, 31.47, 31.49.

The specific rotation of D′-methoxy-D-hydroxymethyl-diglycolic acid in water, obtained by liberating it from the pure anhydrous strontium salt with an equivalent of hydrochloric acid, was +25.5° (*c*, 1.6).

Brucine alpha-methyl-*d*-mannuronide was prepared from 16 g. of crude barium salts. After removal of the bromine ions and the barium, the aqueous solution of the organic acids was heated on the steam-bath for three hours with excess of brucine; the excess was removed by filtration followed by extraction with chloroform, and the solution was concentrated *in vacuo* to a dry sirup. The sirup was crystallized from absolute ethanol and the product, which appeared to be a mixture of several brucine salts, yielded on fractionation from 95% ethanol about 4.5 g. (12%) of nearly pure brucine alpha-methyl-*d*-mannuronide. This was recrystallized to the constant melting point of 232° (dec.) from 95% ethanol, in which it is difficultly soluble. The pure compound lost 6.1% in weight upon being dried at 105° *in vacuo* and then showed a specific rotation of −2.5° in water (*c*, 2).

Anal. Calcd. for $C_{30}H_{38}O_{11}N_2$: C, 59.77; H, 6.36; OCH_3, 15.45; N, 4.65. Found (dried at 105° *in vacuo*): C, 59.70, 59.73; H, 6.26, 6.31; OCH_3, 15.4, 15.4; N, 4.70, 4.72.

This identification of the brucine salt was confirmed by the preparation from it of crystalline potassium alpha-methyl-*d*-mannuronide.[10] The calculated potassium hydroxide was added to a solution of 10 g. of pure brucine salt in 200 ml. of water, the brucine was removed and the solution was concentrated *in vacuo* to a thin sirup, which was crystallized with the aid of ethanol. The potassium salt showed $[\alpha]^{20}\text{D}$ + 45.2° in water (*c*, 1.5), from which is calculated $[\alpha]_{5780}^{20}$ +47.1° using the dispersion coefficient[11] 1.042. Ault, Haworth and Hirst reported $[\alpha]_{5780}^{17}$ +48° in water.

Anal. Calcd. for $C_7H_{11}O_7K \cdot {}^1/_2C_2H_5OH$: K, 14.5; OR (as OCH_3), 17.3. Found: K, 14.5, 14.4; OR (calcd. as OCH_3), 16.4.

Periodic Acid.—The subsequent oxidation reactions were carried out with solutions of pure periodic acid. In some preliminary experiments in which certain alpha-methyl-hexosides were oxidized by periodic acid prepared in aqueous solution from potassium periodate and an equivalent of sulfuric acid, the yield of strontium D′-methoxy-D-hydroxymethyl-diglycolate was low, probably due to the difficulty of complete removal of potassium ions which would interfere with the crystallization of the strontium salt. Crystalline periodic acid[12] (H_5IO_6) was found more satisfactory. To avoid interference with polarimetric observations by a small precipitate which separates in oxidations with fresh solutions of the product which we used, the solutions were kept overnight or longer at 20° and filtered prior to analysis[13] and use in oxidation experiments. Suitable solutions of periodic acid in water may also be prepared from barium periodate ($Ba_3I_2O_9$). A solution of 75 g. of potassium periodate in 2500 ml. of hot distilled water was cooled cautiously to the beginning of crystallization (about 65°); to this was added a solution of 89.2 g. of pure barium acetate monohydrate in 500 ml. of cold water. It was shaken thoroughly while cooling in ice-water and then kept at 5° for about six hours. The barium periodate was filtered off, washed free from acetic acid with cold water, air-dried for two days and then at 25° *in vacuo* over calcium chloride; yield 115–120 g., containing 37.6% barium. A solution of periodic acid was prepared by shaking mechanically for one and one-half hours a suspension of 20.6 g. of powdered barium periodate in 45 ml. of distilled water to which was added *N* sulfuric acid exactly equivalent to the barium found by analysis; the filtered solution was made to 200 ml. with water.

Oxidation of the Methyl-pentopyranosides.—To 98 ml. of 0.2693 *M* aqueous periodic acid (HIO_4) solution at 20° in a 100-ml. volumetric flask was added 2.0568 g. of the pure, powdered methyl-pentopyranoside crystals. The crystals were dissolved as quickly as possible, and the solution was kept in a 20° room while the rotatory changes recorded in Table II were observed. When the rotation

[a] See Fig. 2. [b] The volume of the solution, measured at 20° after completion of the reaction, was 99.8 ml. [c] Although the reaction solution was kept in a 20° room, its temperature did not remain constant, due to the heat evolved in each of the oxidation reactions. *Cf.* α-methyl-galactoside, Table V, note *c*. [d] Calcd. from the usually accepted specific rotations in water of the methyl-pentopyranosides, which are in the order listed: −17.3, −245.5, +153.9, −65.5.

ceased to change, 5 ml. of the solution was analyzed for periodic acid at the time specified in Table III; the amount found in each case corresponded approximately to the excess (5%) over two molecular equivalents added at the start. The remainder of the solution was neutralized to phenolphthalein with hot strontium hydroxide solution with care to avoid any excess. The precipitate (strontium iodate and a little strontium periodate) was filtered off and washed with cold distilled water. After the addition of 1 g. of strontium carbonate the solution[14] was concentrated *in vacuo* (bath, 50°) to about 25 ml., filtered and the concentration (bath, 40°) continued to dryness. The residue was extracted thrice with 25-ml. portions of cold absolute ethanol and thrice with 10-ml. portions. An aqueous extract (35 ml.) of the crystals insoluble in ethanol showed no optical activity, indicating the complete solution of the dialdehyde in the ethanol. The dialdehyde was recovered from the ethanol solution as a colorless sirup by distillation of the solvent *in vacuo* (bath, 40–45°); its rotation in 250 ml. of solution in water is shown in Table III. The solution then was diluted with water to 500 ml.; 38 g. of strontium carbonate and 3 ml. of bromine were added and the mixture shaken until the bromine dissolved. The mixture was kept in the dark at room temperature for about eighteen hours with frequent shaking during the first hour. Excess bromine was removed by aeration and excess strontium carbonate by filtration. The rotation of the filtrate, containing principally strontium methoxy-diglycolate and strontium bromide, is given in Table III. After the strontium carbonate was washed with cold water, the combined solution and washings were shaken with silver carbonate (about 25 g.) until free from bromine ions, and the solids were filtered off and washed with cold water. The silver was removed from the filtrate as silver sulfide, excess hydrogen sulfide was expelled by aeration and the solution was concentrated *in vacuo* (bath, 50–60°) to about 50 ml., filtered and the concentration continued to 10–15 ml., when crystals of strontium methoxy-diglycolate began to separate. After completion of crystallization in the refrigerator the crystals were filtered off and washed with about 2 ml. of cold water. A second crop was obtained by evaporating the filtrate *in vacuo* to dryness and crystallizing the sirup from about 5 ml. of water to which ethanol was added to saturation. The yield of strontium methoxy-diglycolate trihydrate (air-dried, or dried at 25° *in vacuo* over calcium chloride) was the same from each of the four methyl-pentopyranosides, 3 g. or 79%. The crude trihydrate derived from the two alpha-methyl-*d*-pentopyranosides showed a specific rotation of about −43° in water (*c*, 0.6); the trihydrate from the two beta forms rotated about +43°. The strontium salt from each of the four sources was recrystallized thrice from eight parts of distilled water, yielding needles of the trihydrate; the rotation of the anhydrous salt, dried to constant weight at 100° *in vacuo*, was then constant. The rotations and

[a] Dried to constant weight at 100° *in vacuo*. The anhydrous salts are quite hygroscopic. [b] C = 1.07–1.15 g. per 100 ml. of solution. At concentrations of 0.6–1.2 g. per 100 ml. the rotation, which varies with the concentration, may be expressed by the equation: $[\alpha]^{20}D = \pm 48.5° \pm 6.33\ C$, the positive sign pertaining to the salt from the β-methyl *d*-pentopyranosides.

analyses are shown in Table IV. The rotation of the dibasic acid from each of the strontium salts is recorded in Table I.

Proof of Structure.—To a solution of 15.0 g. of pure strontium salt ($C_5H_6O_6Sr \cdot 3H_2O$), derived from beta-methyl-*d*-arabinopyranoside, in 250 ml. of water, was added 98.8 ml. of N sulfuric acid and 350 ml. of 95% ethanol; after fifteen hours the strontium sulfate was filtered off and washed with cold 50% ethanol. The filtrate was concentrated *in vacuo* to about 50 ml., the solution was diluted with 50 ml. of ethanol, filtered and the concentration continued to a colorless sirup, which was taken up in water and again concentrated *in vacuo* (bath, 50°) to a thick sirup. The dextrorotatory solution of the sirup in 100 ml. of water was heated on the steam-bath for two hours; it then showed no rotation[15] in a 4-dm. tube. After dilution of the solution with water to 200 ml., 4 ml. of bromine was dissolved in it and the mixture kept in the dark at room temperature for forty-five hours. Excess bromine was removed by aeration, and the solution was neutralized to phenolphthalein with barium hydroxide solution. The precipitated barium oxalate was filtered off, washed and dried at 25° *in vacuo* over calcium chloride; yield, 6.1 g. From the barium oxalate was prepared oxalic acid dihydrate which was identified by its melting point of 99.5–101° and by titration with solutions of sodium hydroxide and potassium permanganate.

To the filtrate from the crude barium oxalate was added sufficient sulfuric acid to precipitate the barium exactly. The filtered solution was freed from bromine ions by shaking with 25 g. of silver carbonate, after which excess silver was removed as sulfide and the solution concentrated *in vacuo* to about 50 ml., filtered and the concentration continued to make exactly 25 ml. of solution, aliquots of which were used for the preparation of derivatives of glycolic acid. Calcium glycolate was prepared by neutralizing 11.5 ml. to phenolphthalein with pure calcium hydroxide solution and concentrating; fine needles; air-dried; yield 2.5 g. or 83%, containing 28.6% of combined water. One recrystallization from water gave the pure compound.

Anal. Calcd. for $C_4H_6O_6Ca$: Ca, 21.08. Found (dried at 115° *in vacuo*): Ca, 21.09, 21.11.

S-Benzylthiuronium glycolate was prepared from 5 ml. of the glycolic acid solution; after neutralization with 5 N sodium hydroxide and evaporation nearly to dryness, a solution of the sodium glycolate in 3–4 ml. of hot water was added to a hot solution of 2.18 g. of S-benzylthiuronium chloride in 14 ml. of 95% ethanol. The product, isolated according to Donleavy,[16] was purified by recrystallization from 95% ethanol; m. p. 143° (corr.) alone or mixed with the salt prepared from authentic glycolic acid. *p*-Bromophenacyl glycolate, prepared from 8.5 ml. of the glycolic acid solution by the usual procedure[17] and recrystallized several times from aqueous ethanol, melted at 142° (corr.) and showed no depression when mixed with the ester from authentic glycolic acid.

Anal. Calcd. for $C_{10}H_9O_4Br$: Br, 29.3. Found: Br, 29.6.

Oxidation of Alpha-Methyl-*d*-arabinofuranoside.[18]—The furanoside (1.8300 g.), dried to constant weight in an evacuated desiccator over phosphorus pentoxide, was made up to 25 ml. of solution in water at 20°; its specific rotation was +120.5°, the solution rotating 17.64° to the right in a 2-dm. tube. Exactly 24 ml., containing 1.7568 g. of the furanoside, was added to 25 ml. of 0.5365 M periodic acid solution (1.25 molecular equivalents) in a 50-ml. volumetric flask; the solution, made up to 50 ml. at 20° with water and kept in a 20° room, showed $[M]_D \times 10^{-2}$: +196.9 (five minutes); +194.8 (twenty minutes); +193.5 (thirty-five minutes); +191.2 (eighty minutes); +189.2 (three hours); +188.4 (five hours); +186.4, constant (twenty-four hours). After twenty-three hours an analysis of 5 ml. of the solution showed 12.6% excess periodic acid, or the reaction of 1.09 molecular equivalents.[19]

---

[15] L′-methoxy-diglycolic acid, because of its acetal structure, should be expected to undergo hydrolysis readily; apparently the acetal is hydrolyzed nearly completely during the heating and the subsequent bromine oxidation by which hydrobromic acid is generated. It is noteworthy that the parent methyl-aldopentopyranoside is much more resistant to acid hydrolysis than the derived acetal; the cleavage of the carbon chain of the pyranoside ring increases the ease of hydrolysis.

[18] Supplied by Miss Edna Montgomery. The properties of the furanoside, particularly pertinent being its hygroscopicity, are described by Montgomery and Hudson.[5]

[19] From the difficulty experienced in obtaining sufficiently large samples of the furanoside in the anhydrous condition, it seems probable that the discrepancy between the rotation of +120.5° of the sample oxidized and the value +123° assigned to the pure compound[5] is due to moisture. Calculated on this assumption the sample (1.7210 g.) reacted with 1.12 molecular equivalents of periodic acid and the final $[M]_D \times 10^{-2}$ was +190.2 (twenty-four hours) corresponding to a specific rotation of +117.3° for the dialdehyde. The reaction of the excess of one molecular equivalent of periodic acid

[a] See Fig. 1. [b] The volume of the solution, measured at 20° after completion of the reaction, was practically 100 ml. [c] The solutions were prepared at 20° and kept thereafter in a 20° room, but the temperature was variable due to the heat evolved in each of the oxidation reactions, the increase being 10° for α-methyl-*d*-galactoside. [d] Calcd. from the usually accepted specific rotations in water of the methyl-hexosides which are in the order listed: +196.1, +158.9, +109.4, +79, +0.7, −34.2. The value for α-methyl-guloside refers to its monohydrate.

Strontium D′-methoxy-D-hydroxymethyl-diglycolate in a yield of about 60% was prepared from the oxidation solution by the general directions given under the methyl-pentopyranosides. Recrystallized twice as fine needles from fifteen parts of water to which 10–15% of ethanol was added, and dried to constant weight at 105° *in vacuo* the anhydrous salt showed a specific rotation of −53.3° in water (*c*, 0.6).

Anal. Calcd. for $C_6H_8O_7Sr$: C, 25.74; H, 2.88; OCH_3, 11.1; Sr, 31.33. Found: C, 25.74, 25.80; H, 3.16, 3.12; OCH_3, 11.0, 10.9; Sr, 31.29, 31.36.

The identification of the strontium salt as a derivative of D′-methoxy-D-hydroxymethyl-diglycolic acid is confirmed by the specific rotation +26.1° (*c*, 1.4) of the dibasic acid obtained by liberating it from its pure strontium salt with an equivalent of hydrochloric acid (*cf.* Table I).

Oxidation of the Methyl-hexosides.—The procedure was the same as described for the methyl-pentopyranosides, using 98 ml. of 0.2689 *M* periodic acid solution and 2.4296 g. of pure anhydrous methyl-hexoside,[20] or a multiple of these quantities. The rotatory changes are shown in Table V; the results of analyses for periodic acid, carried out with 5 ml. of the solutions at specified times, are recorded in Table VI and show for each methyl-hexoside about the excess (5%) over two molecular equivalents added at the start. After completion of the oxidation reaction the solution from each alpha-methyl-hexoside was neutralized with strontium hydroxide solution and treated as outlined for the methyl-pentopyranosides. In Table VI is recorded the rotation of the sirupy D′-methoxy-D-hydroxymethyl-diglycolic aldehyde, isolated from each alpha-methyl-hexoside, and also the rotation after oxidation with bromine water in the presence of strontium carbonate. The yield of the crystalline hydrate of strontium D′-methoxy-D-hydroxymethyl-diglycolate, dried at 25° *in vacuo* over calcium chloride, was 65–70% from each alpha-methyl-hexoside; at this stage it usually showed a specific rotation in water of about −47° (*c*, 0.7). The strontium salt was recrystallized from fifteen parts of water, to which 10–15% ethanol was added, until the rotation of the anhydrous salt was constant. It crystallizes readily as fine needles which, after being dried in an evacuated desiccator over calcium chloride, contain two moles of combined water. Calcd. for $C_6H_8O_7Sr{\cdot}2H_2O$: H_2O, 11.41. Found H_2O (dried at 105° *in vacuo*): 11.66. The identity of the strontium salt from the four alpha-

α-Methyl-*d*-mannoside	−53.0°				31.27	31.13

[a] Dried to constant weight at 105° *in vacuo*. The anhydrous salt is quite hygroscopic. [b] C = 0.58–0.65 g. per 100 ml. of solution. At concentrations of 0.6–1.2 g. per 100 ml. the rotation, which varies with the concentration, may be expressed by the equation: $[\alpha]^{20}\mathrm{D} = -48.6° - 7.36\ C$.

methyl-hexosides is shown by the rotations and analyses given in Table VII. A confirmation of this identification is afforded by the agreeing values of the specific rotation of D′-methoxy-D-hydroxymethyl-diglycolic acid, obtained by liberating it with an equivalent of hydrochloric acid from the pure strontium salt derived from each of the four alpha-methyl-hexosides (*cf.* Table I).

Barium L′-Methoxy-D-hydroxymethyl-diglycolate from Beta-methyl-*d*-glucoside.—The strontium salt prepared from beta-methyl-*d*-galactoside by the usual procedure unfortunately was not crystalline. The galactoside as shown by the data in Tables V and VI utilizes two moles of periodic acid in the manner typical of the hexopyranoside structure and yields a dialdehyde rotating about the same as that from beta-methyl-*d*-glucoside. This amorphous strontium salt appeared therefore to be the normal product from the beta-methyl-*d*-aldohexopyranosides, but its amorphous nature caused us to change to the barium salt, which crystallized quite readily when prepared from beta-methyl-*d*-glucoside.

After completion of the oxidation of beta-methyl-*d*-glucoside, the solution was neutralized with barium hydroxide solution and the procedure for the methyl-pentopyranosides was followed with the substitution of barium carbonate for strontium carbonate. The yield of crystalline barium salt, dried in an evacuated desiccator over calcium chloride and showing a specific rotation of +34 to +35° in water (c, 1.5), was 15 g. from 12.2 g. of beta-methyl-*d*-glucoside hemihydrate. Recrystallized twice from water as fine needles of the dihydrate (air-dried), the barium salt after being dried at 100° *in vacuo* showed the specific rotation[21] +35.9° in water (c, 3.4) which was unchanged by another recrystallization. The anhydrous salt is quite hygroscopic.

Anal. Calcd. for $C_6H_8O_7Ba{\cdot}2H_2O$: H_2O, 9.86. Found (dried at 100° *in vacuo*): H_2O, 9.92, 9.97. Calcd. for $C_6H_8O_7Ba$: C, 21.86; H, 2.45; OCH_3, 9.4; Ba, 41.70. Found: C, 21.84, 21.91; H, 2.58, 2.67; OCH_3, 9.3, 9.2; Ba, 41.72, 41.66.

The rotation of L′-methoxy-D-hydroxymethyl-diglycolic acid in water, from the barium salt and an equivalent of hydrochloric acid, is recorded in Table I.

Proof of Structure of the Strontium and Barium Salts from the Methyl-hexosides.—D′-Methoxy-D-hydroxymethyl-diglycolic acid, prepared from 15 g. of pure hydrated strontium salt,[22] was hydrolyzed in aqueous solution; the hydrolyzed acid was oxidized with bromine water and neutralized with barium hydroxide solution, all as described for the structure of strontium L′-methoxy-diglycolate. From the barium oxalate (5.7 g.) was prepared oxalic acid dihydrate of m. p. 99.5–101° which, after dehydration at 100°, melted at 189–190°; it was characterized further by the previously mentioned analyses.

The filtrate from the barium oxalate, freed from barium with sulfuric acid, from bromine ions with silver carbonate and from excess silver with hydrogen sulfide, was concentrated *in vacuo* to about 200 ml., filtered and neutralized to phenolphthalein with pure calcium hydroxide solution. The solution was concentrated *in vacuo* to a sirup which crystallized readily, yielding about 6 g. of crude calcium *d*-glycerate. After two recrystallizations from water and drying in the air, the calcium *d*-glycerate dihydrate melted at 141–142° (uncorr.) and showed a specific rotation in water of +14.6 ± 0.5° compared with m. p. 138° and specific rotation +14.07° found by Anderson.[23]

After the exact removal of the barium with sulfuric acid from 250 ml. of an aqueous solution containing 19.4 g. of pure anhydrous barium salt (barium L′-methoxy-D-hydroxymethyl-diglycolate) prepared from beta-methyl-*d*-glucoside, the solution was concentrated *in vacuo* to 200 ml., the organic acid was hydrolyzed by heating and treated thereafter by the above procedure for the preparation of barium oxalate (6.9 g.) and calcium *d*-glycerate (8.5 g. of crude). The oxalic acid dihydrate from the barium oxalate melted at 99.5–101°, and was characterized further as previously described. The calcium *d*-glycerate dihydrate after three recrystallizations from water showed m. p. 141–142° (uncorr.) and specific rotation +14.9 ± 0.5° in water.

Anal. Calcd. for $C_6H_{10}O_8Ca{\cdot}2H_2O$: H_2O, 12.59; Ca, 14.00. Found (from the strontium salt): H_2O, 12.78; Ca, 13.95, 13.78; (from the barium salt) H_2O, 12.61; Ca, 13.91, 13.86.

We express our thanks to Dr. R. M. Hann for a supply of galactose and S-benzylthiuronium

---

[21] Variation of the rotation with the concentration should be anticipated from the close relationship to the strontium salts.

[22] The sample of strontium salt was prepared by the oxidation of alpha-methyl-*d*-mannoside with barium hypobromite.

[23] Anderson, *Am. Chem. J.*, **42**, 421 (1909); *cf.* Nef, Hedenburg and Glattfeld, THIS JOURNAL, **39**, 1650 (1917); Fischer and Jacobs, *Ber.*, **40**, 1069 (1907).

chloride, to Dr. Alice T. Merrill for the methylguloside, to Miss Edna M. Montgomery for the methyl-arabinosides and to Mr. C. G. Remsburg for carrying out some of the analyses.

Summary

The oxidation of alpha-methyl-*d*-mannopyranoside with barium hypobromite was shown[2] to produce a dibasic acid which was isolated as its crystalline strontium salt and was proved to be a derivative of diglycolic acid (D′-methoxy-D-hydroxymethyl-diglycolic acid). The same strontium salt has been prepared in yields of 65–70% through oxidation of four alpha-methyl-hexosides (alpha-methyl-*d*-mannoside, *d*-glucoside, *d*-galactoside and *d*-guloside) with periodic acid followed by oxidation of the resulting dialdehyde with bromine water kept neutral with strontium carbonate. The structure of the strontium salt, particularly the presence of the *d*-glyceric acid moiety in its molecule, proves each of the four alpha-methyl-hexosides to be of the pyranoside type, this being the first proof for alpha-methyl-*d*-guloside. Beta-methyl-*d*-glucoside produces by way of these oxidation reactions a crystalline barium salt which also has the *d*-glyceric acid grouping in its molecule; evidence is presented that this salt is barium L′-methoxy-D-hydroxymethyl-diglycolate from which follows the pyranoside structure for beta-methyl-*d*-glucoside.

The alpha forms of methyl-*d*-arabinoside (−17°) and methyl-*d*-xyloside (+154°) yield another crystalline strontium salt (strontium D′-methoxy-diglycolate) and the beta forms of these two glycosides −245 and −65°, respectively) produce strontium L′-methoxy-diglycolate, the optical antipode of the salt from the alpha forms. Since the latter two strontium salts contains the glycolic acid structure in their molecules the four parent methyl-pentosides must have the pyranoside structure. A third crystalline methyl-*d*-arabinoside (+123°) yields the strontium salt with the *d*-glyceric acid grouping (the one from the alpha-methyl-*d*-aldohexopyranosides); this new methyl-arabinoside must therefore possess the furanoside structure and the alpha configuration.

The cleavage type of oxidation, having wide application among the glycosides, thus provides a new method for the determination of ring structures and for the correlation of the configuration of carbon atom 1 of glycosides. It also affords the most direct way of correlating the configuration of the sugars with glyceric acid.

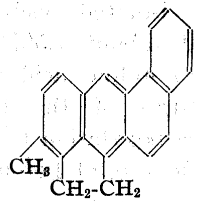
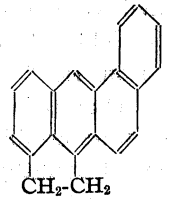
The Synthesis of 1,2-Benzanthracene Derivatives Related to 3,4-Benzpyrene

BY MELVIN S. NEWMAN

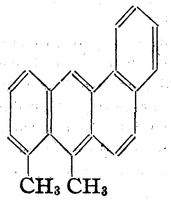
In seeking to account for the carcinogenic activity of methylcholanthrene, I, and cholanthrene, II, in terms of chemical constitution,[1] Fieser and the author[2] prepared 5,10-dimethyl-1,2-benzanthracene, III, and 10-methyl-1,2-benzanthracene, IV. In that publication it was reported that III is comparable in rapidity of action to I and II. The results of further biological tests[3] indicate that IV has approximately the same activity as I, II and III. Thus, in viewing the structures of these four compounds, the conclusion is to be drawn that the structural feature necessary for strongly developed cancer-producing properties in hydrocarbons of the 1,2-benzanthracene series is substitution at position 10.



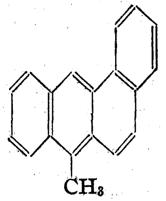
I



II



III



IV

---

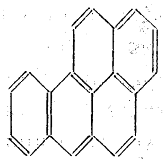
(2) Fieser and Newman, THIS JOURNAL, **58**, 2376 (1936).

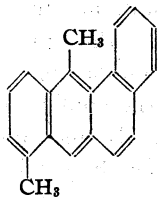
(3) Private communication from Dr. M. J. Shear. See also Fieser and Hershberg, *ibid.*, **59**, 394 (1937).

Since position 10 is a meso position, the question arises as to what effect substitution at the other meso position 9 would have. In this connection it is interesting to note that 3,4-benzpyrene, V,[4] the only known actively carcinogenic hydrocarbon which is not a 10-substituted 1,2-benzanthracene, may be considered as a 9-substituted derivative. Furthermore, 8,9-dimethylene-1,2-benzanthracene,[5] an isomer of II, is carcinogenic although its action is slow.[6]

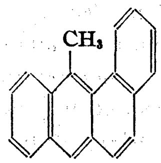


V

In order to obtain further information concerning the effect of substitution at position 9, the preparation of 5,9-dimethyl-1,2-benzanthracene, VI, and 9-methyl-1,2-benzanthracene, VII, was undertaken. In this paper the synthesis of these two hydrocarbons is reported.[7]



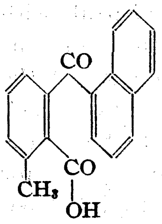
VI



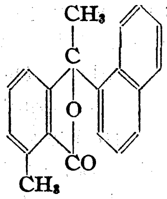
VII

From the reaction of 1-naphthylmagnesium bromide with 3-methylphthalic anhydride, prepared by sulfur dehydrogenation of the addition product from piperylene and maleic anhydride[8] a mixture was obtained from which the desired keto acid, VIII, was isolated easily in 52% yield. A small amount (about 1.5%) of the isomeric 2-(1-naphthoyl)-*m*-toluic acid was also separated. The structures of the keto acids were established by decarboxylation to the known 1-naphthyl *m*-tolyl and *o*-tolyl ketones.[9] This ratio of isomers produced from 3-methylphthalic anhydride in the Grignard reaction stands in marked contrast to the ratio of isomers formed in the Friedel–Crafts condensation. Hayashi, *et al.*,[10] condensed 3-methylphthalic anhydride with benzene and obtained approximately 38% of 2-benzoyl-*m*-toluic acid and 10% of 6-benzoyl-*o*-toluic acid.

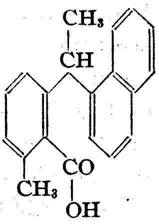
On treatment with an excess of methylmagnesium bromide, VIII was converted into the lactone, IX, in 74% yield. This lactone was reduced by zinc amalgam and hydrochloric acid in acetic acid to the acid, X, and, on cyclization with concentrated sulfuric acid at room temperature followed by reduction of the crude anthrone with zinc dust and alkali, the hydrocarbon, VI, was obtained.



VIII



IX



X

By repeating the above series of reactions using phthalic anhydride in place of 3-methylphthalic anhydride, the hydrocarbon, VII, was prepared. Of interest are the poor yields obtained in the two-step conversions of X and 2-(1-naphthylethyl)-benzoic acid into VI and VII, respectively, in contrast to the good yields in the somewhat similar preparation of III and IV.[2]

Experimental[11]

Preparation of 3-Methylphthalic Anhydride.—From the reaction between maleic anhydride and piperylene[12] was obtained 3-methyl-1,2,3,6-tetrahydrophthalic anhydride,[8] m. p. 61–62°, b. p. 155–156° at 12 mm. The observations of Farmer and Warren concerning the drop in yield of addition product when the reaction was carried out without cooling were confirmed. On dehydrogenation of 52 g. of addition product by heating at 250–260° for two hours with 20 g. (1 mol) of sulfur there was obtained, after

(6) Shear, *Am. J. Cancer*, **28**, 334 (1936).

(7) The new hydrocarbons are being tested for carcinogenic activity by Dr. M. J. Shear. After approximately three and one-half months, 5,9-dimethyl-1,2-benzanthracene, VI, has produced tumors in 18 of 20 mice and appears to rank with I in rapidity of production of tumors. During the same period, 9-methyl-1,2-benzanthracene, VII, has only produced one tumor in 20 mice. While in press the synthesis of VII by Cook, *et al.*, *J. Chem. Soc.*, 393 (1937), has been reported.

(8) Diels and Alder, *Ann.*, **470**, 102 (1929); Farmer and Warren, *J. Chem. Soc.*, 3221 (1931).

(9) Fieser and Martin, THIS JOURNAL, **58**, 1443 (1936); Bachmann, *J. Org. Chem.*, **1**, 347 (1936). Bachmann reports a melting point of 59–61° for 1-naphthyl *o*-tolyl ketone whereas Fieser and Martin, *loc. cit.*, Fieser and Newman, ref. 2, and the author give 51.5–52.5°. To clear up this discrepancy the author synthesized this ketone by Bachmann's method. The product melted at 59–61° but on crystallization of a small amount from methanol another form (thin plates) crystallized having a melting point of 51.5–52.5°. On standing for several months this sample had a melting range of 53–57°.

vacuum distillation and crystallization from benzene–ligroin, 28 g. (54%) of sulfur-free 3-methylphthalic anhydride, m. p. 115–116°.

Synthesis of 5,9-Dimethyl-1,2-benzanthracene

6-(1-Naphthoyl)-*o*-toluic Acid, VIII.—The filtered Grignard reagent prepared from 23 g. of 1-bromonaphthalene and an excess of magnesium in 120 cc. of ether and 15 cc. of benzene[13] was added rapidly (during thirty seconds) to a well-stirred solution of 16.2 g. of 3-methylphthalic anhydride in 125 cc. of benzene. No attempt was made to condense the ether which boils off during this vigorous reaction as experience showed that when this was done, the increase in pressure was sufficient to cause mercury to splash out of the mercury-sealed stirrer. The reaction mixture was worked up as before[2] and the crude keto acids (17.8 g.) recrystallized from 65 cc. of glacial acetic acid, yielded 15.2 g. (52%) of VIII, m. p. 164–165.5°. For analysis a portion was recrystallized twice from acetic acid, the melting point rising to 165.6–166.8°.

Anal. Calcd. for $C_{19}H_{14}O_3$: C, 78.60; H, 4.86. Found: C, 78.44; H, 4.85.

From the original mother liquors on concentration, slow crystallization, separation of crystals by hand, and recrystallization from acetic acid, was obtained 0.45 g. (1.5%) of the isomeric 2-(1-naphthoyl)-*o*-toluic acid as fine white needles, m. p. 234–235° after sintering at 230°.

Anal. Calcd. for $C_{19}H_{14}O_3$: C, 78.60; H, 4.86. Found: C, 78.23; H, 5.25.

Decarboxylation of the Acids.—These reactions were carried out as before:[2] from VIII was obtained 1-naphthyl *m*-tolyl ketone, m. p. and mixed m. p. 74.5–75.8°;[9] and from 2-(1-naphthoyl)-*m*-toluic acid was obtained 1-naphthyl *o*-tolyl ketone, m. p. and mixed m. p. 51.5–52.5°.[9]

Lactone of 6-(α-Hydroxy-α-1-naphthylethyl)-*o*-toluic Acid, IX.—The filtered Grignard reagent from 1.8 g. of magnesium and methyl bromide in 90 cc. of ether was added slowly to a warm well-stirred solution of 8.7 g. of VIII in 250 cc. of benzene. The initial cream colored complex turned greenish-yellow and finally light yellow. After two hours of refluxing the mixture was decomposed with dilute hydrochloric acid. From the neutral fraction, freed of acids by a sodium carbonate washing, was obtained 6.4 g. (74%) of lactone, IX, m. p. 131.4–132.0° as white plates. A portion was recrystallized from alcohol, m. p. 131.6–132.0°.

Anal. Calcd. for $C_{20}H_{16}O_2$: C, 83.30; H, 5.66. Found: C, 83.07; H, 5.67.

6-(α-1-Naphthylethyl)-*o*-toluic Acid, X.—A solution of 4.74 g. of IX in 100 cc. of acetic acid was refluxed over zinc amalgam[14] for ten hours with gradual addition of 100 cc. of concentrated hydrochloric acid. The acid fraction yielded 1.9 g. (40%) of X as colorless needles, m. p. 156.0–158.5° from benzene. A portion twice crystallized from acetic acid had a melting point of 162–162.6°.

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 82.72; H, 6.25. Found: C, 82.77; H, 6.09.

5,9-Dimethyl-1,2-benzanthracene, VI.—To 20 cc. of concentrated sulfuric acid at 20° was added 1.54 g. of powdered X with swirling until a homogeneous orange solution resulted. After two hours the acid was poured on ice and the pale yellow anthrone collected by filtration. It was immediately transferred to a flask with 2 g. of zinc dust, previously activated with copper sulfate, and 100 cc. of 15% sodium hydroxide. The mixture was refluxed for five hours, a few drops of amyl alcohol being added to prevent excessive foaming. After strongly acidifying with hydrochloric acid, the product, VI, was collected on a filter and crystallized from benzene–alcohol to yield 0.50 g. of white shiny plates, m. p. 135–135.5°. In ultraviolet light the hydrocarbon has a brilliant blue fluorescence.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.70; H, 6.30. Found: C, 93.51; H, 6.57.

Synthesis of 9-Methyl-1,2-benzanthracene

Lactone of 2-(α-Hydroxy-α-1-naphthylethyl)-benzoic Acid.—The filtered Grignard reagent from 7.29 g. of magnesium and methyl bromide in 200 cc. of ether was added slowly to a warm well-stirred solution of 13.80 g. of *o*-(1-naphthoyl)-benzoic acid[15] in 200 cc. of ether and 250 cc. of benzene. The pale yellow complex which immediately separated gradually took on a greenish tinge and finally dissolved to give a pale yellow solution. After two hours of refluxing the mixture was decomposed with dilute hydrochloric acid. From the neutral fraction, freed of acids by washing with sodium carbonate, was obtained 8.0 g. (58%) of almost colorless plates, m. p. 152.8–153.6°. A sample of this compound, the desired lactone, recrystallized from alcohol melted at 154.5–155.0°.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.18; H, 5.15. Found: C, 83.35; H, 5.33.

***o*-(α-1-Naphthylethyl)benzoic Acid.**—A solution of 8.6 g. of the above lactone in 150 cc. of acetic acid was refluxed over 50 g. of zinc amalgam for twelve hours with slow addition of 150 cc. of concentrated hydrochloric acid in 50 cc. of acetic acid. The mixture was diluted with water and thoroughly extracted with ether. The acid reduction product was separated by means of extraction with sodium carbonate and on crystallization from benzene–ligroin, 7.1 g. (82%) of the desired acid was obtained as white needles, m. p. 168–169°. A sample recrystallized from acetic acid melted at 169.4–170°.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84. Found: C, 82.49; H, 5.89.

9-Methyl-1,2-benzanthracene.—For cyclization, 1.94 g. of the above acid was powdered and added to a cold solution of 1 g. of boric acid in 20 cc. of concentrated sulfuric acid. After two hours at room temperature the orange solution was poured on ice and the crude pale yellow anthrone reduced by boiling for six hours with 2 g. of zinc dust (activated) and 100 cc. of 12% sodium hydroxide. Amyl alcohol was again necessary to prevent foaming. After working the reaction mixture up as above there was obtained 0.45 g. (26%) of pale yellow flat needles, m. p.

---

[13] All benzene used in this and other Grignard reactions was thiophene free.

[14] The poor yield in this step which ordinarily (reference 2 and in this paper below) proceeds in excellent yield was probably due in this case to the poor quality of the zinc used. During the reduction the surface of the zinc had an entirely different appearance from the usual bright surface in such reactions.

138.4–138.8°. Neither the color nor the melting point was improved by chromatographic adsorption using activated alumina.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.83. Found: C, 94.20; H, 5.93.

Summary

A rather general method is described for the synthesis of 1,2-benzanthracenes containing a substituent at the meso position 9. This method involves the following steps: reaction of 1-naphthylmagnesium bromide with phthalic anhydride (or 3-methylphthalic anhydride); addition of methylmagnesium bromide to the ketonic carbonyl group of the resulting keto acid; reduction of the resulting lactone to an acid; and cyclization and reduction to the hydrocarbon. In this manner, 5,9-dimethyl-1,2-benzanthracene and 9-methyl-1,2-benzanthracene have been prepared for the purpose of comparing their possible carcinogenic activity with that of 10-methyl-1,2-benzanthracene and that of 3,4-benzpyrene.

COLUMBUS, OHIO RECEIVED APRIL 3, 1937

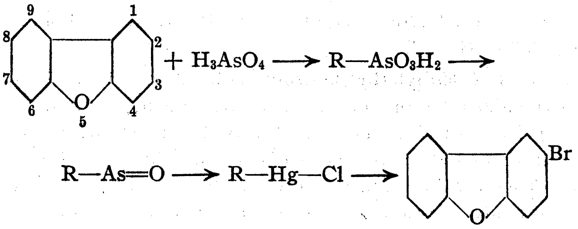
Arsenicals Containing the Dibenzofuran Nucleus

BY BENJAMIN F. SKILES[1] AND CLIFF S. HAMILTON

Dibenzofuran was arsonated directly by heating it with arsenic acid. The structure of the arsonic acid formed was problematical for, in the case of dibenzofuran, the nature of the entering groups has a marked effect upon the position assumed by nuclear substituents. Nitration involves principally the 3-position;[2] sulfonation,[3] and halogenation[4] favor the 2-position exclusively, while in metalation[5] the substituent enters the 4-position. The following sequence of reactions



was used to prove that dibenzofuran on direct arsonation yields 2-dibenzofurylarsonic acid.[3,6]

3-Dibenzofurylarsonic acid[7] was prepared by means of a Bart[8] reaction utilizing 3-aminodibenzofuran as a starting material. The product was nitrated to yield nitro-3-dibenzofurylarsonic acid, and then converted into nitro-3-dibenzofuryldichloroarsine which on heating to 350° with mercuric acetate gave 2-nitrodibenzofuran. This indicated that the nitro group entered either the 2- or the 8-position. Since the arsono group is a meta director in the benzene ring, and 3-nitrodibenzofuran on nitration yields 3,8-dinitrodibenzofuran, the latter structure seemed the more probable. The nitration product was shown to be 8-nitro-3-dibenzofurylarsonic acid by preparing a sample of this acid having a known structure and converting it into the dichloroarsine which was identical with the one prepared from the nitration product (mixed m. p.).

3-Dibenzofurylarsonic acid on sulfonation gave sulfo-3-dibenzofurylarsonic acid. The structure of this compound has not been established but it is probably 8-sulfo-3-dibenzofurylarsonic acid.

(7) Since the completion of this investigation, an article by Davies and Othen has appeared recording the preparation of dibenzofurylarsonic acids containing the arsono group in the 2-, 3- and 4-positions; *J. Chem. Soc.*, 1236 (1936).

(8) Bart, *Ann.*, **429**, 55 (1922).

Experimental

2-Dibenzofurylarsonic Acid.—An intimate mixture of 30 g. of arsenic acid and 30 g. of dibenzofuran was heated at 175° for three hours with constant stirring. The temperature was then increased to 220° for ten minutes, the mixture becoming very tarry. This mass was extracted first with water and then with *N* sodium hydroxide. The alkaline solution was made neutral to litmus with hydrochloric acid and the precipitated tar filtered off. Acidification of the filtrate to Congo red paper precipitated 2-dibenzofurylarsonic acid; purified by extraction with hot concentrated hydrochloric acid and crystallization from glacial acetic acid; yield 6 g., not melted at 250°.

Anal. Calcd. for $C_{12}H_9O_4As$: As, 25.68. Found: As, 25.52, 25.57.

2-Dibenzofurylarsine Oxide.—Five grams of 2-dibenzofurylarsonic acid was suspended in 50 cc. of boiling glacial acetic acid and 5 cc. of phosphorus trichloride, dissolved in 20 cc. of glacial acetic acid, was added slowly. The solution was refluxed for thirty minutes and then cooled in an ice-bath, the 2-dibenzofuryldichloroarsine separating as an oil which solidified on standing. This product was not isolated, but was hydrolyzed to the arsine oxide by refluxing with boiling water for two hours. The water-insoluble product was recrystallized from a methyl cellosolve–water mixture; yield 80%, not melted at 250°.

Anal. Calcd. for $C_{12}H_7O_2As$: As, 28.96. Found: 29.02, 29.00.

Structure Proof.—Two grams of 2-dibenzofurylarsine oxide and 5 g. of mercuric acetate were dissolved in 150 cc. of glacial acetic acid and refluxed for one hour. Addition of a glacial acetic acid solution of calcium chloride gave a white precipitate of 2-dibenzofurylmercuric chloride which was extracted with water and recrystallized with acetone; yield 80%, m. p. 235° (checks value in literature[3]).

Gilman's method[3] was used to convert the 2-dibenzofurylmercuric chloride to 2-bromodibenzofuran. The product obtained was identified by means of a mixed melting point with a known sample of 2-bromodibenzofuran prepared by brominating dibenzofuran.[4]

3-Dibenzofurylarsonic Acid.—Eighteen grams of 3-aminodibenzofuran was diazotized in 1.0 liter of *N* hydrochloric acid and the solution added slowly to a mechanically stirred mixture containing 19 g. of sodium arsenite, 0.25 g. of copper sulfate, and 300 g. of sodium carbonate dissolved in 8.0 liters of water and cracked ice. The resulting solution was stirred for four hours, allowed to stand at room temperature for twelve hours, and then filtered through a charcoal mat. Acidification of the filtrate with concd. hydrochloric acid precipitated the 3-dibenzofurylarsonic acid; yield 70%. Recrystallization from glacial acetic acid gave a white crystalline compound, not melted at 275°.

Anal. Calcd. for $C_{12}H_9O_4As$: As, 25.68. Found: As, 25.55, 25.58.

3-Dibenzofuryldichloroarsine.—An 85% yield of this compound was obtained by adding slowly a solution of 10 cc. of phosphorus trichloride, dissolved in 25 cc. of glacial acetic acid, to a boiling suspension of 3-dibenzofurylarsonic acid in 75 cc. of glacial acetic acid, and refluxing the resulting solution for thirty minutes. On cooling, the dichloroarsine crystallized out as a white solid; an additional amount was obtained by adding 10 cc. of concd. hydrochloric acid to the mother liquor; m. p. 130°, after recrystallization from glacial acetic acid.

Anal. Calcd. for $C_{12}H_7OAsCl_2$: As, 23.96; Cl, 22.68. Found: As, 24.00, 24.04; Cl, 22.44, 22.52.

3-Dibenzofurylarsine Oxide.—A theoretical yield of the oxide was obtained by boiling 3-dibenzofuryldichloroarsine for two hours with water. Recrystallization from a methyl cellosolve–water mixture gave a white solid, not melted at 250°.

Anal. Calcd. for $C_{12}H_7O_2As$: As, 28.96. Found: As, 29.03, 29.01.

8-Nitro-3-dibenzofurylarsonic Acid.—This compound was prepared by two different methods. In one, 8-nitro-3-aminodibenzofuran served as the starting compound, while in the other 3-dibenzofurylarsonic acid was used.

Method I.—Four grams of 8-nitro-3-aminodibenzofuran[9] dissolved in 120 cc. of glacial acetic acid was diazotized with 3 g. of sodium nitrite dissolved in 20 cc. of water. This solution was diluted with 200 cc. of aqueous 2 *N* hydrochloric acid and added slowly to a mechanically stirred solution containing 10 g. of sodium arsenite, 0.25 g. of copper sulfate, and 200 g. of sodium carbonate dissolved in 1.0 liter of water and cracked ice. The solution was stirred for three hours and after standing for twelve hours at room temperature was filtered through a charcoal mat. On acidification of the filtrate with hydrochloric acid 8-nitro-3-dibenzofurylarsonic acid separated; yield 35%; purified by extraction with glacial acetic and concd. hydrochloric acids followed by solution in alkali, filtration and precipitation with hydrochloric acid; yellow solid, not melted at 280°.

Anal. Calcd. for $C_{12}H_8O_6NAs$: As, 22.26. Found: As, 22.35, 22.37.

Method II.—Nine grams of 3-dibenzofurylarsonic acid was treated for two hours at 5° with fuming nitric acid (d. 1.48) and the resulting solution poured into 400 cc. of ice water. The arsonic acid separated as yellow solid; purified as above; yield 70%.

8-Nitro-3-dibenzofuryldichloroarsine.—Twenty grams of 8-nitro-3-dibenzofurylarsonic acid was suspended in 100 cc. of boiling glacial acetic acid and 20 cc. of phosphorus trichloride, dissolved in 30 cc. of glacial acetic acid, was added slowly. The solution was refluxed for thirty minutes and on cooling the dichloroarsine precipitated as a yellow solid. An additional amount was obtained by adding 125 cc. of concd. hydrochloric acid to the mother liquor. Recrystallization from glacial acetic acid gave an 80% yield; m. p. 152°.

Two preparations of 8-nitro-3-dibenzofuryldichloroarsine were made by this procedure. In one, the 8-nitro-3-dibenzofurylarsonic acid prepared from 8-nitro-3-aminodibenzofuran was used. In the other the product, obtained when 3-dibenzofurylarsonic acid was nitrated, served as the starting material. The dichloroarsines obtained from these two reactions were identical (mixed melting points).

---

(9) Cullinane, *J. Chem. Soc.*, 2365 (1932).

Anal. Calcd. for $C_{12}H_6O_3NAsCl_2$: As, 20.95; Cl, 19.83. Found: As, 21.05, 21.04; Cl, 19.57, 19.61.

Structure Proof.—An intimate mixture of 15 g. of 8-nitro-3-dibenzofuryldichloroarsine and 15 g. of mercuric acetate was fused for ten minutes at 350°. An acetic acid extract of this melt on dilution with water gave 1 g. of a yellow solid, m. p. 149° after crystallization from an alcohol-acetone mixture. It was identified as 2-nitrodibenzofuran by means of a mixed melting point.[9] Reduction of this compound gave 2-aminodibenzofuran, m. p. 125°, and acetylation of the amine produced 2-acetaminodibenzofuran, m. p. 162°.

8-Nitro-3-dibenzofurylarsine Oxide.—A quantitative yield of the oxide was obtained by the hydrolysis of 2 g. of 8-nitro-3-dibenzofuryldichloroarsine with boiling water for four hours; light orange product after crystallization from methyl cellosolve, not melted at 250°.

Anal. Calcd. for $C_{12}H_6O_4NAs$: As, 24.75. Found: 24.67, 24.65.

8-Amino-3-dibenzofurylarsonic Acid.—A quantitative yield of this acid was obtained by reducing an alkaline solution of 8-nitro-3-dibenzofurylarsonic acid with hydrogen using the Raney catalyst.[10] Acidification to litmus with concd. hydrochloric acid produced a white precipitate of the amine which was recrystallized from dilute hydrochloric acid; not melted at 250°.

Anal. Calcd. for $C_{12}H_{10}O_4NAs$: As, 24.43. Found: As, 24.48, 24.44.

Sulfo-3-dibenzofurylarsonic Acid.—A suspension of 9 g. of 3-dibenzofurylarsonic acid in 60 cc. of concd. sulfuric acid was heated over a steam-bath for two hours. The solution was then cooled in an ice-bath and diluted with water until a heavy white precipitate was formed; not melted at 300° after recrystallization from water. The structure of this compound has not been proved but it is probably 8-sulfo-3-dibenzofurylarsonic acid.

Anal. Calcd. for $C_{12}H_9O_7SAs$: As, 20.16. Found: As, 20.30, 20.27.

Sulfo-3-dibenzofurylarsine Oxide.—An 80% yield of the oxide was obtained by bubbling sulfur dioxide through a solution of 0.5 g. of potassium iodide, and 1 g. of sulfo-3-dibenzofurylarsonic acid in 150 cc. of 2 *N* hydrochloric acid. At the end of twenty minutes the precipitated arsine oxide was filtered out and purified by salting it out of a water solution, not melted at 275°.

Anal. Calcd. for $C_{12}H_7O_6SAs$: As, 22.19. Found: As, 22.39, 22.37.

Summary

1. Direct arsonation of dibenzofuran gives 2-dibenzofurylarsonic acid as shown by structure proof; its oxide is described.

2. 3-Dibenzofurylarsonic acid has been prepared through the diazo reaction and converted into the dichloroarsine and oxide by reduction. Nitration of 3-dibenzofurylarsonic acid gives the 8-nitro derivative and from this the corresponding amine compound has been obtained by catalytic reduction.

3. 3-Dibenzofurylarsonic acid has been sulfonated directly.

Antioxidants and the Autoxidation of Fats. IX. The Antioxidant Properties of the Tocopherols

BY H. S. OLCOTT AND O. H. EMERSON

The unsaponifiable fraction of some vegetable oils exhibits marked antioxidant properties when small amounts are added to lard. Olcott and Mattill[1] have recorded some of the characteristics of the active principles which they called inhibitols. When wheat germ oil or cottonseed oil was used as the source, the inhibitol concentrates contained a large amount of vitamin E from which the inhibitols could not be separated. The successful isolation of three individual compounds possessing vitamin E activity from these oils by Evans, Emerson and Emerson[2-4] provided an opportunity for ascertaining the relationship between the inhibitols and tocopherols.

The three tocopherols and their allophanates were assayed for antioxidant activity by the oxygen absorption method previously described.[5] The tocopherols were effective antioxidants in lard and oleo oil, but had no activity in esters prepared from hydrogenated cottonseed oil (Table I). Since the inhibitol concentrates from wheat germ oil and cottonseed oil behave similarly,[6] it seems apparent that they owe at least part, and possibly all, of their antioxidant activity to the tocopherols. However, the inhibitols obtained

from lettuce[7] and tomatoes[8] in the methanol fraction after distribution between petroleum ether and 92% methanol are presumably not tocopherols, since the latter, on distribution between these solvents, are found in the petroleum ether phase, and have, moreover, appreciably higher boiling points.

	.02	2.0	2.0

[a] Approximate minimum effective dose when administered to vitamin E deficient female rats; α-tocopherol, 1–3 mg.; β-tocopherol, 3–5 mg.; γ-tocopherol, 1–3 mg. Biological assays from the two laboratories showed reasonable agreement. [b] The γ-tocopherol and its allophanate used in these tests contained some α-tocopherol. [c] M. p. 157–158°. [d] M. p. 138°. [e] M. p. 135–135.5°.

The tocopherols are increasingly effective as antioxidants in the order α, β, γ. On the other hand, as vitamin E, β is less effective than α or γ. This lack of correlation between the antioxidant and vitamin properties of the pure substances offers an explanation for the previously observed lack of direct relationship in the concentrates.[1,6]

Vitamin E concentrates virtually free from antioxidant activity have been described.[7,8] A possible explanation of these results may be based on the assumption that the preparations were not completely hydrolyzed. Simple esters of the tocopherols are effective as the vitamin, but ineffective as antioxidants. The possibility that vitamin E may occur in nature in the form of an ester has been suggested previously.[9]

The antioxidant activity of the tocopherol allophanates (Table I) was unexpected, inasmuch as previous observations had indicated that the activity of inhibitols and of antioxidants of known structure depended on the presence of a free hydroxyl group.[1,10] However, the fact that α-naphthol allophanate[11] is also an effective antioxidant while cholesterol allophanate is not, suggests that the activity of the allophanates parallels that of the parent compounds.

Since antioxidants of known structure are phenolic in nature,[10] the antioxygenic activity of the tocopherols suggests that they may belong to this class of substances. The absorption spectrum of the tocopherols resembles that of hydroquinone; however, the tocopherols differ from most phenols in having little or no acidic properties.

Acknowledgment.—One of us (H. S. O.) is indebted to Lever Brothers Company for a grant in support of this work.

Summary

α, β and γ tocopherols and their allophanates are effective antioxidants in lard. The degree of protection afforded by the tocopherols is not proportional to their vitamin E activity.

The Condensation of Acetic Acid and Cyclohexene in the Presence of Boron Fluoride

BY H. L. WUNDERLY AND F. J. SOWA

The purpose of this study was to determine the effect of boron fluoride upon the formation of cyclohexyl acetate from cyclohexene and acetic acid.[1] A series of reactions was carried out at constant temperature with a variation in the percentage of boron fluoride and the time of reaction.

Experimental Part

The experimental procedure for all reactions was the same as that described below. The boron fluoride was used in the form of the acetic acid–boron fluoride compound which was prepared according to the method of Bowlus and Nieuwland.[2] The acetic acid and acetic acid–boron fluoride compound were weighed into a 250-cc. glass bottle.

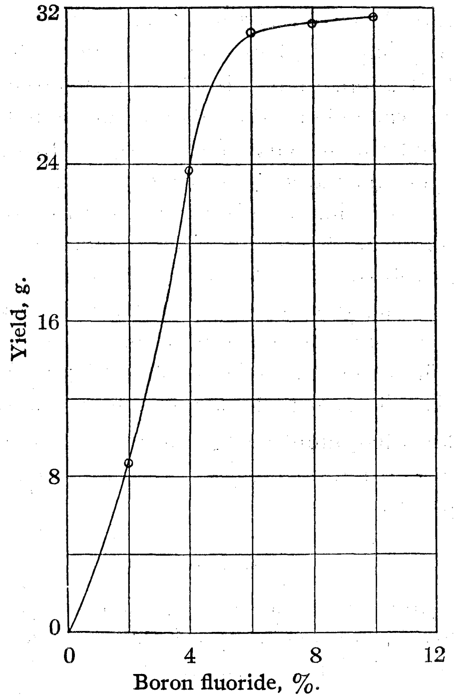

Fig. 1.

The percentage of boron fluoride used was calculated on the basis that the sum of the weight percentages of acetic acid and of boron fluoride was equivalent to 100%. One-third of a mole of cyclohexene,[3] b. p. 82°, distilled twice through a 45-cm. Widmer column, was weighed separately and then added to the acetic acid–boron fluoride mixture in the glass bottle. The reaction bottle was sealed and immediately put into a thermostatically regulated oil-bath kept at a temperature of 80 ± 0.5°. The reaction time was varied from fifty to two hundred and twenty hours. Upon the elapse of time the reaction bottle was removed from the bath and cooled to room temperature. Then the bottle was opened and the contents weighed in order to check whether any loss due to leakage had occurred. The mixture was neutralized with saturated sodium carbonate solution and the upper layer separated (all residues were collected in ether and added to the upper layer). After the ester and cyclohexene layer was washed with water and dried over calcium chloride the mixture was fractionated carefully and the fraction boiling at 175° was collected as the ester. Upon the removal of the ester fraction the temperature rose rapidly and the distillation was discontinued. The quantity of residue varied from 1.5 to 8.9 g. depending upon the quantity of boron fluoride used. The following yields for the varying amounts of boron fluoride, substantially unchanging with time, were obtained. The apparent equilibria were plotted against the percentage boron fluoride as shown in Fig. 1.

TABLE I

BF$_3$, %	2	4	6	8	10	15	18
Yield, g.	8.1–8.8	23.5–23.8	30.7–31	31.3	31.6	31.9[a]	29.3[a]

[a] Diminishing slowly with time.

The solubility of boron fluoride in cyclohexyl acetate was determined by slowly passing boron fluoride into 0.868 mole of the ester. After a period of eleven hours it was found that 0.882 mole of the boron fluoride was absorbed. Heat was liberated during the absorption of the boron fluoride; however, as the quantity of boron fluoride reached a mole per mole ratio with the ester the mixture gradually cooled to room temperature. The absorption also became extremely slow as the molar ratio was reached.

Discussion

It had been noticed throughout the purifications that the quantity of residue obtained from the individual runs having concentrations of boron fluoride equivalent to 10% and less ranged between 1.5 and 1.9 g. Beyond these concentrations of boron fluoride the quantity of residue increased rapidly. This indicates that higher concentrations of boron fluoride rapidly effects polymerization. In addition it was found that one mole of boron fluoride was absorbed by one mole of cyclohexyl acetate. Thus when a sufficient quantity of ester was produced with the lower concentrations of boron fluoride the boron fluoride was made inactive by absorption in the ester. Thereupon the yield of ester remained constant for that particular percentage of boron fluoride giving the appearance of an equilibrium. As higher percentages of boron fluoride were used

these equilibria approached one another until a maximum was reached. Beyond this point polymerization occurred with a prolongation of reaction time and the yield of ester subsequently decreased.

An explanation for this gradual approach to a maximum is offered on the basis of the following considerations: that the concentration of boron fluoride necessary for bringing about a reverse of the condensation reaction having a reaction velocity equal to that of the condensation reaction, is greater than that used for the condensation itself. Thus in those reactions where low concentrations of boron fluoride are used a state is reached in which the boron fluoride is absorbed by the ester and the concentrations are not sufficient to effect a reversal having a velocity equal to the condensation velocity. As the concentration of boron fluoride is increased in the ester the velocity of the reverse reaction is increased. When the proper amount of boron fluoride is present the velocity of the reverse reaction is equivalent to the velocity of the condensation reaction: there being sufficient boron fluoride on both sides of the reaction to cause the reverse and condensation reactions to proceed with equal velocities. Beyond this concentration of boron fluoride polymerization is more pronounced.

Summary

The influence of time and concentration of boron fluoride upon the condensation of acetic acid with cyclohexene at a constant temperature has been studied. The concentration of boron fluoride is shown to have a marked effect upon the quantity of ester obtained. An explanation was offered for the change in apparent equilibria with the quantity of boron fluoride used.

Sulfur Studies. XI. Some Sulfur Derivatives of Benzaldehyde

BY J. H. WOOD AND R. W. BOST

Practically nothing is known about monomeric thioaldehydes since they polymerize immediately upon formation. However, the conditions under which they are formed profoundly influence the nature of the resulting polymerization and we have found that reactions by which one would expect to obtain monomeric thiobenzaldehyde lead to a variety of compounds such as the thioester, the mercaptan, the dithio acid, the disulfide, the cyclic trimer, and other polymers. It is the purpose of this paper to describe some of these reactions and to offer a mechanism for the formation of some of the compounds obtained.

Benzal chloride and sodium sulfide react in alcoholic solution to form monomeric thiobenzaldehyde, C_6H_5CHS. However, the compound cannot be isolated and it immediately undergoes polymerization or side reactions. A part polymerizes to β-trithiobenzaldehyde. Some undergoes the Cannizzaro reaction to give benzyl mercaptan, dithiobenzoic acid, and a small amount of benzyldithiobenzoate. A portion of the mercaptan then reacts with thiobenzaldehyde to form a small quantity of benzyl mercaptal of benzaldehyde.

It has been suggested that the Cannizzaro reaction proceeds through ester formation. Our work confirms this belief. That is, thiobenzaldehyde readily undergoes polymerization to dithiobenzoate, and in the presence of alkalies such as sodium sulfide, the ester is saponified to the thio alcohol and dithio acid. On the other hand, the Cannizzaro reaction involving thiobenzaldehyde can be arrested at the ester stage provided that the monomer is formed under conditions which do not produce saponification of the ester. This is accomplished by depolymerizing β-trithiobenzaldehyde by distilling it at 3 mm. in the presence of a few drops of sulfuric acid. A part of the monomer in the distillate immediately re-polymerizes to the trimer and the rest polymerizes to the ester. The Cannizzaro reaction can then be completed from this point if desired by adding sodium sulfide whereupon the thio acid and thio alcohol are immediately formed.

While β-trithiobenzaldehyde is mainly depolymerized by distilling at low pressure in the presence of sulfuric acid, some decomposition also occurs with the formation of stilbene and sulfur. Some tetraphenylthiophene is also formed by the interaction of stilbene and sulfur. When the distillation is carried out in the absence of sulfuric acid, decomposition into stilbene and sulfur with the resultant formation of tetraphenylthiophene is the main course of the reaction rather than depolymerization.

When hydrogen sulfide is passed into an alcoholic solution of benzaldehyde previously saturated with dry hydrogen chloride, trithiobenzaldehyde is formed exclusively.[1] By reducing the acid concentration other types of polymers, perhaps linear, are obtained in the form of pink gums along with varying quantities of the trimer. The pink gum cannot be purified by recrystallization or by vacuum distillation. The latter brings about complete decomposition, mainly into stilbene and sulfur. The monomer does not undergo the Cannizzaro reaction in acid solution.

Hydrogen sulfide reacts with benzaldehyde in the presence of small amounts of potassium hydroxide or sodium hydroxide to form thiobenzaldehyde. Most of the thiobenzaldehyde immediately polymerizes to form a viscous, pink oil; the remainder undergoes the Cannizzaro reaction. Upon distillation *in vacuo*, the pink oil is decomposed to form mostly stilbene and sulfur. However, some benzyl dithiobenzoate also is formed which indicates slight depolymerization.

Fromm and Forster[2] report the preparation of benzyl dithiobenzoate by refluxing an alcoholic solution of C_6H_5CSSNa and sodium hydroxide with an excess of benzyl chloride. They describe the ester as being white prisms, m. p. 55°. Since the other known esters of dithiobenzoic acid are red oils, we repeated the work of Fromm and Forster and obtained in good yield benzyl sulfide, m. p. 50°, instead of the ester. The sulfide was identified by conversion into the sulfone by the method of Bost, Turner and Norton.[3] One would not expect to obtain the ester under the experimental conditions specified by Fromm and Forster since as rapidly as the ester was formed, it would be saponified by the sodium hydroxide, at the elevated temperature, with the formation of C_6H_5CSONa and $C_6H_5CH_2SNa$. The mercaptide would then react with the excess benzyl chloride to form benzyl sulfide. By modifying the experimental conditions, we have obtained the ester in good yield as a red oil, b. p. 179–180° at 3 mm.

Experimental Work

The Reaction of Sodium Sulfide and $C_6H_5CHCl_2$.—Seven and eight-tenths grams of sodium sulfide and 16.1 g. of $C_6H_5CHCl_2$ were dissolved in 125 cc. of anhydrous ethyl alcohol and allowed to stand at room temperature in an atmosphere of nitrogen for a week or longer. A red supernatant liquid and a white precipitate resulted. The same results were also obtained by refluxing six to eight hours. After the reaction was complete, the precipitate was filtered off in an atmosphere of nitrogen and later showed to be sodium chloride and β-trithiobenzaldehyde. A search was made immediately for the monomeric thiobenzaldehyde in the red alcoholic solution. This was done by examining a portion with 2,4-dinitrophenylhydrazine (since benzal chloride, the oxobenzaldehyde, and the thiobenzaldehyde all give the same hydrazone, the first two compounds would interfere with the test and their presence or absence had to be determined); by testing for a thiocarbonyl group with Grote's reagent;[4] and by a fractional vacuum distillation with the subsequent identification of the compounds thus obtained. Benzyl mercaptan and benzyl dithiobenzoate were identified in the distillate. No monomer of thiobenzaldehyde was isolated. The remaining red alcoholic solution was examined as follows: an equal volume of 4% aq. sodium hydroxide solution was added and the whole was then extracted with benzene. Dithiobenzoic acid was isolated from the aqueous portion. The benzene extract was permitted to evaporate spontaneously and the residue was then recrystallized from ethyl alcohol. Benzyl disulfide, benzyl mercaptal of benzaldehyde, and benzyl dithiobenzoate were identified in this portion.

The Reaction of Benzaldehyde and Hydrogen Sulfide in the Presence of Acids.—Hydrogen sulfide passed into an alcoholic solution of benzaldehyde previously saturated with dry hydrogen chloride gives exclusively trithiobenzaldehyde. We have tried varying concentrations of hydrogen chloride from a few bubbles to complete saturation with the hope of finding an acid concentration in which the monomeric thiobenzaldehyde would be stable. The runs were carried out by saturating 5 cc. of benzaldehyde in 20 cc. of absolute ethyl alcohol at −5° with hydrogen sulfide. A few bubbles of dry hydrogen chloride were then passed in while the passage of hydrogen sulfide was continued. An intense blue color formed and rapidly faded with the formation of a sticky white precipitate and a pink gum. Upon increasing the quantity of hydrogen chloride the blue color faded more rapidly. The sticky white precipitate was soluble in benzene from which it was deposited as a pink gum upon complete evaporation of the benzene. Some trithiobenzaldehyde also was formed. Other runs were carried out at room temperature with the same results. Other runs were carried out in which sulfuric acid, zinc chloride, acetic acid, magnesium perchlorate, and phosphorus pentoxide were substituted for hydrogen chloride and gave results identical with above.

The Action of Hydrogen Sulfide upon Benzaldehyde in Presence of Potassium Hydroxide.—Concentration: 0.5 g. KOH; 20 cc. C_6H_5CHO; 100 cc. absolute ethyl alcohol. Hydrogen sulfide was passed in at room temperature for

four days. A large quantity of a viscous, pink oil separated during this time and the alcohol layer was colored red. Benzyl mercaptan was identified as one of the products of the reaction by vacuum distillation of a portion of the red alcohol layer. The mercaptan thus obtained was converted into the benzyl 2,4-dinitrophenyl thioether by the method of Bost, Turner and Norton.[3] To the remaining red alcohol layer, an equal volume of 4% aq. sodium hydroxide was added whereupon benzyl disulfide precipitated and was filtered off. The aqueous solution was acidified with hydrochloric acid and then extracted with benzene. The red benzene extract was shaken with lead acetate solution. A precipitate formed which was recrystallized from hot toluene. Red needles resulted, m. p. 205°, which were lead dithiobenzoate.

Vacuum Distillation of Pink Oil.—A special distilling apparatus had to be used in this work due to the fact that a number of compounds distilled over together once depolymerization or decomposition began, and some of these compounds were solids which immediately solidified in the side-arm. The side-arm of the distilling flask had an inside diameter of 2 mm. and at a distance of about 15 mm. from the neck was bent downward so as to make a vertical connection with a bulb to receive solids and high boiling liquids. A horizontal connection at the bend led to an ice trap to condense the more volatile components. All connections and joints were made of ground glass. The neck was a separate piece with ground glass connections so as to permit the use of different size distilling bulbs. An oil-bath was used to heat the distilling flask. The pressure was 3 mm. Decomposition started at about 120° with a change of color to deep red. Heating was continued to 200°. The following compounds were identified in the distillate: benzyl mercaptan, benzyl disulfide, stilbene, and benzyl dithiobenzoate. The mercaptan was in the more volatile portion. The disulfide, stilbene, and the ester distilled over together and had to be separated by fractional recrystallization from ethyl alcohol. The residue left in the distilling flask was recrystallized from ethyl alcohol and gave sulfur and tetraphenylthiophene.

Vacuum Distillation of β-Trithiobenzaldehyde.—The distillation was carried out in the apparatus described above and at a pressure of 3 mm. Depolymerization and decomposition started upon melting (225°). Sulfur, stilbene, tetraphenylthiophene, a few drops of benzyl dithiobenzoate, and a few drops of benzaldehyde were identified as the decomposition products.

Sulfuric acid catalytically depolymerizes paraldehyde and we have attempted to do the same with β-trithiobenzaldehyde. Ten grams of the trimer and 3 drops of concd. sulfuric acid were distilled at a pressure of 3 mm. β-Trithiobenzaldehyde and benzyl dithiobenzoate were the main products of distillation. A few drops of benzaldehyde and a small quantity of stilbene were also formed. Depolymerization instead of decomposition undoubtedly occurred in this distillation since the large quantities of stilbene, sulfur, and tetraphenylthiophene were not formed as was the case of the distillation carried out in the absence of sulfuric acid. However, the distillate immediately polymerized to the trithiobenzaldehyde, or underwent the Cannizzaro reaction.

Another vacuum distillation of the trimer in which phosphoric acid was used as the depolymerizing agent gave the same results.

Preparation of Benzyl Dithiobenzoate.—When the calculated quantity of benzyl chloride is added to a solution of 5.2 g. of dithiobenzoic acid in 50 cc. of ethyl alcohol and 35 cc. of 10% aq. sodium hydroxide at 80° and shaken, a red oil separates. This oil boils at 179–180° at 3 mm.; decolorizes Feigel's solution; upon standing in contact with concd. ammonium hydroxide for six days gives benzamide, benzyl mercaptan, and hydrogen sulfide. This red oil is benzyl dithiobenzoate. Sulfur found: 26.07%. Calcd.: S, 26.20%.

Saponification of Ester.—Three grams of sodium sulfide was dissolved in 40 cc. of absolute alcohol and 1 cc. of benzyl dithiobenzoate was added. The temperature was about 25°. In a few minutes the bright red color of the ester had changed to the darker red color of the acid. After a few hours, the reaction seemed to be complete and an equal volume of water was added. No precipitation of the ester occurred showing that the soluble sodium dithiobenzoate and sodium benzyl mercaptide had been formed. The dithio acid was isolated as described previously; the mercaptan was converted into the insoluble benzyl disulfide by bubbling air through a portion of the solution followed by filtration and recrystallization of the disulfide from alcohol. Incidentally, these reactions offer a satisfactory method for identifying benzyldithiobenzoate.

Action of Hydrogen Sulfide upon $(C_6H_5CH{=}NH\cdot HCl)_2\cdot SnCl_4$.—The aldimine stannichloride was prepared by the method of Stephens.[5] Hydrogen sulfide was passed into an alcoholic solution of the salt for twenty-four hours. A transparent plastic substance that melted between 100–110° was obtained. Some pink gum was also formed. No definite products could be isolated.

The work is being continued with certain high molecular weight aromatic aldehydes and also with certain aliphatic aldehydes to see if similar results are obtained.

Summary

1. Reactions designed to produce monothiobenzaldehyde in neutral or acid solutions lead to polymers of varying types depending upon the acid concentration.

2. Reactions designed to produce the monomer in alkaline solution lead to products which are accounted for on the basis of the Cannizzaro reaction.

3. Monomeric thiobenzaldehyde was formed but existed only for a short time in solution.

4. Benzyl dithiobenzoate has been prepared and characterized.

5. Evidence that the Cannizzaro reaction goes through ester formation as an intermediate was obtained.

6. Polymerized thioaldehydes have been depolymerized.

The Reaction between Sulfur Dioxide and Olefins and Acetylenes. VI.[1] Ascaridole as a Catalyst for the Reaction

BY L. L. RYDEN, F. J. GLAVIS AND C. S. MARVEL

Previous work[2] has demonstrated that oxygen and various peroxides are catalysts for the addition reaction between sulfur dioxide and olefins and acetylenes. In this communication, we report experiments which prove that ascaridole, a naturally occurring terpene peroxide, is a very effective catalyst for the above reaction with olefins of the type $RCH{=}CH_2$, and for certain monosubstituted acetylenes.

The most striking illustration of the effectiveness of ascaridole is furnished in the case of the reactions between sulfur dioxide and olefin derivatives containing carboxyl, cyano, carbethoxy and phenolic groups. Previously[3] it was shown that these types of olefin derivatives did not combine with sulfur dioxide when paraldehyde, which contained peroxides, was used as a catalyst. However, with ascaridole as a catalyst, polysulfones have now been obtained from undecylenic acid, allylacetic acid, allyl cyanide, methyl undecylenate and *o*-allylphenol in good yields. In the case of simple olefins, ascaridole is very effective when the double bond is in the terminal position as in 1-pentene, but does not seem to be superior to other peroxides when the double bond is buried in the molecule, as in 2-pentene and cyclohexene. The polysulfones obtained when ascaridole is used as a catalyst are the same as those obtained with other peroxides.

No catalyst has yet been found which will promote a reaction between a tri- or tetra-substituted olefin and sulfur dioxide. Conjugation of the double bond with a carbonyl group also seems to block the addition reaction, as no polysulfones have yet been prepared from ethyl crotonate, crotonaldehyde, methyl acrylate or acrolein and sulfur dioxide.

Ascaridole seems to be superior to any other catalyst which has been found for promoting the addition of sulfur dioxide to acetylenes. In this series, paraldehyde which contains peroxides catalyzes the same reactions, but to a somewhat less degree. Either catalyst will promote the reaction between sulfur dioxide and acetylenes of the type $RCH_2C{\equiv}CH$, even when R is a normal alkyl group of twelve carbon atoms. Phenylacetylene also adds sulfur dioxide in the presence of either of these catalysts. However, no satisfactory yields of addition products have been obtained from acetylenes of the type $RC{\equiv}CR$ or $R_2CHC{\equiv}CH$ with either of these catalysts.

The synthesis of 1-pentadecyne is reported in the experimental part of this communication.

Experimental

Preparation of the Polymers.—To a mixture of equal volumes of the liquid olefin, olefin derivative or acetylene and liquid sulfur dioxide, were added a little alcohol (to prevent darkening) and some ascaridole. The reaction mixture was placed in a pressure bottle, sealed and allowed to stand at room temperature. Typical experiments with individual compounds are described in Table I. In general, the compounds were isolated as described in previous papers from this Laboratory.

Using the same general experimental conditions described above, it has not yet been possible to obtain polysulfones from oleyl alcohol, allyl bromide, crotonaldehyde, acrolein, methyl vinyl ketone, methyl acrylate, ethyl crotonate, dimethylacetylene, *t*-butylacetylene or cyclohexylacetylene.

Purification and Properties of New Polysulfones.—*o*-Allylanisole polysulfone is soluble in dioxane, and was purified by dissolving it in this solvent and reprecipitating with water. The compound melted to a clear, glassy substance, and did not decompose below 200°.

o-Allylphenol polysulfone is soluble in acetone, ether, ethyl acetate, ethyl alcohol and 0.1 *N* sodium hydroxide solution. It could be reprecipitated from the alkaline solution by addition of acid.

p-Bromoallylbenzene polysulfone is insoluble in all common organic solvents. It was purified by washing with alcohol and ether.

Allylacetic acid polysulfone separated as a white, rubbery polymer in the reaction flask. It was purified by removing some impurities by steam distillation and then dissolving in dioxane and precipitating it by adding water. This polymer is soluble in ethyl alcohol. It can be dissolved in alkali and reprecipitated.

Allyl cyanide polysulfone separated in the reaction flask as a white, insoluble powder. It was purified by washing with alcohol and ether. It was insoluble in all of the common organic solvents which were tried.

Undecylenic acid polysulfone is slightly soluble in alcohol and insoluble in most other common organic solvents.

Found: C, 64.6; H, 10.1.

It dissolves in 2% sodium hydroxide solution and reprecipitates on acidification. It is a soft, rubbery mass, very difficult to purify, and hence the analyses were somewhat unsatisfactory.

Methyl undecylenate polysulfone is a very soft, glass-like product which is soluble in hot alcohol, but insoluble in the cold. It was purified by dissolving in hot alcohol and allowing to cool. It was finally washed with hot petroleum ether and dried in a vacuum desiccator. The compound is very soluble in acetone and slightly soluble in chloroform, benzene, ether, dioxane, carbon disulfide and carbon tetrachloride. The product gradually becomes sticky as the temperature is raised, and decomposes completely at 230–250°.

1-Pentadecyne polysulfone is a soft, wax-like product soluble in hot acetone and insoluble in the cold.

2-Bromo-1-pentadecene.—A solution of 0.33 mole of lauryl-magnesium bromide in 200 cc. of dry ether was added to 0.3 mole (59 g.) of bromoallyl bromide, and the reaction mixture was worked up as described by Lespieau and Bourguel[4] for the preparation of cyclohexylbromopropene. The yield of product was 22 g., b. p. 145–155° (3–4 mm.); $n^{20}D$ 1.4670; $d^{20}{}_4$ 1.032.

Anal. Calcd. for $C_{15}H_{29}Br$: C, 62.3; H, 10.03. Found: C, 61.3; H, 10.95.

1-Pentadecyne.—Twenty-five grams of 2-bromo-1-pentadecene was added to a solution of 0.3 mole of sodamide in liquid ammonia.[5] The ammonia was allowed to evaporate, and the residue was treated with water, then dilute hydrochloric acid. The acetylene was taken up in ether and distilled. The yield was 2 cc. of material boiling at 112–113° (5 mm.); $n^{20}D$ 1.4410; $d^{20}{}_4$ 0.8261.

The mercury derivative, prepared by the procedure of Johnson and McEwen,[6] melted at 93°.

Anal. Calcd. for $C_{30}H_{56}Hg$: Hg, 32.6. Found: Hg, 32.1.

Summary

Ascaridole has been shown to be an active catalyst for reaction between sulfur dioxide and olefins of the type $RCH{=}CH_2$, and sulfur dioxide and acetylenes of the type $RC{\equiv}CH$.

o-Allylanisole, *o*-allylphenol, *p*-bromoallylbenzene, allylacetic acid, allyl cyanide, undecylenic acid, methyl undecylenate and 1-pentadecyne, when treated with sulfur dioxide in the presence of ascaridole, give good yields of polysulfones.

The Addition of Dienes to Halogenated and Hydroxylated Naphthoquinones

BY LOUIS F. FIESER AND J. T. DUNN

The chief purpose of this investigation was to explore further the possibility of synthesizing derivatives of phenanthrene by the addition of dienes to ortho quinones of the naphthalene series. While attempts to utilize β-naphthoquinone itself in the Diels–Alder reaction have not been attended with success, possibly because of the extremely sensitive character of the quinone, it was found[1] that 2,6-dimethyl-3,4-naphthoquinone adds 2,3-dimethylbutadiene very smoothly, a methyl group attached to the active double bond of the quinone effecting a stabilization of this component without offering too great hindrance to the addition. It was thought that other substituted β-naphthoquinones might possess sufficient stability to survive under the conditions required for the addition, possibly even when the substituents are located in the benzenoid ring. 6-Bromo-1,2-naphthoquinone was found in an investigation with Hartwell[2] to be less sensitive than β-naphthoquinone and better adapted to a study of the reactions with diazomethane derivatives, and in a preliminary experiment Dr. Hartwell found that dimethylbutadiene reacts fairly readily with this quinone.[3] With this encouragement, we undertook a study of hydroxylated compounds of a type which would yield polynuclear substances of considerable interest. The condensation of 7-hydroxy-1,2-naphthoquinone with vinylcyclopentene, for example, might afford a 7-hydroxy-1,2-cyclopentenophenanthrene derivative having some features of the oestrone structure. Both 6- and 7-hydroxy-1,2-naphthoquinone were prepared for the purpose in a very satisfactory condition of purity, but the compounds decomposed badly in attempted condensations with the reactive 2,3-dimethylbutadiene and no addition products were isolated.

While the difficulty seemed to be associated chiefly with the tendency of the quinones to undergo decomposition before addition could occur, we thought it worth while to determine whether a hydroxyl group *per se* influences the reaction adversely. In order to establish this point, a few hydroxyl derivatives of α-naphthoquinone were studied under comparable conditions, and it was found that the addition reaction becomes definitely slower with the progressive introduction of hydroxyl groups. Nearly all of the para quinones studied can be condensed satisfactorily with dienes in absolute alcoholic solution at 100° when highly purified products are used, but the time required for complete addition, as indicated fairly accurately by the fading of the original color and by crystallization tests, differs considerably. The addition product of juglone (I) was obtained in 95% yield after heating for twenty minutes, while with naphthazarin (II) a comparable yield (83%) was obtained only after heating for six hours. Naphthopurpurin reacts still more slowly (33% yield in sixty hours), and it was found that addition does not occur to the form which is regarded[4] as the predominant tautomer, IIIa, for water is not eliminated as with 2-hydroxy-1,4-naphthoquinone;[1b] addition occurs rather to the tautomer (IIIb) having an unsubstituted quinonoid nucleus. It is interesting that the acetylation of naphthopurpurin with sulfuric acid as catalyst also proceeds through the form IIIb, for the product is identical with 5,6,8-triacetoxy-1,4-naphthoquinone, prepared[5] from 1,4,5,8-naphthodiquinone by the Thiele reaction. This triacetate

(3) The crude product (45% yield) apparently suffered oxidation during crystallization from alcohol–benzene and acetic acid, for analysis of the material, m. p. 237–238°, dec., indicated the formula $C_{16}H_{13}O_2Br$ (found: C, 60.8, 60.6; H, 3.90, 3.75).

(4) Fieser, THIS JOURNAL, **50**, 439 (1928).

(5) Zahn and Ochwat, *Ann.*, **462**, 72 (1928).

of IIIb adds dimethylbutadiene more slowly (twenty-seven hours) than the diacetate of naphthazarin (three hours).[6] The acetyl derivatives react considerably more rapidly than the corresponding di- and trihydroxyquinones, while juglone appears to add dienes slightly more readily than its acetate. 2-Methyl-8-hydroxy-1,4-naphthoquinone[7] reacts smoothly with dimethylbutadiene, as in comparable cases,[1] and the methyl group merely retards addition.

It is evident from these results that the additive power of a naphthoquinone for dienes is diminished by the presence of hydroxyl groups in the benzenoid nucleus. A lower reactivity of the hydroxylated compounds is manifested also in the Thiele reaction. Dimroth and Roos[8] found it necessary to allow ten days for the completion of the reaction of diacetylnaphthazarin with acetic anhydride–sulfuric acid, and a similar observation concerning acetyljuglone was made in the course of the present work. The marked influence of substituent hydroxyl groups at a considerable distance from the ethylenic linkage involved in the additions is rather surprising. It may be significant that in this series of quinones the additive ability parallels the oxidation–reduction potentials,[4] the compounds of inferior additive propensity being those of low potential.

Since the hydroxylated β-naphthoquinones studied seemed unsuitable for use in the Diels–Alder reaction both because they lack the requisite stability and because of the adverse influence of this type of substituent group, we turned to another line of attack which was suggested by the observation, cited above, that a 3-methyl group stabilizes a 1,2-naphthoquinone and renders it capable of reacting with dienes in very satisfactory fashion. It occurred to us that the same beneficial influence might be exerted by substituents capable of being subsequently eliminated, and we consequently investigated the 3-chloro and 3-bromo derivatives of β-naphthoquinone, and later included the 4-chloro and the 3,4-dichloro compounds in the study. It has been reported already in the patent literature[9] that dienes add to 2-chloro- and 2,3-dichloro-1,4-naphthoquinone, and that hydrogen chloride can be eliminated from the addition products with aromatization of the new ring. We found that the halogenated ortho quinones add dimethylbutadiene very readily in pure chloroform or tetrachloroethane solution, the fading of the color from red to yellow providing a reliable indication of the course of the reaction. To obtain satisfactory results it is essential to prepare the quinones in a state of high purity and to employ pure solvents. Alcohol has a deleterious effect, and even the small quantity present in commercial chloroform brings about extensive decomposition.

3-Chloro-1,2-naphthoquinone reacts with dimethylbutadiene in chloroform solution to an appreciable extent at room temperature, and at 100° the reaction is complete within one hour. A further change occurring under more drastic conditions will be described in another paper. For the isolation of the normal addition product, V, it was necessary to avoid overheating during both the preparation and the recovery of the material. The crude product was obtained as an oil and, once seed was secured, the crystalline substance could be prepared in 70% yield. The pure substance forms pale yellow needles, m. p. 87–88°, but it cannot be preserved for more than a few hours before decomposition sets in. The compound loses hydrogen chloride very readily and the dihydrophenanthrenequinone first formed undergoes oxidation in the air to the phenanthrenequinone VI, or to the quinhydrone. 2,3-Dimethylphenanthrenequinone (VI) can be obtained in excellent yield by the action of alcoholic sodium acetate solution on either the crude or crystalline addition product. With the use of the halogenated quinone, it is thus possible to utilize

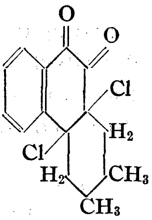
the Diels–Alder reaction for the synthesis of phenanthrene derivatives in satisfactory yield.

3-Bromo-1,2-naphthoquinone behaves much like the corresponding chloro compound. 4-Chloro-1,2-naphthoquinone is less stable in solution than the 3-isomer, and, as the addition proceeds much more slowly, the compound is not well suited to synthetic uses. The addition product was not isolated but converted in the crude state into VI. The two halogen atoms of 3,4-dichloro-1,2-naphthoquinone seem to hinder the addition to a considerable degree, for the color faded to an appreciable extent only after heating the mixture for three days at 100°. The addition product (VII), isolated as a crystalline solid, is much more stable than the monochloro compound V, probably because the hydrogen atoms adjacent to the halogens are not located on bridge carbon atoms. The substance is attacked only slowly by dilute alcoholic alkali at the boiling point.



VII

Experimental Part[10]

1. Preparation of Hydroxynaphthoquinones

6-Hydroxy-1,2-naphthoquinone[11] was prepared by the method of Dimroth and Kerkovius,[12] the average yield (pure) from 2,6-dihydroxynaphthalene being 31.5%. Reduction of the benzeneazo compound with sodium hydrosulfite gave less satisfactory results. It was found advantageous to use a small amount of stannous chloride as an antioxidant in the crystallization of both the starting material and 1-amino-2,6-dihydroxynaphthalene hydrochloride. The quinone formed bronze-red leaflets from dilute acetone, dec. about 165°. Attempts to isolate products of the reaction of the substance with 2,3-dimethylbutadiene and with diazomethane were unsuccessful, the quinone undergoing extensive decomposition. An acetyl derivative could not be obtained with the use of sodium acetate or in pyridine solution; in the presence of sulfuric acid catalyst, the quinone undergoes the Thiele reaction.[12]

7-Hydroxy-1,2-naphthoquinone was prepared from 2,7-dihydroxynaphthalene by the standard procedure described by one of us,[13] using sulfanilic acid rather than aniline[12] as the coupling component, and reducing the dye with sodium hydrosulfite. For the preparation of 2,7-dihydroxynaphthalene, technical "naphthalene-2,7-disulfonic acid" (220 g.) was crystallized with calcium chloride (equivalent to 55 g. of anhydrous material) from water (250 cc.), and after a further crystallization using Norite the dried, colorless calcium salt (134 g.) was fused with 500 g. of potassium hydroxide and 10 cc. of water, initially at 200° and finally at 300°. The slightly cooled melt was ladled into ice and hydrochloric acid, the material was brought into solution at the boiling point, using sufficient acid to decompose any calcium bisulfite and, after decolorizing with Norite and cooling, the product separated as large colorless needles in 66% yield, based on the purified calcium salt. To obtain 7-hydroxy-1,2-naphthoquinone satisfactorily it is essential to use pure, colorless, 1-amino-2,7-dihydroxynaphthalene hydrochloride (recrystallized in the presence of stannous chloride), to add the ferric chloride to the solution of this substance all at once with efficient mixing, and to collect the product rapidly as soon as the crystals separate. The quinone, obtained as dark red microcrystals, melting at 203–204°, dec., in 30% yield from the dihydroxy compound, could not be recrystallized without undergoing decomposition. The behavior in attempted reactions was like that of the isomer.

Juglone.—We attempted without success to convert 1,5-dihydroxynaphthalene into the 4-amine through the *p*-sulfobenzeneazo compound, and eventually adopted the oxidation method of Willstätter and Wheeler.[14] The 1,5-dihydroxynaphthalene was conveniently precipitated from alcohol with water, washed, and added to the dichromate mixture in the form of a thin paste. The juglone extracted with petroleum ether was further purified by crystallization from alcohol and the yield of material melting at 153–154° was 15%. **Acetyljuglone** was prepared more satisfactorily than described by Bernthsen and Semper[15] by adding 2 drops of concentrated sulfuric acid to a suspension of 0.25 g. of juglone in 2 cc. of acetic anhydride, stirred in an ice-bath. The solid soon dissolved, and after cautiously decomposing the excess anhydride with water and adding more water at the boiling point, the acetyl compound crystallized as yellow plates (0.3 g., 97%). Recrystallized from alcohol, it formed yellow needles, m. p. 153–154°.

1,2,4,5(or 8)-Tetraacetoxynaphthalene was obtained by suspending 1 g. of powdered juglone in a cold solution of 4 drops of concentrated sulfuric acid in 8 cc. of acetic anhydride and allowing the mixture to stand with occasional shaking for ten days. The quinone dissolved, the color of the solution faded and colorless crystals of the product separated. After treatment with water, the crude product (1.4 g., 68%) was crystallized from alcohol, forming clusters of colorless prisms, m. p. (camphor-like) 154°.

Anal. Calcd. for $C_{18}H_{16}O_8$: C, 59.98; H, 4.48. Found: C, 60.37; H, 4.67.

2,5(or 8)-Dihydroxy-1,4-naphthoquinone was obtained by hydrolyzing the tetraacetate with 25% methyl alcoholic potassium hydroxide, oxygenating the solution, and acidifying an aqueous solution of the red salt which separated. The crystalline precipitate (76% yield) separated from aqueous acetone as clusters of lemon yellow microcrystals,

dec. about 220°. The properties corresponded to those of the oxidation product of juglone obtained by Mylius.[16]

Naphthazarin was prepared according to Fieser[4] (using 15% fuming acid) in the yield reported, and purified by repeated crystallization from benzene, when it formed beautiful long deep green needles having a metallic reflex. Less pure material is red and gives inferior results in the Diels–Alder reaction. The diacetate, m. p. 195–196°, was prepared with the acetic anhydride (8 cc.)–sulfuric acid (6 drops) mixture,[17] and it was noted that no appreciable addition of the reagent occurred on heating the solution at 80° for ten minutes.

Naphthopurpurin was prepared according to Fieser[4] and crystallized twice from benzene; small, red needles were obtained in 22.5% yield.

5,6,8-Triacetoxy-1,4-naphthoquinone.—1,4,5,8-Naphthodiquinone was prepared as described by Zahn and Ochwat[5] and crystallized from glacial acetic acid–petroleum ether, taking care to avoid overheating and employing no decolorizing carbon (which causes reduction). Pale yellow crystals were obtained in 40% yield. The above triacetate was prepared from the diquinone as described[5] in 56% yield and it formed yellow prisms from alcohol, m. p. 165–166°. The sample became red on storage. An identical product was obtained in 94% yield by the action of acetic anhydride–sulfuric acid on naphthopurpurin at room temperature; the reaction was complete after warming for a few minutes.

2. Preparation of Halo-β-naphthoquinones

3-Chloro-1,2-naphthoquinone was prepared in 56% yield from β-naphthol through 1,1,3,4-tetrachloro-2-ketotetrahydronaphthalene according to Zincke,[18] and the properties were as reported. **3-Bromo-1,2-naphthoquinone**, m. p. 177–178°, was obtained in 67% yield by the bromination of β-naphthoquinone.[19] The crude **3,4-dichloro-1,2-naphthoquinone** prepared according to Zincke and Engelhardt[20] contained a considerable amount of dark, resinous material which can be removed by liberal washing with ether. The yield of pure product, m. p. 183.5–184.5°, was 45%.

As Zincke's method of preparing **4-chloro-1,2-naphthoquinone**[21] seemed unsatisfactory, an adaptation of Fries and Schimmelschmidt's[22] method of preparing the 3-bromo compound was employed. 1,1-Dichloro-2-ketodihydronaphthalene was prepared[22] from β-naphthol in 55% yield, and rearranged[22] to 1,4-dichloro-2-naphthol, the yield of distilled material, m. p. 121–122°, in this step being 63%. A fine suspension of 14 g. of the dichloronaphthol in 70 cc. of glacial acetic acid was stirred at 15° and treated slowly with 7 cc. of concentrated nitric acid, when the material soon dissolved. After brief cooling at 0° the crystalline 1,4-dichloro-1-nitro-2-ketodihydronaphthalene which separated was collected and washed with dilute acetic acid and then with water. The substance was obtained as pale yellow needles which cannot be preserved for long at room temperature without decomposing; yield, 10 g. (59%). This material (10 g.) was warmed cautiously with 25 cc. of benzene until dissolved and the solution was boiled for a short time to eliminate nitrosyl chloride. On adding ligroin and cooling, dull orange-red needles of 4-chloro-1,2-naphthoquinone separated; m. p. 132–136°, dec.; yield 5.9 g. (80%). It was not found possible to purify the quinone further by crystallization, as some decomposition invariably occurred. On attempting to prepare the hydroquinone diacetate for analysis by reductive acetylation with acetic anhydride, zinc dust and sodium acetate, it was found that the halogen atom is replaced by an acetyl group, the product being 1,2,4-triacetoxynaphthalene, m. p. and mixed m. p. 134–135°; yield 60%.

3. Addition of Dienes to the Hydroxynaphthoquinones

The condensation of the para quinones with dienes seemed to proceed better in absolute alcohol than in other solvents. The amount of alcohol used was more than ample to bring the quinone into solution at the boiling point (see Table I), one-tenth this volume of freshly prepared diene[23] was added, and the tube was sealed and heated in a steam bomb at 100°. The progress of the reaction could be followed sometimes by the fading of the color, although the change usually is not great. A more reliable indication can be obtained by removing and cooling the tube, for the addition products of the para quinones crystallize quite readily and in characteristic form. The heating was discontinued as soon as the change seemed to be complete, and the figures given in the third column of the table represent the approximate times required for completion of the reactions under comparable conditions. The yields recorded refer to purified, crystalline material. Naphthopurpurin-dimethylbutadiene was extracted from the crude reaction product with petroleum ether and recrystallized from this solvent; the other addition products were crystallized from alcohol. Traces of impurities in the starting material seem to promote extensive decomposition during the condensation.

5,9,10 - Triacetoxy - 2,3 - dimethyl - 1,4 - dihydroanthracene was obtained in 67% yield by the action of acetic anhydride and fused sodium acetate on juglone-dimethylbutadiene. The compound formed colorless needles, m. p. 197–198°, from alcohol.

Anal. Calcd. for $C_{22}H_{22}O_6$: C, 69.07; H, 5.80. Found: C, 69.46; H, 6.02.

2,3-Dimethyl-5-hydroxyanthraquinone was prepared by the action of alcoholic potassium hydroxide solution on both the above triacetate and on juglone-dimethylbutadiene. A solution of 0.2 g. of the latter compound in 8 cc. of alcohol was warmed with 1 cc. of 10% aqueous potassium hydroxide solution, crystals of a red salt which separated were dissolved by adding water, and the solution was oxygenated and acidified. Crystallization of the product from alcohol gave glistening yellow needles melting at 178.5–179.5°; yield 0.18 g.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.16; H, 4.80. Found: C, 76.37; H, 4.96.

[23] In preparing 2,3-dimethylbutadiene by the catalytic method,[1a] it has been found expedient to control the rate of distillation of pinacol through the reaction tube to 35 cc. per twenty minutes. Under these conditions there is less high-boiling material (pinacolone) requiring re-passage through the tube and the total yield of redistilled product is increased to 75%.

4. Addition Products of Halogenated β-Naphthoquinones

3 - Chloro - 1,2 - naphthoquinone - 2,3 - dimethylbutadiene.—A mixture of 4 g. of the quinone, 8 cc. of the diene, and 40 cc. of purified chloroform (shaken with concentrated sulfuric acid, washed with water, dried, distilled) was sealed in a tube and heated in a steam-bath with exclusion of light. The tube was shaken vigorously until all solid material had dissolved, for it is generally found that solid particles of a quinone tend to suffer decomposition and initiate the destruction of material in solution. The red color of the solution soon began to fade and in forty-five to fifty minutes changed to yellow. After one hour the solution was cooled, shaken with Norite for ten minutes at room temperature, and the solvent was distilled from the filtered solution in vacuum, keeping the temperature below 60°. The resulting viscous yellow oil could be preserved for some time as such or in ethereal solution without decomposing. Crystalline material eventually was obtained by cooling an ethereal solution in a bath of solid carbon dioxide and adding petroleum ether, and with seed available the crystalline compound was obtained easily. Recrystallized from ether–petroleum ether, the substance formed glistening, lemon yellow needles, m. p. 87–88°; yield, 4 g. (70%).

Anal.[24] Calcd. for $C_{16}H_{15}O_2Cl$: C, 69.92; H, 5.51. Found: C, 69.61; H, 5.37.

A sample of the pure material kept in a vacuum desiccator at 10° showed signs of decomposition within three hours and soon changed to a greenish black amorphous mass. When shaken with air in suspension in either alcohol or ether, this soon changed to an orange powder; on crystallization from glacial acetic acid orange plates of 2,3-dimethylphenanthrenequinone were obtained in 87% yield. The quinone was identified by mixed melting point determination, using for comparison a sample prepared previously in this Laboratory.[25] Both samples melted at 237–238° (242–243°, corr.[26]). When the oily addition product was heated for a few minutes on the steam-bath at reduced pressure, hydrogen chloride was eliminated suddenly and the dark residue yielded the above quinone when digested with solvents. 2,3-Dimethylphenanthrenequinone was obtained in theoretical yield when the oily or crystalline addition product was warmed with alcoholic sodium acetate solution.

3-Bromo-1,2-naphthoquinone.—The reaction with dimethylbutadiene was conducted exactly as above, except that the heating was continued for two hours, and a solution of the oily addition product in 2–3 cc. of glacial acetic acid was treated with a solution of 1 g. of chromic anhydride in 6 cc. of 80% acetic acid. The solution became warm and, on cooling, 2,3-dimethylphenanthrenequinone crystallized in a nearly pure condition; yield, 0.38 g. (76%).

4-Chloro-1,2-naphthoquinone.—Under the conditions specified for the isomer, the addition of dimethylbutadiene proceeded only slowly; the red color faded slowly and then the solution began to darken. Heating was discontinued after seventy-two hours and the crude reddish oil obtained on removing the solvent was taken into ether–petroleum ether. Attempts to obtain crystals of the addition product were unsuccessful, but the solution on standing slowly deposited orange material from which pure 2,3-dimethylphenanthrenequinone was obtained on recrystallization in 15% yield.

3,4 - Dichloro - 1,2 - naphthoquinone - 2,3 - dimethylbutadiene, prepared by heating 3 g. of the quinone, 6 cc. of the diene, and 30 cc. of pure chloroform at 100° for sixty hours, was obtained crystalline from ether–petroleum ether and recrystallized from this solvent pair; yield 1 g. (24%). The compound formed large, pale yellow prisms melting at 130.5–131.5°.

Anal. Calcd. for $C_{16}H_{14}O_2Cl_2$: C, 62.14; H, 4.57. Found: C, 61.82; H, 4.79.

The dichloro compound is not appreciably attacked by short boiling in an alcoholic solution of sodium acetate; boiling 10% alcoholic potassium hydroxide slowly produces a yellow coloration and gives a resinous product.

Summary

Hydroxylation of the benzenoid ring of α-naphthoquinone results in a decrease in the velocity of addition of dienes; similarly substituted β-naphthoquinone derivatives, like the parent compound, are not suitable for use in the diene synthesis.

3-Chloro- and 3-bromo-1,2-naphthoquinone add

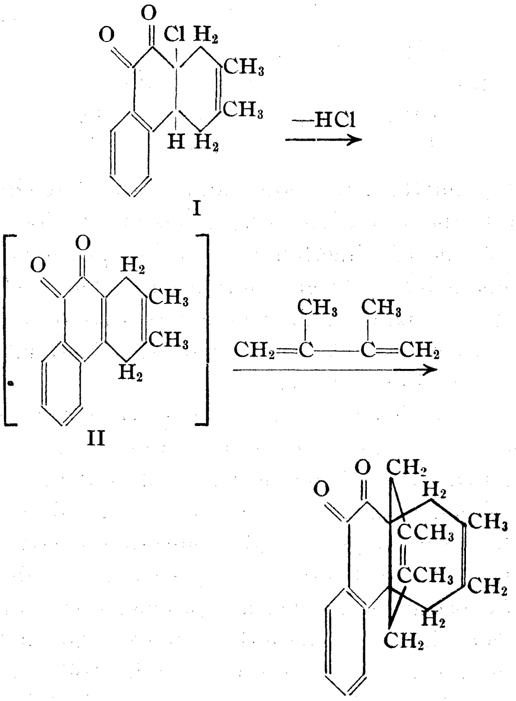
A Further Reaction Product from 3-Chloro-1,2-naphthoquinone and Dimethylbutadiene

BY LOUIS F. FIESER AND J. T. DUNN

In studying the reaction between 3-chloro-1,2-naphthoquinone and 2,3-dimethylbutadiene in chloroform solution at 100°,[1] it was observed that the initially red solution fades to yellow as addition proceeds and that the formation of the halogen-containing addition product (I, below) is complete in slightly less than one hour. When the heating is continued much beyond this point the solution slowly acquires a red color, and this second change occurs particularly rapidly when the hot reaction tube is exposed to direct sunlight. In the presence of excess diene, the red color again fades to yellow and when the changes are finally complete the solution exhibits a greenish fluorescence. The reaction product, isolated from this solution in 36% yield in a nicely crystalline condition, is free from halogen and has the composition of the chloroquinone plus two molecules of dimethylbutadiene, less the elements of hydrogen chloride.

The only plausible interpretation of these observations which we have been able to construct is that the yellow addition product I first loses hydrogen chloride from adjacent, bridge carbon atoms, and that the dihydrophenanthrenequinone II adds a second molecule of the diene at the reactive ethylenic linkage thus established, giving a tetracyclic diketone of the structure III. It is assumed that the dihydrophenanthrenequinone II, being a substituted β-naphthoquinone derivative, is responsible for the transient red color of the solution, and if this explanation is correct the influence of light is to catalyze the formation of this substance from I by the elimination of hydrogen chloride.



I

II

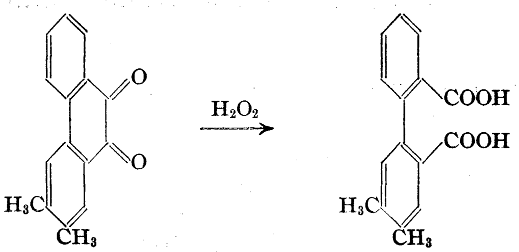
III

Attempts to characterize the unusual reaction product regarded as III were disappointing, as were attempts to establish the structure by degradation. In nearly all reactions tried the first change seemed to consist in a reversal of the Diels–Alder reaction, for the only transformation products isolated were derived from the dihydrophenanthrenequinone II. Perbenzoic acid titration alone gave a positive result, for this indicated the presence of two reactive double bonds, as required for the formula III. When heated somewhat above the melting point (135°), the product decomposed with effervescence and left a dark green residue which underwent air-oxidation in contact with solvents and afforded pure 2,3-dimethylphenanthrenequinone in good yield. This quinone was obtained also on heating the supposed tetracyclic compound in glacial acetic acid solution for twelve hours and, more rapidly and in nearly quantitative yield, by the action of chromic acid on the compound in the same solvent. The tetracyclic product did not absorb hydrogen readily in the presence of Adams catalyst, and

---

(1) Fieser and Dunn, THIS JOURNAL, **59**, 1016 (1937).

the only product isolated (after exposure to the air) was 2,3-dimethylphenanthrenequinone. Alkaline hydrogen peroxide gave a substance identified as 4,5-dimethyl-2,2′-diphenic acid (V) by comparison of a sample of the acid prepared from 2,3-dimethylphenanthrenequinone by the action of hydrogen peroxide in acetic acid solution.

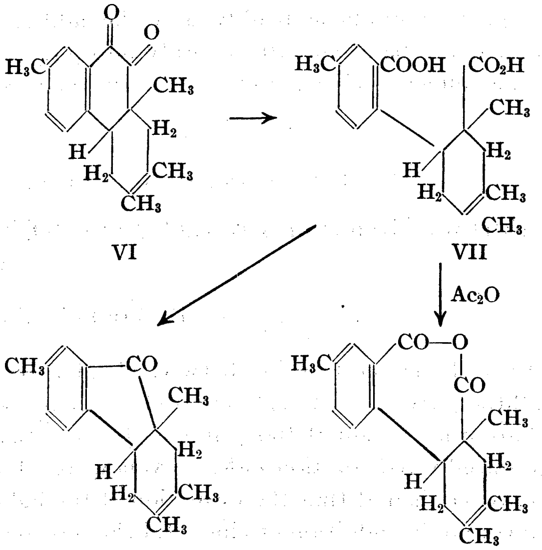


IV V

In all these reactions, and in the Zerewitinoff test, the tetracyclic product seems to lose one molecule of dimethylbutadiene in preference to undergoing other transformations. On attempting to prepare a quinoxaline derivative or a semicarbazone (or acetate), the starting material was recovered unchanged.

Although entirely rigid evidence is not available, the analysis of the new product, the results of titration with perbenzoic acid, and the ready conversion of the substance into 2,3-dimethylphenanthrenequinone all point to the structure III for the compound. Under similar conditions of experiment, an identical product was obtained from 3-bromo-1,2-naphthoquinone. An interesting property of the compound is its ability to exist in the two forms which differ strikingly in appearance. When prepared in the dark and purified with but little exposure to light, the product crystallized in the form of bright yellow prisms. When these were exposed for a short time to direct or diffused sunlight, the yellow color faded and the crystals became very nearly colorless, while retaining the original form. Both modifications have the same melting point.

In the course of the investigation of the tetracyclic diketone III it seemed desirable to determine if any of the peculiarities of this compound are exhibited by the structurally similar addition product VI from 2,6-dimethyl-3,4-naphthoquinone and 2,3-dimethylbutadiene.[2] This is not the case, for the addition compound VI can be distilled in vacuum without loss of dimethylbutadiene; it reacts normally with *o*-phenylenediamine, and yields on catalytic hydrogenation a colorless dihydro derivative possibly similar to that obtained by Smith and Hac[3] from prehnitenequinone-cyclopentadiene. The diketone is cleaved smoothly by alkaline hydrogen peroxide to the dibasic acid VII. The behavior of this tetramethyltetrahydrodiphenic acid on pyrolysis is similar to that of the two perhydrodiphenic acids studied by Vocke.[4] When heated at 300–330°, the acid very slowly loses carbon dioxide and gives a ketone VIII in small yield. The anhydride (IX) can be obtained easily with the use of acetic anhydride, but it does not appear to be formed in the pyrolytic reaction. The behavior of VII therefore accords with the prediction of the Blanc rule and the acid thus differs from those 1,4-dibasic acids derived from steroids in which the acid groups are attached to adjacent rings.



VI VII VIII IX

Experimental Part[5]

1. The Addition Product

2,3-Dimethyl-1,4,11,12-tetrahydrophenanthrenequinone-11,12-endo-2′,3′-dimethylbutene-2′ (III).—A solution of 4 g. of 3-chloro-1,2-naphthoquinone and 16 cc. of 2,3-dimethylbutadiene in 32 cc. of pure chloroform was sealed in a tube and heated in a pan of boiling water with exposure to the sunlight. The red solution became yellow in about forty-five minutes, and after thirty-five to fifty minutes the color changed again to red and this slowly began to fade. After a further period of about two hours the solution had become yellow and acquired a greenish fluorescence. After a total of five hours the tube was cooled, the solution was clarified with Norite, and the sol-

(5) The melting points are uncorrected.

vent was removed on the steam-bath. From a portion of the residual reddish oil seed was obtained with the use of chloroform–petroleum ether by thorough cooling and scratching. A solution of the main product in alcohol slowly deposited crystals on being seeded, and after washing this material free of oil with alcohol and recrystallizing it from alcohol, a pure product was obtained; average yield, 2.4 g. (36%). The compound is very readily soluble in benzene and moderately soluble in alcohol; the solutions ordinarily are colorless but become slightly yellow when exposed to direct sunlight. The solution in glacial acetic acid (readily soluble) becomes yellow on boiling, even without exposure to light. The solutions in alcohol or benzene tend to remain supersaturated, but slowly deposit the compound in the form of large, flat, diamond-shaped prisms which are practically colorless but show a faint tinge of yellow. The melting point is like that of camphor, softening occurring at about 130° with a finely ground sample, and the crystal structure disappearing at 135°. The melt is slightly yellow, but after partial crystallization the sample re-melts at 135°.

Anal. Calcd. for $C_{22}H_{24}O_2$: C, 82.45; H, 7.55. Found: C, 82.43, 82.57; H, 7.56, 7.79.

When the reaction was conducted in the dark, or with but little exposure to light, it was found necessary to continue the heating for sixteen to twenty hours. The reaction product on purification with but little exposure to light crystallized in diamond-shaped prisms similar to those above but having a brilliant yellow color. The melting point was the same as that of the nearly colorless crystals and no depression was observed on mixing the samples. On exposing the yellow prisms to direct sunlight the color faded without change of crystalline form and white crystals, faintly tinged with yellow were obtained. The colorless form seems to be the more stable of the two. A partial reversal occurs when the initially colorless solution of this form in chloroform is exposed to direct sunlight, for the solution acquires a yellowish color and the crystals subsequently deposited are pale yellow.

The compound III was prepared also in a similar manner from 3-bromo-1,2-naphthoquinone and identified by comparison with the above sample. The color changes were less distinct, and heating in the sunlight was conducted discontinuously for a total of thirteen hours; yield 35%.

Titration of III with perbenzoic acid in chloroform solution, conducted by Dr. M. S. Newman, indicated the absorption of 1.7 atoms of oxygen after forty-eight hours and 1.8 atoms after seventy-two hours.

Unsuccessful attempts to prepare derivatives of III and to effect a hydrogenation have been reported above. On heating the compound somewhat above the melting point at 4 mm. pressure, the oil suddenly began to effervesce. When this had ceased, the product was distilled and the glassy distillate was triturated with ether. This gave an orange powder from which pure 2,3-dimethylphenanthrenequinone, m. p. 237–238°, was obtained by crystallization; yield, 72%. A better conversion was obtained by adding 0.25 g. of chromic anhydride in 4 cc. of 90% acetic acid to 0.25 g. of III in 3 cc. of glacial acetic acid. Orange crystals of the quinone soon separated and the total product, collected after adding a little water, amounted to 0.17 g. (91%).

4,5-Dimethyl-2,2′-diphenic Acid (V).—This acid was conveniently prepared by heating a suspension of 1 g. of 2,3-dimethylphenanthrenequinone in 5 cc. of glacial acetic acid with 2 cc. of 30% hydrogen peroxide just below the boiling point until solution was complete and the color had faded to a very pale yellow. On dilution with water, the acid separated as colorless crystals; yield of once recrystallized material, 1 g. (88%). The pure acid separates from dilute acetic acid as clusters of colorless microcrystals, m. p. 203–204°.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.09; H, 5.22. Found: C, 70.71; H, 5.49.

The same acid was obtained by warming a mixture of 1 g. of III, 0.7 cc. of 30% hydrogen peroxide solution, 45 cc. of alcohol, and 3 cc. of 10% sodium hydroxide (added in drops) at 50–60° for three hours. The solution was acidified, evaporated to dryness, and the organic material was taken successively into ether, alkali and ether and obtained as clusters of microneedles from ether–petroleum ether (0.75 g.). After repeated crystallization from ether, the product melted at 202–204° and gave no depression with V, above.

2. 2,6-Dimethyl-3,4-naphthoquinone–2,3-Dimethylbutadiene (VI)

The yield in the preparation[2a] of the intermediate 2,6-dimethyl-4-amino-3-naphthol was improved considerably by employing more acid to dissolve the crude amine. The dye from 0.3 mole of the dimethylnaphthol was prepared and reduced exactly as described for the preparation of 1,2-aminonaphthol,[6] and the moist amine was mixed with 800 cc. of water, 45 cc. of concentrated hydrochloric acid, and 0.8 g. of stannous chloride and added to 2.2 liters of boiling water. Solution occurred in forty-five minutes and 200 cc. of concentrated acid was added to the filtrate. The yield of colorless hydrochloride was 62 g. (92%). In conducting the oxidation the amount of acid was increased from 10 cc. to 25 cc.; yield 94%; m. p. (recrystallized), 151–152°.

The addition product VI was obtained in somewhat improved yield (93%) by using 2.9 cc. of dimethylbutadiene and 16 cc. of absolute alcohol per gram of pure quinone, heating the mixture for seventy-five hours at 100°, and crystallizing the product once from dilute methanol.

The quinoxaline derivative, prepared by heating 1 g. of VI and 0.5 g. of *o*-phenylenediamine in 7 cc. of glacial acetic acid on the steam-bath for one hour and crystallizing the product (1.25 g.) from acetic acid, formed yellow plates, m. p. 137–138°.

Anal. Calcd. for $C_{24}H_{24}N_2$: C, 84.66; H, 7.11. Found: C, 84.46; H, 7.44.

A dihydro derivative was obtained by shaking 1 g. of VI dissolved in alcohol and 30 mg. of Adams catalyst with hydrogen, absorption ceasing after five minutes, even when fresh catalyst was added. The product formed colorless needles, m. p. (camphor-like) 131°, from alcohol; yield 0.72 g. The substance dissolves in alcoholic sodium hydroxide solution in the cold to give a pale red solution.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.94; H, 8.21. Found: C, 80.00; H, 8.50.

---

[6] Fieser, *Organic Syntheses*, **17**, 9, 68 (1937).

Reduction of VI in alcohol with aqueous hydrosulfite solution gave a colorless product, m. p. 107–108°, which was not further characterized.

2,4,5,4'-Tetramethyl-1,2,3,6-tetrahydro-2,2'-diphenic Acid (VII).—A solution of 2 g. of VI and 1.4 cc. of 30% hydrogen peroxide in 20 cc. of dioxane at 80–90° was treated cautiously with 7 cc. of 10% sodium hydroxide in portions. A vigorous reaction ensued and the yellow color disappeared. Acidified and diluted with 100 cc. of water, the solution slowly deposited needles of good product; yield, 2 g. (92%). The acid is very soluble in dioxane, moderately so in alcohol or ether, very sparingly soluble in benzene. Recrystallization from acetic acid gave small, colorless needles, m. p. 248–249°.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.48; H, 7.34. Found: C, 71.43; H, 7.53.

The dimethyl ester, prepared with diazomethane, formed glistening needles, m. p. 88–89°, from dilute methanol.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.68; H, 7.94. Found: C, 72.66; H, 7.98.

The ester was hydrolyzed completely on being boiled for six hours with 25% potassium hydroxide solution.

The anhydride (VIII) was prepared by refluxing a solution of 0.9 g. of VII in 6 cc. of acetic anhydride for fifteen hours. The solvent was removed in vacuum and the product was crystallized from ligroin, giving 0.45 g. (53%) of nearly pure material. The anhydride forms lustrous, colorless needles from ligroin, m. p. 97–98°.

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.00; H, 7.09. Found: C, 76.06; H, 7.42.

2,3,7,10-Tetramethyl-1,4,10,11-tetrahydrofluorenone-9-semicarbazone.—The acid VII (0.8 g.) when heated under nitrogen in a bath at 330–33° slowly evolved carbon dioxide. After ten hours the dark residue, which gave no test for anhydride when treated in benzene with aniline, was taken into ether and the solution was extracted with dilute alkali, which gave on acidification 0.65 g. of unchanged acid. The oily residue from the ether was treated in alcohol with semicarbazide solution, heating for three hours on the steam-bath. Some of the semicarbazone crystallized during this period and, after cooling, the total yield was 0.2 g. (22%). The compound forms yellow microcrystals from alcohol; it softens at 244° and melts at 260° with decomposition.

Anal.[7] Calcd. for $C_{18}H_{23}ON_3$: N, 14.14. Found: N, 14.01.

Summary

The product obtained by the addition of 2,3-dimethylbutadiene to 3-chloro-1,2-naphthoquinone loses hydrogen chloride in chloroform solution at 100° and a second molecule of the diene adds to the resulting product giving an interesting compound which probably is a tetracyclic diketone. For comparison with this substance, a further characterization was made of 2,6-dimethyl-1,2-naphthoquinone-2,3-dimethylbutadiene.

Application of the Diene Synthesis to Halogenated 1,2- and 3,4-Phenanthrenequinones

BY LOUIS F. FIESER AND J. T. DUNN

Having found that the 3-halo derivatives of β-naphthoquinone react smoothly with dienes and afford products which can be converted easily into 9,10-phenanthrenequinones,[1] we investigated the possibility of utilizing corresponding ortho quinones derived from phenanthrene for the synthesis of compounds of the chrysene and 3,4-benzphenanthrene series.

A suitable starting material derived from 3,4-phenanthrenequinone[2] (I) was obtained very satisfactorily by a process of bromination analogous to that developed by Zincke[3] for the preparation of 3-bromo-1,2-naphthoquinone. Treated with bromine in acetic acid solution, the quinone forms a yellow dibromide from which hydrogen bromide is eliminated by the action of boiling water. That the resulting crimson-red product has the structure of 2-bromo-3,4-phenanthrenequinone is established by the following observations. The Thiele reaction proceeds without disturbance of the halogen atoms and on hydrolysis of the triacetate (V) and oxidation there is obtained a compound having the properties of an hydroxy-*p*-quinone (VI). The bromine atom therefore cannot be located at position 4. Only one other position is available in the quinonoid nucleus, and the behavior of the bromo-3-hydroxy-1,4-phenanthrenequinone under the conditions of a Fischer esterification reaction indicates that the substituent is indeed located at the position (2) in question. Whereas the unsubstituted hydroxyquinone is converted rapidly by the action of meth-

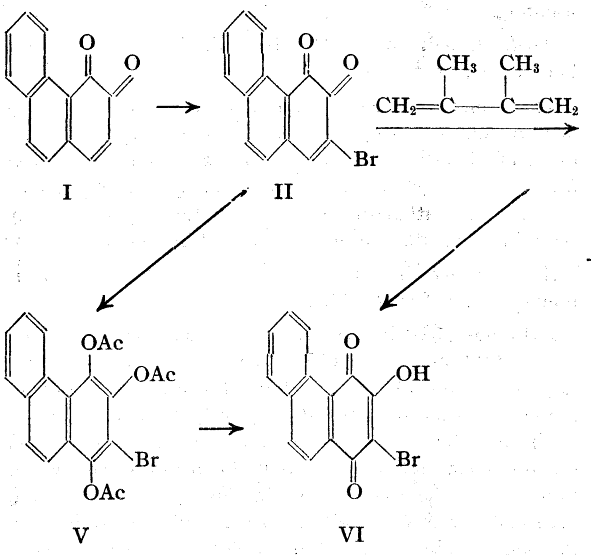
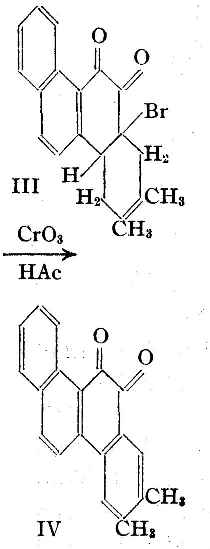
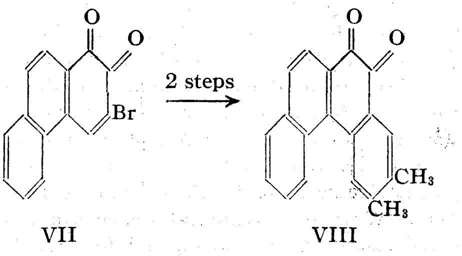
anol–hydrogen chloride into the ether,[2] the bromo compound is unaffected on prolonged boiling with the reagent. As with 2-hydroxy-3-bromo-1,4-naphthoquinone,[4] the failure of the reaction is attributable to the blocking influence of a substituent adjacent to the hydroxyl group. Another difference for which the substituent probably is responsible is that the bromo compound, unlike the parent hydroxyquinone, is not subject to ready cleavage by alkalies.





The presence of the bromine atom in the quinonoid ring is shown also by its ready elimination from the addition product (III) of 2-bromo-3,4-phenanthrenequinone and 2,3-dimethylbutadiene. The reaction between these components proceeded smoothly in chloroform solution at 100° (two hours), and the addition product, collected as an oil and not purified, was converted by the action of chromic acid into pure 8,9-dimethyl-5,6-chrysenequinone (IV) in 90% over-all yield.

1,2-Phenanthrenequinone[5] was submitted to the same series of reactions with similar results, the 3-bromo derivative VII being converted through the dimethylbutadiene addition product into 6,7-dimethyl-3,4-benz-9,10-phenanthrenequinone (VIII) in 79% yield. Using butadiene, which reacted somewhat more slowly than its dimethyl derivative, the known 3,4-benz-9,10-phenanthrenequinone[6] was obtained in satisfactory yield.



The advantage of using bromo derivatives in the diene synthesis of polynuclear compounds from ortho quinones was further demonstrated by the results of experiments with 1,2-phenanthrenequinone itself. Since this quinone is considerably more stable than β-naphthoquinone and can be obtained in a high state of purity, it seemed particularly suitable for use in the Diels–Alder reaction. A reaction with dimethylbutadiene was indeed found to occur, and the crude product was converted successfully into 6,7-dimethyl-3,4-benz-9,10-phenanthrenequinone (VIII). The addition, however, proceeded much more slowly than with the 3-bromo derivative, and considerable decomposition occurred during the long period of heating (forty-eight hours). The yield of the quinone VIII (29%) was less than half that obtained from the bromo compound.

A shorter route to halogenated phenanthrenequinones of the type required as starting materials was investigated without success. In analogy with Zincke's[7] observations concerning the chlorination of β-naphthol, it seemed possible that 3-phenanthrol might be convertible through intermediate chloro ketones similar to IX and X into 2-chloro-3,4-phenanthrenequinone. The phenanthrol, however, is attacked not only in the hydroxylated ring but also at some other part of the molecule, probably at the reactive 9,10-double bond. On conducting the chlorination in glacial acetic acid solution at a low temperature, the chief product isolated in a crystalline condition

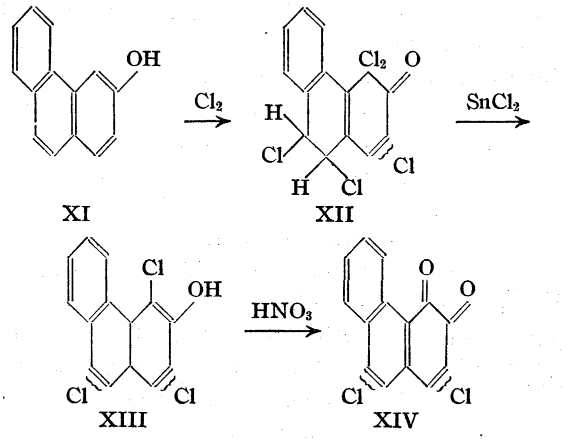
(7) Zincke and Kegel, *Ber.*, **21**, 3378, 3540 (1888).

was an orange pentachloro ketone. This substance corresponds in properties to Zincke's unsaturated trichloro ketone X except for the presence of an additional pair of chlorine atoms, and the compound probably has the structure XII. Reduction with stannous chloride gave a trichlorophenanthrol (XIII), hydrogen chloride evidently being eliminated from the central nucleus simultaneously with a change in the terminal ring comparable with that observed by Zincke in the naphthalene series. The trichlorophenanthrol yielded on oxidation with nitric acid a dichlorophenanthrenequinone of the probable structure XIV. Acetic anhydride–sulfuric acid adds slowly to the quinone to give a colorless triacetate, and one halogen atom is displaced in the process. The chlorine atom in the quinonoid ring therefore is probably located at the 1-position.



Experimental Part[8]

3,4-Phenanthrenequinone Series

2 - Bromo - 3,4 - phenanthrenequinone.—A solution of 2.25 g. of 3,4-phenanthrenequinone[2] (conveniently purified by one crystallization from acetone–water, using Norite) in 235 cc. of glacial acetic acid was treated at room temperature with 1.9 g. of bromine in 40 cc. of the same solvent. The red solution turned yellow at once. (With more concentrated solutions the yellow addition product crystallized and was not easily redissolved without decomposition.) After fifteen minutes the yellow solution was stirred quickly into 410 cc. of vigorously boiling water and the resulting deep red solution was allowed to stand without disturbance. Within less than one minute the bromoquinone began to separate in long, glistening, deep crimson-red needles. The average yield of product, m. p. 211–212°, was 2.3 g. (77%). The quinone crystallizes well from glacial acetic acid, dioxane, chloroform, or benzene, in which solvents it is moderately soluble; it is sparingly soluble in alcohol or ether. The recrystallized material melted at 212–213°.

Anal. Calcd. for $C_{14}H_7O_2Br$: C, 58.54; H, 2.46. Found: C, 58.36; H, 2.75.

2-Bromo-3,4-dihydroxyphenanthrene.—A suspension of 1.1 g. of the quinone in 15 cc. of alcohol and 20 cc. of water was treated with sulfur dioxide until the solid had dissolved to a pale red solution; this was warmed slightly until pale yellow and diluted with water until crystallization commenced. The hydroquinone separated as glistening, almost colorless needles (1 g.). It is very soluble in alcohol, ether, or benzene, and moderately soluble in chloroform. A sample crystallized from the latter solvent formed colorless needles, m. p. 164–165.5°, which darkened on standing.

Anal. Calcd. for $C_{14}H_9O_2Br$: C, 58.13; H, 3.14. Found: C, 57.79; H, 3.52.

The dimethyl ether, prepared by treatment with dimethyl sulfate and potassium hydroxide in an atmosphere of nitrogen, extracted with ether, and crystallized from methanol (slow), was obtained in 98% yield as colorless, transparent prisms melting at 79–80°, and further crystallizations did not change the melting point.

Anal. Calcd. for $C_{16}H_{13}O_2Br$: C, 60.43; H, 4.13. Found: C, 60.21; H, 4.36.

2-Bromo-1,3,4-triacetoxyphenanthrene.—A suspension of 1 g. of 2-bromo-3,4-phenanthrenequinone in a cold solution of 12 drops of concentrated sulfuric acid in 10 cc. of acetic anhydride was stirred frequently at room temperature; after four to five hours a nearly colorless solution was obtained, and this was treated cautiously with water to hydrolyze the excess anhydride, using 10 cc. in all and eventually bringing precipitated material into solution at the boiling point. The filtered solution deposited nearly pure material which, after recrystallization from acetic acid, formed very fine, colorless needles, m. p. 195–196°; yield, 1.4 g. (93%).

Anal. Calcd. for $C_{20}H_{15}O_6Br$: C, 55.68; H, 3.51. Found: C, 55.91; H, 3.36.

2 - Bromo - 3 - hydroxy - 1,4 - phenanthrenequinone.—The triacetate (0.8 g.) was warmed with 10% sodium hydroxide (15 cc.) and a little alcohol until dissolved. Air was passed through the solution until the solution was dark red and showed no further change. Water (150 cc.) was added to dissolve some crystalline salt at the boiling point, and the solution was acidified. The orange-yellow precipitate when crystallized from methanol (moderately soluble), formed glistening, orange-red needles, m. p. 198–199°; yield, 0.5 g. (89%).

Anal. Calcd. for $C_{14}H_7O_3Br$: C, 55.45; H, 2.33. Found: C, 55.37; H, 2.37.

The bromohydroxyquinone (58 mg.) was recovered unchanged (50 mg.) after a solution of the substance in methanol had been refluxed for five hours. Under identical conditions, a solution of 3-hydroxy-1,4-phenanthrenequinone (56 mg.) began to deposit crystals of the ether in two minutes and after refluxing for ten minutes the ether[2] was collected and recrystallized; yield, 49 mg. (84%); m. p. 170–171°. Whereas 3-hydroxy-1,4-phenanthrenequinone is cleaved completely by boiling, dilute alkali in about four hours,[2] the 2-bromo derivative (0.4 g.) was largely recovered unchanged (0.35 g.) after being boiled for fifteen

---

[8] The melting points are uncorrected. Analyses marked with an asterisk were performed by Mrs. G. M. Wellwood.

hours with 150 cc. of water containing 2.9 cc. of 10% sodium hydroxide solution.

8,9-Dimethyl-5,6-chrysenequinone (IV).—A solution of 0.5 g. of 2-bromo-3,4-phenanthrenequinone and 2 cc. of 2,3-dimethylbutadiene in 20 cc. of pure chloroform was heated at 100° for two hours, when the color had faded from red to yellow. The reddish-yellow oil remaining after removing the solvent was treated in 3 cc. of glacial acetic acid with 1 g. of chromic anhydride in 10 cc. of 80% acetic acid with gentle warming. By gradually adding water to the red solution and scratching, the reaction product was caused to separate in a microcrystalline condition; yield, 0.45 g. (90%). Recrystallized from glacial acetic acid, the quinone formed bright orange-red blades having a golden reflex, m. p. 250–251°.

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.89; H, 4.93. Found: C, 83.74; H, 4.96.

1,2-Phenanthrenequinone Series

3-Bromo-1,2-phenanthrenequinone.—A fine suspension of 3.8 g. of 1,2-phenanthrenequinone (as prepared[5]) in 180 cc. of glacial acetic acid at 25° was treated with 3.3 g. of bromine in 20 cc. of this solvent, and after stirring for twenty minutes the material had dissolved. The yellow-red solution, filtered from a small amount of black material, was poured into 290 cc. of vigorously boiling water. The bromoquinone began to crystallize at once and, after cooling, it was collected and recrystallized from chloroform. It formed glistening, very dark crimson-red needles, m. p. 245–246°; yield, 3.6 g. (68%). The substance is darker in color than the isomer, and considerably less soluble in all solvents.

*Anal.** Calcd. for $C_{14}H_7O_2Br$: C, 58.54; H, 2.46. Found: C, 58.65; H, 2.83.

3-Bromo-1,2-dihydroxyphenanthrene.—A solution of 1 g. of the quinone in 20 cc. of hot dioxane was diluted with 15 cc. of water and sulfur dioxide was passed into the resulting fine suspension. After the quinone had dissolved, the solution was heated to boiling, diluted with water, and allowed to stand. On cooling, the hydroquinone separated as long, slender, colorless needles (0.9 g.). A sample recrystallized from chloroform melted at 195–196°.

*Anal.** Calcd. for $C_{14}H_9O_2Br$: C, 58.13; H, 3.14. Found: C, 58.20; H, 3.11.

The dimethyl ether, prepared as described for the isomer, crystallized from methanol as thin, elongated, transparent plates, m. p. 82–83°.

*Anal.** Calcd. for $C_{16}H_{13}O_2Br$: C, 60.43; H, 4.13. Found: C, 60.36; H, 3.92.

3 - Bromo - 1,2,4 - triacetoxyphenanthrene, obtained as above in nearly theoretical yield, formed fine, colorless needles, m. p. 188–189°, from glacial acetic acid.

*Anal.** Calcd. for $C_{20}H_{15}O_6Br$: C, 55.68; H, 3.51. Found: C, 55.62; H, 3.75.

Hydrolysis of the triacetate and air oxidation as above gave a hydroxyquinone which forms very dark red needles, m. p. 222° dec., from alcohol; analytical results were variable and undecisive.

6,7 - Dimethyl - 3,4 - benzphenanthrenequinone (VIII).—The quinone (1 g.) and diene (6 cc.) were heated in chloroform (70 cc.) for three hours and the addition product was oxidized as above; yield of crystalline product, 79%. Recrystallized from alcohol, the compound formed lustrous, fiery red plates, m. p. 194–195°.

*Anal.** Calcd. for $C_{20}H_{14}O_2$: C, 83.89; H, 4.93. Found: C, 83.63; H, 5.01.

This quinone, identified by mixed melting point determination, was obtained also on heating 1,2-phenanthrenequinone (0.5 g.), dimethylbutadiene (2 cc.) and chloroform (20 cc.) for forty-eight hours and oxidizing the crude product as above; yield, 0.2 g. (29%). The diene addition occurred only slowly, for the initially clear red solution faded only slightly during the first few hours of heating; after a time the solution began to grow steadily darker, indicating decomposition.

3,4-Benzphenanthrenequinone, prepared in the usual way from 1 g. of bromoquinone and 4 cc. of butadiene, heated in 40 cc. of chloroform for five hours, was obtained in a satisfactory condition in yield of 0.6 g. (65%). It crystallized from alcohol as bright red blades, m. p. 190–191°. Cook[6] reports the melting point 187–188° for material prepared by the oxidation of 3,4-benzphenanthrene. Attempts to convert the above substance (100 mg.) into the hydrocarbon by zinc dust distillation were unsuccessful. Reductive acetylation of 100 mg. of the quinone by the usual method gave 115 mg. of the pure **hydroquinone diacetate,** which forms small, colorless needles from dilute alcohol and melts at 194–195°.

*Anal.** Calcd. for $C_{22}H_{16}O_4$: C, 76.72; H, 4.69. Found: C, 76.38; H, 4.77.

Chlorination of 3-Phenanthrol

Pentachloro Ketone XII, Probably 1,4,4-Trichloro-3-keto - 3,4 - dihydrophenanthrene - 9,10 - dichloride.—Excess chlorine was passed at a moderate rate into a solution of 5 g. of 3-phenanthrol in 50 cc. of glacial acetic acid at 13–17°, and after standing for a few minutes the greenish-yellow solution was poured slowly into 500 cc. of cold water. The flocculent yellow precipitate which separated was washed by decantation, collected on a suction funnel, and washed thoroughly with water. The rather sticky, yellow-orange product was triturated with glacial acetic acid, which dissolved the gummy material, and on collecting the residue and washing it thoroughly with fresh solvent a clean, orange-yellow powder was obtained. The yield of this material, m. p. 175–180° dec., was 2.9 g. (30%). A sample recrystallized from glacial acetic acid (with little heating) formed thick, orange needles, m. p. 182–185°, dec.

*Anal.** Calcd. for $C_{14}H_7OCl_5$: Cl, 48.14. Found: Cl, 47.82; 47.77.

The compound is not attacked by 10% aqueous sodium carbonate solution in the cold, and extensive decomposition occurs when the mixture is heated. The chloro compound gives a dark red anilide on reaction with aniline in benzene solution. In one experiment a small amount of another chlorination product separated slowly from the initial acetic acid mother liquor in the form of colorless prisms (m. p. 191° dec.) but when this material was collected and dried it turned yellow within a few hours.

1(?),4,9(or 10)-Trichloro-3-phenanthrol (XIII).—A solution of 0.9 g. of the above compound in 18 cc. of glacial acetic acid was treated at room temperature with a concentrated solution of stannous chloride in dilute acetic acid, added by drops until a test portion of the solution gave with water a precipitate which dissolved completely in dilute alkali. On gradual dilution with water the solution deposited colorless needles of the reduction product (0.7 g., 96%). The phenanthrol formed long needles, m. p. 130–131°, from dilute alcohol.

*Anal.** Calcd. for $C_{14}H_7OCl_3$: Cl, 35.78. Found: Cl, 35.74.

The acetate crystallized from alcohol as lustrous plates, m. p. 164–165°.

*Anal.** Calcd. for $C_{16}H_9O_2Cl_3$: Cl, 31.35. Found: Cl, 31.15.

1(?),9(or 10)-Dichloro-3,4-phenanthrenequinone (XIV).—A solution of 0.35 g. of the trichlorophenanthrol in 8 cc. of glacial acetic acid was oxidized with 3 cc. of concentrated nitric acid added all at once. The solution became red immediately and then began to darken; after three to four minutes it was gradually diluted with an equal volume of water, thus precipitating the quinone in a microcrystalline condition. Recrystallization from glacial acetic acid gave small, dark red needles melting at 239–240° dec.; yield, 0.22 g. (67%).

Anal. Calcd. for $C_{14}H_6O_2Cl_2$: C, 60.65; H, 2.18. Found: C, 60.53; H, 2.53.

1(?),3,4 - Triacetoxy - 9(or 10) - chlorophenanthrene.—A suspension of 90 mg. of the quinone XIV in 6 cc. of acetic anhydride containing 6 drops of concentrated sulfuric acid was shaken at intervals and frequently warmed on the steam-bath. The material dissolved in about six hours, and after standing overnight the red-yellow solution was treated with water. One crystallization from acetic acid gave 70 mg. of yellowish rods, and after further crystallizations from alcohol the compound was obtained as slender, colorless needles, m. p. 230–231°.

*Anal.** Calcd. for $C_{20}H_{15}O_6Cl$: Cl, 9.17. Found: Cl, 9.65.

Summary

3-Bromo-1,2-phenanthrenequinone and 2-bromo-3,4-phenanthrenequinone add dienes readily and the addition products can be converted in good yield into 3,4-benzphenanthrenequinones and chrysenequinones, respectively.

From a preliminary study of the chlorination of 3-phenanthrol it appears that the substance not only is attacked in the hydroxylated ring but adds chlorine at the 9,10-position.

10-Substituted 1,2-Benzanthracene Derivatives

BY LOUIS F. FIESER AND E. B. HERSHBERG[1]

The observation that 10-methyl-1,2-benzanthracene[2] is a potent carcinogenic agent comparable with cholanthrene and methylcholanthrene in the rapidity and regularity with which it produces tumors in experimental animals[3] has made it a matter of considerable interest to investigate additional 10-substituted derivatives of the tetracyclic hydrocarbon. The 10-methyl derivative contrasts strikingly with 1,2-benzanthracene itself, for in experiments conducted at the Royal Cancer Hospital the latter hydrocarbon has produced only one tumor (papilloma) in eighty mice tested.[4] Since compounds of more complex structure than the methyl derivative, namely, the 10-isopropyl and 10-benzyl compounds, have been tested by the English investigators[4] with entirely negative results, it is important to determine whether 10-methyl-1,2-benz anthracene occupies a unique position or is one of a possibly limited series of homologs possessing some carcinogenic activity. A series of closely related hydrocarbons of graduated potency would offer many interesting possibilities for biological and chemical experimentation.

None of the synthetic methods hitherto employed for the preparation of 10-alkyl-1,2-benzanthracenes seemed adequate for the purpose at hand without some modification. The synthesis of Fieser and Newman[2] provides a quite satisfactory, if somewhat lengthy, route to the 10-methyl compound, but it suffers from the limitation that considerable reduction occurs as a side reaction in the condensation of higher alkylmagnesium halides with 2-*o*-toluyl-1-naphthoic acid. Cook[5] obtained the 10-benzyl compound in small yield by the action of benzyl chloride on 1,2-benzanthracene in the presence of zinc dust, but direct alkylation clearly is out of the question as a general method. A third synthesis,

briefly investigated by Cook[5,6] with only moderate success, consists in the addition of a Grignard reagent to 1,2-benz-10-anthrone (IV, below) and the dehydration of the resulting dihydroanthranol. Cook prepared 10-benzyl-[5] and 10-isopropyl-1,2-benzanthracene[6] in unspecified yield by this method. Recently, Cook, Mrs. Robinson and Goulden[5a] have overcome earlier difficulties[5] and succeeded in preparing the 10-methyl compound in the same way. The 1,2-benz-10-anthrone used in these experiments was a crude product prepared[5] by heating 2-(α-naphthylmethyl)-benzoic acid with anhydrous zinc chloride at 180°. The material was found to be so unstable that purification was not feasible.

It seemed likely that the anthrone synthesis of Cook would be capable of wide application if the anthrone were available in a more satisfactory condition, and we consequently investigated this phase of the problem. The preparation of the 2-(α-naphthylmethyl)-benzoic acid required as starting material by the reduction of 2-(α-naphthoyl)-benzoic acid with zinc dust and alkali[7] has been tried repeatedly in this Laboratory with disappointing results. Although with closely analogous keto acids reduction by this method usually proceeds very well, a product of satisfactory purity is obtained with the specific example at hand only after a tedious process of purification and in poor yield. A much better method was found in the high-pressure hydrogenation of the keto acid without solvent at 175° in the presence of copper chromite catalyst,[8] a pure product being obtained in excellent yield after a single crystallization. No reduction occurred when solvent alcohol was employed. The 2-(α-naphthoyl)-benzoic acid was at first prepared by the Friedel and Crafts reaction, but the separation of the desired product from the β-isomer[9] proved to be so tedious and wasteful that this was abandoned in favor of the Grignard condensation between phthalic anhydride and α-bromonaphthalene,[10] which was found very satisfactory. On one occasion, when commercial α-bromonaphthalene was used without further purification, the keto acid obtained had the correct melting point but failed to undergo hydrogenation even after repeated crystallization. The difficulty was traced to the reduction of the catalyst to the metallic condition under the influence of a trace of hydrogen bromide liberated from a small amount of bromonaphthoylbenzoic acid present in the material prepared from halide contaminated with dibromonaphthalene.

Cook[5] noted that sulfuric acid alone is not a satisfactory reagent for effecting the cyclization of 2-(α-naphthylmethyl)-benzoic acid since it leads to considerable oxidation and sulfonation. We found that these side reactions can be avoided to some extent by using a suitable diluent. Employing for the ring closure a mixture of sulfuric and phosphoric acids at room temperature, the crude anthrone was obtained in over 90% yield. This material, however, deteriorated badly on standing and extensive decomposition occurred on attempted crystallization. Submitted to reaction with methylmagnesium iodide or ethylmagnesium bromide, the crude products gave, after dehydration, some of the expected 10-methyl- and 10-ethyl-1,2-benzanthracene, but the yields were low and considerable unreacted material was recovered. This recovered product is quite easily purified and considerably less subject to decomposition than the starting material.

The pure, crystalline substance isolated in this way was found to be the enolic form of the compound, 1,2-benz-10-anthranol (III). It was subsequently established that the anthranol is not produced under the influence of the Grignard reagent but is present to a considerable extent in the crude product of cyclization and that addition occurs only to such of the keto-form as is contained in the material submitted to reaction. The stability in solvents of the recovered anthranol in contrast to the crude starting material suggested that a purification of the latter might be accomplished most effectively through some other functional derivative of the anthranol, such as the acetate. We were not able to prepare 1,2-benzanthranyl-10-acetate (II) satisfactorily from the very sensitive anthrone–anthranol mixture resulting from cyclization with sulfuric–phosphoric acid, but found that some of this substance is produced, along with some 1,2-benz-10-anthrone (IV), when the acid I is warmed with a mixture of sulfuric and acetic acids. It seemed likely that under conditions more favorable to acetylation

IV (faintly yellow, m. p. 181°)

V VI

the tautomeric equilibrium would be displaced by the removal of the anthranol as the acetate, and various mixtures containing acetic anhydride were tried. Since zinc chloride in the molten state effects ring closure,[5] we investigated the action of this substance in solution and eventually developed a method of cyclization which leaves little to be desired.

The new method consists in heating 2-(α-naphthylmethyl)-benzoic acid (I) with about 0.1 molecular equivalent of zinc chloride in a mixture of acetic anhydride and acetic acid at the boiling point for about one hour. After adding water and cooling, 1,2-benzanthranyl-10-acetate separates in a crystalline and completely pure condition in yield of about 90%. Zinc chloride in catalytic amounts also promotes cyclization in acetic anhydride solution alone, but the anhydride itself is attacked under these conditions with consequent darkening. This effect is eliminated by using some acetic acid as a diluent. Stannous chloride can be used also as the catalyst, but it does not seem to offer any advantages. The method of cyclization has been found applicable to some, if not all, other 2-arylmethyl-benzoic acids, γ-arylbutyric acids, and β-arylpropionic acids thus far investigated; a study of additional examples is under way and will be reported separately.

The hydrolysis of the acetate II was accomplished very satisfactorily by treatment with excess Grignard reagent, the pure enolic tautomer III being obtained in over 80% yield. 1,2-Benz-10-anthranol forms bright golden yellow blades melting at 155°. The substance is completely stable in the solid state and it undergoes only very slow isomerization in most solvents. Acetone combines rapidly with the anthranol to give what appears to be a labile, colorless molecular compound and in the boiling solvent the enol form partially isomerizes at a moderately rapid rate to 1,2-benz-10-anthrone (IV), which was isolated in a pure condition by crystallization from acetone–ligroin after boiling the solution to effect a partial equilibration. This process could not be carried to completion, however, for solutions containing acetone suffer decomposition after refluxing for a few hours, apparently before equilibrium is established. The anthrone IV is a faintly yellow substance melting at 181°, and it is more soluble in hydrocarbon solvents than the anthranol III. Both tautomers can be crystallized without change from benzene or toluene if the heating is not prolonged, but when a toluene solution of the anthranol is refluxed for several hours partial isomerization to the anthrone occurs. Little decomposition takes place in hydrocarbon solvents, and this was the most satisfactory method found for obtaining the anthrone in a condition suitable for the Grignard reaction.

For the preparation of the methyl ether of 1,2-benz-10-anthranol, the usual process of methylation in alkaline solution did not appear practical because in such a medium the substance is rapidly oxidized by the air to the corresponding quinone. It was found that the ether can be obtained conveniently by cleaving the acetate II with a Grignard reagent and heating the resulting solution of the magnesium bromide salt with dimethyl sulfate.

From such general comparisons as can be made with K. H. Meyer's observations concerning the parent pair of tautomers, anthranol and anthrone,[11] it appears that the enol form is a somewhat more favored structure in the 1,2-benzanthracene series than with the anthracene compounds, as would be expected from theoretical considerations,[12] but until a direct comparison of

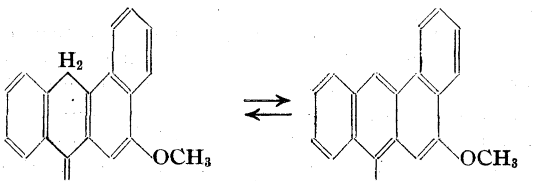
the two systems can be made it is perhaps well to reserve judgment on this point.

Having developed a good method of preparing pure 1,2-benz-10-anthranol and a reasonably satisfactory method of effecting its isomerization, little difficulty was experienced in synthesizing a series of 10-alkyl-1,2-benzanthracenes. In some instances crystallizates consisting wholly or largely of the keto form were employed for the Grignard reaction, but the best procedure consists in refluxing a solution of the anthranol in toluene for several hours and adding the cooled solution containing a large proportion of the anthrone to a solution of the Grignard reagent. Addition of the reagent proceeds rapidly and smoothly and moderate heating of the reaction product is sufficient to effect dehydration of the dihydroanthranol derivative (V). Some 1,2-benz-10-anthranol not originally isomerized usually can be recovered with ease in a satisfactory condition and traces of oxygen-containing compounds are eliminated readily by adsorption on alumina. Pure *n*-alkyl compounds were obtained in this way in average yield of about 50%. The 10-methyl-1,2-benzanthracene obtained was identical with the material synthesized by Fieser and Newman.[2] The 10-isopropyl compound was prepared for comparison with Cook's material[6] and the properties were as reported. The yield in this preparation was poor and in one experiment the principal product isolated was a substance having the composition of a tetrahydro derivative of 10-isopropyl-1,2-benzanthracene; it yielded the latter hydrocarbon on dehydrogenation with sulfur. We plan to investigate this substance further and to study the reduction of 1,2-benzanthracene derivatives under other conditions. The more usual type of reduction, resulting in the formation of 1,2-benzanthracene, was observed to occur to an appreciable extent only in one instance. The series of 10-substituted derivatives prepared included the ethyl, *n*-propyl, *n*-butyl, *n*-amyl, and allyl compounds. 10-Allyl-1,2-benzanthracene is converted smoothly on hydrogenation into a hydrocarbon identical with the synthetic 10-*n*-propyl derivative.

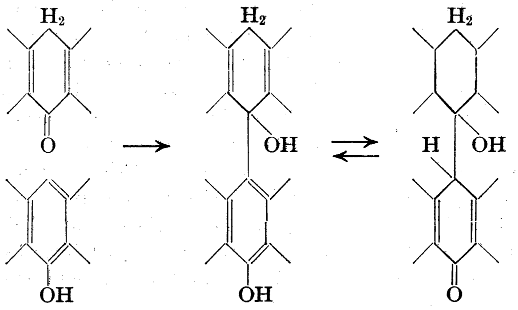
A few 10-alkyl derivatives of the weakly carcinogenic[13] 3-methoxy-1,2-benzanthracene also were prepared, and here the process proved to be considerably simpler. The pale yellow, crude product resulting from the cyclization of 2-(4′-methoxy-1′-naphthylmethyl)-benzoic acid with cold sulfuric acid,[14] although tending to decompose on attempted crystallization from most solvents,[14] is less sensitive than the methoxyl-free material.



VII (faintly yellow, m. p. 184°)

VIII (deep brown, m. p. 193°)

In each case cyclization with sulfuric acid seems to produce initially the keto form, which isomerizes to some extent when washed with water and undergoes slow change even on storage in the solid state. It was found that pure 3-methoxy-1,2-benz-10-anthrone (VII) can be obtained easily in fair yield by quickly crystallizing the crude, moist cyclization product from acetone. The anthranol, VIII, was first isolated in small amount from the mother liquor, and this tautomer later was prepared by the isomerization of the pure anthrone with boiling pyridine. There was isolated as a by-product in this reaction a high-melting, sparingly soluble, yellow compound having the composition of the starting material. This most likely is formed by the condensation of the enol and keto forms, giving the dianthranol-like substance IXa or the tautomer IXb. A similar substance was isolated as a by-product in the preparation of 10-*n*-amyl-1,2-benzanthracene and, since it is colorless, it probably has the ketonic structure IXb.



IXa IXb

From the pure anthrone VII, the 10-methyl, 10-ethyl, and 10-*n*-propyl derivatives of 3-methoxy-1,2-benzanthracene were obtained in good yield by the Grignard synthesis.

[14] Fieser and Dietz, *ibid.*, **51**, 3141 (1929).

The 1,2-benzanthracene derivatives described in this paper are being tested for carcinogenic activity by Dr. M. J. Shear. The synthesis of 10-substituted compounds is being continued.

Experimental Part[15]

2-(α-Naphthoyl)-benzoic Acid.—Material prepared by the Friedel and Crafts reaction in tetrachloroethane solution at 10° and obtained in 84% yield after one crystallization, melted at 150–170° and afforded a pure product only after several recrystallizations and with heavy losses. In the large-scale preparation by the alternate method,[10] 145 g. of carefully fractionated α-bromonaphthalene, b. p. 155.0–155.5° (25 mm.), m. p. 4–5°, was converted into the Grignard reagent in benzene (100 cc.)–ether (400 cc.) solution and this was added slowly to a vigorously stirred suspension of 111 g. of phthalic anhydride in 700 cc. of hot benzene. After stirring for two hours on the steam-bath, the mixture was worked up as usual and the product, collected after removing the solvent with steam, was mixed with soda solution and submitted to steam distillation. The dinaphthyl phthalide present remained undissolved, and after treating the solution with Norite at 10–15° the acid was precipitated, washed, drained well with the use of a rubber dam, and crystallized from an alcohol (500 cc.)–water (300 cc.) mixture; yield, 144 g. (75%); m. p. 174–176°.

2-(α-Naphthylmethyl)-benzoic Acid.—Reduction with zinc and alkali[7] gave satisfactory material, m. p. 147–148°, in about 20% yield after several crystallizations from benzene–ligroin and methanol.

In a typical hydrogenation experiment 144 g. of the once crystallized, halogen-free keto acid and 8 g. of copper chromite catalyst (37 KAF[8]) were shaken with hydrogen at 2300–1500 lb. (156–102 atm.) pressure and 175° for two and one-half to three hours, when the reaction was complete. The temperature may be raised to 200° without ill effect. On cooling the bomb the product was found as a light green, crystalline cake. It was dissolved in a solution of 60 g. of sodium carbonate in 500 cc. of water by warming on the steam-bath and the solution was treated with Norite and poured into dilute hydrochloric acid. The collected and washed precipitate, crystallized while damp from 1500 cc. of methanol and 500 cc. of water, gave in the first crop 113 g. (82%) of colorless product, melting at 144–146° and suitable for cyclization. Only oily material was obtained from the mother liquor. The recrystallized acid formed flat needles, m. p. 148–148.5°.

Keto acid prepared by the Friedel and Crafts synthesis also was hydrogenated easily; with repeatedly recrystallized acid prepared from Eastman α-bromonaphthalene, b. p. 146–149° (16 mm.), the catalyst invariably was reduced to the metallic condition and the keto acid was recovered unchanged.

Cyclization of 2-(α-Naphthylmethyl)-benzoic Acid (I). (a) With Sulfuric–Phosphoric Acid.—The finely powdered (ball mill) acid (25 g.) was added to a vigorously stirred mixture of 200 cc. of concentrated sulfuric acid and 400 cc. of sirupy phosphoric acid (85%) at 20–30° and after two and one-half hours the deep red solution was filtered through sintered glass to remove unchanged acid (3.3 g.) and poured on cracked ice. The collected pale yellow precipitate was washed well with water and with dilute hydrochloric acid and dried in vacuum at room temperature; yield, 19.5 g. (94%); m. p. 130–135°.

This material deteriorates rapidly on standing; it is considerably less stable when washed with dilute soda solution, for this seems to promote isomerization to the enol form and secondary changes. Some isomerization probably occurs during the process of drying. Solutions of the acid-washed product darken rapidly, and attempted crystallizations were unsuccessful. In a typical Grignard reaction with freshly prepared material, 12 g. of the crude anthrone–anthranol mixture gave 2.25 g. of hydrocarbon and 5.5 g. of recovered 1,2-benz-10-anthranol, indicating the presence of at least 20% of keto form and 50% of enol form in the mixture.

(b) **With Sulfuric–Acetic Acid.**—A solution of 6 g. of the acid (I) in 70 cc. of glacial acetic acid was added to 90 cc. of concentrated sulfuric acid diluted with 20 cc. of glacial acetic acid, and after maintaining the mixture at 50–60° for twenty minutes it was poured on ice. The collected solid, washed with acetone and crystallized from this solvent, gave 2.3 g. of 1,2-benzanthranyl-10-acetate, m. p. 152–154°, together with some 1,2-benz-10-anthrone.

(c) **With Zinc Chloride as Catalyst.**—The most satisfactory procedure found was as follows. A mixture of 5 g. of 2-(α-naphthylmethyl)-benzoic acid, 30 cc. of glacial acetic acid, 20 cc. of acetic anhydride, and 0.4 g. of anhydrous zinc chloride was refluxed for one hour, during which time the solution acquired only a pale yellow color. Water was added cautiously under reflux in amount sufficient to produce a saturated solution, and on slow cooling very pure **1,2-benzanthranyl-10-acetate (II)** separated in beautiful, colorless needles; yield, 4.95 g. (91%). The material softened at 161° and melted at 163–163.5°. Cook[5] reports that the ("straw-colored") sample prepared by acetylation of the crude anthrone melted at 156° to a cloudy liquid becoming clear at 163°.

In earlier experiments, using as much as 75 g. of the acid I, the acetate was obtained in a slightly less pure condition in 70–80% yield on heating the acid for about one hour in acetic anhydride containing catalytic amounts of zinc chloride, stannous chloride, or a mixture of these halides. Acetic anhydride itself is attacked at the boiling point by these reagents, with considerable darkening, and when the undiluted anhydride was employed for cyclization the solution invariably turned dark brown. The acetate was brown and usually melted at about 153–156°; the melting point became constant at 162.5–163° only after seven crystallizations. Dilution with acetic acid eliminated this difficulty.

1,2-Benz-10-anthranol (III).—To effect cleavage, 16.1 g. of the acetate (II) was added to the Grignard reagent from 38 g. of *n*-butyl bromide, 150 cc. of benzene was added, the ether was allowed to distil, and the clear, deep orange to brown solution was refluxed for one hour. After treatment with dilute hydrochloric acid, the benzene layer was separated while hot, and on concentrating the solution a first crop of product (10.3 g.), m. p. 152–154°, and a second crop (1.3 g.), m. p. 148–150°, were obtained (yield,

---

[15] All melting points are corrected. Analyses by Mrs. G. M. Wellwood.

84%). On recrystallization from benzene the substance separated as rosets of lustrous, golden yellow prismatic blades, m. p. 154.5–155.5°.

Anal. Calcd. for $C_{18}H_{12}O$: C, 88.49; H, 4.96. Found: C, 88.49; H, 4.85.

1,2-Benz-10-anthranol is readily soluble in glacial acetic acid or benzene and moderately soluble in alcohol; the solutions are only pale yellow in color and exhibit a blue fluorescence in ultraviolet light. The first two solvents are most satisfactory for crystallization. When the powdered anthranol is covered with a little acetone it sets to a cake, and on stirring the yellow substance rapidly changes to a colorless solid. This appears to be a labile molecular compound of the enol form, for when it was collected rapidly by centrifugation it turned yellow on drying and the melting point was that of the anthranol. The pure anthranol dissolves in dilute alkali very slowly in the cold but rapidly when warmed, yielding a yellow solution which on being shaken with air soon becomes cloudy, owing to the separation of the corresponding quinone (vat test).

1,2-Benz-10-anthranol was obtained also by refluxing the acetate (1 g.) with methanol (100 cc.) saturated with hydrogen chloride for fifteen hours. The product was precipitated with water and crystallized from benzene–ligroin, giving 0.5 g. of anthranol, m. p. 150–153°.

1,2-Benz-10-anthrone.—Isomerization of the anthranol seems to take place more rapidly in acetone than in other solvents, but secondary changes occur fairly soon in boiling acetone and considerable material is destroyed if refluxing is continued for more than a brief period. In isolated experiments the pure anthrone was obtained in about 50% yield by crystallization of the anthranol from dilute acetone, but the results were irregular and the material in the mother liquor was not recoverable. The keto form was isolated in yields of 20–25% by crystallization from acetone–ligroin, and by evaporating solutions of the anthranol in acetone at room temperature in vacuum.

Pure 1,2-benz-10-anthrone can be recrystallized without change from acetone or benzene and forms faintly yellow needles melting at 180–181°, dec.

Anal. Calcd. for $C_{18}H_{12}O$: C, 88.49; H, 4.96. Found: C, 88.34; H, 5.01.

The compound is insoluble in cold alkali but dissolves fairly readily on boiling to a yellow solution which soon becomes cloudy through oxidation. The anthrone is more soluble in hydrocarbon solvents than the anthranol and the solutions are colorless and non-fluorescent.

10-Methoxy-1,2-benzanthracene.—To the Grignard reagent from 3.84 g. of *n*-butyl bromide in ether, 2 g. of 1,2-benz-10-anthranyl acetate was added. After refluxing for one hour, 7.1 g. of dimethyl sulfate was added in 50 cc. of toluene and the mixture was heated for four hours on the steam-bath, allowing the ether to distil. Water was added, the mixture was warmed and stirred for one hour on the steam-bath to decompose the excess reagent, and the washed toluene layer was diluted with benzene and passed through a tower of activated alumina, which removed some unmethylated anthranol. The filtrate was evaporated to dryness and the residue crystallized from benzene–ligroin, giving 1.0 g. (55%) of satisfactory material, m. p. 108–110°. The recrystallized ether formed colorless, diamond-shaped prisms, m. p. 110.5–111°.

Anal. Calcd. for $C_{19}H_{14}O$: C, 88.35; H, 5.47. Found: C, 88.19; H, 5.72.

10-Alkyl-1,2-benzanthracenes

In the most satisfactory procedure, a solution of pure 1,2-benz-10-anthranol in toluene was refluxed for twelve hours to effect partial isomerization and allowed to cool; the solution was decanted from crystals of anthranol which separated, this material was refluxed with fresh toluene for seven hours, and the two solutions were combined and added to the Grignard reagent. Yields of hydrocarbon up to 66% show that at least this proportion of the keto form is produced by this treatment. The keto form does not appear to suffer isomerization to any appreciable extent in the course of the reaction, for the yield of hydrocarbon (ethyl) from the pure anthrone was 82%. The Grignard reaction is rapid, and usually the mixture was decomposed after stirring and warming for about one hour on the steam-bath. The organic layer was separated and washed, and after removing the solvent by distillation the residue was heated for a few minutes on the hot-plate in order to effect the complete dehydration of the dihydroanthranol derivative (V). The material was then taken into benzene and the solution was allowed to cool. Some unchanged 1,2-benz-10-anthranol often crystallized at this point and could be recovered in a satisfactory condition. The anthranol can be separated very easily from the (very soluble) hydrocarbon present in the solution, but the recovered material was not employed for the preparation of a sample of a different hydrocarbon when this was to be used for biological experiments. This limitation does not apply to the preparation of the anthranol from its acetate, for here there is little chance of the formation of a hydrocarbon and the purification was more than adequate to remove possible traces of the very soluble *n*-butyl compound. Traces of the anthrone, anthranol, and other contaminants were removed very effectively by next passing the benzene solution through a tower of activated alumina, and the hydrocarbon was obtained in a very satisfactory condition from the filtrate.

The properties and analyses of the hydrocarbons and their picrates are given in the table. The hydrocarbons crystallize well from methanol or ethanol, as do the picrates. The hydrocarbons and their solutions show a brilliant blue fluorescence in ultraviolet light. 10-Methyl-1,2-benzanthracene, prepared only in a qualitative experiment from a crude anthrone–anthranol mixture, melted at 139–140° and gave no depression when mixed with the sample of Fieser and Newman.[2] Additional details of individual experiments are recorded below. Where fractionation of a commercial sample of an alkyl halide was required, the boiling point of the material used is recorded.

Ethyl Compound.—A solution of 1.8 g. of pure 1,2-benz-10-anthrone, m. p. 180–181°, in 100 cc. of hot benzene was added slowly to the stirred Grignard reagent from 8.1 g. of ethyl bromide in 100 cc. of ether. After a transient red phase, the solution became light greenish-yellow; refluxing was continued for three hours. The yield of once crystallized (from alcohol) hydrocarbon, m. p. 112–113°, was 1.55 g. (82%).

***n*-Propyl Compound.**—Eight grams of 1,2-benz-10-anthranol was refluxed for twelve hours with 100 cc. of toluene, the unchanged enol which crystallized on cooling was refluxed with 100 cc. of fresh toluene; the solutions were combined and added to the Grignard reagent from 3.9 g. of *n*-propyl chloride, b. p. 45.7–46.2°. On working up the mixture, 2.1 g. of 1,2-benz-10-anthranol was recovered and the first crop of *n*-propyl-1,2-benzanthracene from methanol melted at 100–102° and weighed 4.3 g. (66%, allowing for the recovery). The melting point was constant after four recrystallizations. The second crop of crystals (0.45 g.) consisted largely of 1,2-benzanthracene, which after further purification was identified by mixed melting point determination.

10-*i*-Propyl-1,2-benzanthracene and the Tetrahydro Derivative.—In the first experiment 4.5 g. of crude 1,2-benz-10-anthrone collected from several isomerization experiments was added in benzene solution to the Grignard reagent from 2 g. of magnesium and 6.5 g. of commercial isopropyl chloride (which on subsequent fractionation distilled at 34.9–35.0°). The ether was largely removed by distillation and the greenish-yellow solution was refluxed for five hours. The crude oily product crystallized only slowly; recrystallization from dilute acetic acid gave 2 g. of material, m. p. 71–73°, and 0.5 g., m. p. 69–71° (50%). On further crystallization from methanol the hydrocarbon formed iridescent, cream colored leaflets, m. p. 72.5–73.5°. The picrate separates as reddish-black, well-formed needles from methanol and melts at 134.5–135.5°. The analyses indicate that the hydrocarbon is a **10-*i*-propyltetrahydro-1,2-benzanthracene.**

Anal. Calcd. for $C_{21}H_{22}$: C, 91.91; H, 8.10. Found: C, 92.00; H, 7.95. Picrate, calcd. for $C_{21}H_{22}{\cdot}C_6H_3O_7N_3$: C, 64.41; H, 5.00; N, 8.34. Found: C, 64.67; H, 4.81; N, 8.58.

Later observations suggest that the reduction to the tetrahydro compound may have occurred at an earlier stage in the process rather than in the Grignard reaction, and this possibility is being investigated further.

When the hydrocarbon (0.5 g.) was heated with selenium at 300–305° for ten hours, the extracted product crystallized from methanol as colorless plates (0.15 g.) melting at 157–159°. The melting point was raised to 159–160° on further purification, and the substance gave no depression when mixed with an authentic sample of pure 1,2-benzanthracene melting at the same temperature. The isopropyl group at the 10-position evidently is eliminated in the course of the high-temperature dehydrogenation, but when the tetrahydro compound (0.2 g.) was heated for one-half hour with sulfur (50 mg.) at 240–245° the reaction product obtained melted at 93–93.5° and was found by mixed melting-point determination to be identical with the sample of 10-isopropyl-1,2-benzanthracene prepared as described below. The tetrahydro compound (0.2 g.), warmed in glacial acetic acid solution (5 cc.) with chromic anhydride (0.16 g.) in dilute acetic acid (2 cc.) for one and one-half hours, was converted into 1,2-benzanthraquinone (25 mg.), identified by comparison with an authentic sample.

In further experiments the Grignard reagents from redistilled isopropyl chloride (b. p. 34.9–35.0°) and from isopropyl bromide (b. p. 59.3–59.5°) were brought into reaction with crude 1,2-benz-10-anthrone under conditions very similar to those described above, but the only product isolated in a pure condition was 10-*i*-propyl-1,2-benzanthracene. In the experiment with the bromide there was obtained from 6 g. of the anthrone 2 g. of a crude hydrocarbon crystallizate melting at about 58–62°. After five crystallizations from methanol, the 10-isopropyl compound was obtained in a satisfactory condition, m. p. 93–93.5° (0.8 g.). The results were similar in the second experiment with isopropyl chloride.

Allyl Compound.—1,2-Benz-10-anthranol was isomerized with toluene as above and treated with two equivalents of allylmagnesium bromide, prepared in 80% yield according to Gilman and McGlumphy.[16] Once crystallized hydrocarbon, m. p. 117–122°, was obtained in 49% yield, and three crystallizations from ethyl alcohol gave a pure product. On hydrogenation in absolute alcoholic solution, using Adams catalyst, the allyl compound was converted into 10-*n*-propyl-1,2-benzanthracene, m. p. 106.5–107.5° (78% yield).

10-ALKYL-1,2-BENZANTHRACENES

[a] Cook[6] reports 94–95°. [b] Cook[4] reports 157–158°. [c] About a twofold excess of picric acid is required in the crystallization of the picrate to prevent its dissociation.

***n*-Butyl Compound.**—Using crude 1,2-benz-10-anthrone (3.45 g.) and *n*-butyl chloride (10.5 g.), b. p. 77.5–78.4°, the yield of crude hydrocarbon, m. p. 92–95°, was 2.25 g. (56%).

***n*-Amyl Compound.**—From 7.6 g. of the anthranol, isomerized with toluene, and 9.4 g. of *n*-amyl bromide, b. p. 127.5–128°, there was obtained 1 g. of a sparingly soluble condensation product, which crystallized from the toluene solution after concentration, and 3.4 g. (37%) of the hydrocarbon, m. p. 77–79° (a second crop of 1.2 g. (13%) melted at 65–70°). The pure hydrocarbon, obtained on three crystallizations from methanol, exhibits a brilliant bluish-green fluorescence even in daylight.

---

(16) Gilman and McGlumphy, *Bull. soc. chim.*, **43**, 1322 (1928).

The condensation product forms colorless needles from toluene and melts at 265–267°, dec. The composition is that of the anthrone and anthranol, and the properties are suggestive of a dimolecular, dianthrone-like structure (keto form of IX).

Anal. Calcd. for $C_{36}H_{24}O_2$: C, 88.49; H, 4.94. Found: C, 88.95, 88.89; H, 4.98, 5.11.

3-Methoxy-10-methyl-1,2-benzanthracenes

3-Methoxy-1,2-benz-10-anthrone (ol).—It was found expedient to conduct the cyclization of 2-(4′-methoxy-1′-naphthylmethyl)-benzoic acid (20 g.) at 3–5° rather than at 20°.[14] The pale yellow precipitated material was drained well with the use of a rubber dam and divided into three portions. Each portion, while still moist, was dissolved quickly in hot acetone and the solution was rapidly concentrated until crystals began to form. The combined first crops, consisting chiefly of the anthrone, weighed 6.6 g. (35%) and melted at 170–175°. A second combined crop of 6.2 g. consisted of a mixture of the keto and enol forms, and some brown crystals of the anthranol could be separated mechanically with little difficulty.

After three crystallizations from acetone the anthrone melted constantly at 183–184° and formed long, silky, pale yellow needles. The substance is very soluble in benzene or glacial acetic acid and moderately soluble in acetone or alcohol. It is insoluble in cold, dilute alkali and hot alkali gives a yellow oil. The **anthranol,** obtained as above and also by the action of boiling pyridine on the pure ketone, crystallizes from glacial acetic acid as fan-shaped clusters of short, deep brown prisms melting at 192–193°. The anthranol is more soluble in hydroxylic solvents and acetone than the tautomer.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.18; H, 5.15. Found (anthrone): C, 82.85; H, 5.24; (anthranol) C, 82.84; H, 5.50.

On isomerizing the anthrone with pyridine there was obtained in addition to the anthranol a sparingly soluble **condensation product** (probably IXa) which formed yellow needles from glacial acetic acid and melted with decomposition in the range 268–275°. When the capillary was inserted in a bath at 230°, the sample melted and resolidified without darkening, and melted with decomposition at 268–275°.

Anal. Calcd. for $C_{38}H_{28}O_4$: C, 83.18; H, 5.15. Found: C, 83.29; H, 5.02.

3-Methoxy-10-methyl-1,2-benzanthracene.—3-Methoxy-1,2-benz-10-anthrone (3.2 g., m. p. 179–181°) was added as a solid to the Grignard reagent from 4 g. of magnesium and methyl chloride in 150 cc. of ether, 100 cc. of benzene was added to the clear solution, the ether was distilled, and the solution was refluxed for three hours. After decomposition and separation of the layers, the benzene solution was evaporated, the residue was heated on the hot-plate to effect dehydration of the dihydroanthranol, and after passing a solution of the residue in benzene through a tower of alumina, the reaction product was obtained by concentrating the solution and adding ligroin; yield, 1.7 g. (53%); m. p. 182–183°. Recrystallization from alcohol and from benzene–ligroin gave slender, faintly yellow needles, m. p. 183–183.5°. The picrate, when prepared in alcohol–benzene, formed brown needles, m. p. 141–143°, but it changed to orange-red needles, m. p. 149–150°, when recrystallized from benzene–ligroin. The compound contains two molecules of picric acid, one probably being associated with the hydrocarbon residue and the other with the ether group.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.92. Found: C, 88.24; H, 6.34. Picrate, calcd. for $C_{20}H_{16}O \cdot 2C_6H_3O_7N_3$: N, 11.51. Found: N, 11.27.

3-Hydroxy-10-methyl-1,2-benzanthracene was prepared by refluxing the ether (0.5 g.) in glacial acetic acid (20 cc.) with 48% hydrobromic acid for one hour. The deep green solution deposited green needles on cooling. After recrystallizing the product twice from dilute acetic acid and once from benzene–ligroin, the hydroxy compound (0.2 g.) formed straw-colored, silky needles, m. p. 193–194°, dec. The compound is very soluble in alcohol or acetic acid and moderately soluble in benzene.

Anal. Calcd. for $C_{19}H_{14}O$: C, 88.35; H, 5.47. Found: C, 88.39; H, 5.71.

3-Methoxy-10-ethyl-1,2-benzanthracene, prepared as above, was obtained in a satisfactory condition in 67% yield. The substance crystallizes from benzene–alcohol as faintly yellow, diamond-shaped prisms, m. p. 161–161.5°. The picrate forms brick-red needles, m. p. 143.5–144°, from benzene–ligroin.

Anal. Calcd. for $C_{21}H_{18}O$: C, 88.01; H, 6.36. Found: C, 88.11; H, 6.52. Picrate, calcd. for $C_{21}H_{18}O \cdot 2C_6H_3O_7N_3$: N, 11.29. Found: N, 11.12.

3-Methoxy-10-*n*-propyl-1,2-benzanthracene.—Using *n*-propyl chloride, the yield of material, m. p. 134–135°, was 76%. After three crystallizations from benzene–alcohol, the compound formed nearly colorless needles, m. p. 136–136.5°. The picrate separated from benzene–ligroin as glistening, brick-red elongated plates, m. p. 140–140.5°.

Anal. Calcd. for $C_{22}H_{20}O$: C, 87.94; H, 6.73. Found: C, 87.77; H, 6.45. Picrate, calcd. for $C_{22}H_{20}O \cdot 2C_6H_3O_7N_3$: N, 11.11. Found: N, 11.35.

Summary

The preparation of a series of 10-alkyl-1,2-benzanthracenes, of interest in connection with the correlation of carcinogenic activity and structure, presented certain difficulties largely associated with the instability of the crude 1,2-benz-10-anthrone obtained by known methods of cyclization. The difficulty was overcome by the development of a new method of cyclization, using zinc chloride as a catalyst in acetic acid–anhydride solution, and yielding the anthranol acetate. Cleavage with a Grignard reagent gave the pure anthranol, and this was partially isomerized to the anthrone with boiling toluene. By the addition of Grignard reagents to the anthrone, and dehydration, the desired hydrocarbons were easily synthesized.

10-Alkyl derivatives of 3-methoxy-1,2-benzanthracene were obtained by a similar but simpler process.

The Heat Capacities of Selenium Crystals, Selenium Glass, and Tellurium at Low Temperatures[1]

BY C. TRAVIS ANDERSON[2]

The data presented in this report represent a portion of an investigation being carried out at the Pacific Experiment Station of the U. S. Bureau of Mines on the possible specific heat anomalies of manganese selenide, and telluride, similar to those already found in the oxide[3] and the sulfide.[4]

Since it was necessary to prepare pure selenium and tellurium to be used in this investigation, it was considered desirable to make low temperature specific heat measurements on these materials.

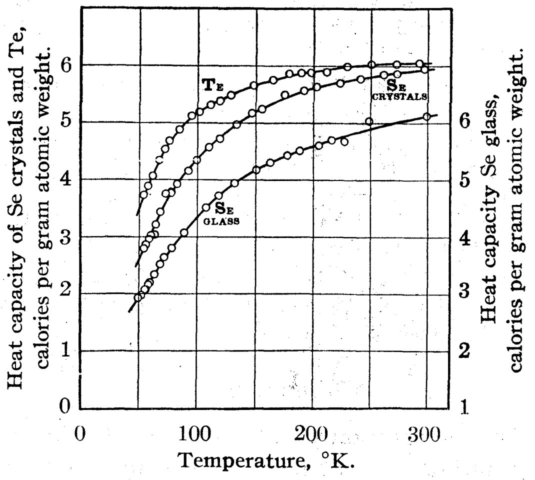

Fig. 1.—The heat capacity of selenium crystals, selenium glass and tellurium, in calories per gram atomic weight.

Materials.—The tellurium used in this investigation was furnished through the courtesy of Mr. J. O. Betterton of the American Smelting and Refining Co. The sample of selenium was of regular C. P. quality.

Both the selenium and tellurium were purified further by vacuum distillation. At temperatures slightly above their melting points, the purification of the selenium was carried out in a glass apparatus while quartz was used for the tellurium. The samples were distilled a number of times, until no residue remained in the distilling flask or condensed material accumulated above the main body of distillate.

In preparing the samples, the glassy form of selenium was usually obtained in the distillation. To convert the glass to the crystals, the selenium was alternately warmed and cooled until the mass crystallized. The only detectable impurities found to be present were approximately 0.2% tellurium in the selenium and a similar amount of selenium in the tellurium. No corrections were made for these small amounts of impurities. Measurements were made on 261.3 g. of the selenium crystals, 237.4 g. of the selenium glass, and 374.2 g. of the tellurium.

The Specific Heats.—The results obtained in this Laboratory on the heat capacities of selenium crystals, selenium glass, and tellurium, expressed in gram calories (15°) per gram atomic weight, are shown graphically in Fig. 1. The experimental values for the heat capacities are given in Tables I, II, and III. The calculations were made on the basis of Se = 78.96 and Te = 127.61.

Calculation of Entropies

In fitting the experimental data with Debye and Einstein functions it was found desirable to plot three times the specific heat against the logarithm of the temperature. This method can best be demonstrated by use of the recent data given by Eastman and McGavock[5] for sulfur, which is a member of the same periodic group. Their measurements were extended to lower temperatures than those reported in this paper, and the heat capacity of sulfur was lower than that of either selenium or tellurium at corresponding temperatures. By plotting 3 C_p *vs.* log T, their points fall on a Debye curve up to about 30°K., while on the usual C_p *vs.* log T plot the points fall below the Debye curve above 17°K. Combinations of Debye and Einstein functions can be used to fit their experimental data accurately to above 100°K. Unless this method of extrapolating were used it would be very difficult to obtain good values for the entropies of selenium and tellurium. The extended curves coincided with Debye functions having the following parameters (Θ): selenium crystals, 74; selenium glass, 65; and tellurium, 45.

The following combinations of Debye and Einstein functions were found to fit the specific heat curves.

$$C_{\text{Se cryst.}} = \frac{1}{3}\,\mathrm{D}\left(\frac{74}{T}\right) + \frac{1}{3}\,\mathrm{E}\left(\frac{180}{T}\right) + \frac{1}{3}\,\mathrm{E}\left(\frac{321}{T}\right)$$

$$C_{\text{Se glass}} = \frac{1}{3}\,\mathrm{D}\left(\frac{65}{T}\right) + \frac{1}{3}\,\mathrm{E}\left(\frac{152}{T}\right) + \frac{1}{3}\,\mathrm{E}\left(\frac{361}{T}\right)$$

$$C_{\text{Te}} = \frac{1}{3}\,\mathrm{D}\left(\frac{45}{T}\right) + \frac{1}{3}\,\mathrm{E}\left(\frac{142}{T}\right) + \frac{1}{3}\,\mathrm{E}\left(\frac{206}{T}\right)$$

The results of the entropy calculations from the experimental heat capacity data as well as from the function sums are given in Table IV. The reader should note that the entropies given are the summations from 0 to 298.1°K., which are identical with $S^{\circ}_{298.1}$ for the crystalline materials, but not for the selenium glass, which presumably has zero-point entropy. Existing high temperature specific heat measurements on selenium from 298.1° to the melting point are inadequate to calculate the actual entropy of the glass at 298.1°.

TABLE IV

ENTROPY DATA

	Selenium crystals	Selenium glass	Tellurium
Extrap. (0–50.1)°K.	2.26	2.61	3.54
Graph. (50.1–298.1)	8.23	8.54	9.31
$S_{0-298.1}$ graphical	10.49 ± 0.4	11.15 ± 0.4	12.85 ± 0.5
$S_{0-298.1}$ calcd. from functions	10.4	10.8	12.8

Summary

The heat capacities of selenium crystals and tellurium from about 50 to 300°K. have been determined and their corresponding entropies calculated as 10.49, and 12.85, respectively. Measurements for selenium glass over the same range indicate the difference in entropy from 0 to 298.1° for this material to be 11.15.

The Photolysis of Azomethane

BY MILTON BURTON, THOMAS W. DAVIS AND H. AUSTIN TAYLOR

In an investigation begun in this Laboratory it was hoped to use free methyl radicals formed in the photolysis of azomethane to induce chains in acetaldehyde at temperatures below that at which thermal decomposition could proceed. Inasmuch as previous investigators appeared to be quite certain of the mechanism of the decomposition of azomethane, it appeared likely that absolutely accurate information might be obtained about the length of chains initiated by free radicals.

According to Ramsperger[1] both the pyrolysis and the photolysis of azomethane proceed according to the over-all reaction

$$CH_3N{=}NCH_3 \longrightarrow C_2H_6 + N_2$$

with the latter having a quantum yield of about 2.0. Forbes, Heidt and Sickman[2] have challenged the latter figure and have produced evidence which, they claim, indicates that the quantum yield approaches 1.0 as an upper limit at pressures around 100 mm.; at higher pressures the quantum yield is reduced to a much lower figure by deactivating collisions. Heidt and Forbes[3] later published a statement on the products of pyrolysis and photolysis which indicated that methane was formed to a large extent in the later course of the decomposition. This conclusion was based upon pressure measurements at room temperature, -78.5, and $-183°$.

Leermakers[4] on the basis of experiments involving the simultaneous pyrolysis of lead tetraethyl and azomethane, concluded that neither decomposition affected the other and that consequently the ethyl radicals known to be produced in the decomposition of the former[5] were not initiating chains in the latter. It was suggested that, inasmuch as methyl radicals might be expected to behave similarly to ethyl radicals, methyl radicals likewise would not initiate chains at 270° and less. The work of Leermakers[6] and that of F. O. Rice and Evering[7] employing the mirror methods of Paneth[8] had shown that in all probability the reaction proceeded by a primary mechanism

$$CH_3N{=}NCH_3 \longrightarrow N_2 + 2CH_3$$

Consequently, Leermakers concluded that the decomposition of azomethane is not a chain reaction. O. K. Rice and Sickman[9] reached the same conclusion from their own work and that of Forbes, Heidt and Sickman.[2]

These conclusions of previous investigators seemed so decisive that it appeared only necessary to measure the nitrogen yield in the photolysis of azomethane in order to determine accurately the number of methyl radicals produced; the nitrogen determination was conducted because of the conclusions of Heidt and Forbes[3] that reaction 1 does not represent the over-all reaction.

The analyses conducted in this work changed the course of the investigation completely. It was found impossible to reconcile the amount of nitrogen formed with the proportions of the hydrocarbon products. The results of actual analyses given below indicate that many of the conclusions reached by previous investigators solely on the basis of pressure changes may require some modification. Pending the establishment of other data it does not seem feasible to use the photolysis of azomethane as a source of known quantities of methyl radicals.

Experimental Method

Azomethane.—The azomethane was prepared by the method of Ramsperger[1] except that the symmetrical dimethylhydrazine dihydrochloride was prepared according to the method of Hatt.[10] In our more recent preparations the mercury cut-offs recommended by Ramsperger were eliminated and large stopcocks were used. It was found that the yield of azomethane could be improved by reducing the pressure of the system initially to such a point that the azomethane would distil out of the preparation flask as soon as formed. As with previous investigators it was found that the principal impurities were probably moisture and air (perhaps nitrogen). Care must be taken that the former is not drawn from the drying tubes into the azomethane by the liquid air used for condensation. The entrapment of nitrogen in the condensed azomethane was best avoided by distilling toward the evacuating system from a dry-ice–toluene mixture to liquid air. In distilling

backward through a stopcock to dry-ice–toluene the liquid air was removed and the system was opened to a large reservoir. This enabled most of the nitrogen to escape into the reservoir. The stopcock to the dry-ice–toluene receiver was then closed and the reservoir was opened to the pumping system. After this the azomethane was again distilled forward from the dry-ice–toluene to the liquid air. This operation was repeated about six times (after about fifteen other distillations). At the end it was concluded that various samples distilled from the approximately 6 cc. of azomethane so formed (using four times the quantities indicated by Ramsperger) were reasonably pure.

It was not practicable to obtain true vapor pressure data. With the small amounts of our samples it was found that traces of grease or other impurity present in the reservoirs, might cause one fraction to present two different vapor pressures in two different reservoirs. Different fractions of the same 6-cc. yield all had vapor pressures between 744 and 756 mm. at 0° in different reservoirs. All together the various readings indicated that the last fraction was substantially like the first.

Light Source.—The light source used throughout these experiments was a constricted mercury arc of the type described recently.[11] Unless otherwise noted there was interposed between the light source and the reaction system a Corning No. 534 blue nultra filter. According to the specifications this filter transmits only wave lengths longer than 3500 Å. In all the experiments except the one at −22.5° the arc was located 2.5 cm. from the reaction vessel; at −22.5° the arc was 3.3 cm. from the reaction vessel.

Reaction Vessel and Thermostat.—The reaction vessel was a Pyrex flask of 1015-cc. volume connected to the vacuum system, the manometer, and the gas analysis system by means of capillary tubing closed off with simple greased stopcocks. The thermostat was a Pyrex beaker to which the filter was affixed in most of the experiments. The temperature was maintained manually at 20° or (in one experiment) at −22.5°. The total thickness of Pyrex between the arc and the reacting gas was of the order of 2 mm. This thickness transmits only at more than 2900 Å., transmitting the 3130 mercury line and the 3020 and 2960 to a slight extent.

Gas Analysis.—A Fischer Scientific Co. Gas Analysis Apparatus was permanently connected to the reaction system, through a mercury gas buret, a Töpler pump, and a trap. The large volumes of azomethane used made possible analyses on a macro-scale. The products of the decomposition were separated into condensable and non-condensable portions in the liquid air trap, measured in the mercury buret, bubbled through an auto-bubbler pipet (of the type described by Burton and Davis[12]) containing hydrochloric acid, and measured again over water. The hydrochloric acid was removed for analysis after each experiment. Any azomethane residue was removed by acid stannous chloride solution in an auto-bubbler pipet. Other pipets contained potassium hydroxide (for removing carbon dioxide and other acid gases), chromous chloride, and potassium pyrogallate (for the direct determination of residual oxygen after the combustions). Hydrogen was determined by cupric oxide oxidation while the volume of paraffin gases and the average value of n in the formula C_nH_{2n+2} were determined by oxidation over a hot platinum wire with subsequent measurements of the volume before and after bubbling through potassium hydroxide. After the removal of the unused oxygen, the fraction of nitrogen in the sample was calculated from the volume of the residual gas. Corrections were made, of course, for the nitrogen initially present in the oxygen.

The procedure of dividing the gases into condensable and non-condensable portions made it possible to determine approximately the amounts of methane, ethane and propane in the original gas. Naturally, the amounts of ethane and propane may be in error. They involve the assumption that these gases are the only saturated hydrocarbons in the condensed gas sample, while the calculated n might actually be the average for a mixture of ethane and some much higher hydrocarbon. Furthermore, it will be shown below that even in the non-condensable gases there is the possibility that the presence of some other hydrocarbon may require a recalculation of the results.

Photolysis of Azomethane.—Ordinarily, the azomethane was stored in a small reservoir immersed in a dry-ice–toluene mixture. The reservoir and its contents were constantly shielded from the light except when the cooling mixture was deliberately removed to permit distillation of the sample. In fact, during the whole course of the investigation the room was darkened to avoid the entrance of daylight. Preceding each run a sample was distilled into the reaction vessel, which was maintained at a constant temperature of 20°, and the initial pressure was determined. The reaction vessel was exposed to the arc when the latter had become steady at 4 amperes with the arc stretched through the capillary as previously described.[11] At the conclusion of each run the gas was permitted to stand in the vessel for at least five minutes to obtain check readings. In a few cases the gas stood for as long as three days without affecting the pressure.

Successive samples were withdrawn through the liquid air trap where they were fractionated into condensable and non-condensable portions and analyzed as already described. The results of these analyses for different fractions decomposed and different initial pressures are summarized in Table I.

In both Tables I and II P_0 is the initial pressure of the gas in the reaction vessel in mm. and P_F the final pressure. ΔP is the pressure change during the photolysis. All ratios, for example, $\Delta P/P_0$, are expressed in per cent. V_A is the volume of gas in cc. measured over water after all azomethane or possible alkaline gas has been removed by successive treatments with hydrochloric acid, stannous chloride and potassium hydroxide (the latter to remove acid vapors). V_G is the calculated volume of di-acid (alkaline) gas in the sample based upon titration of the hydrochloric acid in the first auto-bubbler pipet. The values are extremely variable; the reason for the variation will be explained below. V is the volume of gas after the photolysis measured over mercury before any chemical treatment. Mention should be made of the fact that, except for V, volumes (in Table II) are given only for moist gases. The values for N_2/V as given in Table I are corrected for moisture in the nitrogen so that the percentage given is the true one. The other percentages involving

[a] F_N represents the fraction not condensed by liquid air; F_C represents the condensed fraction.

V_A are, of course, self-corrected. Although hydrogen was looked for in every experiment none ever was found.

It will be noticed that for experiments 28 and 31 data on the alkane content have been omitted. The detailed summary for those two is shown in Table II.

The volume of oxygen used is that required for the oxidation of the hydrocarbon gases. The *contraction* is the decrease in volume in cc. due to water formation during the combustion and the *absorption* represents the volume of carbon dioxide formed at the same time. n is the calculated value in the hypothetical mixed alkane C_nH_{2n+2}. The figures given for the alkanes are evidently idealized; they are based on the assumption that only two gases are present in the sample analyzed: in the uncondensed fraction—methane and ethane, and in the condensed—ethane and propane. In both experiments 28 and 31 the values for the contraction and absorption in the uncondensed fraction are so unusual as to preclude the calculation of a significant value for n. The results are presented for what they are worth without an attempt at interpretation other than the remark that a compound such as acetylene might account for the effect; however, acetylene would not be expected to pass the bromine pipet. It is possible that the high value for n in the condensable fraction of expt. 31 may be due to the presence of such a gas and that the computed value for propane is consequently wrong. In any event, the percentage given for propane or the presence of an equivalently large quantity of such another gas would be enough to differentiate expt. 31 (which was conducted at −22.5°) from all the other experiments. Judging from the small volumes of the contraction and the absorption in both experiments it is apparent that even if the actual hydrocarbons in the uncondensed portion were known the percentages reported would be only slightly changed.

As Ramsperger, and Forbes, Heidt and Sickman, have noted, it was found that when the photolysis was conducted at shorter wave lengths, as in experiments 30 and 31, a solid deposit settled on the walls of the reaction vessel; the deposit in experiment 31 (at −22.5°) was much lighter than in experiment 30. When the reaction vessel was removed for cleaning, the deposit disappeared completely, probably due to oxidation by the inrushing air.

Photolysis of Azomethane plus Acetaldehyde.—In some early experiments, in which azomethane was photolyzed in the presence of acetaldehyde using the blue nultra filter, it was found that, in a time which later experience demonstrated was sufficient to cause about 20% pressure increase ($\Delta P/P_0$) in pure azomethane, no acetaldehyde was decomposed at 20° according to the analyses. This result was in line with the conclusions of Leermakers on chain lengths in the photolysis of acetaldehyde at low temperatures[13] and was, of course, expected. The formation of a fog in the reaction vessel during runs and the deposition of an extremely viscous, non-volatile material was, however, unexpected. In the case mentioned the results are summarized in Table III. The method of calculation is obvious from the table. The following were known by measurement at the end of the photolysis: the initial pressures of the acetaldehyde and the azomethane, the volume of the reaction vessel (1015 cc.), the weight of acetaldehyde in the deposit (determined by Ripper's method[14]) and the total pressure change. The value for N_2/V was determined by difference after analysis of the resultant gases. However, as is shown in Table III, there are sufficient data for a calculation of N_2/V on the assumption that the average value for a/b calculated in Table I for $\Delta P/P_0 = 20\%$ holds in this case also. The check between the observed and the calculated values for N_2/V is good. No allowance has been made in these calculations for a pressure decrease due to a loss of azomethane from the vapor phase by inclusion chemically or otherwise, in the deposit. This was not deemed necessary since the agreement between the observed and calculated nitrogen values would indicate that the deposit contained solely acetaldehyde. The conclusion may be drawn from Table III that, for every 3.3 molecules of nitrogen liberated, approximately two molecules of acetaldehyde are lost by an association reaction.

TABLE III

SUMMARY OF EXPT. 5. AZOMETHANE PLUS ACETALDEHYDE AT 20°

Initial pressure CH_3CHO, obsd., mm.	104.2
Initial weight CH_3CHO, calcd. = c, g.	0.255
Wt. CH_3CHO in deposit (by analysis) = d, g.	.042
d/c, %	16.5
ΔP_A (due to CH_3CHO) calcd., mm.	−17.2
$\Delta P_{\text{obsd.}}$[a], mm.	7.2
ΔP (due to CH_3NNCH_3) calcd., mm.	24.4
P_0 = initial pressure CH_3NNCH_3, obsd., mm.	106.3
$\Delta P/P_0$, %	22.9
$\Delta P/P_F$ (= b) from $\Delta P/P_0$, %	18.6
a/b from Table I (assumption)	1.08
N_2/V (= a) calcd., %	20.1
N_2/V by analysis (approximate), %	19.9
V (at 760 mm., 20°) calcd., cc.	173.8
N_2, calcd., cc.	35.0
CH_3CHO (at 760 mm., 20°) in deposit, cc.	21.2

[a] $\Delta P_{\text{obsd.}}$ is the final total pressure increase on prolonged standing after the completion of the run. The figure given is somewhat lower than that immediately at the completion of the run before the fog had a chance to settle. The value at that time was 11.6 mm.

It was noticed that the deposit had a faint musty odor similar to that of aldehyde ammonia and was quite readily soluble in water without change of odor. When a small amount of hydrochloric acid was added, the odor of acetaldehyde was quite strong.

The formation of the deposit is definitely linked to the photolysis of azomethane for blank runs with acetaldehyde alone were without effect and prolonged standing of mixtures of the two gases without illumination was also without results.

Rate of Photolysis of Azomethane.—With the exception of experiments 30 and 31 in which unfiltered light was used, the conditions of light intensity during the photolyses were fairly well reproduced in most experiments. The arc was maintained constant at 4.0 amperes and was cooled constantly with running water. The distance from the arc to the reaction vessel was rigidly fixed. While no photometer readings were taken there is no reason to expect a large order of variation between experiments on the basis of light intensity alone. Consequently, the pressure–time relationships during the photolyses of azomethane are of some significance if the different experiments are considered relatively to each other.

Neglecting for the moment the effect of decreased light absorption by azomethane as the reaction proceeds, it is evident that the rate of change of partial pressure of azomethane may be represented by the equation

$$\mathrm{d}p/\mathrm{d}t = Kp$$

or

$$\ln P_0/p_t = Kt$$

where P_0 is the initial pressure of the system, p is the partial pressure of azomethane (when $t = 0$, $p = P_0$) and p_t is the partial pressure of azomethane at time t. Now, if $p_{N_2,t}$ be the partial pressure of nitrogen at time t

$$p_{N_2,t}/p_t = V_{N_2,t}/V_t$$

where P_t is the observed pressure and V_t the total measured volume at time t, while $V_{N_2,t}$ represents the volume of nitrogen as determined by actual analysis. But, from Table I, ($V_{N_2,t}/V_t$ and N_2/V are the same)

$$p_{N_2,t}/P_t = \frac{a}{b} \times \frac{\Delta P}{P_t}$$

and

$$P_{N_2,t} = \frac{a}{b} \times \Delta P$$

But

$$p_t = P_0 - P_{N_2} = P_0 - \frac{a}{b}\,\Delta P$$

Consequently

$$\ln \frac{P_0}{P_0 - a/b\ \Delta P} = Kt$$

In Fig. 1, a curve is plotted showing the relation between a/b and $\Delta P/P_0$ (see Table I) where the

latter is indicated in per cent. The values of a/b, as taken from this curve, were used in plotting the rate curves in the three experiments illustrated in Fig. 2. It is seen that the initial portion of each curve follows a straight line, as may be expected, but that the rate later falls off. In experiment 28, where $P_0 = 13.5$ mm., this departure from linearity is evident sooner than in experiment 29, where $P_0 = 99.0$ mm. The values for K during the linear (initial) portions of the curves, as determined from Fig. 2 and similar plots, are summarized in Table IV.

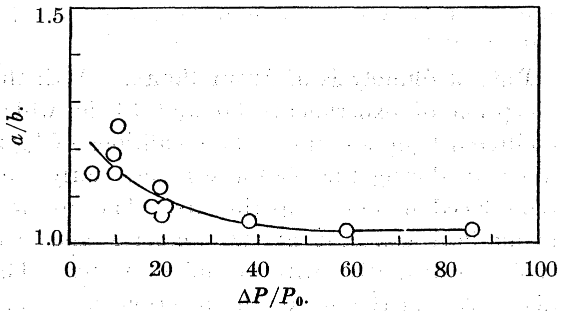

Fig. 1.—Relationship between a/b and $\Delta P/P_0$, the latter being expressed in per cent.

TABLE IV

Experiment	P_0	$K \times 10^3$
21	100.7	1.66
22	101.6	1.69
23	101.0	1.63
26	100.3	1.40
27	100.7	1.57
29	99.0	1.38
20	57.8	1.65
24	51.0	1.67
25	25.0	1.85
28	13.5	1.88

There appears to be a slight drift toward higher K values at lower initial pressures. This is in the direction which might be expected on the basis of relative probabilities of light absorption and confirms the measurements of Goldfinger.[15]

Discussion of Results

The analyses reported here are the first complete ones recorded in the literature of azomethane since those of Thiele,[16] who examined the products both of explosion and of complete decomposition in a hot tube.

The most significant feature to be observed at the outset is that the percentage of nitrogen in the yield of gases insoluble in acid, averages 54.7% regardless of the stage of reaction at which the analysis is made. This excess of nitrogen over that expected from a simple decomposition of azomethane suggests that azomethane may be removed from the system by some means other than decomposition to yield nitrogen. Hence the use of the amount of nitrogen as a measure of the azomethane disappearing may be invalid. Such an assumption was actually made in calculating the data in Table IV. Furthermore, the use of pressure change observed during reaction, as a measure of the azomethane decomposed, also requires further consideration.

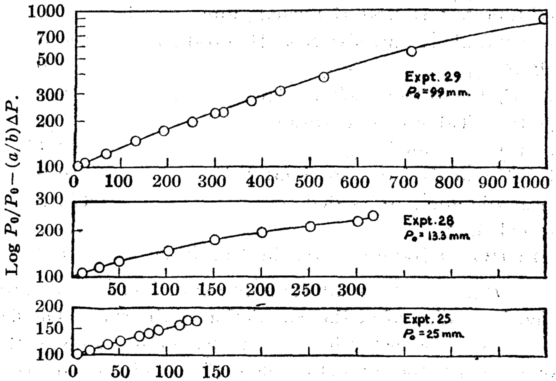

Fig. 2.—Rate of photolysis according to equation 1.

The simplest assumptions of the primary step in the decomposition appear to be either

$$CH_3N{=}NCH_3 + h\nu \longrightarrow C_2H_6 + N_2 \quad (1)$$

or

$$CH_3N{=}NCH_3 + h\nu \longrightarrow 2CH_3 + N_2 \quad (2)$$

the one yielding stable molecules of nitrogen and ethane by a rearrangement of the suitably activated azomethane; the other yielding free radicals by disruption of C–N bonds. Such a reaction as

$$CH_3N{=}NCH_3 + h\nu \longrightarrow CH_3 + N{=}NCH_3 \quad (3)$$

has little probability,[17] although not denied, it will not be further considered here, as the ultimate fate of the radical $NNCH_3$ would be pure conjecture. Furthermore, in the hydrolysis of azomethane Thiele[16] finds the principal products to be formaldehyde and methylhydrazine, which result would suggest a possible isomeric form of azomethane of the type $CH_2{=}N{-}NH{-}CH_3$. The decomposition of such an isomeric form might be expected to give readily a radical with an ability to confer definite basic properties

$$CH_2{=}N{-}NH{-}CH_3 + h\nu \longrightarrow CH_2N{-}NH + CH_3 \quad (4)$$

TABLE V

COMPARISON OF ALKANE YIELD AND PRESSURE INCREASE

Expt.	P_0	V	V_{Alk}	V_0 (calcd.)	$V-V_{Alk}$	V_{Alk}/V_0, %	$V_{Alk}/(V-V_{Alk})$, %	$\Delta P/P_0$, %
22	101.6	141.4	5.6	135.9	135.8	4.1	4.1	4.9
16	99.8	143.3	13.6	133.2	129.7	10.2	10.0	10.1
19	100.6	148.0	12.0	134.5	136.0	8.9	8.8	9.4
26	100.3	144.6	11.8	134.1	132.8	8.8	8.9	9.8
27	100.7	160.1	25.3	134.5	134.3	18.8	18.8	20.1
29	99.0	252.8	113.5	132.2	139.3	86.0	81.5	85.8
20	57.8	89.9	12.4	77.3	77.5	16.0	16.0	17.8
24	51.0	79.7	11.0	68.2	68.7	16.1	16.0	19.2
30	49.7	78.7	11.8	66.5	66.9	17.7	17.6	19.6
25	25.0	45.6	11.2	33.4	34.4	33.5	32.6	38.0

The fate of the methyl radicals produced in any of the above reactions is likewise as doubtful as the primary step for azomethane. The simplest course would be the production of ethane. The possibility nevertheless exists of such a chain reaction as

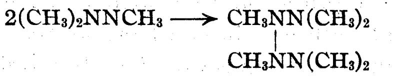
$$CH_3 + CH_3N{=}NCH_3 \longrightarrow C_2H_6 + N_2 + CH_3 \quad (5)$$

even though the work of previous investigators indicates its improbability. On the other hand, an addition of CH_3 to azomethane seems never to have been considered

$$CH_3 + CH_3N{=}NCH_3 \longrightarrow (CH_3)_2NNCH_3 \quad (6)$$

$$CH_3 + (CH_3)_2NNCH_3 \longrightarrow (CH_3)_2NN(CH_3)_2 \quad (7)$$

or



$$2(CH_3)_2NNCH_3 \longrightarrow \begin{array}{c} CH_3NN(CH_3)_2 \\ | \\ CH_3NN(CH_3)_2 \end{array} \quad (8)$$

The only definite statement that can be made is that the reaction may be much more complicated than has been assumed previously.

Of the above reactions, 8 is the only one which would involve a pressure decrease and does not appear highly probable. In the other reactions, the pressure either increases or is unchanged. It may be concluded therefore that the pressure increase occurring during the decomposition is due to the formation of alkane molecules. The data in Table V substantiate this.

P_0, V and ΔP have the significance previously indicated. V_{Alk} is the total volume of dry alkane gases as determined by analysis. V_0 is the initial volume of azomethane calculated to 760 mm. and 20° approximately the conditions at the time of the gas analysis. The correspondence between V_0, a calculated value, and $V-V_{Alk}$, a measured one, indicates that the pressure increase is to be accounted for by the alkane produced. It is, however, apparent that in some cases there is a discrepancy between the ratios in the last three columns, especially in the values of $\Delta P/P_0$. The only satisfactory explanation of this appears to lie in the doubtful accuracy of ΔP which, involving as it does a difference, frequently small relative to P_0, is correspondingly less accurate. This error, however, does not affect the validity of any of the calculations reported above.

Comparing now those cases of small decomposition, where $\Delta P/P_0$ is no greater than 20%, the nitrogen formed averages 55.3% while the alkane formed, calculated as ethane, averages 44.4%. Evidently some compound is produced during the reaction which has a higher carbon to nitrogen ratio than that in azomethane. Reaction 7 above presents such a possibility. Assuming that such a possibility requires free methyl radicals it would appear that out of five molecules of azomethane *decomposing* to give nitrogen, only four give alkane and hence *at least* one of them must have yielded methyl radicals.

Turning to the results in Table III on the photolysis of azomethane in presence of acetaldehyde, it is seen that for every two molecules of acetaldehyde precipitated (presumably as a polymer) 3.3 molecules of nitrogen were produced from the azomethane. If every methyl radical is assumed involved in the polymerization of two aldehyde molecules, it would appear that of every 6.6 molecules of azomethane decomposed, one decomposed yielding free methyl radicals.

It should be realized that the latter figure of one in 6.6 would tend to be a maximum ratio, while the former 1 in 5 is a minimum. The agreement is by no means perfect but is sufficiently significant to suggest that azomethane may not decompose entirely into nitrogen and free methyl radicals.

With regard to the possible existence of some compound formed with azomethane and methyl radicals, reference to Table I will show values of V_G, the volume of gas, assumed di-acid, calculated from the titration of the hydrochloric acid used in the first absorption pipet. As already stated the values are extremely variable since it was not at first realized that the hydrolysis of azomethane was rapid enough to cause interference. The values for the later experiments were obtained as rapidly as possible after the exit gases from the decompositions had been washed with the acid, the time of contact between the undecomposed azomethane and acid being as short as practicable. The results definitely indicate some basic material present. In experiments 28 and 29, corresponding to over 50 and 80% decomposition, the amount of this basic material is very small and the values of V_G may be due simply to azomethane hydrolysis. It should be noted further that in precisely these experiments the discrepancy between nitrogen and alkane produced is by no means as large as that discussed above for decompositions amounting to less than 20%. In experiment 29 the nitrogen value is 52% while the alkane calculated as ethane is approximately 51%. In addition to this evidence, is the formation of the deposit during photolysis at shorter wave lengths. The observation already mentioned that the deposit disappeared immediately on contact with air is in line with the known easy oxidation of many hydrazines.[18]

The belief that methyl radicals are without effect on azomethane rests largely on Leermakers' study of the simultaneous thermal decomposition of azomethane and lead tetraethyl.[4] Leermakers calls attention to the falling off in the rate constant for the decomposition of lead tetraethyl of some 25% at 260° in presence of azomethane. This is calculated from the over-all pressure change observed assuming the azomethane pressure change to be found in pure azomethane. No interpretation is offered of the falling off since Leermakers' primary object was to discover the presence of chains initiated by the ethyl radicals from the lead tetraethyl in the azomethane. Such chains would have caused a rising constant. An examination of his data at 275° shows a similar 10 to 15% falling off. The decrease in rate constant finds a ready explanation on the basis of one conclusion from this study, namely, that ethyl radicals could disappear by addition to azomethane whereas Leermakers assumes the ultimate fate of all the ethyls to be butane. Two possibilities, however, present themselves: either, all the lead tetraethyl decomposes into free radicals and only a part of them combine with azomethane, or, part of the lead tetraethyl decomposes to form butane directly. If the latter were true, it would be expected that the proportion of lead tetraethyl decomposing into radicals would be greater the higher the temperature and that therefore the greater would be the effect of azomethane. Actually, however, the effect of azomethane is less at 275 than at 260°. Hence it must be concluded that not all of the ethyl radicals react with azomethane at these temperatures. Such a result is not necessarily true at lower temperatures though it would appear reasonable to conclude that there also some of the methyl radicals may actually combine to give ethane and hence that our results do not prove decisively that azomethane does decompose to give nitrogen and ethane directly. Allen and Sickman[19] in studying the azomethane induced decomposition of acetaldehyde came to the conclusion that the chain length varied between 500 at 244.8° and 22 at 328.7°. If the conclusion be derived from our work that azomethane does not decompose exclusively by a free radical mechanism it appears that the calculated figures for the chain length may be considerably too low, since fewer but longer chains would not be required to explain the effects observed. This would be in line with Leermakers' estimate[13] of quantum yields of about 300 in acetaldehyde at 309.5°. In the latter case also, the chain length based upon free radical production would be higher than the figure given because it would be expected that during photolysis most of the acetaldehyde decomposes by a rearrangement mechanism.[20] It now appears that in many of those reactions where clear-cut rupture into free radicals or alternatively clear-cut rearrangement to form stable molecules was thought to be occurring, actually both processes might have been taking place. Formic acid dissociates into stable molecules[21] but acetic acid apparently gives both stable molecules[22] and free radicals.[11] Formaldehyde gives stable molecules[23]; acetaldehyde apparently dissociates in

[23] Locker and Patat, *ibid.*, **B27**, 431 (1934).

both ways.[20] The results of this work indicate that azomethane may resemble acetaldehyde and acetic acid in its tendency to suffer both rupture and rearrangement.

Forbes, Heidt and Sickman[2] showed that the quantum yield of decomposition of azomethane (based upon pressure measurements) approached a value of unity at low pressures (*i. e.*, in the neighborhood of 100 mm.) and apparently decreased both at longer wave lengths (about 3660 Å.) and with increasing pressure. Their measurements appear to have been made on only three or four different samples of azomethane; several runs at different wave lengths and successively decreasing partial pressures of azomethane were made with the same sample. Our results would indicate that the partial pressures of azomethane as calculated by them were too high and that a correction should be made for azomethane disappearing in an association reaction with methyl. This would tend to bring up the quantum yields. Whether it would bring the quantum yields up to unity we do not know; however, there is not very much concordance between their various results. The quantum yields as reported by them do decrease with successive runs on the same sample and our results indicate the reason why. Also, our work indicates a deposit of some product even at >3500 Å.; perhaps it is the formation of such a product which might account for the extremely low quantum yields they report in certain runs.

In conclusion, some mention should be made of our results both at low temperatures and in protracted runs. In both cases (experiment 31 at −22.5° and experiments 28 and 29 for long runs) it may be seen in Tables I and II that the propane yields (as idealized from the n values) are high. The explanation in the long runs is that the methyl radicals combine with some of the products to form the higher carbon compounds. In no case is there a simple replacement reaction such as

$$CH_3 + C_2H_6 \longrightarrow C_3H_8 + H \qquad (10)$$

for no hydrogen has been found in the analyses. To be sure, the reaction

$$CH_3 + C_2H_6 \longrightarrow CH_4 + C_2H_5 \qquad (11)$$

followed by

$$CH_3 + C_2H_5 \longrightarrow C_3H_8 \qquad (12)$$

or

$$2C_2H_5 \longrightarrow C_4H_{10} \qquad (13)$$

would account for the result. However, such considerations lie entirely in the realm of conjecture. Suffice it to say that the probability of that general type of reaction increases as the relative concentration of azomethane decreases.

Similarly, as the temperature is lowered, the probability of methyl radical adding on to azomethane by such a reaction as 7 decreases. Reactions such as 12 and 13 would then be favored; the analysis of Table II is in agreement with such an hypothesis.

Conclusion.—Methods heretofore used depending exclusively on pressure measurement for the calculation of the amount of azomethane decomposed photolytically have been in error. There is a greater amount of azomethane decomposed than is represented by the pressure increase. The amount of nitrogen formed for small decompositions exceeds the hydrocarbons produced. The evidence appears to indicate that azomethane decomposes by a rearrangement mechanism as well as by rupture into free radicals, which latter has hitherto been thought to be the exclusive path.

Summary

1. The results of a number of analyses of the products of the photolysis of azomethane have been reported.

2. In general, the amount of nitrogen produced exceeds the amount of hydrocarbon gas. The amount of higher hydrocarbon produced (expressed as propane) increases with degree of decomposition and at reduced temperatures. No hydrogen and but a small smount of unsaturated hydrocarbons are produced.

3. The results of some preliminary work with azomethane photolyzed in the presence of acetaldehyde are also reported. This work is being continued.

4. The results obtained are consistent with an hypothesis that azomethane does not decompose exclusively by rupture but that it may also decompose by a rearrangement mechanism to form stable molecules.

5. The hypothesis that some of the free methyl radicals formed react with azomethane to form an addition compound is consistent both with the results reported here and with the results of previous investigators.

6. The rates of the photolyses are in approximate agreement with what might be expected from the hypotheses offered as to the mechanism of the reactions.

Studies on the Vapor Pressure–Temperature Relations of the Binary System Zinc Nitrate–Water

BY WARREN W. EWING AND H. M. FISHER

Vapor pressure data on the binary system zinc nitrate–water are presented in this article, which is a continuation of a series of similar studies being carried on in this Laboratory. Reports on the calcium nitrate system and the magnesium nitrate system have been published. The cadmium nitrate system is now being investigated. These systems are particularly suitable for these types of studies since, in general, they are quite stable over ordinary temperature ranges, they form various hydrates, they are quite soluble and the solutions can be supercooled readily, especially in the concentrated ranges. Due to this supercooling, vapor pressures can be measured on very concentrated solutions; up to 82% on the zinc nitrate system.

According to solubility studies,[1–3] zinc nitrate crystallizes with varying amounts of water, namely, $Zn(NO_3)_2 \cdot 9H_2O$ (T. P. = −17.6°), $Zn(NO_3)_2 \cdot 6H_2O$ (m. p. = 36.1°), $Zn(NO_3)_2 \cdot 4H_2O$ (m. p. 44.7°), $Zn(NO_3)_2 \cdot 2H_2O$ (m. p. 55.4°), $Zn(NO_3)_2 \cdot H_2O$ (m. p. 73.9°). Probably the anhydride also exists.[4] In this investigation, vapor pressures of two-phase systems (unsaturated and supersaturated solutions plus vapor), and the three-phase systems hydrated salt-saturated solution–vapor (in the stable and the metastable regions) and mixtures of two hydrated salts–vapor have been measured over the temperature range 20 to 60°.

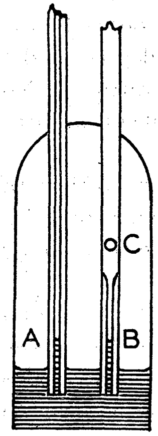

Fig. 1.—Tensimeter trap.

Preparation of Materials.—A c. p. grade of zinc nitrate was purified by three recrystallizations, first as tetrahydrate and subsequently twice as hexahydrate, from solutions containing a little nitric acid. The hexahydrate crystals were freed from excess water and nitric acid by continuous evacuation.

The unsaturated solutions for the vapor pressure experiments were made by dissolving the hexahydrate. The more concentrated solutions were made by evaporating the molten hexahydrate crystals at 80°. This resulted in some decomposition of zinc nitrate. Consequently, all solutions were adjusted to neutrality, where necessary, with 100% nitric acid, using brom thymol blue indicator.

Experimental

The vapor pressure measurements were made in a modified Smith–Menzies apparatus which was described in the magnesium nitrate article.[5]

The only alteration was the redesign of the dibutyl phthalate trap. The new design is illustrated in Fig. 1. A and B are two capillary tubes of identical bore. Consequently, when the pressures on the two sides of the dibutyl phthalate are the same, the liquid rises in A to the same height that it does in B due to capillary attraction. This makes the measuring of the difference from the true equilibrium height much easier. C is an opening through which air and vapor can pass. This arrangement also has an advantage in the measurement of pressures below one millimeter. In this low range the errors in measuring the difference in heights of two mercury columns are a large percentage of the total pressure. When the external system is evacuated completely, the dibutyl phthalate trap then serves as a manometer which is about thirteen times as sensitive as a mercury manometer, due to the different densities of the two liquids. This sensitivity is diminished somewhat due to the greater difficulty in measuring the exact position of the meniscus of dibutyl phthalate.

Vapor pressure studies were made on the following systems: (1) a mixture of hexahydrate and tetrahydrate crystals from below the eutectic temperature down to 10° (Table I); (2) a mixture of tetrahydrate and dihydrate crystals from the eutectic temperature down to 20° (Table II); (3) saturated solutions over the range from a saturated solution of hexahydrate at 10° to a saturated solution of dihydrate at 55° (Table III); (4) solutions ranging in concentration from 10 to 57% from 20 to 50°; solutions from 63 to 72% from 30 to 60°; and two solutions 80 and 82% from 35 to 60° (Table IV).

				20	.42

These data are shown in Fig. 2. Curve ABC represents the vapor pressure–temperature relations of saturated solutions of hexahydrate. Curve CEF represents saturated solutions of tetrahydrate, while FI represents saturated solutions of dihydrate. Curve FH represents saturated solutions of dihydrate in a metastable region. Curves CD and FG are, respectively, the mixtures of hexahydrate–tetrahydrate crystals, and tetrahydrate–dihydrate crystals. The remaining curves, numbers 1 to 15, represent vapor pressure–temperature relations of the solutions designated in Table IV. The points at which these curves cross ABC, CEF, and FI, are the freezing points of the various solutions. Supersaturation was obtained in a few cases, more easily for solutions supersaturated with respect to tetrahydrate than with the other hydrates.

Solution 15 20° 0.37 25° 0.53 30° 0.75

The method of least squares was used on an equation of the form, $\ln p = A/T + BT + C$ to coördinate the data on the fifteen solutions in Table IV. The pressures were calculated at each temperature and usually showed less deviation than the probable errors computed for each set of readings at one temperature. After a consideration of all errors, it may be said that the data presented is accurate to 0.2%.

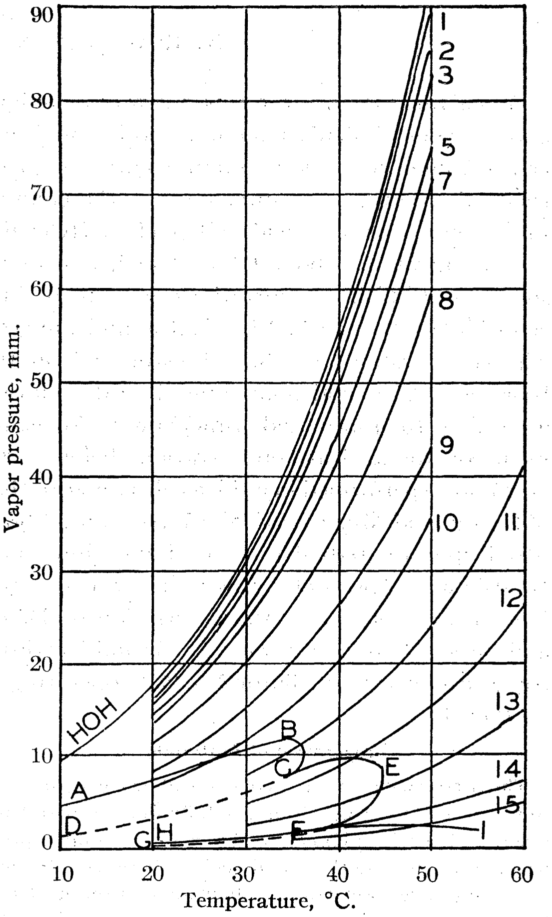

Fig. 2.

Vapor pressure measurements were not made at concentrations higher than 82%, which is the concentration of the saturated dihydrate solution at 50° (see Fig. 2), because at higher concentrations than this the zinc nitrate decomposed to such an extent that the data obtained were not reliable enough to warrant publication. This decomposition became noticeable at the higher temperatures above 82% concentrations. Consequently, the complete data for the dihydrate curve and the data on the monohydrate saturated solutions are not given.

Summary

Complete vapor pressure data on the system zinc nitrate–water from 0 to 82% concentration and from 10 to 60° are given. This includes vapor pressures for unsaturated, saturated and supersaturated solutions and for eutectic mixtures of crystals.

The Ionization Constant of α-Crotonic Acid at 25° from Conductance Measurements[1]

BY BLAIR SAXTON[2] AND GEORGE W. WATERS

A general outline of the experimental technique and method of calculation employed in this study can be found in previous communications[3,4] from this Laboratory. Measurements of the conductance of α-crotonic acid ($CH_3CH{=}CHCOOH$) at concentrations above 0.002 demal, and of its sodium salt at all concentrations, were made in a cell of Type B described by Saxton and Langer.[3] The cell constant was 3.7261 estimated on the basis of a 0.1 demal potassium chloride solution according to Jones and Bradshaw.[5] Measurements on the acid at concentrations below 0.002 demal were performed in a silica cell similar to that of Saxton and Meier,[4] and of cell constant, 1.0830 based upon the 0.01 demal solution of Jones and Bradshaw.[5] The bridge was built by Leeds and Northrup according to the description of Dike,[6] and the source of power was a Leeds and Northrup Audio Frequency Oscillator No. 9842 operating at 1000 cycles.

Preparation of Materials

The α-crotonic acid was a commercial product subjected to five recrystallizations from carefully purified petroleum ether, and slowly sublimed. The white crystalline product was almost odorless, and melted between 71.5 and 71.7° according to measurements made in a simple Thiele tube with a recently calibrated thermometer. The value 71.4° was previously obtained in this Laboratory[7] from cooling curves with acid from the same source. The acid was stored in a vacuum desiccator over calcium chloride and suffered no appreciable change in melting point during the course of the conductance measurements.

The sodium salt was prepared from sodium carbonate (*ex* bicarbonate) and α-crotonic acid in sufficient excess to bring the resulting solutions to a *p*H of 6.7 to 7.0 on the basis of Lamotte standard buffers and brom thymol blue. Conductivities of these solutions were corrected[8] for the effect of the excess acid.

The experimental results, $\Lambda_{(\text{obsd.})}$, for sodium α-crotonate are recorded in Table I along with values derived from the semi-empirical equation[9]

$$\Lambda_{(C_4H_5O_2Na)} = 83.30 - 78.84\sqrt{c} + 97.27c(1 - 0.2276\sqrt{c}) \tag{1}$$

TABLE I

SODIUM α-CROTONATE

$c \times 10^3$	$\Lambda_{(\text{obsd.})}$	$\Lambda_{(\text{Eq. 1})}$
0.18773	82.13	82.24
.75176	81.19	81.21
1.6436	80.23	80.29
2.6083	79.45	79.52
2.8315	79.38	79.38
3.9861	78.68	78.71
4.5069	78.48	78.44
5.6194	77.95	77.93
7.2425	77.31	77.28
9.8864	76.46	76.40
14.735	75.19	75.12
20.222	74.04	73.99
23.334	73.49	73.45
29.457	72.48	72.52
32.616	72.08	72.10

The parameters of this equation were adjusted to fit the data by the method of least squares. Assuming the validity of the Kohlrausch principle, equation (1) may be combined with the expressions

$$\Lambda_{HCl} = 426.28 - 156.84\sqrt{c} + 169.7c(1 - 0.2276\sqrt{c}) \tag{2}$$

$$\Lambda_{NaCl} = 126.47 - 88.65\sqrt{c} + 94.8c(1 - 0.2276\sqrt{c}) \tag{3}$$

previously obtained in this Laboratory[10] to yield the relation

$$\Lambda_{C_4H_5O_2H} = 383.11 - 147.03\sqrt{c_i} + 172.2c_i(1 - 0.2276\sqrt{c_i}) \tag{4}$$

for the hypothetical completely dissociated α-crotonic acid at an ion concentration c_i.

[8] MacInnes and Shedlovsky, *ibid.*, **54**, 1429 (1932).

[9] Shedlovsky, *ibid.*, **54**, 1405 (1932).

[10] The values of the characteristic parameters determined by Saxton and Langer (ref. 3) have been altered slightly to conform to present cell constants; *cf.* ref. 5.

The experimental equivalent conductances, Λ_c, of α-crotonic acid solutions are recorded in Table II. The ion concentrations,[11] c_i, and the values of the dilution constants are also included. Multiplication of K'

$$K' = c_i^2/(c - c_i) \quad (5)$$

by the activity coefficient ratio, y_i^2/y_u, should yield the thermodynamic ionization constant, K, but because of the approximations introduced in the calculation of K', and our use of[11]

$$\log (y_i^2/y_u) = -1.013\sqrt{c_i} \quad (6)$$

for estimating the unknown activity coefficients, the values of K recorded in the last column of Table II are not independent of the concentration. Fortunately the variation in log K is linear in $c_u (= c - c_i)$, which readily permits evaluation of the true thermodynamic constant by the extrapolation[12] illustrated in Fig. 1.

TABLE II

α-CROTONIC ACID

$c \times 10^3$	Λ_c	$c_i \times 10^3$	$K' \times 10^5$	$K \times 10^5$
0.95825	51.632	0.12970	2.0303	1.9771
1.7050	39.473	.17655	2.0394	1.9771

3.2327	29.083	.24686	2.0410	1.9675
4.0138	26.249	.27675	2.0495	1.9715
4.9736	23.677	.30942	2.0527	1.9702
4.9974	23.602	.30992	2.0491	1.9667
5.8329	21.926	.33614	2.0556	1.9695
7.1422	19.861	.37297	2.0550	1.9645
10.259	16.652	.44946	2.0592	1.9598
14.511	14.053	.53691	2.0629	1.9544
17.779	12.716	.59554	2.0641	1.9499
22.512	11.318	.67150	2.0647	1.9437
27.730	10.200	.74587	2.0617	1.9340
33.246	9.3166	.81715	2.0591	1.9258
39.342	8.5629	.88915	2.0560	1.9178
49.149	7.6506	.99305	2.0478	1.9027

The intercept on this plot corresponds to $K = 1.97_5 \times 10^{-5}$. The same value was derived from the familiar extrapolation[8] of log K' *vs.* $\sqrt{c_i}$, but with less precision.

The value 2.03×10^{-5} previously obtained by Ives, Linstead and Riley[13] differs from ours by about ten times the discrepancy to be expected from experimental errors alone, but is readily accounted for by differences in primary standards. The limiting conductances of the hydrogen and sodium ions which they employ[14] would tend to make their K about 1% larger than ours, and their cell constants are based upon data[15] which are higher than the generally accepted standard[5] by amounts ranging from a few tenths to several per cent., depending upon the concentration. In the light of these considerations there is little doubt that the present determination is the more reliable.

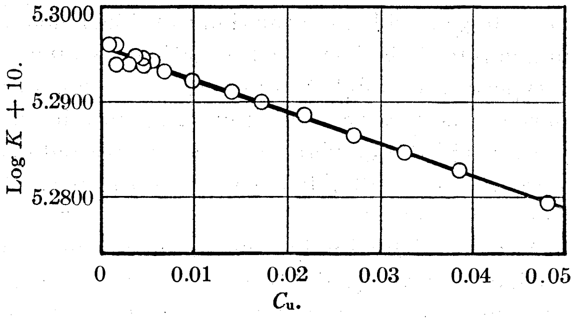

Fig. 1.

Summary

The equivalent conductances of α-crotonic acid and its sodium salt have been measured in dilute solution at 25°. The limiting equivalent conductance of sodium α-crotonate was found to be 83.30.

From these results, and data available in the literature, the value $K = 1.97_5 \times 10^{-5}$ was obtained for the thermodynamic ionization constant of α-crotonic acid at 25°.

The Fatty Acids Associated with Banana Starch

BY LEO LEHRMAN AND ELVIN A. KABAT

It has already been shown that the starches of some of the common cereals (corn, rice and wheat)[1] and one of the tubers (cassava)[2] have fatty acids combined with carbohydrate in the α-amylose component. However, the amount in the latter starch is much smaller than in the former and also contains an additional fatty acid. Furthermore, another tuber (potato) starch does not contain any combined fatty acid.[3] Thus it is apparent that the combined fatty acids may vary in kind and amount with the type of starch. In order to gain added information as to the amount and nature of the fatty acids in different starches, a typical fruit starch was investigated. For this purpose the banana was selected, because in the green stage a large percentage of the dry pulp is starch. Specifically, bananas from the port of Limon were used.[4]

At first the dried pulp from the green fruit was used, but it was found that some naturally occurring substance made it very difficult to pulverize the residue, after drying, liberated by acid hydrolysis. As this is necessary in order to completely extract the fatty acids, the pure starch was made instead.[5] A total of about 3500 g. of starch was obtained starting with approximately 350 bananas.

In order to be sure that any fatty acids obtained were not originally present extraneously, all the starch was extracted with alcohol before carrying out the experimental work. Furthermore, to settle any question as to the presence of any glycerides as the source of the fatty material, the aqueous filtrate from the hydrolysis was analyzed for glycerol. As in previous investigations, the liberated fatty acids were examined also for other substances and phytosterol that might occur in the starch.

Experimental Part

Mixed Fatty Acids.—Extraction of a sample of the starch with petroleum ether for several hours showed a negligible amount of extractable material. Two separate portions of the starch weighing about 600 g. each were hydrolyzed with hydrochloric acid[1b] and the liberated fatty acids recovered by extraction with petroleum ether. This "fat by hydrolysis," a light yellow semi-solid, amounted to 0.2% in each case and had an iodine number of 59.4.[1a]

Examination of Filtrate for Glycerol.—Four liters of filtrate, reddish-brown in color, was evaporated on a steam-bath until a moist solid mass, black in color, was obtained. Alcohol was added, the mixture stirred well and filtered. The dark brown filtrate was again evaporated on the steam-bath to moist dryness. This process was repeated several times until a small amount of brown material, soluble in alcohol, resulted. A portion of this brown material gave a negative test for acrolein when heated with potassium bisulfate, indicating the absence of glycerol originally. Other tests[6] likewise showed the absence of glycerol.

Isolation and Identification of Saturated Fatty Acids.—In the separation of the saturated from the unsaturated fatty acids by the magnesium soap–alcohol method,[7] the insoluble magnesium soap was decomposed by heating with concentrated hydrochloric acid. The liberated fatty material, after several crystallizations from alcohol, was a white solid, melting point 62°. The phenylhydrazide was made[8] and had a melting point of 110°.[9]

The molecular weight of the acid was determined by titrating a weighed amount dissolved in alcohol with standardized sodium hydroxide using phenolphthalein as the indicator. Below are also given the results of micro carbon and hydrogen determinations.[10]

Anal. Calcd. for palmitic acid, $C_{16}H_{32}O_2$: C, 74.91; H, 12.59; mol. wt., 256.3. Found: C, 75.01; H, 12.16; mol. wt. (monobasic), 265.

The above data indicate the presence of palmitic acid in the mixed fatty acids.

Identification of Unsaturated Fatty Acids. A. By Oxidation.—The unsaturated fatty acids, separated from the saturated by the magnesium soap–alcohol method, was a light yellow oil having an iodine number of 147.1.

One and one-half grams was oxidized by potassium permanganate in alkaline solution.[11] The white solid oxidized acids were filtered, washed and allowed to dry. Then they were extracted with chloroform to effect a separation.[1b] On evaporation of the chloroform a fatty material was obtained which was re-oxidized and the resultant solid oxidized acids extracted with chloroform.

[10] The authors are indebted to Mr. William Saschek of the College of Physicians and Surgeons, Biochemical Department, for most of the analyses (micro) recorded in this paper.

[11] Lewkowitsch, "Chemical Technology and Analysis of Oils, Fats and Waxes," The Macmillan Company., New York, N. Y., 5th ed., Vol. I, p. 564.

The slight quantity of residues, insoluble in the chloroform extractions above, were combined and extracted with hot water. On cooling a small amount of white solid separated, which was crystallized from alcohol and water and had a melting point of 170–172°.

Anal. Calcd. for tetrahydroxystearic acid, $C_{18}H_{36}O_6$: C, 62.05; H, 10.34. Found: C, 61.95; H, 10.15.

Due to the small amount of material a molecular weight determination by titration could not be made.

The data indicate the presence of α-linoleic (linolic) acid,[12] in the unsaturated fatty acids.

The residue, obtained by the evaporation of the chloroform extracts, was extracted with petroleum ether to remove unoxidized fatty material. It was then extracted with ether in order to make a separation. The residue, insoluble in ether, was crystallized from alcohol and water, yielding a white solid, melting point 154–155°.

Anal. Calcd. for tetrahydroxystearic acid, $C_{18}H_{36}O_6$: C, 62.05; H, 10.34; mol. wt., 348. Found: C, 62.00; H, 9.95; mol. wt. (monobasic), 354.

The above data are added evidence of the presence of α-linoleic (linolic) acid[12] in the unsaturated fatty acids.

The ether extract was allowed to evaporate and the residue crystallized several times from alcohol. It was a white solid, melting point 115–117°.

Anal. Calcd. for dihydroxystearic acid, $C_{18}H_{36}O_4$: C, 68.35; H, 11.39; mol. wt., 316. Found: C, 68.00; H, 11.22; mol. wt. (monobasic), 319.

The data indicate the presence of oleic acid in the unsaturated fatty acids.

The water filtrates from the two oxidations were combined and examined for higher hydroxy acids,[11] with negative results. This indicates the possible absence[2] of acids more unsaturated than linoleic (linolic) in the unsaturated fatty acids.

B. Bromination.—One gram of the unsaturated fatty acids was brominated[13] yielding a small amount of white precipitate in the cold petroleum ether. This precipitate, together with a small amount of similar material recovered from the evaporated petroleum ether filtrate (see below), was extracted with hot petroleum ether. After evaporation of the petroleum ether, the residue was crystallized from ether yielding a white solid, melting point 176.5–177°.

Anal. (Carius) Calcd. for hexabromostearic acid, $C_{18}H_{30}O_2Br_6$: Br, 63.34. Found: Br, 63.55.

The data indicate the presence of linolenic acid in the unsaturated fatty acids. Additional qualitative tests for linolenic acid were obtained in both the mixed and unsaturated fatty acids using arsenotungstic acid.[14] It is interesting to note the detection of this acid by its bromide and the failure to find its oxidized product, hexahydroxystearic acid. This result is similar to that found previously by the first author with linolenic acid from cassava starch.[2] This further confirms his conclusion that bromination is a more delicate method for detecting small amounts of linolenic acid than oxidation.

The petroleum ether filtrate was allowed to evaporate and the residue treated with ether. A small amount of white solid did not dissolve. As the melting point indicated the presence of the hexabromo compound, it was combined with the material insoluble in the cold petroleum ether (see above). The ether was allowed to evaporate and the residue recrystallized first from ether and finally from petroleum ether. It was a white solid, melting point 113°.

Anal. (Carius) Calcd. for tetrabromostearic acid, $C_{18}H_{32}O_2Br_4$: Br, 53.33. Found: Br, 53.00.

These data are added evidence for the presence of α-linoleic (linolic) acid in the unsaturated fatty acids.

Examination for Other Substances.—Tests on the resultant solution from a sodium fusion with a portion of the mixed fatty acids showed the absence of nitrogen, sulfur and halogens. Results obtained from the fusion of another portion of the mixed fatty acids with a mixture of equal parts of sodium carbonate and sodium nitrate indicated the absence of phosphorus.

The mixed fatty acids were tested for phytosterol by the Liebermann–Burchard reaction[11] (p. 270) and the precipitation with 1% alcoholic digitonin,[11] (p. 264) both being positive. The precipitate of the latter, after washing and drying, was silky white platelets having a melting point of 208–212°. However, there was too small an amount to obtain any added data. An attempt was made to isolate enough of the pure phytosterol,[15] for further identification, from a portion of the mixed fatty acids, but the amount again was too small to work with. In order to ascertain whether or not the phytosterol could have its source in some extraneous material, the alcohol used for the extraction of the starch was evaporated to dryness. The residue was then subjected to the same tests with negative results. As a further check 500 g. of alcohol extracted starch was extracted with petroleum ether. After evaporation of the petroleum ether a very small residue was obtained in which the absence of phytosterol was shown by the same tests.

Summary

The amount of fatty acids liberated by the hydrolysis of banana starch free from extraneous fatty material has been determined to be 0.2%.

The fatty acids have been found to consist of a mixture of palmitic, oleic, linoleic (linolic) and linolenic acids together with a very small amount of phytosterol.

The detection of small amounts of linolenic acid in the presence of oleic and linoleic (linolic) by bromination has again been shown to be a more sensitive method than oxidation.

This is the first time that phytosterol has been found combined in a starch.

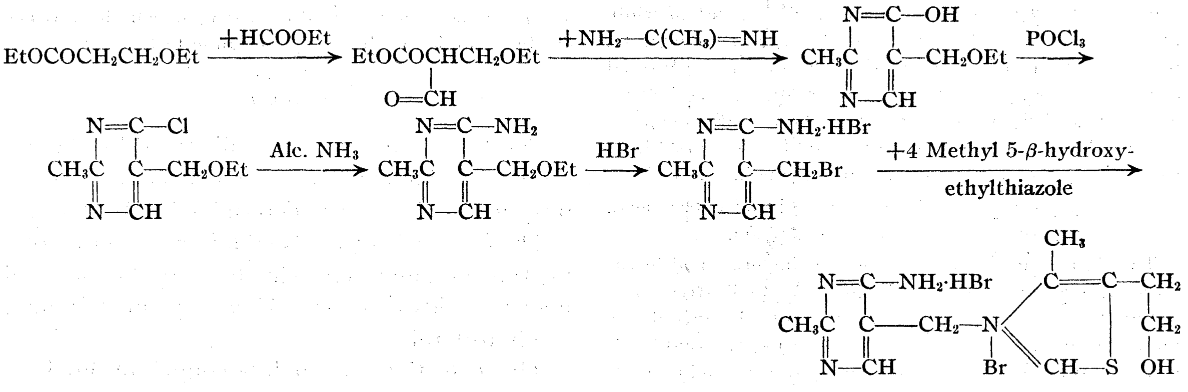
Studies of Crystalline Vitamin B_1. XVII. Synthesis of Vitamin B_1

BY JOSEPH K. CLINE, ROBERT R. WILLIAMS AND JACOB FINKELSTEIN

The structure of vitamin B_1 having been determined by previous identification and ultimate synthesis of several degradation products, notably 4-methyl-5-beta-hydroxyethylthiazole,[1] 2,5-dimethyl-6-aminopyrimidine,[2] 2-methyl-6-oxypyrimidine-5-methylene sulfonic acid[3] and the mode of linkage of the two nuclei indicated by the presence of quaternary nitrogen in the vitamin,[4] a synthesis of the vitamin was undertaken.

The possibilities of three principal routes of synthesis leading to the pyrimidine portion of the vitamin were explored: (1) the addition of formaldehyde to the 5-position of an appropriate pyrimidine; (2) a Curtius, Hoffmann or Loessen degradation of appropriate derivatives of 2-methyl-6-oxypyrimidine-5-acetic acid whose ethyl ester, hydrazide and amide we had prepared in excellent yields; and (3) the conversion of a 5-ethyoxymethyl-pyrimidine into the corresponding 5-halomethyl derivative.

Of these the first two proved difficult to control at one or more stages. The third offered more promise of amenability. As has been indicated in a preliminary communication,[5] a successful synthesis has been worked out according to the scheme



The final condensation step in the synthesis took place less readily than had been anticipated and numerous trials were necessary before crystalline material was obtained in a state of apparent purity although ample antineuritic potency could be demonstrated in the reaction mixtures by physiological tests. The difficulty of isolating the crystals was enhanced by their surprising solubility in alcoholic solvents. As first obtained, the crystalline bromide hydrobromide melted at 219–220° and the chloride hydrochloride at 232–234°. These were obtained by adding ether to methanol solutions. Presently, however, through the cooperation of Dr. A. G. Stein, a method was evolved whereby the vitamin was recrystallized as the bromide hydrobromide from methanol and as the chloride hydrochloride from water and ethanol. The bromide hydrobromide so obtained melted at 227–231° and the chloride hydrochloride at 248–250°. In no case is the melting point of either natural or synthetic vitamin very satisfactory as a criterion of purity as melting is preceded by decomposition. Further, melting on a hot stage under crossed Nicols reveals that in all cases a loss of birefringence occurs at about 190°, suggesting some intramolecular transformation at that temperature.

We have compared the low and high melting forms somewhat elaborately by crystallographic, spectrometric and electrometric means as well as analytically without detecting clear evidence of the presence of an impurity in the low melting crystals. Furthermore, numerous physiological tests including both curative and prophylactic experiments have likewise indicated as yet no significant deviations among the two forms of synthetic and the natural chloride. Further re-

port will be made when these experiments are complete.[6]

Immediately after the publication of our preliminary communication of the synthesis,[7] there reached us a paper by Dr. Rudolf Grewe[8] confirming the structure previously proposed by ourselves[5] and containing the information that a synthesis of the vitamin had been achieved in recent months by Drs. Andersag and Westphal at the Elberfeld Laboratories of the I. G. Farbenindustrie A.-G. To date no publication has appeared revealing the route of this synthesis or the characteristics of the product. It is therefore impossible to compare the results with our own at this time. Happily, however, for science there appears to be no ground for dispute regarding the true constitution of the vitamin.

The yields reported herein have in many instances been improved by modifications which are still under investigation. Our synthesis has proved amenable to large scale development and has already been utilized for the production of many kilos of the vitamin on an economical basis.

Ethyl Sodioformyl-β-ethoxypropionate.—A mixture of 73 g. of ethyl β-ethoxypropionate and 40 g. of ethyl formate was dropped slowly during eight hours onto 12 g. of sodium wire covered with anhydrous ether. The yellow sodioformyl derivative thus formed appeared as a solid mass which occluded all the ether and unreacted esters. The sodioformyl derivative was used without isolation for the subsequent reaction. It must be protected from atmospheric moisture and should be used promptly as it is not very stable.

2-Methyl-5-ethoxymethyl-6-oxypyrimidine.—To the crude sodioformyl derivative obtained above 45 g. of acetamidine hydrochloride, 100 cc. of absolute alcohol, and a solution of 12 g. of sodium in 200 cc. of absolute alcohol were added. The ether was distilled off and the mixture heated, under reflux, for sixteen hours. The contents of the flask was then cooled, neutralized with 10% acetic acid and evaporated on the steam-bath. The residue was taken up in a small amount of water and extracted repeatedly with chloroform. The combined chloroform extracts were dried over anhydrous sodium sulfate and the chloroform removed by evaporation *in vacuo*. The remaining brown gummy substance was treated with dioxane, which dissolved a portion and left a discolored white solid. The residual solid was separated, dried, and sublimed in high vacuum at 140°. The sublimate was placed in a Soxhlet extractor, extracted repeatedly with anhydrous ether and the residue again sublimed in high vacuum. The sublimate was a pure white cake of 2-methyl-5-ethoxymethyl-6-oxypyrimidine which melted at 175–176°; yield 3.5%.

Anal. Calcd. for $C_8H_{12}O_2N_2$: C, 57.11; H, 7.20. Found: C, 56.92, 56.96; H, 7.04, 6.84.

2-Methyl-5-ethoxymethyl-6-chloropyrimidine.—One gram of 2-methyl-5-ethoxymethyl-6-oxypyrimidine was heated with 8 cc. of phosphorus oxychloride for three hours at 78°. The pyrimidine dissolved slowly and left but a small quantity of undissolved material. The excess phosphorus oxychloride was then distilled off *in vacuo*. To the residue was added a small amount of crushed ice and water and the excess acid neutralized by the addition of solid sodium bicarbonate. The dark colored solution was extracted repeatedly with chloroform and the combined chloroform extracts were dried over anhydrous sodium sulfate. The chloroform was removed *in vacuo* and the residue distilled. A fraction which boiled at 78–80° at 1 mm. was collected. On redistillation the pure chloropyrimidine boiled at 72–73° at 0.5 mm. and was obtained as a colorless oil with an odor resembling acetamide; yield 70%.

Anal. Calcd. for $C_8H_{11}N_2OCl$: C, 51.46; H, 5.94; N, 15.01; Cl, 19.01. Found: C, 50.84, 50.82; H, 5.64, 5.70; N, 14.85, 14.92; Cl, 18.95.

2-Methyl-5-ethoxymethyl-6-aminopyrimidine.—One gram of 2-methyl-5-ethoxymethyl-6-chloropyrimidine was treated with 15 cc. of saturated alcoholic ammonia in a bomb-tube at 140° for fifteen hours. The contents of the tube were concentrated *in vacuo* and a partly crystalline residue remained. The residue was dissolved in a small amount of water, the solution made alkaline by addition of sodium carbonate and the solution then extracted repeatedly with chloroform. The combined chloroform extracts were dried over anhydrous sodium sulfate and the chloroform was removed *in vacuo*. A gummy residue containing a small amount of crystals was left. When this residue was treated with hot anhydrous ether a solid separated immediately. The solid was removed by centrifuging and discarded. The ethereal mother liquors on standing and partial evaporation of the ether deposited large crystals of the impure aminopyrimidine, which were filtered off, dried, and purified by repeated sublimation in high vacuum at 60–80°. The product, a pure white pyrimidine with an odor reminiscent of piperidine, melted at 89.5–90.5°; yield 70%. *Anal.* Calcd. for $C_8H_{13}ON_3$: C, 57.45; H, 7.58; N, 25.13. Found: C, 57.31, 57.62; H, 7.62, 7.65; N, 25.64, 25.50, 25.82.

2-Methyl-5-bromomethyl-6-aminopyrimidine Hydrobromide.—One hundred and fifty mg. of 2-methyl-5-ethoxymethyl-6-aminopyrimidine was heated with 10 cc. of a 10% solution of anhydrous hydrobromic acid in glacial acetic acid for two hours at 100°. At the end of this time the mixture was cooled and the liquid remaining decanted from the crystals which separated out. The crystals were washed several times with anhydrous ether and then purified by dissolving in a small amount of cold methanol and reprecipitating by the addition of ether. The pure compound as obtained melts at 192–193° and is the hydrobromide of 2-methyl-5-bromomethyl-6-aminopyrimidine; yield 90%. *Anal.* Calcd. for $C_6H_9N_3Br_2$: C, 25.45; H, 3.21; N, 14.85. Found: C, 26.36, 26.55, 26.45; H, 3.50, 3.62, 3.34; N, 14.71, 14.99.

Vitamin B1 Bromide Hydrobromide.—One hundred and fifty mg. of 2-methyl-5-bromomethyl-6-aminopyrimidine hydrobromide was heated with 150 mg. of 4-methyl-5-β-

hydroxyethylthiazole[9] and 0.2 cc. of butanol for fifteen minutes at 120°. The pyrimidine went into solution and shortly thereafter a precipitate settled out. The reaction mixture was diluted with 1 cc. of boiling absolute ethyl alcohol and allowed to stand until no more material settled out. The alcoholic mother liquors were removed by filtration and the precipitate washed several times with small amounts of cold absolute ethyl alcohol. The precipitate then was recrystallized by dissolving in hot methanol, adding absolute alcohol to the hot solution until a permanent cloud appeared and allowing to cool slowly.

The condensation product thus obtained occurs as rosets of needles which melt at 229–231°; yield 45%.

With doses of 6 γ, cures of polyneuritis were effected in rats on a vitamin B_1-free diet. These cures endured for several days, indicating an activity equal to the natural vitamin. It appears to hold one-half molecule of water of crystallization. *Anal.* Calcd. for $C_{12}H_{17}ON_4SBr \cdot HBr \cdot 0.5\,H_2O$: C, 33.09, H, 4.51; N, 12.87. Found: C, 33.18, 32.76; H, 4.82, 4.70; N, 12.73.

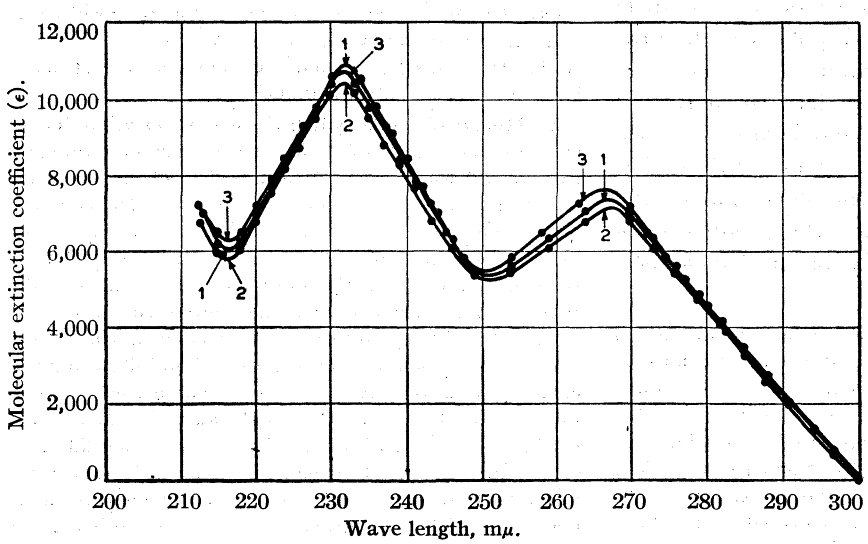

Fig. 1.—Curve 1, natural vitamin (hydrochloride); curve 2, synthetic vitamin (hydrochloride); curve 3, synthetic vitamin (hydrobromide).

Vitamin B_1 Chloride Hydrochloride.—One hundred and fifty mg. of vitamin B_1 bromide hydrobromide was dissolved in hot methanol and shaken with slight excess silver chloride for a half hour.

The silver salts were filtered off and to the hot solution absolute alcohol was added to incipient cloudiness. On cooling the vitamin hydrochloride crystallized out. To free it from traces of silver chloride it was dissolved in a little water and filtered. The filtrate was evaporated *in vacuo* to dryness, the crystalline residue was dissolved in a minimum amount of water and to the hot aqueous solution ten volumes of absolute alcohol was added. On standing the crystalline chloride hydrochloride separated melting at 248–250°; yield 90%. *Anal.* Calcd. for $C_{12}H_{17}ON_4SCl \cdot HCl \cdot 0.5H_2O$: C, 41.60; H, 5.53; N, 16.17; Cl,[10] 21.04; S,[10] 9.51. A comparison of the ultraviolet absorptions of the natural and synthetic products is shown in Fig. 1. Curative tests on polyneuritic rats have given the following results:

No. rats	Dose in γ	Cured	Recurrence of polyneuritis, days
7	3	2	6
7	4	2	5.5
7	4.5	3	6.7
12	5	7	6.3
8	5.5	7	7
9	6.0	9	5.6

We gratefully acknowledge our indebtedness to Mr. D. F. Hayman and Mr. S. Adler for the microanalyses, to Mr. A. E. Ruehle for the spectrograms, to Dr. E. R. Buchman for several samples of 4-methyl-5-β-hydroxyethylthiazole, and to Mr. H. W. Hermance for the crystallographic comparison of the synthetic and natural vitamin. Thanks are also due to Dr. R. T. Major for advice and for facilities put at our disposal. We also wish to express our appreciation to Dr. Hans Molitor and Mr. W. L. Sampson for the many physiological assays necessary in the course of the work.

Summary

1. A practical synthesis of vitamin B_1 has been described.

2. The synthesis of several new pyrimidines useful as intermediates in the synthesis of vitamin B_1 has been described.

3. The structure previously proposed for vitamin B_1 has been confirmed by synthesis.

The Decomposition of 2-Fluorenediazonium Chloride and 2-Fluorenonediazonium Chloride in Acetic Acid

BY H. V. CLABORN AND H. L. HALLER

In preparing derivatives of fluorene to be tested for their insecticidal action, it became desirable to prepare 2-acetoxyfluorene and 2-acetoxyfluorenone. These compounds are not described in the literature, but it was found that they could be obtained readily by the acetylation of the corresponding hydroxy compounds. The latter compounds were first prepared by Diels,[1] who obtained them by the decomposition of the corresponding diazonium chlorides with water in the usual manner. The yield of the 2-hydroxyfluorene was reported to vary considerably, and this observation has been confirmed by us. When, however, the decomposition of the diazonium chloride was carried out in 3% sulfuric acid, as suggested by Ruiz,[2] an 80% yield of the 2-hydroxyfluorene was obtained.

The decomposition of 2-fluorenonediazonium chloride in water gave 2-hydroxyfluorenone in a yield of 55%, whereas in dilute acetic acid, as suggested by Patrizietti,[3] an 80% yield of the same compound was obtained.

The replacement of the amino group by the acetoxy group through the diazo reaction has been accomplished by the decomposition of a dry diazonitrate or sulfate with glacial acetic acid;[4] by the interaction of a diazo bromide and acetic anhydride;[5] by the diazotization of an amine in glacial acetic acid;[6] and more recently by the interaction of solid aryl diazonium borofluorides and acetic acid.[7,8] In the last reaction the acetates of phenols are obtained in good yield, and this reaction is particularly useful when the normal decomposition does not take place readily. Since 2-fluorenediazonium chloride and 2-fluorenonediazonium chloride are fairly stable solids, it seemed of interest to attempt the preparation of the acetoxy compounds directly from the diazonium chlorides and acetic acid. When the experiment was carried out with 2-fluorenediazonium chloride, three compounds were obtained, with the following yields: 2-chlorofluorene, 10%; 2-acetoxyfluorene, 46.7%; and 2-hydroxyfluorene, 11%. The last-named compound separated readily from the reaction mixture by extraction with alkali. Although a partial separation of the chloro and the acetoxyfluorenes could be effected by recrystallization from methanol, it was found expedient to separate the two by saponifying the acetate with alkali to the phenol and removing the chloro compound by filtration from the alkaline solution.

The interaction of 2-fluorenonediazonium chloride and acetic acid gave a 60% yield of 2-acetoxyfluorenone.

Experimental

Interaction of 2-Fluorenediazonium Chloride and Acetic Acid.—A solution of 10 g. of 2-fluorenediazonium chloride in 50 cc. of glacial acetic acid was heated gently under a reflux condenser until nitrogen began to be evolved. After the vigorous reaction had subsided, the solution was boiled for five minutes and then concentrated under reduced pressure until most of the acetic acid was removed. The concentrated solution was poured into ice water; the separated product was removed by filtration and dried; yield 7.6 g.; m. p. 85–100°. The product was dissolved in ether and extracted twice with 5% potassium hydroxide solution. The combined alkaline solutions were acidified with dilute hydrochloric acid, and the precipitated phenol was separated by filtration. It was recrystallized from 50% acetic acid; yield 1.1 g.; m. p. 168°. When mixed with an equal quantity of authentic 2-fluorenol, there was no depression of the melting point.

From the ether solution there was obtained, after drying over sodium sulfate and removal of the ether, 5.8 g. of a mixture of the chlorofluorene and acetoxyfluorene. This mixture was best separated by heating it to boiling for thirty minutes with 30 cc. of 10% potassium hydroxide solution, cooling, and then removing the chloro compound by filtration. The chloro compound was then purified by steam distillation; yield 1 g.; m. p. 168°. It was identified as 2-chlorofluorene by a mixed melting point determination with authentic material prepared according to the method of Chanussot.[9]

2-Acetoxyfluorene.—One gram of 2-fluorenol was refluxed for thirty minutes with 5 cc. of acetic anhydride and 0.5 g. of anhydrous sodium acetate. The solution was cooled and a small volume of methanol added to decompose the acetic anhydride. The solution was poured slowly, with stirring, into ice water. The acetate sepa-

rated as colorless crystals, which were removed by filtration. These were washed with water and dried; yield 1.1 g. After recrystallization from dilute methanol the compound melted at 128°.

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 80.32; H, 5.40. Found: C, 80.16; H, 5.46.

2-Acetoxyfluorenone.—One gram of 2-fluorenonediazonium chloride in 5 cc. of glacial acetic acid was heated gently until the evolution of nitrogen began. After the initial reaction subsided, the solution was again heated carefully until the evolution of nitrogen ceased and then boiled for five minutes. Fifteen cubic centimeters of ethanol was then added and the solution chilled in ice. The product which separated consisted of large yellow plates; yield 0.6 g.; m. p. 154°. After recrystallization from 95% ethanol, it melted at 157°. The compound was identified as 2-acetoxyfluorenone by a mixed melting point determination with an authentic sample of 2-acetoxyfluorenone. The latter was obtained by acetylation of 2-hydroxyfluorenone (1 g.) according to the method described for the preparation of 2-acetoxyfluorene. The yield was 1.15 g. On recrystallization from 95% ethanol it melted at 157°.

Anal. Calcd. for $C_{15}H_{10}O_3$: C, 75.60; H, 4.23. Found: C, 75.43; H, 4.28.

On saponification with 5% potassium hydroxide solution 2-acetoxyfluorenone (1.9 g.) was converted into 2-hydroxyfluorenone (1.5 g.), which after recrystallization from 50% acetic acid melted at 204°. Diels[1] reports this compound as sintering at 200° and melting at 206.7°.

Summary

The interaction of 2-fluorenediazonium chloride and acetic acid gives three compounds in the following yields: 2-chlorofluorene, 10%; 2-acetoxyfluorene, 46.7%; and 2-hydroxyfluorene, 11%.

From 2-fluorenonediazonium chloride and acetic acid there was obtained a 60% yield of 2-acetoxyfluorenone.

Identification of Alkylbenzenes. I. Identification of Monoalkylbenzenes by Means of the Acetamino Derivative[1]

By V. N. Ipatieff and Louis Schmerling

In the course of the study of the alkylation,[2] depolyalkylation,[3] and destructive alkylation[4] of aromatic hydrocarbons, the need for a simple method for the identification of alkylbenzenes became apparent. The boiling points and other physical constants are fairly satisfactory for distinguishing the homologous compounds but are inadequate in the case of isomers. Oxidation to benzoic acid or to one of the phthalic acids may be used to differentiate between mono- and dialkylbenzenes but is of no aid in the determination of the structure of the alkyl groups.

In the present investigation, the characterization of monoalkylbenzenes by means of their mono- and diacetamino derivatives was studied. Although there was nothing inherently new in the preparation of such derivatives by nitration, followed by reduction of the nitro compound and subsequent acetylation of the amine, there had been no previous study of the nitration of a series of alkylbenzenes under a single set of conditions; furthermore, it was not possible to predict whether the solid derivative would be a single compound or a mixture. If the nitration yielded a mixture of ortho and para isomers, the reaction would not be applicable. On the other hand, the preparation of a dinitro derivative would eliminate this difficulty since there is ample evidence[5] to show that only the 2,4-dinitro compound would be obtained.

The problem, then, consisted essentially in determining the conditions necessary for the formation either of a mononitro derivative, unadmixed with isomers, or of the dinitro derivative. This was less difficult than had been anticipated, and a procedure was developed by means of which monoalkylbenzenes may be identified easily and quickly using small amounts of material. It was found that under the prescribed conditions pure 4-nitroalkylbenzenes may be obtained by use of a nitrating mixture consisting of equal volumes of concentrated nitric and sulfuric acids. The ortho-substituted isomers are present in such small amount, if at all, that they do not interfere. It

was found further that by use of more vigorous nitrating solution (namely, one composed of two volumes of sulfuric acid to one of nitric acid) it is the 2,4-dinitroalkylbenzenes[6] which are formed.

It is thus possible to obtain either the 4-acetamino- or the 2,4-diacetaminoalkylbenzenes as desired. The first are more suitable in the characterization of pure hydrocarbons; the second, because of solubility and other physical properties, in the identification of the components of aromatic mixtures. An important application of the latter consists of distinguishing between *n*- and isopropylbenzene when they occur separately or in a mixture with each other. Such an analysis is, of course, very desirable since the boiling points of the hydrocarbons are too close together to permit of their separation or definite identification. Although their diacetamino derivatives melt only 8° apart, there is little danger of confusing the derivatives since they crystallize in markedly different form and can be distinguished easily with the aid of a polarizing microscope.

In some cases, the mononitro compound may be contaminated with a small amount of the dinitrated hydrocarbon, and *vice versa*. Fortunately, the two may readily be separated by means of an ether extraction of the solution obtained on reducing the compounds with tin and hydrochloric acid. The monoamino compound forms an ether-soluble salt (presumably, $2RC_6H_4NH_2 \cdot SnCl_2 \cdot 2HCl$) with tin chloride in the presence of hydrogen chloride, whereas the analogous salt of the diaminoalkylbenzene is ether-insoluble. The material obtained from the ether extract is worked up separately from the other, and both the mono- and the diacetaminoalkylbenzenes may thus be obtained in a pure state from a single nitration product, giving a check on the identity of the hydrocarbon.

This method has been applied successfully by us in the determination of the structure of the different amylbenzenes obtained by the alkylation of benzene with cyclopentane and with methylcyclobutane, full details of which will be given in a forthcoming publication by Grosse and Ipatieff.

Experimental

Procedure.—A mixture of 0.5–1.0 cc. of the aromatic hydrocarbon and 5 cc. of a nitrating mixture was shaken for three to five minutes. The nitrating mixture consisted of equal volumes of sulfuric acid (d. 1.84) and nitric acid (d. 1.42), when the mononitro compound was desired as the chief product (Note 1), or of two volumes of the sulfuric acid to one of the nitric when it was the disubstituted derivative which was to be obtained. No attempt was made to cool the reaction mixture. When the evolution of heat had ceased, the mixture was poured upon a small amount of cracked ice; the oily nitro layer was taken up in ether, washed twice with water, and the ether was evaporated on a water-bath. To the residue was added 5 g. of granulated tin, 5 cc. of concentrated hydrochloric acid, and sufficient ethyl alcohol to bring all, or nearly all, of the nitrocompound into solution. The mixture was shaken until reduction was complete as was shown by the absence of marked turbidity on pouring a test portion into water (Note 2). This usually required less than ten minutes. In those cases in which the reduction took place more slowly, the reaction was hastened by heating the mixture on the water-bath; usually, however, the reduction was very exothermic and did not require the application of external heat. When reduction was complete, the aqueous alcoholic solution was decanted from the excess tin into about 20 cc. of water. The solution was extracted with ether and sufficient concentrated alkali was added to the aqueous solution to dissolve most of the precipitate of tin hydroxide which formed at first. The amino compound was extracted with ether, washed with water, dried by shaking for a few minutes with potassium carbonate, and the ether removed by evaporation. To the residue there was added 1 cc. of acetic anhydride. The derivative usually crystallized almost immediately. The material was warmed with 5 cc. of water to hydrolyze the excess anhydride. Since some of the acetamino derivatives are quite soluble in dilute acetic acid, it was occasionally necessary to evaporate almost to

100 ×.

Fig. 1.—Mixture of the diacetamino derivatives of *n*- and isopropylbenzene.

---

[6] The orientation of the nitro groups has been proved for toluene, ethylbenzene, *n*-propylbenzene, and *t*-butylbenzene (*cf.* references in preceding footnote). It is presumably the same in the case of all the disubstituted monoalkylbenzenes prepared by the procedure described in this paper.

dryness the aqueous solution containing the hydrolyzed acetic anhydride. The crude derivative was filtered and then recrystallized from hot water or dilute alcohol, yield 40–70%.

The ether extract of the reduction solution was tested in order to determine whether it consisted of traces of unreduced nitro compound or of an amine–tin chloride complex. In the latter case the amine was liberated by the addition of alkali and worked up separately from the main batch of derivative. Although the amount of material thus received was often only a small portion of the total, this was well worthwhile since it was the monoacetaminoalkylbenzene only which was obtained, even when the derivative prepared from the major portion was the diacetamino compound. When the chief or only product was the monosubstituted derivative, two alternatives were possible: either part of the compound could be obtained from the ether extract and the remainder from the aqueous solution, or the ether extraction could be made complete and all the monoamine isolated therefrom. The latter procedure gave the more satisfactory results, especially when small amounts of diaminoalkylbenzene were present.

The time required for the preparation of the derivative, exclusive of the recrystallization of the product, was about thirty minutes.

NOTE 1.—Both toluene and ethylbenzene yielded practically only the 2,4-dinitroalkylbenzene regardless of which nitrating mixture was used. For neither hydrocarbon could more than traces of the monosubstituted derivative be isolated. The *n*-alkylbenzenes showed a marked tendency to yield dinitro derivatives even with the milder nitrating solution. In the case of *n*-propylbenzene and of *n*-butylbenzene the formation of the dinitrated by-product could be greatly diminished by cooling the reaction mixture.

[a] Beilstein, 4th ed., Vol. XIII, p. 133. [b] *Ibid.*, p. 177. [c] The diaminocyclohexylbenzene (presumably the 2,4-compound) recrystallized from water or heptane: m. p. 105–106°. Calcd.: N, 14.74. Found: N, 14.42.

NOTE 2.—In some cases the monoaminoalkylbenzene–tin chloride complex was quite insoluble in dilute acid solution and precipitated when the reduction solution was poured into water. In such cases, the precipitate could be differentiated from unreduced nitro compound by extracting with ether and testing with alkali.

Identification of *n*- and Isopropylbenzene in a Mixture with Each Other.—The diacetamino derivative of *n*-propylbenzene crystallizes from water or dilute alcohol in the form of soft, white, feathery aggregates (spherical clusters) which are seen to be made up of short thread-like crystals when viewed under high magnification. On filtering, the aggregates are easily broken up and a powdery material is obtained. The isomeric isopropyl derivative, on the other hand, crystallizes in the form of hard, glistening prisms which retain their shape even when filtered. These are anisotropic and show up beautifully in the polarizing microscope with crossed nicols, whereas under the same conditions the diacetamino-*n*-propylbenzene crystals are barely visible.

These rather surprisingly marked differences in the crystalline properties of the derivatives at once suggested a means for distinguishing each in a mixture of the two. Experiments which were made with synthetic mixtures gave very satisfactory results. The more vigorous nitrating mixture was used so as to lead eventually to the production of the diacetamino derivatives. The nitration and subsequent reduction proceeded smoothly. When acetic anhydride was added to the mixture of diamines, the acetamino derivatives crystallized out almost immediately. Water was added to hydrolyze the excess anhydride, and the mixture was heated until all of the derivative dissolved.

On cooling, there crystallized white feathery crystals, having the physical appearance of the diacetamino-*n*-propylbenzene. When viewed under the microscope, it was chiefly the short needles of the *n*-propylbenzene derivative which were seen. The melting point of the material so obtained was 202–204°, indicating the presence of a small amount of the isomeric compound. The mother liquor from this first crystallization, then, contained the major portion of the more soluble isopropylbenzene derivative. Hence, it was evaporated to about 3 cc. and allowed to stand. Crystals soon appeared and even with the unaided eye the glistening flakes of diacetaminoisopropylbenzene could be discerned. When examined under the microscope, both the small needles of the *n*-propylbenzene derivative and the large prisms of the isomeric isopropyl derivative were observed. When the nicols were crossed, the former disappeared from view and the latter shone brilliantly in the dark field.

After several fractional crystallizations from hot water the isopropyl derivative was isolated in an almost pure state, m. p. 214°.

Acknowledgment.—We wish to thank Dr. J. D. Kurbatov for assistance in the study of the crystal forms and Mr. R. W. Moehl for taking the photomicrograph.

Summary

A simple, uniform procedure is described for the preparation of the mono- and the diacetamino derivatives of monoalkylbenzenes. The physical properties of a series of such compounds is given.

Nitration of the alkylbenzene is shown to yield either the mononitro or the dinitro derivative or a mixture of both depending upon (a) the nature of the side chain, and (b) the composition of the nitrating mixture.

Under the prescribed conditions the *p*-acetaminoalkylbenzene was obtained unadmixed with ortho or meta isomers.

A method is presented for separating monoaminoalkylbenzenes from diaminoalkylbenzenes, based on the solubility in ether of the monoamine–tin chloride–hydrogen chloride complex.

It is shown that by means of the diacetamino derivatives it is possible to distinguish between the two propylbenzenes, when they occur either separately or in a mixture with each other.

Studies in the Ketone Sugar Series. VII.
The Action of Titanium Tetrachloride on the Methylfructoside Acetates

BY EUGENE PACSU AND FRANCIS B. CRAMER

It has been shown in a series of investigations[1] that titanium tetrachloride is capable of transforming the acetylated β-alkyl glycosides and the fully acetylated derivatives of the aldoses into the corresponding α-forms. A characteristic of the reaction appears to be the formation of halochromic addition compounds which do not occur when stannic chloride[2] is employed to promote the same transformation. It has also been shown that the α-acetates of the sugars undergo a secondary change and are smoothly transformed to the corresponding α-acetochloro compounds. In order to test the generality of the conversion it seemed necessary to submit a ketose derivative, tetraacetyl-β-methylfructoside <2,6>, to the action of titanium tetrachloride. A yellow halochromic salt was produced immediately when this reagent was added to the chloroform solution of the fructoside. Contrary to expectation, no conversion into the α-form could be detected after the mixture had been heated for four hours. Neither did the starting material undergo any secondary reaction, since only unchanged tetraacetyl-β-methylfructoside was recovered after the reaction mixture had been worked up in the usual way. Such behavior of the β-methylfructoside acetate might be compared with that of β-pentaacetylfructose <2,6> which has been shown in Part VI[3] to undergo isomerization into the α-form only to a very slight extent when treated with zinc chloride in acetic anhydride solution. Since α-pentaacetylfructose <2,6>, on the other hand, has been found to suffer a rapid and almost complete conversion into the β-pentaacetate of fructose in the presence of zinc chloride, it was thought that tetraacetyl-α-methylfructoside <2,6> might readily rearrange into the β-isomer when treated with titanium tetrachloride. The result of the experiment was an unexpected one. The reaction product

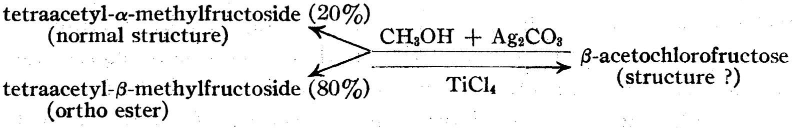
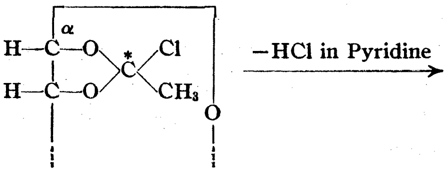
[3] Cramer and Pacsu, THIS JOURNAL, **59**, 711 (1937).

was found to be β-acetochlorofructose, with which unchanged starting material was admixed. The presence of unchanged α-fructoside in connection with the result of the previous experiment shows that no conversion into the β-fructoside could have taken place. It is to be concluded, therefore, that titanium tetrachloride is without any action on the methylglycosidic group of fructose of β-configuration, but that it easily replaces the glycosidic group of fructose of α-configuration with a chlorine atom. At present, any interpretation of this strange behavior is conjectural.

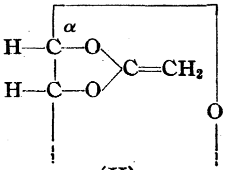
Tetraacetyl-α-methylfructoside <2,6> has recently been shown[4] to be the true diastereomer of tetraacetyl-β-methylfructoside which, according to Haworth,[5] possesses a normal structure. On the strength of the above experiment, one may infer that the formation of β-acetochlorofructose from the α-fructoside proves definitely that β-acetochlorofructose itself possesses normal structure as is generally assumed although not proved by direct evidence. On the other hand, the formation of about 80% of the tetraacetylmethylfructoside having ortho ester structure from β-acetochlorofructose, which reaction has recently been shown[6] to take place when using standard procedures, might be construed as evidence that β-acetochlorofructose has an ortho ester structure. Therefore, a study of the action of titanium tetrachloride on the tetraacetylmethylfructoside with ortho ester structure was made. Formation of a new acetochlorofructose would have established beyond doubt the structure and would have confirmed indirectly the normal structure of β-acetochlorofructose. However, it was found that the reaction yielded pure β-acetochlorofructose as the only crystalline product. Similarly, rapid formation of β-acetobromofructose was observed when this methylfructoside acetate was treated with hydrogen bromide dissolved in glacial acetic acid. In the light of these transformations β-acetochlorofructose appears to be a substance which readily undergoes molecular rearrangement. Obviously, it is not possible to prove by the above chemical methods whether β-acetochlorofructose possesses a normal or an ortho ester structure.



The only authentic representative of an acetohalogenose with ortho ester structure appears to be Freudenberg's "third acetochloromaltose"[7] (I). The allocation of an ortho ester structure[8] to this compound is justified not so much by its giving rise to an ortho ester α-methylmaltoside acetate as by the fact that it represents a surplus isomer which demands a chemical formula that is in harmony with the present views on the structure of maltose. The difference in the behavior of a freshly prepared and a several days old pyridine solution of this unstable "third acetochloromaltose" toward potassium permanganate was suggested by Freudenberg as being due to the formation of a ketene acetal (II).



(I)



(II)

In Part VI[3] it has been shown that crystalline acetochloro- and acetobromoturanose, which were previously described[9] as possessing ortho ester structures, exhibit common properties with acetochloro- and acetobromofructose. In aged pyridine solution the bromo derivatives develop reducing power toward potassium permanganate, whereas the more stable acetochloro compounds do not and can be recovered unchanged. The ability of several days old pyridine solutions of certain acetohalogenoses to reduce potassium permanganate might be due to slight decomposition, since some coloration always occurs during that period of time. Therefore, unless ketene acetals are actually *isolated*, their assumed formation in pyridine solutions cannot be used as evidence for the ortho ester structures of the aceto

halogenoses. Notwithstanding this conclusion, Freudenberg's acetochloromaltose may very well possess ortho ester structure which, although unproved by chemical evidence, is suitable as an explanation for the existence of this surplus isomer. The existence of this compound makes it possible to determine whether a methylglycoside acetate with ortho ester structure, on treatment with titanium tetrachloride or hydrogen bromide, will give back a halogeno compound of the same "abnormal" structure, or will suffer rearrangement and give rise to the "normal" acetohalogenose. Accordingly, a chloroform solution of α-methylmaltoside acetate with ortho ester structure was treated with titanium tetrachloride. The product of the reaction was found to be the normal α-acetochloromaltose. In another experiment, when dry hydrogen bromide dissolved in glacial acetic acid was used, a rapid formation of the normal α-acetobromomaltose was observed. Obviously, in the following transformations

$$\underset{\text{(ortho ester)}}{\alpha\text{-acetochloromaltose}} \xrightarrow{CH_3OH + Ag_2CO_3} \underset{\text{(ortho ester)}}{\alpha\text{-methylmaltoside acetate}} \xrightarrow{TiCl_4} \underset{\text{(normal)}}{\alpha\text{-acetochloromaltose}} \xrightarrow{CH_3OH + Ag_2CO_3} \underset{\text{(normal)}}{\beta\text{-methylmaltoside acetate}}$$

the replacement of the methoxyl group of the ortho ester glycoside by a halogen atom is accompanied by a rearrangement of the ortho ester molecule. A similar case, where titanium tetrachloride had been used on an ortho ester glycoside of an aldose, was recorded by Isbell.[10] He found that, when treated with titanium tetrachloride, the heptaacetyl-4-glucosido-"γ"-methylmannoside gave back the known chloroheptaacetyl-4-glucosidomannose which is considered to be of normal structure.

If the very plausible assumption is made that not only the ortho ester methylmaltoside acetate, but *any* ortho ester glycoside will suffer rearrangement when treated with titanium tetrachloride into what is regarded as the normal acetohalogenose, then this reaction can be used to ascertain the structure of those acetohalogenoses from which the ortho ester glycosides have been prepared. On this basis, the crystalline acetohalogenoses of fructose and turanose now appear to possess normal structures. The acetohalogeno derivatives of turanose were previously described[9] as ortho esters. This was done partly because the two octaacetates from which they had been prepared were considered as ortho ester derivatives. However, in Part VI[3] it has been pointed out that, at present, it is not possible to determine whether any sugar acetate possesses normal or ortho ester structure. Therefore, only the surplus *number* of turanose octaacetates, now five altogether, demand that other than normal structures should be assigned some of them in order to avoid conflict with the accepted structure of turanose. This sugar, being regarded as 6-glucosidofructose[11] or 5-glucosidofructose,[12,13] permits the existence of only three acetates excluding ortho esters, namely, the open-chain acetate and an α,β-pair of octaacetates. On this basis, unless the unwarranted assumption is made that some of the five acetates possess ring structures other than pyranoid or furanoid, the number of isomers demands that both the fifth and sixth carbon atoms in the fructose constituent must carry unoccupied hydroxyl groups. In this difficult situation a complete reinvestigation of the structure of turanose becomes necessary. The structure of this disaccharide was based on methylation experiments that gave a sirupy trimethylfructose. Using the method of elimination, Zemplén[11,12] concluded that his product contained the methyl groups in the 1,3,4-positions. This was later confirmed by Leitch.[14] Crystalline 1,3,4-trimethylfructose with m. p. 75° subsequently was described by several investigators.[15] Since Zemplén's sirupy product shows $[\alpha]_D + 30°$ in water and $+25°$ in alcohol solution, and Leitch's product has the rotation $+55.5°$ in alcohol solution, it appears that the identity of this key substance with the crystalline 1,3,4-trimethylfructose having $[\alpha]^{18}_{5780}$ $-52°$ in water solution is questionable.

Experimental Part

Treatment of β-Methylfructoside Tetraacetate with Titanium Tetrachloride.—To 2.0 g. of β-methylfructoside tetraacetate (specific rotation[16] −124°) dissolved in 200 cc. of absolute chloroform was added 3.7 g. (3.5 mols) of titanium tetrachloride in 25 cc. of the same solvent. An insoluble yellow halochromic salt formed. After heating

(16) Unless otherwise stated, all specific rotations recorded in this paper were observed at 20° C. using light of the wave length of the sodium D lines with chloroform as solvent.

it at 55–60° for four hours, the mixture was worked up in the usual way.[1] The sirupy product had the specific rotation −117°. This was again dissolved in absolute chloroform and refluxed for one hour with 2.1 g. (2 mols) of titanium tetrachloride. Upon working up the mixture as before, a sirup was obtained having the unchanged rotation −117°. The material contained no chlorine and did not reduce Fehling's solution. In an acetyl estimation, 0.1686 g. of sirup required 17.1 cc. of 0.1 *N* sodium hydroxide solution. The calculated value for four acetyls is 18.6 cc.

Action of Titanium Tetrachloride on α-Methylfructoside Tetraacetate.—To 2.0 g. of α-methylfructoside tetraacetate (specific rotation 45.5°) dissolved in 185 cc. of absolute chloroform was added 3.7 (3.5 mols) of titanium tetrachloride in 15 cc. of the same solvent. The mixture was heated at 55–60° for three and one-half hours and refluxed for one hour. Upon working up the material, a sirup was obtained having the specific rotation −63° and giving a strong test for labile halogen. The sirup was dissolved in 200 cc. of absolute chlorofrom and refluxed with 2 g. (2 mols) of titanium tetrachloride for one hour. Considerable material was lost due to emulsification while working up the reaction mixture. The 0.9 g. of sirup obtained had the specific rotation −70.4°. The ether solution of the substance deposited in several crops 0.44 g. of a crystalline mixture from which 0.09 g. of α-methylfructoside tetraacetate and 0.07 g. of β-acetochlorofructose were isolated in pure condition and identified by their specific rotations and melting points.

Action of Titanium Tetrachloride on Ortho Ester Methylfructoside Tetraacetate.—The material used in this experiment was prepared by the first method described in Part IV,[6] was without action on Fehling's solution, contained about 6% of α-methylfructoside tetraacetate, and had the specific rotation −8.6°. To 4.0 g. of this substance dissolved in 100 cc. of absolute chloroform was added 2.1 g. (1 mol) of titanium tetrachloride in 25 cc. of the same solvent. An insoluble yellow halochromic salt formed. After refluxing for one hour the mixture had become brown and was worked up immediately. The ether solution of the product deposited 1.2 g. of crystalline material which, after recrystallization, had the correct specific rotation and melting point of β-acetochlorofructose.

Formation of β-Acetobromofructose from Ortho Ester Methylfructoside Tetraacetate and Hydrogen Bromide.—To 0.6859 g. of ortho ester methylfructoside tetraacetate dissolved in 10 cc. of absolute chloroform was added 6 cc. of glacial acetic acid saturated with hydrogen bromide at 0°, the solution was made up to 25 cc. with chloroform and, after mixing, was poured into a polarimeter tube. In five minutes the specific rotation had become −187°, and after ten minutes it remained constant at −194°. The specific rotation of β-acetobromofructose in pure chloroform is −189.1°.

Action of Titanium Tetrachloride on Ortho Ester Methylmaltoside Heptaacetate.—To 0.7 g. of ortho ester methylmaltoside heptaacetate dissolved in 40 cc. of absolute chloroform was added 0.3 g. (1.4 mol) of titanium tetrachloride in 10 cc. of the same solvent. An insoluble yellow halochromic salt formed. After refluxing for one hour, the mixture was worked up. The solid product obtained had the specific rotation 144°. Pure α-acetochloromaltose crystallizes with difficulty and has the specific rotation 159.5°. The "third acetochloromaltose" of Freudenberg has the specific rotation 67.5°.

Formation of α-Acetobromomaltose from Ortho Ester Methylmaltoside Heptaacetate and Hydrogen Bromide.—To 0.0976 g. of ortho ester methylmaltoside heptaacetate dissolved in 6 cc. of absolute chloroform was added 1 cc. of glacial acetic acid saturated with hydrogen bromide at 0°. The solution was made up to 10 cc. with chloroform and transferred to a polarimeter tube. The specific rotation increased rapidly until after one and one-half hours it remained constant at 188°. The specific rotation of α-acetobromomaltose in pure chloroform is 180.1°.

Summary

1. Unlike the β-alkylglycoside acetates of the aldoses, tetraacetyl-β-methylfructoside <2,6>, on treatment with titanium tetrachloride, does not suffer rearrangement into the α-form. Neither does it undergo any secondary reaction, since only unchanged starting material can be recovered. Similarly treated tetraacetyl-α-methylfructoside <2,6> gives rise to the known β-acetochlorofructose, but no conversion into the β-glycoside takes place. Also, tetraacetylmethylfructoside with ortho ester structure yields pure β-acetochlorofructose and not a new acetochlorofructose with ortho ester structure as might be expected.

2. Methylmaltoside heptaacetate with ortho ester structure, on treatment with titanium tetrachloride, gives rise to normal α-acetochloromaltose and not to the "third acetochloromaltose" from which it has been prepared. In the light of this reaction, the acetohalogeno derivatives of fructose and turanose appear to have normal structures.

3. The existence of five octaacetates of turanose in connection with certain other facts makes a reinvestigation of the structure of turanose necessary.

The Mechanism of Substitution Reactions: the Reaction of Benzyl Chloride with Mercuric Salts[1]

BY IRVING ROBERTS AND LOUIS P. HAMMETT

By far the most illuminating picture of the typical substitution reaction of organic chemistry is that suggested by London[2] and developed and applied by Polanyi[3] and by Olson.[4] In this there is a simultaneous addition and dissociation of reactants, a simultaneous formation and breaking of linkages. Thus in the reaction of an alkyl chloride with iodide ion[5]

$$I^- + R_3CCl \longrightarrow ICR_3 + Cl^- \quad (1)$$

the carbon–iodine linkage is thought of as being formed at the same time that the carbon–chlorine linkage is dissociating. While the stereochemical corollaries of this mechanism are important and have been considerably investigated[3b,4b] the energetics of the process lead to even more interesting conclusions. It is in fact an essential part of this theory that the energy of formation of a new linkage may contribute largely toward doing the very considerable amount of work necessary to break an old one. In the above example it is possible to break the carbon–chlorine linkage only because the simultaneous formation of the carbon–iodine linkage involves a considerable decrease in potential energy. In terms of this energy interchange or compensation we can immediately understand the principle which every organic chemist uses that silver salts are the proper reagents to react with chlorine compounds and that strong acids like sulfuric are the proper reagents to use in condensation reactions of hydroxyl compounds. The reason is that the large energy of formation of silver halide or of water furnishes the necessary driving force. Reactions of the type of equation (1) have been much investigated as have also the undoubtedly similar reactions of the type[6]

$$H_3N + R_3CCl \longrightarrow H_3NCR_3^+ + Cl^- \quad (2)$$

There is, however, an entirely different class of reactions of alkyl halides in which the driving force is clearly derived from the energy of formation of a linkage of halide ion to metallic ion. For instance, the rate of hydrolysis of an alkyl halide may be increased by several orders of magnitude by the addition of silver or mercuric salts. This important type of reaction has been subjected to detailed kinetic study in only one case, the reaction of silver nitrate with alkyl halides. Unfortunately, this particular reaction is badly complicated by a pronounced catalysis by the solid silver halide formed in the reaction.[7]

We have therefore studied the corresponding mercuric nitrate reaction with benzyl chloride for which this complication does not exist. As in the silver nitrate reaction, benzyl nitrate is formed in addition to the benzyl alcohol which results from the hydrolysis. The stoichiometric equations are

$$2C_6H_5CH_2Cl + Hg(NO_3)_2 \longrightarrow 2C_6H_5CH_2NO_3 + HgCl_2 \quad (3)$$

$$2C_6H_5CH_2Cl + Hg(NO_3)_2 + 2H_2O \longrightarrow 2C_6H_5CH_2OH + 2HNO_3 + HgCl_2 \quad (4)$$

The total rate of reaction of mercuric nitrate and benzyl chloride could therefore be followed by titration of the mercuric nitrate with chloride ion using diphenylcarbazide indicator,[8] while the relative amounts of the two products benzyl nitrate and benzyl alcohol could be determined by an acidimetric titration. As media we have used dioxane–water mixtures containing 60, 75 and 95% dioxane by volume. These were used because the resulting reaction mixtures are homogeneous, and because the solvent does not react with mercuric compounds, as do alcoholic and ketonic solvents.

The Kinetic Order of the Reaction

The reaction is essentially a second order one of mercuric nitrate and benzyl chloride, uncomplicated by reversibility, or by hydrolysis of benzyl nitrate. There are, however, appreciable de-

---

viations from second order kinetics which are very important for the understanding of the nature of the reaction. A systematic study of the initial rate of reaction showed that it is rigidly first order with respect to benzyl chloride and unaffected by the addition of benzyl nitrate or of benzyl alcohol under all conditions studied. In 75% dioxane, but not in the other media, the reaction is essentially first order with respect to mercuric nitrate, and the rate is unaffected by the addition of mercuric chloride and only slightly affected by the addition of inorganic nitrates. Nevertheless, the second order constant obtained in this medium showed a steady downward drift during the course of the reaction.

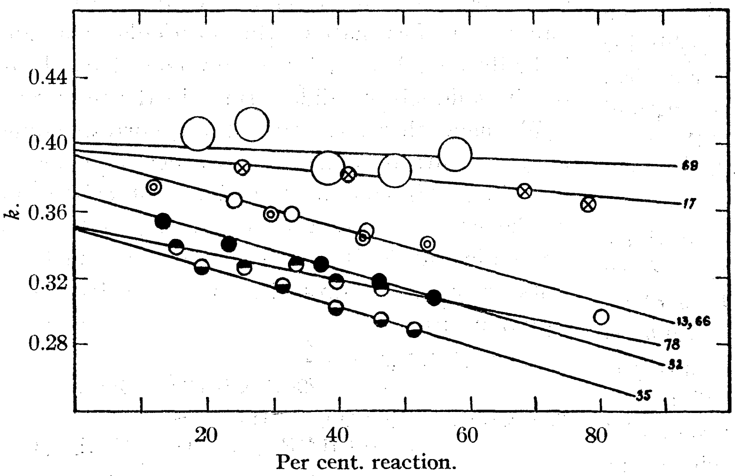

Fig. 1.—The retarding effect in 75% dioxane: ◉ no. 66, $(Hg(NO_3)_2) = 0.025$ *N*, $(BCl) = 0.050$ *N*; ○ no. 13, $(Hg(NO_3)_2) = 0.025$ *N*, $(BCl) = 0.025$ *N*; ⊗ no. 17, $(Hg(NO_3)_2) = 0.050$ *N*, $(BCl) = 0.025$ *N*; ○ no. 69, $(Hg(NO_3)_2) = 0.105$ *N*, $(BCl) = 0.025$ *N*; ● no. 32, a reaction in which $(Hg(NO_3)_2) = (BCl) = 0.025$ *N* is allowed to go to completion, new reactants (0.025 *N*) were then added and the kinetics followed; ◒ no. 35, a reaction in which $(Hg(NO_3)_2) = (BCl) = 0.050$ *N* is allowed to go to completion, new reactants (0.025 *N*) were then added and the kinetics followed; ◓ no. 78, 0.025 *N* $HgCl_2$, $Hg(NO_3)_2$, and BOH allowed to stand for seven hours, BCl was then added and the kinetics followed.

The Retarding Secondary Reaction.—In Fig. 1 we have plotted the second order rate constant *k* against the per cent. of reaction for a number of initial conditions, the solvent being in every case 75% dioxane. The radius of each circle represents the probable error. This is especially large in expt. 69 because of the exceptionally high rate. The resulting series of points, for a given experiment, is linear within experimental error and can be extrapolated satisfactorily to give the initial constant. The identity of the values of this initial constant for expts. 13, 66, 17 and 69, which involve different concentrations of mercuric nitrate and benzyl chloride, demonstrates the true second order nature of the initial reaction. The decrease in slope observed as the concentration of mercuric nitrate is increased suggests that a retarding factor operates by preventing some of the mercuric nitrate from participating in the reaction. Although none of the previously known products of the reaction retard it, something produced in the reaction does retard, as the data plotted in lines 32 and 35 of Fig. 1 demonstrate. Here new mercuric nitrate and benzyl chloride were added to spent reaction mixtures and the extrapolated initial reaction rates were found to be considerably decreased. The magnitude of this decrease was 6.5% when the initial mixture contained 0.025 *N* concentrations of mercuric nitrate and benzyl chloride (expt. 32); it was 11.5% when these concentrations were 0.05 *N* (expt. 35).

To isolate this retarding substance, a large amount of reaction mixture of high concentration (1.0 *N*) was prepared, and the reaction product was subjected to various operations of separation. The efficacy of each such operation was tested by observing the effect of the fractions upon the rate of the mercuric nitrate–benzyl chloride reaction. In this way a new substance which possesses a marked retarding effect upon the reaction was isolated. This substance has the composition of a chloromercuri-benzyl alcohol, and the properties of a weak acid. Its structure has not yet been determined. Subsequently it was found that this substance can be prepared by the action of mercuric nitrate upon benzyl alcohol followed by the addition of chloride ion, and it is apparently produced during the mercuric nitrate–benzyl chloride reaction in this way, the benzyl alcohol being produced in the primary reaction.

That this compound is at least partly responsible for the deviation from the second order course of the primary reaction is shown by the data of line 78 of Fig. 1. Here the new compound was allowed to form by the reaction of mercuric nitrate, mercuric chloride and benzyl alcohol. When benzyl chloride was added the initial reaction rate was as low as in expt. 35. It should be noted that separate experiments showed that the mere presence without previous reaction of benzyl alcohol and mercuric chloride in a reaction mixture has a negligible effect upon the rate.

That there are still further complications due to side reactions is demonstrated by the fact that the slope of 32, 35 and 78 is no greater than that of lines 13 and 66, whereas the initial presence of benzyl alcohol in these runs would be expected to produce a more rapid formation of the retardant and greater drift in the second order constants. It seems evident, however, that no matter how involved the mechanism of the drift, its cause is a subsequent reaction of a product of the primary reaction. Consequently, we can assume that the initial extrapolated second order constant is the correct one for the mercuric nitrate–benzyl chloride reaction. That this secondary reaction also takes place in 60% dioxane even though the constant increases during the course of the reaction, is evidenced by the fact that the same retardant compound can be isolated from this medium in about the same yield as from 75% dioxane.

The Effects of Nitrates and of Perchlorates.—Nitrates accelerate the reaction in all the media studied, but the effect is largest in 60% dioxane, in which there also appears a deviation from proportionality between rate and mercuric nitrate concentration. The effect of added nitrates in the 60% mixture is shown in Table I and plotted in Fig. 2. The three nitrates used have practically the same effect at equivalent concentrations. Some measurements with calcium nitrate deviate considerably but have been omitted because the solutions were turbid, showing that some complication enters in this case. As Table II shows, a decrease in mercuric nitrate concentration with a constant concentration of nitric acid produces an increase in the second order constant.

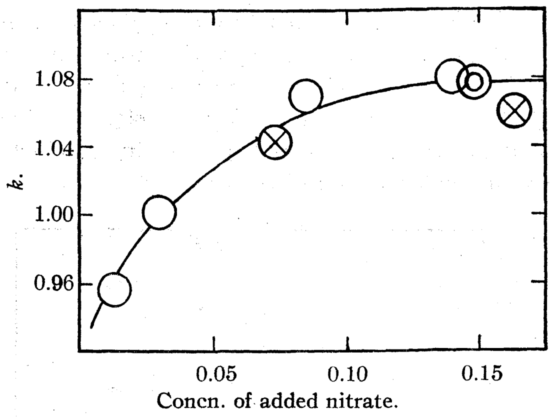

Fig. 2.—Effect of added nitrate on k in 60% dioxane: ○, HNO_3; ⊗, KNO_3; ◉, $Mg(NO_3)_2$.

These phenomena are no doubt due in part to salt effects, and it is therefore impossible to decide from them alone whether the actual reactant is mercuric ion, non-ionized mercuric nitrate, or the intermediate ion $HgNO_3^+$. Conclusive evidence that mercuric ion is not the sole reactant is, however, offered by our experiments with mercuric perchlorate. This reacts much more rapidly with benzyl chloride than does the nitrate, as experiments 51 and 52 in Table I demonstrate. Furthermore, the addition of alkali perchlorate to mercuric nitrate results in a considerably increased rate (expt. 63). Consequently some new more reactive substance is formed when perchlorate is added to the nitrate solution and this can only be $Hg(ClO_4)_2$ or $HgClO_4^+$. But there may be expected to be even more non-ionized nitrate in the mercuric nitrate solution than there is non-ionized perchlorate in the mercuric perchlorate solution, because of the considerably greater tendency toward the formation of non-ionogen compounds exhibited by nitrate ion. The idea that these mercuric salts should not be completely ionized is entirely reasonable in view of the known tendency of mercuric salts toward complex formation and the favorable effect of the low dielectric constant of the medium.

The Effect of Mercuric Chloride.—As has been stated previously, addition of mercuric chloride to the reaction mixture in 75% dioxane has no effect upon the rate. In 95% dioxane, however, 0.05 *N* mercuric chloride lowers the rate constant from 0.116 to 0.072. Since mercuric chloride is produced as the reaction goes on, this negative catalysis explains the larger downward drift found in this medium, a drift so large as to make accurate extrapolation difficult. On the other hand, in 60% dioxane where mercuric chloride speeds up the reaction, the small upward drifts or constant values of the specific rate observed may be attributed to the opposing effects of the retarding secondary reaction and the accelerating products, mercuric chloride and nitric acid.

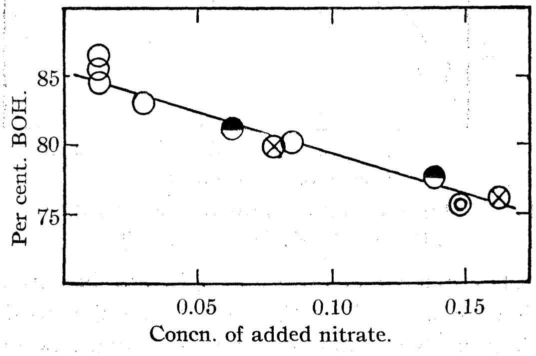

Fig. 3.—Effect of added nitrate on % BOH in 60% dioxane: ○, HNO_3; ⊗, KNO_3; ◎, $Mg(NO_3)_2$; ◓, $Ca(NO_3)_2$.

Table III shows the effect of mercuric chloride on the velocity in 60% dioxane. Concentrations higher than 0.04 *N* could not be used because of the low solubility of mercuric chloride in this medium. It can be seen, however, that the catalysis is a large one with no sign of levelling off in this concentration range.

TABLE III

EFFECT OF MERCURIC CHLORIDE ON *k* IN 60% DIOXANE

64	.025 *N* $Hg(ClO_4)_2$	016 *N* $HClO_4$	.040	1.924

Morse[9] has demonstrated the existence in water of the ion $HgCl^+$ as the result of the first dissociation of mercuric chloride. The equilibrium constant for the equilibrium $HgCl_2 + Hg^{++} \rightleftarrows 2HgCl^+$, is the quotient of the first and second dissociation constants of mercuric chloride and has a value of about 8 in water. The above data on the effect of mercuric chloride on the reaction are completely explained if we assume that $HgCl^+$ (or $HgClNO_3$ in this solvent) also reacts with benzyl chloride. The differing effects of mercuric chloride in the various media may be attributed to a shift in the above equilibrium and in the relative velocities of the $Hg(NO_3)_2$ and the $HgClNO_3$ reactions.

The Distribution of Products

The most striking property of the reaction of silver nitrate with alkyl halides is the complete lack of dependence of the proportion of alkyl nitrate in the reaction product upon the concentration of ionic nitrate in the reacting mixture. By contrast, the mercuric nitrate reaction shows a distribution of product between benzyl alcohol and benzyl nitrate which varies with varying concentration of nitric acid or alkali nitrate in the solution. The results in 60% dioxane are shown in Table IV and plotted in Fig. 3. The distribution is, however, effectively independent of the concentration of mercuric nitrate as Table V indicates. This result supports our previous conclusion that much of the mercuric nitrate is in the non-ionized condition.

TABLE IV

EFFECT OF ADDED NO_3^- ON % BOH IN 60% DIOXANE

($Hg(NO_3)_2$) = (BCl) = 0.025 *N*

	Added NO_3^-	%BOH

0.000	85.5 (mean of 3)
.026	86.5
.039	85.4

The effect of nitrates and the lack of effect of mercuric chloride on the distribution applies in the same way to 75% dioxane. The percentage of benzyl alcohol decreases as the amount of dioxane in the medium is increased: in 75% dioxane, 68% of the product is benzyl alcohol, and in 95% dioxane, 35% of the product is benzyl alcohol.

In the perchlorate experiments in 60% dioxane the product is 100% benzyl alcohol during the whole course of the reaction, even in the presence of excess perchlorate. In the mixed nitrate–perchlorate run (expt. 63, Table I) the product was found to be 88.6% benzyl alcohol, an intermediate value.

The Mechanism of the Reaction

The possibilities may be classified into three general types.

(1) **Double Decomposition,** AB + CD ⟶ AC + BD.—Let us consider a pair of concurrent reactions, one of mercuric nitrate or of $HgNO_3^+$ to form benzyl nitrate, and one of mercuric ion, which is of course hydrated, to form benzyl alcohol. If we use the most probable formulas with a coördination number of four for the mercuric ion, the equations are

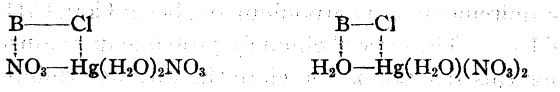
$$C_6H_5CH_2Cl + Hg(H_2O)_2(NO_3)_2 \longrightarrow C_6H_5CH_2NO_3 + Hg(H_2O)_2NO_3Cl \quad (5)$$

$$C_6H_5CH_2Cl + Hg(H_2O)_4^{++} \longrightarrow C_6H_5CH_2OH + Hg(H_2O)_3Cl^+ + H^+ \quad (6)$$

As we have indicated previously, however, one of the actual reactants, when perchlorates are present, must be mercuric perchlorate or the ion $HgClO_4^+$. On the basis of this mechanism these reactants could only form benzyl perchlorate. Actually no measurable amount of perchlorate ester is formed at any time, and it is most improbable that it is formed as an unstable intermediate, because the known alkyl perchlorates are far from instantaneously hydrolyzed.[10] Therefore, since benzyl alcohol may be formed by the reaction of mercuric perchlorate, there is every reason to expect that it should be formed by the reaction of mercuric nitrate. We must therefore add a third equation to the first two

$$C_6H_5CH_2Cl + Hg(H_2O)_2(NO_3)_2 \longrightarrow C_6H_5CH_2OH + Hg(H_2O)(NO_3)_2Cl^- + H^+ \quad (7)$$

This reaction scheme would suppose two possible modes of addition of the hydrated mercuric nitrate to benzyl chloride, one leading to benzyl nitrate, the other to benzyl alcohol



$$\begin{array}{ccc} B\text{——}Cl & \qquad & B\text{—}Cl \\ \vdots \quad \vdots & & \vdots \quad \vdots \\ NO_3\text{—}Hg(H_2O)_2NO_3 & & H_2O\text{—}Hg(H_2O)(NO_3)_2 \end{array}$$

On this basis the greater rate of benzyl alcohol formation from mercuric perchlorate than from mercuric nitrate may be attributed to a weaker binding of the water molecules in hydrated mercuric perchlorate than in the nitrate.

The objections to this mechanism are two-fold. In the first place, if this one-step picture is correct, there should be a parallelism between the effect of nitrates on the reaction velocity and on the proportion of benzyl nitrate produced. Actually the curve showing the former levels off at about 0.1 *N* added nitrate (Fig. 2), while the latter shows a linear relationship with concentration (Fig. 3).

In the second place, the failure of mercuric chloride to affect the distribution requires, if this mechanism is adopted, the assumption that the ratio of the rates of formation of benzyl nitrate and of benzyl alcohol from $HgClNO_3$ be the same as the corresponding ratio for the formation from $Hg(NO_3)_2$. There is no reason to expect so simple a relationship, and still less to expect that it should occur in both 60 and 75% dioxane.

(2) **The Termolecular Mechanism** A + BC + D ⟶ AC + BD.—This would be formulated as follows

$$C_6H_5CH_2Cl + Hg^{++} + NO_3^- \longrightarrow C_6H_5CH_2NO_3 + HgCl^+ \quad (8)$$

$$C_6H_5CH_2Cl + Hg^{++} + H_2O \longrightarrow C_6H_5CH_2OH + H^+ + HgCl^+ \quad (9)$$

The objections are of the same nature as for the first case, from which this mechanism is indeed kinetically indistinguishable.

(3) **The Ionic Intermediate Mechanism.**—These difficulties vanish if it is supposed that the reaction proceeds through an unstable intermediate which can react either with nitrate ion to form benzyl nitrate or with water to form benzyl alcohol. The effects of added nitrates upon the total rate of reaction are exerted only upon the rate of

---

[10] Ethyl perchlorate may be distilled from water without hydrolysis [Roscoe, *Ann.*, **124**, 124 (1862)]. The compound $Cl{\cdot}CH_2{\cdot}CH(OH){\cdot}CH_2{\cdot}ClO_4$ in 0.5 molar concentration is half hydrolyzed at 17° after forty hours [Hoffman, Zedwitz and Wagner, *Ber.*, **42**, 4390 (1909)].

formation of this intermediate, whereas the effect of nitrate upon the distribution depends upon an increased rate of formation of benzyl nitrate from the intermediate and nitrate ion. The two effects are consequently independent. Since mercuric chloride does not affect the distribution, the intermediate formed when the reactant is $HgClNO_3$ must be the same as when the reactant is $Hg(NO_3)_2$, and the only substance which fits these requirements is a carbonium ion, benzyl ion, $C_6H_5CH_2^+$. The overwhelmingly probable mechanism for this reaction is therefore the rate determining step

$$\left\{\begin{matrix} Hg(NO_3)_2(H_2O)_2 \\ HgClNO_3(H_2O)_2 \\ Hg(H_2O)_4^{++} \end{matrix}\right\} + C_6H_5CH_2Cl \longrightarrow \left\{\begin{matrix} HgClNO_3(H_2O)_2 + NO_3^- \\ HgCl_2(H_2O)_2 + NO_3^- \\ HgCl(H_2O)_3^+ + H_2O \end{matrix}\right\} + C_6H_5CH_2^+ \quad (10)$$

followed by the concurrent reactions

$$C_6H_5CH_2^+ + NO_3^- \longrightarrow C_6H_5CH_2NO_3 \quad (11)$$

$$C_6H_5CH_2^+ + H_2O \longrightarrow C_6H_5CH_2OH + H^+ \quad (12)$$

It is interesting to speculate on the possibility that the transient yellow color observed when the reaction is run in high concentration (see experimental part) is that of benzyl ion.

Since reaction (11) is subject to a large salt effect, and reaction (12) to a small one, the effect of added inorganic nitrates upon the distribution will not be a simple one. The fraction R of the product which is benzyl alcohol is easily shown to be given by the equation

$$R = 1/\left(1 + \frac{k_1}{k_2}[NO_3^-]f_1^2\right)$$

where k_2 and k_1 are rate constants for the reaction of benzyl ion with nitrate ion and with water, respectively, and f_1 is the activity coefficient of a singly charged ion. Addition of nitric acid or a nitrate increases (NO_3^-) but decreases f_1. In view of the incompletely ionized nature of mercuric nitrate and the low dielectric constant of the medium, it is hopeless to attempt to predict the value of f_1. Qualitatively, however, we do find that the rate of change of distribution with nitrate concentration is considerably smaller than that given by the assumption that f_1 is constant. It is rather surprising that the divalent nitrates fall on the same curve. The salt effect also accounts for the fact that the proportion of benzyl alcohol rises to 88.6% when perchlorate is added to the reaction mixture of mercuric nitrate and benzyl chloride.

We have assumed that a wide variety of mercuric compounds can react with alkyl halides by virtue of the tendency of mercuric ion to form stable compounds with chloride ion. Neglecting the dioxane-solvated compounds, the possibilities in this reaction are $Hg(H_2O)_4^{++}$, $Hg(H_2O)_3(NO_3)^+$, $Hg(H_2O)_2(NO_3)_2$, $Hg(H_2O)_3Cl^+$, $Hg(H_2O)_2ClNO_3$, $Hg(H_2O)_3(ClO_4)^+$, $Hg(H_2O)_2(ClO_4)_2$ and $Hg(H_2O)_2Cl(ClO_4)$. Further, Nicolet and Stevens[11] report that the alcoholysis of alkyl halides is accelerated by the corresponding mercuric halides, the mercuric halide being inactivated according to the equation $HgX_2 + 2X^- \rightleftarrows HgX_4^=$. These considerations result in a picture analogous to that of the generalized acid catalysis proposed by Brönsted.[12] If this is true, the velocity of reaction of each of these mercury compounds with alkyl halides should be a function of their tendency to combine with chloride ion as measured by equilibrium constants.

The hypothesis of a carbonium ion as an unstable intermediate has been used successfully to explain a variety of rearrangement reactions.[13] Such ions are certainly not set free in all reactions of substitution; they are very improbable intermediates for reactions of the type of equations (1) and (2). But it seems likely that they appear in many of the reactions of organic halogen compounds with mercuric and silver salts, and with other metallic salts which have a strong affinity for halogen ion.[14] A carbonium ion intermediate is also very probable in the many condensation and other reactions of hydroxyl compounds in which the very strong acid sulfuric is used as condensing agent. Here the driving force must be taken to be the energy of formation of water or of oxonium ion instead of the energy of linkage of metallic ion with chloride ion.

The process of formation of the carbonium ion in these cases may be considered to be a case of the London three-body substitution mechanism, just as much as is the reaction of iodide ion with an alkyl chloride, the type being

$$A + BC \longrightarrow AB + C \quad (13)$$

$$I^- + RCl \longrightarrow IR + Cl^- \quad (14)$$

$$Hg^{++} + ClR \longrightarrow HgCl^+ + R^+ \quad (15)$$

The reaction of equation 14 may be called a sub-

stitution on carbon, that of equation 15 a substitution on halogen.

Experimental

Materials and Solutions.—The preparation and purification of primary standard mercuric oxide have been described previously.[8] C. P. mercuric nitrate was used directly. All other metallic salts were purified by the usual methods. Reagent grade concentrated nitric acid and 20% perchloric acid were used. Benzyl chloride (Mallinckrodt Analytical Reagent) was fractionated *in vacuo*, the middle third (b. p. 56–58° at 4–5 mm.; $n^{25}\text{D}$ 1.5363) being taken for kinetic experiments. Benzyl alcohol (Eastman Kodak Co.) was fractionated *in vacuo*, the middle third being taken; b. p. 77–78° at 4–5 mm. Benzyl nitrate was prepared by the method of Nef.[15] After two fractionations *in vacuo*, the material gave a negative test for chloride on long standing with alcoholic silver nitrate, b. p. 100–101° at 18 mm. Dioxane was purified by a modification of the method of Kraus and Vingee.[16] The sample was refluxed with solid sodium hydroxide until there was no further resin formation. After filtering, it was refluxed with metallic sodium for about six hours and distilled; b. p. 101.1–101.3° at 760 mm. On standing for several days this dioxane develops an impurity which slowly reacts with mercuric nitrate forming mercurous salt; this error was found to be negligible under the conditions of the kinetics.

Mercuric nitrate solutions were prepared both by dissolving mercuric nitrate in nitric acid and by dissolving mercuric oxide in nitric acid with consistent results. Mercuric perchlorate solutions were made up from primary standard mercuric oxide and perchloric acid. The preparation of all other standard solutions already has been described.[8]

Kinetic Experiments.—The details of the titration method for following the reactions have been discussed elsewhere.[8] Into a 300-cc. glass-stoppered bottle was pipetted the appropriate quantity of dioxane and water (or water solution of the other substance to be added). After weighing in the benzyl chloride from a weight buret, the bottle was set into the thermostat at 24.65 ± 0.01° for at least thirty minutes. The reaction was then started by pipetting in 5 cc. of standard mercuric nitrate prepared so as to give the desired concentration. At measured intervals, 10 cc. of the reaction mixture was delivered into 5 cc. of standard 0.1 *N* potassium chloride, thus effectively killing the reaction. The acidity was then titrated with 0.025 *N* sodium hydroxide to a brom phenol blue end-point. After the addition of 4 cc. of 0.2 *N* nitric acid to bring the solution to optimum acidity, and 5 drops of diphenylcarbazide indicator, the excess chloride present was titrated with 0.02 *N* mercuric nitrate. Thus, only one titration mixture was necessary to determine both the nitric acid produced and the mercuric nitrate used up in the reaction.

The initial mixing of the mercuric nitrate solution with the rest of the reaction mixture caused a momentary rise in temperature; the error was negligible except for the very fast runs, in which case the standard mercuric nitrate solutions were made up in 50% dioxane by volume, thus cutting down the heat of mixing.

Only calibrated weights and volumetric apparatus were used. In calculating velocity constants, the volume which in practically all runs was about 100 cc. was corrected for the shrinkage on mixing dioxane and water. Since one mole of mercuric nitrate reacts with two moles of benzyl chloride, the usual equation for a bimolecular reaction must be modified to

$$k = \frac{2}{t(a-b)} \ln \frac{b(a-x)}{a(b-x)}$$

in which the quantities a and b are the concentrations in *equivalents* per liter of mercuric nitrate and benzyl chloride, respectively. The maximum error in any one constant is about 2%; the precision generally found was 1% or better.

Table VII shows the types of kinetics found under various conditions. In three runs presented the initial concentrations of mercuric nitrate and benzyl chloride were both 0.025 *N*. Experiment 66 performed in 75% dioxane by volume, shows the downward drift found in that medium. In 60% dioxane expt. 61 shows the second order constant found with a high concentration of nitrate ion, while with expt. 45, with only a small concentration of added nitrate, a small upward drift in the constants was found.

was run at 1.0 *N* concentrations in a volume of 500 cc. To a solution of 60 cc. (0.5 mole) of benzyl chloride in 300 cc. of dioxane was added a solution of 70 g. (0.65 equiv.) of mercuric oxide in 100 cc. of water and 55 cc. of concentrated nitric acid. After standing for a few minutes mercuric chloride crystallized out and the solution developed a yellow color which disappeared after about forty-five minutes. Twenty-four hours later the mercuric chloride was filtered off and solid potassium chloride was added to convert excess mercuric nitrate to mercuric chloride. Enough sodium bicarbonate was added to neutralize most of the nitric acid. The filtered solution was then extracted twice with ether and the combined ether layers distilled *in vacuo*. The first fraction containing ether, dioxane and a little nitric acid was discarded. The second fraction, b. p. 96–106° at 22 mm., was colorless and had the aromatic odor of benzyl nitrate; no higher boiling fraction was obtained.

That the second fraction was a mixture of benzyl alcohol and benzyl nitrate was proved in the following way.

A portion of the mixture gave a dinitrobenzoate, m. p. 112° after three recrystallizations. Known benzyl dinitrobenzoate melts at 112.5°; mixed melt, 112°. Pure benzyl nitrate alone will not react with dinitrobenzoyl chloride.

The fraction gave a strong nitrate test (diphenylamine) but the nitrate could not be extracted with water. A few cc. was boiled with strong sodium hydroxide for ten minutes, and the excess alkali neutralized with hydrochloric acid. After extracting several times with ether to remove organic material, the water layer gave a strong test for nitrate. The presence of a nitrate ester with the same boiling point as benzyl nitrate was thus proved.

No attempt was made to isolate the products of the mercuric perchlorate reaction because of the explosive nature of perchlorates in the presence of organic matter.

Isolation of the Retardant Compound.—After setting up a reaction mixture as described above, the various extracts, wherever practicable, were tested for their effect on the rate of the mercuric nitrate–benzyl chloride reaction in 75% dioxane. After pumping off the ether and dioxane, 5 cc. of the residue (I) (almost entirely benzyl alcohol, benzyl nitrate and mercuric chloride) was found to lower the velocity constant from 0.396 to 0.110. This residue was extracted with dilute sodium hydroxide; upon addition of hydrochloric acid to the sodium hydroxide layer, a white crystalline compound (II) precipitated. After completely extracting I with dilute sodium hydroxide, the organic layer (III) was washed twice with water, once with 0.2 *N* nitric acid, and once more with water. The washed residue (III) had no retarding effect, showing that the only retardant was the alkali soluble material.

A small portion of the white precipitate (II) was insoluble in hot water; its amount was too small for study. The yield of water-soluble material after four recrystallizations (once with norite) from water was 200 mg., m. p. 126–126.5°. Fifty mg. of the compound produced a retardation from 0.396 to 0.370.

Although the reaction is almost complete in a few hours, the fact that only small amounts of the compound are obtained if the reaction mixture is not allowed to stand overnight, indicates that it is formed by a secondary reaction. It was then found that the compound could also be prepared by allowing mercuric nitrate to stand with benzyl alcohol in dioxane–water, using the same method of extraction. Allowing the other products of the reaction to stand together or with mercuric nitrate gave no result. It thus appears that the retardant compound is formed solely by a slow reaction of mercuric nitrate and benzyl alcohol in these media.

The compound itself is a new one and answers to the empirical formula of a chloro-mercuri benzyl alcohol. This is surprising in view of its acidic nature, and its structure is now being investigated further. Calcd. for C_7H_7OHgCl: acid eq., 343; C, 24.49; H, 2.04. Found: acid eq., 345; C, 24.52, 24.47; H, 1.69, 1.99.[17]

Summary

The rate of the reaction of mercuric nitrate with benzyl chloride and the distribution between the two major products, benzyl nitrate and benzyl alcohol, have been studied in dioxane–water mixtures of various proportions. The effects of the addition of nitrates, of perchlorates and of mercuric chloride upon both rate and distribution have been investigated, and kinetic complications due to a slow secondary reaction have been unraveled. A two-step mechanism involving non-ionized mercuric nitrate as the principal reactant and benzyl ion as an intermediate has been shown to be extremely probable.

The Rare Earth Metals and their Compounds. I. The Binary System Hexahydrated Lanthanum and Magnesium Nitrates

BY LAURENCE L. QUILL AND RICHARD F. ROBEY

Although the reality of the existence of the rare earth double nitrates is supported by a multitude of early accumulated evidence, some doubt has been cast by the more recent work of di Capua.[1] In an endeavor to clarify the question a series of investigations on binary and ternary systems containing salts of the rare earth elements has been undertaken. The first results of these investigations, consisting of the thermal analysis of the system hexahydrated lanthanum and magnesium nitrates, are herein reported.

Experimental

The magnesium salt was prepared from Baker and Adamson "C. P. Reagent" magnesium nitrate employing the procedure of Ewing and others.[2] The lanthanum was originally purchased as a "pure" oxide from the Maywood Chemical Co. This oxide was mixed with pure magnesium oxide in the ratio 1 mole to 3.1 moles, dissolved in nitric acid, and fractionally crystallized in a series of a constant number of fractions for at least fifty times. A middle fraction of the series finally was chosen as the purest for the intended purpose. The magnesium was removed by repeated precipitation of the lanthanum oxalate in acid solution, washing, ignition, solution. Ultimately the nitrate was crystallized from the nitric acid solution, twice from water, and dried over 55% sulfuric acid in a desiccator. A 20-cm. layer of a sirupy solution of the nitrate showed no absorption spectrum of the didymium elements. The arc emission spectrum gave no indication of the presence of any of the rare earth elements other than lanthanum.

The experimental method was that used by other investigators in similar systems.[2] Briefly it consisted of heating the mixtures in Pyrex glass tubes inserted in a well-stirred oil-bath to a temperature somewhat above their melting points. The constantly stirred mixtures were then permitted to cool, the rate of cooling being determined by means of a thermometer. The thermometer was comparatively calibrated with a Bureau of Standards certified instrument. The temperature difference between the mixtures and the bath was always kept as small as possible.

Results.—The data of Table I have been derived from time-differential temperature cooling curves of the various mixtures. Slight losses of water were noted, especially among the higher melting mixtures on repeated determination.

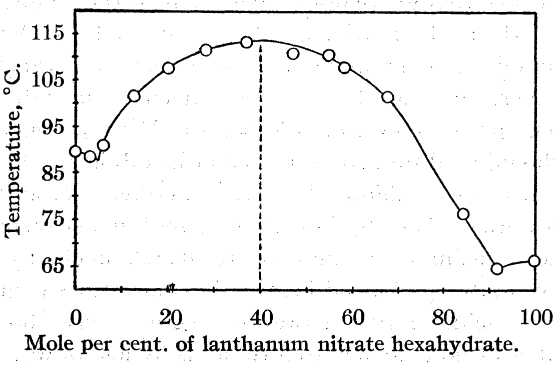

Fig. 1.—Liquidus of the system hexahydrated lanthanum and magnesium nitrates.

The observed temperature points have been plotted in Fig. 1 against the mole percentage composition. The melting point of the magnesium nitrate (89.7°) agrees well with that already recorded in the literature (89.9°);[2] the melting point of the lanthanum nitrate (66.5°) is slightly higher than that for the *beta* form (65.4°), as reported by Friend.[3] The type of the liquidus curve confirms the formation of a compound by these nitrates with the ratio $2La(NO_3)_3{:}3Mg(NO_3)_2$. A comprehensive study of the ternary system rare earth metals–magnesium nitrates–water is being conducted at the present time.

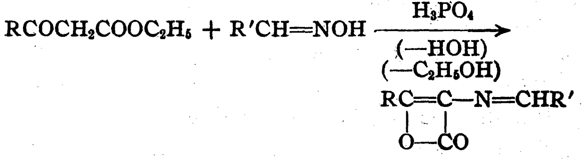
A Synthesis of Arylidene Isoxazolones[1]

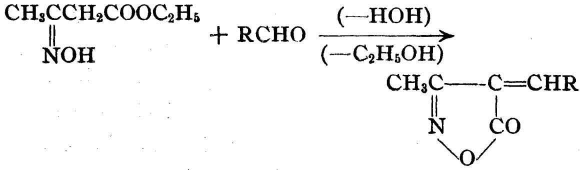
BY JOHN J. DONLEAVY AND EVERETT E. GILBERT

In 1928–1929 G. Minunni and others published a series of papers[2–4] in which a reaction between aromatic aldoximes and beta keto esters was investigated. The interaction of these substances in the presence of phosphoric acid was described as leading to the formation of alpha arylidene crotonic acid lactones in the case of acetoacetic ester, and alpha arylidene cinnamic acid lactones in the case of benzoyl acetic ester



A careful study of their conditions of experiment and a consideration of the structures assigned to the reaction products led the writers to believe that grave doubt existed as to the validity of their observations. As formulated by Minunni these products are beta lactones, which experience[5] has shown to be extremely unstable. The presence of a double bond in these products should tend toward even greater instability. The substances exhibit, however, marked stability toward acids since they are prepared in a strongly acid medium and may be recovered unchanged even after prolonged heating in concentrated sulfuric acid. Furthermore, oximes as a class show little or no tendency to form anils by loss of water in reaction with activated hydrogens. Finally, beta keto esters as a class have never been observed to condense in the sense of beta lactone formation.

As a result of these conclusions, the work of Minunni and his collaborators has been repeated in its entirety. The striking similarity of the products obtained in this way to those obtained by R. Schiff and M. Betti[6] by treating acetoacetic ester oxime or its anilide with various aromatic aldehydes led to the thought that the substances obtained by Minunni might be isoxazolones of the same type as those obtained by Schiff and Betti. The corresponding methylisoxazolones were accordingly prepared by the independent



method of Schiff and Betti, and upon comparison proved to be identical with the products obtained by Minunni. In the case of the phenylisoxazolones derived from benzoylacetic ester, we have treated the aldehydes directly with 3-phenylisoxazolone-5 according to the technique developed by A. Wahl and A. Meyer.[7] These are also identical with the corresponding products obtained by Minunni from benzoylacetic ester and aromatic aldoximes.

As a result of the above observations it is now established beyond any reasonable doubt that the products described by Minunni and his coworkers as alpha arylidene amino lactones are in fact arylidene isoxazolones.

Minunni further studied the behavior of his so-called lactones with phenylhydrazine and with warm dilute alkali. By using his method of treatment we have obtained products with the properties and with the empirical formulas he has described; however, these reaction products also arise from the corresponding isoxazolones by exactly the same course of treatment. In this way we have proved that both the parent substances and the derivatives must have very different structures from those originally assigned by him.

In a typical case he treated what we now know to be 3-phenyl-4-benzylidene-isoxazolone-5 with phenylhydrazine (2 moles) and obtained what he termed α-amino-β-hydroxycinnamic acid phenylhydrazide. We have found this to be the phenylhydrazine salt of 3-phenylisoxazolone-5; it is identical with the salt obtained directly from 3-phenylisoxazolone-5 by the action of phenylhydrazine

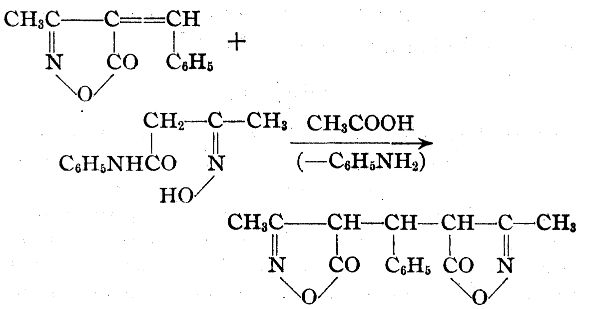
by the method described by R. Uhlenhuth.[8] (In the case of the arylidene isoxazolones, the corresponding aldehyde phenylhydrazone was also formed.)

We have found the action of alkali on these compounds to be specific for each compound. On treating 3-methyl-4-benzylidene-isoxazolone-5 with hot aqueous 5% sodium carbonate, Minunni obtained a product which he made no attempt to analyze or identify. We have obtained a product agreeing with the physical properties he has cited. It also agrees in every way with a product originally obtained by Schiff and Betti[6] by alkaline hydrolysis of the isoxazolone. They tentatively proposed the structure I. We have also produced this compound by the action of phenylhydrazine on the parent substance under mild conditions. Minunni obtained it from the parent substance by the mild action of hydroxylamine. He also corroborated Schiff and Betti's observation that exactly half a mole of benzaldehyde was removed per mole of product formed. We have also been able to synthesize this product by treating acetoacetic ester oxime anilide with 3-methyl-4-benzylidene-isoxazolone-5 in glacial acetic acid.



I

We have also found it possible to prepare a new diethyl derivative of this substance. However, all attempts made by us to synthesize this product by the direct action of hydroxylamine on benzylidene bis-acetoacetic ester resulted in failure because of the practical impossibility of preparing the last-mentioned material in pure form.

On heating 3-phenyl-4-benzylidene-isoxazolone-5 with 10% aqueous sodium carbonate for several hours, we obtained benzaldehyde and 3-phenylisoxazolone-5, which behavior is in marked contrast to that of the methyl analog just discussed. 3-Methylanisylidene-isoxazolone-5 could be reprecipitated unchanged by mineral acid after the above treatment; in cases where Minunni observed more than the melting point, he tended to assign formulas to all the above-mentioned compounds without the support of corroborative data, and often even without analyses.

In an attempt to widen its scope, a further study of the mechanism of the above reaction was made. Condensation will occur in the presence of any strong acid. Minunni used concentrated phosphoric acid of unspecified strength; Schiff and Betti[6] used hydrogen chloride gas or strong aqueous hydrochloric acid. We have found that sulfuric acid of strength from 40 to 60% may be employed. Hydrated oxalic acid may be used to advantage because of its mildness. Concentrated sulfuric acid and concentrated hydrochloric acid tend to produce decomposition into black tarry products. Acetic acid gave no evidence of reaction; several basic catalysts were tried without success. Iodine also gave no reaction. Maximum yields of 65% were obtained in the case of acetoacetic ester by allowing the components to stand for one day at room temperature mixed with 10% of the total weight of 85% phosphoric acid. However, in the case of benzoylacetic ester, heating for three hours at 100° was necessary for condensation to occur. Prolonged heating or too high temperatures tended to reduce the yields and to produce decomposition.

Aliphatic oximes in general we have found to produce viscous glassy polymeric products when applied in the above reaction. Aliphatic and alicyclic ketoximes condensed with poor yields (20%) or not at all.

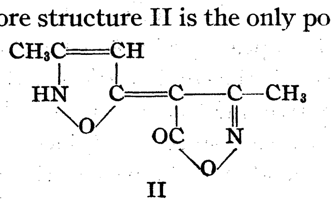
The mechanism of this reaction appears to be as follows. First hydrolysis of the oxime occurs, liberating the parent aldehyde and hydroxylamine. Formation of the glassy polymers from the aliphatic oximes is due no doubt to the polymerization of the aldehydes in the strongly acid medium. It appears probable that the next step in the reaction is the condensation of the aldehyde with the active methylene group. We believe such to be the case since *n*-butylacetoacetic ester could not be made to take part in the above reaction, even to the extent of forming *n*-butylisoxazolone. The next step consists of the formation of the beta ketoxime by means of the hydroxylamine split out in the first stage and its ring closure to form the isoxazolone ring.

---

[8] R. Uhlenhuth, *Ann.*, **296**, 44 (1897). The carbonyl group in the isoxazolone ring does not condense in the sense of a ketone. Since isoxazolones as a class are strongly acidic, they form very stable salts with bases. This particular product reduces Fehling's solution, a behavior to be expected from phenylhydrazine salts, but not from phenylhydrazones.

Structure of the Alleged Methylisoxazolone.—Thinking that the methyl arylidene isoxazolones might easily be prepared by condensing an aldehyde with 3-methylisoxazolone-5 (as Wahl and Meyer[7] had done in the case of the 3-phenyl analog), we prepared what was described as this substance by several authors. It was found to be unexpectedly inert toward aldehydes, while the phenyl analog condensed easily under the same conditions. A. Hantzsch[9] had obtained the so-called methylisoxazolone by allowing acetoacetic ester to stand with an equivalent weight of hydroxylamine for several hours in strongly alkaline solution; he cites unconvincing analytical data. A product of identical physical properties was obtained by L. Knorr and B. Reuter[10] by treating acetoacetic ester oxime anilide with strong acids or with strong bases; they cite no analytical data. R. Uhlenhuth[8] prepared an exhaustive series of salts and alkyl derivative of this substance. By a long series of careful analyses (which did not include an analysis of the original substance), he proved that they were all mono derivatives of two methylisoxazolone molecules minus one molecule of water. He made no attempt to propose structures, but merely suggested that methylisoxazolone might be "dimolecular," or that when salt formation occurred, two molecules united with loss of water. A molecular weight determination made by Uhlenhuth agrees well with a dimolecular structure of some sort.

We have resynthesized this substance according to the method of Hantzsch, and on analysis have found it to correspond exactly to a molecule formed from two methylisoxazolone molecules by loss of one molecule of water. Since the alkylation of isoxazolones always occurs on the nitrogen[8] (which exhibits strongly acidic behavior), and since the formation of mono derivatives only has been observed, we have concluded that one of the two rings must lack the necessary hydrogen, and that therefore structure II is the only possible one.



II

The melting points of related isoxazolones found in the literature also preclude any monomolecular structure. 3-Methyl-4-chloroisoxazolone-5 melts at 86°,[11] 3-methyl-4-benzylisoxazolone-5 melts at 106°;[11] other cases could be cited to show that melting points of the 3-methylisoxazolones become higher with increasing molecular weight of the substituent in the 4-position. It is therefore strange that the alleged methylisoxazolone should melt at 169°, a figure higher than any of its recorded 4-substituted derivatives. Methylisoxazolone has accordingly never been prepared. The compound thought by various workers to be this substance was actually "dimethyl-diisoxazolone."

The structure and the autocondensation reaction of methylisoxazolone bear striking similarities to those of gamma-butyrolactone. This lactone is composed of a five-membered ring containing an active methylene group adjacent to an ester grouping; the same is true of the isoxazolone. Butyrolactone also condenses with itself in the presence of alkaline agents to form a "dimolecular" product, water being liberated between a keto and a methylene group. However, it might be expected that methylisoxazolone would condense even more easily in this sense, since its active methylene would be rendered even more active by the possibility of a double bond on the nitrogen (producing activity similar to that found in the methyl group of quinaldine).

Experimental

Preparation of 3-Methyl-4-benzylidine-isoxazolone-5.—One-half mole each of benzaldoxime (60.5 g.) and acetoacetic ester (65 g.) were mixed, and 10% of the total weight of phosphoric acid (12.5 g.) was added with gentle shaking. The mixture was allowed to stand overnight at room temperature. The solid product which separated was then filtered, and successive crops were obtained from the sirupy filtrate by allowing it to stand further. The pure product was obtained in the form of yellow crystals upon recrystallization from benzene. It melted to a clear yellow liquid at 146–147° (corr.). The yield of recrystallized product was 65% of the theoretical (94 g.).

Anal. Calcd. for $C_{11}H_9O_2N$: N, 7.49. Found: N, 7.53, 7.30.

The same isoxazolone was then made by the method of Schiff and Betti[6] from benzaldehyde and acetoacetanilide oxime; glacial acetic acid was used instead of hydrochloric as they suggest. The melting point and physical properties were found to be the same as those of the above compound, and a mixed melting point showed no depression.

3-Phenyl-4-benzylidene-isoxazolone-5.—Equivalent amounts of benzoylacetic ester (19.2 g.) and benzaldoxime (12.1 g.) were condensed in the presence of phosphoric acid (5 g.) by heating for three hours at 100° with occasional shaking. The combined crops of crystals were

[9] A. Hantzsch, *Ber.*, **24**, 498 (1891).

[10] L. Knorr and B. Reuter, *ibid.*, **27**, 1174 (1894).

[11] R. Schiff and G. Viciani, *ibid.*, **30**, 1159 (1897).

recrystallized from ethanol, and melted to a clear yellow liquid at 193–194° (corr.). The yield of pure product was 48% (12.8 g.).

Anal. Calcd. for $C_{16}H_{11}O_2N$: N, 5.62. Found: N, 5.42, 5.32.

The same isoxazolone was synthesized from phenylisoxazolone and benzaldehyde, using the method described by Wahl and Meyer,[7] 3-phenylisoxazolone-5 being first made by the method of Hantzsch.[9] The crystals were exactly similar to those obtained above. A mixed melting point showed no depression.

3-Phenyl-4-anisylidene-isoxazolone-5.—This compound was synthesized by heating equivalent amounts of benzoylacetic ester (19.2 g.) and anisaldoxime (15.1 g.) with phosphoric acid (5.0 g.) at 100° for three hours. Lemon-yellow needles were obtained from ethanol in a yield of 60% of the theoretical (17.0 g.); it melted at 164–165° (corr.) to a clear yellow liquid.

Anal. Calcd. for $C_{17}H_{13}O_3N$: N, 5.02. Found: N, 5.07, 5.17.

Yellow crystals exactly similar to those just described were obtained by the method of Wahl and Meyer used above; in this case phenylisoxazolone was condensed with anisaldehyde. A mixed melting point showed no depression. The products were identical.

3-Methyl-4-anisylidene-isoxazolone-5.—Acetoacetic ester (13.0 g.) and anisaldoxime (15.1 g.) condensed in 75% (16.1 g.) yield by being allowed to stand at room temperature in the presence of phosphoric acid (5 g.). On recrystallization from alcohol yellow needles were obtained melting to a clear liquid at 180–181° (corr.). This product has never before been described as such in the literature.

Anal. Calcd. for $C_{12}H_{11}O_3N$: N, 6.45. Found: N, 6.38, 6.68.

3-Methyl-4-isopropylidene-isoxazolone-5.—Acetone oxime (7.3 g.) and acetoacetic ester (13.0 g.) condensed in 20% yield (2.6 g.) on being allowed to stand at room temperature with phosphoric acid. On recrystallization from ethanol white flakes were obtained from ethanol which melted to a clear liquid at 120–121° (corr.). Attempts to obtain further crops failed in this case. This product is identical in properties with that obtained by Schiff and Betti from acetoacetic ester oxime and acetone.[6]

Anal. Calcd. for $C_7H_9O_2N$: N, 10.08. Found: N, 10.03, 10.00.

Cyclohexanoneoxime, acetaldoxime, and heptaldoxime could not be condensed in the above sense. In the last two cases viscous glasses were obtained on allowing the oximes to stand with acetoacetic ester and phosphoric acid. *n*-Butylacetoacetic ester gave no reaction in the above sense even when heated to 120° for one hour; some starting material and its hydrolytic products were recovered.

Preparation of Compound I. Alkaline Hydrolysis of the Isoxazolones.—3-Methyl-4-benzylidene-isoxazolone-5 (15.0 g.) was suspended in 200 cc. of aqueous sodium carbonate solution. This was kept at 70° until solution was complete (about one hour). During this time benzaldehyde collected on the surface in an oily layer. The solution was cooled, and ether extracted to remove benzaldehyde. It was then acidified strongly with dilute hydrochloric acid. A gum separated which always crystallized on trituration with the acid. The crystals were filtered and washed with dilute acid. The yield of crude product was 90% of the theoretical (9.6 g.). It may be recrystallized from hot water, observing precautions to carry out the operation at maximum speed since the compound decomposed to red products if heated for a prolonged period at the temperature of boiling water. It was a yellow powder, melting with decomposition and effervescence to a red liquid at 150–151° (corr.). If it was recrystallized from ethanol, it separated as a white powder which turned pink and then yellow on exposure to the air. However, the compound crystallized only with difficulty from this solvent. The product was soluble in bases and could be reprecipitated on acidification with mineral acids. It was slightly soluble in cold water, quite soluble in hot water. Its water solution was acid toward litmus.

Anal. Calcd. for $C_{15}H_{14}O_4N_2$ (as in formula I): N, 9.79. Found: N, 9.82, 9.82.

The same hydrolysis product was obtained from samples of 3-methyl-4-benzylidene-isoxazolone-5 made both by Minunni's method and by the method of Schiff and Betti. A mixed melting point showed no depression.

A compound identical with the hydrolysis product just described was prepared by a new and independent method. One gram of 3-methyl-4-benzylidene-isoxazolone-5 was dissolved in glacial acetic acid and 1 g. of acetoacetanilide oxime was then added with shaking. It went into solution with evolution of heat and on standing for several hours yellow prisms formed. One recrystallization from glacial acetic acid and one from hot water gave a product melting as above. The yield was 1.1 g. or 69% of the theoretical. A mixed melting point with the above compound showed no depression.

To prepare its diethyl derivative, 10 g. of the above compound was dissolved in 5% aqueous sodium carbonate. Slightly more than two molecular quantities of diethyl sulfate (11.0 g.) were added and the mixture was shaken at room temperature for twelve hours. It was then extracted three times with ether. On evaporation of the ether, white prisms were obtained, which were recrystallized from alcohol. It melted to a clear colorless liquid at 159–161° (corr.). The yield was 50% of the theoretical (6.0 g.).

Anal. Calcd. for $C_{19}H_{22}O_4N_2$: N, 8.19. Found: N, 8.0, 8.04.

3-Phenyl-4-benzylidene-isoxazolone-5 was dissolved in excess 10% aqueous sodium carbonate and heated for three hours on a boiling water bath. On acidification a gum formed, which crystallized on trituration. Recrystallized from benzene, the product showed no definite melting point, but began to soften at 120°, finally melting with decomposition to a red liquid at about 155°. A mixture of phenylisoxazolone and phenylbenzylideneisoxazolone showed the same melting phenomena. Final proof that the product was a mixture of the two was obtained by refluxing it with excess benzaldehyde in glacial acetic acid solution. The solid which formed on pouring into water was washed with a little ethanol. Without further purification it melted at 191–192°, forming a clear yellow liquid, showing that it was pure 3-phenyl-4-benzylidene-isoxazolone-5. Minunni obtained 3-phenylisoxazolone-5 from 3-phenyl-4-benzylidene-isoxazolone-5, but he considered it to be alpha-aminocinnamolactone, a compound which would have the same empirical formula.

Reaction with Phenylhydrazine.—The salt was prepared directly from 3-phenylisoxazolone and phenylhydrazine by the method described by Uhlenhuth.[8] It can be recrystallized in the form of white flakes from methanol; it melts with decomposition to a red liquid at 153–154°. The yield was quantitative. It easily reduced Fehling's solution, showing it to be a phenylhydrazine salt and not a phenylhydrazone. The same salt (plus the corresponding aldehyde phenylhydrazone) was obtained by mixing warm methanol solutions of 3-phenyl-4-benzylidene-isoxazolone-5 (1 mole) and phenylhydrazine (2 moles); the same was done with 3-phenyl-4-anisylidene-isoxazolone-5. The aldehyde phenylhydrazones were separated from the salt in each case by taking advantage of the greater solubility of the former in warm benzene. Mixed melting points showed no depression, and salts from the varying sources showed identical analyses.

Anal. Calcd. for $C_{15}H_{15}O_2N_3$: N, 15.61. Found: N, 15.52, 15.76.

When 3-methyl-4-benzylidene-isoxazolone-5 was treated as above, a 50% yield of compound II was obtained, plus benzaldehyde phenylhydrazone.

Preparation of Dimethyl-diisoxazolone.—The method of Hantzsch[9] was employed using 65.0 g. acetoacetic of ester. On recrystallization from ethanol a 33% yield (17.1 g.) of white flakes was obtained. It melts with decomposition to a red liquid at 168–169° (corr.).

Anal. Calcd. for $C_8H_8O_3N_2$: N, 15.56. Found: N, 15.58, 15.58.

Summary

1. It is shown that aromatic aldoximes and beta keto esters react in the presence of acids to form arylidene isoxazolones, and not arylidene amino lactones as previously reported.[2–4]

2. The action of phenylhydrazine and of an alkaline hydrolytic agent has been studied, and the earlier work has been corrected and extended.

3. The optimum conditions for condensation have been found. The probable mechanism of the reaction is discussed. It has been found that reaction occurs in the presence of strong acids in general.

4. An unsuccessful attempt was made to extend the reaction to aliphatic and alicyclic aldoxime and ketoximes. Acetone oxime did condense, however.

5. It is shown that the compound reported as 3-methylisoxazolone-5 in the literature has actually never been prepared. The product reported as such was actually dimethyldiisoxazolone. Its structure is demonstrated.

NEW HAVEN, CONN. RECEIVED MARCH 27, 1937

Two Forms of Anhydrous *l*-Rhamnose and a New Method for the Preparation of Crystalline β-Tetraacetyl-*l*-rhamnose[1]

BY ERNEST L. JACKSON AND C. S. HUDSON

l-Rhamnose usually crystallizes as a monohydrate of its α-modification having an initial specific rotation in water of −7.7°, which becomes constant at +8.9° after mutarotation is complete. This form is usually regarded as the configurational analog of α-*d*-mannose of initial rotation +30°, its final value being +14°. In 1895 Emil Fischer[2] crystallized a new form of rhamnose, anhydrous crystals of initial rotation about +31° which is regarded as β-rhamnose, the analog of β-*d*-mannose of initial rotation −17°. Minsaas[3] on repeating Fischer's preparation recently found "about +44°" as the initial rotation, and mentioned that the yield of this anhydrous form is small. We also had been engaged in studying this form and in devising methods for obtaining it in higher yields; our β-rhamnose showed +38° as the initial specific rotation.[4] After the publication of Minsaas' article we repeated our work and again obtained +38° for crystals which by appearance seemed to be of one form only. In the course of the preparation of these β-rhamnose crystals another anhydrous form of quite different crystalline appearance frequently separated. This third form of the sugar shows an initial rotation of about +14°, mutarotating in water at the

---

[4] Except where otherwise specified, all rotations in this article are specific rotations at 20° for sodium light.

same rate as the two other forms to the equilibrium value +8.9°. It is apparently a true chemical individual in the crystalline state. Its formula, on the assumption that its components are the known α- and β-forms, is α,β-rhamnose if the rotation of β-rhamnose is +38° (our value), or $3\alpha,2\beta$-rhamnose if the rotation of β-rhamnose is +44° (Minsaas' value). This is the second sugar for which a molecular combination of α- and β-forms in the crystalline state has been found; the other sugar, α,β-lactose, has been described by Hockett and Hudson.[5]

For a long period of years it was not possible to obtain a crystalline tetraacetate of rhamnose. In 1920 Fischer, Bergmann and Rabe[6] showed that crystalline β-tetraacetylrhamnose can be prepared in an indirect way through acetobromorhamnose. It is now shown that the acetylation of β-rhamnose with acetic anhydride and pyridine at low temperature gives a high yield (about 90%) of this crystalline β-tetraacetate. Since β-rhamnose may now be prepared in 85–90% yield from ordinary α-rhamnose hydrate, the present directions furnish the best way of obtaining the crystalline β-tetraacetate. The similar acetylation of α,β-rhamnose gives, besides a sirup, a 43% yield of the β-tetraacetate, which confirms the presence of the β-sugar as one component; the other constituent is presumably α-rhamnose, the tetraacetate of which is known only as a sirup.

Experimental

Dehydration of Rhamnose Monohydrate with Barium Monoxide.—A solution of 50 g. of pure rhamnose hydrate in 2 liters of pure acetone was refluxed with 100 g. of barium monoxide for two hours with exclusion of atmospheric moisture, the barium oxide was filtered off and the drying was repeated with fresh barium monoxide for three and one-half hours. The filtered solution, concentrated to about 700 cc. and kept overnight at 25°, deposited long prismatic needles (32.5 g.); the yield was increased to 40.3 g. (90%) by further concentration of the mother liquor. The crops rotated +8.5 to +10.3° (three minutes) in water and +8.9° (constant). On recrystallization from acetone, which had been dried by refluxing over barium monoxide, the initial rotation increased to an approximately constant value. In the course of three successive recrystallizations and drying in an evacuated desiccator over calcium chloride, the extrapolated initial rotation in water was respectively +13.2, +14.2 and +14.6°. The crystals from each recrystallization were characteristic long primatic needles with m. p. 112.5–113.5° (corr.) and rotation +8.9° (constant) in water.

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.88; H, 7.37. Found:[7] C, 44.18, 44.13; H, 7.44, 7.36.

These crystals of α,β-rhamnose, from their appearance and repeated preparation with the same physical constants, might be mistaken for a homogeneous crystalline isomer of the sugar. Tanret[8] obtained crystals ($[\alpha]_D$ +10.1°) which may be the same as those here described; if so, he was mistaken in their identification, as is now generally recognized, since he considered his product to be anhydrous β-rhamnose.

Dehydration with Absolute Ethanol.—A solution of 10 g. of pure rhamnose hydrate in 25 cc. of absolute ethanol was concentrated on the steam-bath to a sirup. After repeating the process the sirup was crystallized by stirring it with 25 cc. of cold dry acetone, the solvent was evaporated on the steam-bath and the crystals were boiled thrice with 10-cc. portions of dry acetone. Recrystallization from 250 cc. of dry acetone gave long prismatic needles (4 g.) showing the extrapolated initial rotation +14.4° in water and +9.0° (constant); m. p. 112.5–113.5° (corr.). Concentration of the mother liquor increased the yield to 7.7 g. (85%).

After seeds of the two forms of anhydrous sugar were available, either form could be prepared by seeding the acetone solution of the crude dry sugar with the appropriate crystals.

β-Rhamnose.—The conversion of crystals of the lower rotating form (+14°) into the β-sugar was accomplished by adding some crystals of the β-form (fine needles) to an acetone solution from which a considerable quantity of long prismatic needles had separated, and keeping it tightly stoppered at 20° for several weeks when the prismatic needles had changed to clusters of fine needles showing an initial rotation of +37.9° in water. The conversion was effected more rapidly[9] by seeding the acetone solution of the lower rotating form with crystals of β-sugar. Samples of β-rhamnose for analysis and mutarotation were recrystallized twice from dry acetone and dried in a high vacuum at 76° in the presence of phosphorus pentoxide; m. p. 123.5–124.5° (corr.); extrapolated initial rotation +38.4° ($k_1 + k_2 = 0.045$ in minutes and decimal logarithms) in water at 20 ± 0.5° (*c*, 2.24).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.88; H, 7.37. Found:[10] C, 44.09; H, 7.19.

Acetylation.—To a mixture of 8 cc. of acetic anhydride and 8 cc. of pyridine at −12° was added 1.6 g. of powdered β-rhamnose of initial rotation +37.7°. It was shaken at −12° until the sugar dissolved, kept overnight at 0° and poured into 150 cc. of ice and water. After partial neutralization of the solution with sodium bicarbonate, the tetraacetate, which crystallized readily, was filtered off, washed with ice water and dried at 25° *in vacuo* over calcium chloride; weight 2.2 g., rotating +12.7° in chloroform. An additional 0.65 g. of crystals rotating +11.2° (yield, 89%) was obtained from the filtrate by thorough extraction with chloroform, followed

by washing the chloroform solution twice with 3% hydrochloric acid, once with dilute sodium bicarbonate solution, and crystallization of the sirup, recovered from the dried extract, from ether–petroleum ether at 0°. After one recrystallization from 90% ethanol, the acetate rotated +13.4° in chloroform and melted at 98.5–99° (corr.) alone or mixed with pure β-tetraacetate prepared from β-triacetylrhamnose by the directions of Fischer, Bergmann and Rabe,[6] whose method gave a product rotating, after purification, +13.3° in chloroform (*c*, 3.87) and +14.2° in acetylene tetrachloride compared with their $[\alpha]^{16}_D$ +13.75° in the latter solvent.

The lower rotating form of anhydrous rhamnose was acetylated as described for the β-sugar. One gram of sugar with initial rotation +13.2° yielded 0.85 g. (43%) of β-tetraacetate, most of which melted at 97–98° (corr.) and rotated +12.5° in chloroform. The remainder of the product was a sirup.

Summary

Anhydrous rhamnose, hitherto obtainable only in small yield, has been prepared in 85–90% yield by two methods. The initial rotation of Fischer's β-rhamnose was found to be +38° in water; Minsaas recently reported about +44°. During the preparation of β-rhamnose a second form of the anhydrous sugar rotating about +14° in water frequently separated; this substance appears to be a molecular compound having the composition α,β-rhamnose if the rotation of β-rhamnose is +38° or 3-α,2-β-rhamnose if it is +44°. The presence of the β-isomer as one component of this molecular compound is confirmed by the preparation from it of crystalline β-tetraacetylrhamnose in 43% yield. Acetylation of β-rhamnose yields about 90% of the crystalline β-tetraacetate, which is now best obtained in this way.

Acetopentamethylbenzene[1]

BY LEE IRVIN SMITH, ISABELLA M. WEBSTER AND CYRUS GUSS

In a recent paper, Henri Clément[2] has discussed the properties of pentamethylphenylmagnesium bromide, which was prepared by the entrainment method of Grignard[3] by allowing an equimolecular mixture of bromopentamethylbenzene and ethyl bromide in ether to react with magnesium. Among other reactions discussed by Clément was that between acetyl chloride and pentamethylphenylmagnesium bromide, which was claimed to give acetopentamethylbenzene in 34% yield. This substance was described as crystallizing in small rods which melted at 110°. In view of the work of Kohler and Baltzly[4] and of Smith and Guss[1] upon the behavior toward Grignard reagents of diortho substituted aromatic ketones of the type of acetomesitylene and acetopentamethylbenzene, it seemed very unlikely that any enolizable ketone of this type could be prepared by dropping acetyl chloride into a highly hindered Grignard reagent especially when ethylmagnesium bromide also was present. When Smith and Guss[1] prepared acetopentamethylbenzene from the hydrocarbon by the Friedel–Crafts synthesis and found the substance to melt at 84°, it was obvious that Clément's compound which melted at 110° could not be acetopentamethylbenzene.

At first it was supposed that Clément's compound was the triketone I, formed from pentamethylphenylmagnesium bromide and acetyl chloride by a sequence of reactions which included: (a) formation of acetopentamethylbenzene, a slow reaction; (b) enolization of the ketone by excess Grignard reagent, a more rapid reaction; and (c) reaction of the enolate with acetyl chloride to give the triketone, also a reaction faster than (a). Accordingly acetopentamethylbenzene was con-

verted to the bromomagnesium enolate by methylmagnesium iodide and by ethylmagnesium bromide, and when the enolate was subjected to the action of acetyl chloride, there resulted a white crystalline substance having the composition $C_{17}H_{22}O_3$ (I), which melted at 110° and which formed a dusty blue, insoluble copper compound from which it could be regenerated by the action of acids. Clément[3b] stated that he had prepared the oxime (m. p. 190.6°) and the semicarbazone (m. p. 241.7°) of his acetopentamethylbenzene. That his "ketone" should form an oxime was in itself an indication that it was not acetopentamethylbenzene, for Baum[5] and also Meyer[6] found that acetomesitylene could not be converted into an oxime by any of the usual methods, although Feith and Davies[7] obtained acetylmesidine, the Beckmann rearrangement product of the oxime, by heating acetomesitylene with hydroxylamine hydrochloride at 160°. Although Clément stated that the analysis of his oxime was in accordance with the theory, he did not publish the figures nor the procedure used, and the logical supposition was that his oxime was the isoxazole II or III, derived from the triketone I. When the triketone I was subjected to the action of hydroxylamine, there resulted the isoxazole II which however, melted at 176° and not at 190.6° as recorded by Clément for his "oxime."

Because the triketone II melted at 110°, the melting point given by Clément for his "acetopentamethylbenzene," the work of Clément was repeated many times before the conviction gradually arose that the agreement between the two melting points was a coincidence and that Clément never had in hand either acetopentamethylbenzene or the triketone. Pentamethylphenylmagnesium bromide was prepared both by the full entrainment method of Grignard, and by the modified method of Kohler and Blanchard.[8] The yield, determined roughly by conversion of an aliquot portion into the acid, was 80 ± 10%. Yet when an ethereal solution of pure acetyl chloride was run into this same Grignard solution, although there was a vigorous reaction, not a trace of acetopentamethylbenzene or of the triketone could be obtained from the reaction product. The product consisted of pentamethylbenzene, bromopentamethylbenzene, and an oily material which, judging from its odor, was largely methyldiethylcarbinol although an appreciable amount of a very high boiling material (b. p. about 180° at 10^{-5} mm.) also was present. Experiments on a known mixture of bromopentamethylbenzene (0.5 g.), pentamethylbenzene (2.0 g.), acetopentamethylbenzene (0.5 g.), triketone (0.39 g.) and ether (25 cc.) showed that 0.12 g. of triketone could be recovered *via* the copper compound, and 0.45 g. of acetopentamethylbenzene could be recovered by treating the remainder of the material with ethylmagnesium bromide, decanting from the insoluble enolate of the ketone, washing the latter thoroughly with ether and then decomposing it with dilute acid.

No product was ever obtained from the reaction between pentamethylphenylmagnesium bromide and acetyl chloride which gave a precipitate when shaken with copper acetate solution; in most cases the yellow or brown ethereal solution merely turned green. And with one exception, no product was ever obtained which gave any enolate of acetopentamethylbenzene when treated with ethylmagnesium bromide. The one exception was the product which resulted when an aliquot portion of a Grignard solution was *added to* excess acetyl chloride. This product (2.5 g.) gave no copper compound, but it did give a crystalline enolate when treated with ethylmagnesium bromide. Decomposition of this enolate gave 0.15 g. (6%) of acetopentamethylbenzene.

Although acetyl chloride, when added to an ethereal solution of pentamethylphenylmagnesium bromide, did not produce either the monoketone or the triketone, nevertheless the Grignard reagent was destroyed by this procedure and the product of the reaction was pentamethylbenzene. This was shown by carbonation of an aliquot portion of the reagent before addition of acetyl chloride, when pentamethylbenzoic acid was obtained; after the reaction with acetyl chloride, carbonation produced no pentamethylbenzoic acid; the only alkali soluble material was a very small amount of a thick orange oil.

The failure to obtain acetopentamethylbenzene from acetyl chloride and the Grignard reagent was surprising in view of the fact that Kohler and Blanchard[8] (p. 370) obtained acetotriphenylbenzene from 2,4,6-triphenyl-phenylmagnesium bromide and acetyl chloride. However, this result was not due to any peculiarity of pentamethylphenylmagnesium bromide, for essentially the

same results were obtained when mesitylmagnesium bromide was treated with acetyl chloride. Neither acetomesitylene nor the triketone[4] (p. 4017) derived from it was obtained; the chief product was mesitylene, but along with the hydrocarbon there resulted a small amount of an oily by-product. It appears, therefore, that two methyl groups ortho to the functional group in an aromatic Grignard reagent give rise to a greater hindrance to addition than do two phenyl groups in the same position.

We have not repeated all of Clément's work. He claimed to have obtained (42% yield) acetopentamethylbenzene, also melting at 110°, from the reaction between the Grignard reagent and ethyl acetate. Certainly this is in error. In addition, Clément prepared pentamethylbenzophenone from the Grignard reagent and either benzoyl chloride or ethyl benzoate, and this ketone also gave an "oxime" and a "semicarbazone," a statement which, if true, would indicate that the ketone was not pentamethylbenzophenone. With ethyl formate, Clément obtained *pentamethylbenzaldehyde* in 34% yield, and he reported that the substance melted at 130.5°. Some time ago, Mr. J. H. Paden of this Laboratory prepared this aldehyde from the hydrocarbon, zinc cyanide, hydrochloric acid and aluminum chloride. He found that the aldehyde melted at 142–147° and it was not possible to get a narrower range in the melting point by recrystallizing it, or by distilling it (b. p. 144° at 6 mm.) in an atmosphere of carbon dioxide, followed by crystallization. Nevertheless the aldehyde was analytically pure; it gave an oxime (m. p. 187–188°) and a semicarbazone (m. p. 270–275°), both of which gave excellent analytical values, and on oxidation the aldehyde readily gave the known pentamethylbenzoic acid (m. p. 209–210°).

Experimental Part[9]

Acetopentamethylbenzene was prepared in 80% yield by the method of Smith and Guss.[1] The ketone boiled at 144–145° under 8 mm. pressure, and after crystallization from methanol, the melting point was 84°.

Anal. Calcd. for $C_{13}H_{18}O$; C, 82.11; H, 9.47. Found: C, 82.09; H, 9.21.

When an ethereal solution of the substance was shaken with saturated aqueous copper acetate, no copper compound was formed, nor was there any color developed in the ethereal layer. When subjected for twenty-four hours to the action of hydroxylamine and alkali in aqueous-alcoholic solution according to the procedure of Kamm[10] the ketone (0.2 g.) was recovered quantitatively. No trace of an oxime could be found in the reaction mixture. As shown by Smith and Guss[1] the ketone was enolized completely by methylmagnesium iodide, one equivalent of methane being liberated.

Diacetylpentamethylbenzoylmethane (I).—Acetopentamethylbenzene (5 g.) in ether (50 cc.) was dropped slowly into a solution of ethylmagnesium bromide (25 cc.) prepared from 0.75 g. of magnesium and 2.5 g. of ethyl bromide. The solution developed a light tan color and the white crystalline enolate precipitated. Acetyl chloride (10 cc. freshly distilled from dimethylaniline) in ether (30 cc.) was added slowly. A copious tan precipitate formed, and the ether solution became yellow. The mixture was refluxed for two hours and then allowed to stand for two days, after which it was decomposed by addition of iced hydrochloric acid. The ether layer was separated, the aqueous layer was extracted thoroughly with ether and the combined ethereal solutions shaken with excess saturated aqueous copper acetate. The ethereal layer became blue, and in a short time a bluish-gray precipitate appeared, which was removed and washed with ether. The dull blue copper compound (2.01 g.) turned brown at 234°, sintered at 242° and melted at 244–247° to a deep reddish-brown liquid. The ethereal layer after removal of the copper compound, contained 3.43 g. of acetopentamethylbenzene (m. p. 76–81°) which was contaminated by a small amount of yellow oil.

The copper compound was suspended in ether and decomposed by shaking it with hydrochloric acid (1:1). There resulted 1.67 g. of the triketone (I) which melted at 95–108°. After repeated recrystallization from methanol (6 cc.) the substance melted at 110–111°.

Anal. Calcd. for $C_{17}H_{22}O_3$: C, 74.45; H, 8.03. Found: C, 74.66; H, 7.71.

When examined quantitatively in the Grignard machine, the triketone in contrast to the analogous compound of Kohler and Baltzly[4] (p. 4021) liberated 1.9 moles of gas and consumed 1.26 moles of reagent by addition (average of two closely agreeing determinations).[11] A few milligrams of the triketone in ether was shaken with copper acetate. After removal of the copper compound, the colorless ether layer was evaporated. Only a trace of material remained.

Isoxazole, II or III.—Two formulas are possible for this substance. It could be 3,5-dimethyl-4-pentamethylbenzoylisoxazole (II) or 3-methyl-4-acetyl-5-pentamethylphenylisoxazole (III), depending upon which carbonyl group enolized after addition of hydroxylamine. The exact structure was not determined. The triketone (0.2 g.) was added to a mixture of hydroxylamine hydrochloride (0.5 g.) in water (2 cc.) and sodium hydroxide (2 cc., 10%). A little alcohol was added to dissolve the triketone, and the mixture was heated on the steam-bath for forty-five minutes. Dilution with water precipitated the isoxazole, which was removed and crystallized from methanol. The melting point was 176°.

[9] Micro analyses by J. W. Opie.

[10] Kamm, "Qualitative Organic Analysis," John Wiley & Sons, Inc., New York, 1932, p. 172.

[11] The authors are indebted to Mr. Wm. Prichard for the Grignard analyses.

Anal. Calcd. for $C_{17}H_{21}O_2N$: C, 75.28; H, 7.75. Found: C, 75.62; H, 7.85.

Before starting the work on the reactions of pentamethylphenylmagnesium bromide, a control experiment was carried out in order to test the efficiency of the method of analysis which it was proposed to use in handling the products. A mixture (total weight 3.09 g.) of triketone (0.39 g., 0.00146 mole), acetopentamethylbenzene (0.50 g., 0.00338 mole), bromopentamethylbenzene (0.50 g., 0.00186 mole) and pentamethylbenzene (2.00 g., 0.0135 mole) was dissolved in ether (25 cc.) and shaken with copper acetate. There resulted 0.18 g. of copper compound from which 0.12 g. of triketone was obtained. The remaining ethereal solution was shaken with hydrochloric acid, washed with water, and dried. Evaporation of the ether left 2.23 g. of solid material. This was taken up in dry ether (50 cc.) and the solution was added to excess ethereal ethylmagnesium bromide. A white precipitate slowly formed. Stirring and refluxing were continued for six hours and then the mixture was allowed to stand for thirty-six hours at room temperature. The ethereal solution was removed by decantation, the precipitate was washed with a little ether and decomposed in the usual way. There resulted 0.45 g. of crude acetopentamethylbenzene which melted at 64–78°; when mixed with acetopentamethylbenzene, the melting point was 68–78°. The combined ethereal solutions were evaporated; the residue weighed 1.23 g.

The Grignard Reactions.—To a mixture of bromopentamethylbenzene (20 g., 0.088 mole), ether (70 cc.) and magnesium (5.26 g., 0.22 mole) was added dropwise a solution of ethyl bromide (9.62 g., 0.088 mole) in ether (30 cc.). The reaction started at once and the bromopentamethylbenzene began to dissolve. When about half of the ethyl bromide had been added, the Grignard reagent began to precipitate as a white crystalline solid. After all the ethyl bromide was added, the mixture was stirred and refluxed for about an hour. The volume was then made up to 150 cc. by addition of ether and while stirring vigorously 25 cc. was drawn out with a pipet and immediately run onto crushed dry ice in an open beaker. After all the dry ice had disappeared, the mixture was worked up in the usual way. The portion soluble in alkali yielded 1.49 g. (53%) of pentamethylbenzoic acid melting at 202–206°, which when mixed with an authentic specimen (m. p. 209–210°) melted at 205–209°. The alkali insoluble material weighed 0.83 g. and was largely pentamethylbenzene. It melted at 50–58° and the melting point was not changed by addition of pure pentamethylbenzene. Based upon the weights of pentamethylbenzoic acid and pentamethylbenzene (80% pure) obtained, and assuming that both these substances were derived from the Grignard reagent, then the yield of the latter was 80%.

A second 25 cc. of the Grignard solution was pipetted out and dropped slowly into a well-stirred solution of acetyl chloride (10 cc.) in ether (25 cc.). There was a vigorous reaction, a yellow color developed and a precipitate formed. After addition of the Grignard solution the mixture was refluxed for one and one-half hours and then set aside at room temperature for two days. The product was decomposed in the usual way and the combined ethereal solution and extracts when evaporated, gave 2.5 g. of a granular solid which melted at 55–77°. The solid was dissolved in ether and shaken with copper acetate; no copper compound precipitated. The ethereal solution (30 cc.) was dried thoroughly and added slowly to an excess of ethylmagnesium bromide in ether (50 cc.). The mixture was stirred and refluxed for several hours and then set aside overnight. The ether was decanted from the small amount of crystalline precipitate (needles), the latter was washed with ether and then decomposed with acid. There resulted 0.15 g. (6%) of acetopentamethylbenzene which melted at 78–81° and which did not depress the melting point of a known specimen. The ethereal solution and washings, when evaporated, gave 1.19 g. of impure pentamethylbenzene which melted at 50–67°.

Several experiments were carried out in which acetyl chloride in ether was added to the mixed Grignard reagents prepared by the entrainment method. The reaction mixtures were decomposed in the usual way, and the products were worked up as follows.

I. (From 13.3 g. of bromo compound.) The ethereal solution gave no precipitate when it was shaken with copper acetate. The ether was then evaporated and the residue was vacuum distilled. The products were: (a) a colorless oil (1.5 g.) with a sharp odor, which boiled at 33–34.5 under 23 mm., and was probably the chloride of diethylmethylcarbinol; (b) a white solid (6.0 g.) which boiled at 107–114° under 14 mm., and melted at 47.5–51.5° (pentamethylbenzene); (c) a residue of dark viscous liquid in the distilling flask. This was distilled in a high vacuum apparatus. The first material to collect in the receiver was a white solid (0.23 g.) which melted at 95–110° and which gave no copper compound. It was impure bromopentamethylbenzene. When the residue remaining in the distilling flask was heated to 180° under 10^{-5} mm. it gave a distillate (1.39 g.) of light orange oil which darkened immediately on exposure to the air. The non-volatile residue weighed 1.16 g.

II. (From 20 g. of bromo compound.) Before decomposition 50 cc. of the material (total volume 186 cc.) was pipetted out and run into a sufficient excess of ethylmagnesium bromide to destroy the acetyl chloride and enolize any acetopentamethylbenzene that might have been present. Acetyl chloride was then added and the mixture was allowed to stand overnight. Decomposition in the usual way resulted in a dark brown liquid which gave no copper compound. The substance was then steam distilled. The distillate contained pentamethylbenzene (2.97 g.) which melted at 52–55°. The residue remaining in the distilling flask was 1.8 g. of dark oil.

The remainder of the material (136 cc.) after decomposition was first tested with copper acetate (negative) and then steam distilled. From the distillate there was isolated 8.92 g. of pentamethylbenzene which melted at 53–55.5°. The residue consisted of a thick brown oil (3.57 g.).

The total recovery of pentamethylbenzene (11.89 g.) was 91% based on 20 g. of bromo compound used.

III. A Grignard reagent was prepared by refluxing together a dilute ethereal solution of ethylmagnesium bromide (5 cc.), magnesium (2.1 g.), bromopentamethylbenzene (10 g.) and xylene (30 cc.). After refluxing for five hours, excess acetyl chloride was added and refluxing was continued for another hour. The reaction mixture, decomposed in the usual way, gave a negative test with copper acetate, and after drying, gave only a trace of precipitate with excess ethylmagnesium bromide. Acid was added and the mixture was steam distilled. The distillate contained 4.38 g. (68%) of pentamethylbenzene which melted at 54–55° and in the distilling flask there remained 1.79 g. of a thick yellow oil.

IV. A Grignard reagent was prepared by refluxing together the bromo compound (10 g.), magnesium (1.46 g.), ether (100 cc.) and ethyl bromide (1 cc.). The reaction was very slow, but a considerable amount of the Grignard reagent had precipitated after three hours. One-fourth (25 cc.) of the solution was removed and this, dropped onto crushed dry ice and worked up in the usual way yielded 0.65 g. (34.5%) of pentamethylbenzoic acid and 1.12 g. of a mixture of bromo compound and pentamethylbenzene which melted at 77–123°. To the remainder of the Grignard reagent was added acetyl chloride (10 cc.). The mixture was refluxed for two hours and then excess crushed dry ice was added. After carbonation there was obtained as alkali soluble material only 0.3 g. of a yellow malodorous oil which, however, gave a deep green color when it was dissolved in ether and shaken with copper acetate. The alkali insoluble material (5.81 g.) was steam distilled. The distillate contained 3.17 g. of pentamethylbenzene which melted at 51–55° and the residue contained 1.59 g. of yellowish impure bromopentamethylbenzene which melted at 130–140°. Thus, although the Grignard reagent was not converted into acetopentamethylbenzene or the triketone by acetyl chloride, nevertheless it was destroyed by this reagent and in the process it was converted into pentamethylbenzene.

V. An experiment similar to IV was carried out starting with bromomesitylene (10 g.), magnesium (1.3 g.), ether (30 cc.) and ethyl bromide (8 drops). Carbonation of an aliquot portion gave the known carboxymesitylene which melted at 146–150° and which showed no depression in melting point when mixed with an authentic specimen. The remainder of the Grignard solution was refluxed for three hours with acetyl chloride (6 cc.). After decomposition in the usual way, a distillate of 2.98 g. of mesitylene (b. p. 53° under 23 mm.) was removed. The residue (3.59 g.) was taken up in ether and added slowly to excess ethylmagnesium bromide.[4] No precipitate of the enolate of acetomesitylene was obtained after the mixture had stood overnight, nor was any obtained when half the ether was evaporated. The mixture was decomposed and steam distilled, giving a distillate containing 1.2 g. of bromomesitylene and a residue of dark, thick oil (0.89 g.). Hence the Grignard reagent from bromomesitylene behaved toward acetyl chloride in the same manner as the reagent from bromopentamethylbenzene.

Summary

1. Contrary to the report of Clément, pentamethylphenylmagnesium bromide does not give acetopentamethylbenzene when it reacts with acetyl chloride. The products of the reaction are pentamethylbenzene and condensation products of the acid chloride.

2. Mesitylmagnesium bromide behaves toward acetyl chloride in the same manner as does the reagent from bromopentamethylbenzene, no acetomesitylene resulting. The behavior of the two methylated Grignard reagents differs from that of 2,4,6-triphenyl-phenylmagnesium bromide, which Kohler and Baltzly found gave the aceto compound with acetyl chloride, and these results indicate that two methyl groups in the ortho position to the functional group of a Grignard reagent offer more hindrance to addition than do two phenyl groups similarly placed.

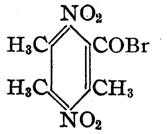
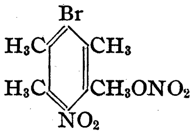
Polymethylbenzenes. XVIII. The Action of Nitric Acid upon Bromodurene[1]

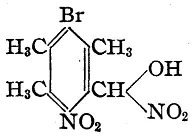
BY LEE IRVIN SMITH, F. LOWELL TAYLOR AND ISABELLA M. WEBSTER



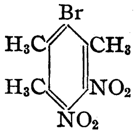
I



II



III



IV

In a recent paper, Smith and Tenenbaum[2] have shown that the product obtained by Willstätter and Kubli[3] by action of fuming nitric acid upon bromodurene, and regarded by them as dinitrodurylic acid bromide (I), could not possibly be an acid bromide. Moreover, the analyses of Smith and Tenenbaum, as well as those of Willstätter and Kubli, agreed much better with the formula $C_{10}H_{11}O_5N_2Br$ than with the formula $C_{10}H_9O_5N_2Br$ (I). The chief reactions of the substance which was discovered by Smith and Tenenbaum were the ready conversion to 3-bromo-5,6-dinitropseu-

---

(1) Paper XVII. THIS JOURNAL, **59**, 1078 (1937).

documene (IV) by action of cold concentrated sulfuric acid, and reduction to aminodurene (V). On the basis of these reactions, Smith and Tenenbaum, assuming that the skeleton of bromonitrodurene was still intact in the substance, suggested provisionally that the substance might possess structure II or III. Further work has shown that II, a benzyl nitrate, is the most probable structure for this substance.

The formation of IV ($C_9H_9O_4N_2Br$) from the W.–K. compound ($C_{10}H_{11}O_5N_2Br$) must proceed by elimination of the elements CH_2O. Close observation of the reaction resulted in the detection of the odor of formaldehyde. It was not possible to obtain enough formaldehyde from the reaction to prepare a derivative, due, no doubt, to the destructive action of sulfuric acid upon formaldehyde. A color test with guaiacol carbonate was apparently positive, but was rather indefinite because of the interfering colors.

The W.–K. compound, warmed in acetic anhydride with a little sulfuric acid, gave a substance (VI) having the composition $C_{12}H_{14}O_4NBr$. This substance was the acetate of a bromonitropseudocumyl alcohol, for it was obtained also by acetylation of the substance $C_{10}H_{12}O_3NBr$ (VII) which resulted *along with nitric* acid when the W.–K. compound in 50% acetic acid was refluxed with dilute (0.1 *N*) sulfuric acid. Only traces of nitrous acid were produced in this reaction. The acetate (VI) was hydrolyzed to the alcohol (VII) by the action of alcoholic hydrochloric acid.

When the W.–K. compound was dissolved in absolute ethanol and subjected to the action of sodium ethoxide; there resulted sodium *nitrite* and an orange-yellow solid having the composition $C_{10}H_{10}O_3NBr$ (VIII) which was an aldehyde. A solution of the aldehyde in acetone when treated with alkali, turned green, then blue, and finally a purple substance precipitated. Because of this color reaction, VIII was considered to be an ortho nitro aldehyde. A synthesis of the *o*-nitro-*m*-bromo aldehyde VIII was attempted, but although 6-nitropseudocumyl aldehyde was readily prepared, it could not be brominated, and the action of bromine on durylic aldehyde apparently converted it to a polybromopolymethylbenzyl benzoate.

Since the action of sulfuric acid converts the W.–K. compound into IV, the skeleton D must be intact. Further since reduction gives rise to aminodurene, the fourth side chain carbon must be in place (E). Starting with E($C_{10}H_9O_2Br$) the elements of water and nitrogen dioxide must be added to make up the composition $C_{10}H_{11}O_5N_2Br$ of the W.–K. compound. While the fourth methyl group has been oxidized, it must be in a state such that it can be reduced to methyl again. Both II and III would account for the reduction to aminodurene, but in addition to these two formulas, structures A, B, and C were considered. The chief objection to formulas II and III was the fact that the W.–K. compound gave different products when hydrolyzed in acid and basic media, respectively. Formula C was eliminated entirely on two counts: it would require migration of a methyl group to form IV, and it would lead to an ortho bromo aldehyde for VIII whereas VIII is quite definitely an ortho nitro aldehyde. Formula B also was discarded because it would require a rearrangement with migration of a nitro group to produce IV. Formula A with the trimethylene oxide ring can account for all of the known reactions of the W.–K. compound without the necessity of recourse to any rearrangements, and at first this formula was selected as best representing the chemical behavior of the W.–K. compound. However, Nef[4] and especially Klason and Carlson[5] have shown that the alkaline hydrolysis of benzyl and other nitrates leads to aldehydes and nitrite[6] and that the intermediate compounds are probably peroxides.

$$RCH_2NO_3 + KOH \longrightarrow RCH_2OOH + KNO_2$$
$$RCH_2OOH \longrightarrow RCHO + H_2O$$

With these facts in view, the chief objection to structure II was eliminated and it became necessary to consider this formula as very likely correct. To decide this point, the alcohol VII was converted to the nitrate *via* the chloride IX, and the iodide X. The nitrate so prepared was identical in all respects with the W.–K. compound. While this proof of the structure of the W.–K. compound is not wholly explicit because the intermediates were themselves derived from the W.–K. compound, yet the synthesis, combined with the reversibility of many of the transformations, constitute good implicit proof. Curiously enough, the alcohol VII cannot be converted to the chloride IX by boiling it for an hour with alcoholic hydrochloric acid, a procedure which con-

verts the W.-K. compound almost quantitatively to the chloride. These facts indicate that the alcohol is not an intermediate in the latter transformation. Moreover, once the chloride is formed, it is not readily hydrolyzed to the alcohol although the acetate can be converted into the alcohol with ease.

The formation of compounds analogous to the W.-K. compound derived from bromodurene appears to be a general reaction of the highly methylated benzenes and their derivatives. Further work, now in progress, indicates that pentamethylbenzene, dibromodurene, dinitrodurene and possibly some other substances all behave toward cold fuming nitric acid in the same manner that bromodurene does.

While the present work establishes definitely the analogy between the W.-K. compound and Nef's benzyl nitrate, the questions as to whether these compounds are actually nitrates, and if so, the mechanism of their hydrolyses in acid and basic solutions, remain unsettled. Klason and Carlson[5] believed that the nitrates were best represented as derivatives of a per-acid HOONO, but this hypothesis merely shifts the scope of the problem from a peculiar basic hydrolysis to a peculiar acid hydrolysis. It may be that a relationship exists among the forms represented by II, III, and A. The exact relationship, if any, is a problem for future work and it is the present opinion of the authors that while II probably best represents the structure for the W.-K. compound, structure A is not yet definitely excluded.

This work was made possible by a grant from the Fluid Research Fund of the Graduate School of the University of Minnesota.

Experimental Part

Action of Concentrated Sulfuric Acid upon the W.-K. Compound.—As shown by Smith and Tenenbaum, the product of this reaction was IV, and the experiments described below were directed toward detection of formaldehyde. Guaiacol carbonate was dissolved in 90% alcohol and the solution was treated with a little ferric chloride. The W.–K. compound was suspended in sulfuric acid (yellow to orange color) and the solution of guaiacol carbonate was added carefully. At the junction of the two solutions a pink to red ring formed (positive test).

Although it was not likely that formaldehyde could be removed from the sulfuric acid in quantity sufficient for the preparation of a derivative, since sulfuric acid polymerizes and dehydrates it, several attempts were made to isolate the aldehyde. The W.–K. compound (0.5 g.) was placed in a small flask with sulfuric acid (5 cc.). The mixture was warmed while a current of air was passed through it (forty-five minutes) and then bubbled through cold water. The water solution gave no precipitate with dimedon. In a similar experiment, the vapors from the decomposition of the W.–K. compound were passed through a liquid air trap. The condensate in the trap was white when cold, but when warmed to room temperature it became red and had a strong odor of oxides of nitrogen. Nevertheless the water solution was neutralized with bicarbonate and treated with dimedon. No precipitate was obtained.

The W.–K. compound (1 g.) was dissolved in dry ether (50 cc.), sulfuric acid (10 cc.) was added and the ether was slowly distilled through a condenser and an adapter dipping below the surface of cold water. As the ether distilled, fresh ether was added and the distillation was continued until 200 cc. of ether had distilled in four hours. The (neutral) water layer was separated, and the ether was extracted once with water. Dimedon (1.1 g.) in alcohol was added to the combined aqueous solutions, the mixture was warmed and allowed to stand overnight. No derivative of formaldehyde resulted.[7]

2,4,5-Trimethyl-3-bromo-6-nitro-benzyl Alcohol (VII).—The W.–K. compound (3 g.) was dissolved in acetic acid (50 cc.) at room temperature. Water (50 cc.) and sulfuric acid (2 *N*, 5 cc.) were added (precipitation) and the mixture was refluxed in an apparatus which was connected to a wash bottle containing aqueous potassium hydroxide (130 cc., 2%). There was no noticeable evolution of gas, and after refluxing for fourteen to fifteen hours, air was drawn through the apparatus in order to sweep out any oxides of nitrogen. Water was then added and the precipitate (1.8 g.) was removed. The filtrate gave a positive test for nitrate ion with ferrous sulfate and sulfuric acid; a test for nitrite ion was negative, and the solution in the wash bottle when acidified with acetic acid and warmed with Griess' reagent (sulfanilic acid and α-naphthylamine in dilute acetic acid) developed only a faint red color. No more than traces of nitrite were present. The precipitate (m. p. 100–150°) was refluxed with ethanol (25 cc.) and hydrochloric acid (10 cc.) for fifteen minutes. The hot solution was filtered and the filtrate was cooled. The product was removed, washed, and crystallized first from alcohol (20 cc.) and then from benzene (12 cc.)–petroleum ether (5 cc.). The substance was white and melted at 188°.

Anal. Calcd. for $C_{10}H_{12}O_3NBr$: C, 43.78; H, 4.41. Found: C, 43.75, 43.50, 43.95, 43.88; H, 4.38, 4.54, 4.41, 4.38.

When the alcohol (0.38 g.) was dropped into fuming nitric acid (10 cc., d. 1.5) at 0°, a red solution resulted which gradually became lighter and a white solid separated. The product (0.43 g., 97%) was the W.–K. compound, m. p. and mixed m. p. 118–122°.

Acetate (VI).—The alcohol was treated with acetic anhydride and a drop of sulfuric acid; dilution of the mixture precipitated the acetate. Crystallized from ethanol it melted at 85°.

The W.–K. compound (3 g.) was covered with acetic anhydride (20 cc.). Sulfuric acid (6 drops) was added and the mixture was warmed gently (not above 40°) for three days. The mixture when poured into ice water precipitated unchanged material. This was removed and while still damp was treated with the same quantities of reagents. There was a vigorous reaction. The mixture was heated at 70° for twenty-one hours. The product, isolated as before, was crystallized first from ethanol (10 cc.) and then from petroleum ether (12 cc.). It weighed 1.35 g. and melted at 86°. There was no depression in the melting point when the substance was mixed with the acetate prepared from the alcohol.

Anal. Calcd. for $C_{12}H_{14}O_4NBr$: C, 45.57; H, 4.46. Found: C, 45.14, 45.41, 45.02; H, 4.10, 4.50, 4.05.

When the acetate (0.21 g.) was refluxed for fifteen minutes with alcohol (6 cc.) and hydrochloric acid (2 cc.), the product was the alcohol VII, m. p. and mixed m. p., 185–190°.

Chloride (IX).—The W.–K. compound (1 g.) was refluxed with alcohol (40 cc.) and hydrochloric acid (20 cc.) for an hour. The clear yellow solution, when cooled, deposited 1.01 g. of white needles which melted at 110–112°. After crystallization from ethanol or dilute acetic acid, the substance melted at 112.5–113.5°. The chloride (0.85 g.) was also formed when the W.–K. compound (2 g.) was refluxed for sixteen hours with acetone (50 cc.), water (10 cc.) and hydrochloric acid (10 cc.), although the product, when prepared this way, was quite impure.[8]

Anal. Calcd. for $C_{10}H_{11}O_2NBrCl$: C, 41.03; H, 3.79. Found: C, 41.55, 41.85, 41.72; H, 4.23, 4.03, 3.78.

The alcohol (VII) was refluxed with alcoholic hydrochloric acid for one hour and the reaction mixture then allowed to stand overnight. The product was unchanged alcohol. Since this procedure converts the W.–K. compound smoothly into the chloride, the alcohol cannot be an intermediate.

The alcohol (VII) (1 g.) was added to thionyl chloride (5 cc.). A clear solution resulted. The mixture was warmed for five minutes, the excess thionyl chloride was removed under reduced pressure and the yellow residue was crystallized from dilute acetic acid. The substance melted at 107–110° and the melting point was not depressed by mixture with a specimen of the chloride prepared directly from the W.–K. compound.

Hydrolysis of the chloride (0.57 g.) by boiling it with alcohol (50 cc.), water (10 cc.) and potassium carbonate (2 g.) yielded 0.44 g. of product which was essentially unchanged chloride, although the melting point was lowered about 15°.

---

[7] Klein and Linser, *Mikrochemie*, Pregl Festschr., 204 (1929).

[8] The preparation of the chloride by both methods was first carried out by J. A. Anthes.

Iodide (X).—The chloride IX (0.86 g.) was added to a solution of sodium iodide in acetone (30 cc., 10%). The reaction was practically instantaneous; sodium chloride was precipitated at once. The mixture was warmed gently for two or three minutes and then allowed to stand for half an hour. The precipitate of crude sodium chloride was removed (weight 0.19 g., theoretical, 0.17 g.) and the filtrate was poured into water. The product weighed 0.97 g. (86%) and melted at 111–113°. Addition of the chloride (m. p. 112–113°) depressed the melting point to 91–96°. After two crystallizations from acetone, the substance formed long white needles which melted at 113–115°.

Anal. Calcd. for $C_{10}H_{11}O_2NBrI$: C, 31.26; H, 2.89. Found: C, 31.30, 31.38; H, 3.33, 3.19.

Nitrate (II) (The W.-K. Compound).—Although the chloride (IX) readily reacted with silver nitrate in ether or in alcohol, precipitating nearly the theoretical amount of silver chloride, the organic product was a mixture from which no pure material could be separated. The reaction was apparently complicated by hydrolysis, for the impure material, even the oily residues obtained by evaporating the mother liquors after crystallization, gave the W.-K. compound when they were dropped into fuming nitric acid.

The iodide, however, could be converted smoothly to the nitrate. The iodide (0.65 g.) and silver nitrate (1 g.) were refluxed in dry dioxane (20 cc.) for two hours, and then kept at 100° for seventeen hours longer. The inorganic material was removed and the dioxane solution was poured into water. The precipitated solid (0.43 g.) was removed and crystallized from alcohol. The melting point, 121–122.5°, was not depressed by addition of the W.-K. compound.

2,4,5 - Trimethyl - 3 - bromo - 6 - nitrobenzaldehyde (VIII).—The W.-K. compound (3 g.) was added to absolute ethanol (25 cc.). The mixture was heated to boiling and to it was added dropwise 2–3 cc. of a solution prepared from sodium (0.3 g.) and absolute ethanol (50 cc.). The color became orange yellow and all the solid dissolved. When cooled, unchanged material precipitated. The mixture was heated again and the alkali added, 1–2 cc. at a time until the transient greenish-yellow color became permanent (30 cc. of the alkali, thirty minutes total time). A precipitate of sodium nitrite separated out. The cooled solution was poured into dilute acetic acid and the solid was filtered off. The filtrate was examined for nitrite ion (positive). The product, crystallized first from ethanol (20 cc.)–benzene (10 cc.) and then from petroleum ether, formed faintly orange needles melting at 193°.

Anal. Calcd. for $C_{10}H_{10}O_3NBr$: C, 44.12; H, 3.71. Found: C, 43.89, 44.09; H, 3.81, 3.67.

The aldehyde could be sublimed. It was sensitive to light, which caused a greenish coloration. A small portion in aqueous acetone was warmed with potassium hydroxide. The solution turned green, then blue, and finally a purple solid precipitated. The same color changes were observed when the W.-K. compound was subjected to the action of alcoholic alkali.

Action of Oxidizing Agents upon the W.-K. Compound.—The substance was rather stable toward oxidizing agents, although it was attacked slowly. After refluxing it with permanganate in 50% acetic acid and sulfuric acid (0.5 cc., 2 *N*) for one and one-half hours, the only isolable product was unchanged material (0.1 g. from 0.3 g.). A similar treatment with sodium dichromate (0.4 g.) in acetic acid (10 cc.) also gave unchanged material (0.28 g. from 0.32 g.).

Bromination of Durylic Aldehyde.—Bromine (6.7 g.) was added to a solution of the aldehyde (6 g.) in cold sulfuric acid (20 cc.) and the mixture was allowed to stand at room temperature for twenty-three hours. The solution was poured into ice water; the small amount of free bromine was removed with bisulfite. The product was removed, extracted with petroleum ether, and the solid residue was crystallized from benzene. It formed colorless needles melting at 219–220° and weighed 1.1 g. It was probably α,2,5-tribromoduryl-2,5-dibromodurylate. It was analyzed but was not examined further.

Anal. Calcd. for $C_{20}H_{19}O_2Br_5$: C, 34.75; H, 2.77. Found: C, 34.32; H, 3.07.

Nitration of Durylic Aldehyde.—The aldehyde (3 g.) and sulfuric acid (10 cc.) were cooled in a freezing mixture (−8°) and nitrated by slow addition (one hour) of a solution of potassium nitrate (2 g.) in sulfuric acid (10 cc.). The cherry red solution after standing for thirty minutes at −15° was poured into ice water. The solid was removed, triturated with bicarbonate, and washed with water. It was dissolved in ethanol (25 cc.), the hot solution was filtered and the filtrate, slowly cooled, deposited 1.6 g. of fine plates melting at 139–140°. The aldehyde could not be brominated.

Summary

1. A further study of the reaction between bromodurene and fuming nitric acid has shown that of the formulas heretofore suggested, II, 2-nitro-5-bromo-3,4,6-trimethylbenzyl nitrate, at present best represents the chemical behavior of the product.

2. The reaction appears to be a general property of the highly alkylated benzenes and certain of their derivatives.

The Bromination of 4-Phenylphenylbenzenesulfonate

BY STEWART E. HAZLET[1]

Although much work has been done to determine the orienting effect of phenolic hydroxyl groups, only a few studies have been made of the modification of the directive influence of such functional groups by esterification. In the present work a study has been made of the bromination of 4-phenylphenol and one of its esters. It has been found that bromination of 4-phenylphenol (I) yields 2-bromo-4-phenylphenol (II), but when the hydroxyl group is modified to benzenesulfonyloxy the bromination product is 4-(4-bromophenyl)-phenylbenzenesulfonate (V). The reactions and proof of structure of the compounds are summarized in Chart I.

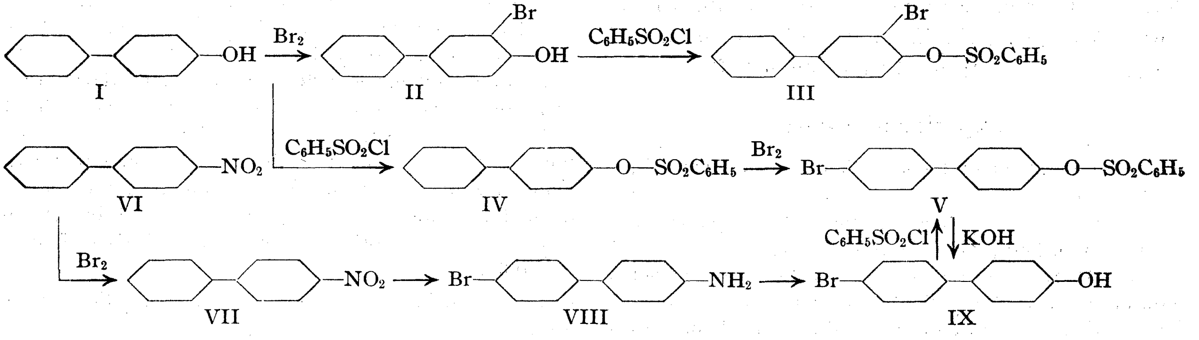

CHART I

There are some other cases on record in which esterification of phenolic groups modified their directive influence. Raiford and Stoesser[2] found that, although bromination of vanillin gives a high yield of the 5-bromo derivative, acetylvanillin, under the same circumstances, gives only the 6-bromo substitution product. Benzoylvanillin was found by Raiford and Milbery[3] to behave in the same manner. It is claimed that halogen takes the position (6) because of the directive influence of the methoxy radical, and that this influence comes into play after the directive power of hydroxyl has been largely suppressed by acylation.

Also it is known that, although halogenation and nitration of 4-phenylphenol[4] follow the normal course, the first substituent entering the position ortho to hydroxyl, when the hydroxyl group is modified to the methoxy group, nitration yields 80% of 2-nitro-4-phenylanisole, and 15% of 4-(4-nitrophenyl)-anisole is obtained as well.[5] When the 4-toluenesulfonyloxy group is present in the molecule rather than the hydroxyl or methoxy, the nitration product is reported[5] as "mainly, if not exclusively" 4-(4-nitrophenyl)-phenyl-4-toluenesulfonate. Apparently the bromination of similar substances has not been studied.

Upon nitration, 4-phenylacetanilide gives 2-nitro-4-phenylacetanilide,[6] and 4′-phenyl-4-toluenesulfonanilide gives 2′-nitro-4′-phenyl-4-toluenesulfonanilide.[5] The bromination of the first of these compounds has been shown to give 50% of 2-bromo-4-phenylacetanilide and 30% of 4-(4-bromophenyl)-acetanilide,[7] and in the case of the sulfonanilide bromination gives a mixture of compounds.[8] Hence, it was desirable to know whether bromination of esters such as IV would parallel nitration. From the results here reported, it is evident that the bromination of IV proceeds as does the nitration of the similar compound.

By the method of mixed melting points, V was shown to be different from III and identical with the benzenesulfonic acid ester of IX. By the same procedure, the phenolic hydrolysis product from V was shown to be IX and not II.

---

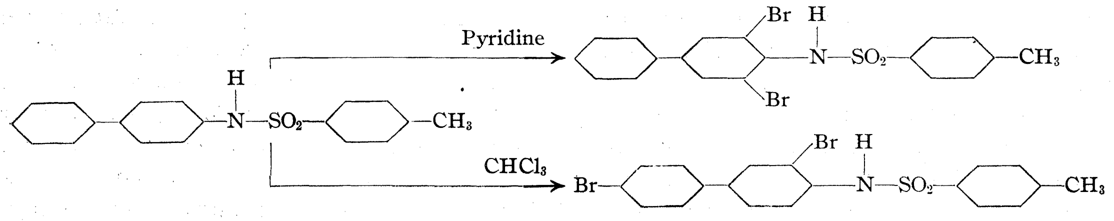
Since glacial acetic acid was the solvent used in the bromination of IV, whereas chloroform had been used previously in the preparation of II,[7] it was necessary to determine whether the solvent might have caused the difference. Such a difference due to solvent has been observed in the case of the bromination of a sulfonanilide[8]



However, bromination of I in glacial acetic acid under the same conditions which were used for the bromination of the ester (IV) gave the same product (II), in 82.5% yield, as had been obtained using chloroform as solvent. Therefore, the difference in directive influence must be due to the presence of benzenesulfonoxy in place of hydroxyl and cannot be attributed to a solvent effect.

Experimental Part

4 - (4 - Bromophenyl) - phenylbenzenesulfonate (V).—4-Phenylphenylbenzenesulfonate[9] (IV) (20 g.) was suspended in 200 cc. of glacial acetic acid and heated on a boiling water-bath, with vigorous stirring. Bromine (4.5 cc.) was then introduced slowly, and a trace of powdered iron was added. After all of the bromine had been added, the reaction was allowed to proceed for three hours; then the mixture was cooled and poured into five volumes of cold water. After filtering, the reaction product represented a 97% yield. It was recrystallized from alcohol, and a colorless product, m. p. 79–81°, was obtained.

Anal. Calcd. for $C_{18}H_{13}O_3BrS$: Br, 20.57. Found: Br, 20.95.

To prove the structure of the above, it was prepared in the following manner. 4-(4-Bromophenyl)-nitrobenzene (VII) was prepared according to the method of Le Fèvre and Turner.[10] The nitro compound (VII) was reduced to 4-(4-bromophenyl)-aniline (VIII),[10] and this was converted to 4-(4-bromophenyl)-phenol (IX), as directed by Bell and Robinson.[11] The product thus obtained melted between 163 and 165°. When 4-(4-bromophenyl)-phenol (IX), in pyridine solution, was treated with benzenesulfonyl chloride, 4-(4-bromophenyl)-phenylbenzenesulfonate (V), m. p. 78–80°, was obtained. This material was mixed with the brominated ester, and a melting point of 78–80° was observed.

Hydrolysis of 4-(4-Bromophenyl)-phenylbenzenesulfonate.—One gram of the ester (V) was suspended in 100 cc. of a 10% potassium hydroxide solution (alcohol: water:: 1:1), and allowed to reflux for twenty-four hours. The reaction mixture was diluted with an equal volume of water and extracted with ether. The aqueous solution was acidified and the phenolic component extracted with ether. The ethereal solution was dried with anhydrous sodium sulfate to which some Norite had been added. After filtering and removing the solvent by evaporation, an 86% yield of crude 4-(4-bromophenyl)-phenol (IX) was obtained. This was crystallized from alcohol, and the purified material (55% yield) melted at 165–166°. The product prepared in this manner was purified much more easily than that prepared by the method of Bell and Robinson.[11] The mixed melting point of the substances prepared by the two methods was 163–165°.

2-Bromo-4-phenylphenylbenzenesulfonate (III).—Five grams of II was dissolved in pyridine and treated with 1.1 mols. of benzenesulfonyl chloride. The oily product, obtained by extraction with ether in the usual manner,[9] represented an 81% yield. After standing several months, it solidified and was crystallized from slightly diluted methanol. The colorless product (51% yield) melted at 102–103°.

Anal. Calcd. for $C_{18}H_{13}O_3BrS$: S, 8.24. Found: S, 8.18.

2,6 - Dibromo - 4 - phenylphenylbenzenesulfonate.—2,6-Dibromo-4-phenylphenol was prepared by a known method.[11] From 5 g. of this hydroxyl compound, the pure benzenesulfonic acid ester was obtained in 84% yield by the usual method;[9] alcohol was used as solvent for recrystallizations. The colorless product melted between 145 and 147.5°.

Anal. Calcd. for $C_{18}H_{12}O_3Br_2S$: Br, 34.19. Found: Br, 34.44.

Summary

1. Although bromination of 4-phenylphenol in glacial acetic acid solution yields 2-bromo-4-phenylphenol, under the same circumstances bromination of 4-phenylphenylbenzenesulfonate yields 4-(4-bromophenyl)-phenylbenzenesulfonate.

2. Some related compounds have been reported.

3. Further work is in progress.

The Preparation and Properties of a Series of Alkyl Thiolacetates[1]

BY F. W. WENZEL, JR., AND E. EMMET REID

This is a continuation of the comparison of sulfur compounds with their oxygen analogs.[2] The task undertaken was the preparation of the thiolacetates of the normal alcohols, or rather the acetyl derivatives of the mercaptans, from methyl to octyl, and the determination of their physical properties.

Thiol esters usually have been prepared by the action of an acid chloride on a mercaptan or mercaptide. The esters here described were made from the mercaptans (a) by treating them with acetyl chloride, (b) by refluxing them with acetanhydride and sodium acetate, and (c) by dissolving them in strong caustic soda and adding acetanhydride. Method (c) is preferred for the lower mercaptans which are too volatile for (b) and which dissolve readily in aqueous alkali, while (b) is best for the higher members. The properties of these esters are given in Table I and some are plotted in Figs. 1 and 2 along with the corresponding data for the oxygen esters.

TABLE I

Normal alkyl	B. p., °C. 760 mm.	d^0_4	d^{25}_4	n^{25}_D	Mol. refraction Calcd.	Mol. refraction Found	Sulfur, % Calcd.	Sulfur, % Found

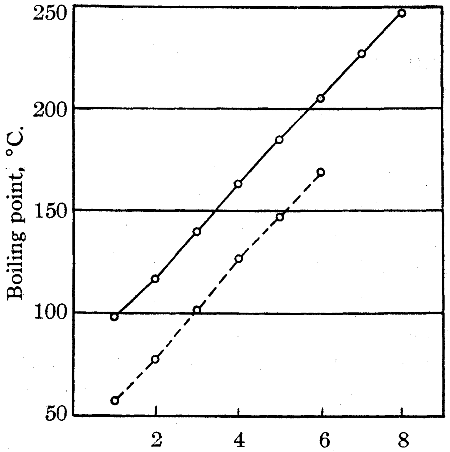

Fig. 1.—Boiling points: normal thiolacetates ————; normal acetates – – – – –.

The amount by which the boiling point of an acetate is raised by the substitution of —S— for —O— is 40° for the methyl and decreases slightly as the series is ascended. Methyl thiolacetate has the same molecular weight as butyl mercaptan and both boil at 98°, but the higher members of the series boil somewhat lower than the mercaptans of the same molecular weight.

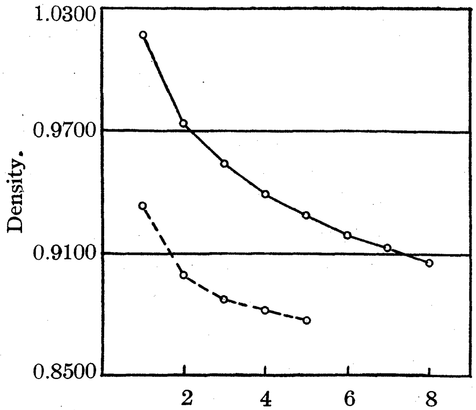

Fig. 2.—Densities: normal thiolacetates at 25° ————; normal acetates at 20° – – – – –.

Experimental

The higher alcohols, alkyl bromides, and mercaptans were prepared by standard methods and fractionated through precision stills,[3] cuts taken of 1° or less. Ethyl mercaptan was purchased and methyl mercaptan was prepared according to Klason.[4]

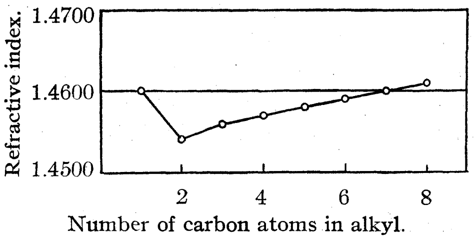

Fig. 3.—Refractive indices of normal thiolacetates.

Preparation of the Esters. Method (a).—To the mercaptan in a flask packed in ice the calculated amount of acetyl chloride was added slowly from a dropping funnel through a reflux condenser. The flask was allowed to come to room temperature at which it was kept for three days and then emptied into water. The ester was washed, dried over calcium chloride, and distilled. Four hundred and ten grams of ethyl thiolacetate, b. p. 115.5–116.5°, was prepared by this method with yields from 60–70%; also 55 g. of *n*-propyl, b. p. 138–140°, yield 70%, and 67 g. of *n*-butyl, b. p. 162–164°, yield 91%.

Method (b).—A mixture of 1 mole of mercaptan and 1.2 moles of acetanhydride and one-fifth of its weight of anhydrous sodium acetate was refluxed for an hour by the use of an oil-bath which was raised from 130° at the start to 150° at the end of this time. The reaction usually became so vigorous, after short heating, that the flask had to be removed from the oil-bath for a time. The cooled mixture was poured into water, the ester separated, washed free of acid, dried, and distilled. Thirty-three grams of ethyl thiolacetate, b. p. 115.5–116.5°, yield 78.5%, was prepared by this method; also 35 g. of *n*-butyl, b. p. 162–164°, yield 95%; 68 g. of *n*-amyl, b. p. 182.5–185°, yield 92.5%; 64 g. of *n*-hexyl, b. p. 204–206°, yield 94%; 108 g. of *n*-heptyl, b. p. 145.5–146° at 70 mm., yield 91%; and 48 g. of *n*-octyl, b. p. 146.5–147° at 38 mm., yield 93%. Seventy grams of the methyl thiolacetate, b. p. 98–99°, was prepared by passing methyl mercaptan directly into the boiling anhydride–sodium acetate mixture.

Method (c).—A mixture of 40 g. of sodium hydroxide, 75 cc. of water, and 1.2 mole of mercaptan was poured over 500 g. of shaved ice in a flask and 1.25 mole of acetanhydride was added rapidly with vigorous stirring which was continued for five minutes. The ester was separated immediately and worked up as in method (b): 100 g. of ethyl thiolacetate, b. p. 115.5–116.5°, yield 79.3%, was prepared by this method.

Conclusion

A series of normal alkyl thiolacetates have been prepared by various methods and their physical properties determined.

Some Monothioformals

BY F. W. WENZEL, JR., AND E. EMMET REID

Formals are well known, and a few dithioformals have been prepared, but the intermediate monothioformals, $ROCH_2SR$, have been neglected.[1] The purpose of this investigation was to prepare and study several of these, so as to compare them with the formals and the dithio compounds.

They are obtained readily from a chloromethyl alkyl ether and a mercaptan in alkaline solution

$$RSNa + ClCH_2OR = RSCH_2OR + NaCl$$

They can be made also from lead mercaptides in benzene solution. On account of side reactions the yields are only fair, about 50%. Care must be taken to get rid of any remaining chloromethyl ether, otherwise hydrochloric acid will be generated and the product decomposed.

The compounds chosen for study were the ethyl, *n*-propyl, and *n*-butyl. The data obtained are given in Table I.

The monothioformals are stable; the diethyl compound was refluxed for eight hours without any sensible change. However, if 1% of hydrogen chloride is added, rearrangement takes place and a formal and a dithioformal are obtained, the equilibrium being readjusted as the most volatile constituent is removed. On account of this instability in the presence of acid, care must be taken in the preparation of a monothioformal not to leave any of the chloroether in the crude product.

It is known that a Grignard reagent does not react with formals below 100°.[2] We have found this to be true with a monothioformal. Heating

Ethylal boils 47.8° below and the diethyl methylene mercaptal 48° above the diethyl monothioformal.

the diethyl compound with ethylmagnesium bromide at 100° for five hours decomposed less than one-third of it. Ethyl mercaptan and ethyl propyl ether were identified as the reaction products, which shows that the —SR is replaced more readily than the —OR.

Oxidation of a monothioformal takes place readily, but we have been unable to isolate a sulfone.

Experimental

In the preparation of the monothioformals the mercaptan was dissolved in about five volumes of alcohol and the equivalent amount of sodium hydroxide added. This solution was cooled to 0° and an equivalent of the chloroether added dropwise with stirring. Sodium chloride precipitated at once. The mixture stood overnight and was diluted with an equal volume of water. The top layer was separated, washed with water, dried over potassium carbonate, and fractionated at 100 mm., a 1° cut being taken. There was always a considerable amount of a low boiling fraction, apparently the formal. The boiling points of the best fractions were determined with a Cottrell apparatus with a calibrated thermometer and analysis for sulfur made by a Parr bomb.

A sample of the diethyl monothioformal was refluxed for eight hours and distilled. The boiling point and other properties were unchanged. Into a 90-g. sample (0.75 mole) about 1% of hydrogen chloride was passed. It was refluxed for eight hours, moisture being excluded. Fractionation separated it into two main fractions: (1) 30 g. (0.29 mole) boiling at 85–89° at 760 mm., d^{25}_4 0.8301, n^{25}_D 1.3715; and (2) 48.5 g. (0.36 mole) boiling at 186° and containing 45.87% sulfur, yielded a sulfone, m. p. 103°. Ethylal has b. p. 88° and d^{20}_4 0.8318 and diethyl methylene mercaptal has b. p. 184°, 47.07% sulfur, and gives a sulfone, m. p. 104°.[4]

To 148 g. of the dipropyl monothioformal the Grignard reagent from 137 g. of butyl bromide in ether was added and the mixture refluxed for four hours. By working this up in the usual way 86% of the monothioformal was recovered with unchanged properties and tests for mercaptan were negative. In a second experiment 120 g. of the diethyl derivative was treated with ethylmagnesium bromide, the ether distilled off, and the residue heated to 100° for five hours. The product was worked up as usual and fractionated. The first fraction was ethyl mercaptan, identified by the α-anthraquinone thio ether.[5] The second fraction had b. p. 63.5°, d^{25}_4 0.7360, n^{25}_D 1.3745 which identified it as ethyl *n*-propyl ether, b. p. 61.4, d^{20}_4 0.732, n^{20}_D 1.3695. The third fraction, 71–78° at 100 mm. was the unreacted thioformal and accounted for 70% of that taken.

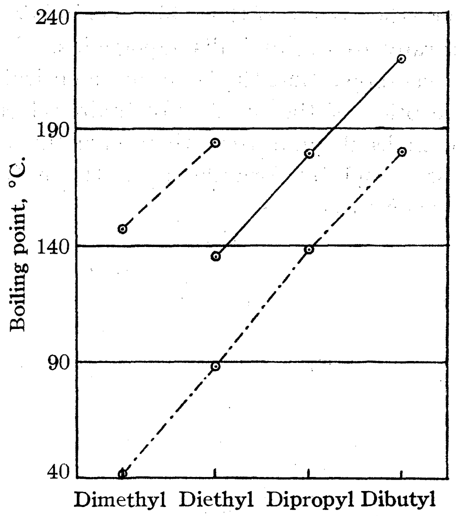

Fig. 1.—Boiling points: monothioformals ————; dithioformals - - - - - -; formals — - — - - - -.

Summary

1. Diethyl, di-*n*-propyl and di-*n*-butyl monothioformals were prepared by treating the sodium mercaptide with the chloromethyl alkyl ether, and their physical properties were determined.

2. A monothioformal, heated with hydrogen chloride, rearranges into a formal and a dithioformal.

3. They react, but not readily, with ethylmagnesium bromide.

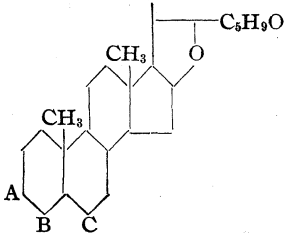
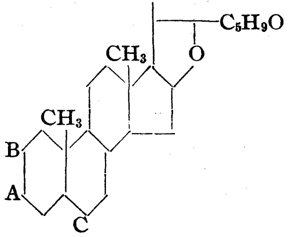
Saponins and Sapogenins. V. Oxidation Products and Structure of Chlorogenin

BY C. R. NOLLER

Chlorogenin, one of the two sapogenins isolated from the hydrolysis products of extracts of *Chlorogalum pomeridianum*[1] has the empirical formula $C_{27}H_{44}O_4$.[2] It is therefore isomeric with gitogenin and like gitogenin contains two hydroxyl groups and two oxygen atoms having non-reactive linkages which are assumed to be oxidic. Since the other sapogenin accompanying chlorogenin is apparently identical with tigogenin, which accompanies gitogenin and digitogenin in the hydrolysis products of extracts of digitalis, it was further assumed that chlorogenin is related structurally to the digitalis sapogenins. Recent work[3] has shown that the latter are identical with the exception of the number of hydroxyl groups in the molecule and that their structures may be represented by formula I or II, preference being given to II.



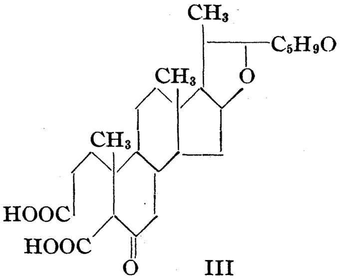
I



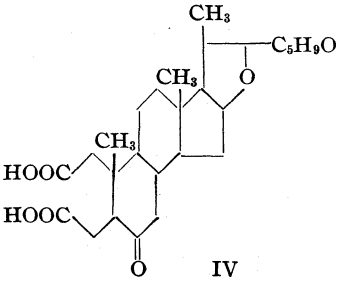
II

Tigogenin has its one hydroxyl group at A, gitogenin's two are at A and B, and digitogenin's three at A, B and C. A third sapogenin of unknown structure but isomeric with gitogenin is also present in the hydrolysis products of digitalis extracts, since Windaus and Shah[4] report the isolation from the oxidation products of crude digitogenin of a diketone, $C_{27}H_{40}O_4$, which is not the diketone corresponding to gitogenin.

It was thought that chlorogenin might have structure I or II with its two hydroxyl groups at A and C. If this were the case one might expect to find digitogenic acid, III or IV, in the oxidation products since opening of ring I might take place on either side of A with simultaneous conversion of the secondary hydroxyl group at C to a carbonyl group.



III



IV

On the other hand, it was conceivable that chlorogenin was identical with the unknown sapogenin of Windaus and Shah, in which case their diketone would be obtained on oxidation.

Oxidation of chlorogenin by the procedure of Kiliani and Merk[5] for the preparation of digitogenic acid showed that neither of these possibilities is actually the case. Both a diketone, $C_{27}H_{40}O_4$, and a ketodibasic acid, $C_{27}H_{40}O_7$, were obtained but they were not identical with the previously reported diketone or with digitogenic acid.

Since a diketone is formed, both hydroxyl groups in chlorogenin must be secondary. The diketone forms a dioxime but only a mono-*o*-phenylenediamine derivative which is not a quinoxaline. This shows that the two ketone groups are not adjacent and indicates that one is

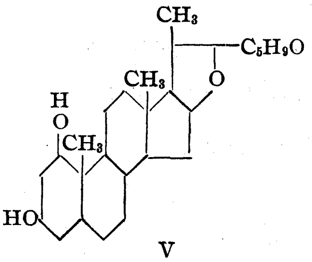
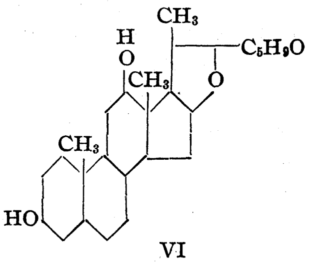
sterically hindered. The pure diketone on further oxidation gives the same ketodibasic acid obtained by the direct oxidation of chlorogenin so that the diketone is probably an intermediate in the formation of the acid. The dibasic acid gives a dimethyl ester which is readily saponified to the original acid indicating that neither carbomethoxy group is sterically hindered. Chlorogenin is not precipitated from alcoholic solutions by digitonin but if the diketone is reduced with sodium and alcohol, a small amount of material is obtained which is slowly precipitated by digitonin.[6] This indicates that one of the hydroxyl groups in chlorogenin is at A but that the configuration is the opposite of that present in cholesterol.[7]

Assuming that the side chain has the same structure as that in the digitalis sapogenins, a consideration of the above data leads to formulas V and VI as being the most likely for chlorogenin. Because of the small amount of the ketodibasic acid that has been available it has not been possible to determine its structure but it does not appear to be either an α- or β-keto acid so that formula VI is favored.



V



VI

Experimental

Oxidation of Chlorogenin.—In a typical run 5 g. of chlorogenin, m. p. 277–279°, was covered with 50 cc. of glacial acetic acid, the flask placed in a pan of water and 40 g. of the sodium dichromate–sulfuric acid oxidizing mixture of Kiliani and Merk[5] added in small portions with shaking during the course of two or three minutes. The chlorogenin goes into solution almost completely and then the product begins to precipitate. After standing overnight the product was filtered, washed with 30% acetic acid until the filtrate was colorless, and then thoroughly with water.

Diketone, $C_{27}H_{40}O_4$.—The moist oxidation product was taken up in 200 cc. of benzene and extracted twice with 5% sodium carbonate solution and once with water. The cloudy benzene solution settled on standing overnight and was decanted. Concentration on the steam-bath to 30 cc., filtering hot and cooling gave 1.7 g., m. p. 233–235°. Evaporation of the mother liquor to dryness gave 1.1 g., m. p. 230–235°. The product is too soluble in benzene or dioxane for good crystallization, but crystallizes well from methyl alcohol, ethyl alcohol and acetone. After repeated recrystallization from all three solvents the fine needles shrink at 236° and melt at 247–248°; $[\alpha]^{22}_{D}$ − 69.6, $[\alpha]^{22}_{546.1}$ −81.4 in dioxane. The diketone appears to be dimorphous as it sometimes melts sharply at 236–238° and the melting point is not raised by further recrystallization.

Anal.[8] Calcd. for $C_{27}H_{40}O_4$: C, 75.67; H, 9.40. Found: C, 75.37; H, 9.45.

Dioxime, $C_{27}H_{42}O_4N_2$.—A mixture of 0.1 g. of diketone and 0.14 g. of crystalline sodim acetate was dissolved in boiling alcohol, and 0.07 g. of hydroxylamine hydrochloride added. After refluxing for four hours, the solution was poured into water, washed and dried in air. After several recrystallizations from absolute ethyl acetate, it melted at 242–243°. An alcoholic solution of the dioxime does not react with solutions of nickel salts.

Anal. Calcd. for $C_{27}H_{42}O_4N_2$: C, 70.72; H, 9.22; N, 6.11. Found: C, 70.70; H, 9.15; N. 5.80.

o-Phenylenediamine Derivative, $C_{33}H_{46}O_3N_2$.—A solution of 0.08 g. of diketone and 0.04 g. of *o*-phenylenediamine in 5 cc. of alcohol was refluxed for one hour. On cooling, tan colored crystals separated which melted at 254–261° with decomposition to a red oil. Repeated crystallization from alcohol gave a pale yellow product which melted at 255–261° when heated slowly but melted at 265–267° when the capillary tube was placed in a bath preheated to 255°.

Anal. Calcd. for $C_{33}H_{44}O_2N_2$: C, 79.16; H, 8.85; N, 5.59. Calcd. for $C_{33}H_{46}O_3N_2$: C, 76.40; H, 8.95; N, 5.40. Found: C, 76.30; H, 8.90; N, 5.26.

Ketodibasic Acid, $C_{27}H_{40}O_7$.—The sodium carbonate extracts of the crude oxidation product were acidified with 15% hydrochloric acid. Only the first extract gave a precipitate, which was filtered, washed and dried in air. There was obtained 0.109 g., m. p. 196–200°. This acid is insoluble in benzene, very soluble in dioxane and soluble in hot acetone, ethyl acetate and chloroform. It does not crystallize well from any of these solvents or their mixtures with benzene. It is very soluble in acetic acid but crystallizes well from hot concentrated solutions. The combined acid fractions from several oxidations after repeated crystallization from acetic acid melted at 235–237° with decomposition and preliminary shrinking; $[\alpha]^{22}_{D}$ − 42.8, $[\alpha]^{22}_{546.1}$ − 49.0 in dioxane. As the analyses show, this product, which was dried by allowing it to stand for several weeks in a vacuum desiccator over potassium hydroxide, contains one molecule of acetic acid of crystallization.

---

(6) We are indebted to Mr. F. M. McMillan for this information.

(7) Fernholz, *Z. physiol. Chem.*, **232**, 97 (1935).

(8) All carbon, hydrogen and nitrogen analyses are by Dr. A. Schoeller, Berlin.

Anal. Calcd. for $C_{25}H_{38}O_3(COOH)_2 \cdot CH_3COOH$: C, 64.91; H, 8.26; neut. equiv., 178.7. Found: C, 65.89; H, 8.53; neut. equiv., 176.1.

The solutions from the above determinations of neutralization equivalent were evaporated to a small volume on the steam-bath, diluted to 25 cc. with water, filtered and acidified with 0.05 *N* hydrochloric acid. The precipitate was filtered on a hardened paper and washed with hot water until free of chlorides. After drying it melted at 234–236° and analysis showed it to be free of acetic acid.

Anal. Calcd. for $C_{25}H_{38}O_3(COOH)_2$: C, 68.05; H, 8.46; neut. equiv., 238.3. Found: C, 68.03; H, 8.30; neut. equiv., 240.5.

In order to determine whether this dibasic acid was derived from the diketone, 3.5 g. of pure diketone was covered with 35 cc. of acetic acid and treated with 28 g. of the oxidizing mixture of Kiliani and Merck. After fifty-two hours the product was filtered and washed, and amounted to 0.8 g. The filtrate was diluted to 1 liter and filtered. The light green precipitate was dissolved in 15 cc. of hot glacial acetic acid and poured into 500 cc. of water. The precipitate after drying weighed 0.5 g. The total product of 1.3 g. was dissolved in benzene, extracted with sodium carbonate solution and the extract acidified. After filtering, washing and drying, the acid fraction weighed 0.3 g. and melted at 210–215°. After recrystallization from acetic acid it melted at 235–237° with decomposition and did not depress the melting point of the acid obtained by the direct oxidation of chlorogenin.

Dimethyl Ester of Ketodibasic Acid.—A solution of diazomethane in ether was added in excess to 0.3 g. of the dibasic acid containing acetic acid of crystallization. On evaporation of the ether an oil remained which soon solidified. It was soluble in methyl alcohol and acetone and only slightly soluble in petroleum ether, but crystallized well from 60–70° ligroin. After two crystallizations it melted at 158–159°; $[\alpha]^{22}_{D}$ − 39.1, $[\alpha]^{22}_{546.1}$ − 46.5. These rotations were microdeterminations which are not as accurate as the macro determinations made on the diketone and ketodibasic acid. Titration showed the product to contain no free carboxyl groups.

Anal. Calcd. for $C_{25}H_{38}O_3(COOCH_3)_2$: C, 69.02; H, 8.78; sap. equiv., 252.2. Found: C, 68.76; H, 8.55; sap. equiv., 256.5.

The acid recovered from the determinations of saponification equivalent did not depress the melting point of the original ketodibasic acid.

Summary

A tentative structural formula for chlorogenin is proposed which is based on the products of oxidation with dichromic acid.

Identification of Alcohols by 3-Nitrophthalic Anhydride[1]

BY G. M. DICKINSON, LEO H. CROSSON AND J. E. COPENHAVER

The use of 3-nitrophthalic anhydride as a reagent for the identification of alcohols was suggested by Nicolet and Sachs,[2] who prepared esters from this acid with nine of the lower alcohols. Ashdown and Monier[3] gave an extensive discussion of the use of this reagent at the Atlanta Meeting of the American Chemical Society in 1930. There has been much study of the higher alcohols within the last few years and it was thought that an extension of this series would be of interest.

The general procedure of the above workers was followed for the preparation of the acid anhydride reagent and the lower esters, but it was found that certain modifications were necessary for the higher derivatives. Their work and that of others showed that the 2-mono-alkyl esters were the principal product and that the 3-mono-alkyl esters were eliminated by crystallization.

Esters of the lower, less expensive alcohols were prepared by heating 3 g. of 3-nitrophthalic anhydride with approximately 2.5 g. of the alcohol and refluxed in a 50-cc. Erlenmeyer flask for one hour. The same quantities were used up to nonyl alcohol but with the increase in the boiling point of the alcohols, they were heated to 100° for two hours to ensure better esterification. From *n*-decyl to *n*-octadecyl, 3 g. of 3-nitrophthalic anhydride and one of alcohol were dissolved in purified toluene and refluxed for three hours.

Recrystallization of the Esters

As shown by Nicolet and Sachs, the esters from methyl to *n*-butyl were recrystallized from water without hydrolysis.

Upon the addition of water and warming, the esters above propyl separated as oils, which, up to and including *n*-hexyl, crystallized on cooling.

---

(1) This is an extract from the theses presented by Messrs. Dickinson and Crosson in partial fulfilment of the requirements for the Master of Science degree at the University of South Carolina.

(2) Nicolet and Sachs, THIS JOURNAL, **47**, 2348 (1925).

(3) Ashdown and Monier, *Ind. Eng. Chem.*, *News Ed.*, **8**, No. 6, 6 (1930).

The excess anhydride was decomposed by the water and it was separated as the acid by decantation from the insoluble esters, due to its solubility of 2.05 g. per 100 g. of water. Several solvents were tried but a 30% ethyl alcohol solution was found most satisfactory for esters from *n*-amyl to *n*-heptyl. The concentration had to be increased to 40% for octyl and nonyl. For the lower alcohols, three or four recrystallizations gave constant melting points, but for the higher esters it was necessary to repeat the treatment. Those esters prepared in toluene were separated from the solvent by vacuum distillation and the excess anhydride was removed by warming with 300–400 cc. of water. It was found that the best method to cause these to crystallize was to dissolve them in 95% alcohol, cool slowly and dilute to about 50%, taking care that none of the ester separated as an oil. This process was continued until a constant melting compound was obtained. Higher melting points were obtained by cooling the compounds in a desiccator. The yields of the lower alcohols averaged around 70% and for the higher ones from 60–65%.

n-Pentadecyl	122.4–122.6	...	...
n-Hexadecyl	121.4–122.0	...	...
n-Heptadecyl	121.0–121.8	449.3	449.4
n-Octadecyl	118.3–119.2	...	...

[a] Nicolet and Sachs reported on the following esters listed above: Methyl, 152–153°; ethyl, 156–157°; *n*-propyl, 141–142°; isopropyl, 152–153°; *n*-butyl, 146–147°; isobutyl, 182–183°; isoamyl, 165–166°.

There is not as great a difference in the melting points of the higher esters as might be desired to absolutely distinguish them from a near homolog but they are of value in checking with other methods. Mixed melting points of adjacent esters above decyl alcohol gave a lowering of 3 to 5°.

The melting points were determined in a 200-cc. round-bottomed flask with a side-tube for insertion of thermometer. Standard Anschütz thermometers, graduated in 0.1 and 0.2°, were used and the bath was stirred by a motor at such a rate to ensure uniform distribution of heat. These precautions gave corrected melting points. The melting point range was taken from the point the compound softened and began sliding down the tube to complete melting. The molecular weights were determined by titrating the esters, dissolved in 50% alcohol, against 0.1 normal sodium hydroxide.

The alcohols from methyl to butyl were carefully distilled with a standard thermometer over a 1° range. *n*-Butyl was donated by the Commercial Solvents Corporation, amyl to heptyl were purchased from Eastman Kodak Company, and for octyl to octadecyl, the authors are indebted to Dr. E. Emmet Reid of Johns Hopkins University. All alcohols above butyl were used without further purification.

The Structure of Diborane

BY S. H. BAUER

For over a decade numerous structural representations for diborane have been postulated.[1] Unfortunately, the large body of experimental data regarding this substance which accumulated during that period did not permit an unambiguous selection. Only within the past few years has it been realized that the existence of diborane may be accounted for without the introduction of *ad hoc* hypotheses; theoretical justifications based on the currently accepted theories of valence have been formulated[2] favoring the structure initially proposed by Sidgwick.[3] If the assumption relating interatomic distance in molecules with the corresponding "bond-type" be accepted,[4] a determination of the spatial arrangement of the atoms in diborane would lead to definite conclusions regarding its structure. Such a determination was undertaken and successfully carried through by means of an electron diffraction experiment on the vapor.

The Sample.—The diborane used in this investigation (32 cc. of the gas at S. T. P.) was prepared by Dr. Anton B. Burg at the University of Chicago according to the method devised in that laboratory,[5] purified by fractional condensations, and sent to Pasadena by air mail. Since the thermal decomposition of diborane has an induction period of several days, very little decomposition could have taken place during the time of transit (*circa* twenty-six hours) during which the sample was at room temperature. This was substantiated by the fact that no non-condensable material was found on opening the tube. Had some decomposition taken place among the resulting products there would have been hydrogen (the others—B_4H_{10}, B_5H_{11}, B_5H_9, $B_{10}H_{14}$, and non-volatile solids). The container was placed in liquid air immediately upon arrival and kept at that temperature except during the runs which lasted about twenty minutes during which the gas was permitted to warm up to temperatures in the neighborhood of $-72°$. All manipulations were carried out according to standard borane technique.

The Photographs.—Using electrons of λ 0.0613 Å., twelve photographs of varying density were obtained showing five to seven rings. The general qualitative features are sketched in Fig. 1. The similarity of the pattern produced by diborane to the one produced by ethane should be noted. Except for a change in the s-scale (due to the larger dimensions of the borane molecule its entire pattern is compressed) the two are identical; both have a faint inner peak followed by a shallow minimum and two poorly resolved intense maxima, the last appearing more like a shelf. The next minimum is deep; the fourth peak is of medium intensity and has a shoulder on the further side; there then follow several troughs and peaks in decreasing intensity somewhat regularly spaced. The contrast with the features presented by the ethylene photographs is apparent.[6]

Analysis.—The visually determined values of s [$= (4\ \pi \sin \theta/2)/\lambda$] for the apparent maxima and minima are given in Table I. These are the averages of measurements made by three observers. In the last column the ratios of the corresponding s-values for ethane and diborane are given. Since the measurements on the two sets

were made by different observers, one would not expect the inner rings to give reliable ratios due to the varying St. John effect. As s gets larger, this ratio assumes the essentially constant value 1.18. An estimate for the B–B separation can thus be made immediately. If the C–C distance in ethane is taken to be 1.55 Å., the corresponding distance in diborane would be roughly 1.55 × 1.18 = 1.83 Å. The above conclusions are in complete accord with the X-ray data on rystals of these two substances vith regard both to the simiarity of the structures and to he interatomic distances.[7]

Results of a six term radial stribution calculation using e tabulated intensities and s-lues are plotted in Fig. 2. e prominent internuclear arations indicated are 1.32, 1.79, and 2.59. is is as good as may be expected from the application of the highly simplified procedure[8] to so light a molecule.

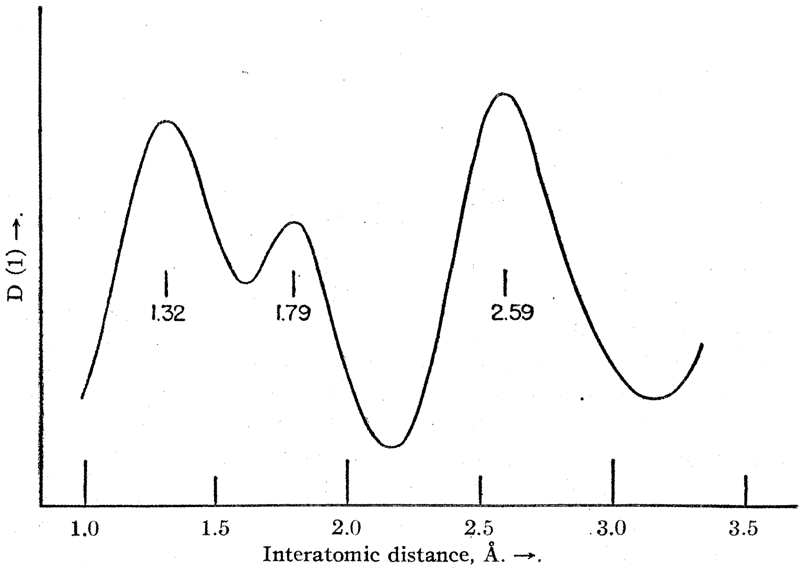

Fig. 2.—Radial distribution curve for diborane.

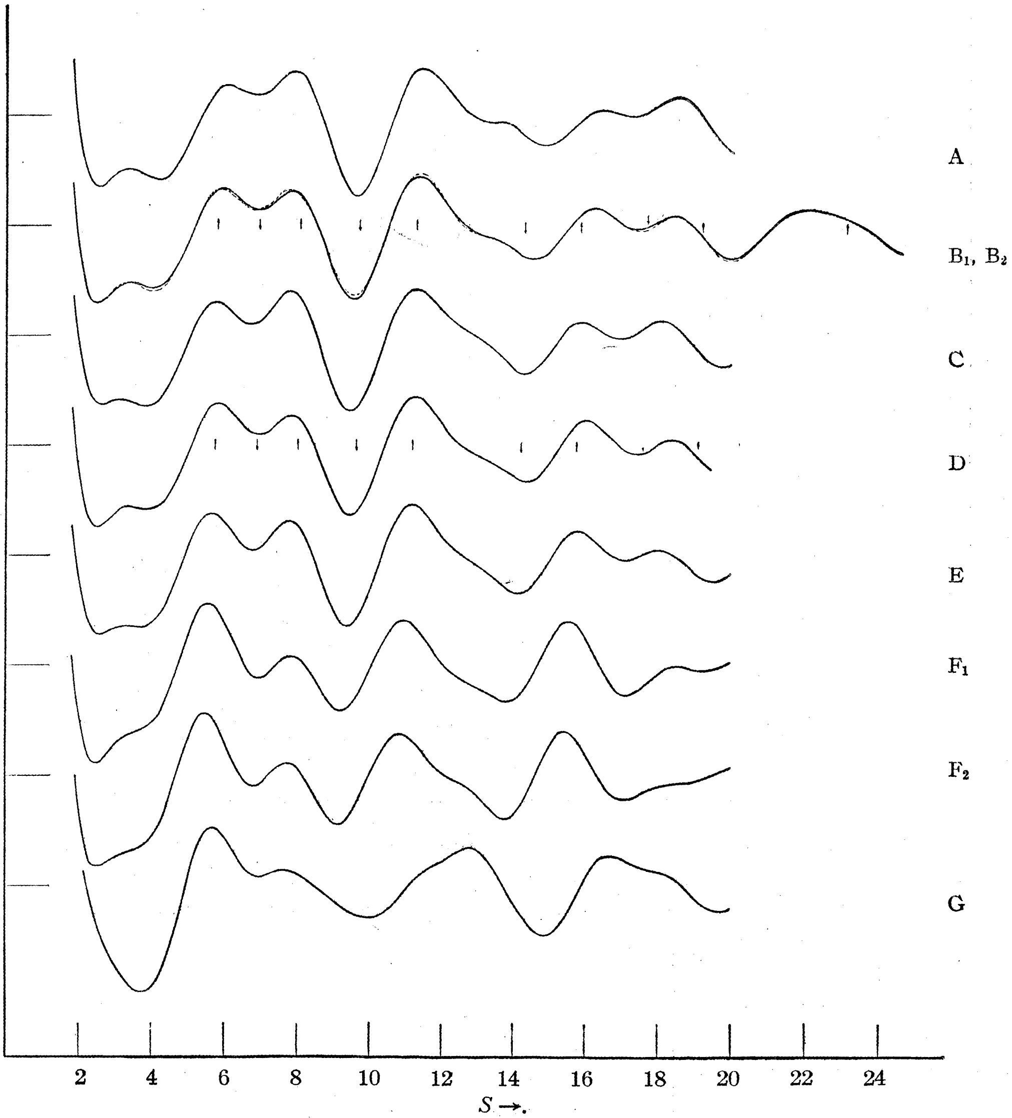

Fig. 3.—Calculated intensity curves. Arrows show best fit with measured ring diameters for models B and D, as obtained from Table I. Curve B_1 is full; B_2 is dashed.

models. Except where explicitly stated, the *cis* (sym. D_{3h}) and *trans* (sym. D_{3d}) orientations were given equal weight. Comparisons of curves B_1 and B_2 conclusively show that the effects on the pattern of free or hindered internal rotation are negligible.[9] In all the models the B–B distance was assumed to be 1.76 Å. except in model G, where it was taken to be 10% less. The curves are shown in Fig. 3.

Model A: Ratio (B–B/B–H) = 1.503 with all angles taken to be tetrahedral.

Eliminated, due to (1) improper intensity relationships between peaks 2 and 3, 5 and 6; (2) prominence of should on the right side of peak 4.

Model B: Ratio = 1.466 with all angles tetrahedr

For curve B_1 (full) equal weights were taken for the and *trans* forms.

For curve B_2 (dashed) only the *trans* position was c sidered.

This model was accepted as the one which gives the qualitative and quantitative agreement with the exp mental data.

Model C: Ratio—the same as for B. The B– angles were assumed to be 113°.

Eliminated, due to (1) improper intensity relation between peaks 2 and 3; (2) the particularly large qua tive discrepancies at the outer rings.

Model D: Ratio = 1.442 with all angles tetrahed

Although this model reproduces very well most qualitative features of the observed diffraction patter

---

[9] For ethane, experimental evidence is available that a potential barrier of the order of 2000–3000 calories restricts freedom of rotation of the methyl groups. See J. D. Kemp and K. S. Pitzer, This Journal, **59**, 276 (1937); J. B. Howard, *Phys. Rev.*, **51**, 53 (1937).

shoulder on the right of peak 4 is too faint. The differences between the final interatomic distances as derived from this model and those obtained from B_1 are of the order of 0.01 Å. (Table I) and hence are well within the experimental error.

Model E: Ratio = 1.431, with the B–B–H angles assumed to be 113°.

Eliminated, due to very poor quantitative agreement at large *s* values.

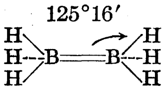
Model F: Ratio = 1.353.

For curve F_1 all angles were assumed to be tetrahedral.

For curve F_2 the B–B–H angles were assumed to be 112°.

Eliminated, due to distinct lack of qualitative and quantitative agreement with data. Model F_2 is the one obtained by taking the distances indicated by the radial distribution curve to correspond to B–H (bonded), B–B, and B–H (non-bonded), respectively.

Model G: Ratio = 1.352. An ethylene-like arrangement with two extra protons.



Eliminated, due to the obvious lack of correspondence with the data.

I found it difficult to construct a spatial model which would correspond unambiguously to the structure proposed by Wiberg.[1] If the distribution of H nuclei is the same as in ethane but with two boron atoms connected by a double bond, the ratio (B–B/B–H) would equal 1.351, *i. e.*, essentially model F_1 which may be eliminated as indicated. If the hydrogen atoms are distributed as shown in model G, the Wiberg structure may be equally well discarded. Indeed, it appears impossible to formulate a model having the two boron atoms doubly bonded which would result in a molecule large enough to produce diffraction rings of the observed diameters. Unfortunately the rings are not sufficiently sharp to warrant treating the data by means of the analytic method.[10]

Comparison of the various theoretical intensity curves with the one observed (Fig. 1) eliminates models A, C, E, F, and G. D has the defect of not indicating a sufficiently prominent shoulder on peak 4, whereas B reproduces well all the qualitative features of the observed pattern and is in good quantitative agreement with the data (Table I). This model corresponds to an ethane-like structure with the ratio of (B–B/B–H) equal to 1.466. From the values of $s_{\text{obsd.}}$ and $s_{\text{calcd.}}$ the following conclusions regarding the dimensions of diborane are deduced: (a) The atoms are arranged in the form of two pyramids (axes coincident), their apices, at which the boron atoms are located, pointing toward each other. (b) The B–B distance is 1.86 ± 0.04 Å.; the B–H distance is 1.27 ± 0.03 Å. (The probable errors indicated were taken somewhat larger than the weighted mean deviation as calculated in Table I.) (c) The valence angles of the boron atoms are tetrahedral to within three degrees. The correspondence of these results with the ones obtained through the comparison of the patterns of ethane and diborane should be noted.

Discussion.—The nuclear configuration found for diborane by the electron diffraction method can be immediately interpreted in terms of the nature of the bonds in the molecule. This is done below; a further more detailed description of the electronic structure of the molecule from the valence-bond and the molecular-orbital points of view is also given, followed by a discussion of the chemical and physical properties of the substance.

The tetrahedral radius for a boron atom with a completed octet has been assigned the value 0.89 Å.,[11] from extrapolation of the sequence F, O, N, C; this value is also indicated by the comparison of BH with CH and other diatomic hydrides. We accordingly would expect for the B–B and B–H single bond distances 1.78 and 1.18 Å., respectively. In the two cases which have been studied experimentally the boron atoms did not possess completed octets, yet dimensions of this order or somewhat smaller were observed; thus the B–B distance in CaB_6 is 1.716 Å.,[12] and in B_5H_9 an average value of 1.76 Å. is obtained.[13] In the molecule BH the B–H separation is found to be 1.226 Å. While it is generally true that in the diatomic hydrides the internuclear distance is greater than in the corresponding polyatomic hydride molecules (C–H = 1.09 in CH_4, 1.12 in CH), in diborane the situation is reversed. *Actually, the values for the B–B and B–H distances in* B_2H_6 *are both considerably larger than the single-bond separations, showing that all the bonds in the molecule have to some extent the character of bonds weaker than "single" bonds.* This is expected for the B–H bonds on the basis of Sidgwick's structure  $\begin{matrix} & \mathrm{H} & & \mathrm{H} & \\ \mathrm{H}\cdot & \ddot{\mathrm{B}} & : & \ddot{\mathrm{B}} & \cdot\mathrm{H} \\ & \ddot{\mathrm{H}} & & \ddot{\mathrm{H}} & \end{matrix}$, which gives each B–H two-thirds single-bond and one-third one-electron-bond character; a slight extension of this configuration considering resonance to structures such as

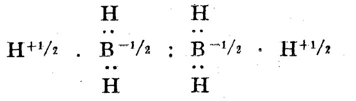
$\mathrm{H}\cdot\underset{\ddot{\mathrm{H}}}{\overset{\mathrm{H}}{\ddot{\mathrm{B}}}}\cdot\underset{\ddot{\mathrm{H}}}{\overset{\mathrm{H}}{\ddot{\mathrm{B}}}}:\mathrm{H}$ also would further account for the observed increase of the B–B bond distance. The observed distances are equally compatible with Lewis' structure, representing resonance among the seven arrangements $\mathrm{H}:\underset{\ddot{\mathrm{H}}}{\overset{\mathrm{H}}{\ddot{\mathrm{B}}}}\ \underset{\ddot{\mathrm{H}}}{\overset{\mathrm{H}}{\ddot{\mathrm{B}}}}:\mathrm{H}$, $\mathrm{H}\,\underset{\ddot{\mathrm{H}}}{\overset{\mathrm{H}}{\ddot{\mathrm{B}}}}:\underset{\ddot{\mathrm{H}}}{\overset{\mathrm{H}}{\ddot{\mathrm{B}}}}:\mathrm{H}$, etc., and giving each bond $^6/_7$ single-bond character and $^1/_7$ no-bond character. However, strong theoretical arguments may be given to support the view that *the molecule resonates among all the structures of the Sidgwick and Lewis types*, the B–B and the B–H bonds having single-bond, one-electron-bond, and no-bond character.

It is especially significant that shortening the B–B distance below the single-bond value, as would be required for any structure giving the B–B bond some double-bond character, is not observed. This eliminates all structures such as Wiberg's.

In the language of atomic orbitals the structure of diborane should therefore be described as follows: The allowed orbitals for boron are four in number, of the hybridized sp^3 type, directed toward the corners of a tetrahedron. Each of these may be occupied by a shared electron-pair, by a single electron, or left empty. Thus the valence-bond configurations which contribute to the ground state are (formal charges indicated):

I



$$\begin{array}{ccccccc} & & \mathrm{H} & & \mathrm{H} & & \\ & & \cdot\cdot & & \cdot\cdot & & \\ \mathrm{H}^{+1/2} & . & \mathrm{B}^{-1/2} & : & \mathrm{B}^{-1/2} & \cdot & \mathrm{H}^{+1/2} \\ & & \cdot\cdot & & \cdot\cdot & & \\ & & \mathrm{H} & & \mathrm{H} & & \end{array}$$

(6)

so that the wave function of diborane may be represented approximately by a linear combination of the wave functions of the above structures. The question as to their relative weights will be discussed later; nevertheless, it is evident that the contributions of the structures II and III will tend to weaken the B–B bond. Combination of II and IV alone gives the arrangement proposed by G. N. Lewis.[15] His description requires that all the electrons remain paired but not that they occupy all the orbitals simultaneously. Through this argument he was led to predict the diamagnetism and characteristic weak bonds of diborane.

Although the individual members of the structural types II, IV, and V do not have the symmetry which we associated with diborane (D_{3d}),

---

(14) Justification for writing structures of type I, that is, configurations involving a one-electron bond between B_2H_5 and H, has already been presented [L. Pauling, THIS JOURNAL, **53**, 3225 (1931)]. Professor Pauling then estimated that the coulomb attraction, at small distances, of $B_2H_5^-$ and H^+ may contribute as much as 10 or 11 volts to the energy of the aggregate. In order to justify structures of type II wherein a one-electron-bond is placed between the two BH_3 groups one must show that the systems (a) $BH_3^+ + BH_3^-$ (when in valence state), and (b) $BH_3 + BH_3$ (when in valence state) have energies which are nearly equal at small internuclear separations. The following rough estimates indicate that this is the case.

In (a): The ionization potential of a BH_3 radical when in its ground state ($[sa_1]^2\ [\pi e]^4$, $^1A_1$) may be taken equal to 12.6 volts. This value was suggested by Prof. Mulliken on the ground that the energy of removal of a $[\pi]$ electron (B–H bonding) should be approximately the same when in a free BH_3 group as when in B_2H_6. The configuration of the ion is $[sa_1]^2\ [\pi e]^3$. On the other hand, the electron affinity of a BH_3 radical (closed shell structure) must be rather close to zero; the capture of an electron leads to the ion BH_3^-, $[sa_1]^2\ [\pi e]^4\ [\sigma a_1]$. If the contribution of the coulomb energy of the two ions at small separations is taken to be ten volts, as in the case of $B_2H_5^-$ and H^+, the energy of the resulting aggregate is in the neighborhood of 2–3 volts above that of two BH_3 ($^1A_1$) groups. On very close approach these will combine to form the molecule B_2H_6, $[sa_1]^2\ [sa_1]^2\ [\pi e]^4\ [\pi e]^3\ [\sigma + \sigma, a_{1g}]$, $^{1,3}E_g$, etc. If a $^1A_1$ state is desired for the final diborane the process which must be followed is described schematically

$$\left.\begin{array}{l} \mathrm{BH_3(^1A_1)} \xrightarrow{12.6\mathrm{v}} \mathrm{BH_3}^+,\ ([sa_1]^2\ [\pi e]^3 \xrightarrow{4\mathrm{v}} \\ \qquad\qquad\qquad\qquad (\mathrm{BH_3}^+)^*,\ ([sa_1]\ [\pi e]^4) \\ \\ \mathrm{BH_3(^1A_1)} \xrightarrow{0\mathrm{v}} \mathrm{BH_3}^-,\ ([sa_1]^2\ [\pi e]^4\ [\sigma a_1]) \end{array}\right\} \xrightarrow{-10\mathrm{v}}$$

$$\underbrace{(\mathrm{BH_3}^+)^* + \mathrm{BH_3}^-}_{\text{is approximately seven volts above two } \mathrm{BH_3}\ (^1\mathrm{A_1}) \text{ groups.}} \longrightarrow (\mathrm{B_2H_6})^*,\ [sa_1]\ [sa_1]^2\ [\pi e]^4\ [\pi e]^4\ [\sigma + \sigma, a_{1g}],\ {}^1\mathrm{A_{1g}}, \text{ etc.}$$

In (b): Since the combination of two BH_3 radicals results in repulsive states only, it is necessary to excite one of them to the configuration $(BH_3)''$, $[sa_1]^2\ [\pi e]^3\ [\sigma a_1]$. This process requires an energy equivalent to 2–3 volts. Hence the resulting aggregate is near in energy to that obtained above from the close approach of the unexcited ions, *i. e.*, leading to B_2H_6, $^{1,3}E_g$, etc. Again, if a $^1A_1$ state is desired for the diborane molecule, the corresponding schematic process is

$$\left.\begin{array}{l} \mathrm{BH_3(^1A_1)} \xrightarrow{2\text{–}3\mathrm{v}} (\mathrm{BH_3})'',\ ([sa_1]^2\ [\pi e]^3\ [\sigma a]) \xrightarrow{4\mathrm{v}} \\ \qquad\qquad\qquad\qquad (\mathrm{BH_3})''^*,\ ([sa_1]\ [\pi e]^4\ [\sigma a]) \\ \mathrm{BH_3(^1A_1)} \end{array}\right\} \xrightarrow{0\mathrm{v}}$$

$$\underbrace{(\mathrm{BH_3})''^* + \mathrm{BH_3}}_{\text{is approximately 6–7 above two unexcited } \mathrm{BH_3} \text{ groups.}} \longrightarrow (\mathrm{B_2H_6})^*,\ {}^1\mathrm{A_{1g}}, \text{ etc.}$$

(15) G. N. Lewis, *J. Chem. Phys.*, **1**, 17 (1933).

symmetric and antisymmetric linear combinations of the six components of each type will result in two configurations of equal energy, one of which (the symmetric) may be used in further combinations with I and III. The latter interaction will cause the energy of the over-all symmetric combination to be lowered and of the remaining antisymmetric one to be raised, so that the ground state of diborane will be of the A_1 type. Let us now attempt to deduce its multiplicity. Structures III and IV are in singlet states; I, II, and V may have the spins of the electrons participating in the one-electron-bonds either parallel or antiparallel, but only when in the latter arrangement are the structures permitted to combine with III and IV.[16] The relative energies of the singlet and triplet states of the structures belonging to the Sidgwick configuration will vary with the different types, but this we cannot estimate in the present treatment. However, since the interaction of the structures having resultant spin zero with the ones belonging to the Lewis configuration will give a state whose energy is lower than that of either configuration alone, we may conclude that the ground state will be singlet, *i. e.*, that diborane has a ground state ($^1A_1$) which is diamagnetic, as observed, and a low-lying paramagnetic state ($^3A_2$) whose existence has not yet been verified.

Professor Mulliken has already given a molecular orbital treatment of this and related molecules.[2] The present data make possible unambiguous decisions for several questions arising in that discussion, the answers for which heretofore could be only surmised. Very roughly, the following configurations may be correlated with the various structures listed above[17] (omitting the 1s electrons of boron):

IM $[s + s, a_{1g}]^2\ [s - s, a_{2u}]^2\ [\sigma + \sigma, a_{1g}]^2\ [\pi e]^3\ [\pi e]^3$, $^1A_{1g}$, etc. with I

IIM $[s + s, a_{1g}]\ [s - s, a_{2u}]^2\ [\sigma + \sigma, a_{1g}]\ [\pi e]^4\ [\pi e]^4$, ^1A_1g, etc. with II

IIIM $[sa_1]^2\ [sa_1]^2\ [\pi e]^4\ [\pi e]^4$, $^1A_{1g}$ with III

IVM $[s + s, a_{1g}]^2\ [s - s, a_{2u}]^2\ [\sigma + \sigma, a_{1g}]^2\ [\pi e]^4\ [\pi e]^2$, $^{1,1}A_{1g}$, etc. with IV + V

where the $[\sigma + \sigma]$ electrons are mainly B–B bonding and the others are essentially confined to the B–H bonds (the $[s + s]$ electrons also contribute to the B–B bond).

It will be noted that whole-molecule orbitals were written for the $[sa_1]$ electrons in IM, IIM, and IVM, whereas this was not done for the $[\pi e]$ electrons. The reason is evident. Since the former are nearly but not entirely confined to the BH_3 groups, while the $[\sigma + \sigma]$ electrons, although strongly B–B bonding, also assist in the B–H bonds, their wave functions overlap, so that a hydridization (between the $[s + s]$ and $[\sigma + \sigma]$) which becomes possible only after the linear combination of the $[sa_1]$ orbitals is made, would result in a somewhat better representation of the electron configuration. As in ethane, this interaction will cause the $[\sigma + \sigma]$ electrons to have a somewhat lower ionization potential and the $[s + s]$ electrons a correspondingly higher one. Similarly, the use of whole-molecule orbitals $[\pi + \pi, e_u]$, $[\pi - \pi, e_g]$ would indicate a resonance between the $[\pi e]$ electrons of the two BH_3 groups. This would necessitate that the $[\pi]$ bonding be very strong, and that there be considerable overlapping of their wave functions in the region between the boron atoms, introducing effectively a double bond contribution. Each of the BH_3 groups would then have a tendency to be planar. The observed spatial structure is distinctly contrary to such an hypothesis. The B–H as well as the B–B distances are larger than might have been expected even for pure single bonds, and the BH_3 groups are pyramidal. Indeed this state of affairs was anticipated by Mulliken on the basis of the fact that diborane does not have an absorption region in the visible. Hence,[2] his configurations 1a, 2a, and 3a are definitely eliminated. In IIIM the $[sa_1]$ electrons were placed in the radical orbitals since this arrangement corresponds to repulsion between the BH_3 groups.

The question arises whether all the states listed have sufficiently low energies to contribute appreciably to the ground state. By correlating, respectively, the IM and IIIM configurations with the two $^1A_1$ ($[sa_1]^2\ [\pi e]^4$) and two ^3E ($[sa_1]^2\ [\pi e]^3\ [\sigma a_1]$) states of the separated BH_3 groups, Mulliken was able to estimate that the unperturbed levels corresponding to the $^1A_{1g}$ states of IM and IIIM would be approximately one volt apart and that the interaction energy would be of the order of one-half volt. The energy of con-

---

[16] For the resonance criteria among several structures see L. Pauling, THIS JOURNAL, **54**, 988 (1932).

[17] For the present, configurations giving rise to $^1A_1$ states will be considered since only these are permitted to interact with the structures which appear to give the largest contribution to the ground state (I and III). The correlations indicated to the right refer to the symmetric linear combinations of the individual members of the particular type.

figuration IVM is probably slightly above that of IM since in going from the latter to the former an electron is merely transferred from a $[\pi]$ orbital of one BH_3 group to the same orbital in the other. State IIM, however, is highly excited. The corresponding unexcited one is given by Mulliken

$$\text{IIM}\ [s+s, a_{1g}]^2\ [s-s, a_{2u}]^2\ [\sigma+\sigma, a_{1g}]\ [\pi e]^4\ [\pi e]^3,\ {}^{1,3}E_g, \text{ etc.}$$

Since the ionization potential of the $[s]$ electrons was estimated at approximately 17 volts while that of the $[\pi]$ electrons only 12.6 volts and of the $[\sigma + \sigma]$ at 13.0 volts,[2,18] IIM lies far above IIm. The latter cannot interact with IM, IIIM, and IVM while the former may but can contribute only slightly to the ground state due to the fact that it is so far removed from the other components. Hence, when diborane is in its lowest energy state, its structure may best be represented by a combination of the configurations IM, IIIM, and IVM with very little of IIM. (IIIM must make an appreciable contribution in order that the large B–B separation may be accounted for.) Let us now return to the atomic orbital treatment and specify that the magnitudes of the coefficients in the linear combination for the wave function of diborane are probably in the order: I, III, IV, and V with very little of II (excited).

The compounds B_4H_{10} and B_5H_{11} which presumably have chain-like structures should have electron configurations, and B–B and B–H distances entirely analogous to those found in diborane, as contrasted with the ring structure of B_5H_9.[13]

Discussion of the Physical Properties.—Four physical constants of diborane have been measured. These are quoted by Wiberg[1] in support of his structure. Let us see how they may be interpreted in terms of the structure given by the electron diffraction study.

(1) **Diamagnetism.**—The ground state of the configuration discussed above is of the singlet symmetric type and hence is diamagnetic.

(2) **Lack of Electric Dipole Moment.**—Both Profs. Pauling and Mulliken stressed the fact that in their formulation (as in the amplified one presented in this paper) all the hydrogen atoms are equivalent. Diborane consequently should have no moment.

(3) **Similarity of Ultraviolet Absorption Spectrum to that of Ethylene.**—The deduction that in diborane the boron atoms are doubly bonded from the similarity of its ultraviolet absorption spectrum to that of ethylene is fallacious. An explanation of the two continuous regions of absorption on the basis of Mulliken's electron configuration (which is essentially the one given in this analysis) has been suggested by E. Blum and G. Herzberg.[19]

Professor Mulliken reports [*J. Phys. Chem.*, February, 1937] that diborane shows no absorption in the near ultraviolet, visible, and photographic infrared (λ2500–λ12,000). This is somewhat puzzling since various low-lying electronic levels to which transitions from the ground state are not forbidden have been predicted.[2]

(4) **Parachor.**—Stock and collaborators made a careful determination[20] of the surface tension and density of diborane. As far as the author is aware, this is the first investigation of its kind which has been carried out on a compound the structure of which must be represented by one-electron-bonds resonating with electron-pair-bonds. Since the contribution to the parachor of any type of bond can only be determined experimentally, one cannot draw any conclusions regarding the structure of this compound from the value of its surface tension. Deductions made from phosphorus and arsenic pentachlorides (which gave the value -12.4, employed by Wiberg, in obtaining the parachor of the Sidgwick structure) are entirely without foundation since most chemists believe that the latter molecules have no "singlet" bonds. However, the work of Stock and collaborators would permit one to calculate an appropriate number which might be used in future structure determinations.

Wiberg admits[1] that the available chemical evidence is in harmony with the Sidgwick configuration. The modifications introduced by Pauling, Mulliken and in the present discussion do not alter this state of affairs. Since the types of bonds found in diborane and its homologs are essentially unlike those in other molecules ordinarily dealt with by chemists one cannot safely reason by analogy. Predictions as to how such molecules behave chemically can be made only after sufficient empirical data have been gathered.

Resonance Energy of Diborane.—The heat of formation of diborane from solid boron and molecular hydrogen was recently determined to

---

[18] A similar inequality amounting approximately to eight volts is given for ethane; R. S. Mulliken, *J. Chem. Phys.*, **3**, 517 (1935).

[19] E. Blum and G. Herzberg, *J. Phys. Chem.*, **41**, 91 (1937).

[20] A. Stock, E. Wiberg and W. Mathing, *Ber.*, **69**, 2811 (1936).

be 44 ± 3 kcal.[21] We are now in a position to make an estimate of the resonance energy in diborane. Let us first consider the reaction B(s) + $1^1/_2H_2$ = BH_3(g). Since the electronegativities of boron and hydrogen are identical for purposes of calculation there are no heat effects due to the ionic contributions of the bonds. Hence if the solid consists of boron atoms which are bonded to three others by single bonds it is clear from Pauling's additivity rule that the above reaction will be accompanied by a zero heat effect since for every B–H bond which is formed one-half an H–H and one-half a B–B bond will be broken. On the other hand, it appears quite likely that in the solid the boron atoms are tetrahedrally bonded, thus making use of all the orbitals available to them by means of some resonance scheme; then more bonds will be broken in the vaporization process than will be formed in the hydrogenation. Consequently the reaction giving rise to BH_3 radicals will be endothermic by an amount equivalent to the resonance energy present in solid boron. But the heat of formation of diborane from the elements was found to be exothermic. Hence we must conclude that the reaction $2BH_3 = B_2H_6$ is exothermic to the extent of 44 kcal. if the first alternative is assumed or to the extent of 44 kcal. plus the resonance energy available for each pair of atoms in solid boron if the second is preferred.

The stability of B_2H_6 relative to BH_3 or B_2H_4 is due to the resonance energy made possible in the former compound by the complete use of all the four orbitals permitted to boron atoms. From the arguments presented in the preceding paragraph we may estimate that a minimal value for this energy is 44 kcal. and may be set equal to the latter figure plus the resonance energy for a pair of boron atoms in the solid element.

Acknowledgments.—The author expresses the sincerest appreciation to Dr. Anton B. Burg for providing the sample, to Professor Pauling for numerous helpful discussions, to Dr. L. O. Brockway for the use of his diffraction apparatus, and to Mr. H. Levy for aid in taking the electron diffraction photographs.

Summary

Electron diffraction photographs of diborane indicate that this compound has an ethane-like structure with the B–B distance equal to 1.86 ± 0.04 Å. and the B–H distance 1.27 ± 0.03 Å.; the valence angles of the boron atoms are found to be tetrahedral within three degrees. An electron configuration compatible with the large interatomic distances is presented both in terms of the atomic and molecular orbital modes of description and the conclusion is reached that the stability of B_2H_6 relative to BH_3 is due to the resonance energy made available through the full use of the four orbitals of boron.

The Activation of Specific Bonds in Complex Molecules at Catalytic Surfaces. III. The Carbon–Hydrogen and Carbon–Carbon Bonds in Propane and Ethylene

BY KIYOSHI MORIKAWA,[1] N. R. TRENNER[2] AND HUGH S. TAYLOR

The present research represents an extension to propane and ethylene of investigations previously reported by Morikawa, Benedict and Taylor dealing with methane[3] and ethane.[4] In the latter communication attention was directed to an abnormally high inhibitory action of hydrogen on the surface hydrogenation decomposition of ethane to yield methane. We have examined in the present work, in a more detailed manner, the kinetic relations of the decomposition and exchange reactions between propane and deuterium with results which confirm and extend our observations with ethane. Isotope exchange reactions with ethylene are also included as well as other supporting studies leading to a general discussion of the whole problem of activation in such hydrocarbon systems.

Experimental Details

Materials.—In addition to those gases described in the previous papers,[3,4] we have employed propane, ethylene

[4] Morikawa, Benedict and Taylor, *ibid.*, **58**, 1795 (1936).

and propylene. In each case the gases were obtained from cylinder supplies and purified by repeated fractionation. With propane the only likely impurity in the purified sample would be a trace of butane. The ethylene was 100% C_2H_4 within the analytical error. The propylene analyzed 98% C_3H_6, 2% C_3H_8.

Experimental Method.—A static method was employed, essentially the same as that described in Part II but of $\sim$135 cc. reaction volume. After definite reaction times the products were removed by a Töpler pump. About 95% of the gas could thus be removed within five minutes, but fifteen minutes were required to remove all the gas. Temperature control of the reaction was by means of vapor baths.

Analytical Procedure.—Hydrogenation decomposition was followed by the increase in saturated hydrocarbon, $+\Delta$H.C. after removal of hydrogen by combustion over copper oxide at 230°. In some cases, a fractionation method was employed to define the composition of the hydrocarbon products.

The isotope exchange reaction was followed by a determination of the C–D content of the *hydrocarbons*. This was checked occasionally by the D content of the hydrogen. Both analyses were made with a thermal conductivity gage to be described elsewhere.[5] An accuracy of 0.5% in the analyses of the ethanes and propanes and 0.1% for the hydrogens was possible.

Propane and ethane were separated from hydrogen by passage through a liquid-air trap. Traces of hydrogen were removed from the condensate by repeated vaporizations, freezings and evacuations at liquid-air temperature. The final purification of the gases for analysis was by fractional distillation under reduced pressure ($\sim$2 mm.). Details of this fractionation technique will be described in a separate communication[6] since it has general applicability and is essential to our method of analysis by thermal conductivity.

Experimental Results

Exchangeable Hydrogen in a Nickel–Kieselguhr Catalyst.

—It was necessary to determine the extent to which deuterium would exchange with hydrogen sources in a nickel–kieselguhr catalyst in the ranges of temperature in which exchanges with hydrocarbons occur. Two series of experiments detailed in Table I were performed. The same catalyst, 2 g. in weight, $\sim$ 15% Ni, was used in both series. The catalyst was prepared from nickel carbonate precipitated on kieselguhr, by reduction for four hours at 425° followed by evacuation with a mercury diffusion pump system for two hours at the same temperature. Between each experiment the catalyst was washed thoroughly with hydrogen at the reaction temperature and then evacuation, for intervals of time noted in the table, followed. Then $\sim$23 cc. of deuterium was introduced. After definite time intervals the gas was recovered by a Töpler pump and analyzed on the thermal conductivity gage. The experiments in Series II were made after the catalyst had been changed in activity by heating to 500° with evacuation.

These experiments lead to the following conclusions. From Expts. 51 and 52 it is evident that one hour of evacuation is adequate and that equilibrium is also established in one hour. From Expts. 58 and 59 we conclude that thirty-six minutes is not sufficient for equilibrium at 302°. Experiments 53 and 60 show that evacuation at 302° decreases the hydrogen content by 5.5%, but this is still only a fraction of the hydrogen available at 98°. On the other hand, it removes all of the hydrogen available at 55° (see Expts. 104 and 111).

Experiments labelled a, b, c referred to successive experiments without intermediate washing and evacuation.

From the whole series (51–60) we conclude that the amount of hydrogen available increases as the temperature rises, but that the data detailed above indicate two types of available hydrogen, one readily removed by evacuation at high temperature, the other not so removable.

---

[5] N. R. Trenner, *J. Chem. Phys.*, forthcoming paper.

[6] Morikawa and Trenner, THIS JOURNAL, forthcoming paper.

Prior to Expt. 102 four hours of evacuation at 450° yielded 8.4 cc. of water vapor and a further four hours at 500° gave an additional 8.5 cc. After this removal the hydrogen content of the wash gas decreased by 11% at 218° but only by 3% at 55° (*cf.* Expts. 51, 52, 104). From the data of Expts. 102, 103 it is obvious that evacuation at 218° removes all of the more readily available hydrogen.

Assuming an equilibrium constant of 1 between deuterium and the hydrogen source on the catalyst the values for this source are given in the final column of Table I, and represented in curve A, Fig. 1. The calculations are made with the aid of the equation

$$\text{Cc. of available } H_2 = \frac{\text{cc. of } D_2 \text{ introduced (99\% D found)}}{\text{\% D found}}$$

The same volume of hydrogen is recoverable at 218° as at 55°. Experiments detailed in Table II indicate that, in this range of temperature, the activated adsorption of hydrogen decreases as the temperature rises. The amount adsorbed at 0.15 mm. pressure was found to be ~5.5 cc., a value to be compared with 4.5 cc. available at 55° with an evacuation pressure of 10^{-3} mm. as revealed by the exchange reaction. We therefore conclude that the available hydrogen which can be evacuated at 55° is hydrogen gas and that the other available hydrogen which is difficultly removable at higher temperatures results from water. We further conclude that this water does not exist on the nickel surface but is present in the kieselguhr support, the silicates of which hold water with varying degrees of tenacity. These hydrogen sources are quite reproducible and so point to the establishment of equilibria of the type

$$\text{Ni–Kieselguhr } H_2O + D_2 = \text{Ni–Kieselguhr } D_2O + H_2$$

The experimental value of the total available hydrogen at 218° is ~16 cc., which is in agreement with the calculated value of 16 cc. assuming an equilibrium constant $K = 1$. If we use the constant $K = 1.46$ obtained from Farkas' data[7] for the equilibrium between free water and deuterium, a calculated value of 13.6 cc. of available hydrogen would be obtained. We may ascribe the difference in equilibrium constants to the existence of hydrated kieselguhr as the water source.

These conclusions are substantiated by the following two series of experiments. A 2-g. sample of fresh unreduced catalyst was heated to 425° with evacuation and held at that temperature for two hours. It was then cooled and washed with deuterium at room temperature. The catalyst was then gradually raised in temperature in a stream of deuterium to 400°, samples of gas being withdrawn at intervals and analyzed. The deuterium consumed in the reduction was 66.3 cc. and the water frozen out in a carbon dioxide trap corresponded to 60.2 cc. The hydrogen received in the deuterium gas amounted to 16.8 cc. The hydrogen content of the water condensed out was determined by equilibrating the water vapor with deuterium on the catalyst at 138°. In this manner, using $K = 1.46$, we determined in all 22.4 cc. of hydrogen in the water and a total hydrogen in both gas and water of 16.8 + 22.4 = 39.2 cc. If we use $K = 1$ the corresponding amounts are 16.8 + 31 = 47.8 cc., which values determine the upper and lower limits for the total hydrogen.

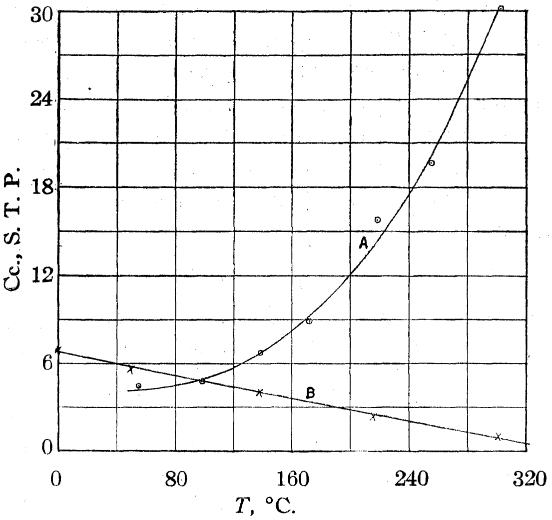

Fig. 1.

The catalyst was then evacuated for two hours at 138° and 56.8 cc. of water vapor was frozen out in the carbon dioxide trap. The catalyst was then well washed with hydrogen at 218° and evacuated for ten hours at the same temperature. The water removed was 7.7 cc., making a total recovered water of 64.5 cc. The close correspondence of this with the deuterium consumption, 66.3 cc., indicates that almost all the water produced in the reduction process could be desorbed at 218°. This implies that the water available in the experiments of the first two series is not water on the nickel surface but in the kiesel-

---

(7) Farkas, "Light and Heavy Hydrogen," p. 180, *et seq.*

guhr. This was confirmed by introducing 22 cc. of deuterium gas, equilibrating for three and a half hours at 218° when, after evacuation, the desorbed gas contained only 37% deuterium corresponding to a source of 34 cc. of available hydrogen.

Adsorption Isobars (p ~ 0.15 mm.) of Deuterium on Nickel.—The nickel catalyst was evacuated at a temperature T_1 for about twenty minutes by the Töpler pump and the pressure (P_1) built up in the next thirty minutes was measured. The temperature was then raised to T_2 and the pressure (P_2) was read. The desorbed deuterium (ΔD_2) was measured and the pressure (P_3) built up on standing for one-half hour was noted. These operations were repeated from −83 to 302°. The data obtained are shown in Table II.

TABLE II

ISOBAR OF D_2 ON Ni CATALYST AT ~0.15 MM. PRESSURE

T_1, °C.	P_1 at T_1, mm.	T_2, °C.	P_2 at T_2., mm.	ΔD_2, cc.	P_3 at T_2, mm.
0	0.18	55	2.1	1.39	0.14
55	.14	138	4.0	1.65	.16
138	.16	218	3.2	1.56	.18

−24	..	22.4	3.9	1.29	.25
−83	.16	21.3	9.1	2.88	.25

Evacuation for twenty minutes with the Töpler pump corresponds approximately to evacuation for five minutes with our mercury diffusion pump train. A plot of deuterium adsorbed against temperature shown in Fig. 1 shows a decreasing hydrogen adsorption with increasing temperature, curve B, Fig. 1.

The Hydrogenation Decomposition of Propane.—The experimental data on the conversion of propane and hydrogen to ethane and methane are collected in Table III.

The original catalyst, as for the experiments in Table I, was used. It will be seen that the reaction acquires an appreciable velocity at 138°, which is about 10° lower than in the case of ethane. The decomposition with deuterium was again slower than that with hydrogen, as with ethane. The fractional analyses of the hydrocarbon products, given in Table IV, shows that the initial reaction yields ethane and methane and that the ethane thus formed decomposes further to methane, but not to an appreciable extent under the majority of our conditions. We, therefore, represent the total over-all reactions, thus

$$C_3H_6 + H_2 = CH_4 + C_2H_6$$
$$C_2H_6 + H_2 = 2CH_4$$

Kinetics.—The kinetic studies were made at three temperatures and are summarized in Table V. Figure 2 shows the comparative rates of the ethane and propane reactions. With propane as with ethane the rate of decomposition increases slightly with time. Analysis of the rate measurements indicates a reaction strongly inhibited by hydrogen and weakly by hydrocarbon products, the numerical data yielding the values presented in

47	11.6	23.6	110	3.0		38.6	

In addition to the hydrocarbon exchange in this system there is, as pointed out in an earlier section, another source of exchange, namely, the kieselguhr support. Therefore, the hydrocarbon concentrations of equilibrium mixtures depend on the previous history of treatment of the catalyst. Exact equilibrium constants require, therefore, analysis of *both* hydrogen and hydrocarbon contents of the equilibrium mixture. In the experiments for which these analyses are available satisfactory constants are obtained with mean values, $K_{98} = 2.34$ and $K_{80} = 2.57$. From these we deduce a heat of reaction of 1.4 kcal.

(b) Kinetics.—In the kinetic experiments the catalyst was washed with deuterium before each run. The initial condition of the catalyst was therefore identical in all runs. The variation in the C–D percentage is undoubtedly the better way to measure the rate of reaction because, as the last column in Table VIII shows, lower values of exchange in the hydrogen occur due to the existence of the water–deuterium exchange.

The exchange reaction with propane occurs at temperatures ~40° lower than that with ethane.

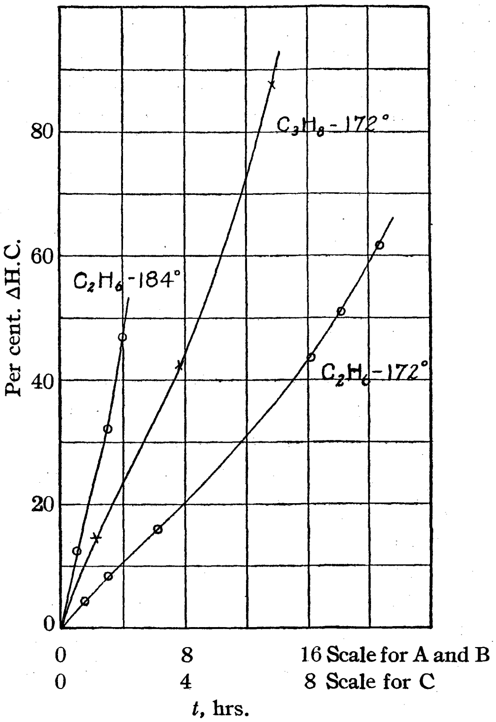

Fig. 2.

The activation energy of the process, ~19 kcal., is again much smaller than the value of ~34 kcal. found for the hydrogenation decomposition process. The inhibiting effect of hydrogen is also much less marked than in the decomposition process, the kinetics following the equation, $k \propto (C_3H_8)^{0.62}\ (D_2)^{-0.76}$, in contrast to $(H_2)^{-2.6}$ in the decomposition reaction. We refer to this point later.

Preparation of Propane-*d*$_8$.—The previous data suggested the following method of preparation of C_3D_6. A mixture of 22.6 cc. of C_3H_8 and 45 cc. of D_2 was left in contact with the nickel catalyst for three hours at 98° and then the equilibrated propane was separated in a liquid air trap. The propane thus recovered was subjected to six further successive treatments with deuterium under similar conditions. In the sixth conversion the deuterium recovered was 95% D. In the seventh it was 97.5% D. From the equilibrium constant $K_{98°} = 2.34$ this value corresponds to a propane of C–D content 98.9%. The product was fractionated under reduced pressure to remove a trace of ethane-d_6. The gas was then analyzed in the thermal conductivity gage. The properties of this preparation will be described elsewhere.

Hydrogenation of Ethylene.—The interaction of hydrogen and ethylene on the nickel catalyst under the conditions specified in Table IX showed no breaking of the carbon–carbon bond up to a temperature of 138° and was the straight hydrogenation.

TABLE IX

No.	C_2H_4, cc.	H_2, cc.	Temp., °C.	Gas recovered, cc.	H.C. (C_2H_6), cc.
24	18.5	37.4	20	38.0	18.4
25	18.9	38.7	80	38.7	18.9
101	19.9	44.2	138	44.2	20.1

Experiments with deuterium are recorded in Table X. The catalyst was again that used in the experiments of Table I. Experiment 82 is not comparable with Experiments 107–112 in which latter group the activity of the catalyst was changed due to a previous heat treatment. The comparison experiments were with a copper catalyst obtained by alternate reduction and oxidation of copper oxide granules (1.5 g.) with a final reduction and evacuation at 270°. The catalysts were in all cases well washed with deuterium.

TABLE X

REACTION OF ETHYLENE AND PROPYLENE WITH D_2 ON Ni AND Cu CATALYST

No.	Catalyst	C_2H_4, cc.	D_2, cc.	Temp., °C.	% D in H_xD_y	% C–D in H.C.	C–D exchanged, cc.	% exchange in C–H of C_2H_4

113	Cu	19.4	38.5	0	91.8	35.1	2.6	3.4
		C_3H_6						
115	Cu	19.0	40.4	0	83.8	28.5	6.5	5.7

On nickel the rate of hydrogenation was very rapid throughout the whole temperature range studied, −80 to 65°. Reaction at each temperature was complete within fifteen minutes. On the copper catalyst about one hour and a half was required at 0°. On this catalyst the amounts of hydrogen and saturated hydrocarbon adsorbed are very small and the catalytic hydrogenation can be used for analytical determinations of ethylene and propylene in gaseous mixtures.[6]

If no exchange reaction occurred between ethylene and deuterium the C–D concentration in the ethane obtained would be 32.9 and 24.2% if propylene were converted to $C_3H_6D_2$ since the deuterium content of the gas used was 98.7% D. Excess C–D percentages in the product indicate exchange.[8] The eighth column of Table X shows the results of calculations of exchange on this basis, expressed as cc. of C–D bonds, to be compared with the amount of hydrogenation, expressed also as cc. of C–D bonds, in each experiment approximately 39 cc. It will be observed that the C–D bonds produced by exchange increase with the temperature, that the activation energy of exchange is higher than that of hydrogenation and that the former is slower than the latter throughout our temperature range. These conclusions are different from those reached by Farkas, Farkas and Rideal.[9]

The copper catalyst becomes, consequently, a most convenient contact agent on which to prepare partially exchanged ethanes and propanes of known deuterium content from controlled mixtures of ethylene or propylene and deuterium, since the amounts of residual adsorption of hydrogen and hydrocarbon on copper after evacuation are negligibly small and exercise no measurable effect on the composition of the mixture introduced.

Polymerization of Ethylene.—The nickel catalyst used in the preceding experiments was evacuated for one and a half hours at 340°, 19.9 cc. of ethylene was introduced at 23° and left in contact for thirteen hours. The amount of permanent gas ($H_2 + CH_4$) produced was negligible. The gas recovered by freezing-out in a liquid air trap had a volume of 11.5 cc. This recovered gas was fractionated under a reduced pressure and found to contain 8.8 cc. of a C_2-fraction, a negli-

(8) Wheeler and Pease [THIS JOURNAL, **58**, 1665 (1936)] found no exchange.

(9) Farkas, Farkas and Rideal, *Proc. Roy. Soc.* (London), **A146**, 630 (1934).

gible amount of C_3-fraction and 2.7 cc. of a C_4- or higher fraction. By hydrogenation with the copper catalyst the C_2-fraction proved to be 86% ethylene and 14% ethane. The higher fraction was hydrogenated to methane at 300° on nickel and the average number of carbon atoms in the molecule was found to be 4.17.

The gas left on the original catalyst after the liquid-air removal process was converted on the catalyst to methane with hydrogen at 300°. Methane to the extent of 9.6 cc. was thereby produced.

From these data we can calculate the following carbon balance of the polymerization process: H_2, CH_4, C_3H_6 and C_3H_8 are produced in negligible amounts; 38% C_2H_4 was recovered unchanged; in addition 6.3% C_2H_6 and 29% (and C_4H_{10}?) with some higher hydrocarbons were formed. The residue on the catalyst amounting to 24% was recoverable as methane by hydrogenation, leaving 3% of the carbon not accounted for in the analysis. This result shows that ethylene certainly polymerizes on a nickel catalyst at room temperatures and that the reactions with hydrogen present must be quite complex, involving hydrogenation, exchange, polymerization and, at sufficiently high temperatures, a decomposition process. It is thus much more complex than the ethane case. The absence of methane and propane indicates the remarkable stability of the C—C bond which does not materially break while these several processes of hydrogenation, exchange and polymerization are freely occurring.

Discussion of Results

As in the case of ethane[2] the apparent activation energy required to break the C–C bond in propane on the catalyst surface is higher than that required to break the C–H bond. Kinetic studies reveal, as in the case of ethane, that the inhibitory effect of hydrogen is much more marked in the case of C–C bond breaking than in the case of the C–H bond. The exchange reaction is proportional to the -0.76 power of the hydrogen concentration and the decomposition to the -2.6 power. In our present experiments we have studiously avoided experimental conditions in which carbon deposition might occur and the excellent constancy of activity of the catalyst throughout a long series of experiments is additional evidence that such carbon deposition has not occurred. We therefore can eliminate this possibility as the cause of the high inverse power effect of hydrogen from those discussed in Section II of this series. The form of the kinetic expression in both reactions indicates that the catalyst surface is largely occupied by hydrogen. The bare centers available for activated adsorption of propane should therefore be inversely proportional to some fractional power of the deuterium concentration. The data on the exchange reaction agree with this conclusion and indicate a fraction, -0.76. The much higher inhibitory effect in the decomposition reaction indicates quite decisively that much larger areas of surface are required for the propane to undergo this reaction than for the exchange process. At least two elementary spaces (in the sense of Langmuir) of a less frequent type than those adequate for exchange are demanded by an exponent of magnitude, -2.6. It is possible that even more than two elementary spaces are required for the dissociative adsorption which sunders the C–C bond. Whatever the area demanded, the kinetic studies here reported are excellent proof of the theory of active centers specific for a particular reaction even though the reactions studied are, as in this case, two different reactions with the same two gases present in the same concentrations. The range of temperatures in which the reactions could be studied was not sufficiently great for any variation in the dependence on the hydrogen pressure to be revealed. The abnormally high activation energy of the process may, however, as in the case of ethane, be explained as due to the composite effects of reaction temperature and relative surface coverage.

In the case of ethylene and propylene it is to be noted that exchange occurs even on a relatively inactive exchange catalyst such as copper, on which, under the conditions employed, no activation of the C–H or C–C bonds in saturated hydrocarbons occurs. We thus conclude that the presence of the double bond in the olefin markedly weakens the C–H bonds so that exchange occurs prior to hydrogenation, or at least during the hydrogenation process, possibly according to the suggested mechanism of Horiuti and Polanyi.[10]

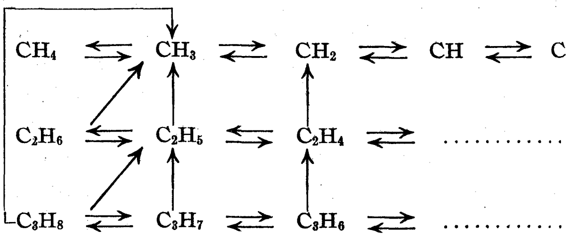
General Discussion

From the data presented in the group of papers of which this is the third, we conclude that, under

---

[10] Horiuti and Polanyi, *Trans Faraday Soc.*, **30**, 1171 (1934).

the conditions of our experimental work, the activated adsorption of saturated hydrocarbons is dissociative in type. We illustrate the various possibilities diagrammatically (the hydrogen atoms formed by dissociation being omitted for simplicity) thus



In respect to the positions of equilibria in such a complex system we observe that, with a high partial pressure of hydrogen, the equilibrium is largely on the molecular side and at low hydrogen partial pressure the equilibrium shifts toward carbon. The higher the hydrocarbon the more pronounced the shift toward the carbon side. In the absence of hydrogen, ethane changes to methane and carbon which are the only thermodynamically stable molecules in a system so constituted.[4] Below 300°, the equilibrium in the system $CH_4 \rightleftarrows C + 2H_2$ is pronouncedly on the methane side so that if the carbon is in a sufficiently active form it can be converted to methane with hydrogen.[4]

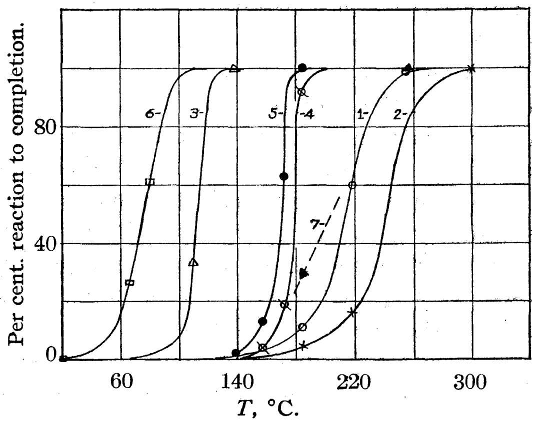


Fig. 3.—

Curve	Reaction	Time, hrs.
1	$CH_4 + CD_4 \rightarrow$ Ex.	1
2	$CH_4 + D_2 \rightarrow$ Ex.	1
3	$C_2H_6 + D_2 \rightarrow$ Ex.	2.5
4	$C_2H_6 + H_2 \rightarrow 2CH_4$	1
5	$C_3H_8 + 2H_2 \rightarrow 3CH_4$	1
6	$C_3H_8 + D_2 \rightarrow$ Ex.	1
7	$CH_4 + D_2O \rightarrow$ Ex.	11

With mixtures of methane and D_2O vapor, owing to the low H-atom concentration on the surface, the dissociative adsorption of methane will proceed markedly toward carbon. The deuteromethane which results will be formed not only from CH_3 fragments but also from CH_2 and CH fragments. We thus explain the abnormal distribution of the deuterium in the deuteromethanes produced by interaction with water[3] in contrast to the approximately equilibrium distribution when deuterium is used for the exchange process, methyl groups being the predominant fragments in this case.

The relatively strong adsorption of hydrogen and deuterium in comparison with the hydrocarbons explains the slowness of the $CH_4 + D_2$ exchange in comparison with the CH_4–CD_4 exchange.[3] With the higher hydrocarbons, two types of activation of the C–H and C–C bonds are involved. The activation of the former requires less apparent energy than that of the latter, is less adversely affected by hydrogen than is the latter. Our data reveal no evidence of the occurrence of reverse processes such as $2CH_2 = C_2H_4$, occurring from an upper to a lower level in the diagram given above. Under different conditions, as for example in the Fischer process of gasoline synthesis, such processes may be occurring.

We summarize, for comparative purposes in Fig. 3, the velocities of the various reactions we have studied on nickel catalysts. There are variations in the activities of the catalysts used, so that the data are only to be taken as approximate for comparison purposes. They do, however, reveal, the general course of activation as we proceed from methane toward the more complex hydrocarbons.

Summary

1. The exchange reaction between propane and deuterium on a nickel catalyst takes place in a lower temperature range, by ~90°, than that of the hydrogenation–decomposition to yield ethane and methane.

2. The kinetics of the two processes have been studied. The reactions are inhibited by hydrogen, the exchange to the −0.76 power, the decomposition to the −2.6 power of the hydrogen concentration.

3. Methods for the preparation of propane-d_8 as well as deuteropropanes and deuteroethanes of known C–D content have been described.

4. The availability of the hydrogen in a nickel–

kieselguhr catalyst for exchange reactions has been studied. Adsorbed hydrogen and adsorbed water vapor may be removed by evacuation at 218°. Other hydrogen sources of reproducible availability are held tenaciously in the kieselguhr, probably as bound water. These are difficult to remove even at 400–500°, and exchange with deuterium to increasing extents with increase of temperature.

5. The deuterium–ethylene reactions on nickel in the range −80 to 65° results in some exchange as well as the addition reaction. A copper catalyst also shows activity in exchange.

6. Ethylene polymerizes to C_4 and higher hydrocarbons at 0° on nickel, but the breaking of the C–C linkage is negligible.

7. A general discussion in terms of the dissociative adsorption of the saturated hydrocarbons has been given.

Aqueous Solubilities of the Isomeric Pentanols

BY P. M. GINNINGS AND RHODA BAUM

An important factor in most investigations of the relationship between molecular structure and aqueous solubility of organic compounds is the molecular weights of the compounds studied. In fact its domination frequently tends to obscure the effect of lesser factors. Evidently, limitation of a study to isomers should simplify considerably analysis of the results and for this reason, a study of the aqueous solubilities of the eight isomeric pentanols or amyl alcohols seemed worthwhile. Search of the literature revealed approximate solubilities for many of these isomers but apparently only two have been measured precisely. Butler[1] using an interferometric method measured the solubility of *n*-pentanol (*n*-butylcarbinol) at 25° as 2.208 weight percentage. Kablukov[2] using the volumetric method of Hill[3] determined the value for isobutylcarbinol (isoamyl alcohol) at a number of temperatures. Values for the latter are also given in the "International Critical Tables."[4]

The solubilities of these two compounds were also determined in the present paper as a check upon our experimental work and the results seem to agree within the accuracy of our method.

Results of our determination of the weight percentage solubilities of these eight isomers are given in the table. The difference between the larger weight percentage for a given temperature and isomer and one hundred represents the solubility of water in that particular isomer. Analysis of the data indicates that the one tertiary isomer is more soluble than any of the three secondary isomers and that these in turn are more soluble than any of the four primary isomers. The solubility increases as the hydroxyl group approaches the center of the molecule (Nos. 1, 5 and 6). If the analysis is limited to either the primary or secondary isomers, it is evident also that the solubility in water increases as the structure of the molecule becomes more compact. However, the most compact primary isomer (No. 4) is not as soluble as the least compact secondary isomer (No. 5). Usually the more soluble the alcohol in water, the more soluble the water is in the alcohol. Of interest also is the fact that as the temperature increases from 20 to 30°, the solubility of all eight isomers decreases.

Experimental

With one exception, the compounds used for the final determinations were prepared by purification of products synthesized by one of the Grignard reactions. *t*-Butylcarbinol was prepared in this Laboratory by the action of *t*-butylmagnesium chloride upon paraformaldehyde with the usual hydrolysis, etc. Dimethylethylcarbinol was prepared by the action of ethylmagnesium bromide upon acetone in the usual Grignard procedure. The other compounds were Eastman best grade of products. The isobutylcarbinol probably was obtained originally as a by-product from a fermentation process and was known to contain some of the active amyl isomer. Approximately seventy-five aqueous extractions, drying with anhydrous potassium carbonate and final fractional distillation over metallic calcium seemed to purify this satisfactorily.

In general, all products from the Grignard syntheses were fractionally distilled with a short column (reflux

ratio about 7:1) off metallic calcium, using a precision thermometer, graduated in 0.1° with the range of 100–150°. Dimethylethylcarbinol was distilled off calcium oxide. All boiling points given in the table have been corrected to 760 mm. pressure using Craft's rule when the dT/dp was not known; stem correction was applied when needed.

Compounds 3, 5, 6, and 8 in the table were also obtained in the Technical grade of purity. These had as their origin the isomeric pentenes of petroleum and were quite difficult to purify completely. However, for purposes of comparison these four were purified as carefully as possible by fractional distillation through a 1-m. column, fractionally extracted with water, fractionally salted-out with potassium carbonate and again fractionally distilled through the 1-m. column. In all cases the middle fractions were taken and the extremes discarded. The solubilities of the products were then compared with those obtained on the compounds prepared by the Grignard syntheses and which are given in the table. Agreement was usually close except in the case of the dimethylethylcarbinol; the solubility of the product derived from the Technical was approximately 0.3 wt.% higher than the other at all three temperatures.

Hill's volumetric method mentioned previously in this article was used with some adaptations and refinements to measure the solubilities. A pair of two-bulb graduated and calibrated flasks was constructed mainly from portions of Babcock milk test bottles. The two constricted portions of each double-bulbed flask were made from the graduated necks and so were already graduated in intervals of 0.02 ml. This permitted measurement of the volumes of the liquid phases with an accuracy better than 0.01 ml.

The general procedure was to introduce known weights of the particular alcohol and distilled water (weighings accurate to better than 1 mg.) into the flask stoppered with an excellent grade cork stopper. Flask and contents were then shaken mechanically in a constant temperature water-bath, maintained thermostatically and manually to the desired temperature plus or minus 0.1°. Sufficient time was allowed for the liquids to reach equilibrium, the two liquid phases were allowed to separate and the total volume reading in the flask noted. The flask was then centrifuged in the usual Babcock centrifuge to sharpen the dividing line between the two liquid phases and then returned to the constant temperature bath. After the total volume reading had returned to the same as the original one noted, the reading of the line dividing the two phases was made. From these data, volumes of the two phases were calculated. Ratios of the volumes of the two sections of the two flasks were approximately 1:5 in one and 5:1 in the other. Total volume of each flask was approximately 65 ml. With the weights of the components in both flasks known and both pairs of volumes calculated, sufficient data were in hand to substitute in the pair of simultaneous equations to get the concentrations of each component in each phase. Subsequently, the weight percentages were calculated from the latter values as explained in detail by Hill.

The reliability of the method was better than 0.1 wt. % in practically all of the cases and the authors feel that the validity of the results will approach this limit. Increase of the limits to 0.2 wt.% should probably be allowed in the case of the dimethylethylcarbinol.

Summary

Aqueous solubilities of the eight isomeric pentanols have been determined for 20, 25 and 30°.

The one tertiary isomer is more soluble than any of the three secondary isomers which in turn are more soluble than any of the four primary isomers. The solubility increases as the hydroxyl group approaches the center of the molecule. Limitation of the comparisons to either the primary or the secondary group reveals that the more compact the molecular structure, the greater is the aqueous solubility. The solubility of all eight isomers decreases as the temperature increases from 20 to 30°.

Equimolar Condensations of Aldehydes with Phenols. The Preparation of Primary Saturated Alkylphenols[1]

BY JOSEPH B. NIEDERL, VICTOR NIEDERL, S. SHAPIRO[2] AND MARTIN E. MCGREAL

Condensation of carbonyl compounds (aldehydes and ketones) with multimolar quantities of a phenol usually results in the formation of the corresponding alkylidene-di-phenol.[3] Dianin and von Braun,[4] however, made the observation that saturated secondary or tertiary alkylphenols are obtained when the intermediate polymeric condensation products resulting from the action of hydrochloric acid upon a mixture consisting of several moles of a phenol and one mole of a ketone, aliphatic (di-*n*-propyl, methyl hexyl ketone and dichloroacetone) as well as aromatic ketones (acetophenone, ω-chloroacetophenone) are subjected to pyrolysis. The formation of saturated alkylphenols from ketone-phenol polymers was a rather unexpected observation and the expression "disproportionation" process was suggested by von Braun for this phenomenon.

In all of the above investigations multimolar quantities of phenol were used. It was the purpose of the research set forth in this communication to investigate equimolar condensations of saturated aliphatic aldehydes with phenols to establish experimentally the following: (a) whether it is possible to obtain mole for mole addition; (b) whether these additions take place analogous to the addition of halogen acids or hydrocyanic acid to the carbonyl bond, or whether the addition takes place as in aldol condensations; (c) to investigate the chemical nature of the intermediate polymer; and (d) to investigate the behavior of these aldehyde–phenol polymers upon pyrolysis, particularly as to the possibility whether a similar "disproportionation" could be observed in the aldehyde series as has already been established in isolated cases in the ketone and indane series.[5] Although the end-products, the saturated primary alkylphenols, could be identified easily, analysis of the intermediate polymeric condensation products did not lead to uniformly interpretable results. Some of these products, when reprecipitated, powdered and completely dried in a vacuum desiccator over phosphorus pentoxide for several months, gave results upon quantitative analysis which corresponded closely to polymeric alkylenephenols. The pyrolysis of the condensation products of phenols and the three cresols with the following aldehydes were studied.

Formaldehyde and phenol yielded a small amount of a cresol. Acetaldehyde and phenol (I) and the three cresols (II, III, IV) gave the corresponding ethylphenol and ethylcresols upon pyrolysis of the Claisen solution soluble polymeric condensation products. Substitution of vinyl acetate for acetaldehyde yielded similar polymers. Propionaldehyde (V), *n*- and isobutyraldehyde (VI, VII), *n*-valeric aldehyde (VIII) and *n*-heptaldehyde (IX) and phenol gave the respective alkylphenols. These primary saturated alkylphenols were purified by repeated fractional distillation, then analyzed and further characterized as crys-

talline aryloxy-acetic acids, prepared according to Shriner and Fuson.[6]

Experimental

_p_-Ethylphenol, _p_-Ethyl-_o_-cresol, _p_-Ethyl-_m_-cresol, _o_-Ethyl-_p_-cresol.—Molar mixtures of phenol or cresol and acetaldehyde were placed in a 2-liter 3-necked round-bottomed flask provided with a reflux condenser, a thermometer and a gas inlet tube extending to the bottom of the vessel. Two hundred cc. of glacial acetic acid was added and the reaction mixture cooled to about −5° by immersing the flask in an ice–salt mixture. A vigorous stream of dry hydrochloric acid gas was passed through the system for two hours and then the condensation product, a dark red oil, was poured into a large volume of cold water. A yellowish white precipitate formed which was washed repeatedly with cold and hot water, then filtered and dried; yield, almost quantitative. The thoroughly dry product was powdered, placed in a 250-cc. distilling flask and distilled under atmospheric pressure. The distillate, consisting of water, the respective phenol or cresol and the alkylated ethylphenol or ethyl cresol was taken up in ethyl acetate, this solution dried over calcium chloride and filtered. The solvent was distilled off and the residue fractionally distilled under atmospheric pressure. The lower boiling portion (about 30%) consisted mostly of the original phenol or cresol; the higher boiling portion (about 40%) was redistilled and consisted of the respective ethylphenol or ethylcresol. A charred residue (about 20%) remained in the distilling flask after pyrolysis.

Aryloxyacetic Acid (HAc Deriv.).—By the method of Shriner and Fuson, 1 g. of *p*-ethylphenol was dissolved in 5 cc. of a 33% sodium hydroxide solution and 1.5 g. of chloroacetic acid added. The mixture was shaken thoroughly and heated on a water-bath at 100° for one hour. The solution was then diluted with 15 cc. of water, acidified with dilute hydrochloric acid to congo red and extracted with 50 cc. of ether. The ether was washed with an equal volume of water and then shaken out with 25 cc. of a 5% sodium carbonate solution. This solution was acidified with dilute hydrochloric acid and the *p*-ethylphenoxyacetic acid which precipitated out filtered and dried on porous tile. It was recrystallized from diisobutylene. The cresoxyacetic acids were prepared in the same manner.

_p_-_n_-Propylphenol, _p_-_n_-Butylphenol, _p_-Isobutylphenol, _p_-_n_-Amylphenol, _p_-_n_-Heptylphenol.—These compounds were prepared in a similar manner as described above, except that the reaction was carried out at room temperature and condensation was complete in two and one-half to three hours. The temperature inside the reaction vessel rose to 60 to 80° and diminishing temperature indicated completion of the reaction. The condensation product was then poured into cold water and a heavy oil separated out which was taken up in ethyl acetate. This solution was washed exhaustively with water, then dried and distilled under atmospheric pressure. The distillate, consisting of water, phenol and the corresponding alkylated phenol, was again taken up in ethyl acetate, dried and fractionally distilled under reduced pressure. The higher boiling fraction, representing the respective alkylated phenol, was purified by redistillation. The yield ranged from 20 to 40%.

The acetic acid derivatives were prepared as described above, except that wherever the final precipitate was an oil it was extracted from the aqueous solution with ether, the ether permitted to evaporate at room temperature, whereupon the acetic acid derivative crystallized. All the derivatives were recrystallized from diisobutylene.

The phenol coefficients given are the average of six tests, performed in 30% alcoholic solution with *staphylococcus aureus* at 37°. The authors are indebted to Dr. Wm. A. Feirer of the Mulford Biological Laboratories, Glenolden, Pa., for performing these tests. The authors are further indebted to the Lambert Pharmacal Co., St. Louis,

Mo., for a research grant for the completion of this investigation.

Summary

Equimolar condensations of monohydroxyphenols with saturated aliphatic aldehydes were studied. It was found that polymers result in quantitative yields. Upon slow pyrolysis, these polymers yield the corresponding saturated primary alkylphenols. These types of condensations are being extended to unsaturated and aromatic aldehydes, reducing saccharides as well as to ketones, particularly cyclic ketones (cyclopentanone, cyclohexanone, alkyl cyclohexanones and camphor).

Some Derivatives of Ortho-Hydroxyphenylmercuric Chloride

BY HANS P. ANDERSEN AND MERRILL C. HART

In earlier reports it has been shown that variations in structure have a limited influence on bacteriostatic properties of organic mercury compounds,[1] and that more complex structures were not as effective as mercury derivatives of hydrocarbons or phenols with limited substituents.[2] One very effective mercurial was found to be *o*-hydroxyphenylmercuric chloride, this compound also being bactericidal at some dilutions.[2] It seemed that possible derivatives of this compound could be prepared which would have similar properties.

Some imide derivatives of phenylmercuric nitrate have been described as being used in germicidal detergent or cosmetic compositions.[3]

In the present work some imide derivatives of *o*-hydroxyphenylmercuric chloride have been prepared and their bacteriological properties evaluated.[4] One has been found to be equally as good as the parent compound. It was found that, in general, imide derivatives were readily formed in alkaline solution, especially if the imide contained a carbonyl group. An attempt was made to prepare derivatives of pyrrole, auramine, carbazole and piperidine but only in the case of piperidine was a product obtained in the form of the hydrochloride. This was formed in the absence of alkali.

Although the simplest structures are most effective, it was thought that fatty acid derivatives might facilitate the *in vivo* activity by increasing diffusion into the surfaces in contact with the antiseptic. A few representative phenolmercuric fatty acid compounds have been prepared and described.

The table gives the results obtained together with melting points and analytical data.

[a] This compound was bactericidal 1–1000. [b] Phenol control 1–80. [c] This is the mercury content of the hydrochloride. Calcd. for $C_{11}H_{15}OHgHCl$: Cl, 8.81. Found: Cl, 8.41. [d] Monohydrate. [e] Mixed melting points with pelargonic and lauric acid derivatives were depressed.

Experimental

***o*-Hydroxyphenylmercuric Succinimide.**—Three and three-tenths grams of succinimide in 18.7 cc. of water, was added to 10.95 g. of *o*-hydroxyphenylmercuric chloride in 25 cc. of warm alcohol. This was cooled as much as possible without forming a precipitate and then 18.7 cc. of 10% potassium hydroxide was added. After shaking and further cooling, 11 g. of crude product was obtained melting at 222°. This was recrystallized from 200 cc. of alcohol and 100 cc. of water to give a final yield of 72.3%. The melting point was 232–235°.

The other imide derivatives were made in the same manner using either water or alcohol, depending on which was the better solvent for carrying out the reaction.

***o*-Hydroxyphenylmercuric Piperidine Hydrochloride.**—Five cubic centimeters of piperidine was added to 16.4 g.

(4) We are indebted to Mr. E. A. Gibson, Bacteriological Laboratory, for these results.

of *o*-hydroxyphenylmercuric chloride in 25 cc. of alcohol. The product melted at 126°; yield 79.3%. The analytical data indicate that the hydrochloride is formed and that treatment with potassium hydroxide gives an *o*-hydroxyphenylmercuric hydroxide derivative. It is not stable to acetic acid, probably forming *o*-hydroxyphenylmercuric acetate.

***o*-Hydroxyphenylmercuric Hydroxide.**—Ten grams of *o*-hydroxyphenylmercuric chloride in 25 cc. of alcohol was treated with 17 cc. of 10% alcoholic potassium hydroxide, warming slightly and stirring vigorously. The product is insoluble.

Anal. Calcd. for $C_6H_6O_2Hg$: Hg, 64.5. Found: Hg, 64.7.

***o*-Hydroxyphenylmercuric Fatty Acid Compounds.**—The calculated quantity of *o*-hydroxyphenylmercuric hydroxide was suspended in warm alcohol and the fatty acid added and stirred with warming until solution resulted. On cooling the fatty acid derivative precipitated. It was recrystallized from alcohol and dissolved in dilute alcohol or alkaline solution for bacteriological study.

Summary

A number of imide derivatives of *o*-hydroxyphenylmercuric chloride have been prepared, one of which has bacteriostatic properties similar to the parent compound.

Some fatty acid compounds with *o*-hydroxyphenylmercuric hydroxide have been made which may promise to give enhanced *in vivo* activity.

The Identification of the Amino Acids: *p*-Toluenesulfonyl[1] Chloride as a Reagent

BY EVAN W. MCCHESNEY AND WM. KIRK SWANN, JR.

I. Introduction

Numerous reagents have been employed for the identification of the amino acids. Among these perhaps the most important group are those reagents which conjugate readily with the amino group, such as benzoyl chloride, β-naphthalenesulfonyl chloride, benzenesulfonyl chloride, *p*-nitrobenzoyl chloride, and phenyl isocyanate. With the passing of years, however, and the discovery of new amino acids, there have come to be gaps in our knowledge such that the derivatives of all of the known amino acids with any one of these reagents do not seem to have been described. Also, in some cases, the derivatives have been prepared, but it has not been possible to crystallize them. The result of this situation is that an investigator who has at hand a small amount of an unknown amino acid cannot rely safely on one derivative for the identification, since it may not crystallize, or it may not have been described. The object of this work has been to find, if possible, one derivative which would be satisfactory for all of the amino acids, and to describe it for those which are at present recognized as products of protein hydrolysis and are commercially available.

For this work two reagents not extensively used thus far in amino acid work were selected for study: *p*-toluenesulfonyl chloride and *p*-bromobenzenesulfonyl chloride. It was soon found that the derivatives obtained with the former crystallized much more readily; therefore it was selected to complete the study. The idea of using *p*-toluenesulfonyl chloride as a reagent for the amino acids is not a new one, Oseki[2] having prepared about a dozen of the compounds, and several other investigators having prepared one or more of them (see references to Table I). A considerable number of the amino acids have not been included in these studies, however, and in some cases there are serious discrepancies in the melting points recorded (see, for example, *d*-alanine, *d*-valine, and *l*-leucine in Table I). It therefore seemed worth while to try to repeat all of the work previously done and, if possible, to complete the list.

II. Materials.—The amino acids used in this work were the highest grade products of the Eastman Kodak Co., the Pfanstiehl Chemical Co., and Hoffman-La Roche, Inc., except those which are commonly prepared in the laboratory (glycine, *d,l*-alanine, *l*-tyrosine, *l*-cystine, and *d*-glutamic acid). The latter were prepared by the standard methods, crystallized from the appropriate solvents, and their purity was demonstrated by nitrogen analyses. The *p*-toluenesulfonyl chloride was an Eastman product, m. p. 67-69° (m. p. in the literature is 69°[3]).

III. Method.—The method used[4] is such a familiar one that it requires little comment. The amino acid, 0.01 equivalent as to combining power, is dissolved in 20 cc. of *N* sodium hydroxide, an ethereal solution of 2 g.

---

(0.01 mole) of *p*-toluenesulfonyl chloride is added, and the mixture is shaken mechanically for three to four hours. The ethereal solution is then separated off and the aqueous solution is acidified to congo red with hydrochloric acid. The derivative begins to crystallize at once (or separates as an oil which, on standing in the refrigerator, will eventually crystallize except in special cases to be discussed later). The crystals are collected on a filter and are recrystallized from a very small amount, usually 5 cc. or less, of 60% alcohol. The yield at this point is about 50% of the theoretical. Two or three crystallizations give a constant melting point.

Exceptions.—In the case of phenylalanine and tyrosine, the sodium salt of the derivative is sparingly soluble in water and separates out during the reaction. The semi-emulsion which results is acidified to congo red, whereupon the sodium salt goes into solution and the mixture separates into two layers. The derivative passes into the ethereal layer from which it begins to crystallize spontaneously in a few minutes; it may be collected on a filter. With these amino acids the yield is nearly quantitative and more of the solvent, up to 25 cc., is needed for crystallization. There is a second exception in the dicarboxylic acids, the derivatives of which are very soluble in water, therefore do not precipitate on acidification. They are converted to their dibutyl esters by the method of Gurin and Clarke[5] as described later.

IV. Experimental Data

The amino acid derivatives which could be crystallized were dried *in vacuo* over boiling ethyl alcohol in a drying pistol. They were analyzed for nitrogen by a semi-micro Kjeldahl method in order to demonstrate their purity; in the cases of cystine and methionine, sulfur was also determined, the Parr bomb method being used. The data are shown in Table I, which includes derivatives reported by other investigators to crystallize, but found in this work, however, to form persistent oils.

The *p*-toluenesulfonyl derivatives of the amino acids formed colorless crystals which usually separated in the form of needles or rods. The only important exceptions were the derivatives obtained from cystine and histidine; the former crystallized in the form of prisms of a gritty character, while the latter crystallized as rosets of needles. Of the various solvents used for recrystallization, only 60% alcohol seemed suitable for all of the derivatives. A few (notably those from glycine and alanine) crystallize from water, a few crystallize from benzene (only those from leucine and phenylalanine were tried), and a large number crystallize from β,β'-dichloroethyl ether (those from cystine, serine and histidine were the only exceptions found). However, the question of solubility has been studied extensively by others, notably Oseki, and no discussion seems called for in this paper.

In addition to the melting points, further evidence as to the nature of the compounds is obtained readily by analyzing for nitrogen or sulfur, or by titrating the carboxyl group in alcoholic solution, using phenolphthalein as an indicator. This gives results which agree exactly with the nitrogen determinations.

TABLE I

DATA ON THE *p*-TOLUENESULFONYL DERIVATIVES OF SOME AMINO ACIDS

Amino acid	Melting point of derivative, °C. In literature	Melting point of derivative, °C. Found (uncorr.)	N, % Calcd.	N, % Found

Sulfur analyses: For di-*p*-toluenesulfonyl-*l*-cystine calcd., 23.35%; found, 23.58%. For *p*-toluenesulfonyl-*d,l*-methionine, calcd., 21.14%; found, 21.36%.

V. Treatment of Non-Crystalline Derivatives.—The derivatives of glutamic and aspartic acids, arginine, lysine, tryptophane and proline were found not to crystallize. The same experience was reported by Oseki as regards arginine and lysine, but the other four derivatives have been crystallized by various investigators. In this work, for lack of material, tryptophane was not studied further; the preparation of a crystalline derivative from it would be of little practical value, however, since it is readily recognized by other means. The other derivatives were taken up in butyl alcohol if they precipitated as oils, or were extracted from aqueous solution by butyl alcohol if they did not precipitate. They were then converted

(18) The N-*p*-toluenesulfonyl derivative has been described by Fischer and Lipschutz, ref. 14, p. 376. M. p. 187–188°C. The derivative reported here is N,O-di-*p*-toluenesulfonyl-*l*-tyrosine.

(19) Karrer and van der Sluys Veer, *Helv. Chim. Acta*, **15**, 750 (1932).

to their butyl esters by the method of Gurin and Clarke.[5,20] After evaporation of the butyl alcohol as directed by these authors, the oil remaining was taken up in ether and precipitated by petroleum ether. The precipitate, on standing in the refrigerator, crystallized and was recrystallized from petroleum ether with alcohol added. The derivatives of glutamic and aspartic acids crystallized as silky needles (yield nearly quantitative), lysine also as silky needles (yield 20%), and proline as clear prisms (yield 50%). The arginine derivative was soluble in alcohol but insoluble in ether or petroleum ether. It has not been possible to cause this derivative to crystallize. The characteristics of these compounds are shown in Table II.

Acknowledgment.—One of us (E. W. M.) acknowledges with pleasure his indebtedness to: (1) Dr. H. B. Lewis, for the privilege of working in his laboratories at the University of Michigan, and for the gift of samples of several of the amino acids; (2) The Rockefeller Fund, an appropriation from which partly supported this investigation; (3) Dr. Wm. de B. MacNider, for the gift of a part of his research funds; (4) Dr. O. P. Wintersteiner, through whose courtesy certain of the analyses reported in Table II were made.

Summary

The *p*-toluenesulfonyl derivatives of nineteen amino acids have been prepared of which six have not been described previously. The *p*-toluenesulfonyl derivatives of aspartic acid, *d*-glutamic acid, *d,l*-lysine and *l*-proline did not crystallize. The non-crystalline derivatives, except tryptophane, were converted to their butyl esters and these crystallized, with the exception of arginine. The butyl esters of the derivatives of the four remaining amino acids are described for the first time in this paper.

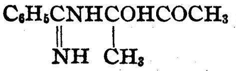
The Structure of Benzamidine-glyoxal and of its Compounds with Aromatic Aldehydes

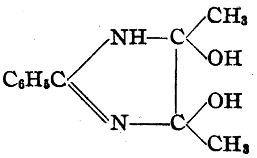
BY JOHN B. EKELEY AND ANTHONY R. RONZIO

In former papers[1] it has been shown that in alkaline solution aromatic amidines form addition products with glyoxal which can be isolated as the free bases or as their hydrochloride salts. In water solution the addition products are dissociated into amidine and glyoxal since from the solutions the osazone and dioxime of glyoxal can be obtained. We now have absorption spectra evidence which confirms this conclusion. We have exactly the same kind of evidence that the addition product from benzamidine and diacetyl obtained by Diels and Schleich[2] is, like that of benzamidine-glyoxal, an open chain compound as they assumed.



$C_6H_5C(=NH)NHC(OH)(CH_3)COCH_3$

and not



Inspection of the absorption spectra curves for benzamidine hydrochloride, benzamidine-glyoxal and benzamidine-diacetyl confirms the above statements.

There has been described[1] a long series of compounds which were obtained by the action of aromatic aldehydes upon aromatic amidines and glyoxal in alkaline solution. From the evidence then at hand we assumed them to contain either a pyrimidine or a glyoxaline ring. Ruhemann and Cunnington[3] prepared derivatives from benzamidine and phenylpropiolic ester, one of which, diphenylglyoxalidone, a yellow compound, pos-

sesses properties similar to the one obtained by us from benzaldehyde, benzamidine and glyoxal.

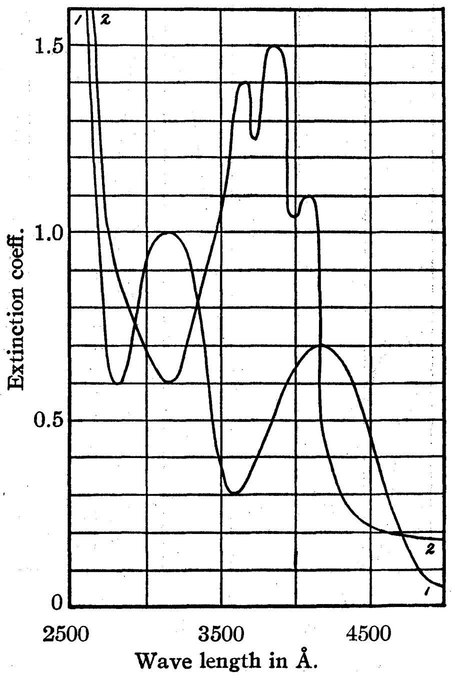

Fig. 2.—Curve 1, Ruhemann and Cunnington's glyoxalidone, 0.00090/50 ml. of KOH–95% E + OH soln., 1-cm. cell; curve 2, same, 0.00100 g./50 cc. of dioxane, 1-cm. cell.

The second compound they proved to be identical with Pinner's[4] diphenylhydroxypyrimidine. We have prepared these compounds and compared the absorption spectra curves obtained from them both in dioxane[5] and in dilute potassium hydroxide solution with the curves obtained from our benzaldehyde, benzamidine, glyoxal compound in the same solvents. The similarities between the curves from R. and C.'s glyoxalidone and those from our benzaldehyde-benzamidine–glyoxal compound are so very pronounced that we are forced to the conclusion that their structures are similar and that both have a glyoxaline ring in acid, basic, or neutral solution, the change from acid to alkaline solution bringing about a corresponding change in the two compounds, namely, to that of a tautomeric form.

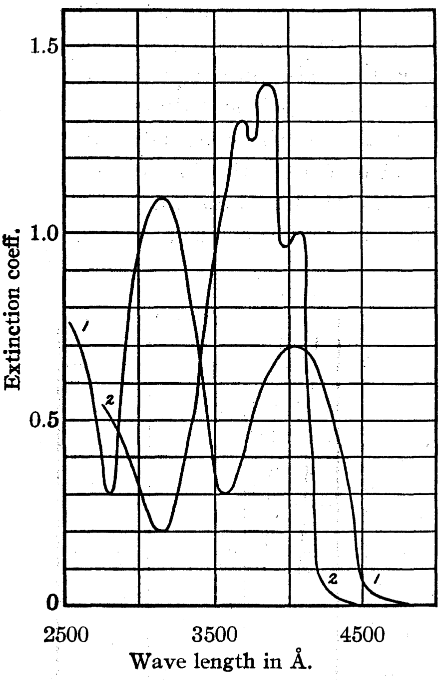

Fig. 3.—Curve 1, benzamidine–benzaldehyde–glyoxal compound, 0.00215 g./100 ml. of KOH–H_2O solutions, 1-cm. cell; curve 2, same, 0.00135 g./100 ml. of dioxane, 1-cm. cell.

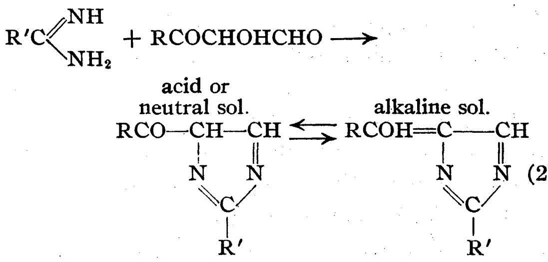
The reactions involved in the formation of the condensation product between aromatic aldehydes, aromatic amidines and glyoxal are

$$\text{RCHO} + \text{OCHCHO} \longrightarrow \text{RCOCHOHCHO} \qquad (1)$$

---

(4) Pinner, *Ber.*, **22**, 1612 (1889).

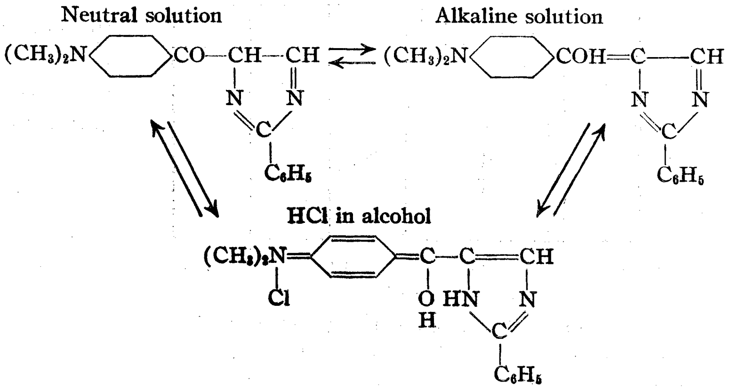
(5) Technical dioxane purified by the method of Oxford [*Biochem. J.*, **28**, 1325 (1934)] gives very faint narrow absorption bands at 2610, 2550, 2500 Å. These bands are too weak and narrow to interfere in absorption spectra work.



(2)

In one case out of forty-five compounds obtained from aromatic aldehydes, namely, that from *p*-dimethylaminobenzaldehyde, does the solution change color when made acid, especially in alcohol solution. In this case the color becomes deep red. The absorption spectrum curves show that the presence of the *p*-dimethylamino group in the original aromatic nucleus causes the loss of the characteristic triplet in dioxane solution, while in acid the curve suffers a further change and is shifted toward the red end of the spectrum. The changes in acid solution may be explained by the assumption of the formation of a quinonoid structure, while in alkaline solution the color is due to the presence of the fulvenoid chromophore alone.

From the mother liquor of the benzamidine-glyoxal addition product we obtained a small amount of an acid[1] which from the empirical formula we assumed to be a condensation product of glyoxylic acid, benzamidine and glyoxal, since



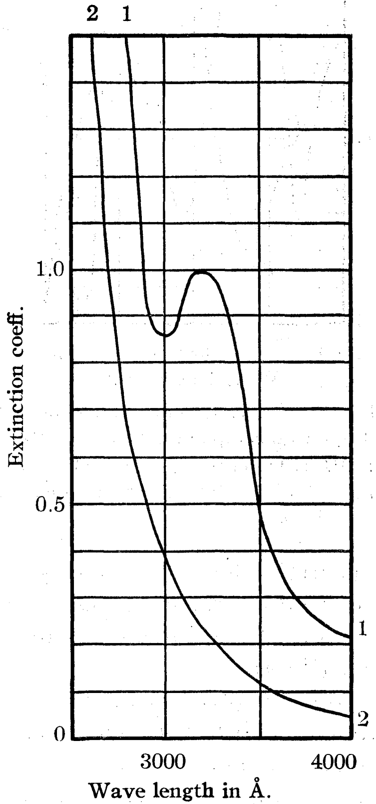


Fig. 4.—Curve 1, diphenylhydroxypyrimidine, 0.00170 g./50 ml. of dioxane, 1-cm. cell; curve 2, same, 0.00085 g./50 ml. of KOH–H₂O solution, 1-cm. cell.

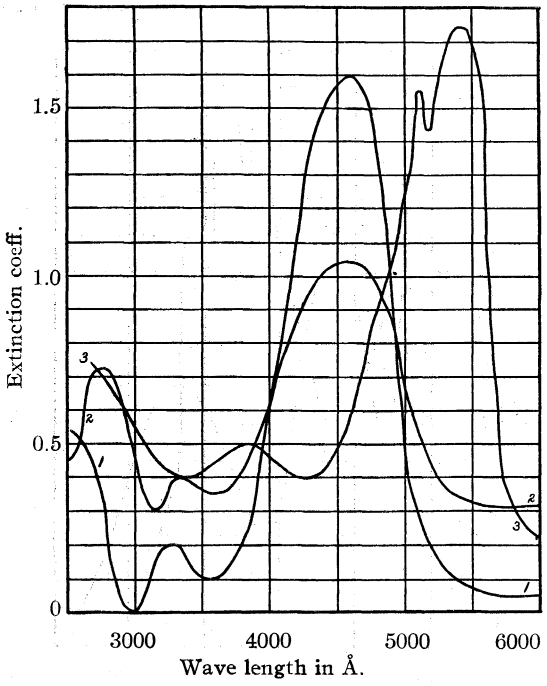

Fig. 5.—Curve 1, benzamidine–glyoxal–*p*-dimethylaminobenzaldehyde compound, 0.00056 g./50 ml. of dioxane, 1-cm. cell; curve 2, same, 0.00060 g./50 ml. of KOH–H₂O solution, 1-cm. cell; curve 3, same, 0.00067 g./50 ml. of 95% ethyl alcohol containing 1 cc. of concd. HCl, 1-cm. cell.

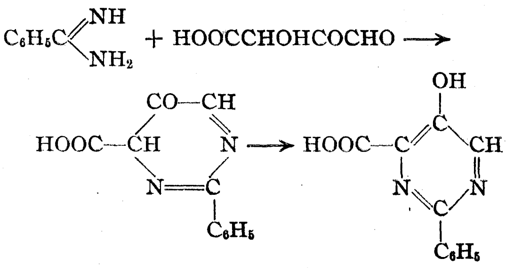
the glyoxal used contained glyoxylic acid together with oxalic acid. The same compound in a 75% yield was then prepared from glyoxylic acid (prepared by the method of Tafel and Friedrichs[6]) and benzamidine-glyoxal. They were both recrystallized from alcohol–water solution, m. p. 255°. *Analyses.* Calcd. for $C_{11}H_8N_2O_3$, compound from mother liquor: C, 61.11; H, 3.70; N, 12.95. Found: C, 61.50; H, 3.90; N, 12.82. Compound from glyoxylic acid and benzamidineglyoxal, found: C, 61.00; H, 3.90; N, 13.08.

Comparison of the absorption spectrum curve of this compound with that of Pinner's diphenylhydroxypyrimidine reveals such striking similarities that we must assign to this acid the pyrimidine structure, so that in this case the compound is phenylhydroxypyrimidine carboxylic acid. The formation of the acid would seem to be according to the following reactions

$$\mathrm{HOOCCHO + OHCCHO = HOOCCHOHCOCHO} \quad (1)$$



(2)

The absorption spectra curves herein given were obtained using a Hilger E3 quartz spectrograph, a Hilger sectorphotometer and a high frequency under-water spark. Eastman panchromatic plates were used. In plotting the curves we used wave lengths as abscissas and "extinction coefficients" as ordinates.

Summary

1. Absorption spectra data are in accord with chemical data pointing to an open chain formula for the addition products of aromatic amidine and glyoxal and for those of benzamidine with diacetyl.

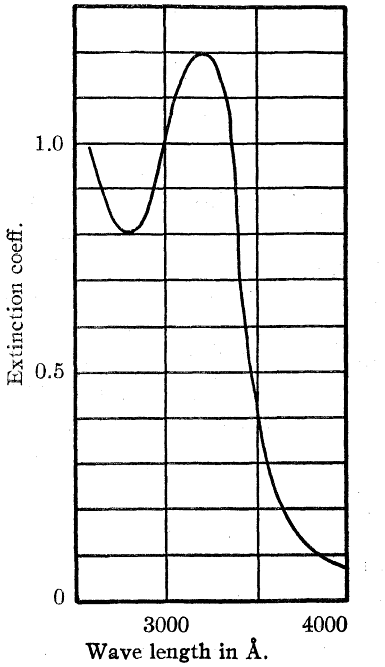


Fig. 6.—Glyoxylic acid–benzamidine-glyoxal compound, 0.00170 g./50 ml. of dioxane, 1-cm. cell.

2. The structures of the compounds formed from aromatic aldehydes, aromatic amidines and glyoxal are generally phenylbenzoylglyoxalines in acid or neutral solution and existing in a tautomeric form in alkali solutions.

3. The compound derived from *p*-dimethylaminobenzaldehyde, benzamidine and glyoxal gives absorption spectra curves in dioxane in which the characteristic triplet has become a single band, in alkaline solution it suffers a further change and in hydrochloric acid solution is shifted toward the red probably due to the formation of a quinonoid ring.

4. The compound derived from glyoxylic acid gives absorption spectra similar to diphenylhydroxypyrimidine, hence is assumed to be a phenylhydroxypyrimidine carboxylic acid.

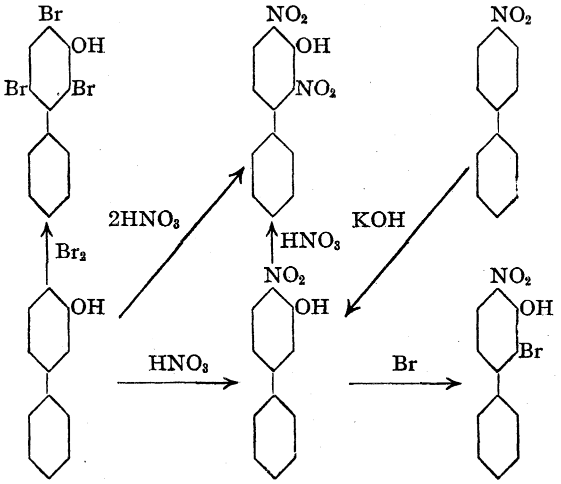
Derivatives of the Hydroxydiphenyls. III. 4-Nitro-3-hydroxydiphenyl

By J. C. Colbert, Wyman Meigs and R. L. Jenkins

In the 4-hydroxydiphenyl molecule the usual orienting effect of the hydroxyl group should open positions 3,5,4′ to substitution. That substitution does follow the normal course, namely, (1) mono-ortho, (2) di-ortho, and (3) di-ortho-*p*′ has been demonstrated by Bell and Robinson[1] for nitration, and by Colbert and others[2] for chlorination. The substitution reactions of 2-hydroxydiphenyl, in which postions 3,5 are open, have been investigated by Borsche and Scholten.[3]



Very little work has been reported for the less readily obtainable 3-hydroxydiphenyl. This latter phenol presents an interesting case since positions 2,4,6 are open on the same ring with the hydroxyl group—a circumstance which should lead to the preparation of phenyl substituted picric acid as well as like compounds.

Nitration and Bromination of 3-Hydroxydiphenyl.—When 3-hydroxydiphenyl is treated in acetic acid solution with one molar proportion of nitric acid, the solution warms up, turns a deep red, and when added to boiling water throws down a crystalline precipitate of mononitro-3-hydroxydiphenyl. Further dilution of the mother liquor leads to precipitation of a dark colored oil, the nature of which is still under investigation. Nitration with two or more molar proportions of nitric acid yields a dinitro derivative. This is the highest nitration product it has yet been possible to obtain by the direct nitration of 3-hydroxydiphenyl. Since this dinitro derivative does not form a diphenyl ether, or a benzoate, reactions given readily by the mononitro-3-hydroxydiphenyl, it is thought to be a di-ortho derivative and is tentatively assigned the structure 2,4-dinitro-3-hydroxydiphenyl. It should be pointed out that this lack of reactivity is also found in the case of 3,5-dinitro-4-hydroxydiphenyl as we have often observed in this Laboratory. The nitration of mononitro-3-hydroxydiphenyl forms the same dinitro derivative as that obtained by use of a double portion of nitric acid upon 3-hydroxydiphenyl.

Bromination in carbon disulfide of 3-hydroxydiphenyl yields oils save when three or more molar proportions of bromine are added. In the latter case a crystalline tribromo derivative results. The formula 2,4,6-tribromo-3-hydroxydiphenyl is assigned tentatively although it has not yet been possible to degrade to recognizable products. While mononitro-3-hydroxydiphenyl brominates readily in acetic acid solution, only one bromine atom enters the ring. Henkel and Hey[4] report the preparation of 5-bromo-3-hydroxydiphenyl and 4,5-dibromo-3-hydroxydiphenyl, but not by direct bromination of the corresponding phenol.

Proof of Structure for 4-Nitro-3-hydroxydiphenyl.—Wohl[5] has shown that when nitrobenzene is allowed to stand in contact with finely powdered potassium hydroxide an intermolecular oxidation–reduction reaction occurs which gives rise to *o*-nitrophenol as one of the principal products of the reaction. It has also been shown[6] that on the large scale and with special care to avoid the presence of moisture the principal reaction comprises the interaction of five moles of nitrobenzene in the presence of the potassium hydroxide to form three moles of nitrophenol, in the form of the potassium salt, and one mole of azoxybenzene. A relatively small amount of the *p*-nitrophenol is produced at the same time.

The reaction appears to be fairly general, hav-

ing been used to convert nitrotoluene, *m*-nitrochlorobenzene and nitronaphthalene to the corresponding *o*-nitrophenols[7] but it has not, so far as we are aware, been applied to a nitrodiphenyl.

When 4-nitrodiphenyl is heated on the water-bath with an excess of powdered potassium hydroxide, the medium being benzene, a nitrophenol is obtained. The melting point as well as the microscopic appearance of this phenol is in agreement with the mononitrophenol obtained by the direct nitration of 3-hydroxydiphenyl. A mixed melting point confirms this conclusion. Since introduction of the hydroxyl group into 4-nitrodiphenyl yields the same phenol as that obtained by introducing the nitro group into 3-hydroxydiphenyl, the nitrophenol must be 4-nitro-3-hydroxydiphenyl.

The nature of the oil formed in the mononitration of 3-hydroxydiphenyl is still under investigation. The oil may contain the 2-nitro, the 5-nitro or a mixture of such mononitro derivatives. Preliminary experiments indicate that when 2-nitrodiphenyl is treated with potassium hydroxide, a mononitrophenol is formed. This compound may be found identical with a component of the oil.

Experimental Part

4-Nitro-3-hydroxydiphenyl from 3-Hydroxydiphenyl.—Seven grams of 3-hydroxydiphenyl was dissolved in 100 cc. of glacial acetic acid, the solution cooled to 10–15° and 2.6 cc. of concd. nitric acid in 20 cc. of glacial acetic acid added. The solution became a dark red within two minutes and after standing for thirty minutes at room temperature was precipitated by pouring with stirring into an equal volume of boiling water. The solution was allowed to cool and the rather small precipitate of irregular yellow plates filtered. The yield varied from 15.6 to 24.4%, the larger figure being obtained by permitting the nitration mixture to stand overnight before precipitation. The larger yields were darker colored and somewhat tarry. Recrystallization from 80% alcohol gave a product melting from 102.5–103.5°.

Anal. Calcd. for $C_{12}H_9NO_3$: N, 6.52. Found: N, 6.80.

4-Nitro-3-hydroxydiphenyl from 4-Nitrodiphenyl.—Two hundred and eighty-four grams of potassium hydroxide, previously ground in a corn mill, 112 g. of benzene and 112 g. of 4-nitrodiphenyl were well mixed and heated on the water-bath at 72–76° for seventy-two hours. At the end of that time a small amount of water and benzene was added with good agitation and the mixture filtered. It was finally pulped twice with fresh benzene and the benzene filtered off after each pulping. Weight of air-dried precipitate was 45 g.

The precipitate was dissolved in 500 cc. of hot water, the solution filtered hot and allowed to cool slowly. The deep red, crystalline, precipitate was filtered off, washed with a little cold water, and dried in a desiccator; weight 18.1 g.

A small portion (4 g.) of this material was dissolved in water and the solution acidified with hydrochloric acid, whereupon a greenish-yellow crystalline solid precipitated. After being filtered off, washed and dried, the material weighed 3.0 g. and melted at 103.1 to 103.2°. It was recrystallized from 20 g. of Skellysolve E. The recrystallized material occurred in the form of glistening greenish-yellow plates, weighed 2.5 g. and melted at 103.1 to 103.3°.

When a sample of this material was mixed with that obtained by direct nitration of 3-hydroxydiphenyl, the m. p. was 102.7 to 103.2°. When crystallized from 80% alcohol and examined under the microscope the crystals from the two sources appeared identical.

Dinitro-3-hydroxydiphenyl.—Seven grams of 3-hydroxydiphenyl was dissolved in 20 cc. of glacial acetic acid and 7.8 cc. of concd. nitric acid added. This was sufficient nitric acid for the formation of a trinitro derivative. The solution became red and boiled vigorously. Upon cooling coarse yellow, prismatic crystals precipitated and 2.95 g. of product was obtained, or a yield of 27.5%. Evaporation of the mother liquor to half volume led to the further crystallization of less pure material. Recrystallization from 95% alcohol gave a lemon-yellow product melting at 172.5–173°. This compound is very inert chemically and forms neither benzoate, bromo derivative, nor diphenyl ether.

Dinitro-3-hydroxydiphenyl from 4-Nitro-3-hydroxydiphenyl.—Six-tenths gram of 4-nitro-3-hydroxydiphenyl was dissolved in 8 cc. of glacial acetic acid and 0.25 cc. of concd. nitric acid in 3.0 cc. of glacial acetic acid added. After standing a few minutes the solution was heated to boiling, cooled to 15° and precipitated by pouring over ice. The precipitate weighed 0.54 g., m. p. 165°. Recrystallization from 95% alcohol raised the m. p. to 170°. A mixed melting point confirmed the identity of the product from the two sources.

Anal. Calcd. for $C_{12}H_8N_2O_5$: N, 10.76. Found: N,10.30.

Tribromo-3-hydroxydiphenyl.—When 28.2 g. (8.9 cc.) of bromine was added to 10.0 g. of 3-hydroxydiphenyl in 100 cc. of carbon disulfide, the ensuing reaction was quite vigorous. After standing for five days the solution was washed with sodium carbonate solution, acidified, separated, and dried over calcium chloride. The carbon disulfide was distilled off and crystals obtained after long standing. The product was light brown, slightly gummy, and formed in 86.1% yield, *i. e.*, 20.62 g. Recrystallization was accomplished with difficulty from 200 cc. of 80% acetic acid; m. p. 92°.

Anal. Calcd. for $C_{12}H_7OBr_3$: Br, 58.93. Found: Br, 58.10.

Other Derivatives of 3-Hydroxydiphenyl.—Ethers and other derivatives have been obtained by methods similar to those reported in a preceding paper.

3′-Phenyl-2,4-dinitrodiphenyl ether, $C_6H_5C_6H_4OC_6H_3(NO_2)_2$, from potassium hydroxide, pyridine, $C_6H_3Cl(NO_2)_2$; m. p. 100°; yield 90.0%; calcd. N, 8.33; found: N, 8.53.

---

[7] German Patent 116,790 (1899).

3′-Phenyl-2,4,6′-trinitrodiphenyl ether, $C_6H_5C_6H_3(NO_2)OC_6H_3(NO_2)_2$, from potassium hydroxide, pyridine, $C_6H_3Cl(NO_2)_2$; m. p. 131°; yield 95.7%; calcd. N, 11.03; found: N, 10.99.

3′-Phenyl-2,4,6-trinitrodiphenyl ether, $C_6H_5C_6H_4OC_6H_2(NO_2)_3$, from potassium hydroxide and picryl chloride; m. p. 143°; yield 92.4%; calcd. N, 11.03; found: N, 11.80.

?-Bromo-4-nitro-3-hydroxydiphenyl, $C_6H_5C_6H_2Br(NO_2)OH$; m. p. 109°; yield 40.0%; calcd. Br, 27.18; found: Br, 26.62.

Summary

1. When 3-hydroxydiphenyl is nitrated the first compounds formed are probably isomeric mononitro derivatives. One of these isomers has been isolated in pure form.

2. The structure of the mononitro derivative isolated has been proved by preparation from 4-nitrodiphenyl by the use of powdered potassium hydroxide.

3. While with bromine 3-hydroxydiphenyl yields a tribromo derivative, with nitric acid only a mono and a dinitro compound have been prepared. Due to the reduced activity of the hydroxy group the dinitrophenol is believed to be 2,4-dinitro-3-hydroxydiphenyl.

4. Work is continuing in an effort to obtain higher nitro derivatives, bromo derivatives containing less than three bromine atoms, and in the expectation of obtaining definite compounds from the oily by-product obtained in the mononitration of 3-hydroxydiphenyl.

Crystalline Acetal Derivatives of *d*-Arabinose[1]

BY EDNA M. MONTGOMERY, RAYMOND M. HANN AND C. S. HUDSON

Solutions of methyl glycoside acetates of the pyranose type, such as β-methyl glucoside tetraacetate, in a mixture of acetic acid and acetic anhydride, upon catalysis by sulfuric acid, have been shown to be transformed to α-acetates of the pyranose type,[2] while those possessing a furanoside linkage are changed under the same conditions to form either aldehydo acetates[3] or ring acetates probably of furanoid structure. It seemed of interest to investigate the course of this reaction in the case of an acetylated methyl glycoside of arabinose, in which the ring, while pyranoid in structure, involves the hydroxyl group of the terminal carbon atom. The results obtained were so novel that it seemed desirable to extend the investigation to include observations upon the catalytic effect of zinc chloride; here again, a novel change was disclosed.

A solution of triacetyl-β-methyl-*d*-arabinoside (I) in a mixture of three volumes of acetic acid and seven volumes of acetic anhydride (hereafter called the acetylating mixture), containing 4% by weight of sulfuric acid, reached an equilibrium rotation (−17°)[4] in three minutes at 20°, in contrast to the behavior of tetraacetyl-β-methyl glucoside, which required forty-eight hours under the same conditions. The crystalline reaction products that were isolated from the pentose derivative included 56% of an open chain compound, aldehydo-*d*-arabinose hexaacetate (II), but there was present only 11% of the expected ring compound, β-*d*-arabinose tetraacetate (III); under similar conditions β-methyl glucoside tetraacetate yielded 92% of the ring compound, α-glucose pentaacetate.

The fact that this concentration of sulfuric acid thus led largely to rupture of the pentopyranoside ring, removal of the methyl group, and peracetylation, suggested the substitution of zinc chloride or a weaker sulfuric acid concentration as milder catalytic agents. The zinc chloride (8%) caused a decided shift in the equilibrium value (+30°) of the acetylating solution and resulted in *complete* rupture of the lactonyl ring, ***but without removal of the methyl group***, the elements of acetic anhydride being added to yield a mixture of two pentaacetyl-*d*-arabinose methyl hemi-acetals (IV and V), which were isolated in high (86%) yield. No ring compound could be isolated and the rotations of the pure hemi-acetal pentaacetates, +25° and +32° (in the acetylation mixture), compared to the equilibrium rotation of +30°, indicated the

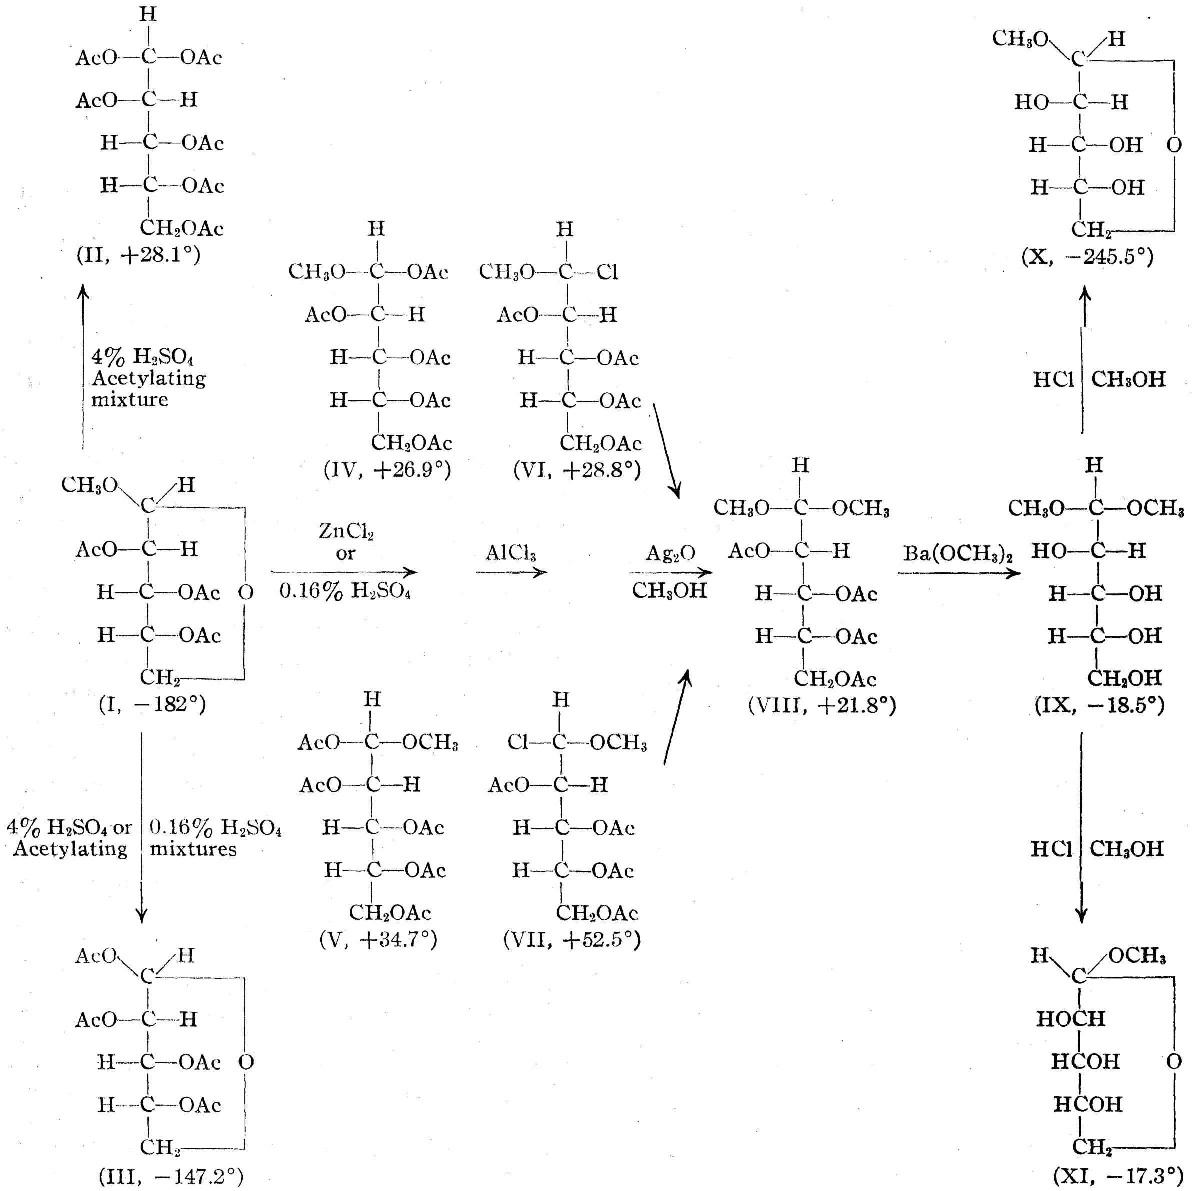
[3] Montgomery and Hudson, *ibid.*, 56, 2463 (1934).

[4] All rotations are specific rotations at 20° in sodium light.



absence of a levorotating reaction product. The diastereomers, moreover, are interconvertible in the zinc chloride solution, reaching an equilibrium value of +28° and being present in approximately equal amounts. They are quantitatively converted to aldehydo-*d*-arabinose hexaacetate by the 4% sulfuric acid solution, indicating their formation as an intermediate step in the production of the latter substance from β methyl-*d*-arabinoside triacetate when dissolved in this solution.

The weaker sulfuric acid (0.16%) brought about the same equilibrium value (−17°) obtained with the stronger acid, and examination of the reaction products indicated a comparable degree of ring rupture since it was possible to isolate β-*d*-arabinose tetraacetate in a yield of only 8% of the theoretical; however, with this weaker acid concentration removal of the methyl groups *did not* occur from the simultaneously formed isomeric pentaacetyl-*d*-arabinose methyl hemi-acetals and they were isolated as the main reaction products. The agreement of the equilibrium rotations for the weaker and the stronger acid catalysts is thus fortuitous and is due to the fact that the rotations of the aldehydo hexaacetate and the two pentaacetyl methyl hemi-acetals are nearly alike.

The results obtained with the various catalysts are summarized in Table I, which also includes ob-

TABLE I

RESULTS OF CATALYTIC TRANSFORMATION OF ACETYLATED *d*-ARABINOSE DERIVATIVES

Substance	Rotation in non-catalyzed acetylating mixture	Rotation in acetylating mixture + 8% $ZnCl_2$	Products	Rotation in mixture + 0.16% H_2SO_4	Products	Rotation in mixture + 4% H_2SO_4	Products

servations upon α-methyl-*d*-arabinoside triacetate and the changes of the hemi-acetal pentaacetates in catalyzed acetylating mixtures. These data indicate that zinc chloride catalysis slowly but completely ruptures the ring and introduces an acetyl radical at each of carbon atoms 1 and 5 without breaking the methoxyl union; 0.16% sulfuric acid produces much more rapidly an equilibrium between a small amount of a ring acetate and the interconvertible open chain methyl hemi-acetal pentaacetates; and 4% sulfuric acid is believed to bring about very rapidly the same equilibrium as the dilute acid and then to remove, also rapidly, the methyl group of the hemi-acetals which is followed by acetylation to yield the aldehydrol hexaacetate.

Whether these reactions which rupture the oxygen ring are a specific property of the arabinose configuration or are a general reaction of pyranoside linkages involving a terminal carbon atom is at present left undecided; further studies on this subject will be made.

It would be anticipated that the acetyl group in combination with the aldehydic carbon in a pentaacetyl-*d*-arabinose methyl hemi-acetal could be differentially substituted by halogen. Treatment of the two pure isomeric acetylated hemi-acetals with anhydrous aluminum chloride formed two different crystalline isomeric tetraacetyl-*d*-arabinose-1-chloro-1-methyl acetals (VI and VII). Upon solution in methyl alcohol and treatment with silver oxide these two compounds yielded the same crystalline tetraacetyl-*d*-arabinose dimethyl acetal (VIII) which could be deacetylated readily to form *d*-arabinose dimethyl acetal in quantitative yield. Hydrolysis of the dimethyl acetal in 0.05 *N* aqueous acid led to the isolation of crystalline *d*-arabinose, while the action of acid methyl alcohol gave a mixture of methyl-*d*-arabinosides (X and XI), the latter reaction being consonant with Fischer's view that dimethyl acetals may be one of the intermediate products in the synthesis of glycosides.

We are indebted to Dr. O. E. May of the Industrial Farm Products Laboratory, U. S. Department of Agriculture, for a supply of calcium gluconate, to Mr. George L. Keenan, of the Food and Drug Administration, U. S. Department of Agriculture, for optical-crystallographic examination of crystals, and to Dr. W. T. Haskins, of the National Institute of Health, for microchemical analyses of some of the described compounds.

Experimental

General.—The 4% acid acetylation solution was prepared by adding 4% by weight of concentrated sulfuric acid dropwise to an ice cold mixture of 70 cc. of acetic anhydride (99.5%) and 30 cc. of acetic acid (99.5%). The weak acid solution (0.16%) was prepared by diluting the 4% acid solution with the anhydride–acid mixture. The zinc chloride solution contained 8 g. of the fused salt in 100 cc. of the anhydride acid mixture. All polarimetric observations of the acetylating reaction were made at 20 ± 0.5° in a 1-dm. glass polariscope tube with sealed glass end-plates. Specific rotations of pure compounds were measured in 2-dm. tubes in the specified solvent.

Transformation of Triacetyl-β-methyl-*d*-arabinoside in the 4% Acid Acetylating Mixture. Isolation of Aldehydo-*d*-arabinose Hexaacetate.—A solution of 10 g. of triacetyl-β-methyl-*d*-arabinoside in 250 cc. of the strong acid reagent changed in rotation from −184° to a constant equilibrium value of −17° in three minutes at 20°. After standing twenty-four hours, the solution was poured into crushed ice, yielding 7.0 g. of a crystalline precipitate (rotation, +26° in chloroform). Extraction of the aqueous solution yielded 5.8 g. of sirup (rotation, −60° in chloroform) which slowly deposited about 3 g. of crystalline material. The combined crystals were fractionally recrystallized from a mixture of 20 cc. of alcohol and 10 cc. of water, yielding 8.2 g. (56%) of aldehydo-*d*-arabinose hexaacetate and 1.2 g. (11%) of β-*d*-arabinose tetraacetate.

Aldehydo-*d*-arabinose hexaacetate crystallizes from 3 parts of 70% alcohol in needles melting at 89.5° (corr.). Its specific rotation in chloroform is +28.1° (*c*, 1.33), comparable in value with but opposite in sign to Wolfrom's[5] observation of −27° for the 1-isomer which also melts at 89.5°.

Optical-crystallographic examination by Mr. G. L. Keenan showed the crystals to be rodlike, many with six sides. The refractive indices were $n_\alpha = 1.455$, $n_\beta = 1.472$ and $n_\gamma = 1.495$, all ±0.003. In parallel light with crossed nicols the extinction was straight, the double refraction strong, the sign of elongation ±, and in convergent parallel light interference figures were rare.

Anal. Calcd. for $C_5H_6O_6(COCH_3)_6$: C, 48.6; H, 5.8; acetyl, 14.28 cc. of 0.1 *N* NaOH per 100 mg. Found: C, 48.8; H, 6.0; acetyl, 14.25 cc.

Transformation of Triacetyl-β-methyl-*d*-arabinoside in the 8% Zinc Chloride Acetylating Mixture. Isolation of Two Isomeric Crystalline Pentaacetyl-*d*-arabinose Methyl Hemi-acetals.—A solution of 10 g. of the acetylated methyl glycoside in 125 cc. of the zinc chloride reagent slowly changed in specific rotation from −184° to an equilibrium value of +30° in forty-eight hours at 20°. The slightly yellow solution was poured into one liter of ice water and after decomposition of the excess acetic anhydride the solution was extracted with chloroform. The solvent-free sirup that was obtained (13 g.) by removal of the chloroform was dissolved in 30 cc. of absolute ether and after one week crystallization of clusters of rodlike prisms, rotating +26.9° in chloroform when pure, occurred in a yield of 5.7 g. (42%). From the mother liquors a crop of a second type of prisms, short, many faced with one pyramidal end, rotating +34.7° in chloroform when pure, was recovered in an amount of 5.9 g. (44%). Upon analysis these substances proved to be isomeric, and contained one methoxyl and five acetyl groups. These facts and other evidence to be presented indicated their structure as pentaacetyl-*d*-arabinose methyl hemi-acetals. Their isomerism is due to the stereo-arrangement of the groups attached to carbon atom I. In further discussion the compound rotating +26.9° will be designated the first isomer, and the one of rotation +34.7° the second isomer. It is emphasized however that the assignment of the relative stereo positions of the methoxyl and acetyl groups on the aldehyde carbon atom in the hemi-acetal formulas is arbitrary.

The first isomer, when recrystallized to constant physical properties from ether, melted at 76° and showed a specific rotation of +26.9° in chloroform (*c*, 1.33). It was very soluble in the usual organic solvents, insoluble in petroleum ether, and soluble in water to the extent of 0.6 g. in 100 cc. at 20°. It reduced Fehling's solution slowly on boiling. Optical-crystallographic examination by Mr. Keenan showed that in ordinary light the refractive indices of the crystals were: $n_\alpha = 1.448$, $n_\beta = 1.500$, $n_\gamma = 1.510$, all ±0.003. In parallel light, with crossed nicols, the double refraction was very strong. In convergent polarized light, crossed nicols, biaxial interferences figures showing sections normal to the acute bisectrix were common, the axial angle being large, 2E = 70° (±5°). The optic sign was negative.

Anal. Calcd. for $C_5H_6O_5(OCH_3)(COCH_3)_5$: C, 49.0; H, 6.2; OCH_3, 7.9; acetyl, 12.75 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.1; H, 6.2; OCH_3, 7.9; acetyl, 12.70 cc.

The second isomer when pure melted at 68–70°, gave a specific rotation in chloroform of +34.7° (*c*, 1.33) and showed the same solubility behavior as the first isomer. Optical-crystallographic examination by Mr. Keenan showed that its optical properties are distinctly different, the refractive indices being $n_\alpha = 1.455$, $n_\beta = 1.464$, $n_\gamma = 1.490$, all ±0.003. In convergent polarized light, crossed nicols, partial biaxial interference figures are frequently obtained, usually showing sections normal to an optic axis or oriented obliquely to the bisectrices. The double refraction is strong.

Anal. Calcd. for $C_5H_6O_5(OCH_3)(COCH_3)_5$: C, 49.0; H, 6.2; OCH_3, 7.9; acetyl 12.75 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.0; H, 6.0; OCH_3, 7.9; acetyl, 12.65 cc.

Transformation of Triacetyl-β-methyl-*d*-arabinoside in 0.16% Acid Acetylating Mixture.—A solution of 10 g. of the acetylated glycoside in 250 cc. of the acetylating mixture declined in rotation from −184 to −17° in four hours at 20°. The solution was worked up in the usual manner and the resulting sirup brought to crystallization by solution in 30 cc. of ether and addition of 10 cc. of petroleum ether. The first yield was fractionally recrystallized, and 2.8 g. (21%) of the first and 2.7 g. (20%) of the second isomeric acetylated methyl hemi-acetals were obtained. The remaining sirup was taken up in 20 cc. of 50% alcohol and upon long standing at 5° separated 0.85 g. (8%) of β-*d*-arabinose tetraacetate.

Transformation of Triacetyl-α-methyl-*d*-arabinoside in Acetylating Mixtures.—Triacetyl-α-methyl-*d*-arabinoside was obtained as a colorless sirup rotating −17° in chloroform by the action of methyl alcohol and silver carbonate on crystalline acetobromo-*d*-arabinose. (1) A solution of 5 g. of the sirup in 67 cc. of the zinc chloride reagent changed slowly from an initial rotation of −19° to an equilibrium value of +30° in about twelve hours. No rise in rotation in a levo direction was observed, indicating the absence of an α to β shift prior to the breaking of the lactonyl ring (contrast the action of acid mixtures). The isolable reaction products were 2.5 g. (37%) of each of the isomeric acetylated methyl hemi-acetals. The rotational behavior and equilibrium value indicated the absence of a ring tetraacetate. (2) A solution of 10 g. of the sirup in 250 cc. of 0.16% acid reagent rose rapidly in rotation from −19 to −116° within forty minutes and then declined slowly to an equilibrium value of −25° at the end of five hours. The products isolated were 2.5 g. (18%) of each of the crystalline acetylated methyl hemi-acetals and 0.9 g. (8%) of β-*d*-arabinose tetraacetate. The ring acetate was isolated in only one case because of the extreme difficulty in getting it to crystallize, but the rotational data in all experiments of this group indicated its presence. (3) A solution of 5 g. of the sirup in 125 cc. of 4% acid reagent rose sharply in rotation from −19 to −114° in one minute and declined to an equilibrium value of −25° at the end of twenty minutes. The products isolated were 3.6 g. (50%) of aldehydo-*d*-arabinose hexaacetate and 0.8 g. (12%) of β-*d*-arabinose tetraacetate. A second experiment was interrupted at the rotation peak

---

(5) Wolfrom, THIS JOURNAL, **57**, 2498 (1935).

of −114° and yielded 1 g. (14%) of crystalline β-methyl-*d*-arabinoside triacetate. The experiments on the α-acetylated glycoside confirm in every instance the similar experiments on the crystalline β-isomer.

Transformation of the Pentaacetyl-*d*-arabinose Methyl Hemi-acetals in Acetylating Mixtures.—(1) A solution of 5 g. of the first isomer (+26.9°) in 67 cc. of the zinc chloride reagent reached an equilibrium rotation of +28° within three minutes. From the reaction mixture 2.3 g. (46%) of unchanged material and 2.2 g. (44%) of the second isomer (+34.7°) was recovered. A similar experiment using 5 g. of the second isomer resulted in the same equilibrium rotation and yielded 2.4 g. (48%) of unchanged material and 2.3 g. (46%) of the first isomer. (2) A solution of 2.0 g. of the first isomer (+26.9°) in 50 cc. of the 0.16% acid mixture gave an equilibrium rotation of +26.8° after two minutes. The reaction products were 0.88 g. (44%) of the second isomer and 0.85 g. (42%) of the first isomer. The second isomer (+34.7°) in a similar experiment gave an equilibrium rotation of +27° in two minutes, the reaction products being 0.80 g. (40%) of the first isomer and 0.85 g. (42%) of the second one. No evidence was obtained of the presence of ring isomers. (3) A solution of 5.0 g. of the first isomer in 125 cc. of the 4% acid mixture showed no change in rotation from an initial value of +25° upon standing for eighteen hours. From the reaction mixture aldehydo-*d*-arabinose hexaacetate was recovered in a yield of 4.9 g. (91%). A similar experiment with the second isomer showed a change in rotation from +32 to +25° and yielded 5.0 g. (92%) of the aldehydo-*d*-arabinose hexaacetate.

2,3,4,5-Tetraacetyl-1-chloro-*d*-arabinose Methyl Hemi-acetal from Pentaacetyl-*d*-arabinose Methyl Hemi-acetal of Rotation +26.9° (the First Isomer).—A solution of 10 g. of the first isomeric acetylated hemi-acetal in 100 cc. of anhydrous alcohol-free chloroform was cooled to 5° and 10 g. of pulverized anhydrous aluminum chloride added, with gentle agitation; a light brown granular addition product separated. After one-half hour the mixture was washed with ice and water and the chloroform layer was dried with calcium chloride and concentrated *in vacuo* to a sirup, which separated crystalline material upon solution in 20 cc. of ether and addition of 10 cc. of petroleum ether. The crude product was recrystallized once in the same way, yielding 6.3 g. (67%). The compound melts at 71° (corr.) and shows a specific rotation of +28.8° in chloroform (*c*, 1.33). It is quite unstable, decomposing slightly upon recrystallization, and quite rapidly upon standing. A confirmatory experiment was conducted by Freudenberg's[6] method, yielding 65% of the chloro compound, melting at 70° and having a rotation of +29°.

Anal. Calcd. for $C_{14}H_{21}O_9Cl$: Cl, 9.6; OCH_3, 8.4. Found: Cl, 8.8; OCH_3, 7.8.

The Isomeric 2,3,4,5-Tetraacetyl-1-chloro-*d*-arabinose Methyl Hemi-acetal from Pentaacetyl-*d*-arabinose Methyl Hemi-acetal of Rotation +34.7° (the Second Isomer).—Under the same experimental conditions of chlorination by aluminum chloride the second isomeric acetylated hemi-acetal yielded 73% of a second chloro tetraacetyl methyl hemi-acetal melting at 73° (corr.) and showing a rotation of +52.5° in chloroform. The Freudenberg procedure gave a yield of 60% of the same product.

Anal. Calcd. for $C_{14}H_{21}O_9Cl$: Cl, 9.6; OCH_3, 8.4. Found: Cl, 8.8; OCH_3, 7.4.

Tetraacetyl-*d*-arabinose Dimethyl Acetal.—(1) A solution of 10 g. of crystalline tetraacetyl-1-chloro-*d*-arabinose methyl hemi-acetal, of rotation +28.8°, in a mixture of 25 cc. of absolute ether and 25 cc. of methyl alcohol was cooled to 0° and agitated with 10 g. of silver oxide. After five minutes, the separated silver salts were removed, the solution was concentrated to a sirup, the sirup was dissolved in 15 cc. of ether and brought to crystallization by addition of 5 cc. of petroleum ether. A yield of 4.2 g. (42%) of the acetylated dimethyl acetal was obtained readily. (2) A similar experiment employing the crystalline chloro derivative of rotation +52.5° yielded 4.4 g. (44%) of the same tetraacetyl-*d*-arabinose dimethyl acetal.

Tetraacetyl-*d*-arabinose dimethyl acetal crystallizes in prisms, melting at 80° (corr.) and showing a specific rotation of +21.8° in chloroform (*c*, 1.33). It is readily soluble in ether and chloroform, almost insoluble in water, and insoluble in petroleum ether. It does not reduce Fehling's solution.

Anal. Calcd. for $C_5H_6O_4(OCH_3)_2(COCH_3)_4$: C, 49.4; H, 6.6; OCH_3, 17.0; acetyl, 10.98 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.5; H, 6.7; OCH_3, 16.9; acetyl, 11.00 cc.

***d*-Arabinose Dimethyl Acetal.**—A solution of 6 g. of tetraacetyl *d*-arabinose dimethyl acetal in 120 cc. of absolute methyl alcohol was cooled to 0°, 0.4 cc. of 2 *N* barium methylate added, and allowed to stand at 0° for two hours. Upon volatilization of the solvent a crystalline residue of 3.3 g. (quantitative) rotating −16.8° in water was obtained, and recrystallization from 5 parts of methyl alcohol to constant rotation, yielded 2.8 g. (88%) of pure *d*-arabinose dimethyl acetal. This compound crystallizes in clear hexagonal prisms melting at 122° and showing a specific rotation of −18.5° in water. It does not reduce Fehling's solution, but upon hydrolysis at 98° in 0.05 *N* hydrochloric acid it yielded *d*-arabinose, and upon treatment with acid methyl alcohol it gave a mixture of methyl-*d*-arabinosides. We expect to study its change to glycosides in more detail later.

Anal. Calcd. for $C_5H_{10}O_4(OCH_3)_2$: C, 42.8; H, 8.2; OCH_3, 31.6. Found: C, 42.8; H, 8.2; OCH_3, 31.6.

Summary

Studies have been made of the action of catalyzed acetylating mixtures upon α and β methyl-*d*-arabinopyranoside triacetates. The results indicate: (1) that zinc chloride catalysis completely ruptures the lactonyl linkage without hydrolysis of the methyl group, to yield two isomeric pentaacetyl-*d*-arabinose methyl hemi-acetals; (2) that 0.16% sulfuric acid causes an equilibrium between a small amount of ring acetate and these hemi-acetals; and (3) that 4% sulfuric acid brings

---

[6] Freudenberg, Hochstetter and Engels, *Ber.*, **58**, 668 (1925).

about a similar equilibrium followed by hydrolysis of the methyl group and peracetylation to yield aldehydo-*d*-arabinose hexaacetate.

The isomeric pentaacetyl-*d*-arabinose hemi-acetals have been converted to two isomeric chloro derivatives, which by the usual methods are converted into the same tetraacetyl-*d*-arabinose dimethyl acetal.

d-Arabinose dimethyl acetal has been synthesized in crystalline condition by deacetylation of its tetraacetate.

The Densities and Vapor Pressures of Some Alkylbenzenes, Aliphatic Ketones and *n*-Amyl Chloride[1]

BY J. C. RINTELEN, JR., J. H. SAYLOR AND P. M. GROSS

During the course of an investigation of the solubility of some organic compounds being carried out in this Laboratory, it became necessary to know the vapor pressures and densities of these compounds at 10, 30 and 50°. An examination of the literature showed that there were no available density and vapor pressure data for some of the substances and that there were rather serious discrepancies in the vapor pressure data for ethylbenzene, the xylenes and mesitylene. Therefore, their vapor pressures together with the vapor pressures and densities of *n*-amyl chloride and some ketones were determined. After the experimental part of this work was completed, Kassel[2] called attention to the erroneous data of Woringer[3] for the vapor pressures of the xylenes and mesitylene that are given in the "International Critical Tables." Kassel redetermined the vapor pressures of these compounds.

Experimental

Materials.—The ethylbenzene and the dibutyl ketone were prepared in this Laboratory. The other substances were the best grades commercially available. All were subjected to a careful purification by successive fractionation using efficient stills and calibrated thermometers. Boiling points were corrected to 760 mm. by means of Craft's rule whenever the value of d*T*/d*P* could not be found in the literature. The boiling ranges of the samples used are given in Table I.

TABLE I

BOILING POINT RANGES OF THE COMPOUNDS

Substance	B. p. range, °C.	Previously observed b. p., °C.	Ref.
Ethylbenzene	136.13–136.18	136.15	4a
o-Xylene	144.0 –144.1	144.0	4b
m-Xylene	138.99–139.15	139.3 (139.00)	4b (6)
p-Xylene	138.27–138.37	138.4 (138.3)	5 (6)
Mesitylene	164.5 –164.6	164.6	4b
n-Amyl chloride	107.74–107.78	105.7 (106.6, 740 mm.)	6, (7)
Methyl isopropyl ketone	94.0 –94.52	95–96, 93–94, 95–95.3	8, 9, 10
Methyl isobutyl ketone	116.71–116.78	116.85	4c
Diethyl ketone	101.59–101.74	101.7	8
Dipropyl ketone	144.05–144.12	144.1	4b
Dibutyl ketone	187.4 –188.4	187.65	4d

Method.—The vapor pressures were measured by a differential static method. As the form of apparatus used has been found to be particularly convenient, it is shown in Fig. 1.

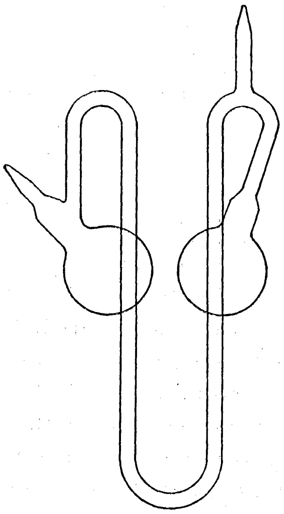

Fig. 1.—Vapor pressure apparatus.

Mercury was introduced into the manometer through the vertical tube, water placed in one bulb and the organic liquid in the other. The mercury in the manometer was

heated and the water and organic liquid in the bulbs were boiled. Then both sides of the apparatus were evacuated simultaneously while gentle heating continued for thirty minutes. The capillaries were then sealed off.

Temperatures were controlled by thermostats regulated to within ±0.02°. The difference in the mercury levels in the arms of the manometer was read with a cathetometer and corrected to 0°. This added to or subtracted from the vapor pressure of water at the temperature in question, gave the vapor pressure of the liquid. Each apparatus was set up in duplicate for each substance and readings made at 10, 30 and 50°. The method was checked by carrying out the procedure with water in both sides of the apparatus. Several trials gave an average deviation from zero of 0.1 mm.

The densities were determined with a 10-cc. specific gravity bottle, in the same thermostats. These determinations were also made in duplicate at 10, 30 and 50°.

Results

Table II gives a summary of the vapor pressure and density data. Each result is the average of two independent determinations. The duplicate vapor pressure determinations agreed within 0.6 mm. in most cases and the density determinations to within less than 1 part in 10,000.

TABLE II

VAPOR PRESSURE AND DENSITY DATA

Substance	Vapor pressures, mm. 10°	30°	50°	Densities, d_4^t, g./ml. 10°	30°	50°
Ethylbenzene	2.9	11.6	34.6			
o-Xylene	1.6	7.4	25.1			
m-Xylene	2.2	9.1	29.3			
p-Xylene	2.3	10.7	32.3			
Mesitylene	0.6	3.8	11.5			
n-Amyl chloride	15.0	41.2	100.8	0.8940	0.8750	0.8544
Methyl isopropyl ketone	27.4	67.3	166.7	.8239	.8052	.7847
Methyl butyl ketone				.8198	.8025	.7845
Methyl isobutyl ketone	8.0	26.2	70.1	.8094	.7922	.7736
Diethyl ketone	16.9	46.1	117			
Dipropyl ketone	3.0	9.5	25.6			
Dibutyl ketone	1.5	4.7	12.6	.8296	.8148	.7981

The constants of the equation $\log_{10} P = (A/T) + B$ have been determined from a plot of the data for those substances for which no other vapor pressure data is known. While the limitations of such equations based on a few points is, of course, realized, they are given for convenience in interpolation. In these equations 0°C. = 273.16°K. The values of the constants are given in Table III. The average deviation of the observed values from those calculated is less than 1% in all cases.

TABLE III

CONSTANTS FOR THE VAPOR PRESSURE EQUATIONS

Substance	$-A$	B
n-Amyl chloride	1892	7.8573
Diethyl ketone	1926	8.0236
Dipropyl ketone	2126	7.9864
Dibutyl ketone	2101	7.6031

Kassel's values are in fair agreement with our own results although they are usually higher. Kassel points out that the accuracy of his data is limited by the fact that he did not purify his substances. Whether the differences noted here arise because of this or because of a small systematic error in our method or in his is not clear.

The results of Woringer used in the "International Critical Tables" are obviously wrong with the possible exception of those for *m*-xylene. This is probably attributable to a systematic error in method or more likely to the use of impure materials as he reported determinations by the same method for other compounds such as benzene and toluene which agree fairly well with the well established data of others.

Values for the vapor pressures of the hydrocarbons at 0° are given by Linder.[11] When our values are extrapolated to 0°, they are found to agree well with his except in the case of *m*-xylene and *p*-xylene. Values for *m*-xylene at higher temperatures given by Kudryavtzev[12] check with our results. Values for the vapor pressures for ethylbenzene at higher temperatures given by Kurbatov[13] check fairly well with our results while those given by Vvendenski[14] do not.

The values of Mayberry and Aston[15] for the vapor pressures of methyl isopropyl ketone and methyl isobutyl ketone given in Table III are only in fair agreement with ours.

Summary

The vapor pressures of ethylbenzene, *o*-xylene, *m*-xylene, *p*-xylene, *n*-amyl chloride, methyl isopropyl ketone, methyl isobutyl ketone, diethyl ketone, dipropyl ketone and dibutyl ketone have been determined at 10, 30 and 50°. The densities of *n*-amyl chloride, methyl isopropyl ketone, methyl butyl ketone, methyl isobutyl ketone and dibutyl ketone have been determined at 10, 30 and 50°.

An Improved Method of Purifying Europium*

BY HERBERT N. McCOY

WITH NOTES BY ARTHUR S. KING ON ITS "SPECTROSCOPIC PURITY," BY LINUS PAULING ON THE "ISOMORPHISM OF EUROPOUS SULFATE WITH STRONTIUM AND BARIUM SULFATES," AND BY G. P. BAXTER AND F. D. TUEMMLER ON THE "ATOMIC WEIGHT OF EUROPIUM"

The method described earlier[1-3] for the separation of europium from other rare earths leads easily to a fairly complete recovery of this element from monazite residues and gives, after a sufficient number of repetitions of the process, substantially pure europium. However, the material obtained after eight or nine successive precipitations as sulfate still contains a few tenths of a per cent. of impurities—principally neodymium, samarium and gadolinium. Doubtless any required degree of purity might be obtained by further repetitions of the process. The method though fast compared with fractional crystallization is rather laborious when the object is the preparation of material spectroscopically free from other rare earths.

The new process here described leaves little to be desired in the matter of speed, convenience and purity of product obtained. It depends upon the fact that a concentrated solution of europous chloride containing up to 30% of other rare earths gives with concentrated hydrochloric acid a crystalline precipitate of europous chloride dihydrate, $EuCl_2 \cdot 2H_2O$. This precipitate is practically free from other rare earths. By aid of this reaction in three days' time 125 g. of exceptionally pure europium oxalate was prepared. The progress of purification is shown by the following observations.

After one precipitation as europous chloride, no absorption bands of the other rare earths could be seen in a 10-cm. layer of the concentrated solution. The rare earths extracted from the filtrate showed strong bands of neodymium and weaker ones of samarium. After a second precipitation the rare earths from the filtrate showed in addition to europium only the strongest bands of neodymium (λ 5205 and λ 5522, and the group at λ 5726 to 5782) and these were very faint. After a third precipitation, europium recovered from the filtrate showed no bands of the other rare earths. The method is therefore very effective in the purification of europium. How effective was shown by an examination of its emission spectrum.

This work was kindly undertaken by Dr. Arthur S. King, who has made exhaustive studies of rare earth spectra.[4]

Dr. King states: "A spectrogram made with the 15 foot [454 cm.] concave grating having 15,000 lines to the inch [2.54 cm.] showed the sample of europium chloride to be of high purity. An examination of the ultraviolet region where many strong lines of gadolinium normally occur showed only faint traces of the strongest of these. One or two of the strongest lines of lanthanum may be present in this region. Barium and calcium are also present."

Following this examination, which showed traces of gadolinium present and probably lanthanum and by inference also some neodymium and samarium, the whole of the material was given two further precipitations (making a total of five) as europous chloride. A new sample in the form of trichloride was examined by Dr. King who reported: "The spectrogram of this new sample made with a normal exposure (for europium) showed no lines of other rare earths. The strongest lines of neodymium, samarium and gadolinium were looked for especially but not found."

"A second spectrogram, so much overexposed as to be useless for europium, showed three or four lines of neodymium, especially the strongest at λ 4303. No samarium or gadolinium lines could be seen on this plate. By comparison with plates exposed similarly and made with europium-neodymium mixtures of known composition, the amount of the latter present in the purest europium was estimated as not more than one in 100,000. Barium and calcium are still present in noticeable amounts."

Experimental Part

The starting material was a rare earth chloride solution of density 1.35. It had been partially purified by three successive precipitations as europous sulfate.[3] About 70% of its rare earth content was europium, the remainder being mostly neodymium, samarium and gadolinium. Four

hundred ml. of this chloride solution was put in a quart (liter) bottle[5] with a few ml. of concentrated hydrochloric acid and 100 g. of 30-mesh amalgamated C. P. zinc. The bottle, tightly stoppered, was shaken vigorously by hand and from time to time was placed directly before the slit of the spectroscope for the observation of the absorption spectrum of the solution. The latter, nearly colorless at first, turned yellowish and the europium band at λ 5253 gradually faded until after thirty or forty minutes it was no longer visible. All other absorption bands of europium had disappeared also, thus showing complete reduction.[2] The solution was next decanted from the remaining zinc into a second quart bottle in an atmosphere of carbon dioxide. The second bottle was closed by a two-holed stopper carrying a 250-ml. dropping funnel and a capillary outlet for the escape of gas. Concentrated hydrochloric acid was now run in slowly from the dropping funnel, while the contents of the bottle was kept well mixed. When about 200 ml. of acid had been added crystallization of hydrated europous chloride began and reached a maximum with about 500 ml. of acid. Ninety per cent. of the europium present separated out. The somewhat warm mixture was set in a refrigerator for two or three hours. It now consisted of nearly equal parts by volume of pure white crystals with a light blue fluorescence and an almost colorless mother liquor.

In filtering the crystals, which oxidize in air with great ease, a 12-cm. porcelain funnel with cotton filter cloth was used. It was fitted with a cardboard collar extending 12 to 15 cm. above the rim of the funnel. Carbon dioxide was led into the filter and collar in a rapid stream during filtration.[6] The crystals were not washed but were sucked as dry as possible.

With care, very little oxidation occurs. If oxidation takes place the filter cake gets very hot and fumes of hydrogen chloride come off. The cake of europous chloride was dissolved in water and the solution poured into a carbon dioxide filled bottle for repetition of the whole process. The second and following operations went much like the first, excepting that less time was required for the reduction as the material was mostly in the reduced state at the start.

After five repetitions of the process, the final europous solution was oxidized with nitric acid in the presence of sufficient hydrochloric acid to form the trichloride, filtered from a trace of insoluble matter—largely carbon left from the zinc dissolved—and precipitated with a solution of oxalic acid. The yield of oxalate from 400 ml. of original solution was 125 g. This was about half of the rare earth content of the starting material.

Subsequently three further lots of material were refined in this way. Five successive precipitations of each lot as europous chloride yielded a total of about 500 g. of pure europium oxalate.

The preparation of europous chloride dihydrate for analysis and its subsequent weighing was carried out wholly in an atmosphere of carbon dioxide since the substance oxidized rapidly on exposure to air. The chloride was made as already described, and filtered, washed, and weighed in a 130-ml. filtering tube having a coarse fritted glass filter plate.

The apparatus was arranged so that the tube could be kept filled with pure dry carbon dioxide (from "dry ice"). A 10% solution of hydrogen chloride in methyl alcohol, contained in an attached dropping funnel, was used for washing the europous chloride. The alcohol and excess hydrogen chloride were finally removed by a fast stream of carbon dioxide gas while the tube and its contents were gently warmed. When the outflowing gas no longer affected congo paper the material was free from excess acid and was dry.

The outlet of the filtering tube was now closed with a rubber plug and the stopper replaced by a solid rubber stopper. The tube and contents were weighed, the crystals, 1.9165 g., were dissolved in water and made up to 250 ml. Fifty-ml. portions were analyzed for europium and chlorine. The solution was oxidized with nitric acid and the europium precipitated as oxalate, ignited and weighed as oxide. The chloride was determined in a separate portion of solution as silver chloride.

0.3833 g. of substance gave 0.2619 g. of europium oxide and 0.4301 g. of silver chloride. Calcd. for $EuCl_2 \cdot 2H_2O$: Eu, 58.7; Cl, 27.4. Found: Eu, 59.0; Cl, 27.8.

The crystals of europous chloride dihydrate could not be distinguished under the microscope from those of barium chloride dihydrate which are similarly precipitated by hydrochloric acid. The two may be isomorphous.

The carrying down of europous sulfate with barium sulfate[7] and with strontium sulfate[8] suggests that these salts may also be isomorphous. In fact the possible isomorphism of strontium and europium sulfate led Brukl to use the former to carry down the latter in extracting 12 g. of europium from a rare earth mixture by an electrolytic method closely resembling that used by Yntema.[9]

Europous sulfate, like barium and strontium sulfates, is not hydrated and is almost insoluble in water. In acids it is but little soluble except when oxidation occurs. The density of europous sulfate was determined and was found to be still greater than those of barium and strontium sulfates.

These facts made it seem desirable to discover whether isomorphism plays a part in the similarities mentioned. Dr. Linus Pauling of the California Institute of Technology kindly offered to make the examination. As the method used was not well suited to a body so readily oxidized as europous chloride, the determinations were confined to the sulfates.

The density determinations of europous sulfate were made by the use of two auxiliary liquids—tetrachloroethane and benzene. The former led to a value of 4.981 at 25°, the latter to one of 4.989 at 20°.

Report on the X-Ray Study of the Isomorphism of Compounds of Bivalent Europium and Barium

BY LINUS PAULING

The X-ray powder photographs taken during this investigation were prepared with the use of

---

[5] Quart milk bottles are admirably suited for this purpose and are superior to any of the usual chemical shapes.

[6] This was supplied by 300 to 400 g. of solid carbon dioxide in a liter flask.

[7] Selwood, THIS JOURNAL, **57**, 1145 (1935).

[8] Brukl, *Angew. Chem.*, **49**, 159 (1936).

[9] Yntema, THIS JOURNAL, **52**, 2782 (1930).

CuK α radiation (λ = 1.539 Å.) filtered through nickel. The camera radius was 5.00 cm. The crystal powder was mounted on the surface of a small glass fiber; a correction for absorption in the sample was applied.

Photographs of barium sulfate, europous sulfate, and a powder formed by precipitation of a solution containing equal mole fractions of europous chloride and barium chloride with sulfuric acid were found to be closely similar in appearance. The barium sulfate photographs could be indexed on the basis of the accepted orthorhombic unit with a_0 = 8.85 Å., b_0 = 5.44 Å., and c_0 = 7.13 Å. The europous sulfate photographs show lines corresponding to an orthorhombic unit with a_0 = 8.46 Å., b_0 = 5.37 Å., and c_0 = 6.90 Å. (all ± 0.02 Å., the errors being larger than usual because of uncertainty in the correction for absorption). The space group criteria for V_h^{16}, with the orientation Pnma as in barium sulfate, are satisfied, and the intensities of corresponding lines on the two photographs are about the same. This indicates strongly that the substances are isomorphous. Verification is provided by the photographs of the powder prepared by simultaneous precipitation of europous sulfate and barium sulfate, which shows instead of the lines of the two substances but a single pattern midway between them, proving that the powder is a solid solution of europous sulfate and barium sulfate.

The density calculated from the X-ray data for europous sulfate, assuming 4 $EuSO_4$ in the unit cell, is 5.22 g./cc., in approximate agreement with the directly determined value 4.99 g./cc.

The lattice constants of europous sulfate are intermediate between those of barium sulfate and those of strontium sulfate, which also has the barium sulfate structure:

	a_0, Å.	b_0, Å.	c_0, Å.
$BaSO_4$	8.85	5.44	7.13
$EuSO_4$	8.46	5.37	6.90
$SrSO_4$	8.36	5.36	6.84

Taking 1.35 Å. as the ionic radius (for coördination number 6) of Ba^{++} and 1.13 Å. as that of Sr^{++}, we interpolate to obtain 1.17 Å. as the ionic radius of Eu^{++}. It may be pointed out that this lies closer to the value for Sr^{++} than to that for Ba^{++}.

These results give a definite answer to the question of the isomorphism of europous sulfate with barium and strontium sulfates. It is thus plain why the last two salts are effective in aiding the precipitation of the first from dilute solutions.

A part of my best europium oxalate amounting to 190 g., essentially free from all rare earth impurities, but still contaminated with traces of calcium and barium, was sent to Dr. Gregory P. Baxter of Harvard University who kindly agreed to undertake a new determination of the atomic weight of europium. A preliminary report of the results obtained follows.

Report by G. P. Baxter and F. D. Tuemmler

A preliminary determination of the atomic weight of europium has been made by analysis of europous chloride. The original oxalate was ignited and after solution in nitric acid the europic nitrate was purified by several crystallizations from concentrated nitric acid. After two precipitations of europic oxalate in the presence of half normal acid, with conversion to oxide, the latter was dissolved in hydrochloric acid and europic chloride purified by crystallization from hydrochloric acid. Spectroscopic examination gave no evidence of the presence of barium or calcium.

Attempts to prepare anhydrous europic chloride by careful dehydration in dry hydrogen chloride even in the presence of high percentages of chlorine were uniformly unsuccessful. The product contained much europous chloride, even when not fused, while fusion accentuated the difficulty.

On the other hand, if the europic chloride is carefully dehydrated and fused in a current of hydrogen chloride and hydrogen, complete reduction to europous chloride is apparently attained, and the fused material remains essentially constant in weight in dry air.

Weighed quantities of europous chloride were dissolved and allowed to oxidize in the air, in the presence of a small excess of nitric acid to prevent the precipitation of basic salt. The solutions were then compared with solutions of weighed nearly equivalent amounts of pure silver by the equal opalescence method. Pending the determination of the density of the anhydrous europous chloride the value 5.00 is assumed for the computation of the vacuum correction. The following table gives the results so far obtained.

THE ATOMIC WEIGHT OF EUROPIUM

EuCl$_2$, g.	Ag, g.	Ratio EuCl$_2$:2Ag	At. wt. Eu
2.37131	2.29571	1.03293	151.95
3.08192	2.98364	1.03294	151.95
2.81855	2.72847	1.03301	151.97
4.88930	4.73350	1.03291	151.95
	Average	1.03295	151.95

Urbain and Lacombe [*Compt. rend.*, **138,** 627 (1904)] found 151.96; Jantsch [*ibid.*, **146,** 473 (1908)], 152.04; Aston [*Proc. Roy. Soc.* (London), **A146,** 46 (1934)] from the isotopic constitution, 151.90; Hopkins and Meyers [THIS JOURNAL, **57,** 241 (1935)], 152.30. The International value has been 152.0 for some time.

Summary

1. A concentrated solution of the chlorides of the rare earths containing 70% or more of europium gives upon reduction of the latter with zinc and treatment with concentrated hydrochloric acid a crystalline precipitate of europous chloride dihydrate, EuCl$_2$·2H$_2$O, practically free from accompanying rare earths.

2. By means of this reaction about 500 g. of europium oxalate has been prepared, the high purity of which is shown by spectrograms by Dr. King.

3. An X-ray examination by Dr. Pauling has established the isomorphism of EuSO$_4$ and BaSO$_4$, and therefore also of SrSO$_4$.

4. Dr. Baxter and Mr. Tuemmler have completed the purification of europium and determined its atomic weight to be 151.95.

The Raman Spectrum and the Structure of Water

BY PAUL C. CROSS, JOHN BURNHAM AND PHILIP A. LEIGHTON

The tridymite-like structure of ice as regards the distribution of the oxygen atoms appears to be definitely established,[1] and Pauling's[2] explanation of the discrepancy between the third law and statistical entropies in ice leaves little doubt that the hydrogens are unequally spaced between the oxygens. Each four-coördinated oxygen nucleus, at 0°, has bonded at tetrahedral angles four oxygens at d = 2.76 Å., with a proton along each oxygen–oxygen axis; two chemically bonded at d = 0.99 Å. (see section III) and two "hydrogen bonded" at d = 1.77 A. Present theory, as developed by Bernal and Fowler[3] and modified by Katzoff[4] and others, considers liquid water at ordinary temperatures as having essentially a broken down ice structure, with a considerable amount of coördination still persisting through hydrogen bonding which, however, decreases with increasing temperature or addition of electrolytes. Little progress has been made beyond this qualitative picture, and to obtain further evidence on the nature and extent of coördination in water the authors have reinvestigated, using rather high dispersion, the Raman spectrum of water over a wide range of temperatures, of ice at 0°, and of deuterium oxide. The results are treated on the basis of a model consisting of coupled O—H oscillators perturbed by various types of coördination.

An empirical treatment of the perturbation forces leads to an estimate of the intermolecular frequencies which confirms their identification. For earlier measurements and their interpretation we refer to the review and bibliography of Magat[5] and to the recent paper of Hibben.[6]

I. Experimental Data

The Raman spectra were excited by the unreversed 2536.52 Å. line of a mercury–argon discharge lamp and photographed on a quartz spectrograph of 3.5 Å./mm. dispersion at 2650 Å. The water was placed in a fused silica tube of 30 mm. diameter for the work below 100°, while at higher temperatures the high pressures (up to 218 atm. at 375°) necessitated the use of a smaller bore; a 4-mm. tube with 1.1-mm. walls being employed. For frequency measurements each spectrum was partially overlaid with an iron arc spectrum. Wave lengths were corrected to vacuum.

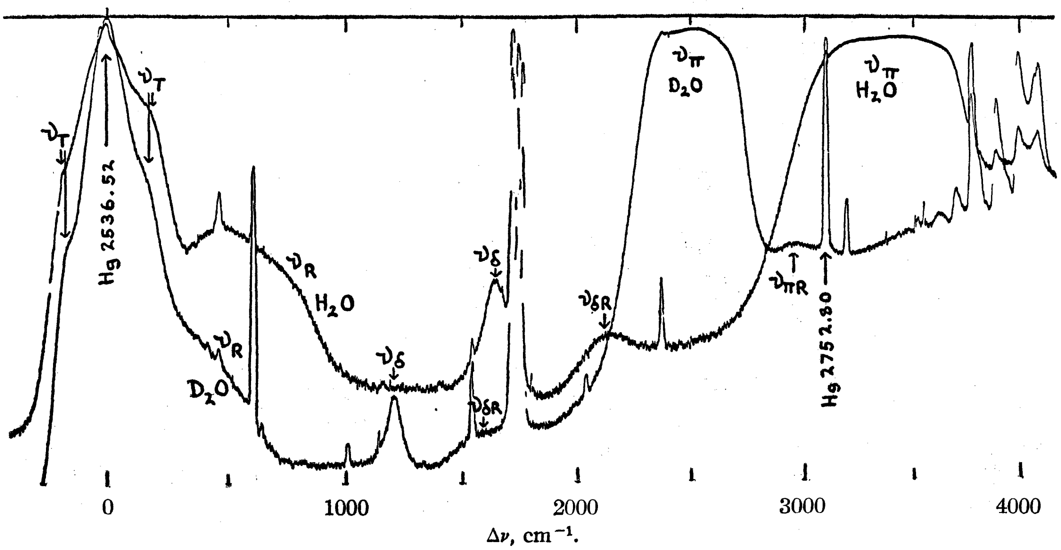

Fig. 1.—Comparison of the Raman spectra of H_2O (40°) and D_2O (50°).

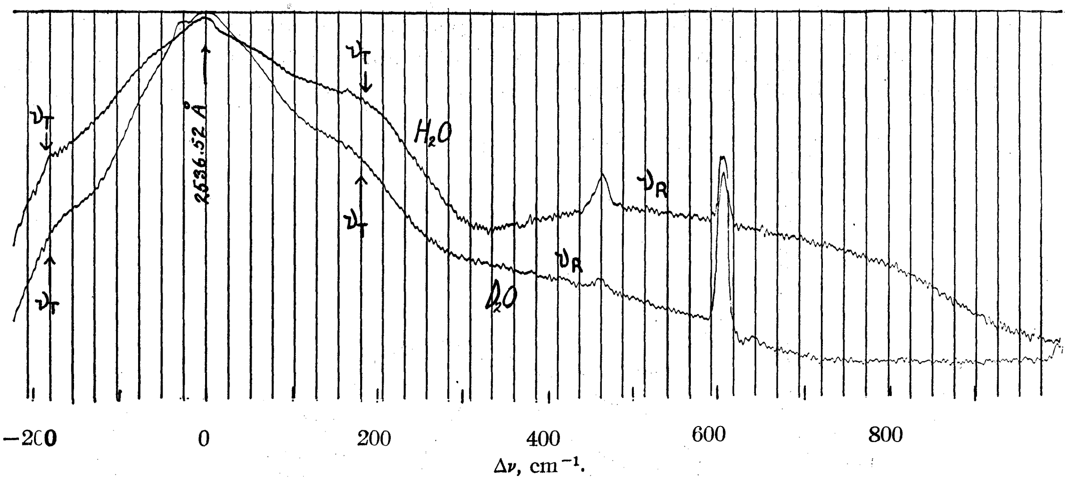

Fig. 2.—Low frequency Raman bands of H_2O (40°) and D_2O (50°).

In Fig. 1 are shown microphotometer records, obtained by use of the instrument described recently,[7] of the entire Raman spectrum of H_2O at 40° and D_2O at 50°. The main bands of each are overexposed in order to bring out the low frequencies. These low frequency bands are compared with greater linear magnification in Fig. 2, while in Fig. 3 the low frequency spectrum of melting ice at 0° is compared with that of water at 26 and at 80°. The exposures required to show these bands even to the small extent to which they appear in Fig. 3 were about twenty times greater than those required to give the main band the intensity shown in Figs. 4 and 5. Particularly noteworthy in Fig. 3 are the broadening in the neighborhood of the source line in liquid water as compared with ice; the sharp "hindered translation," ν_T, frequency in ice, observable both as a Stokes and anti-Stokes band; and the decrease in intensity of this frequency with increasing temperature in liquid water on the Stokes side as compared with its increasing intensity with increasing temperature on the anti-Stokes side. Frequencies of intensity maxima, taken from these figures, are given in Table I. Owing to the breadth and flatness of the ν_R (hindered rotation) band, which extends at least from 320 to 1020 cm.$^{-1}$ for H_2O and from 250 to 730 cm.$^{-1}$ for D_2O, no estimates of the maxima are attempted. The differences between the maxima of $\nu_{\delta R}$ and ν_δ are 511

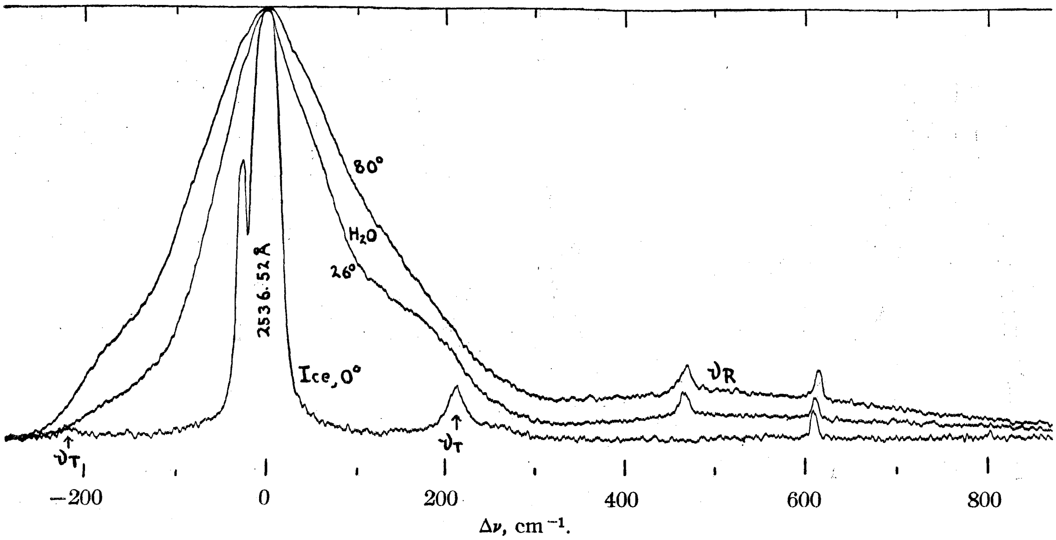

Fig. 3.—Low frequency Raman bands of ice at 0° and water at 26 and 80°.

and 392 cm.$^{-1}$ for H_2O and D_2O, respectively. All frequencies in D_2O, in accordance with theory, are approximately in the ratio of $2^{-1/2}$ to those in H_2O, with the exception of ν_T where the ratio, in agreement with the assignment of this frequency as a hindered translation, is $(20/18)^{-1/2}$.

The main band for melting ice at 0° is compared with that for water at two temperatures, 26 and 75°, in Fig. 4, and to facilitate comparison of shapes, the main bands of H_2O and D_2O at 40° are superimposed, using different frequency abscissas, in Fig. 5. The change in position and shape of the band with temperature in liquid water up to the critical temperature is shown in Fig. 6. The low intensity at 374° is due to an explosion of the cell before the exposure was completed, which shattered the discharge tube and terminated the experimental work. Although this band (as well as the ν_R band) is to be treated by a procedure which attaches minor significance to the precise positions of maximum intensity, such positions are recorded for reference in Fig. 7. Variations among different authors in the reported frequencies of the three apparent components,

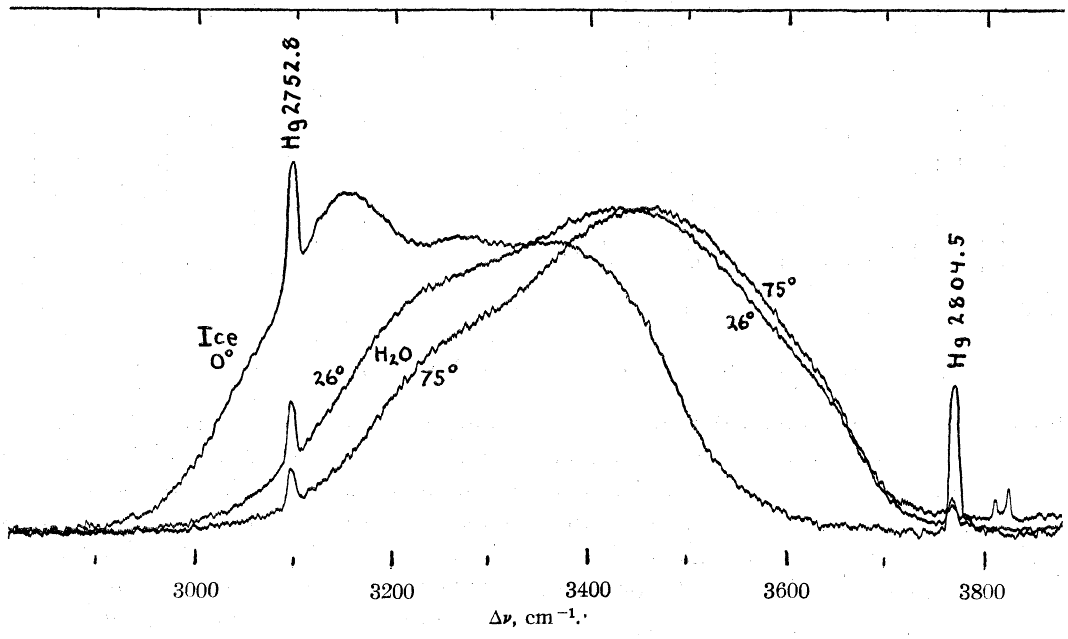

Fig. 4.—Main (ν_π) Raman band of ice at 0° and water at 26 and 75°.

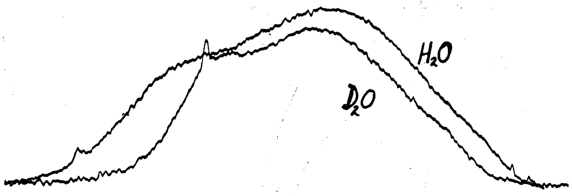

Fig. 5.—Main bands of H_2O and D_2O superimposed for comparison of shapes.

including the maximum, of the main band may be traced in part to temperature differences and in part to differences in the density of the photographic image obtained. The latter effect is illustrated in Fig. 8. Estimates, obtained from Figs. 4 and 8, of the positions of the principal components of the main band are given in Table II (notation from section II, 2).

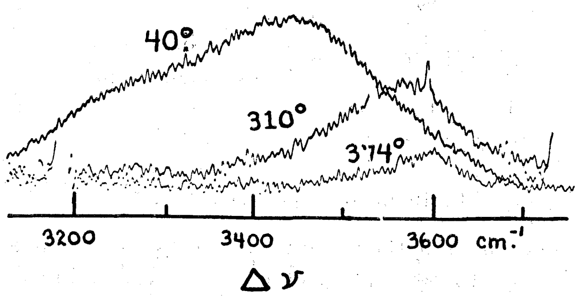

Fig. 6.—Shift in the main Raman band of water between 40° and the critical temperature.

TABLE I

FREQUENCIES OF INTENSITY MAXIMA

Band	Ice, 0°	H_2O, 40°	D_2O, 50°	Ratio ν_{D_2O}/ν_{H_2O}
ν_T	210 ± 2	200[a]	190[a]	0.95
ν_R	...	See Text		
ν_δ	...	1656 ± 2	1208 ± 2	.73
$\nu_{\delta R}$	...	2167 ± 5	1600[a]	.74
ν_π	3156 ± 3	3440 ± 5	2515 ± 5	.73
$\nu_{\pi R}$		4000[a]	2965 ± 5	.74

[a] No definite maximum; frequencies approximate.

II. Interpretation

1. The Hydrogen Bond and Coördination in Water.—The generally accepted theory of the structure of water is that formulated by Bernal and Fowler.[3] According to present views, the relatively open four-coördinated tridymite-like structure of ice is sufficiently broken down in liquid water to permit a closer packing of the water molecules than that in the ice crystal.

TABLE II

FREQUENCIES OF MAIN BAND COMPONENTS

Designation of component	Ice, 0°	Water, 40°	D_2O, 50°	Ratio ν_{D_2O}/ν_{H_2O}
$''\nu''_\pi$	3150	3190	2360	0.74
$'\nu''_\pi$	3270	..	..	
ν_π'' and $''\nu_\pi$	3390	3440	2515	.73
ν_π	..	3650	2680	.73

Although little definite information as to the extent of the coördination of liquid water has been published, it is generally implied that, in the range 0 to 100°, a high percentage (50–80%) of the maximum coördination still persists.

The coördination of water may be considered as due to the formation of hydrogen bonds between the oxygens. Pauling[2] has shown that two of the four hydrogens which tetrahedrally surround a four-coördinated oxygen atom are probably bonded to that oxygen in much the same manner as in an isolated water molecule, while the other two hydrogens are at a greater distance from the oxygen and essentially bonded to other oxygen atoms.

The energy of sublimation of ice, plus the knowledge that water is unassociated in the gas phase, permits an estimate of the energy of the hydrogen bond in water as very small, certainly less than about 6 kcal. per mole. This suggests that the intramolecular vibrations of a coördinated water molecule could be represented as perturbed vibrations of the isolated water molecule. The authors are indebted to Professor Linus Pauling for suggesting the simplified procedure for carrying out this treatment as outlined in the following paragraphs.

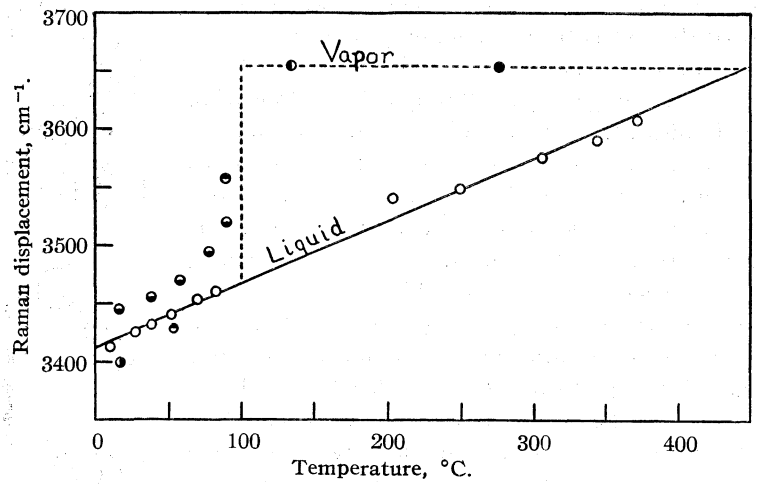

Fig. 7.—Frequency of maximum intensity in the main band (ν_π) as a function of temperature; ○, Authors; ◒, Specchia; ◓, Meyer; ◑, Magat; ◐, Bender; ●, Johnston.

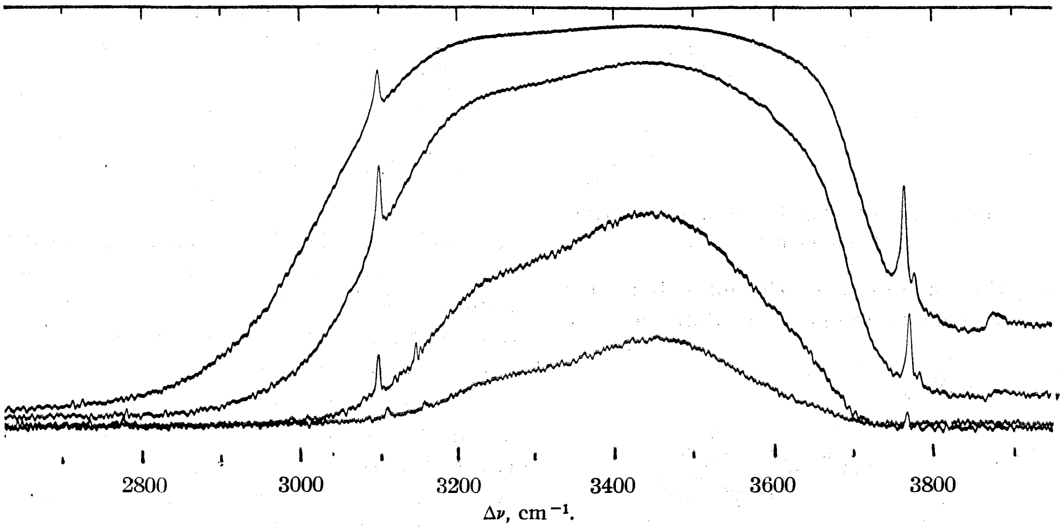

Fig. 8.—The main Raman band of water at 40°, as obtained with different times of exposure.

2. Model of Water Molecule for Perturbation Treatment.—By virtue of the large mass of the oxygen atom relative to the hydrogen atoms and the small value of the cross terms in the "valence force" representation of the potential energy of water, one may use as a satisfactory model for water, as far as the radial frequencies ν_σ and ν_π are concerned, simply two coupled O–H oscillators with a common oxygen atom, and each having a frequency ν_0.

A given water molecule has two possible types of perturbing hydrogen bonds:

I. Hydrogen bonds through the hydrogens of the molecule being considered. One may further assume that hydrogen bonds of this type perturb only the O–H oscillator of which the hydrogen is involved in the hydrogen bond, and that the perturbation is by an amount Δ cm.$^{-1}$, *i. e.*, ν_0 (perturbed) $= \nu_0 - \Delta$.

II. Hydrogen bonds through the hydrogens of molecules other than the one being considered. This type of perturbation may be assumed to affect equally both O–H oscillators by an amount δ cm.$^{-1}$. Furthermore, assuming that the interaction between the hydrogen bonds is negligible, two bonds of type II would shift the frequency of both O–H oscillators by 2δ cm.$^{-1}$. These two types of perturbation may combine to give nine varieties of perturbed water molecules, as shown in Fig. 9. The perturbation type is indicated by P with primes to the right for bonding through hydrogens of the molecule considered, type I, and primes to the left for bonding through hydrogens of neighboring molecules, type II. The secular equations and their solutions are given in equations (1) to (9). These equations are given in two groups, the first group of six including those which, according to our model, represent coupled identical oscillators and hence have symmetric and antisymmetric wave functions. The other three equa-

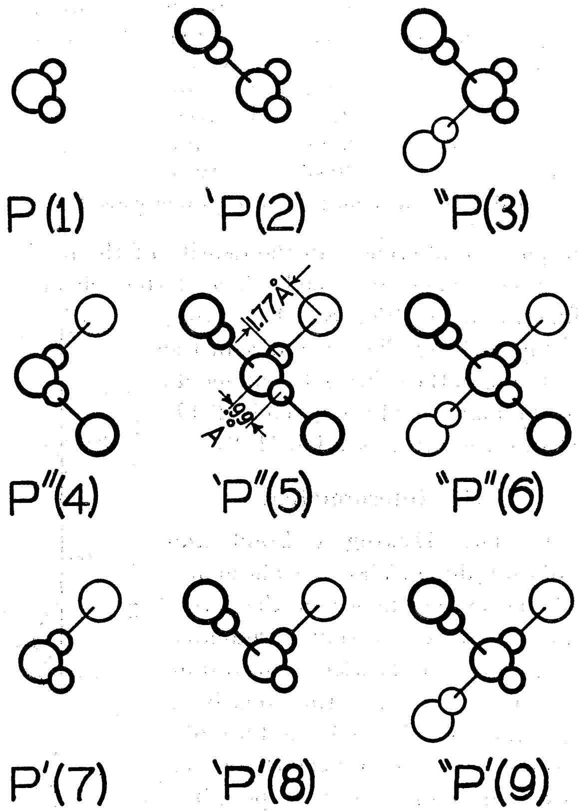

Fig. 9.—Types of coördinated water molecules, with numbers of the corresponding secular equations.

tions are for molecules having non-identical oscillators. Only approximate solutions are given for the latter.

Symmetrically Perturbed Types.—

$$\psi_A = \psi_\sigma = 2^{-1/2}\,\psi_1 - 2^{-1/2}\,\psi_2 \text{ and }$$
$$\psi_S = \psi_\pi = 2^{-1/2}\,\psi_1 + 2^{-1/2}\,\psi_2$$

(ψ_1 and ψ_2 refer to the wave functions of the respective OH oscillators, ψ_1 and ψ_2 refer to the antisymmetric combination, while ψ_S and ψ_π refer to the symmetric combination. ϵ is the coupling coefficient.)

$$\text{P,} \quad \begin{vmatrix} \nu - \nu_0 & \epsilon \\ \epsilon & \nu - \nu_0 \end{vmatrix} = 0 \qquad (1)$$
$$\nu_\sigma = \nu_0 + \epsilon,\ \nu_\pi = \nu_0 - \epsilon$$

$$\text{'P,} \quad \begin{vmatrix} \nu - \nu_0 + \delta & \epsilon \\ \epsilon & \nu - \nu_0 + \delta \end{vmatrix} = 0 \qquad (2)$$
$$\nu_\sigma = \nu_0 - \delta + \epsilon,\ \nu_\pi = \nu_0 - \delta - \epsilon$$

$$\text{''P,} \quad \begin{vmatrix} \nu - \nu_0 + 2\delta & \epsilon \\ \epsilon & \nu - \nu_0 + 2\delta \end{vmatrix} = 0 \qquad (3)$$
$$\nu_\sigma = \nu_0 - 2\delta + \epsilon,\ \nu_\pi = \nu_0 - 2\delta - \epsilon$$

$$\text{P}'', \quad \begin{vmatrix} \nu - \nu_0 + \Delta & \epsilon \\ \epsilon & \nu - \nu_0 + \Delta \end{vmatrix} = 0 \qquad (4)$$
$$\nu_\sigma = \nu_0 - \Delta + \epsilon,\ \nu_\pi = \nu_0 - \Delta - \epsilon$$

$$\text{'P}'', \quad \begin{vmatrix} \nu - \nu_0 + \Delta + \delta & \epsilon \\ \epsilon & \nu - \nu_0 + \Delta + \delta \end{vmatrix} = 0 \qquad (5)$$
$$\nu_\sigma = \nu_0 - \Delta - \delta + \epsilon,\ \nu_\pi = \nu_0 - \Delta - \delta - \epsilon$$

$$\text{''P}'', \quad \begin{vmatrix} \nu - \nu_0 + \Delta + 2\delta & \epsilon \\ \epsilon & \nu - \nu_0 + \Delta + 2\delta \end{vmatrix} = 0 \qquad (6)$$
$$\nu_\sigma = \nu_0 - \Delta - 2\delta + \epsilon,\ \nu_\pi = \nu_0 - \Delta - 2\delta - \epsilon$$

Unsymmetrically Perturbed Types.—

$$\psi_{\text{I}} = \frac{\Delta}{(\Delta^2 + \epsilon^2)^{1/2}}\,\psi_1 - \frac{\epsilon}{(\Delta^2 + \epsilon^2)^{1/2}}\,\psi_2$$
$$= \frac{\Delta + \epsilon}{(2\Delta^2 + 2\epsilon^2)^{1/2}}\,\psi_\sigma + \frac{\Delta - \epsilon}{(2\Delta^2 + 2\epsilon^2)^{1/2}}\,\psi_\pi$$
$$\psi_{\text{II}} = \frac{\epsilon}{(\Delta^2 + \epsilon^2)^{1/2}}\,\psi_1 + \frac{\Delta}{(\Delta^2 + \epsilon^2)^{1/2}}\,\psi_2$$
$$= \frac{\epsilon - \Delta}{(2\Delta^2 + 2\epsilon^2)^{1/2}}\,\psi_0 + \frac{\epsilon + \Delta}{(2\Delta^2 + 2\epsilon^2)^{1/2}}\,\psi_\pi$$

$$\text{P}', \quad \begin{vmatrix} \nu - \nu_0 & \epsilon \\ \epsilon & \nu - \nu_0 + \Delta \end{vmatrix} = 0 \qquad (7)$$
$$\nu_{\text{I}} = \nu_0 + \epsilon^2/\Delta,\ \nu_{\text{II}} = \nu_0 - \Delta - \epsilon^2/\Delta$$

$$\text{'P}' \quad \begin{vmatrix} \nu - \nu_0 + \delta & \epsilon \\ \epsilon & \nu - \nu_0 + \Delta + \delta \end{vmatrix} = 0 \qquad (8)$$
$$\nu_{\text{I}} = \nu_0 - \delta + \epsilon^2/\Delta,\ \nu_{\text{II}} = \nu_0 - \Delta - \delta - \epsilon^2/\Delta$$

$$\text{''P}', \quad \begin{vmatrix} \nu - \nu_0 + 2\delta & \epsilon \\ \epsilon & \nu - \nu_0 + \Delta + 2\delta \end{vmatrix} = 0 \qquad (9)$$
$$\nu_{\text{I}} = \nu_0 - 2\delta + \epsilon^2/\Delta,\ \nu_{\text{II}} = \nu_0 - \Delta - 2\delta - \epsilon^2/\Delta$$

3. Numerical Results.—Before attempting an identification of the component frequencies of the main band in the Raman spectrum of water, one must accept certain views concerning the identification of the unperturbed frequencies in this region.

It is generally admitted that the 3654 cm.$^{-1}$ Raman band of water vapor corresponds to the symmetric or ν_π vibration. This appears to disagree with Mecke's analysis of the infrared spectrum, which suggests that ν_π should have a frequency of about 3600 cm.$^{-1}$.[8] Inasmuch as this treatment gives at best only an approximation to the frequency changes, the absolute values of the frequencies used are not of prime importance. Accordingly, we somewhat arbitrarily select $\nu_\sigma = 3750$ cm.$^{-1}$ and $\nu_\pi = 3650$ cm.$^{-1}$, the observed fundamental frequencies from the infrared and Raman spectra, respectively. This is largely a matter of convenience in that it enables direct comparison of calculated and observed values without any intermediate and uncertain extrapolation to frequencies at infinitesimal amplitude. An additional factor aids in the simplification of the comparison with experimental data, namely, the Raman scattering can be taken as nearly completely due to the excitation of the symmetric vibrations. Thus, in our calculations to follow, the Raman spectrum will be compared to the envelope of the frequencies having wave functions $\psi = a\psi_\pi + b\psi_\sigma$ in which $a \neq 0$. Similarly our results may be compared with infrared measurements on liquid water by considering the frequencies for which $b \neq 0$.[9]

Substituting the above values for ν_σ and ν_π in the equation for the unperturbed molecule gives $\nu_0 = 3700$ cm.$^{-1}$ and $\epsilon = 50$ cm.$^{-1}$. Assuming that the low frequency hump in ice, Fig. 4, is the ν_π vibration of the four-coördinated structure,

---

(8) Mecke, *et al.*, *Z. Physik*, **81**, 313, 445, 465 (1933). It is possible that this disagreement is only apparent and that the difference is due to an unanticipated peculiarity in the intensity pattern of the accompanying rotational transitions of the Raman band. However, the authors do not subscribe to the exceedingly simple structure of the Raman band proposed by Rank, Larsen and Bordner [*J. Chem. Phys.*, **2**, 464 (1934)]. A similar explanation is necessary to account for ν^δ occurring at 1648 cm.$^{-1}$ [Johnston and Walker, *Phys. Rev.*, **39**, 535 (1932)] in the Raman effect, whereas Mecke gives 1595 cm.$^{-1}$ as the center of the infrared band. The frequency ν_σ is so weak as to be unobserved in the Raman spectrum unless one assigns it to Rank's band at 3804 cm.$^{-1}$, which is again about 50 cm.$^{-1}$ higher than Mecke gives from the infrared. Bender [*ibid.*, **47**, 252 (1935)], however, points out that the Raman band of D_2O falls approximately where it is expected from Mecke's analysis, and accordingly holds that the discrepancy can hardly be due to a peculiarity in the intensities of the rotational lines in water. Furthermore, Bender measures the band as only about 10 cm.$^{-1}$ wide, which favors its interpretation as being a *Q* branch. If so, the vibrational frequency should be slightly above 3654 cm.$^{-1}$ rather than much below.

(9) This comparison will be exceedingly difficult because liquid water absorbs so strongly that this region appears in infrared measurements as a band nearly a thousand wave numbers wide with only 0.02 mm. of liquid in the light path [Gordy, *J. Chem. Phys.*, **4**, 769 (1936)] and the maximum is probably shifted by an unsymmetrical enhancement of the wings. The shift of the Raman maximum to lower frequencies with increasing exposure, shown in Fig. 8, supports this view that the apparent maximum of the infrared absorption would shift to higher frequencies if measurements were made with still thinner absorbing layers. Infrared absorption in this region may be further complicated by the contributions of $2\nu_\delta$, the first overtone of the bending frequency.

and taking its maximum as 3150 cm.$^{-1}$, one obtains from equation (6)

$$\Delta + 2\delta = 500 \text{ cm.}^{-1} \qquad (10)$$

A study of the envelope produced by various selections of Δ and δ which satisfy equation (10) led to the final choice of Δ = 250 cm.$^{-1}$ and δ = 125 cm.$^{-1}$. This yields the frequency patterns shown in Fig. 10. Strictly speaking, these patterns for the water spectrum are valid only at or near 0°, because the values of Δ and δ change with increasing temperature due to the increasing distance between the oxygen atoms and the corresponding weakening of the perturbation forces. To compare these calculated frequencies with the experimental intensities of scattering at various temperatures, one must make allowances for two variable factors: first, the distribution of the molecules among the various perturbation types; and, second, the shift of the frequencies themselves due to variations of the magnitude of the perturbing forces. These factors lead one to predictions of the nature of the changes in the main band with increasing temperature which are confirmed by the experimental results.

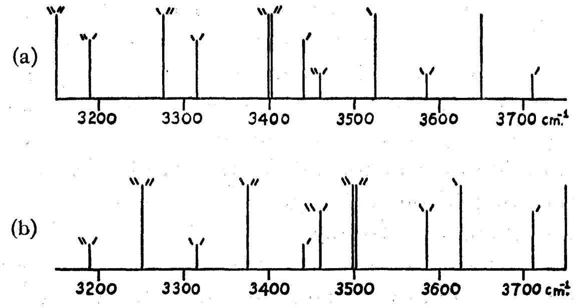

Fig. 10.—Calculated frequency patterns at 0°: (a) strong Raman components. Height of line proportional to a^2 ($\psi = a\psi_\pi + b\psi_\sigma$). (b) Strong infrared components. Height of line proportional to b^2 ($\psi = a\psi_\pi + b\psi_\sigma$).

Consider first the spectrum of ice. As expected, an intense maximum occurs at 3150 cm.$^{-1}$, due to four-coördinated water molecules. However, our picture shows maxima of unexpectedly high intensity at 3270 and 3390 cm.$^{-1}$, which should be assigned to three-coördinated and two-coördinated structures, respectively (see Table II).

If our interpretation is correct, this means that in ice which has been stored under conditions which permit slow melting, several per cent. of the molecules do not show the maximum coördination. Our experiment on ice is not conclusive since the ice was melting rapidly during the exposure, but we interpret the weakness of the scattering near 3600 cm.$^{-1}$ as an indication of relatively little contribution from water. Sutherland's[10] results on ice at −183° are in excellent accord with the idea that there is practically complete four-coördination at that temperature, giving a very sharp maximum at 3090 cm.$^{-1}$, 60 cm.$^{-1}$ below the corresponding maximum of our spectrum at 0° due to the temperature shift of the component "ν_π", which we estimate as about 3150 cm.$^{-1}$. More experiments on ice at and below 0° are very desirable before any definite statements regarding the deviation from complete four-coördination can be made. Our evidence is that hydrogen bonds are being broken before ice melts, and that it is probable that two-coördinated structures are slightly favored over three-coördinated structures,[11] an observation made necessary by the high intensity of the 3390 cm.$^{-1}$ component relative to the 3270 cm.$^{-1}$ component. The latter statement is, of course, based upon the assumption that the perturbations have no appreciable effect upon the intensity of Raman scattering.

When considering the main band of water at 26°, we have to permit a shift of the frequency pattern of Fig. 10 toward 3650 cm.$^{-1}$ by roughly 10% of the difference between 3650 and each component frequency. This gives the four-coördinated maximum at 3200 cm.$^{-1}$ to account for the hump observed at 3190 cm.$^{-1}$. The double frequency corresponding to the two types of symmetrical two-coördination would occur at 3425 cm.$^{-1}$ and account chiefly for the intense maximum of the Raman band at 3440 cm.$^{-1}$. Also, the slight indication of a high frequency component can be attributed to some free water molecules. We make no effort to observe regions specifically assigned to the unsymmetrically perturbed types because their number and lower intensity probably result in their contribution being more or less like a continuous background. The distribution of the molecules among the various perturbation structures has changed so that two-coördination is dominant. It appears from the Raman band intensities that water at 26° averages slightly more than two hydrogen bonds per molecule. Continuing the above considerations

---

(10) Sutherland, *Proc. Roy. Soc.* (London), **A141**, 535 (1933).

(11) This result may be expected because the entropy of the two-coördinated structures will be considerably larger than that of the three-coördinated structures on account of the low-frequency pendulum-like oscillation which is introduced on forming the former from the latter.

to higher temperatures one can nicely account for all the features of the observed spectrum. We thus agree with Rao[12] that there are three components of the band (our ${}''\nu_\pi''$, ν_π'' and ${}''\nu_\pi$ together, and ν_π) which are observable above the background, but we admit many other indistinguishable components, and we consider the component frequencies as well as their intensities to shift with temperature. Needless to say, the considerations upon which our treatment is based attach little or no significance to the existence of definite polymolecular structures such as $(H_2O)_2$, $(H_2O)_3$, etc., so frequently postulated to account for the components of the main band in liquid water.

The measurements near the critical temperature probably represent scattering predominantly due to single water molecules. The slight shift from 3650 may be accounted for by some coördination, or it may be due to factors which we have neglected, especially since these experiments were made at such high pressures (> 200 atmospheres).

The structure of the main band of heavy water readily may be seen to conform to the same interpretation as that of ordinary water. All the frequencies are roughly in the ratio of $2^{-1/2}/$ to those of ordinary water, and the band is correspondingly narrower, as clearly evidenced by Fig. 5. The relatively greater intensity of the ${}''\nu_\pi''$ component in liquid D_2O, indicating relatively more four-coördination as compared with H_2O, is in conformity with other properties indicating higher coördination, *e. g.*, the higher temperature of maximum density, the sharper maxima in x-ray scattering, and the fact that the relative magnetic susceptibility of D_2O liquid/D_2O solid is less than that of H_2O liquid/H_2O solid.

III. Representation of the Perturbation Forces

In the preceding paragraphs perturbations have been invoked to obtain the effective displacements of the vibration frequencies of the water molecule necessary to explain the observed Raman spectrum. In this section it is proposed to give briefly some empirical calculations designed to represent semiquantitatively the perturbation forces. The results will be used later in the discussion of the low frequency bands of liquid water and heavy water.

The simplest function which gives a fair representation of the forces and energies accompanying bond formation as a function of the nuclear separation, r, of the atoms forming the bond is the well-known Morse function

$$V = D(1 - e^{a(r_0 - r)})^2 - D \qquad (11)$$

where D is the dissociation energy of the bond, r_0 the equilibrium separation of the nuclei, and a is a constant related to the vibration frequency of the bond. ($2Da^2 = 4\pi^2c^2\mu\nu^2 = k$, the force constant in the harmonic approximation to the vibration.) Assuming the uncoupled O–H oscillator of the preceding section to have a dissociation energy of one-half that of the water molecule, an equilibrium nuclear separation the same as the O–H separation in the normal state of the water molecule, and a vibration frequency of 3700 cm.$^{-1}$, one obtains the Morse function

$$V_{\text{O—H}} = 110(1 - e^{2.23(0.97-r)})^2 - 110 \qquad \text{(kcal. per mole)} \quad (12)$$

Since the "hydrogen bond" is also formed between hydrogen and oxygen atoms, it may further be assumed that its energy is represented by a function of the type

$$V_{\text{H---O}} = \beta V_{\text{O-H}} = 110\beta(1 - e^{2.23(0.97-r)})^2 - 110\beta \quad (13)$$

with β to be determined from some experimentally measured property of the bond. Selecting as that experimental property the perturbation of the vibration frequency, Δ, due to hydrogen bonding through the hydrogen of the oscillator being considered, β may be determined as a function of the distance between the oxygens.

Combining the two functions represented by equations (12) and (13) to represent the energy of the hydrogen in the hydrogen bond O—H---O as a function of the distance r from the oxygen to which the hydrogen is chemically bonded, and taking the O–O separation, d_0 = 2.76 Å. at 0°, one obtains

$$\begin{aligned} V_{\text{O—H---O}} = {} & -2De^{a(r_0-r)} + De^{2a(r_0-r)} \\ & -2\beta De^{a(r_0-d_0+r)} + \beta De^{2a(r_0-d_0+r)} \qquad (14) \\ = {} & -1910e^{-2.23r} + 8320e^{-4.46r} \\ & - 4.06\beta e^{2.23r} + 0.0375\beta e^{4.46r} \end{aligned}$$

Expanding this function in the vicinity of $r = r_0$ one may determine r'_0, the perturbed O–H distance at equilibrium, and β by the restrictions that the linear term must vanish at r'_0, and the quadratic term must give the proper force constant $k = 4\pi^2c^2\mu(\nu_0 - \Delta)^2$. The results are β = 0.25 and $r'_0 = 0.98_6$ Å.

IV. Calculation of the Intermolecular Frequencies and Other Properties

The potential function $V_{\text{O—H---O}}$ of equation (14), with the value of β = 0.25 just determined,

---

[12] Rao, *Proc. Roy. Soc.* (London), **145**, 489 (1934).

may be used to calculate various other properties of the hydrogen bond. It must be understood that the use of such simple representations of the inherently complicated interactions of chemical bond formation can at best lead to results that are only qualitative.

1. The Shift of the Component Frequencies in the Main Band with Temperature.—The shift of the frequencies contributing to the main band may readily be determined as a function of d_0, the O–O separation, with the assumption that $\Delta = 2\delta$. Thus, from the density of ice, $d_0 = 2.76$ Å. at 0° and 2.735 Å. at −183°, and we may estimate the frequency of the main component of ice (“ν_π”) to shift toward lower frequencies by 30 cm.$^{-1}$ on cooling from 0 to −183°. This is in satisfactory agreement with the observed shift of 60 cm.$^{-1}$, from the frequency of maximum intensity of ice at 0°, 3150 cm.$^{-1}$, to Sutherland's value of 3090 cm.$^{-1}$ at −183°. Our value at 0° is undoubtedly high due to the overlapping of components of higher frequency, causing the maximum to shift upward from the true value of “ν_π”.

Determinations of the observed frequency shifts with temperature in the liquid state are very difficult because no one perturbation type predominates, as in ice, and because the changing distribution of types masks the effect of frequency shift. The large shift which we postulated in order to account for the observed main band of water at 26° (*e. g.*, Δ “ν_π” = 50 cm.$^{-1}$) indicates either that there is an abrupt increase of the O–O distance in the coördinated bond on melting or, more likely, that our function represents too small a change in frequency with O–O separation. The qualitative facts, both theoretical and experimental, are that the components of the main band are all shifted toward higher frequencies with increasing temperature (excepting the unperturbed ν_π, which, to our approximation, remains constant).

2. The Frequency of "Hindered Rotation."—As we pointed out in discussing the experimental results, the region from 320 to 1020 cm.$^{-1}$ represents an appearance of continuous scattering, and measurements of the "maximum" have little significance. Its structure is even more complicated than that of the main band, since most of the nine types of perturbed molecules have ratios of restoring force/moment of inertia which vary with the axis of rotation. The absence of any sufficiently strong components to be evident above the continuous background renders impractical any attempt to treat this band in the same manner in which the main band was treated.

Only one type of associated molecule, P″, lends itself to a convenient calculation of the frequency of hindered rotation from our potential function. In this case, bonds of type II (through hydrogens of neighboring molecules) are absent and no uncertain estimate of their directive forces is necessary. Justifiable approximations which simplify the calculation of the hindered rotation frequency of P″ molecules due to the hydrogen bonding of type I are:

(a) The center of rotation is taken at the oxygen atom.

(b) The O–H chemical bond is considered rigid, $r'_0 = 0.99$ Å.

(c) The force acting on the hydrogen is obtained from the linear term of the potential function $V_{\text{H---O}}$, which represents the energy of the hydrogen as a function of the distance from the oxygen of the neighboring hydrogen-bonded water molecule.

$$V'_{\text{H---O}}\,(r'_0) = 2a\beta D[-e^{a(r_0-d_0+r_0')} + e^{2a(r_0-d_0+r'_0)}] \quad (15)$$

(d) The force restoring the rotated O–H bond to its equilibrium orientation is the component of the above force along the tangent to the arc of motion of the hydrogen atom.

(e) The force constant, $k = 4\pi^2c^2\mu\nu^2$, for the calculation of the frequency (in cm.$^{-1}$) is obtained from the quadratic term of the expansion of the integral of the restoring force as a function of the displacement of the hydrogen atom along the arc of motion. μ may be taken as the mass of the hydrogen atom.

(f) The frequency of hindered rotation of the P″ molecule is independent of the axis of rotation and is equal to the frequency of oscillation of a single hydrogen-bonded hydrogen perpendicular to the line joining the oxygens. This holds for our approximation because the forces on the hydrogens act from points on the extended equilibrium bond directions.

From these considerations the frequency of hindered rotation, for infinitesimal amplitude, becomes

$$\nu = (2\pi c)^{-1}\,(1.56\,V'_{\text{H---O}}\,(r_0')/r_0'\mu)^{1/2} \sim 570 \text{ cm.}^{-1} \quad (16)$$

This falls very nearly in the center of the region described as due to "hindered rotation." If the potential function represents these restoring forces accurately, this result requires that the type II bonds do exert an appreciable directive action in order to account for the existence of scattering up to *ca.* 1020 cm.$^{-1}$. Others have postulated a combination frequency of hindered rotation and hindered translation (see following paragraph) to account for scattering around 700 cm.$^{-1}$, but we consider this unnecessary. Our view is supported by the fact that the upper limits of scattering for D_2O and H_2O are in approximately the ratio of $730/1020 = 0.715 \sim 2^{-1/2}$, whereas a combination of hindered rotation and hindered translation would have an upper limit with a ratio considerably greater than $2^{-1/2}$ (due to the larger ratio of the hindered translation frequencies of D_2O and H_2O $(20/18)^{-1/2}$). Our results indicate that the "hindered rotation" frequency of water molecules in the ice crystal should be of the order of 700 to 900 cm.$^{-1}$, considerably higher than that calculated by Bernal and Tamm.[13] Hibben's recent article[6] indicates that the scattering of ice in this region shows a considerable drop in intensity from that of water on the low frequency side, while the intensity of the high frequency side is enhanced. It is likely that the maximum of the entire region is not far from the component due to P″ type molecules, while the band variously reported to exist between 700 and 800 cm.$^{-1}$, and noticeable as a component near 800 cm.$^{-1}$ on Hibben's microphotometer record for ice, may be due to the contribution of the "P" type molecules.

3. The Frequency of Hindered Translation.—It has recently been suggested that much of the low frequency scattering of liquids is due to hindered translational oscillations rather than to rotational scattering.[14] In the case of water, it is quite certain that hindered translation is largely responsible for the observed scattering near 200 cm.$^{-1}$. This scattering is the water analog of the ice line at 210 cm.$^{-1}$. Here again we see the possibility of a very complex structure in the actual scattering spectrum. However, at this low frequency range, the absolute separation of the components with large relative separation may be too small to be noticeable under ordinary dispersion, hence the apparent sharpness of the ice line in spite of our previous conclusion that there were appreciable amounts of three- and two-coördinated molecules present during the time of our exposure.

The frequency of oscillation of a water molecule about its equilibrium position in the ice lattice may be estimated by an empirical treatment similar to that used in the previous calculations. Here again some assumptions are necessary to give reasonably simple equations.

(a) The O–H chemical bond is considered rigid, $r'_0 = 0.99$ Å.

(b) The energy of the hydrogen bond as a function of the O–O distance, d, is represented by the potential function

$$V_{\mathrm{O}\text{---}\mathrm{O}} = -55e^{2.23(1.96-d)} + 27.5e^{4.46(1.96-d)} \\ -2\gamma Ee^{b(s_0-d)} + \gamma Ee^{2b(s_0-d)} \qquad (17)$$

where the first two terms are from the function $V_{\mathrm{H}\text{---}\mathrm{O}}$ of section III as a function of d, with $\beta = {}^1/_4$, and the last two terms represent an O–O Morse function with an arbitary coefficient γ, to be determined from the equilibrium position $d_0 = 2.76$ Å. (at 0°). A closer examination of the last two terms in Equation (17) reveals that in the vicinity of $d_0 = 2.76$ Å., d is so large relative to $s_0 \sim 1.32$ Å.[15] that the final term may be ignored and the O–O repulsion represented by $-2\gamma\cdot Ee^{bs_0}\cdot e^{-bd}$. Furthermore, since γ is an arbitrary multiplier, $-2\gamma Ee^{bs_0}$ may be set equal to an arbitrary multiplier γ', and the Morse function representation of the oxygen–oxygen repulsion reduces, for our purpose, to the simple exponential form, $\gamma e'^{-bd}$, giving

$$V_{\mathrm{O}\text{---}\mathrm{O}}(d) = -4351e^{-2.23d} + 172100e^{-4.46d} + \gamma' e^{-bd} \qquad (18)$$

$$V_{\mathrm{O}\text{---}\mathrm{O}}(d_0) = -8.47 + \gamma' e^{-bd_0} = -D_{\mathrm{OHO}} \quad \text{(kcal. per mole)} \qquad (19)$$

$$V'_{\mathrm{O}\text{---}\mathrm{O}}(d) = 9703e^{-2.23d} - 767600e^{-4.46d} - b\gamma' e^{-bd} \qquad (20)$$

$$V'_{\mathrm{O}\text{---}\mathrm{O}}(d_0) = 17.1 - b\gamma' e^{-bd} \qquad (21)$$

$$V''_{\mathrm{O}\text{---}\mathrm{O}}(d) = -21640e^{-2.23d} + 3424000e^{-4.46d} + b^2\gamma' e^{-bd} \qquad (22)$$

$$V''_{\mathrm{O}\text{---}\mathrm{O}}(d_0) = -30.5 + b^2\gamma' e^{-bd_0} = k_{\mathrm{OO}} \quad \text{(kcal. per mole per Å.}^2\text{)} \qquad (23)$$

D_{OHO} is the dissociation energy of the hydrogen bond and k_{OO} is the force constant for the harmonic approximation to the vibration frequency of the hydrogen-bonded water molecules against each other. Various estimates of b are given below.

(c) Since definite information is lacking as to the type of vibrational motion concerned in the Raman excitation of the 210 cm.$^{-1}$ frequency of ice, the following calculations are made for two different assumed modes of vibration which are intended to represent approximate extremes of frequencies magnitude as far as Raman excitation is concerned, type II appearing more likely than type I.

---

[13] Bernal and Tamm, *Nature*, **135**, 229 (1935).

[14] Gross and Vuks, *J. phys. radium*, **7**, 113 (1936).

[15] Pauling and Huggins, *Z. Krist.*, **A87**, 205 (1934).

I. The four-coördinated water molecule is vibrating about its equilibrium position against the remainder of the crystal, considered rigid and of infinite mass. In this case the effective force constant can be shown to be approximately twice that of the hydrogen bond, *k*. Thus

$$2k = 4\pi^2C^2\mu\nu^2 = 1.054\nu^2 \qquad (24)$$

where μ is the mass of the water molecule.

II. Two four-coördinated molecules are vibrating against each other along the direction of their common hydrogen bond, each being restrained also by its remaining three hydrogen bonds to the remainder of the crystal, considered rigid and of infinite mass. In this case, it can be shown that

$$3k = 4\pi^2c^2\mu\nu^2 = 1.054\nu^2 \qquad (25)$$

From eq. (21) and the criterion of equilibrium, $V'_{\text{O---O}}(d_0) = 0$, one obtains

$$b\gamma' e^{-bd_0} = 17.1 \qquad (26)$$

Hence, from eq. (19)

$$D_{\text{OHO}} = 8.47 - \gamma' e^{-bd_0} = 8.47 - 17.1/b \qquad (27)$$

and from eq. (23)

$$k_{\text{OO}} = -30.5 + b^2\gamma' e^{-bd_0} = -30.5 + 17.1\ b \qquad (28)$$

(k, the force constant of the hydrogen bond, in the usual units of dynes per cm., is equal to 0.69 k_{oo}).

The O–O Morse function was estimated by various means with resulting b values ranging from 2.5 to 3.0. The extreme values give, respectively, the limits 125 and 165 cm.$^{-1}$ for the frequency of vibration of the water molecule against the remainder of the crystal, type I, and the limits 155 and 200 cm.$^{-1}$ for the mutual vibration of two water molecules, type II. The corresponding dissociation energies of the hydrogen bond are 1.6 kcal. per mole for $b = 2.5$ and 2.8 kcal. per mole for $b = 3.0$. While all these values are of the proper order of magnitude to leave little doubt as to the correctness of the present interpretations of the nature of the low frequency Raman scattering of ice and water, they are definitely low, suggesting that a better representation of the oxygen–oxygen repulsion might be obtained by the use of larger b values.

4. The Energy of Dissociation of the Hydrogen Bond.—By using the experimental data to fit both the linear and quadratic term of the potential function $V_{\text{O---O}}$ a somewhat better approximation to the energy of dissociation of the hydrogen bond should be obtained. The values of b corresponding to vibrations of types I and II are 3.75 and 3.1, respectively. The corresponding limits of the dissociation energy of the hydrogen bond are 3.9 and 3.0 kcal. per mole. Since Raman excitation of the type II motion appears more plausible we favor the latter value. These values are in the range one expects from the comparison of the heat of sublimation of ice with those of the similar solids SO_2 and H_2S. Assuming intermolecular bond formation in the latter two to be negligible compared to that in H_2O, one finds that about half the energy of sublimation of ice is probably due to interactions other than those of hydrogen bond formation, giving approximately 3 kcal. per mole per hydrogen bond broken. Of course, in our calculation the hydrogen bond has been so represented as to imply that it was the only factor responsible for interaction of the molecules, and we should accordingly compare the calculated value of about 3 kcal. per mole per bond to the observed value of 5.9 kcal. per mole per bond. On the other hand, liquids in which the hydrogen bond is absent show very small perturbations of the intramolecular frequencies in the liquid state. Hence it may be significant that the calculated value, based primarily on the perturbation of the molecular vibrations by hydrogen bond formation, comes out with the proper order of magnitude to represent the energy of the hydrogen bond exclusive of the factors which contribute to intermolecular energy in systems where bond formation is of minor importance.

5. Perturbation of ν_δ by Hydrogen Bond Formation.—For the purpose of studying the perturbations of the symmetrical bending frequency, ν_δ, of the water molecule, a sufficiently accurate dynamical model is obtained by considering a harmonic oscillator with a force constant

$$2k/r^2 = 4\pi^2c^2\mu\nu\delta^2 \qquad (29)$$

where $(^1/_2)k(\Delta\phi)^2$ gives the potential energy as a function of the valence angle, ϕ, and μ is the mass of a hydrogen atom. Using again the observed frequency in preference to the extrapolated frequency at infinitesimal amplitude, and ignoring the deviation of water angle from the tetrahedral angle, one obtains

$$2k/r^2 = 0.0585(1595)^2 = 1.49\cdot 10^5 \qquad (30)$$

As in the case of hindered rotation, we can most conveniently calculate the perturbation of the P$''$ type of coördinated molecule, in which case the above restoring force is reduced by the ratio $(0.97/0.99)^2$ because of the stretching of the chemical O–H bond by the formation of the hydrogen bond H---O, and augmented by the amount 1.56 $V'_{\mathrm{H---O}}(r_0')/r'_0 = 0.186 \times 10^5$ (eq. 16), giving

$$4\pi^2c^2\mu(\nu''_\delta)^2 = 1.62 \times 10^5,\ \nu''_\delta = 1665 \text{ cm.}^{-1} \quad (31)$$

This value of ν''_δ, which is shifted toward higher frequencies from ν_δ by 70 cm.$^{-1}$, is in agreement with the maximum of the observed Raman band of water at 1656 cm.$^{-1}$, thus falling at about the same relative position in this band as did the ν''_{R} and ν''_π components in their respective bands. Hibben's curve for ice shows the maximum of this band to be shifted to still higher frequencies due to the presence of relatively more four-coördinated molecules. The calculation of the perturbed ν''_δ at a *higher* frequency than the unperturbed ν_δ is a striking confirmation of the essential correctness of the entire treatment.

6. **Combination Frequencies.**—The only feature of the Raman spectrum of water below 3700 cm.$^{-1}$ which remains to be accounted for is the band with a maximum at 2170 cm.$^{-1}$. This has usually been designated as a combination of ν_δ and ν_{R} the frequency of hindered rotation, a designation with which we agree. In fact, there is no other obvious way to account for this band. It is much wider than the ν_δ band, indicating the plausibility of the very wide ν_{R} being involved in its assignment. The frequency of maximum intensity is considerably less than the sum of the maxima of ν_δ and ν_{R} (1656 + 610 = 2266), but this is exactly what one might expect from the combination of two frequencies having such large amplitudes, especially in view of the very low maximum in the potential energy function which "hinders" the rotation of the water molecule. The harmonic approximation to the potential energy is naturally poor under these conditions and the interaction terms may well be very large. This same factor no doubt contributes to the unusual intensity of this band, considered as a combination frequency, for the usual treatment which predicts low intensity for combination and overtone frequencies is strictly applicable to only harmonic or nearly harmonic oscillations.[16]

Various bands have been reported at frequencies greater than 3700 cm.$^{-1}$. Some of the confusion which exists in the location of these high frequencies is probably due to the same factors we cited to account for the apparent disagreements at lower frequencies. Bands of frequency higher than the main band should be overtones or combinations of the frequencies we have already described.

V. Concluding Remarks

The calculations using modified Morse functions are subjected to many approximations which required the resulting deductions to appear in classical rather than quantum mechanical form.[17] Attention might be called to the fact that the oxygens are oscillating over relatively large amplitude. Even for $n_{\mathrm{O}} = 0$[17] the classical amplitude of the O–O oscillation would permit the oxygen–oxygen separation to vary over a range of more than ±0.1 Å. from the mean value of 2.76 Å. This is undoubtedly important to remember when interpreting X-ray diffraction curves such as those of Katzoff.[4] The maximum of the density distribution curve for liquid water at 2.9 Å. is interpreted by the authors to represent the scattering due to oscillating hydrogen-bonded water molecules plus that due to the "contacting" non-bonded water molecules. Even if close-packed water molecules were separated by more than 3 Å., X-ray measurements would still be unable to resolve their contribution from that of the coördinated structures. Thus Katzoff's maximum at 2.9 Å. may indicate that the close-packed structure in liquid water has a mean water molecule separation of over 3 Å., or at least considerably greater than the mean separation of the hydrogen-bonded oxygens. A similar explanation holds for the second maximum of Katzoff's density–distribution curve. The near-doubling at 3.9–4.5 A. in the distribution at 3° may possibly be due to the fact that molecules oscillating through large amplitudes (with high quantum numbers) tend to spend most of their time near the extremums. (Vibrations which most affect the separations of non-bonded or non-contacting water molecules would have very low frequency and hence appear with high quantum

---

(16) Our calculations of the hindered rotation frequency are also subject to this same poor approximation, but the order of magnitude is, of course, unaffected.

(17) To call attention to one of these in particular, consider the variation of the frequency of the components in the main band with temperature. A better approximation than the one we used would be obtained by considering the O—H---O linear oscillator which would have two internal degrees of freedom with energy levels specified by two quantum numbers, n_{H} and n_{O} corresponding roughly to the modes of vibration $\cdot\leftarrow\quad\cdot$ and $\leftarrow\quad\leftarrow\qquad\rightarrow$, respectively. Our treatment attempted to determine the effect upon the observed transition $n_{\mathrm{H}} = 0 \longrightarrow 1$ of allowing n_{O} to have different distributions through $n_0 = 0, 1, 2, \ldots$ etc. Thus each of the many components we give for the main band of water is split into sub-components depending upon n_0 and the classical calculation of the shift of the maximum with temperature must necessarily be only a rough approximation.

numbers, even at 0°.) Katzoff's results, as well as ours, indicate that relatively small changes in the structure of water take place in the range 0–100°.

Estimates of the number of hydrogen bonds broken by fusion cannot very well be made from the latent heat of fusion. Holding the water molecules in a tetrahedral lattice necessarily involves some strain energy since the hydrogens in free water molecules tend to orient at less than the tetrahedral angle. This strain energy may be estimated as not over 300 cal. per mole. However, the breaking of only a small percentage of the hydrogen bonds appears to cause a collapse of the tridymite structure, and may relieve practically all the strain. This would cancel much of the energy effects of dissociating the first few bonds. Exclusive of the many other factors which influence energy of fusion, the effects of strain indicate that the coördination of water at 0° is less than that indicated by the heat of fusion. New experiments on ice and water just below and above 0° should yield interesting information concerning the role of the hydrogen bond in the fusion process.

An empirical treatment with Morse functions would appear from our results to be superior numerically to any straightforward theoretical treatment so far applicable to such complex systems. The approximate agreements which were obtained with experimental values in the empirical calculations presented here are interpreted by the authors as a tribute to the usefulness of the Morse function in representing interactions of atomic and molecular systems for which straightforward theoretical procedures are hopelessly cumbersome.

The general acceptance of the structure of water upon which this treatment of the Raman spectrum of water was based seems now to be assured. The success of our attempts to explain the complex experimental data here presented and analyzed can be taken not only as a new confirmation of prevailing ideas, but also as a satisfactory application of a new method of studying quantitatively the effects of hydrogen bond formation and association in liquids.

The authors wish to acknowledge their indebtedness to Professor Linus Pauling for helpful discussion of the material presented.

Summary

The Raman spectrum of liquid water over a wide range of temperatures, of ice at 0°, and of deuterium oxide were measured with high dispersion. Excitation was almost exclusively due to the 2537 Å. line of the mercury argon discharge lamp and the spectra are presented in the form of microphotometer records.

The results are discussed on the basis of the prevailing notion of a broken-down ice structure for liquid water. The perturbations of the radial vibration frequencies of the nine types of coordinated water molecules possible in such a structure are calculated from two experimentally determined constants: Δ, the perturbation of an OH oscillator due to hydrogen bonding through its hydrogen to another oxygen, and δ, the perturbation of the OH oscillator due to hydrogen bonding through its oxygen to the hydrogen of another oscillator. The resulting frequency patterns satisfactorily explain the structure and variations with temperature of the main band of ice and water.

Semi-quantitative estimates are made of the relative amounts of the different coördination types of water molecules. Water appears to average slightly more than two-coördinated in the range 25 to 90°, and is slightly less coördinated than is deuterium oxide. The two-coördinated structures predominate in both liquids. In ice at 0° the four-coördinated structure predominates but appreciable amounts of the three- and two-coördinated molecules were found to be present.

An empirical treatment of the perturbing potentials in terms of Morse functions gives the means of estimating the intermolecular frequencies. The results confirm already existing identifications for the "hindered translation" and "hindered rotation" frequencies. It is not necessary to postulate a combination of the two to account for all the data. The "hindered translation" was measured in ice as a sharp band with maximum at 210 cm.$^{-1}$. The bending frequency of water is shown to be shifted toward higher frequencies by the perturbations of the coördinated structures, in agreement with the observed Raman band.

The assignment of the band with maximum at 2170 cm.$^{-1}$ as a combination of the bending frequency with the hindered rotation frequency is discussed and accepted.

This analysis covers all the major features of the liquid water Raman spectrum and is confirmed both qualitatively and quantitatively by the

Raman spectrum of liquid heavy water and of ice.

The empirical treatment of the perturbing potentials as modified Morse functions leads to an estimate of the energy of the hydrogen bond in water as about 3 kcal. per mole per bond.

The essential agreement of the results of this analysis with X-ray data on liquid water is discussed and the usefulness of Raman spectra as tools for further studies of associated liquids is suggested.

NOTES

The Molecular Structures of the 2,3-Epoxybutanes: a Correction

BY L. O. BROCKWAY AND PAUL C. CROSS

In the recently published report of the electron diffraction investigation of the 2,3-epoxybutanes[1] it was incorrectly stated that the identification of the geometric isomers was the same as that found in the chemical[2] investigation. Because of this misapprehension the electron diffraction investigation has been repeated and extended, and the consideration of new molecular models has led to the assignment supported by the chemical investigation.

The original preparations were refractionated and samples were taken having the boiling point ranges, 52.9–53.7 and 59.3–59.9°, respectively, at 746 mm. For each substance the new electron diffraction photographs have a lighter background, the diffraction pattern is more distinct and measurements of the ring diameters are more reliable than on the earlier photographs. The same characteristic features appear as before, however; and although the photographs of the two substances again look very much alike, the chief distinguishing feature is still observed, *i. e.*, photographs of the low boiling modification show a well-defined shoulder on the inside of the second strong maximum near $s = 10$ (see Fig. 1, reference 1).

In the models previously considered it was assumed that the strain introduced in the bond angles on each of the central carbon atoms by the formation of the three-membered ring was distributed only among the angles involving the carbon–oxygen bond. Of the six angles between the four bonds the angle in the ring is 57°26′, the other two strained angles are 125°10′, and the three remaining angles have the value 109°28′. It seems probable that the strain is more widely distributed; and accordingly new curves have been calculated on the basis of models in which the strain of the small angle is divided among four other angles and also on models in which all five of the other angles divide the strain. These curves are very similar, and the pair corresponding to a small angle of 57°26′ and five equal angles of 117°20′ is reproduced in Fig. 1. It will be observed that the inner

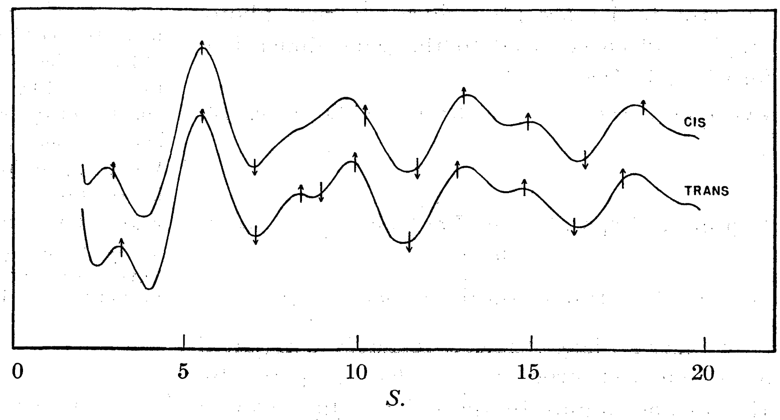

Fig. 1.—Theoretical electron scattering curves for models of the *cis* and *trans* 2,3-epoxybutanes in which five bond angles on each of the central carbon atoms divide equally the strain due to the formation of the three membered ring. The arrows represent maxima and minima observed on the photographs.

[2] C. E. Wilson and H. J. Lucas, *ibid.*, **58**, 2396 (1936).

shoulder on the second strong maximum now appears in the curve for the *trans* form, and accordingly the modification which boils at 53.5° (746 mm.) has the *trans* configuration. It may be mentioned that the new photographs from each of the compounds show the inner maximum (near $s = 3$) with that for the *trans* form having a slightly greater s value in agreement with the curves. That this identification is not based on more extensive data is due to the fact that the two expressions for electron scattering by the *cis* and *trans* forms show only slight differences. In the chemical investigation[2] the *trans* form was identified as that one which was obtained in an optically active state and this choice is now supported by the electron diffraction result. The *cis* form is that boiling at 59.6° (746 mm.).

Accepting the chemical identification of the isomers, we see that the electron diffraction study offers proof that bending the carbon–oxygen bond in forming the three-membered ring also bends the other bonds from their "natural" or unstrained positions, since the model in which the bending effect is confined to the one bond leads to the wrong identification of the isomers.

The interatomic distances previously reported are still to be accepted since the new photographs and curves lead to the same dimensions for the molecules.

Improved Preparation of Pentaacetyl-keto-fructose

BY FRANCIS B. CRAMER AND EUGENE PACSU

Pentaacetyl-keto-fructose, formerly designated as α-pentaacetylfructose, was first prepared by Hudson and Brauns[1] by the action of zinc chloride and acetic anhydride on fructose. The yield was less than 8% of the theoretical. Acetylation of fructose with acetic anhydride and pyridine gave rise to the same compound in less than 5% yield. When tetraacetylfructose is prepared by the improved method of Pacsu and Rich,[2] and this converted into the keto-pentaacetate by the procedure of Hudson and Brauns,[1] the yield, calculated on fructose, is increased to 36%. A procedure has now been worked out by which the keto-pentaacetate may be obtained in about 50% yield by the direct acetylation of fructose without the isolation of an intermediate compound. The production of a good yield of pentaacetyl-keto-fructose appears to take place under conditions which facilitate the preliminary formation of a large amount of β-tetraacetylfructose. As amply demonstrated by Hudson and Brauns,[1] the keto-pentaacetate, once formed, is unaffected when heated with zinc chloride and acetic anhydride in the concentrations used in our experiments.

Experimental

Preparation of Pentaacetyl-keto-fructose.—Ten grams of finely powdered fructose was added in one portion to a solution of 1 g. of fused zinc chloride in 100 cc. of distilled acetic anhydride cooled in an ice-bath. The mixture was stirred vigorously at 0° for four hours, during which time most of the sugar dissolved. The temperature was then kept at 20–25° for one hour and finally at 50° for two hours. The cooled solution was stirred with an equal volume of water for one and one-half hours, further diluted, and neutralized with an excess of sodium bicarbonate. The chloroform solution of the gummy precipitate was united with the chloroform extracts of the water solution, then dried with calcium chloride, filtered, and evaporated to a sirup *in vacuo*. The sirup was dissolved in about 50 cc. of absolute ether, and the solution on standing overnight in the ice-box deposited 10.3 g. of crystalline pentaacetyl-keto-fructose, having $[\alpha]^{20}_{\mathrm{D}}$ 33.5° in chloroform solution.

When half the above amount of acetic anhydride was used, the yield of the crystalline pentaacetate was 9 g. (42%). The keto-acetate was prepared more rapidly by stirring 10 g. of fructose with 50 cc. of acetic anhydride, and 1 g. of zinc chloride for one hour at room temperature and one hour at 50°. The yield was 7.5 g., or 35%. When 10 g. of fructose was stirred with the same acetylating solution at 50° for one hour and the reaction mixture worked up immediately, the yield was only 6 g., or 28%.

Physical Constants of Morpholine

BY V. H. DERMER AND O. C. DERMER

In preparing to study morpholine as an ionizing solvent, we have investigated its purification and measured some of its physical constants. Since the first shipment of morpholine we obtained apparently contained esters, we resorted to chemical purification through the acid oxalate. Later lots proved to be of extraordinary purity, requiring only to be dried over metallic sodium.

Table I gives the results of our measurements and calculations.

Experimental

Commercial morpholine, purchased from Carbide and Carbon Chemicals Corporation, was added gradually to slightly more than a molar equivalent of oxalic acid dissolved in alcohol. The precipitated morpholine hydrogen oxalate was filtered out and recrystallized twice from 60% ethanol. Even then it did not melt sharply, but sintered and decomposed with effervescence at 190–195°. Titration with standard alkali gave indistinct end-points because of the morpholine liberated by hydrolysis; hence the oxalate was titrated with 0.1 *N* potassium permanganate. Molecular weight found: 178, 178; calcd. for $C_4H_8ONH(COOH)_2$, 177. Morpholine hydrogen tartrate was prepared similarly; it melts at 165–166°.

Morpholine was regenerated from the oxalate by adding the salt to concentrated aqueous potassium hydroxide. The layer of free base was separated and dried over solid potassium hydroxide and then sodium. It was then fractionally distilled from sodium through a three-ball Snyder column. After the first quarter had been set aside for further drying, the remainder had a corrected boiling point of 128.9°. This temperature was read on two thermometers, each newly calibrated with pure chlorobenzene and ethylene dibromide to avoid stem correction. Later distillations showed that it is unnecessary to subject good commercial morpholine to the oxalate method of purification; refluxing over sodium followed by fractionation gave a product of boiling point identical with that of the "purified" material.

The freezing point of freshly distilled morpholine was measured with several thermometers calibrated at 0° with pure ice. The refractive index at 20.0° was determined with a Zeiss dipping refractometer in a closed cell. At the same temperature, the surface tension relative to water was measured with Traube's stalagmometer, and the relative viscosity with an Ostwald viscometer. In all cases precautions were taken to exclude moisture and carbon dioxide from samples tested.

The Heat of Combustion and Structure of Cuprene

BY P. J. FLORY

In a recent study of cuprene formed by alpha ray polymerization of acetylene, Lind and Schiflett[1] have reported 265.3 kcal. for the heat of combustion per structural unit —(C_2H_2)—. Although the structure of cuprene has never been determined, they have calculated the heat of polymerization assuming the formation of one C=C and one C—C bond in place of each C≡C bond of acetylene and using Fajans'[2] heats of atomic linkages. The significance of the comparison of this calculated heat of polymerization with that deduced from the heats of combustion of acetylene and of cuprene was obscured by the approximate nature of Fajans' values.

A much more reliable heat of polymerization can be calculated from recent thermochemical data. In conformity with Lind and Schiflett's assumption regarding the constitution of cuprene, a chain structure in which the single and double bonds occur alternately, *i. e.*, $-(CH{=}CH)_n-$, will be assumed.

Expressing heats of combustion (Q) as heat

---

[1] S. C. Lind and C. H. Schiflett, THIS JOURNAL, **59**, 411 (1937).

[2] K. Fajans, *Ber.*, **53**, 643 (1920).

evolved and heats of reaction (ΔH) as heat *absorbed* by the system

$$Q_u = 2Q_{CH_2} - Q_{H_2} - \Delta H_{hyd.}$$

where $\Delta H_{hyd.}$ is the heat of hydrogenation of the polymer per structural unit —(CH=CH) —, and Q_u, Q_{CH_2} and Q_{H_2} are the respective heats of combustion of the polymer per structural unit, of the hydrogenated polymer per $—CH_2—$ group, and of hydrogen. If the hydrogenation of the polymer is imagined to proceed by the hydrogenation of consecutive structural units, the hydrogenation of one unit is seen to be analogous to the partial hydrogenation of 1,3-butadiene to *n*-butene-1, for which $\Delta H_{hyd.} = -26.72$ kcal. per mole.[3] However, allowance should be made for the presence of the saturated substituent (previously hydrogenated) on the one carbon atom of the structural unit undergoing hydrogenation. Although heats of hydrogenation of compounds of the type $CH_2=CH—CH=CH—R$ have not been determined, Kistiakowsky and co-workers[4] have shown that monoalkyl substitution of an α-mono-olefin reduces the magnitude of $\Delta H_{hyd.}$ by about 2 kcal. Hence, the best value for $\Delta H_{hyd.}$ is approximately -25 kcal. Rossini,[5] from heats of combustion of gaseous hydrocarbons, has shown that $Q_{CH_2} = 157.0$ kcal. Taking $Q_{H_2} = 68.3$ kcal.,[5] one obtains for the combustion of the gaseous polymer $Q_u = 271$ kcal. Assuming about 4 kcal. for the heat of sublimation per structural unit, the heat of combustion of solid polymer becomes 267 kcal. per structural unit. This excellent agreement with Lind and Schiflett's experimental value for the heat of combustion of cuprene substantiates the structure assumed above.

Using 311 kcal. for the heat of combustion of acetylene,[6] Lind and Schiflett's experimental heat of combustion of solid cuprene leads to -46 kcal. for ΔH_p, the heat of polymerization of acetylene to cuprene; the calculated heat of combustion of solid cuprene leads to $\Delta H_p = -44$ kcal.; for the formation of gaseous cuprene ΔH_p (calcd.) = -40 kcal. In comparison, ΔH_p for the formation of gaseous linear polymers from gaseous ethylene or higher olefins is -23 kcal.[7]

Reduction of Nitroguanidine. VIII
The Formation of Aminoguanidine by Reduction in Liquid Ammonia Solution[1]

BY LAURENCE P. FULLER, EUGENE LIEBER AND G. B. L. SMITH

The study of the reduction of nitroguanidine in liquid ammonia solution with active metals is unrecorded. This note presents the results of the preliminary study of the behavior of nitro- and nitrosoguanidine in that medium, and describes the conditions necessary for the formation of aminoguanidine by their reduction with metallic sodium.

In contrast to their very low solubility in water and the usual organic solvents, nitro- and nitrosoguanidine were found to be very soluble in liquid ammonia, the latter forming a bright yellow solution. Either can be recovered unchanged by evaporation of the solvent. Addition of either nitro- or nitrosoguanidine to a solution of sodium amide in liquid ammonia causes no visible precipitation of a sodium derivative, and after the evaporation of the solvent the nitro- and nitrosoguanidine can be recovered unchanged. The addition of metallic sodium to a liquid ammonia solution of nitroguanidine produces an extremely vigorous reaction, the sodium undergoing very rapid dissolution. As sodium was added in successive portions to colorless solutions of nitroguanidine in liquid ammonia, a series of color changes and precipitations was obtained which paralleled exactly the reduction of nitrobenzene in liquid ammonia with sodium, as observed by White and Knight.[2] The solutions became yellow, then orange, reddish-orange and finally a murky brownish-orange, while a precipitate which at first is white, gradually darkens as the reduction proceeds. The return of the sodium blue color was taken as the end-point of the reduction.

The formation of nitrosoguanidine from nitroguanidine theoretically requires two atoms of sodium and when this amount of sodium was employed a yellow solution was produced. However, no nitrosoguanidine was obtained. On further addition of sodium, the blue color was always obtained before the six atoms of sodium, theoretically required for the formation of aminoguanidine, could be added. The molar ratios of

---

[1] For more full details see M. S. Thesis by Laurence P. Fuller, Polytechnic Institute of Brooklyn, 1937. Contribution No. 33 from the Department of Chemistry of the Polytechnic Institute of Brooklyn.

[2] White and Knight, THIS JOURNAL, **45**, 1780 (1923).

sodium to nitroguanidine which were obtained to the blue color end-point varied from 3.7:1 to 4.5:1[3] depending on the quantity of the nitroguanidine taken. The residues obtained on evaporation of the ammonia contained no aminoguanidine. Cyanamide was definitely identified to the extent of 10%. Found, %Ag, 83.15; calculated for CN_2Ag_2, %Ag, 84.36. By treatment of the silver derivative with hydrogen sulfide, hygroscopic crystals of melting point 39.5°[4] were obtained.

During the reductions a vigorous evolution of gas takes place. Examination of the gas showed it to be pure nitrogen, and quantitative experiments showed that it was formed to the extent of 27 to 30% of the nitroguanidine taken. This corresponds to a molar ratio of nitrogen to nitroguanidine of 1:1. This suggests,[1] although we are unable to offer complete experimental proof at present, that nitroguanidine (a mixed anammonide of aquo nitric acid and an ammonocarbonic acid) is in some way subject to dearrangement[5] during the reaction (since nitroguanidine had been recovered unchanged from its solution in liquid ammonia or from a liquid ammonia solution of sodium amide) to form another ammono carbonic acid, cyanamide, and a mixed aquo ammono nitric acid, such as $NH_2{\cdot}NO_2$ (nitro-amide) which may be reduced to a mixed aquo ammono nitrous acid. This latter group is known to be unstable, giving N_2.[6] An examination of nitroamide in liquid ammonia with active metals is contemplated. Attempts to prepare aminoguanidine by reduction of a liquid ammonia solution of nitrosoguanidine with metallic sodium gave the same results as with nitroguanidine; no aminoguanidine was obtained.

It was found, however, that the nature of the reduction was changed profoundly if it was carried out in the presence of a solution of ammonium chloride in liquid ammonia. Here no color changes were observed, the solution of nitroguanidine and ammonium chloride remained colorless and only sodium chloride precipitated. Aminoguanidine was obtained only when the molar ratio of nitroguanidine to ammonium chloride was maintained at 1:6. At concentrations of ammonium chloride below this ratio, brilliantly red to reddish-brown substances, containing only small amounts of aminoguanidine, were obtained. Figure 1 summarizes the chief results obtained. It will be observed that by maintaining the molar ratio of nitroguanidine to ammonium chloride constant at 1:6, the hydrazino-(aminoguanidine) formation, as determined by the procedure of Jamieson,[7] is proportional to the molar quantity of sodium added. Substitution of ammonium acetate for ammonium chloride is without effect on the yield (Curve III, Fig. 1); however, doubling the concentration of ammonium chloride considerably lowers the formation of aminoguanidine (Curve II, Fig. 1). The aminoguanidine was identified by its conversion to benzalaminoguanidine, $C_6H_5CH{=}NNHC(NH)NH_2$; m. p. found, 178.5°; reported178.[8]

[8] Thiele, *Ann.*, **270**, 35 (1892).

nitroguanidine in liquid ammonia, yields of 60 to 70% were obtained.

While the ammonium salts of strong acids have been used for decomposition of sodium–liquid ammonia reduction products,[2] this work appears to be the first example in which an acidic solution of liquid ammonia was used to change the environmental condition of the liquid ammonia solvent media during reduction. The importance of the environmental conditions of the solvent media for the reduction of nitroguanidine has been demonstrated.[9] The mechanism will become clear when it is remembered that the ammonium ion is an ammoniated hydrogen ion

$$Na^\circ \longrightarrow Na^+ + e^-$$
$$H^+ + e^- \longrightarrow H^\circ$$

if, however, an oxidant be present

$$\text{Oxidant} + H^+ + e^- \longrightarrow \text{Reductant} + H_2O$$

It, therefore, appears probable that liquid ammonia could also serve as a solvent medium for catalytic hydrogenations in which molecular hydrogen is introduced into a liquid ammonia solution of an oxidant in the presence of a catalytically active metal. We are at present engaged in determining the usefulness of liquid ammonia as a solvent medium for catalytic hydrogenations, and in extending the mechanism of the reduction and behavior of nitroguanidine in that solvent.

BROOKLYN, NEW YORK RECEIVED MARCH 26, 1937

Micro Analysis for Exchangeable Hydrogen

BY WILLIAM H. HAMILL

A technique has been developed for the determination of exchangeable hydrogen with 2–5 mg. of substance (water soluble, non-volatile) and 50–100 mg. of heavy water (98%) which is correct within 3%. The determination depends upon the decrease in density of the heavy water, due to exchange, as measured by a small quartz float[1,2] controlled by temperature at constant pressure. The density of the float was determined with potassium chloride solution, part of which was used for a pycnometric density determination at the same temperature as that required for flotation equilibrium.

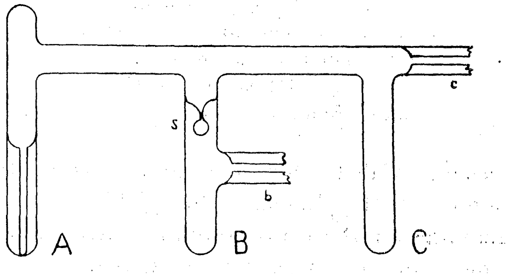

Fig. 1.—Exchange vessel.

Exchange analyses were made in a Pyrex vessel, hereafter referred to as the still (Fig. 1). The float was introduced into the capillary A, the substance into B and the heavy water, in a sealed ampoule, into C. The still was evacuated to about one micron through b and c and sealed. The heavy water was released by immersing C in dry ice, the freezing water shattering the ampoule, and distilled into A for a density measurement. The water was then distilled into the bulb-seal which was broken by freezing in dry ice.[3] The substance was dissolved and the water distilled off quickly at room temperature by cooling C with dry ice. The water was then distilled into A and the density redetermined. This process was repeated to ensure complete solution and exchange.

The number of exchangeable hydrogen atoms per molecule of substance was calculated from equation (1) with a parallel experiment upon a reference substance to minimize errors arising from exchange with glass, temperature coefficient of density of heavy water, etc. Three determinations with urea served for reference.

$$n_1/n_2 = W_1M_1\Delta t_1S_2N_2/W_2M_2\Delta t_2S_1N_1 \qquad (1)$$

n = number of exchangeable hydrogen atoms per molecule
S = weight of substance
M = molecular weight of substance
N = mole fraction D_2O after exchange
W = weight of heavy water
Δt = difference in flotation temperatures due to exchange

The results of these analyses appear in Table I and refer to immediate exchange (three minutes) at room temperature except as noted. Ogawa's[4] observation of slow exchange for urea (60% in five minutes) was not confirmed. Hydrogen in the methylene group of malonic acid has been shown

---

[1] The float, about 8 mm. × 0.6 mm., is maintained upright by means of a quartz bead at one end. The float accelerates 0.01 cm. sec./1° at 30–35°. The effect of pressure upon the density of the float, with respect to heavy water, is only $1(10)^{-5}/1$ atm.

[2] A Pyrex micro float has been employed by Goldfinger and Scheepers, *Compt. rend.*, **198**, 1916 (1934).

[3] This seal is easy to make and positive in action, not failing once. The water freezes quickly at the constriction, sealing the bulb which is broken within two minutes.

[4] Ogawa, *Bull. Chem. Soc. Japan*, **11**, 367 (1936).

to exchange[5] completely in five hours at 100°. In the present work the first two (carboxyl) hydrogen atoms were found to exchange at once, the other two more slowly with a half time of fifteen minutes. The sixth hydrogen atom in histidine hydrochloride apparently is due to a rapidly established equilibrium which corresponds

$$-\mathrm{NH}-\mathrm{CH}{=}\mathrm{N}- \;=\; -\mathrm{N}{=}\mathrm{CH}-\mathrm{NH}-$$

to known methyl derivatives. The fifth slowly exchanging hydrogen atom in vitamin B_1 hydrochloride is not accounted for but agrees with an observed[6] second titratable equivalent of acid in the vitamin with a slow approach to equilibrium. The rate of this slow exchange was measured with 3.2 mg. of vitamin and 76 mg. of heavy water at 37°. Initial, final and four intermediate observations gave a first order velocity constant (min.$^{-1}$ log$_{10}$) $k = 4.3(10)^{-3}$.

This method is more tedious than the one recently described by Williams[7] but has the principal advantage of distinguishing between active hydrogen, as in hydroxyl and amino groups, and labile, slowly exchanging hydrogen, as in the methylene group of malonic acid. Also, since evacuation of the still precedes exchange there is no difficulty with hygroscopic substances. The sensitivity is high, 10^{-5} equivalent of substance in 50 mg. of heavy water lowering the flotation temperature by 0.3° at 30°.

TABLE I

Substance	n
Urea	(4.00)
Glycine	3.13
Histidine, HCl	6.07, 6.36
Vitamin B_1HCl natural	3.94^{a,b} 4.83
Vitamin B_1HCl synthetic	3.6^{a,c} 4.5
Hydroquinone	1.95
Sodium formate	0.00
Succinic acid	2.14, 2.06
Malonic acid	2.0^{a} 3.99

[a] The first value is due to immediate exchange, the second is a final value following an additional slow exchange. [b] The author is indebted to Dr. L. R. Cerecedo and Dr. D. J. Hennessy for the natural vitamin which was extracted from rice polishings. [c] The difference in values between natural and synthetic vitamin may be due to mechanical loss during evacuation in this experiment.

A Rapid Method for the Determination of Lactoflavin in Milk[1]

BY C. H. WHITNAH, BERNICE L. KUNERTH AND M. M. KRAMER

The determination of lactoflavin (vitamin G) by new fluorimetric methods[2] is complicated by elaborate preparation recommended for the sample.[3] It had been observed in this Laboratory that the trichloroacetic acid serum from milk used for vitamin C titrations[4] often had a greenish color whereas the mercuric nitrate serum used for the determination of sugar was colorless. This suggested that fluorimetric tests for flavin might be applied to the former serum.

The following procedure has been used. Add 15 ml. of 10% trichloroacetic acid to 10 ml. of milk, let stand thirty to sixty minutes, centrifuge five minutes at about 2000 r. c. f. Neutralize[5] 10 ml. of the resulting serum, with methyl orange as indicator, and dilute until the sample can be matched in the light of an Eveready Fluoray lamp,[2] with standard flavin solutions (Labco PX grade) containing 0.12 to 0.06 gamma of flavin per ml. Calculate flavin content on the basis of dilutions made. Dilutions until the portions read contain less than 0.12 gamma per ml. seem essential as the values for stronger solutions are easily underestimated.

It was repeatedly shown that a sample of milk tested the same on successive days. Differences between milk samples from different cows were also found to be consistent.

The method was checked by recovery experiments. Duplicate samples of milk were reinforced with lactoflavin (measured amounts of the standard solution) to contain approximately 2 and 3 times the original lactoflavin content. Values secured by calculation and by determination with the Fluoray lamp compared as follows.

	Lactoflavin per ml.		Diff. from calcd. value per ml.	
	Calcd.	Determined by lamp		
	γ	γ	γ	%
(1) Milk	..	1.34	..	..
(2) 9 ml. milk + 11.44 γ flavin made up to 10 ml.	2.35	2.12	0.23	10
(3) 9 ml. milk + 22.87 γ flavin made up to 10 ml.	3.49	3.19	0.30	9

(4) Whitnah and Riddell, *J. Dairy Sci.*, **20**, 9 (1937).

(5) Kuhn and Moruzzi, *Ber.*, **65**, 888 (1932).

Recoveries were only 10% less than the calculated values.

Other composite milk samples have been used for biological assay by the Bourquin-Sherman[6] method, shown[7] to measure the flavin factor. The rats, kept for the customary eight-week period, produced satisfactory composite growth curves. Estimates of the lactoflavin or vitamin G content of the samples were made from the composite growth curves of the rats, compared with the reference curve of rats fed the standard lactoflavin, shown in the table.

Five biological estimates checked the rapid chemical determinations with a maximum difference of 25% as indicated.

Supplements Milk	No. rats	Daily portion, ml.	Av. gain for 8 weeks, g.	Estimated flavin per ml. milk, γ	Flavin per ml. milk Fluoray lamp, γ	Diff. from biological value per ml. γ	%
A	10	3	43	2.2	2.30	+0.10	+ 4
B	10	3	40	2.0	1.76	− .24	−12
C	10	3	46	2.3	2.20	− .10	− 5
D	10	3	54	2.6	2.55	− .05	− 2
E	10	3	50	2.5	1.88	− .62	−25
Lactoflavin		γ		Animals for reference curve			
	9	5.0	33				
None	25	..	±0	Negative control animals			

Effort is being made to apply this rapid method to colostrum, shown by biological work in our laboratory to be higher in lactoflavin content than ordinary milk. Certain characteristics of the colostrum, due to physical or chemical properties, present difficulties not yet overcome.

COMMUNICATIONS TO THE EDITOR

THE THERMAL DECOMPOSITION OF α-TOCOPHEROL

Sir:

Last year, H. M. Evans, O. H. Emerson and G. A. Emerson [*J. Biol. Chem.*, **113**, 319 (1936)] reported the isolation from wheat germ oil and later from cottonseed oil [*Science*, **83**, 421 (1936)] of alcohols having the biological properties of vitamin E. These substances were named "tocopherols" and appear to be isomers with the empirical formula $C_{29}H_{57}O_2$, and to be chemically closely related. Structurally, it is known that the compounds contain a hydroxyl group which accounts for one of the oxygen atoms.

I have recently investigated α-tocopherol, the most active of these substances, using material prepared from cottonseed oil, and wish to report certain observations on the behavior of this compound at higher temperatures which seem to permit deductions to be drawn regarding the constitution of α-tocopherol.

When α-tocopherol is heated decomposition sets in at 350° and a crystalline sublimate is obtained as well as an oily distillate. The crystalline material is very readily obtained in the pure state and its investigation led to a formula $C_{10}H_{14}O_2$. A literature search revealed its close resemblance to durohydroquinone and the identity was established by direct comparison with a sample of this compound kindly furnished through the courtesy of Professor Lee Irvin Smith of the University of Minnesota. Both the diacetyl derivative and the quinone were also prepared and compared by mixed melting point determinations with the corresponding derivatives of the known durohydroquinone.

ANALYSES AND MELTING POINTS

Compound		Diphenol	Diacetate	Quinone
M. p., °C.		230	201	111
Formula		$C_{10}H_{14}O_2$	$C_{14}H_{18}O_4$	$C_{10}H_{12}O_2$
Calcd.	C, %	72.28	67.18	73.14
	H, %	8.40	7.25	7.36
Found	C, %	72.29 72.32	67.12	73.42
	H, %	8.54 8.46	7.21	7.41

The above findings seem to be best explained by assigning the structure of a mono-ether of durohydroquinone to α-tocopherol. The ultraviolet spectrum of α-tocopherol is very similar to that of hydroquinone as has been pointed out to me by Dr. Oliver H. Emerson. Its insolubility in alkalies and its high reducing power, as well as the lack of reducing properties in its esters are also in good agreement with such an assumption.

My present efforts are mainly directed to an elucidation of the alkyl portion of α-tocopherol. On completion of these investigations I intend to publish the details of the above experiments. I wish to express my appreciation of the assistance of Professor H. M. Evans and Dr. Oliver H. Emerson of the University of California who kindly advised me on the production of α-tocopherol and who assayed various concentrates during its preparation.

CIS-TRANS ISOMERIZATION BY BROMINE ATOMS

Sir:

An investigation to ascertain whether halogens and halogen acids add "*cis*" or "*trans*" to maleinoid (*cis*) or fumaroid (*trans*) forms of unsaturated substances has been under way in this Laboratory for some time. It is evident that for a complete understanding of this problem it is necessary to know the effectiveness of the addition reagent causing the transformation of the "maleinoid" and the "fumaroid" form. Yet, while numerous observations on the rearrangement in solution of the "maleinoid" to the "fumaroid" form are available, no critical study has been made of the inter-relationship of the reagents responsible for the transformation, and no comprehensive hypothesis has been advanced which would correlate these diverse observations.

We have found that in the dark, in two hours, carefully purified isostilbene, dissolved in benzene, is not isomerized to stilbene by hydrogen bromide when the reactants are mixed either in air or in a highly evacuated tube, or in the presence of antioxidants (*e. g.*, hydroquinone, catechol, thiophenol). However, the addition of a peroxidic substance (*e. g.*, benzoyl peroxide, ascaridole) to the reaction mixture caused complete isomerization to stilbene in a few minutes. The time required for complete conversion varied with the amount of the peroxide used, but even minute traces of peroxides caused complete conversion in thirty minutes.

In direct sunlight or in artificial light, isostilbene, dissolved in benzene, is transformed to stilbene by hydrogen bromide in about five minutes. Here evacuation of the reaction vessel had a pronounced effect in that twenty minutes was required for complete isomerization. Most striking, however, is the effect of antioxidants. Thus, hydroquinone, ethyl mercaptan, etc., completely prevent the transformation of isostilbene to stilbene by hydrogen bromide in the light, either in the presence or absence of air.

Furthermore, no isomerization of isostilbene to stilbene was observed under any of the above conditions (antioxidant or peroxidic, in the light or in the dark) with hydrogen chloride. Neither has a mixture of bromine and hydrogen bromide caused isomerization in the dark. The halogens are well known to cause isomerization in the light.

The above experiments lead us to believe that bromine atoms[1] are the active catalysts in this transformation. They would be produced by the action of oxygen or a peroxide, or by light, on hydrogen bromide. Once produced, they convert isostilbene to stilbene by a chain reaction. The ineffectiveness of hydrogen chloride in causing isomerization is thus readily explainable on the basis of its relative stability toward oxygen.

Several investigators[2] have observed that alkali metals and traces of certain organo-alkali compounds cause similar isomerizations. We are, therefore, engaged in an extensive study to evaluate the part played by atoms in such conversions, and the role of other agencies.

[1] The hypothesis that bromine atoms are responsible for the "peroxide effect" in the addition of hydrogen bromide to unsaturated molecules is proposed in an article by M. S. Kharasch, H. Englemann and F. R. Mayo, in the *Journal of Organic Chemistry*, in press.

PHOTODECOMPOSITION OF CHLORINE DIOXIDE IN CARBON TETRACHLORIDE SOLUTION

Sir:

We have investigated recently the bromine sensitized photodecomposition of chlorine dioxide in carbon tetrachloride solution and find that appreciable amounts of Cl_2O_6 are formed during the reaction. A reinvestigation of the unsensitized decomposition of chlorine dioxide in carbon tetrachloride solution using λ = 3650 Å. showed that here also relatively large amounts of Cl_2O_6 are formed.

Chlorine dioxide solutions were insolated for some time and then forced into water and shaken. A heavy mist was observed similar to that which forms when Cl_2O_6 reacts with water. Chlorine dioxide and chlorine were removed from the water extract by aspirating air through it for three hours. The resulting solution was neutralized with potassium hydroxide and evaporated. Microscopic examination of the crystals obtained indicated potassium chlorate and potassium perchlorate. The presence of ClO_4^- was also demonstrated by characteristic crystals formed when a drop of 2% brucine solution was added to a drop of the test solution on a microscope slide. The outside of the spot was surrounded by a brown ring which is also characteristic of ClO_3^-. The tests were compared with similar tests on pure substances. The chloric acid and perchloric acid can be explained by the formation of Cl_2O_6 which reacts with water according to

$$Cl_2O_6 + H_2O \longrightarrow HClO_3 + HClO_4$$

Qualitative tests on the water extract also indicated small amounts of hypochlorous acid, presumably due to Cl_2O.

$$Cl_2O + H_2O \longrightarrow 2HClO$$

Methods for the quantitative estimation of chlorine dioxide, chlorine, hypochlorous acid, chloric acid and perchloric acid in the water extract have been developed and checked. The relative amounts of the different components depend in a rather complicated way upon such factors as concentrations, light intensity and time of insolation. This is to be expected since Cl_2O_6 and Cl_2O are themselves photosensitive.

The point which we wish to stress in this note is that relatively large amounts of Cl_2O_6 are formed (corresponding in some experiments to as much as 20% of the chlorine dioxide decomposed). This is in contradiction to the findings of previous workers [E. J. Bowen, *Trans. Faraday Soc.*, **27**, 513, (1931); Y. Nagai and C. F. Goodeve, *ibid.*, **27**, 508, (1931)], who report only chlorine and oxygen. The formation of Cl_2O_6 indicates that the above reactions in solution probably have mechanisms similar in many respects to those for the corresponding gaseous reactions [THIS JOURNAL, **56,** 269 (1934)].

NEW BOOKS

The Chemistry of Natural Products Related to Phenanthrene. By L. F. FIESER, Associate Professor of Chemistry, Harvard University. Second edition, with an appendix. Reinhold Publishing Corporation, 330 West 42d Street, New York, N. Y., 1937. xiv + 456 pp. 15.5 × 23.5 cm. Price, $7.00.

The increased activity and interest in the field of phenanthrene and related compounds have led the authors of this useful and widely accepted book to supplement the second edition with an appendix. This consists of about 90 pages devoted to a description and discussion of the published investigations during 1936.

The topics are grouped in individual chapters which correspond to those in the main portion of the book. They are too numerous to review here but they include the important contributions to the structure of Vitamin D and the stereochemical nomenclature of the sterols, androsterone and analogous compounds. This additional part has been written with the same clarity and completeness as characterized the original work.

The second edition of this book will be of inestimable value to the investigator or scholar in this general field, as it offers a comprehensive résumé of the literature up to January 1, 1937.

ROGER ADAMS

Reagent Chemicals and Standards, with Methods of Assaying and Testing them; also the Preparation and Standardization of Volumetric Solutions and Extensive Tables of Equivalents. By JOSEPH ROSIN, Chief Chemist and Chemical Director, Merck & Company, Inc. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1937. x + 530 pp. 16 × 23.5 cm. Price, $6.00.

This volume is a thoroughly modern and carefully edited treatment of approved methods for testing the commoner chemical reagents, and the standards of purity to be sought. The author, working from the Merck-Krauch book originally published in 1888, the Murray treatise of 1919, reprinted in 1927, and the reports of the American Chemical Society Committee on analytical reagents, has organized into a single accessible source the most recent information regarding reliable methods and tests.

The greater part of the volume is composed of monographs on reagents and their tests, arranged alphabetically. The substances treated include many new organic reagents. Preceding this section several pages are devoted to describing test solutions, and following it are some fifty pages of stoichiometric data including sections on the determination of the hydrogen-ion concentration, on buffer solutions, indicators and related data. A particularly valuable feature is the inclusion of assay tests for many of the reagents discussed.

In his preface the author calls attention to two interesting facts. First, the purity of commercial reagent chemicals has been greatly increased since the earlier books were issued. Second, the methods of testing quantitatively for impurities have been so improved that often tenths or hundredths of a milligram may now be determined instead of milligrams as was formerly the case.

The author is well equipped to issue such a book, for it was due chiefly to his careful and persistent work that the reagent chemicals issued by the Powers–Weightman–Rosengarten Company during the last years of that firm's independent existence, came in general to be recognized as the purest commercially available.

This book will of necessity become a part of the library of every testing, research and educational laboratory.

WILLIS A. BOUGHTON

An Introduction to Nuclear Physics. By N. FEATHER, Ph.D., University Lecturer in Physics and Fellow of Trinity College, Cambridge. Cambridge University Press; The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1936. x + 212 pp. 21 figs. 14.5 × 22.5 cm. Price, $3.00.

As a result of a vast activity in physical research laboratories in the past decade a definite science of "nuclear physics" has come into being. It has all happened so rapidly that it is now impossible to get a grasp of these developments directly from the journal literature. Dr. Feather has provided an admirable summary of the subject which will be read with profit and pleasure by many whose principal interests lie in other directions as well as by those who are actively engaged in nuclear research.

An outstanding quality of the book is its careful emphasis on the logical sequence of the ideas leading up to current theoretical views. The way in which this has been accomplished in a wholly non-mathematical way is truly marvellous. In general this is the outstanding feature of the presentation which makes it so valuable an introduction, for the account is not burdened with technical details of experiments or of mathematical calculations.

The book is divided into four parts: I. *Introductory* reviews the experimental methods of the older studies of radioactivity and the newer methods with artificially accelerated particles, the growth of the understanding of the nuclear atom model as affected by wave mechanics and the picture of the nucleus as a structure composed of elementary particles; II. *Concerning Stable Nuclei* deals with measurements of mass charge, spin, and magnetic moment of the nuclei of naturally occurring atoms; III. *Concerning Unstable Nuclei* deals with the emission of alpha particles, positive and negative electrons, and gamma rays from radioactive nuclei; IV. *Transformations Produced by Fast-moving Particles and by Radiation* deals with effects produced by bombardment of alpha particles from natural radioactive materials, by neutron bombardment, by artificially accelerated protons and deuterons and photodisintegrations produced by radiation.

As the scope of a book is also indicated by mentioning omissions, it may be remarked that there is no discussion of the physics of cosmic rays and very little on the physics of positrons except as they are emitted from positron-active bodies. These omissions are natural enough as not belonging strictly to nuclear physics. A more serious omission is that of the question of relative abundance of the naturally occurring nuclei as studied by the mass spectrograph and by chemical analyses of the earth's crust.

E. U. CONDON

Diffusion. VI. Dans les Liquides. VII. Dans les Gels et les Solides. (Diffusion in Liquids, Gels and Solids.) (Traité de chimie physique appliqué à la biologie, Ch. VI et VII de Tome I.) By J. DUCLAUX, Professeur au Collège de France. Hermann et Cie., 6 Rue de la Sorbonne, Paris, France, 1936. VI: 90 pp. 35 figs. 16.5 × 25 cm. Price, 20 fr. VII: 50 pp. 8 figs. 16.5 × 25 cm. Price, 12 fr.

The physical chemist interested in diffusion will find these two books useful primarily on account of the extensive bibliographies included. They could also be used to advantage to supplement an advanced course in physical chemistry for either chemists, pre-medical students or biologists. The books contain a rather sketchy presentation of the theoretical side of diffusion, a discussion of experimental methods and a fairly detailed presentation of results for various typical cases. Of particular interest to the biochemist is of course the section on diffusion in gels on account of the obvious importance of membrane equilibria in biological processes.

R. M. FUOSS

Thermodynamic Properties of Steam, Including Data for the Liquid and Solid Phases. By JOSEPH K. KEENAN, Associate Professor of Mechanical Engineering, and FREDERICK G. KEYES, Director of Research Laboratory of Physical Chemistry, Massachusetts Institute of Technology. John Wiley and Sons, 440 Fourth Ave., New York, N. Y., 1936. 89 pp. Illustrated. 19 × 26 cm. Price, $2.75.

This book contains the most extensive and the most accurate available tabulation of the thermodynamic properties of steam.

The specific volume, heat content and entropy along the saturation curve are given for liquid and vapor to the critical point, 705.40°F. and 3206.2 lb./sq. in. As is customary, these quantities are tabulated for integral values of both temperature and pressure.

TABLE I

CORRECTIONS FOR THE ROTATIONAL DISTORTION OF THE WATER MOLECULE

	h corr.	1240.3	1433.7	1640.4	1862.0
	S	1.8743	2.0576	2.1989	2.3174
	S corr.	1.8748	2.0591	2.2014	2.3209
5500	h	....	985.0	1518.2	1788.1
	h corr.	....	986.4	1521.1	1792.8
	S	....	1.1093	1.4908	1.6369
	S corr.	....	1.1108	1.4933	1.6404

For superheated steam the tabulation extends to 1600°F. and 5500 lb./sq. in.

The properties of the gas have been obtained principally by an analytical treatment based on an equation of state. It is necessary to have a very accurate equation of state in order to make a reliable calculation of the changes in entropy and heat content with pressure, since the procedure requires that first derivatives be accurate. However, one of the most exacting tests of an equation of state is its use in evaluating such a quantity as the change in heat capacity with pressure since this requires reliable second derivatives. The authors apply this test and find excellent agreement with the available experimental data, which extend to a pressure of 3000 lb./sq. in. and a temperature of 900°F. This significant comparison is appropriately presented as Fig. 1 of the book and it says much for the reliability of the heat content (enthalpy), entropy and volume relationships.

The heat capacity of the gas at zero pressure was taken from the computations of A. R. Gordon. These are based on band spectrum data and are more reliable than values which have been obtained in any other way. Nevertheless, there exists a small inaccuracy in the spectroscopic computations of Gordon [*J. Chem. Phys.*, **2**, 65 (1934)]. While the amount of the inaccuracy is too small to be of importance in engineering calculations, it proves to be of some interest.

Gordon based his calculations of various thermodynamic quantities of steam on the assumption that the water molecule could be treated as a rigid rotator; however, he recognized that molecular vibration and rotation are not independent, by using equations which expressed the moments of inertia as a function of the amount and type of vibration. He did not consider the deformation produced by the rotation of the water molecule. This not only changes the kinetic energy due to the alteration of the moments of inertia but also introduces potential energy changes.

The effect of rotational distortion has been considered by E. B. Wilson, Jr., [*ibid.*, **4**, 526 (1936)] and on page 16, Keenan and Keyes mention a personal communication from Wilson. Presumably because they were not available in time, the simple corrections of Wilson were not included in the tables. In any case, it seems worth while to consider their consequences.

The authors selected the data at the normal boiling point of water in order to evaluate the relationship between the liquid and gas states. Applying Wilson's equations it may be shown that a correction of $2.50 \times 10^{-6} (t_F - 212)$ B. t. u. per deg. Fahr. per lb. should be added to the entropy and the quantity $1.25 \times 10^{-6} (T_F^2 - 671.69^2)$ B. t. u. per lb., where $T_F = 459.69 + t_F$, should be added to the heat content of the gas. As will be seen below the above corrections remove a small discrepancy noted by the authors who state on page 19, "The result . . . (heat of vaporization/T) . . . differs by 3 in the last figure given in the tables or about one part in 7000 of the entropy of the vapor at 32°F. Though this difference is negligible for all uses of the tables it signifies certain defects in our knowledge of water vapor at low temperatures."

The application of Wilson's equations in the region near the critical point shows that the heat content and entropy are changed only by about 0.1%. In Table I a few comparisons are given to show the order of magnitude of the above corrections. In order to preserve the self-consistency of the tables, the above corrections for entropy and heat content have been added to the values for the saturated liquid between 212°F. and the critical temperature. This is certainly within the limit of accuracy with which the properties of the liquid are known at these temperatures. For example, the values of entropy and heat content at the critical point given in the present tables are about 2% lower than those given by Keenan in his 1930 tables. It will be evident from the comparisons in Table I that application of the rotational deformation correction of the water molecule is unnecessary for engineering purposes.

By comparing the 32° values of S_{fg} with h_{fg}/T_F in Table I, it is seen that the corrected values are in agreement within the limits of calculation error whereas the uncorrected values show the 0.0003 discrepancy which the authors have pointed out.

The book contains a table giving the properties of liquid water under pressures to 6000 lb./sq. in. and extending to the critical temperature. The properties of ice and water vapor, along the saturation curve, are given to −40°F. Tables of viscosity, heat conductivity, 8 graphs, a Mollier chart, approximately 2 by 3 ft., and a small temperature entropy chart are included.

W. F. GIAUQUE

Solutions of Electrolytes, with Particular Application to Qualitative Analysis. Second edition. By LOUIS P. HAMMETT, Ph.D., Professor of Chemistry in Columbia University. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1936. ix + 238 pp. Illustrated. 14.5 × 21 cm. Price, $2.25.

In this second edition of Professor Hammett's text-book the material of the first edition has been rearranged and increased. The book is divided into two parts, the first being a modern and thorough treatment of the theory of solutions of electrolytes, and the second part a sketchy laboratory manual for qualitative analysis. Exercises and suggestions for reading are given at the ends of the chapters and lecture experiments are described in an appendix.

The most important change in the new edition comes in the introduction. The Brönsted concept of acids and bases is introduced and employed consistently through the book. The ionization of an acid is treated as the transfer of a proton from the acid to a solvent molecule rather than as a simple dissociation. The writer cannot agree with the author's statement that the newer theory is at least as simple and teachable as the older one; certainly not for students who have had the misfortune to learn the older theory in elementary chemistry. However, there can be no doubt of the value of the newer theory. Professor Hammett is to be congratulated as heartily upon its introduction as upon his modern and simple treatment of the complete ionization of salts, which is common to both editions.

In Chapter II the solubility product principle is discussed, and in Chapter III the law of chemical equilibrium for weak electrolytes. After as thorough a theoretical treatment of both subjects as is possible without the aid of thermodynamics, application of the principles to analytical chemistry is discussed. In Chapter IV, on the ionization of water, the subject of hydrolysis is taken up. It may be noted in passing that the treatment of the hydrolysis of acid salts is not correct. In sodium bicarbonate, the example chosen to illustrate the topic, the amount of ionization of the bicarbonate ion is approximately equal to the amount of hydrolysis. As a result the true concentration of hydroxyl is only one twenty-fifth of that found on page 90. The ionization constants employed here and some of the others given in Table IV on page 60 have not been brought up to date with the new edition.

These are the only flaws which have been noted in this excellent work. Chapter V, on complex compounds, and Chapter VI, on oxidation–reduction reactions, are rich mines of chemical information into which candidates for the doctorate have been seen to delve. Chapter VII, at the end of the theoretical part, deals with oxidation potentials. It is so clearly put and valuable that the writer usually skips to it immediately after Chapter I in a course employing this text.

This is not an easy text. It demands careful study and close attention from the student. It is far superior in its scope and modern viewpoint, however, to any other text in the field.

CHARLES H. GREENE

Structure and Molecular Forces in Pure Liquids and Solutions. A General Discussion. Reprinted from the "Transactions of the Faraday Society." Published for the Faraday Society by Gurney and Jackson, 33 Paternoster Row, London, England, 1937. ii + 282 pp. Illustrated. 16 × 25 cm. Price, 12s./6d., postage 8d.

This volume is a collection of papers presented at the Sixty-fifth General Discussion of the Faraday Society, held in Edinburgh in September, 1936. The papers provide a very comprehensive survey of present knowledge concerning the structure of pure liquids and of non-electrolyte solutions.

The first part of the Discussion, introduced by James Kendall, is devoted to the properties of pure liquids. The heat capacity and viscosity of liquids, their infrared and Raman spectra, and the propagation of ultrasonic waves through them receive considerable attention. The problem of fusion is considered by several authors. There is a noteworthy theoretical discussion of molecular distribution in liquids by J. D. Bernal.

The second part of the Discussion, introduced by J. H. Hildebrand, is concerned with the properties of liquid solutions. The influence of various types of intermolecular force on deviations from ideal behavior in non-electrolyte solutions is the chief topic of discussion.

Those interested in the theory of solutions and in the nature of the liquid state will find the book a valuable source of information.

J. G. KIRKWOOD

Magnetochemie. (Magnetochemistry.) By Dr. WILHELM KLEMM, Professor in the Technical Institute of Danzig-Langfuhr. Akademische Verlagsgesellschaft m. b. H., Leipzig C 1, Germany, 1936. xv + 262 pp. 99 figs. 16 × 23.5 cm. RM. 16; bound, RM. 18.

As a result of the development of the theory of the relation between the magnetic properties and electronic structure of substances, there has occurred during the last decade great progress in the application of magnetic methods to the solution of chemical problems. Klemm's small book on magnetochemistry contains the most extensive and detailed discussion of this field which exists, one hundred pages being devoted to general magnetochemistry, including topics such as Pascal's rules, free radicals and biradicals, the determination of valence states in anomalous compounds [$(NH_4)_2SbBr_6$, perchromates, KO_2, etc.], bond types in coördination complexes, the diamagnetic anisotropy of aromatic crystals, chemical analysis by magnetic methods, etc. A compilation of existent magnetic data is not given; as the author mentions, a complete compilation of these data is badly needed.

This part of Klemm's book is preceded by a well-written elementary discussion of experimental methods, the theory of magnetism and atomic structure, and the diamagnetism, paramagnetism, and ferromagnetism of substances.

Because of its emphasis on chemical applications of magnetic methods, the book provides a useful supplement to the larger treatises of Stoner and Van Vleck.

LINUS PAULING

Enzyme Chemistry. By HENRY TAUBER, Ph.D., Consulting Chemist. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1937. xii + 243 pp. 28 figs. 15.5 × 23.5 cm. Price, $3.00.

Dr. Tauber has rewritten and expanded into book form the material of his earlier "Experimental Enzyme Chemistry."[1] The current edition retains all the merits of the former edition and includes, in addition, an excellent discussion of such recent work as the relationship between the yellow enzyme and lactoflavin, and the enzyme "destroying" vitamin A and ascorbic acid. The author has presented an excellent summary of recent advances in enzyme chemistry and the book is highly recommended.
