The Selective Hydrogenation of Unsaturated Esters to Unsaturated Alcohols

BY JOHN SAUER AND HOMER ADKINS

The hydrogenation of the double bond in such a compound as ethyl oleate is readily accomplished at room temperatures and atmospheric pressures of hydrogen over nickel, platinum or palladium catalysts. In order to bring about satisfactorily the hydrogenation of a carbalkoxy to a carbinol group temperatures in excess of 200° and pressures of the order of 100 atmospheres are required. In other words the alkene linkage reacts with hydrogen under conditions which are as mild as are used in any catalytic hydrogenation, while the carbalkoxy group requires drastic conditions. However, it seemed worth while to attempt the selective hydrogenation of the carbalkoxy groups with certain of the metallic oxides which are relatively inactive in the catalysis of the hydrogenation of alkene linkages.[1]

There are recorded in Table I the results obtained with six such catalysts containing zinc or copper combined with chromium, vanadium or molybdenum. Ethyl or butyl oleates were used in testing the catalysts. The butyl ester is very much to be preferred for this purpose since the ethyl esters boil at so nearly the same temperature as the alcohols that it is difficult to separate the ester from the alcohols.

It may be seen from the data in the table that copper–molybdenum oxide induced the hydrogenation of the double bond with the formation of ethyl stearate, while copper–chromium oxide caused the addition of three moles of hydrogen with the formation of octadecanol. Zinc–chromium oxide was, however, relatively inactive toward the alkene linkage and reasonably active toward the carbalkoxy group so that the unsaturated alcohol $C_{17}H_{33}CH_2OH$ was obtained in yields of over 60%. An unsaturated alcohol $C_{21}H_{41}CH_2OH$ was obtained in similar yield from butyl erucate. Zinc–vanadium oxide and zinc–molybdenum oxide were similar but inferior to zinc–chromium oxide for the production of the unsaturated alcohol.

Thus it is seen to be feasible to prepare unsaturated alcohols by the hydrogenation of certain unsaturated esters. However, the process is not very satisfactory from a preparational standpoint. A very high ratio of catalyst to ester must be used. It is probable that one part of catalyst should be used for two parts of ester. The temperature required for adequate reaction is quite high (300°) and even so seven to eleven hours were required for relatively complete reactions. These factors have made it impossible to obtain yields higher than 68% of the unsaturated alcohol and in the case of the ester of undecen-10-oic acid, the yield was only 37%. The unsaturated alcohol produced by this process is always accompanied by small amounts of saturated alcohol which it appears cannot be readily separated from the unsaturated alcohol by fractionation. The process apparently is not applicable to esters

such as butyl penten-4-oate and ethyl cinnamate which have their double bond near the carbalkoxy group.

The catalysts were prepared by the same general process[2] previously used. The details for preparing zinc-chromium oxide are as follows: 250 g. of ammonium dichromate (1.0 *M*) was dissolved in 600 cc. of water and concd. ammonium hydroxide added until the liquid changed from orange to yellow (400 cc. of concd. ammonium hydroxide). To this solution was added 379 g. (2.0 *M*) of zinc nitrate dissolved in 800 cc. of water. The yellow precipitate (333 g.) was filtered, washed and dried overnight in an oven at 85°. The dried precipitate was decomposed in four portions, washed in 5% acetic acid for several minutes, filtered and dried overnight in an oven at 85°. The final yield of a brown colored catalyst was 220 g.

The oleates were prepared by the alcoholysis of olive oil.[3] Butyl erucate was similarly prepared from rapeseed oil. Butyl undecen-10-oate was prepared from the acid (b. p. 141–143° at 13 mm.)[4] according to a standard method.[5] The hydrogenations were carried out at 200 atmospheres by the standard method.[6] The products were separated by fractionation. The alcohols were shown to be ester free and the yields are based upon iodine numbers for the unsaturated alcohols. The samples of octadecenol,[7] ducosenol,[7] and undecenol[8] referred to in Table I contained 13, 3 and 9%, respectively, of the corresponding saturated alcohols. The octadecenol and ducosenol were also characterized by hydrogenation to octadecanol and ducosanol, m. p. 57–58° and 69°, respectively.

Summary

It has been shown that butyl oleate or butyl erucate may be hydrogenated over zinc–chromium

Studies on the Chemistry of the Fatty Acids. I. The Purification of Linoleic Acid by Crystallization Methods[1]

BY J. B. BROWN AND GEORGE G. STONER

On account of the recently discovered nutritional significance of linoleic acid, $C_{18}H_{32}O_2$, interest in its chemistry has increased greatly during the past few years. The acid occurs naturally in large amounts in the semi-drying oils, especially such oils as cottonseed, corn, soy bean and wheat germ. Despite several investigations on the subject there is still some question whether the acid occurs in these oils as a single geometric isomer or whether it occurs along with one or more of the other three possible forms. (We are considering here only the 9–10, 12–13, octadecadienoic acids although the possibility of other dienoic acids is not precluded.) One reason for this uncertainty is the fact that so far only one method has been available for preparing the pure acid, namely, that of Rollett.[2] In this method the mixed fatty acids of an oil are brominated in cold ether, the petroleum ether–insoluble bromides are isolated and purified and the linoleic acid is regenerated by heating with zinc dust. The product is satisfactory and is designated as α-linoleic acid.

Preparation of the acid by Rollett's method is unsatisfactory from the standpoint of yield, since in the bromination process considerable amounts of material are converted into petroleum ether-soluble isomeric bromides which are lost, and from the standpoint of chemical identity, since there is the question of alteration of the acid during bromination and debromination.

The object of the present work was to prepare linoleic acid by direct crystallization methods which did not involve bromination. As raw materials we have employed the fatty acids of refined cottonseed and corn oils containing approximately 50% of linoleic acid, the other acids present being principally palmitic and oleic.

Crystallization of cottonseed fatty acids from methyl alcohol, 95% ethyl alcohol, petroleum ether and acetone at −20° gave separations of saturated and unsaturated acids with an efficiency approaching that of the widely used lead soap–ether method. Fractional crystallization of cottonseed and corn oil fatty acids from acetone gave linoleic acid preparations 80–93% pure. The chief obstacle to the isolation of purer specimens is the fact that in attempting to obtain the more soluble constituent in every case, the product was always contaminated with oleic acid in proportion to the ratio of the solubility of linoleic acid to oleic acid under the experimental conditions. Crystallization of fatty acid mixtures at low temperatures constitutes a valuable method for the separation of these acids.

A large number of soap separations were tried. Of these, crystallization of the lithium soaps of cottonseed oil fatty acids from *n*-butanol at −20° gave 81% linoleic acid in the filtrate.

Experimental

Materials.—The sources of the fatty acids used in this work were commercial refined cottonseed and corn oils. The following analytical data were obtained on these oils.

	Cottonseed	Corn
	Original oil	
Saponification no.	194.5	194.0
Iodine no.[a]	112.0	129.9
	Fatty acids	
Mean mol. wt.	276	282.9
Iodine no.	119	133.8

[a] All iodine numbers determined by the Wijs method.

Typical analyses of these oils have shown the following fatty acid composition.

	Cottonseed[a]	Corn[b]
Linoleic	45–50	39.1
Oleic	25–30	43.4
Myristic	Small amount	. .
Palmitic	19.8	7.3

The fatty acids were prepared by saponification and acidification. They were distilled at low pressure. Linolenic acid was shown to be absent by the hexabromide test.

Special Equipment.—Through the courtesy of Dr. F. A. Hartman of the Physiology Department we had the use of a room maintained at −20 to −25°. This room was equipped with suction for rapid filtration. For work at temperatures lower than −20° we used the following apparatus. A 200 × 200 mm. specimen jar was boxed and surrounded by rock wool insulation, with a glass plate as a cover. A circular disk was cut from this plate so that when in place it would fit loosely over a 2-liter Erlenmeyer flask, which was set in the jar on a wire tripod to raise it off the bottom. The flask was equipped with a good stirrer and a low temperature thermometer. The jar was partially filled with alcohol. Dry ice was added to the alcohol as needed. By this arrangement temperatures as low as −50 to −60° could be obtained in twenty to thirty minutes, and as low as −75° in a little longer time. This apparatus was used in the laboratory but all low temperature filtrations were carried out by suction in the −20° room in apparatus cooled to that temperature. Practically all of our crystallization mixtures filtered rapidly, so that there was very little "warming" effect before the filtration was complete.

Separation of the Saturated and Unsaturated Acids.—Four hundred and fifty grams of the cottonseed oil acids was dissolved in 4000 cc. of acetone in a 4-liter Erlenmeyer flask and allowed to stand at −20° overnight. They were filtered by suction on a large Büchner funnel previously cooled to −20° and were washed with cold acetone. Acetone was removed from both crystals and filtrate by warming under reduced pressure. The unsaturated acids were distilled before analysis; yield 140 g. of saturated acids and 300 g. of unsaturated acids. The analytical data on these preparations as well as on a number of others prepared under various experimental conditions are given in Table I.

The best separations were from 10% solutions in acetone and in methyl alcohol at −20°. Petroleum ether and ethyl alcohol were almost as efficient. Separation from solutions of higher than 10% concentration was rendered less complete due to the bulk of the precipitate, which makes filtration and washing more difficult. For best results the initial concentration of saturated acids in the acetone solution should not exceed 2.5 to 3.0%. The separation in acetone and methyl alcohol is at least as efficient as the standard lead soap–ether procedure. This is borne out by the fact that lead soaps of the unsaturated acids which were prepared by the acetone method were completely soluble in ether at room temperature, and precipitated no insoluble soaps even at ice box temperature. Further work is in progress, studying the possibility of this method as a substitute for the lead soap–ether procedure.

Assuming the unsaturated acids in experiment 4 to be a mixture of oleic and linoleic acids, and calculating from the iodine number, the mixture contains 70% linoleic acid.

Crystallization of the Unsaturated Fatty Acids of Cottonseed Oil from Organic Solvents at Low Temperatures.—The unsaturated fatty acids, prepared by the −20° treatment in acetone and containing 70% linoleic acid, were crystallized at various temperatures and concentrations from several organic solvents. From a 10% solution in toluene at −70° the acids in the filtrate contained 76% linoleic acid; from the same concentration in ether the crystals contained 53% and the acids of the filtrate 73% linoleic acid. A 10% solution in acetone crystallized at −50° gave crystals of 49% and a filtrate containing 82% linoleic; at −60 and at −70° the separation was less satisfactory, the acids of the filtrate being 78 and 76% linoleic, respectively. A 1% solution in acetone crystallized at −65° gave 79% linoleic acid in the filtrate. Of these data the −50° crystallization in acetone is the most promising. This favorable result is no doubt due in part to removal of further traces of saturated acids which remained unavoidably in the unsaturated acids and in part to the crystallization of an oleic acid rich fraction.

Fractional Crystallization of the Unsaturated Acids.—In order to study further crystallization in certain solvents at various low temperatures, the unsaturated acids of cottonseed oil were fractionally crystallized from methyl alcohol, acetone, ethyl alcohol and 76% acetone. The solution was cooled to a given temperature with fairly rapid

[a] These specimens were distilled before the iodine number was determined.

stirring. It was filtered rapidly in the −20° room; the filtrate was then cooled further, this process being repeated, as shown in Table II.

The precipitate from methyl alcohol at −65°, *i. e.*, that portion of the total acids which came down by cooling a solution, saturated at −60, to −65° contained 86% linoleic acid; that precipitated at −60° from acetone contained 85% of the desired product. These represent the best products we have been able to obtain from cottonseed oil, but they constitute too small a part of the total acids to be of great value. It should be noted especially that in each instance maximum removal of unwanted acids (product of low iodine number) occurred in the first crop of crystals.

In order to take advantage of this fact the following procedure was carried out. Two thousand grams of refined cottonseed oil was saponified and converted into fatty acids. Four hundred and fifty grams of these acids was placed in a 4-liter Erlenmeyer flask and the flask filled with acetone. After standing overnight at −20°, the contents of the flask were filtered with suction. Four such lots were run (1800 g.), the total filtrate being 12 liters. In batches of 2 liters this filtrate was cooled to −40°, which was slightly below the point of initial appearance of crystals. The crystals were filtered off; the resulting filtrate from the entire lot contained 1010 g. of acids with an iodine number of 160 (77% linoleic acid).

Fractional Crystallization of the Unsaturated Methyl Esters from Methyl Alcohol.—Methyl esters (iodine number 152) were prepared from the unsaturated acids previously described. These esters were fractionally crystallized from a 12% solution in methyl alcohol, successive crops of crystals being removed at −45, −65 and −75°. The iodine numbers of the esters of these products and of the esters in the filtrate were 56.7, 142.3, 156.1 and 147.4, respectively, the yields, calculated as percentage total weight of ester used, were 2, 58, 32 and 8, respectively. The crystals at −75° contained approximately 82% methyl linoleate. Undoubtedly this procedure offers possibilities, but, so far, we have not studied it further.

Fractional Crystallization of Corn Oil Fatty Acids.—The unsaturated fatty acids of corn oil were prepared by the −20° acetone procedure; these were fractionally crystallized from this solvent under a variety of conditions. The details and results are shown in Table III.

We have succeeded here in obtaining satisfactory yields of linoleic acid 85, 86 and 88% pure, and less satisfactory yields of the acid 89 and 93% pure. It is possible then to prepare the acid by these latter procedures in sufficient purity for most chemical studies. We hope to have available shortly data comparing the acid which has been purified in this manner with α-linoleic acid prepared by Rollett's procedure.

Attempts to Purify Linoleic Acid by Crystallization of the Soaps of the Fatty Acids of Cottonseed Oil.—Several

of the more useful methods of fatty acid separation involve differences of soap solubility. Early in this work we were hopeful of finding some suitable soaps of oleic and linoleic acids which would exhibit wide enough difference in solubility to be useful in their separation. Only a few of our more promising results will be reported here. Starting with cottonseed oil fatty acids, crystallization of the potassium soaps from a 10% solution in absolute alcohol at 0° gave 45% insoluble soaps and 55% soluble soaps, containing 68% linoleic acid. The lithium soaps, prepared by neutralizing a solution of the acids in alcohol with lithium hydroxide, removing the alcohol and water under reduced pressure and taking up the soaps in butyl alcohol, were fractionally crystallized from that solvent; also the potassium soaps from absolute alcohol with the results in Table IV.

When the fact is considered that we began here with a mixture of cottonseed oil fatty acids, it is clear that either of the separations in Table IV has possibilities. In the former case, a comparatively small amount of the acids comes out as 82% linoleic, while in the latter a much larger portion came out 74% linoleic acid.

Summary

1. The saturated and unsaturated fatty acids of cottonseed and corn oils may be separated conveniently by crystallization of the mixed acids from a 10% solution in acetone at −20°.
2. Linoleic acid preparations containing up to 93% of the acid were obtained by fractional crystallization of the unsaturated acids (and methyl esters) of these oils from acetone and methyl alcohol at low temperatures.
3. Fractional crystallization of the lithium soaps from *n*-butyl alcohol and of the potassium soaps from absolute alcohol may also be used in obtaining linoleic acid concentrates.
4. Crystallization of unsaturated fatty acids from appropriate solvents at low temperatures is a useful procedure for their separation.

Columbus, Ohio Received October 3, 1936

[Contribution from the Laboratory of Physiological Chemistry, The Ohio State University]

Studies on the Chemistry of the Fatty Acids. II. The Preparation of Pure Oleic Acid by a Simplified Method[1]

By J. B. Brown and G. Y. Shinowara

Although oleic acid (*cis*-9,10-octadecenoic) is perhaps the most common of the naturally occurring fatty acids, the pure acid is still one of the rare chemicals. The reason for this state of affairs is that oleic acid always occurs in fats and oils associated with saturated acids and usually with varying amounts of linoleic acid and other acids of higher unsaturation. The methods for separating these impurities are only semi-quantitative so that purification of oleic acid is extremely tedious. Olive oil is usually employed as a source of the acid. The saturated acids, mostly palmitic, are removed by the lead soap separation in alcohol or ether; the unsaturated acids are then converted into barium soaps which are repeatedly crystallized from moist benzene to remove linoleic acids.

Excellent reviews of work previous to 1925 are given by Lewkowitsch[2] and by Lapworth, Pearson and Mottram.[3]

These investigators prepared the pure acid by a procedure which included the lead salt treatment, distillation, barium soap crystallization and finally distillation. Holde and Gorgas[4] claimed

the preparation of a pure product through reduction of dibromostearic acid. Bertram[5] prepared 99.5% oleic acid by use of the Twitchell[6] lead salt–alcohol procedure, formation of the silver salt and crystallization of the acid three times from acetone. Raymond[7] modified the Bertram method by eliminating the use of a silver salt, and crystallizing the acid from cold alcohol in a special apparatus. Shelton[8] likewise used the Twitchell separation and in addition crystallized the barium or lithium salts and distilled the methyl esters of the resulting product.

All procedures so far used that have resulted in satisfactory products have been tedious and have employed a combination of methods to attain the desired results. As a result of experience gained in the course of the preceding work[9] it seemed likely that we could obtain oleic acid of a high degree of purity by direct crystallization of the acids of olive oil from acetone. Our method in brief involves removal of the saturated acids by the −20° acetone precipitation, crystallization of the resultant unsaturated acids from acetone at −60° four or more times, followed by a partial crystallization of the resultant product from acetone at −35° to remove small amounts of palmitic acid not taken out by the original treatment at −20°. Three preparations are described and compared with other preparations reported in the literature. The multifarious operations of previously reported methods are replaced by seven or more crystallizations from the same solvent. No soap preparations are involved after the original saponification.

Experimental Part

Equipment.—For low temperature work we had available the special equipment described previously, namely, a room in which a temperature of −20 to −25° was maintained and a well insulated dry ice–alcohol apparatus designed to accommodate a 2-liter Erlenmeyer flask. All filtrations were carried out by suction in the −20° room.

Procedures.—(1) One kilogram of olive oil (iodine number 85.5; saponification number, 190.1) was saponified and the soaps converted into fatty acids (iodine number 84.5). Two hundred and twenty-five grams of the acids was dissolved in 3450 cc. of C. P. acetone in a 4-liter flask and allowed to stand in the cold room overnight. The precipitate was removed by suction on a large Büchner funnel. The filtrate (3000 cc.) was cooled to −60° with continuous stirring. After filtering, the precipitate was allowed to melt and was made up to 2000 cc. with acetone, and again brought to −60° and filtered. After two more crystallizations at this temperature, the final precipitate was melted and made up to 1250 cc. with acetone and cooled slowly with stirring to the point of first appearance of crystals, about −35°. These, consisting of some oleic acid and any saturated acids which may have escaped the first crystallization, were filtered off in the cold room. The acetone was removed from the filtrate by warming under reduced pressure. The residual product was distilled at 15 mm. pressure in an entire glass apparatus. It was water-white and odorless; yield 90 g. Other constants are in Table I.

TABLE I

ANALYSIS OF OLEIC ACID PREPARATIONS IN COMPARISON WITH THOSE REPORTED IN THE LITERATURE

	M.p., °C.	Mean mol. wt.	Iodine number	n^{20}	Purity, %
Calcd.	...	282.3	89.93	....	
Specimen (1)	13.0	282.2	90.03	1.4585	
Specimen (2)	13.0	282.4	89.63	1.4586	
Specimen (3)	13.0	282.5	90.04	1.4585	
Bertram	13.2	...	...	1.4582	99.5
Shelton	13–14	282.5	90.6	1.4610	

(2) Four hundred and fifty grams of the mixed acids, as above, was treated as before, except that six −60° crystallizations, instead of four, were made; yield 135 g.

(3) The −60° filtrates from the two preceding experiments were combined; the acetone was removed. Two hundred and fifty grams of these acids was made up to 1500 cc. in acetone and crystallized four times at −60°; crystals were washed each time with 200 cc. of acetone cooled to −70°; yield 74 g.

All three of these preparations were practically constant boiling. The boiling point of No. 2 oleic acid was determined accurately at several pressures, using a micro-gage with the following results.

Pressure	B. p., °C. Obsd.	Corr.
15	228–229	234–235
10	219–220	225–226
5	209–210	215–216
1.2	194–195	200–201

Criteria of Purity.—We have employed the following criteria of purity, actual data being given in Table I. (1) Mean molecular weight: The principal saturated acid of olive oil is palmitic. Five per cent. contamination with this acid would lower this value 1.4 points. No appreciable lowering was observed. (2) Iodine number: Method used, Wijs thirty minutes. Palmitic and linoleic acids must be present in equal amounts to maintain the theoretical value. (3) Melting point: Specimens, frozen in a special tube and held overnight. All three preparations melted sharply at 13°. Difference between softening and melting point was less than 0.1°. (4) Oxidation products: Dihydroxystearic acids were prepared from each product by the method of Lapworth and Mottram;[10] yield, 95–96%; molecular weight 315.6–316.0 (calcd. 316.3).

The data are summarized in Table I.

Summary

1. A simplified procedure for preparing oleic acid of high purity is described.

2. The constants of three specimens of oleic acid, prepared by slight modifications of the procedure, are described.

A Method for the Synthesis of Phenanthridine Derivatives by an Application of the Stieglitz Rearrangement

BY LOUIS A. PINCK AND GUIDO E. HILBERT

The rearrangements of hypothetical intermediates $\left.\begin{matrix}R_1\diagdown\\R_2-\\R_3\diagup\end{matrix}\right. C-N:$ resulting from appropriate treatment of tertiary methyl nitrogen substituted compounds of the type $\left.\begin{matrix}R_1\diagdown\\R_2-\\R_3\diagup\end{matrix}\right. C-N\left\langle\begin{matrix}X\\Y\end{matrix}\right.$ where R$_1$, R$_2$ and R$_3$ usually have been aromatic groups and where $-N\left\langle\begin{matrix}X\\Y\end{matrix}\right.$ may be $-N\left\langle\begin{matrix}H\\Br\end{matrix}\right.$,[1] $-N\left\langle\begin{matrix}Cl\\Cl\end{matrix}\right.$,[1] $-N\left\langle\begin{matrix}H\\OH\end{matrix}\right.$,[2] —N(N$_2$),[3] etc.,[4] have been studied extensively by Stieglitz and co-workers.[5] When R$_1$ is aliphatic in nature and R$_2$ and R$_3$ are aromatic, it was noted that either R$_2$ or R$_3$ rather than R$_1$ migrated to the nitrogen atom and largely on the basis of this fact it has been suggested[5] that the migration of the most electronegative group attached to the carbon atom would in general be favored. The rearrangement of intermediates formed from tertiary methyl nitrogen derivatives, where two of the groups attached to the tertiary carbon atom are linked together, as for example in a 9-substituted 9-fluorylchloroamine (II), has not previously been studied. Here the situation is more complicated, since the possible influence that the five-membered ring might have on the rearrangement must be considered in addition to the electronegativities of the radicals. From the general results of recent x-ray and electron diffraction studies[6] fluorene would be expected to have the configuration shown in Fig. 1.[7] In order that the C–C distances be those shown in the figure the normal valence angle from the benzene ring must be distorted approximately 12 to 13°. Since the linkages attached to the benzene ring are known to be quite rigid the five-membered ring in fluorene, because of the considerable distortion of the normal valence angles, must be appreciably strained. Theoretically a 9-substituted fluoryl nitrogen (III) can be stabilized by undergoing two possible types of rearrangement: (1) opening of

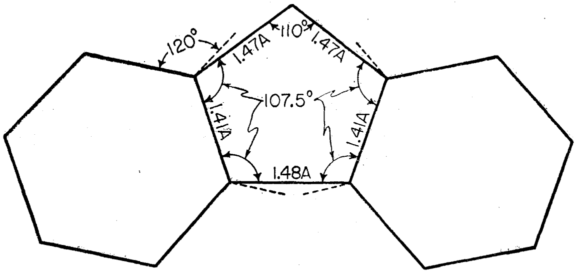

Fig. 1.—Structural formula of fluorene.

[7] Stuart "Molekülstruktur," Verlag von Julius Springer, Berlin, 1934, p. 76, has interpreted the results obtained in an x-ray examination of fluorene by Hengstenberg and Mark, *Z. Krist.*, **70**, 283 (1929), as favoring a planar configuration of the molecule. Since this manuscript was written, additional articles on the configuration of fluorene have appeared. Cook and Iball, *Chemistry and Industry*, **55**, 467 (1936), on the basis of crystallographic data consider it to be a non-planar molecule, whereas dipole moment measurements by Hughes, LeFevre and LeFevre, *ibid.*, **55**, 545 and 561 (1936), suggest that fluorene is a flat molecule.

the ring with subsequent reformation to give a phenanthridine derivative (IV) or (2) migration of R to form an imide (V). As will be shown below even when R is more electronegative than the phenylene radical the rearrangement involves primarily the formation of (IV). Thus it follows that the strained condition of the five-membered ring is an important factor, if not the most important one, in directing the course of the rearrangement.

In order that the electronegativities of R in (I) be widely different, both 9-aryl- and 9-alkyl-9-fluorylamines were investigated. Examples chosen as being representative of the two types were the 9-phenyl- (VI), 9-(α-naphthyl) (VII) and 9-methyl-9-fluorylamines (VIII). Although the first two were prepared smoothly by treating the corresponding 9-chloro compounds with ammonia, considerable trouble was encountered in preparing the 9-methyl derivative. A solution of ammonia in toluene gave with 9-bromo-9-methylfluorene, a mixture of amines, consisting of (VIII), an isomer, probably 9-fluorylmethylamine, and a secondary amine, as well as an appreciable amount of polymerized biphenyleneethylene.[8] The difficulty in this case is to be attributed to the relatively labile hydrogen of the neighboring methyl group. It is of interest that a number of these amine hydrochlorides are soluble in benzene and chloroform and that practically all have an anesthetic action on the tongue.[9]

Interaction of hypochlorous acid with alcoholic solutions of (VI), (VII) and (VIII) gave the corresponding chloroamines. The hydrogen and chlorine atoms attached to the nitrogen were most conveniently removed by treating the chloroamine in anhydrous pyridine with sodium methylate at room temperature. Of some significance in possibly offering a clue as to the nature of the intermediate formed in the reaction may be the color changes exhibited by the reaction mixture. During the degradation of 9-phenyl- and 9-(α-naphthyl)-9-fluorylchloroamine a red color developed in the solution and persisted for a short time; however, in the case of the 9-methyl analog the color remained over a period of twelve hours. The rearrangement products formed from 9-methyl-, 9-phenyl- and 9-(α-naphthyl)-9-fluorylchloroamine are 9-methyl-, 9-phenyl- and 9-(α-naphthyl)-phenanthridine, respectively. In every case the yield was excellent. The structures of 9-methyl- and 9-phenylphenanthridine were established by comparison of these compounds with authentic specimens prepared from acetyl- and benzoyl-*o*-xenylamine according to the method of Morgan and Walls.[10] If the formation of the rearranged compound had been controlled only by a shift of the most electronegative group attached to the tertiary carbon atom, the predicted[11] products from 9-methyl-, 9-phenyl- and 9-(α-naphthyl)-9-fluorylchloroamine would have been 9-methylphenanthridine, 9-phenyliminofluorene (V where R = C_6H_5) and 9-(α-naphthyl)-iminofluorene (V where R = $C_{10}H_9$). Actually, imino compounds, which could have been easily detected even if formed in minor amounts, were found to be absent.

In order to find if other compounds of the type  $\begin{matrix}C_6H_4\\ |\\ C_6H_4\end{matrix}\!\!>\!C\!<\!\!\begin{matrix}C_{10}H_7\\ N\!<\!\!\begin{matrix}X\\ Y\end{matrix}\end{matrix}$ could be converted into derivatives of phenanthridine an investigation of the thermal decomposition of 9-(α-naphthyl)-9-fluorylazide was carried out. 9-(α-Naphthyl)-9-fluorylhydrazine (IX) was prepared by the interaction of 9-(α-naphthyl)-9-chlorofluorene with hydrazine. The reaction was not smooth and owing to its lability the hydrazine derivative was difficult to obtain in the pure state. Nitrous acid with (IX) gave the azide. This when heated to 190–200° evolved nitrogen and formed 9-(α-naphthyl)-phenanthridine in good yield. Because of the difficulty encountered in dealing with (IX), the phenanthridine derivatives are much more conveniently prepared by way of the chloroamines.

The compounds to which the Stieglitz rearrangement has been applied in the past yield imides as the end-products of the reaction. Since these are much more easily prepared by other methods the rearrangement was chiefly of theoretical interest. In view of the present work it appears that this rearrangement may also assume considerable practical importance as a method for converting suitable five-membered cyclic compounds to six-membered nitrogen rings.

We are grateful to Mrs. M. S. Sherman for carrying out the analyses recorded in the experimental work.

[10] Morgan and Walls, *J. Chem. Soc.*, 2447 (1931).

[11] From a comparison of the reactivities of diphenylmethyl with biphenylenemethyl derivatives or of triphenylmethyl with phenylfluoryl derivatives, the phenyl group would be expected to be more electronegative than the phenylene radical.

Experimental

9-Phenyl-9-fluorylamine, its Derivatives and its Conversion to 9-Phenylphenanthridine

9-Phenyl-9-fluorylamine.—A mixture of 10 g. of 9-phenyl-9-chlorofluorene and about 15 cc. of liquid ammonia was heated in a sealed tube at 60° for several hours.[12] An oil separated and upon evaporation of the ammonia a sirupy residue remained. Owing to its marked sluggishness in crystallizing, the amine was purified only with difficulty by numerous crystallizations from either petroleum ether or 75% ethyl alcohol. It separated as colorless prisms melting at 82°[13] and was very soluble in most organic solvents.

Anal. Calcd. for $C_{19}H_{15}N$: C, 88.67; H, 5.88; N, 5.45. Found: C, 88.85; H, 6.15; N, 5.47.

9-Phenyl-9-fluorylamine was not hydrolyzed when heated at 100° for one hour with 20% hydrochloric acid, whereas under similar conditions triphenylmethylamine yielded an appreciable amount of the carbinol. The amine was also recovered unchanged after treatment with a solution of potassium permanganate in purified acetone in the presence of anhydrous sodium sulfate[14] for several days at room temperature. The stability of 9-phenyl-9-fluorylamine toward oxidizing agents is further shown by its recovery after refluxing for two hours an alcoholic solution to which had been added bromine and sodium ethylate.[15]

The hydrochloride was prepared by passing dry hydrogen chloride into a benzene solution of the amine; it crystallized from dilute hydrochloric acid as microscopic prisms melting at 310° with decomposition.

Anal. Calcd. for $C_{19}H_{15}N{\cdot}HCl$: C, 77.66; H, 5.49; N, 4.88. Found: C, 78.00; H, 5.32; N, 4.93.

The acetyl derivative was secured in the usual manner and crystallized from alcohol as microscopic prisms, m. p. 232°.

Anal. Calcd. for $C_{21}H_{17}NO$: C, 84.24; H, 5.72; N, 4.68. Found: C, 83.79; H, 5.92; N, 4.65.

The monobromoamine was prepared according to the method of Vosburgh.[1] The amounts of reagents used were 2.60 g. of 9-phenyl-9-fluorylamine, 1.62 g. of bromine, and 3.22 cc. of an aqueous solution containing 0.41 g. of sodium hydroxide. The chloroform solution was concentrated and the sirupy residue dissolved in 30 cc. of warm, low-boiling ligroin. Upon cooling a pale yellow microcrystalline material separated; yield 1.60 g. After recrystallization it melted at 105° (dec.).

Anal. Calcd. for $C_{19}H_{14}NBr$: Br, 23.78. Found: Br, 24.09.[16]

The monochloroamine was prepared by using a method similar to that of Hellerman and Sanders.[17] A solution of 2.72 g. of 9-phenyl-9-fluorylamine hydrochloride in 75 cc. of 95% ethyl alcohol[18] was treated at 0° with 10 cc. of cold 0.926 *N* potassium hypochlorite. Minute colorless crystals immediately precipitated. The reaction mixture was shaken in an ice-bath for thirty minutes and cold water added to ensure complete precipitation. The colorless solid was collected, washed with cold water and dried *in vacuo* over phosphorus pentoxide; yield, practically quantitative. The monochloroamine separates from hexane as colorless prisms; m. p. 102°.

Anal. Calcd. for $C_{19}H_{14}NCl$: C, 78.20; H, 4.84; N, 4.80; Cl, 12.16. Found: C, 77.68; H, 4.84; N, 4.58; Cl, 12.21.

The dichloroamine was synthesized by passing an excess of chlorine into an alcoholic solution of 9-phenyl-9-fluorylamine. It was obtained in good yield and after crystallizing from ligroin melted at 150° (dec.). This material is unusually stable and may be kept for several years without any apparent alteration.

Anal. Calcd. for $C_{19}H_{13}NCl_2$: C, 69.94; H, 4.02; N, 4.30; Cl, 21.75. Found: C, 70.09; H, 4.43; N, 4.35; Cl, 20.33.

Di-(9-phenyl-9-fluoryl)-amine was obtained as a by-product in the following experiment. Forty grams of 9-phenyl-9-chlorofluorene and a large excess of dry ammonia were heated in a steel bomb at 180° for four hours. The reaction product, after evaporation of the ammonia, was triturated with 100 cc. of alcohol[19] and the residue extracted with toluene. The hot toluene filtrate was treated with an equal volume of hot alcohol and on cooling the secondary amine separated. Several crystallizations from a solution of alcohol and toluene gave 3 g. of glistening, elongated, hexagonal plates, m. p. 230°.

Anal. Calcd. for $C_{38}H_{27}N$: C, 91.71; H, 5.47; N, 2.82. Found: C, 91.89; H, 5.62; N, 2.90.

Conversion of 9-Phenyl-9-fluorylchloroamine to 9-Phenylphenanthridine.—A solution of 2 g. of the chloroamine in 20 cc. of anhydrous pyridine[20] was treated with

---

(12) 9-Phenyl-9-chlorofluorene is much less reactive toward ammonia than triphenylmethyl chloride. Considerable heat was generated when the latter was treated with liquid ammonia at room temperature. Upon slow cooling beautiful crystals of triphenylmethylamine separated; from the interaction between 10 g. of triphenylmethyl chloride and 15 cc. of liquid ammonia 9.3 g. of the amine was isolated. Triphenylmethylamine was recovered unchanged after being subjected to a solution of ammonium chloride in ammonia for several days at room temperature. Evidently the equilibrium is shifted to a remarkable extent by an appreciable temperature change as Kraus and Rosen, THIS JOURNAL, **47**, 2739 (1925), reported that at the temperature of liquid ammonia: (1) triphenylmethyl chloride was ammonolyzed to the amine only to a slight extent and (2) the amine was converted to triphenylmethyl chloride by ammonium chloride.

(13) All melting points are corrected.

(14) Goldschmidt and Beuschel [*Ann.*, **447**, 197 (1926)] used similar conditions in dehydrogenating 9-fluorylamine to 9-iminofluorene.

(15) These conditions were used by Hellerman and Sanders, THIS JOURNAL, **49**, 1745 (1927), to dehydrogenate diphenylmethylamine.

(16) The compounds containing active halogen were analyzed by titrating in chloroformic solution against a standardized solution of sodium thiosulfate in the presence of hydriodic acid.

(17) Hellerman and Sanders, THIS JOURNAL, **49**, 1745 (1927), and private communications from Dr. Hellerman which have facilitated the work immensely.

(18) Water is usually used as the medium for the preparation of the monochloroamines. However, when water was used in the above halogenation, the reaction product was always contaminated with some unchanged amine. The use of alcohol, in which the amine hydrochloride was appreciably soluble, overcame this difficulty.

(19) From the alcoholic extract after suitable manipulation, 24.5 g. of pure 9-phenyl-9-fluorylamine hydrochloride was obtained.

(20) Absolute alcohol as a solvent resulted in the formation of the amine.

an excess of dry sodium methylate.[21] Considerable heat was generated and the solution developed a light red color which persisted for several minutes and then changed to a straw yellow. After standing overnight the pyridine was distilled from the reaction mixture under diminished pressure, the residue triturated with dry ether and the resulting extract treated with dry hydrogen chloride in order to precipitate the base as the salt. The hydrochloride was exceedingly soluble in water and crystallized as straw colored needles containing water of crystallization; m. p. 95–100° and 226°.[22] 9-Phenylphenanthridine was regenerated from the salt and crystallized from petroleum ether; colorless glistening plates, m. p. 107–108°.

Anal. Calcd. for $C_{19}H_{13}N$: C, 89.38; H, 5.13; N, 5.49. Found: C, 89.53; H, 5.36; N (Dumas), 5.48.

Comparison of its properties with those of a specimen synthesized according to the method of Morgan and Walls[10] showed them to be identical; a melting point of the mixture was not depressed.

9-(α-Naphthyl)-phenanthridine

9-(α-Naphthyl)-9-fluorylamine was prepared by heating 9-(α-naphthyl)-9-chlorofluorene (36 g.)[23] with dry ammonia in a steel bomb at 80° for forty hours. The ammonia was evaporated and the amine separated from the residue by dissolving in boiling benzene. After decolorizing with charcoal and numerous recrystallizations from solutions of benzene and alcohol, the amine melted at 186°; colorless prisms; yield 13.4 g.

Anal. Calcd. for $C_{23}H_{17}N$: C, 89.86; H, 5.58; N, 4.56. Found: C, 89.92; H, 5.66; N, 4.52.

The hydrochloride was soluble in benzene; m. p. 271° (dec.).

Anal. Calcd. for $C_{23}H_{17}N \cdot HCl$: N, 4.1. Found: N, 3.9.

The chloroamine was obtained in a practically quantitative yield and separated from a solution of benzene and hexane as beautiful colorless prisms; m. p. 133–135° (dec.).

Anal. Calcd. for $C_{23}H_{16}NCl$: C, 80.80; H, 4.72; N, 4.10; Cl, 10.38. Found: C, 81.11; H, 5.03; N, 3.91; Cl, 10.00.

9-(α-Naphthyl)-phenanthridine was prepared from 9-(α-naphthyl)-9-fluorylchloroamine (1.5 g.) in the same manner as that described for the phenyl analog. The reaction mixture in this case was not as highly colored. After removal of the volatile matter, the phenanthridine derivative was extracted with ether. It crystallized from petroleum ether in clusters of irregularly shaped colorless crystals; yield 1.1 g.; m. p. 123.5°.

Anal. Calcd. for $C_{23}H_{15}N$: C, 90.45; H, 4.96; N, 4.59. Found: C, 90.37; H, 5.08; N (Dumas), 4.59.

The hydrochloride crystallized from boiling water as cream colored needles with water of crystallization melting at 120–125°; the anhydrous product melted at 224° (dec.).

Anal. Calcd. for $C_{23}H_{15}N \cdot HCl$: C, 80.80; H, 4.72; N, 4.10. Found: C, 80.97; H, 5.10; N, 3.99.

The picrate was prepared in and recrystallized from alcohol; yellow prisms; m. p. 251°.

Anal. Calcd. for $C_{29}H_{18}N_4O_7$: C, 65.15; H, 3.40. Found: C, 65.43; H, 3.58.

9-Methyl-9-fluorylamine and 9-Methylphenanthridine

Interaction of 9-Methyl-9-bromofluorene with Ammonia.—A solution of 37 g. of 9-methyl-9-bromofluorene[9] in 30 cc. of dry toluene and 30 g. of liquid ammonia was heated in a steel bomb at 75° for twenty hours. After removing the ammonia, the insoluble fraction was collected, thoroughly washed with 150 cc. of toluene, and identified as the polymeric form of biphenyleneethylene; wt. 6.9 g.; m. p. 270°.[8]

Anal. Calcd. for $(C_{14}H_{10})_x$: C, 94.34; H, 5.66. Found: C, 93.94; H, 5.84.

The filtrate and washings were combined and acidified with an alcoholic solution of hydrogen chloride. On heating, the slight precipitate that formed dissolved and the hot solution was concentrated at reduced pressure. Fractionation of the resulting residue was effected by extraction with water; further manipulation of the aqueous insoluble portion (A) is described below. The aqueous extract was concentrated to about 75 cc. and treated with an equal volume of hydrochloric acid. Upon cooling the hot solution a mixture of colorless crystalline amine hydrochlorides (9.5 g.) separated. Efforts to resolve the mixture into its components by repeated crystallization from water failed. Advantage was taken of the differential solubility of the two amine hydrochlorides in chloroform; 9-methyl-9-fluorylamine hydrochloride was quite soluble in contrast to the other amine hydrochloride which was practically insoluble. To the chloroformic extract of the mixture was added benzene; beautiful needles separated; m. p. 266° (dec.).

Anal. Calcd. for $C_{14}H_{13}N \cdot HCl$: C, 72.55; H, 6.09; N, 6.05. Found: C, 72.62; H, 6.12; N, 5.83.

This salt was decomposed in the usual manner to liberate the free base. **9-Methyl-9-fluorylamine** was recrystallized from ligroin and separated as colorless needles melting at 96°.

Anal. Calcd. for $C_{14}H_{13}N$: C, 86.11; H, 6.71; N, 7.18. Found: C, 86.19; H, 6.80; N, 7.22.

On interacting with nitrous acid, 9-methyl-9-fluorenol was formed in good yield; m. p. and mixed m. p. 176°.

The chloroformic insoluble hydrochloride (*ca.* 1.0 g.) was crystallized from dilute hydrochloric acid; irregular

---

(21) 9-Phenylphenanthridine was also prepared by treating 9-phenyl-9-fluorylbromoamine in ether with freshly precipitated silver oxide [Willstätter and Müller, *Ber.*, **41**, 2580 (1908)] in the presence of preheated sodium sulfate. Under these conditions the reaction, probably because some amine is regenerated, was not as smooth as the above, since numerous recrystallizations were required to purify the phenanthridine derivative.

(22) Pictet and Hubert [*ibid.*, **29**, 1182 (1896)] reported it to melt at 95–96 and 220°.

(23) In working up 9-α-naphthyl-9-fluorenol prepared by a Grignard reaction [Wanscheidt and Moldavski, *ibid.*, **63**, 1362 (1930)] it was noticed that the unchanged fluorenone combined with the fluorenol derivative to form a relatively stable deep yellow crystalline molecular compound melting at 109–110°. This view regarding the nature of the product was confirmed by preparing it from an alcoholic solution containing equimolal amounts of fluorenone and 9-(α-naphthyl)-9-fluorenol. Schlenk and Herzenstein, *Ann.*, **372**, 27 (1910), reported the formation of a similar type of compound between fluorenone and 9-*p*-diphenyl-9-fluorenol.

shaped crystals with marked twinning in the form of crosses; m. p. 294° (dec.).

Anal. Calcd. for $C_{14}H_{13}N \cdot HCl$: C, 72.55; H, 6.09; N, 6.05. Found: C, 72.79; H, 6.24; N, 5.96.

The free base, which is considered to be **9-fluorylmethylamine,** was prepared from the salt and crystallized from ether as colorless needles melting at 99–100°; when mixed with 9-methyl-9-fluorylamine the melting point was depressed considerably. There was insufficient material for further purification and for analysis.

The aqueous insoluble fraction (A) was triturated with benzene and from this benzene extract there was recovered 0.9 g. of a colorless crystalline hydrochloride; m. p. 263–265° (dec.). Treatment of the salt with liquid ammonia gave the free base, which was recrystallized from a solution of 20% benzene and 80% alcohol; colorless prisms; m. p. 166°.

Anal. Calcd. for $C_{28}H_{23}N$: C, 90.04; H, 6.21; N, 3.75. Found: C, 90.19; H, 6.44; N, 3.67.

This analysis agrees with that required for a disubstituted amine. Of the number of secondary amines possible, that which seems to agree best with the facts is **di-(9-methyl-9-fluoryl)-amine.** Thus the peculiar solubility of the salt in benzene suggests that in this solvent it is present in the dissociated form and that the base is therefore a weak one (as compared, for example, to di-(9-fluorylmethyl)-amine which would be expected to be much more strongly basic).[24] The above suggested structure for the secondary amine is in accord with the expectation that it would be formed from the amine present in largest amounts in the reaction mixture.

9-Methylphenanthridine.—9-Methyl-9-fluorylchloroamine was prepared from the hydrochloride (2.1 g.) of 9-methyl-9-fluorylamine. It was isolated as a sirup and gave a strong test for active halogen. Owing to its lability and to the difficulty in purifying it, the product in this crude form was subjected to the rearrangement conditions. When the pyridine solution of the chloramine was treated with sodium methylate a deep reddish-purple color developed and persisted until the reaction mixture was worked up. After twelve hours the pyridine was removed under diminished pressure, and the residue extracted with petroleum ether. The extract was concentrated and the material remaining dissolved in alcohol. Addition of hydrogen chloride precipitated the hydrochloride of 9-methylphenanthridine; yield 1.3 g., m. p. 287°. This was converted to the free base, which was purified by sublimation *in vacuo;* m. p. 83°. The melting point was not depressed when the material was mixed with a specimen prepared from acetyl-*o*-xenylamine.[10]

Anal. Calcd. for $C_{14}H_{11}N$: C, 87.00; H, 5.74; N, 7.28. Found: C, 86.93; H, 5.76; N, 7.13.

The picrate was prepared and crystallized from a solution of nitrobenzene and alcohol as yellow prisms; m. p. 250° (dec.).[25]

Conversion of 9-(α-Naphthyl)-9-fluorylazide to 9-(α-Naphthyl)-phenanthridine

9-(α-Naphthyl)-9-fluorylhydrazine.—Much trouble was met in attempting to prepare this type of compound. In preliminary experiments it was apparent that 9-phenyl-9-fluorylhydrazine has less favorable properties than the 9-(α-naphthyl) analog and the investigation was therefore directed toward the preparation of the latter. Owing to the unstable nature of the free base, which we were unsuccessful in preparing, the work was limited to the preparation and purification of the hydrochloride. Of the numerous experiments carried out the following directions for preparing and purifying the hydrochloride gave the best results; even in this case the salt was not quite analytically pure.

To a cooled, vigorously agitated mixture of 7 cc. of 100% hydrazine hydrate (a large excess in order to minimize the formation of the hydrazo compound) and 75 cc. of acetonitrile was gradually added, over a period of several hours, 13 g. of 9-(α-naphthyl)-9-chlorofluorene. Considerable heat was generated and after standing overnight in the ice chest the two liquid layers of the reaction mixture were separated. The solvent was removed from the upper one by distillation at room temperature under diminished pressure. The resulting residue after triturating with water was practically colorless and had an amorphous appearance; m. p. 98° with dec. and previous sintering. Conversion to the hydrochloride was effected in the manner described by Wieland[26]; yield 10 g. Repeated recrystallizations from solutions of toluene and chloroform and from solutions of alcohol and ether gave colorless prisms melting at 217° (dec.).

Anal. Calcd. for $C_{23}H_{18}N_2 \cdot HCl$: C, 76.96; H, 5.34; HCl, 10.17. Found: C, 76.02; H, 5.93; HCl (by titration), 9.43.

9-(α-Naphthyl)-9-fluorylazide was prepared in the usual manner by treating a slightly acidified aqueous alcoholic solution of the above hydrazine hydrochloride with an aqueous solution of sodium nitrite. The azide separated and was recrystallized from hexane and from 75% alcohol. It crystallized as long needles. The product was desolvated by heating in the molten state under diminished pressure; even under these conditions the process was an extremely slow one; m. p. 133°.

Anal. Calcd. for $C_{23}H_{15}N_3$: C, 82.85; H, 4.54; N, 12.65. Found: C, 82.89; H, 4.72; N, 12.23.

9-(α-Naphthyl)-phenanthridine.—The azide (0.2 g.) was decomposed by heating at 194° for ten minutes. The reaction product was extracted with boiling dilute hydrochloric acid. Upon cooling the acidic extract deposited 0.15 g. of an almost colorless hydrochloride. This was recrystallized from water and after drying at 100° melted at 224° (dec.). The free base was prepared from the hydrochloride and crystallized from hexane; m. p. 124°. The melting point of a mixture of this material with 9-(α-naphthyl)-phenanthridine prepared in a previous section was not depressed.

Summary

The Stieglitz rearrangement has been utilized

---

[24] In this connection it is pertinent to call attention to solubility of 9-methyl-9-fluorylamine hydrochloride in chloroform, as compared to the insolubility of the supposed 9-fluorylmethylamine hydrochloride.

[25] Pictet and Hubert, *Ber.*, **29**, 1182 (1896), reported it to decompose at 233°.

[26] Wieland, *Ber.*, **42**, 3025 (1909).

to develop a new and practical method for the preparation of nitrogen ring compounds of the phenanthridine type. 9-Methyl-, 9-phenyl- and 9-(α-naphthyl)-9-fluorylchloroamine have been converted to 9-methyl-, 9-phenyl- and 9-(α-naphthyl)-phenanthridine. That this method is not restricted to the halogenoamines is indicated by the thermal conversion of 9-(α-naphthyl)-9-fluorylazide to 9-(α-naphthyl)-phenanthridine. The primary factor in directing the course of the rearrangement of the intermediate free radical seems to be the highly strained condition of the five-membered ring in biphenylenemethylene, rather than the electronegativities of the radicals attached to the tertiary carbon atom.

The Adjacent Charge Rule and the Structure of Methyl Azide, Methyl Nitrate, and Fluorine Nitrate

BY LINUS PAULING AND L. O. BROCKWAY

With the recognition of the fact that in many cases the normal state of a molecule cannot be represented satisfactorily by a single valence-bond structure of the Lewis type but can be approximated by a combination of several such structures (among which it is said to resonate) there arose the problem of determining for each resonating molecule the magnitudes of the contributions of various reasonable structures. Information regarding these magnitudes is being obtained in many ways, such as from the interpretation of experimental values of interatomic distances, force constants, electric dipole moments, etc., and some progress is being made in the formulation of empirical rules expressing this information in a succinct form. Four years ago it was pointed out[1] that the observed moment of inertia of nitrous oxide corresponds to resonance between the structures $:\overset{-}{\ddot{N}}=\overset{+}{N}=\ddot{O}:$ and $:N\equiv\overset{+}{N}-\overset{-}{\ddot{O}}:$, the third reasonable structure, $:\overset{=}{\ddot{N}}-\overset{+}{N}\equiv\overset{+}{O}:$, making no appreciable contribution, whereas the closely similar molecule carbon dioxide resonates among all three analogous structures; and in explanation of this unexpected fact the suggestion was advanced that, in general, structures in which adjacent atoms have electrical charges of the same sign are much less important than other structures, the diminution in importance resulting from the increase in coulomb energy corresponding to the adjacent charges. This *adjacent charge rule* was reported also to apply to the methyl azide molecule.[2] We have now reinvestigated methyl azide by electron diffraction and have similarly studied methyl nitrate and fluorine nitrate. The configurations found for all of these substances are those predicted on the basis of the rule.

Methyl Azide.—In our earlier investigation of methyl azide[2] it was concluded that the molecules contain a linear azide group with dimensions corresponding to resonance between the structures  $H_3C-\ddot{N}=\overset{+}{N}=\overset{-}{\ddot{N}}:$ and  $H_3C-\overset{-}{\underset{..}{\ddot{N}}}-\overset{+}{N}\equiv\ddot{N}:$. The photographs used in this work were very light, showing only one measurable apparent maximum and one minimum. With improved technique we have now obtained photographs of methyl azide showing five well-defined apparent maxima, the interpretation of which has led to the verification and refinement of the earlier results. The

sample of methyl azide used was part of that prepared for the first investigation by Dr. G. W. Wheland. The photographs were taken with a film distance of about 10 cm. and electron wave lengths of about 0.06 Å.

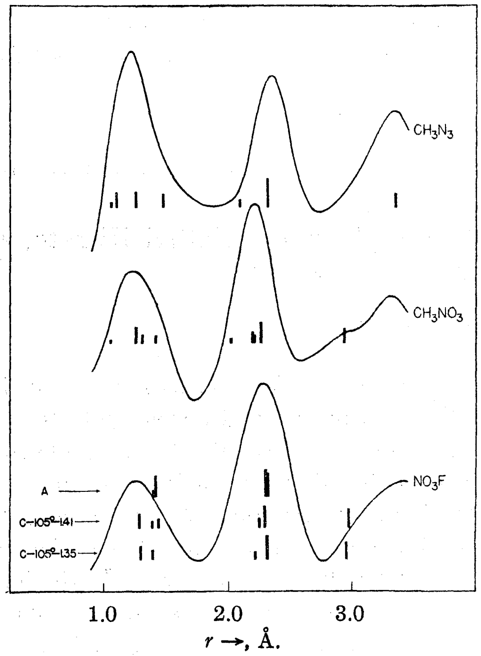

Fig. 1.—Radial distribution curves for methyl azide, methyl nitrate, and fluorine nitrate.

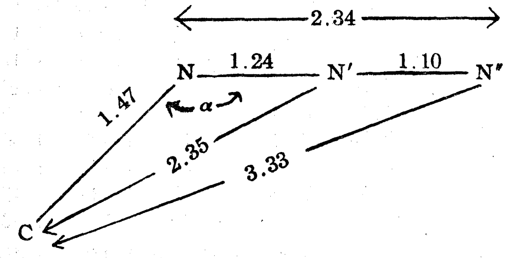
The measured *s* values and estimated intensities, averaged for sixteen photographs, given in Table I lead to the radial distribution curve shown in Fig. 1, with principal peaks at 1.22, 2.34, and 3.33 Å. These correspond closely with C–N = 1.47 Å. (the sum of the single-bond covalent radii), N–N = 1.24 and 1.10 Å., and the C–N–N angle = 120°, the peak at 1.22 Å. representing the unresolved distances 1.10, 1.24, and 1.47 Å. This correspondence was verified in the usual way by the comparison of the photographs with calculated intensity curves. In Fig. 2 there are shown curves for models containing a linear azide group,[3] defined by the following values of the distances N–N′ and N′–N″, respectively: E, 1.10, 1.10; F, 1.26, 1.26; G, 1.26, 1.16; H, 1.26, 1.10; I, 1.22, 1.10; the angle α having the value 180° for E and 125° for F and G, and the values shown for H and I. The C–N distance was assumed to be 1.47 Å., the C–H distances 1.06 Å., and the carbon angles were assumed to be tetrahedral. All interactions were considered, with one orientation of the methyl group.



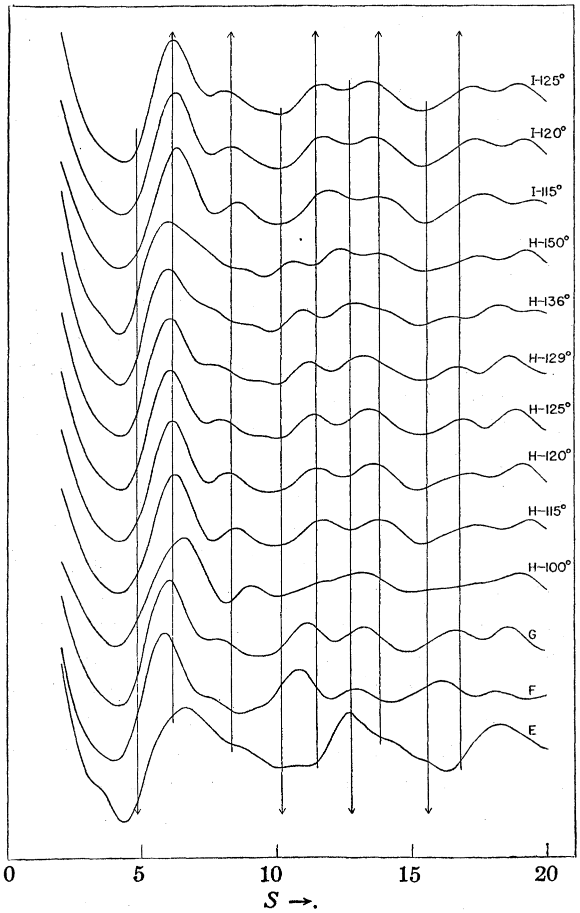


Fig. 2.—Theoretical intensity curves for methyl azide.

It is seen that all of the curves show pronounced disagreement with the photographs except H-120° and I-120° and their immediate neighbors. For these curves the qualitative and quantitative comparisons are satisfactory. The agreement for the second, third, and fourth peaks is somewhat better for the 120° curves than for the 115 or 125° curves, and we accept for the nitrogen bond angle the value 120 ± 5°, which is at the lower edge of the range of values 135 ± 15°

---

(3) The new photographs, like the old ones, are incompatible with a cyclic configuration.

previously reported. The quantitative comparison (Table I) leads to the interatomic distances C–N = 1.47 ± 0.02 Å., N–N′ = 1.24 ± 0.02 Å., and N′–N″ = 1.10 ± 0.02 Å. This final configuration of the model is identical with that indicated by the radial distribution curve.

These results are in good accord with the assumption that the molecule resonates between the two electronic structures  and , the N–N′ distance having essentially the double-bond value and the N′–N″ distance the triple-bond value.[4] The value 120° for the nitrogen bond angle, intermediate between those expected for a single and a double bond (125° 16′) and for two single bonds (109° 28′), is also not unreasonable.

Methyl Nitrate.—Methyl nitrate was prepared from methyl alcohol, nitric acid, and urea nitrate by Mr. Willard McRary under the direction of Professor H. J. Lucas. The product was washed repeatedly with water and dried, and then was redistilled three times.

The photographs show six well-defined and nearly uniformly separated rings, with *s* values and estimated intensities as given in Table II.

TABLE II

METHYL NITRATE

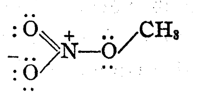
	6		16.21	16.50	1.018
6		1	17.71	17.68	.998
				Average	0.997

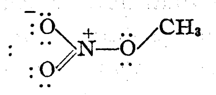
Results (model II–105°): N–O = 1.26, 1.26, 1.36 Å.
O–C = 1.43 Å.
Angle N–O–C = 105 ± 5°

The six-term radial distribution function (Fig. 1) has a broad peak at about 1.24 Å., a sharper peak at 2.21 Å., and another at 3.32 Å. These are compatible with the models discussed below, but provide no basis for choice among them.

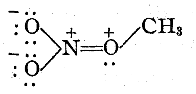
The number of parameters determining the structure of the molecule is so great that it was not possible to carry out a thorough investigation involving their independent variation. We have accordingly contented ourselves with the attempt to decide between the two most reasonable structures. The first, representing resonance among the three structures A, B, and C, leads to the predicted dimensions shown below, all three N–O bonds having approximately the double bond distance. The methyl group is restricted to the plane of the nitrate group by the double-bond character of the N–OCH$_3$ bond. For α a value of about 120 or 125° would be expected; curves calculated for 120, 125, and 130° are shown in Fig. 3. The second reasonable structure, representing resonance between A and B only, corresponds to essentially the double-bond distance for two of the N–O bonds and the single-bond distance for the third. Steric effects probably tend to keep the methyl group out of the plane of the nitrate group. The curves of Fig. 3 are calculated on this assumption; we have found that they are changed only slightly by the assumption of free rotation of the OCH$_3$ group about the N–O bond. For α a value close to the tetrahedral value 109° 28′ is expected; curves for α = 100, 105, 110, and 115° are shown.



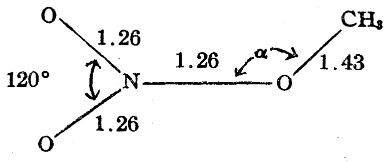
A



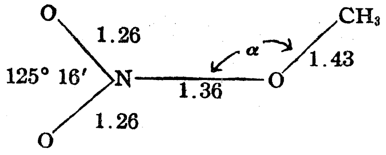
B



C



I



II

All of the curves show rough agreement with the photographs; the curves for model I are,

---

[4] L. Pauling, L. O. Brockway and J. Y. Beach, THIS JOURNAL, **57**, 2705 (1935).

however, all inferior to curve II–105° in regard to the observation of six well-shaped and nearly uniformly spaced rings. Curve II–105° is in nearly complete agreement with the experimental data, the greatest quantitative discrepancy, 3%, being shown by the fourth maximum (see Table II). We accordingly accept model II with α = 105° as supported by the electron diffraction data. The quantitative comparison verifies the interatomic distance values N–O = 1.36 Å. (for the oxygen atom with methyl attached), N–O = 1.26 Å. (for the other oxygen atoms), and O–C = 1.43 Å. to about ± 0.05 Å., the N–O–C bond angle being given the value 105 ± 5°. This configuration is compatible with the radial distribution curve (Fig. 1).

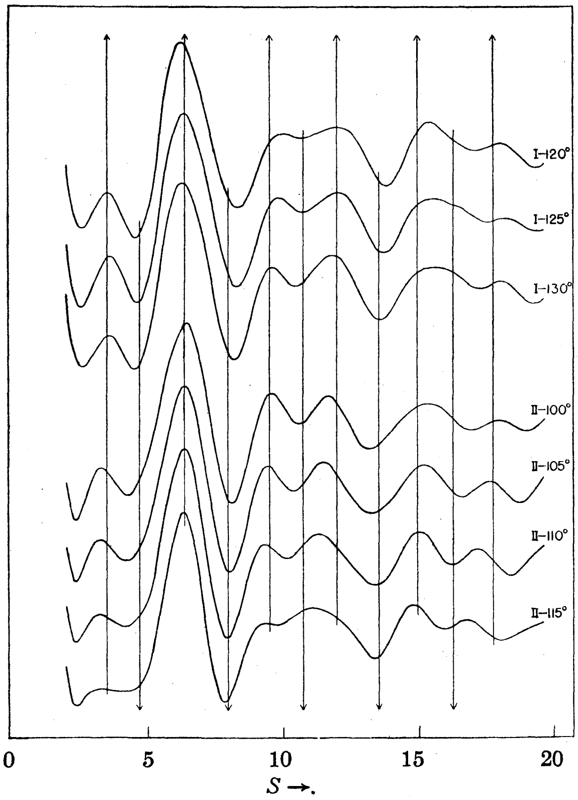


Fig. 3.—Intensity curves for methyl nitrate.

Fluorine Nitrate.—Fluorine nitrate, NO_3F, was first prepared by G. H. Cady[5] in 1934 by bubbling fluorine through dilute nitric acid. At the suggestion of Professor W. A. Noyes, we undertook the electron diffraction investigation of the vapor in order to determine where the fluorine atom is attached and what effect it has on the nature of the bonds in the NO_3 group. Professor D. M. Yost and Mr. A. Beerbower of these Laboratories[6] prepared samples of fluorine nitrate by Cady's method (using the original apparatus of Dr. Cady), and also by another method, consisting in passing fluorine over solid potassium nitrate, and kindly provided us with some of the substance for the electron diffraction work. The vapor of the substance at about 300 mm. pressure was held in a one-liter glass flask connected to the electron diffraction apparatus through an ordinary stopcock. The photographs obtained from the first sample showed four rings. An attempt to prepare heavier photographs from another sample was made unsuccessful by the explosion of the substance at the instant of making the first exposure. It was previously thought that fluorine nitrate gas was stable at room temperature, and the cause of the explosion is still unknown.

The s values and the visually estimated intensities for the four rings observed in the photographs are given in Table IV. The radial distribution function (Fig. 1) shows maxima at 1.27 and 2.29 Å., the second being about twice as large as the first.

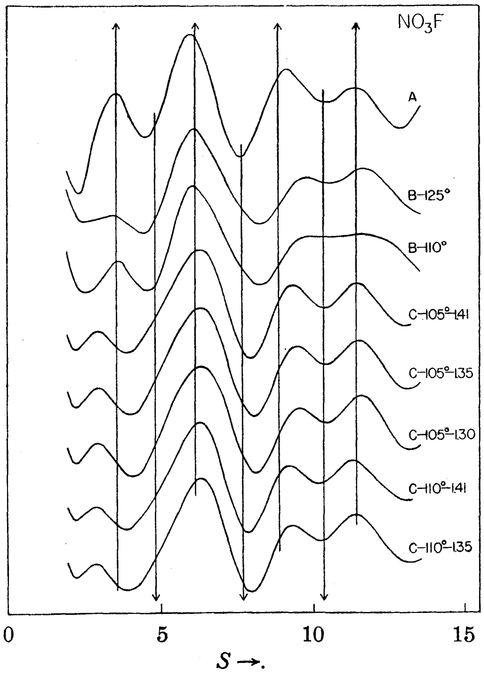

Fig. 4.—Intensity curves for fluorine nitrate.

The molecular models upon which the theoretical intensity curves of Fig. 4 are based have been chosen to distinguish between the three most probable configurations of fluorine nitrate. The

---

[5] G. H. Cady, THIS JOURNAL, **56**, 2635 (1934).

[6] D. M. Yost and A. Beerbower, *ibid.*, **57**, 781 (1935).

first, suggested to us by Professor W. A. Noyes, involves a tetrahedral arrangement of the fluorine and oxygen atoms around the nitrogen atom, in which the bond angles are all 109° 28′ and the ratio of the N–F to the N–O distances is 0.985; the corresponding curve is marked A. The other two models are similar to those considered above for methyl nitrate. In the second (B) the double bond in the NO_3 groups is assumed to resonate equally among the three N–O bonds and the fluorine atom lies in the plane of the other atoms, with the interatomic distances as shown in Table III. In the third (C) the resonance of the double bond does not involve the oxygen atom to which the fluorine is attached (O′) but is restricted to the other two positions; with this structure the molecule is no longer coplanar but instead the NO′F plane is perpendicular to the NO_3 plane.

TABLE III

MODELS FOR NO_3F

Model	NO	NF	NO′	O′F	<ONO	<NO′F
A	1.40	1.38			109° 28′	
B–125°	1.26		1.26	1.34	120°	125°
B–110°	1.26		1.26	1.34	120°	110°
C–105°–1.41	1.26		1.36	1.41	125°	105°
C–105°–1.35	1.26		1.36	1.35	125°	105°
C–105°–1.30	1.26		1.36	1.30	125°	105°
C–110°–1.41	1.26		1.36	1.41	125°	110°
C–110°–1.35	1.26		1.36	1.35	125°	110°

The models for complete resonance, B, are eliminated because in the corresponding curves the third and fourth maxima are not well resolved from each other, as they are in the photographs. The remaining six curves are more satisfactory in this respect, the relative heights of the third and fourth maxima showing better agreement with the photographs for the curves A, C–105°–1.41, and C–105°–1.35 than for the other three.

TABLE IV

					N–O	1.286 Å.	1.296 Å.
					N–O′	1.389	1.400
					O–F	1.440	1.390

Model A cannot be eliminated definitely by the photographs; there are, however, some points which make this model improbable. From the curve for this model the first minimum would be expected to be at least as well pronounced as the second minimum, whereas on the photographs the first minimum is not very well defined. That the qualitative appearance of the photographs supports model C rather than model A is further shown by the fact that the photographs resemble those of methyl nitrate more closely than those of carbon tetrafluoride. Some evidence is also provided by the radial distribution curve (Fig. 1), the first peak being displaced by 0.15 Å. from the position expected for it for model A. For these reasons and the additional reason that it is difficult to correlate the tetrahedral configuration with an electronic structure involving only completed octets, we consider model A not to be satisfactory.[7]

The curves C–105°–1.41 and C–105°–1.35 are in reasonably good qualitative and quantitative agreement with the photographs, the discrepancies shown by the first maximum and second minimum being no larger than usual for inner rings. The quantitative comparison (Table IV) leads to the average interatomic distances N–O = 1.29 Å., N–O′ (with fluorine attached) = 1.39 Å., and O′–F = 1.42 Å., with probable errors of about ± 0.05 Å. The bond angles are O–N–O = 125 ± 5° and N–O′–F = 105 ± 5°. This configuration is compatible with the radial distribution curve (Fig. 1).

The Adjacent Charge Rule.—There are thus now known four substances (nitrous oxide, methyl azide, methyl nitrate, and fluorine nitrate) with configurations supporting the adjacent charge rule. That this rule is reasonable can be seen from the following argument. In general a valence-bond structure involving two charged atoms with opposite signs may correspond to about the same energy value as a structure involving uncharged atoms, the difference between the ionization energy of one atom and the electron affinity of the other being approximately compensated by the coulomb energy of the charges. For example, the coulomb interaction of the charges + *e* and − *e* 2.30 Å. apart stabilizes the structures $:\overset{-}{\underset{\cdot\cdot}{\ddot{O}}}{-}C{\equiv}O\overset{+}{:}$ and $:\overset{+}{O}{\equiv}C{-}\underset{\cdot\cdot}{\ddot{O}}\overset{-}{:}$ for carbon dioxide by 6.3 e. v., which

---

[7] Quantitative comparison for this model leads to the interatomic distances N–O = 1.42 Å., N–F = 1.40 Å.

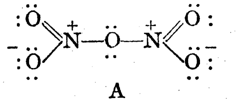
is roughly equal to the estimated energy required to remove an electron from one bound oxygen atom and attach it to another; it is accordingly not unreasonable that these two structures contribute about equally with the structure $:\ddot{O}=C=\ddot{O}:$ to the normal state of the molecule. For nitrous oxide the two structures $\bar{:}\ddot{N}=\overset{+}{N}=\ddot{O}:$ and $:N\equiv\overset{+}{N}-\ddot{O}\bar{:}$ have nearly equal covalent bond energies and coulomb energies and would be expected to make about equal contributions. The structure $\bar{:}\ddot{N}-\overset{+}{\underset{\cdot\cdot}{N}}\equiv\overset{+}{O}:$, however, with adjacent positive charges adding a large positive quantity to the energy of the molecule, corresponds to a higher energy value than the other two structures, and accordingly makes no significant contribution to the normal state of the molecule.

The principal application of the adjacent charge rule is to the compounds of nitrogen. In many compounds a nitrogen atom forms four covalent bonds and has a positive charge; the adjacent charge rule then prevents resonance to structures in which an atom attached to this nitrogen atom also has a positive charge. The covalent azides and nitrates are the principal substances of this type. It is interesting to note that the adjacent charge rule provides an explanation of the large differences in stability shown by covalent and ionic azides and nitrates. Covalent azides and nitrates are restricted by the rule to resonance between two important structures, whereas the ions resonate among three structures. The resonance energy[8] for two structures is about 1 e. v. and for three structures about 2 e. v.; hence ionic azides and nitrates are more stable than the covalent substances by about 25,000 cal. per mole. We accordingly understand why the alkali and alkaline earth azides[9] can be exploded only at high temperatures whereas the heavy metal azides, chlorazide, cyanuric triazide, and other covalent azides are extremely explosive. Similarly the ionic nitrates are relatively stable, whereas the covalent nitrates (methyl nitrate, nitroglycerine, etc.) are exploded easily. It may be pointed out that the covalent nitrates are more closely related to nitro compounds than to the nitrate ion from the resonance point of view, in that in covalent nitrates, as in nitro compounds, the double bond resonates between two oxygen molecules, whereas in the nitrate ion it resonates among three.

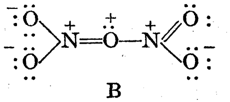
The destabilizing effect of the adjacent charge rule shown in covalent nitrates does not occur in the analogous compounds containing carbon as the central atom, such as carbonates, urea, guanidine, etc., since the quadricovalent carbon atom is neutral.

The question as to whether or not hydrazoic acid and nitric acid are more closely related to the corresponding covalent compounds than to the ions could be answered by determining the configurations of the acids. From general information we would predict that the H–N and H–O bonds are essentially covalent (with perhaps about one-third ionic character) and that the N_3 and NO_3 groups in the acids have the same structures as in methyl azide and nitrates. This prediction is supported by the instability of the acids.

The adjacent charge rule permits resonance of nitrogen pentoxide among the four structures of type A, but excludes the four structures of type B (as well as the structure with two double bonds to the central oxygen atom). We accordingly predict for the molecule a configuration in which the two interatomic distances N–O′ (O′ being the central oxygen atom) have about the single-bond value 1.36 Å. and the four distances N–O have about the double-bond value 1.26 Å., each NO_3 group being coplanar, with the angles ONO equal to about 125° and NO′N to about 110°; the relative orientation of the two NO_3 planes is uncertain, since the single N–O′ bonds permit free rotation.[10]



A



B

The symmetrical configuration  is usually assumed for nitrogen tetroxide.[11] However, the only reasonable electronic structures involving completed octets which can be written for this configuration are the four of the type  which are incompatible with

the adjacent charge rule. We accordingly believe that nitrogen tetroxide has not this configuration but instead the unsymmetrical configuration corresponding to resonance between the two structures of type .

The adjacent charge rule provides some information regarding the nature of the bonds in the oxygen acids of heavier atoms. It has become customary, following Lewis, to assign to the silicate ion and related groups structures such as , the octet rule being considered to hold for the heavier atoms as well as for the first-row atoms. The discovery of Brockway and Wall[12] that structures such as  are important for silicon tetrachloride and other halides of non-first-row atoms suggests that corresponding structures might be important for the oxygen compounds also. Strong support for this idea is provided by the observed interatomic distances in crystals, as determined by W. L. Bragg, Zachariasen, and others, which are approximately equal to the sums of double-bond radii (Table V), indicating strong resonance to structures involving double bonds.[13] Dithionic acid, $H_2S_2O_6$, and hypophosphoric acid, $H_4P_2O_6$, are stable substances, resisting oxidation even by dichromate.[14] This stability would not be expected for the completed octet structures  and , which run counter to the adjacent charge rule; the rule instead requires us to accept as the important structures for these substances those in which a sulfur atom forms two double bonds and a phosphorus atom one double bond, such as ,  etc., and ,  etc.

TABLE V

INTERATOMIC DISTANCES M–O IN IONS MO_4

	SiO_4^{4-}, Å.	PO_4^{3-}, Å.	$SO_4^{=}$ Å.	ClO_4^{-}, Å.
Observed values	1.60	1.53	1.50	1.48
Sums of single-bond radii	1.83	1.76	1.70	1.65
Sums of double-bond radii	1.65	1.58	1.53	1.48

For Cl_2O_6 structures such as , etc., are allowed by the adjacent charge rule. We consider it probable that the dissociation of this substance is due not to its instability (weakness of the Cl–Cl bond) but instead to the unusual stability of the odd molecule ClO_3 through three-electron bond formation, as in the other odd molecules NO_2, NO, ClO_2, etc. It is possible that Cl_2O_6 has an unsymmetrical configuration, $O_3Cl–O–ClO_2$, analogous to that which we have suggested for N_2O_4; however, chlorine, unlike nitrogen, has more than four orbitals in its outer shell and hence the adjacent charge rule does not eliminate the symmetrical configuration, which we consider to be the more likely one because of analogy with the dithionate and hypophosphate ions.

We wish to thank Dr. G. H. Cady for lending us his apparatus, Professor Don M. Yost and Mr. A. Beerbower for preparing the fluorine nitrate used in this work, Mr. K. S. Palmer for assisting in the preparation of the electron diffraction photographs, and Dr. Sidney Weinbaum and Mrs. M. Lassettre for assisting in their interpretation.

Summary

The investigation of methyl azide, methyl nitrate, and fluorine nitrate by electron diffraction is shown to lead to configurations of the molecules corresponding in each case to resonance between two important valence-bond structures. The unimportance of a third otherwise reasonable structure for these molecules as well as for nitrous oxide is ascribed to instability due to the presence of electric charges of the same sign on adjacent atoms. It is shown that the differ-

ences in chemical properties of covalent and ionic azides and nitrates can be correlated with differences in structure. The use of the adjacent charge rule is illustrated by its application in the discussion of the structures of nitrogen pentoxide, nitrogen tetroxide, and the oxygen acids of heavier atoms.

The Reaction between Osmium Tetroxide and Hydrobromic Acid. II. Rate Study

BY H. DARWIN KIRSCHMAN AND WILLIAM R. CROWELL[1]

In a previous article on a study of the equilibrium between osmium tetroxide, hydrogen ion and bromide ion at 100°, it was suggested that at low acid and high bromine concentrations the reaction might be of the type[2]

$$OsO_4 + H^+ + {}^5/_2Br^- \rightleftharpoons Os(OH)O_3^-Br + {}^1/_2Br_3^- \quad (1)$$

The purpose of the present work was to carry out a study of the rate of the reaction between osmium tetroxide, hydrogen ion and bromide ion with a view of learning more of its nature and to determine, if possible, the validity of certain assumptions made in the earlier investigation.

The general plan of the work consisted of the analysis for bromine of the contents of the reaction tubes at various time intervals in experiments conducted in a manner similar to that employed in the equilibrium problem. From the results obtained an attempt was made to determine the order of the reaction with respect to octavalent osmium, hydrogen ion and bromide ion.

The general form of the rate expression can be stated as

$$-\frac{d(OsO_4)}{dt} = k(Os_8)^a\ (H^+)^b\ (Br^-)^c\ \frac{(f_1)^a\ (f_2)^b\ (f_3)^c}{f_4}$$

In the present instance $k = k_0K$ where k_0 is the specific reaction rate constant and K the equilibrium constant of the intermediate complex. f_1, f_2, f_3 and f_4 are the activity coefficients of octavalent osmium, hydrogen ion, bromide ion and the intermediate complex, respectively.

In the first series of experiments, the initial concentration of all the reacting constituents was kept constant except that of the osmium, which was changed about twofold. A second series of runs was made at different concentrations of hydrobromic acid but at a fixed initial concentration of osmium. A third series of runs was made at approximately constant ionic strength and at the same initial concentration of octavalent osmium. Some of these runs were carried out at different concentrations of bromide ion but at a fixed concentration of hydrogen ion. In other runs the bromide ion concentration remained constant while the hydrogen ion concentration was changed. The purpose of the experiments at constant ionic strength was to determine the orders with respect to hydrogen and bromide ion, and to see if the sum of these orders was approximately equal to the order with respect to hydrobromic acid found in the second series of runs. Finally, using the rate data thus obtained, a series of rate constants was calculated.

Experimental

The apparatus was that employed in the equilibrium experiments.[2] The potassium hydroxide solution of osmium tetroxide was prepared as described in our previous article on the determination of octavalent osmium.[3] The hydrobromic acid was prepared from red phosphorus and bromine by the well known method. The middle fraction of the distillate was redistilled until a water white product was obtained.

The experimental procedure was essentially the same as that used in the equilibrium experiments with one modification in the case of the solutions 1.2 and 1.6 *M* in hydrobromic acid. In these solutions there was a tendency for the bromine formed to react with the reduced osmium when the tubes were broken in the chilled water in the titration beaker. To overcome this difficulty, sufficient hydrobromic acid was added to the water in the titration beaker to make the acid concentration after the addition of the contents of the reaction tube about 0.1 *N*.

Results of the Rate Experiments

Table I shows results of rate experiments at 100°. All concentrations of reduced osmium are expressed in moles per 1000 g. of water. Runs 1–7 inclusive are at different concentrations of octavalent osmium and of hydrobromic acid, while runs 8–14 inclusive are at the same osmium concentration and approximately at the same ionic strength as the hydrobromic acid run at 3.50 *M*. In order to keep the solutions at the same ionic strength for different concentrations of hydrogen ion and bromide ion, potassium bromide and potassium chloride were used in addition to the hydrobromic acid. While these salts, particularly potassium chloride, may influence the nature of the reduced osmium complexes, they should not affect markedly the initial rates.

The initial rates were obtained by plotting the data in Table I and obtaining the slopes of the curves by well-known graphical methods. The values for the individual runs are shown in column 2 of Table II. The order of the reaction n_r with respect to any reactant was calculated from the expression

$$n_r = \frac{\text{Log rate ratio}}{\text{Log activity ratio}}$$

By comparing run 4 with run 5, and run 6 with run 7, the effect of doubling the osmium concentration in a fixed concentration of hydrobromic acid was determined. The average of the two values of n_{OsO_4} was 0.98.

In runs 1, 2, 3, 4 and 6 the concentration of osmium was approximately the same while the concentration of acid was changed in steps from 1.24 to 3.50 *M*. The runs compared were 1 and 2, 1 and 3, 1 and 4, 1 and 6, 2 and 3, 2 and 4, and 2 and 6, 3 and 4, 3 and 6, and 4 and 6. To calculate the activity of the hydrobromic acid, the activity coefficients shown in Table II column 5 were used. It was assumed that the ratio of the activity coefficients of the octavalent osmium and the intermediate complex was constant. The calculated order with respect to hydrobromic acid varied from 2.5 to 1.9. For the most part the higher values were obtained when comparing the lower acid concentrations. The average of the series of ten values was 2.17.

TABLE II

INITIAL RATES AND RATE CONSTANTS

Runs	Ionic strength moles per 1000 g. H_2O	$-(OsO_4)/dt$ moles per 1000 g. H_2O per hr. × 10^3	Specific rate $k' \times 10$	$\gamma \pm$ at 100°	Rate constant $k \times 10$
1	1.24	0.84	1.30	0.88	1.7
2	1.66	2.14	1.80	.99	1.8
3	2.10	5.04	2.66	1.14	2.0
4	2.55	10.9	3.87	1.33	2.2
5	2.55	4.92	3.72	1.33	2.1
6	3.50	43.2	7.86	1.94	2.1
7	3.50	21.6	8.55	1.94	2.3
8	3.50	3.79	5.46	1.26	3.4
9	3.50	10.9	7.52	1.26	4.7
10	3.50	12.2	6.50	1.26	4.1
11	3.50	8.2	6.50	1.37	3.5
12	3.50	16.8	6.50	1.37	3.5
13	3.50	23.4	8.20	1.63	3.1
14	3.50	30.4	7.90	1.63	3.0

In runs 8 to 14, inclusive, in which the ionic strength was kept constant, the order with respect to bromide ion was calculated by comparing runs 8 and 9, 8 and 10, 11 and 12 and 13 and 14. While it is realized that the activity coefficient of hydrobromic acid in the solutions used is not exactly constant at constant ionic strength, this fact does not prevent fair estimates of the order being made. The average value of n_{Br^-} was 1.18. The order with respect to hydrogen ion was obtained by comparing runs 6 and 10, 6 and 12, 9 and 13 and 10 and 14. In this case the average value of n_{H^+} was 1.22. Although the general tendency is for the orders in both series to run somewhat above unity, this is presumably due to the fact that the activity effects are not the same in all of the solutions. It seems reasonable to suppose that the order with respect to both bromide and hydrogen ion is one, and this checks fairly well with the results obtained with hydrobromic acid solutions containing no salt. These results indicate that the assumption that the intermediate complex is neutral in character is justified.

In the light of the results described, the rate expression can take the form

$$-\frac{d(OsO_4)}{dt} = k(Os_8)(H^+)(Br^-)(\gamma\pm)^2$$

whence

$$k = -\frac{d(OsO_4)}{dt} \times \frac{1}{(Os_8)(H^+)(Br^-)(\gamma\pm)^2} = \frac{k'}{(\gamma\pm)^2}$$

where $\gamma\pm$ represents the mean ion activity coefficient of the hydrobromic acid.

Table II shows results of calculations of k' and k made in accordance with the above expressions. The activity coefficients were calculated from recent data of Harned[4] obtained from measurements made on solutions of hydrobromic acid and mixtures of hydrobromic acid and potassium bromide. In this calculation it was necessary to make a small extrapolation from 3.0 to 3.5 *M*, and also to correct the values to 100° by use of thermal data given in the "International Critical Tables."[5,6]

Attention is called to the fact that the constants for experiments 1–7 inclusive are in very fair agreement and the same is true for experiments 8–14 inclusive. The value of k for the latter group is definitely higher than that for the former group. The reason for this is not evident, but may be due to uncertainties in the values of γ_{HBr} in these solutions. It is a curious fact that the assumption that γ_{HBr} is equal for all solutions of ionic strength 3.5 *M* leads to better constancy of k for experiments 8–14 as well as to a much better agreement between the k's of both series of experiments.

Conclusions

Since the results indicate that the reaction in the rate determining step is first order with respect to octavalent osmium, hydrogen ion and bromide ion, the mechanism that is suggested for the initial stages of the reaction is as follows.

$$H_2OsO_5 + H^+ + Br^- \longrightarrow H_2OsO_4 + HBrO \qquad (2)$$
(Rate determining step)

$$HBrO + H^+ + Br^- \longrightarrow Br_2 + H_2O \qquad (3)$$
(Rapid follow reaction)

$$Br_2 + Br^- \longrightarrow Br_3^- \qquad (4)$$
(Rapid follow reaction)

$$H_2OsO_4 + {}^1/_2Br_3^- \longrightarrow HOsO_4 + H^+ + {}^3/_2Br^- \qquad (5)$$
(Rapid follow reaction)

$$HOsO_4 + Br^- \longrightarrow Os[(OH)O_3Br]^- \qquad (6)$$
(Rapid follow reaction)

The sum is (1).

The formation of hexavalent and heptavalent forms other than those shown is, of course, quite possible.

In the previous work on the equilibrium study the statement was made that the equilibrium constants indicated that the tendency was for the octavalent osmium to be reduced to the heptavalent state in solutions of low acid and high bromine concentration and that at high acid and low bromine concentration the tendency was toward reduction to the quadrivalent state. The present work seems to show that in all the solutions, 1.2 *M* as well as 3.5 *M* in hydrobromic acid with or without potassium bromide or chloride, the first step of the reaction is a reduction of OsO_4 to the hexavalent state. In solutions of low acid concentration the hexavalent osmium is oxidized to the heptavalent form by rapid follow reactions. With increasing acid concentration some of the rapid follow reactions lead more and more to a reduction to the quadrivalent form with the setting up of more or less complicated equilibria. In all the solutions in which the bromine is not confined in the reaction tubes, the net effect is a reduction to the quadrivalent form.

In conclusion we wish to express our appreciation to Dr. Don M. Yost for his valuable assistance in this work.

---

[4] Harned, This Journal, 57, 1865 (1935).

[5] "International Critical Tables," Vol. V, p. 177.

[6] It should be noted that in the equilibrium study described in a former paper[2] the application of these new values of $\gamma\pm$ will change the absolute values of the equilibrium constant quite radically. The relative values, however, will still be in sufficient accord to justify the conclusions then drawn.

Summary

The rate of the reaction between osmium tetroxide, hydrogen ion and bromide ion at 100° in acid concentrations from 1.2 to 3.5 M has been studied and the reaction in the rate determining step has been found to be of the first order with respect to each of the reacting constituents.

On the basis of this study and an earlier investigation of the equilibrium between octavalent osmium, hydrogen ion, bromide ion, reduced osmium and tribromide ion a mechanism has been suggested indicating the steps in the initial stages of the reaction. In all the acid solutions the first and rate determining step is a reduction of the osmium to the hexavalent state. In solutions of low acid and high bromine concentration, rapid follow reactions carry the osmium to the heptavalent state, but in solution of high acid and low bromine concentration the tendency is toward the quadrivalent form.

In the expression

$$k = -\frac{d(OsO_4)}{dt} \times \frac{1}{(Os_8)(H^+)(Br^-)(\gamma\pm)^2}$$

the value of k has been found to be approximately 0.28 when the time is expressed in hours.

Electrochemical Properties of Diphenylbenzidine Sulfonic Acid

BY L. A. SARVER AND I. M. KOLTHOFF

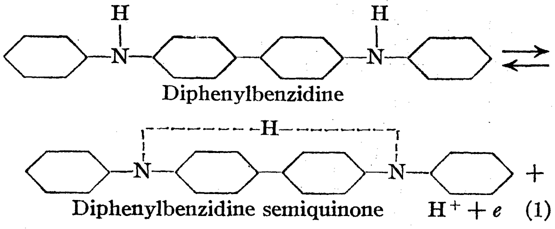
It has been mentioned in previous work[1] that upon oxidation of a substituted aromatic diamine such as diphenylbenzidine there is first formed a green insoluble intermediate product, and then a more soluble violet quinoid compound of high coloring power.

The intermediate product was assumed to be a meriquinone, or double molecular compound composed of one molecule of the diphenylbenzidine itself and one molecule of the oxidized quinoid form; but no proof has ever been presented as to the correctness of this view, and from the recent work of Michaelis[2] it was thought possible that the green substance might be a semiquinone, or compound derived from diphenylbenzidine by the transfer of one electron instead of two.

It has been proved in a number of cases by electrochemical means that the intermediate oxidation products of diamines are really semiquinones and not meriquinones, but this has never been achieved for a compound of the benzidine series because of the insolubility and instability of the oxidation products. The green product from diphenylbenzidine itself is extremely insoluble, while that from diphenylbenzidine disulfonic acid is only slightly soluble. However, a polysulfonic acid of diphenylbenzidine has been obtained recently[3] which gives a fairly soluble and stable green oxidation product, and it appeared that with this substance it might be possible to decide whether or not semiquinones are formed by compounds of the benzidine series.

Since the only function of the sulfonic acid groups is to increase the solubility of the reagent and its oxidation products, let us consider the mechanism for the oxidation of diphenylbenzidine itself. We shall call the first and second oxidation products diphenylbenzidine green and diphenylbenzidine violet, respectively.

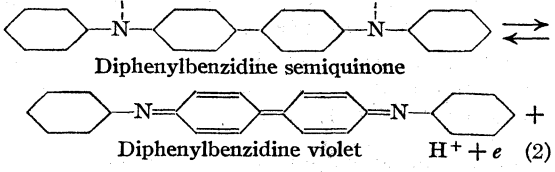
According to the semiquinone theory, the first stage of the oxidation should be:



Diphenylbenzidine

Diphenylbenzidine semiquinone H$^+$ + e (1)

where e represents an electron transferred; the second stage would then be



Diphenylbenzidine semiquinone

Diphenylbenzidine violet H$^+$ + e (2)

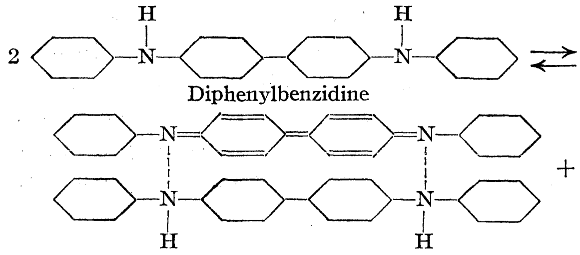
According to the meriquinone theory, on the other hand the first stage of the reaction would be

---

[1] I. M. Kolthoff and L. A. Sarver, THIS JOURNAL, **52**, 4179 (1930).

[2] See L. Michaelis, *Chem. Rev.*, **16**, 243 (1935), where references to earlier work may be found.

[3] L. A. Sarver and Wm. Von Fischer, *Ind. Eng. Chem.*, *Anal. Ed.*, **7**, 271 (1935).



Diphenylbenzidine meriquinone $2H^+ + 2e$ (3)

and the second stage would be

$$\text{Diphenylbenzidine meriquinone} \rightleftarrows 2 \text{ diphenylbenzidine violet} + 2H^+ + 2e \quad (4)$$

If the number of moles of diphenylbenzidine taken for titration is represented by a, and the number of moles oxidized at any time by x, the potentials during the first stage of the reaction should be given by

$$E = E_0 + \frac{RT}{F} \log \frac{x}{a - x}, \text{ at constant } p\text{H} \quad (5)$$

if the green compound is a semiquinone, and by

$$E = E_0 + \frac{RT}{2F} \log \frac{[\text{M. Q.}]}{[\text{D. B.}]^2}, \text{ at constant } p\text{H} \quad (6)$$

if it is meriquinone.

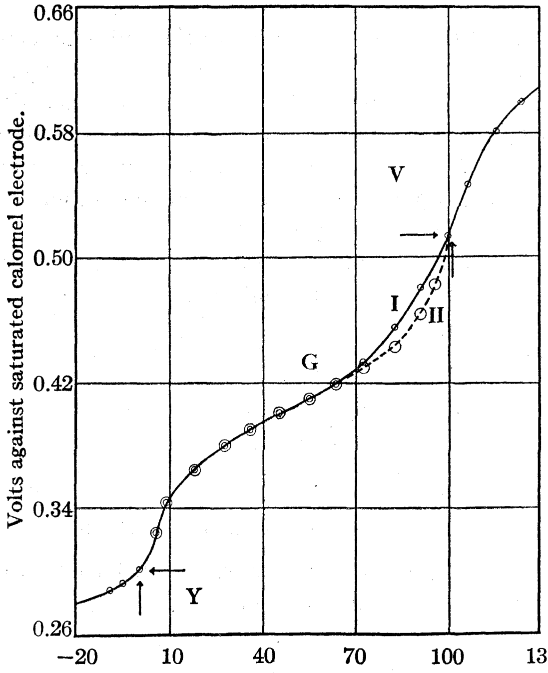


Fig. 1.—I, potentials observed; II, potentials calculated as semiquinone; $E = 0.405 + 0.06 \log([\text{D. B. semiquinone}]/[\text{D. B.}])$; V, violet; G, green; Y, yellow.

Similar equations apply to the second stage of the reaction.

By a comparison of the shapes of the experimental titration curves with those calculated on the basis of the formation of semiquinones and meriquinones, respectively, it should be possible to decide which theory is correct in this case.

Experimental

The diphenylbenzidine sulfonic acid used was prepared and purified by the method of Sarver and von Fischer,[3] and a microscopical examination revealed no appreciable amount of sodium sulfate to be present. Upon ignition, an amount of sodium sulfate corresponding to 52.7% of the sample was obtained; a compound with ten sulfonic acid groups should give 52.1%. Stock solutions in water were prepared which contained 1 g. of the yellow sodium salt per liter, and suitable quantities of sulfuric acid were added in each experiment just before titration.

The reduction potential of ferrous iron in sulfuric acid solution was not sufficiently low to effect complete reduction of the green compound, but in the presence of fluoride the change from green to yellow, indicating complete reduction of the green, occurred at approximately 0.30 v., against the saturated calomel electrode (or at 0.55 v., against the normal hydrogen electrode), in 1.0 N sulfuric acid solution.

Attempts were made to titrate portions of the diphenylbenzidine sulfonic acid with bromine in a buffered solution at a pH of 4, but the oxidation products decomposed so rapidly that no steady potentials could be obtained. However, when the titrations were performed in 1.0 N sulfuric acid, using standard solutions of potassium dichromate and ferrous iron in the same concentrations of sulfuric acid, potentials were obtained which were subject to very little drift, at least during the first stage of the oxidation. The best results were obtained by adding a slight excess of dichromate over that theoretically required for the oxidation of all the diphenylbenzidine sulfonic acid to the corresponding green, allowing the system to come to equilibrium, then adding some hydrofluoric acid to lower the potential of the ferrous–ferric iron system, and back-titrating with standard ferrous solution.

In this way, some very good titration curves were obtained (Fig. 1), which showed distinct breaks at the disappearance of the violet and green, respectively. In a large number of experiments, 1.7 ml. of 0.01 N dichromate was used up in the first stage of the oxidation of 20 ml. of the stock indicator solution, whereas the amount of ferrous solution necessary for the back titration of the green was equivalent to only 1.1 ml., and the quantity theoretically required upon the assumption that the reagent was pure diphenylbenzidine decasulfonic acid was 1.48 ml. The volume of dichromate consumed varied somewhat in the series of experiments, but the amount of ferrous solution required for the reduction of the green remained remarkably constant. Indeed, a portion still needed 1.1 ml. of ferrous solution for back titration after standing for one month in the normal sulfuric acid solution. It would appear that part of the diphenylbenzidine sulfonic acid was oxidized in an irreversible way, but that the green intermediate product itself was very stable.

The potentials observed during a typical titration of this sort are given in Table I, in comparison with the calculated values which should be obtained according to the semiquinone and meriquinone theories, respectively (see also

Fig. 1). In each experiment, 20 ml. of the 0.1% water solution of diphenylbenzidine sulfonic acid was treated with 50 ml. of 1.5 *N* sulfuric acid and 2.0 ml. of 0.01 *N* potassium dichromate in 1.0 *N* sulfuric acid. The potential of the mixture rose gradually during the establishment of equilibrium over a period of twenty to thirty minutes, at the end of which time 5.0 ml. of C. P. 48% hydrofluoric acid was added, and the back titration begun with 0.01 *N* ferrous solution in 1.0 *N* sulfuric acid. Thus the sulfuric acid concentration was approximately 1.0 *N* and constant throughout the titration. The system was allowed to come to equilibrium after the addition of each drop of reducing solution, the whole experiment requiring several hours.

It will be seen from an examination of the data in Table I that the experimental values agree quite well with those calculated on the assumption that the green compound is a semiquinone; they disagree with those calculated for a meriquinone. In the upper part of the curves, the observed values are higher than the calculated ones for a semiquinone, which is what we would expect if there were some overlapping of the first and second stages of the oxidation. Hence, the evidence points quite definitely to the existence of a semiquinone as an intermediate product in the oxidation of benzidine derivatives, rather than to a meriquinone.

TABLE I

(1.47×10^{-5} mole of diphenylbenzidine sulfonic acid in 70 ml. of 1.0 *N* sulfuric acid, and 2 ml. of 0.01 *N* $K_2Cr_2O_7$ in 1.0 *N* sulfuric acid; 5 ml. of 48% C. P. hydrofluoric acid added after thirty minutes, and back titration begun with 0.01 *N* ferrous solution in 1.0 *N* sulfuric acid; potentials referred to satd. calomel electrode.)

$E_{\text{S.Q.}} = 0.405 + 0.06 \log (X/(100 - X))$, where X equals percentage of D. B. oxidized. $E_{\text{M.Q.}} = 0.294 + 0.03 \log [\text{M. Q.}]/[\text{D. B.}]^2$.

As regards the second stage of the oxidation (from green to violet), the experimental results were much less satisfactory. First, the oxidation potential of the potassium dichromate was not high enough to ensure complete conversion of the green intermediate product to the violet holoquinoid form, and, second, more energetic oxidizing agents caused a marked decomposition of the latter, accompanied by drifting potentials. The result was that the quantity of the violet form found varied from experiment to experiment, and only rarely approximated to that consistently found for the green. However, even though the experimental conditions were so unfavorable, the observed potentials always lay closer to the values calculated on the basis of the semiquinone theory than to those required by the semiquinone theory.

Summary

Diphenylbenzidine decasulfonic acid has been oxidized to the corresponding green and violet forms, and the subsequent reduction studied electrometrically. The green form was very stable, the violet considerably less so, and both were reasonably soluble in water and dilute acid solutions. The form of the titration curves indicated that the green intermediate product was a semiquinone, not a meriquinone.

The Apparent Volumes and Thermal Expansions of Certain Salts in Aqueous Solution between 20 and 40°[1]

BY R. E. GIBSON AND JOHN F. KINCAID

In the course of a study of the correlation of the compressions with other thermodynamic properties of solutions we found it necessary to obtain reliable values of the thermal expansions. For a few aqueous salt solutions these quantities could be computed from measurements already published but the general result of a careful survey was the discovery of an almost complete absence of reliable systematic data. Interest in thermal expansions is enhanced by the researches of Gucker,[2] who found that when the apparent molal expansibilities of electrolytes in aqueous solutions are plotted against the square root of the volume concentration straight lines are obtained, but that the slopes of these lines depend markedly on the individual characters of the salts and are negative instead of positive as an extrapolation of the interionic attraction theory would require. It seemed desirable, therefore, to determine some expansions

---

of solutions experimentally so that data on a fair number of typical salts might be available. Accordingly we shall present and discuss in this article the thermal expansions between 20 and 40° of aqueous solutions of barium chloride, potassium bromide, sodium iodide, potassium nitrate and lithium bromide, together with the specific volumes of solutions of the three last-named salts.

Experimental.—Two pycnometers were used in the determination of the specific volumes of the solutions at 25°. They were both of the same design, one being the pycnometer which has been in use in the Geophysical Laboratory for over fifteen years[3] and the other a copy recently made. The volume of the first pycnometer has remained the same, 55.0368 ml. at 25°, for many years; the volume of the second was determined at intervals during the work by weighing its water content. In all, six measurements were made, the mean value being 52.5994 ml. with an average departure from the mean of 2×10^{-4} ml. The thermostats were held at 25.00 ± 0.01°, the temperature being measured with the 10 junction copper–constantan thermoelement already described[4] and a Wolff potentiometer.

The expansions were measured with a dilatometer which, together with the technique, has already been described.[4] The volume of the dilatometer at 25° was redetermined and found to be 47.52 ml. and the capillary was very completely calibrated with weighed threads of mercury. The temperature of the dilatometer thermostat was measured on the Wolff potentiometer with a 5-junction copper-constantan thermoelement, calibrated at the inversion point of sodium sulfate decahydrate (32.384°, 6463 microvolts). The departure from Adams' table[5] at this point was 1.5 microvolts. Temperatures were therefore converted from microvolts to degrees with the aid of this table and a deviation curve. From the change in height of the meniscus of the liquid in the dilatometer capillary, a knowledge of the stem temperature, the expansion of the glass, the cross section of the capillary, the volume of the dilatometer, and the specific volume of the solution, it was possible to compute directly $\Delta_T v$, the change in specific volume of the solution for any finite change of temperature. Readings were taken at even intervals of 2.5°.

Materials.—Each solution was made up separately from weighed amounts of anhydrous salt and distilled water. *Potassium bromide, potassium nitrate, sodium iodide* and *barium chloride* were all obtained from the J. T. Baker C. P. analyzed preparations. *Potassium bromide* and *nitrate* were recrystallized in the ordinary way from water and dried in an oven for several days. Three solutions of approximately 10% were made up with the commercial and the recrystallized potassium nitrate. When interpolation to the same concentration was made, the densities of these solutions departed on an average 0.2×10^{-5} from the mean value. *Sodium iodide* was crystallized from water at a temperature above the decomposition point of the dihydrate, from absolute methanol solution, and was also used without recrystallization. In all cases the solid was powdered and heated for several days around 200°. The solutions were made up and stored in an atmosphere of nitrogen. The densities of concentrated solutions were independent of the sample and it was judged that the salt as obtained commercially was sufficiently pure. *Barium chloride* dihydrate was dehydrated in an Abderhalden apparatus and also in an air oven. No decomposition of the chloride was observed. J. T. Baker C. P. analyzed lithium carbonate and hydrobromic acid were used in the preparation of *lithium bromide.* The former was washed many times with hot distilled water, dissolved in the acid and the alkaline solution was boiled down, filtered, acidified and allowed to deposit crystals of the dihydrate. These were filtered by suction and recrystallized. Two portions were recrystallized five times. The dihydrate was then dried in a vacuum desiccator over phosphorus pentoxide where it was converted to a mixture of the monohydrate and the anhydrous salt. It is of interest to note that, whereas lithium bromide dihydrate loses water at an exceedingly slow rate, if at all, when placed *in vacuo* over "Anhydrone," it loses water rapidly under the same conditions over phosphorus pentoxide. The final dehydration was carried out in the flasks in which the actual solutions were made up. The salt was heated to constant weight in a high vacuum at 100–120° with phosphorus pentoxide absorbing the evolved water. Anhydrous lithium bromide and lithium bromide dihydrate are both extremely hygroscopic.

Two solutions of approximately 10% lithium

bromide and two of approximately 40% lithium bromide were made from entirely different samples and their specific volumes compared. They were consistent to 1 × 10^{-5} and we feel that the purity of the solid lithium bromide justifies specific volumes given to five decimal places.

The experimental results are recorded in the first two tables.[6] Table I gives the specific volumes at 25° and is self-explanatory. Table II gives the changes in specific volume resulting from a temperature change from 25.00° to the temperature indicated together with the corresponding change in apparent volume and the residuals which indicate the consistency of the results and the fit of the equation used to represent the data.

(6) The symbols used in this paper are as follows. The subscripts 1 and 2 refer to the water and salt in solution, respectively, the subscripts w and s stand for pure water and pure solid salt, respectively. The symbol Δ_T indicates the increase with temperature of the quantity to which it is prefixed. The weight fraction is represented by x, the grams per cc. by c, the moles per liter by C, the specific volume by v, the apparent volume by ϕ, the temperature in °C. by t. $\phi_T = (\mathrm{d}\phi_2/\mathrm{d}T)_P$ and M is the molecular weight. The apparent volume is defined by the relation $v = x_2\phi_2 + x_1 v_w$.

Discussion of Results

Apparent Volumes.—The apparent volumes of potassium nitrate in aqueous solutions at 25° are expressible within experimental error over the whole concentration range as a linear function of the square root of the volume concentration, equation (1).

$$\phi_2 = 0.37763 + 0.07164c_2^{1/2} \qquad (1)$$

This same well-known and useful form of equation also represents the apparent volumes of sodium iodide very well in solutions up to 40% but then fails badly. We found that a linear function of the square root of the geometric mean of the weight fraction and the weight ratio, that is, $x_2^{1/2}/x_1^{1/4}$, equation (2), fitted the data over the whole range of concentration much better than the ordinary square root of the volume concentration formula.

$$\phi_2 = 0.23407 + 0.02479x_2^{1/2}/x_1^{1/4} \qquad (2)$$

$$\phi_2 = .37745 + .07242x_2^{1/2}/x_1^{1/4} \qquad (3)$$

Only the point at 60% NaI shows any large departure from the straight line. It should be mentioned that our values of the specific volumes of sodium iodide solutions are the results of two entirely independent measurements made with different samples of salt in different laboratories. The results for potassium nitrate were also well fitted by equation (3), but for certain other salts formulas of the type of equation (2) were not as good as those of the type of equation (1). It must be admitted that no theoretical basis is known as yet for the remarkable way in which the apparent volumes in concentrated solutions are represented by linear functions of the square root of some quantity expressing the concentration, but the practical value of such functions in the handling and checking of data is enormous. The choice of a concentration variable depends on the particular case and is at present justified only by the length of the concentration range over which the linear function fits the data. We have now examples in which each of the variables, x_2, c_2 and $x_2/x_1^{1/2}$, in turn is to be preferred to the other two.

Baxter and Wallace[7] and Geffcken[8] have determined the specific volumes of solutions of sodium iodide at 25°. Our results are in fair agreement with theirs and slightly more consistent.

As has been shown already,[9–11] the square root law breaks down completely for lithium bromide solutions, the apparent volumes passing through a maximum, and our results indicate (see Fig. 1) that even in moderately dilute solutions (5–20%) ϕ_2 does not vary linearly with $c_2^{1/2}$. Special attention was paid to these solutions because of the numerous breaks on the apparent volume–concentration curves at 35° and 200 bars reported by Scott and his associates[10,11] and on similar curves for data at 20° described by Hüttig and Kükenthal.[12] We determined a large number of specific volumes at 25°. The apparent volumes computed from these results varied quite smoothly with the concentration, and when the expansion data were applied we found that the apparent volumes at 35° behaved likewise. These curves are given in Fig. 1. On the same diagram we have plotted the apparent volumes at 35° recalculated from Scott's density data.[10,11] It will be seen that the two sets of results agree quite well in the more concentrated region except for three points which hardly seem consistent with Scott's own data. The conclusion is therefore drawn that the apparent volumes at atmospheric pressure may be represented as a smooth curve when plotted against the concentration and that the assumption of a series of breaks is not necessary. At lower concentrations our results differ markedly from Scott's. We cannot explain this, but we note that in this region our volumes at 25° agree with those of Baxter and Wallace[7] and that the error in thermal expansion from 25 to 35° would have to be of the order of 100% to account for the difference between our values and Scott's. We have also used the expansions to obtain apparent volumes of lithium bromide at 20° and compared these with the apparent volumes computed from Hüttig and Kükenthal's work. The discrepancy is enormous, the curves run parallel but are displaced by an amount which cannot be explained by minor errors in temperature or calibration of weights. As there is certainly not an error of several hundred per cent. in our expansion data we can say that Hüttig and Kükenthal's work disagrees with that of Scott, Baxter and Wallace, and ourselves. Hüttig and Keller[13] published densities of lithium bromide solutions also at 20°. The apparent volumes at 20° calculated from these results lie close to our values for the apparent volumes at 35°.

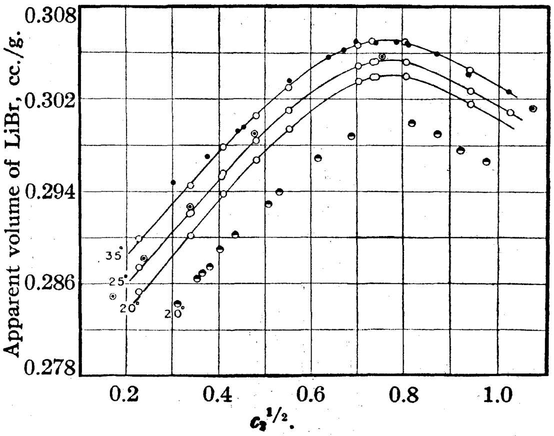

Fig. 1.—The apparent volumes of lithium bromide at different temperatures as functions of the square root of the concentration in grams of lithium bromide per cc. of solution. The results given in this paper are compared with values computed from the work already published. ●, Scott; ◉, Baxter and Wallace; ○, Gibson and Kincaid; ◓, Hüttig and Kükenthal.

Apparent Expansions and Expansibilities.—The apparent expansion $\Delta_T\phi_2$ is the finite change in the apparent volume of the salt corresponding to a finite change in temperature. By the method of least squares quadratic equations of the form

$$\Delta_T\phi_2 = A + B(t - 30) + C(t - 30)^2$$

were fitted to the expansion data for each solution. The values of A, B and C are given in Table III and the fit of the equations may be judged from the residuals in the last column of Table II. When these equations are differentiated, the temperature coefficient of ϕ_2, *viz.*, ϕ_T, is obtainable at any temperature between 20 and 40°. It may be noted that $M_2\phi_T$ is the same as Gucker's[2] (pp. 1018–19) $\Phi(E_2)$. In Fig. 2 we have plotted $M_2\phi_T$ at 25 and at 35° against $C_2^{1/2}$ for the different solutions. The curves for potas-

sium nitrate and potassium bromide at 25° are straight lines confirming Gucker's observations, but the curves for these salts at 35° and for the other three salts both at 25 and 35° are distinctly not linear, running in such a way that one may expect a maximum somewhere between the lowest concentration we investigated and the origin. The general shape of these curves is sigmoid, and an examination of Figs. 2 and 3 in Gucker's paper shows that the same is true of the data he examined. It seems probable that in all cases the initial slopes of the apparent expansion–concentration curves are positive in very dilute solution but that they quickly pass through zero and become negative. At higher concentrations the curves have regions of inflection which may be so drawn out that for all practical purposes the curves may be regarded as linear.

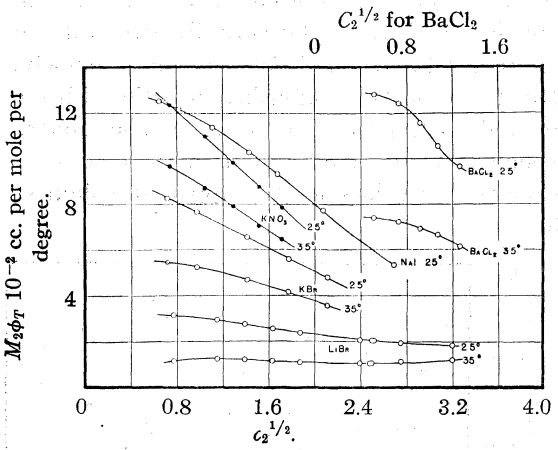

Fig. 2.—The apparent molal expansibilities of salts in aqueous solution at 25 and 35° as functions of the square root of the concentration expressed in moles per liter.

54.980	98.4	17.89	− .358

Although the curve of $M_2\phi_T$ at 25° against $C_2^{1/2}$ is not linear for lithium bromide in aqueous solutions there seems to be no indication of any breaks.

Summary

We have measured the thermal expansions from 20 to 40° of aqueous solutions of barium chloride, potassium bromide, potassium nitrate, sodium iodide and lithium bromide over the entire range of concentration and also the specific volumes at 25° of the solutions of the three last-named salts. From these results apparent volumes, apparent expansions and apparent expansibilities were computed and where possible expressed analytically by simple formulas as functions of temperature and concentration. We have suggested a new concentration variable which sometimes replaces c_2 to advantage in the square root formulas. It seems from our results that the linear relation between apparent expansibilities and the square root of the concentration is fortuitous and not to be expected in general, the complete curve being sigmoid. We find no evidence requiring breaks in the curves of the apparent volumes or the apparent expansions of lithium bromide against the concentration at atmospheric pressure.

The Ammonolysis of Tantalum Pentachloride

BY HENRI MOUREU AND CLEMENT H. HAMBLET[1]

In a recent note[2] the authors have given evidence that the primary product of the reaction of liquid ammonia on tantalum pentachloride was the heptammine of the trichlorodiamide whose formation was accounted for by the equation

$$TaCl_5 + 17NH_3 \longrightarrow Ta(NH_2)_2Cl_3 \cdot 7NH_3 + 2NH_4Cl \cdot 3NH_3$$

It was found that this compound, on progressive heating to 170° in a vacuum, not only was separated from the ammonium chloride formed in the initial reaction but also underwent loss of the seven molecules of ammonia held by secondary valence.

The trichlorodiamide of tantalum could thus be isolated and its properties studied. Thus, it was possible to show that on heating to 1180° in a current of dry ammonia, the mononitride of tantalum was produced

$$3Ta(NH_2)_2Cl_3 + 8NH_3 \longrightarrow 3TaN + 9NH_4Cl + N_2$$

We have since not only obtained additional data confirming these reactions but have also been able to isolate the pentanitride which is formed at an intermediate stage in this latter reaction and to investigate some previously unrecorded properties of these compounds.

Preparation of Tantalum Pentachloride.—This material was made from tantalum pentoxide by a modification of the method discovered by Demarçay[3] and subsequently used by Ruff and Schiller.[4] The oxide was of high purity, having been separated from columbium pentoxide by fractional crystallization of the potassium heptafluotantalate salt. After three sublimations in a vacuum, the practically colorless pentachloride was collected in small Pyrex tubes which were sealed off. Chlorine analysis of this product, after hydrolysis and separation of tantalum by the method of Hönigschmid and Schlee,[5] showed it to be pure tantalum pentachloride within the limits of the analytical precision. Found: 49.12, 49.31%; calcd., 49.49%.

Formation of $Ta(NH_2)_2Cl_3 \cdot 7NH_3$ by the Action of Liquid Ammonia on Tantalum Pentachloride.—When several volumes of liquid ammonia were condensed on tantalum pentachloride and the mixture allowed to warm up slowly to its boiling point at atmospheric pressure, reaction took place, the heat evolved thereby causing the ammonia to be boiled vigorously, and resulted in the practically complete dissolution of the solid to form a pale greenish-yellow solution.

Evaporation of the ammonia left a residue which was composed obviously of at least two different substances, one white and the other pale yellow, and which continued to evolve ammonia even at room temperature. From the quantity of tantalum pentachloride used and its increase in weight on being treated in this manner, it was ascertained that at 20° between ten and eleven (found: 10.12, 10.70, 10.62, 10.80, 10.34, 10.22) moles of ammonia were fixed per mole of tantalum pentachloride originally taken. It was apparent that the mixture consisted of components at least one of which was unstable.

An attempt to separate the ammonium chloride, for such was presumably the white portion of the residue, from the tantalum compound by extraction with anhydrous methanol, in an apparatus which permitted such an extraction to be carried out at room temperature, was of no avail. Most of the tantalum passed into solution under these conditions and instantly formed a precipitate as the extract was cycled back to the hot alcohol still. This behavior incidentally resembles the action of ethanol on tantalum pentachloride.[6] Extraction of the original material with liquid ammonia left only a small residue which was probably composed of unavoidable hydrolysis products.

Equilibrium Pressure–Composition Measurements.—These experiments were made with the object in view of determining the quantity of ammonium chloride formed by the initial reaction and the total quantity of ammonia fixed using a method similar to that employed by Joannis[7] in his study of the ammonia–boron chloride system. By means of liquid ammonia known quantities of tantalum pentachloride were converted to the mixture just described but instead of allowing the residue to warm up to room temperature, it was maintained at 0° by means of an ice-bath, excess ammonia having been evaporated at a pressure always greater than 1035 mm. which at 0° is the pressure of dissociation of the triammine of ammonium chloride, $NH_4Cl \cdot 3NH_3$, reported by Troost.[8] By measuring equilibrium pressures and volumes of ammonia evolved a series of points on the pressure–composition curve was then determined. Data obtained in three experiments (I, II, III) are tabulated in Table I.

Composition in this table represents the number of molecules of ammonia fixed by the mixture per atom of tantalum present, or x in the over-all formulas $TaCl_5 \cdot xNH_3$ (including ammonium chloride triammine). The values obtained in experiment I, in which measurements were carried down to low pressures during the course of four months, are plotted in Fig. 1, Curve A. It is to be noted that only one well characterized monovariant region of composition can be detected in the curve, that this is at a pressure corresponding

sensibly to that of dissociation of the triammine of ammonium chloride, and that on either side of this region the equilibrium pressure changes abruptly in a linear manner. In fact, as the pressure decreases the composition remains practically constant until a pressure of 300 mm. is reached. Figure 2 shows the data obtained in experiment II in the monovariant region plotted to larger scale.

Equilibrium was only slowly attained, possibly due to the formation of a coating on the surface of the decomposing crystals of reaction product which hindered the diffusion of ammonia out from the undecomposed interior part of the crystals. A similar phenomenon was mentioned by Klemm[9] in the case of the ammines of indium.

In deriving from these curves the amount of ammonia evolved by the triammine of ammonium chloride and the quantity fixed by the solid at the end of this decomposition, the points of intersection of the linear parts of the curve with the theoretical 1035-mm. isobar were used. The results are tabulated in the first three lines of Table II.

TABLE II

Experiment	Initial ammonia	Final ammonia	Difference	Ammonium chloride
I	17.20	10.88	6.32	2.11
II	17.17	11.14	6.03	2.01
III	16.66	10.79	5.87	1.96
IV	...	...	7.34	2.45
V	18.12	10.79	7.33	2.44
VI	19.73	9.93	9.80	3.27
VII	19.79	9.63	10.16	3.39

Initial ammonia content values correspond to the point of commencement of decomposition of the triammine of ammonium chloride and final ammonia content represents the composition when all of the triammine has decomposed. The difference between these quantities divided by three gives the moles of ammonium chloride formed per mole of tantalum pentachloride originally taken.

It can be concluded from these experiments that when liquid ammonia reacts with tantalum pentachloride, two atoms of chlorine in the latter are replaced, forming two molecules of ammonium chloride. Furthermore, the over-all content of ammonia in the mixture obtained after the triammine of ammonium chloride has completely decomposed corresponds to the fixation of eleven molecules per atom of tantalum present. Consequently, each atom of tantalum must be combined with nine atoms of nitrogen, if a mixture of tantalum compounds is not formed which is improbable in view of the duplicatibility of results under different conditions in these three experiments.

Since our analogy with the reaction product of phosphorus pentachloride with liquid ammonia[10] indicates that under these conditions of temperature and ammonia pressure an amide rather than an imide or a nitride is to be expected, the most likely formula that can be assigned to this tantalum compound is that of the heptammine of the

diamidotrichloride of tantalum, formed by the reaction

$$TaCl_5 + 17NH_3 \longrightarrow Ta(NH_2)_2Cl_3{\cdot}7NH_3 + 2NH_4Cl{\cdot}3NH_3$$

Confirmatory evidence for this formula will be presented later in this article under the study of the thermal decomposition of this compound.

It is to be noted that a composition corresponding to the fixation of nine moles of ammonia there is a slight change of curvature, indicating the possible presence of pentammine, $Ta(NH_2)_2Cl_3{\cdot}5NH_3$. This is shown more clearly when plotted to larger scale as in Fig. 1-B. To verify the existence of this compound, equilibrium pressure–composition measurements were carried out at 24.5° on a new sample of the ammine of the diamino trichloride. The results are given in Table I, experiment VIII, and are plotted in Fig. 1-C and Fig. 1-D to larger scale. Although there is a definite change of curvature in this plot, it is so gradual that the point of inflection cannot be ascertained definitely. It is to be observed, however, that this pressure curve intersects the one obtained at 0°, indicating that another phenomenon is taking place. It is probable that slight replacement of more chlorine in tantalum pentachloride occurs at this temperature under an appreciable ammonia pressure. Experiments about to be described bear out this supposition.

It seemed advisable at this stage to investigate the tendency of the remaining three atoms of chlorine still attached to the tantalum to be ammonolyzed off by repeated treatment with liquid ammonia and intermediate heating to various temperatures. Since it was by a procedure similar to this that Schwarz and Jeanmaire[11] succeeded in decomposing an ammonium chloride complex of triamido stannic chloride, it was felt that a further replacement of chlorine in $Ta(NH_2)_2Cl_3{\cdot}7NH_3$ might be accomplished in this manner. This actually did occur, for more than three gram atoms of the original five in the pentachloride were ammonolyzed. The procedure, however led to mixtures and consequently the exact nature of the compounds formed could not be ascertained. Experimental conditions in four experiments (IV, V, VI, VII) are summarized in Table III and the corresponding results are tabulated in Table II.

TABLE III

Experiment	IV	V	VI	VII
Heating temp., °C.	100	100	160	240–250
Time, hrs.	5.5	1	1	1
Times performed	1	4	4	4

It is seen that even heating to 100° causes half an additional gram atom of chlorine to be replaced. This was the justification for the assumption previously made that at 24.5° slow replacement of chlorine occurred which interfered with vapor pressure measurements extending over a period of several months. Furthermore, the number of moles of ammonium chloride formed per mole of tantalum pentachloride originally present increases while the quantity of ammonia fixed after the triammine of ammonium chloride has decomposed increases as the severity of treatment is increased. This is not regular, however, as the results obtained in experiments VI and VII approach similarity even though the temperature to which the mixture has been heated differs by almost 100°. This would seem to indicate the formation of stable tantalum compounds but since the molal quantities obtained differ considerably from whole numbers, it is apparently a question of a mixture of two or more substances, the formulas of which cannot be derived directly from the data.

$2NH_4Cl$) primarily formed by the action of liquid ammonia on tantalum pentachloride was heated in vacuum, ammonia was evolved continuously as the temperature was raised to 170° and ammonium chloride sublimed onto the cooler parts of the apparatus. At this latter temperature, the evolution of ammonia ceased and hydrogen chloride began to be evolved, showing the commencement of a new reaction. Up to this point seven moles of ammonia had been evolved and two moles of ammonium chloride appeared in the sublimate.

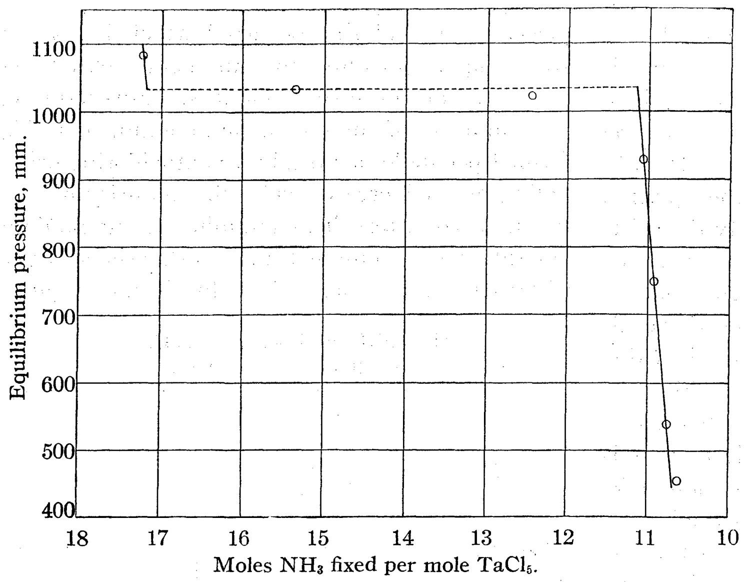

Fig. 2.

As shown by the data in Table IV and by the plot in Fig. 3 there was no indication of a temperature range throughout which there was any discontinuity of evolution, although evolution decreased gradually as the temperature was raised. It is not probable, therefore, that any well-defined intermediate compounds are formed between the heptammine and the amido chloride itself. The data obtained in two experiments are summarized in Table V, all quantities being expressed as total moles per mole of tantalum pentachloride originally present.

[a] Including ammonium chloride.

It is to be noted that although the quantity of ammonia fixed in the end by the tantalum and chlorine (as NH_4Cl) is greater than four by an amount greater than the probable experimental error, nevertheless this deviation was markedly decreased in Experiment II where greater precautions were taken toward the end of the decomposition. Undoubtedly secondary reactions take place to a slight extent with the gaseous ammonia for there was apparently only a very small intermediate temperature range, if any, between cessation of ammonia and commencement of hydrogen chloride evolution, for when the solid residue obtained in expt. 1 was again heated in vacuum to 170°, a small but appreciable hydrogen chloride pressure developed. Another fact which was noted and which undoubtedly did cause a slight error was the formation of a very small quantity of a volatile yellowish tantalum compound of unknown composition which appeared in the sublimate, for a small quantity of white precipitate formed when the latter

was treated with water and was shown to be tantalum hydroxide by microscopic examination of the K_2TaF_7 derivative. However, these factors are both so small that it is felt that they do not seriously impair the conclusions that are to be drawn from these results and are merely suggested as probable explanations of deviations from the main reaction taking place.

The preceding experiments show, then, that when the mixture $[Ta(NH_2)_2Cl_3 \cdot 7NH_3 + 2NH_4Cl]$ undergoes thermal decomposition, no further replacement of chlorine occurs, provided that the ammonia evolved be removed from the system. The ammonium chloride present sublimes off unchanged and the seven molecules of ammonia coordinately bound are evolved completely.

$$Ta(NH_2)_2Cl_3 \cdot 7NH_3 + 2NH_4Cl \longrightarrow Ta(NH_2)_2Cl_3 + 7NH_3 + 2NH_4Cl$$

The composition of this residual tantalum compound was confirmed by analysis.

Analysis of $Ta(NH_2)_2Cl_3$.—The residue in the flask was found to react vigorously with water with evolution of hydrogen chloride and consequently could not be allowed to be exposed to the atmospheric moisture. To determine *nitrogen* content, samples were decomposed with concentrated sulfuric acid, in which reagent gentle heating caused complete dissolution. The ammonia was distilled off from the alkalinized solution and titrated. *Chlorine* was determined by dissolving samples in 33% potassium hydroxide solution (evolution of ammonia), cautious neutralization with nitric acid after dilution, and immediate precipitation of tantalum hydroxide by means of an excess of ammonium hydroxide. The hydroxide was filtered off and washed with dilute ammoniacal ammonium nitrate solution, and chloride in the filtrate determined as silver chloride. Due to occlusion of chloride ion by the colloidal hydroxide[5] it was found helpful, to obtain consistent results, to heat the precipitate of tantalum hydroxide on the water-bath for two days before filtration. *Tantalum* was determined by the method employed by Hahn and Putter,[12] which consisted in treatment of the sample with an excess of sulfuric acid in a weighed platinum crucible and careful evaporation to dryness, the ignited residue being weighed as Ta_2O_5.

	33.04	33.52	
Tantalum, %	56.40	56.77	56.65
	56.62	56.82	

Due to the fact that the substance could not be ground up and mixed to obtain a homogeneous mixture, the analytical results vary slightly. Taking into consideration this factor along with the fact that any impurities introduced were accumulated in the residue along with incidental hydrolysis products from which purification could not be made at any step of the synthesis, the concordance of the results with the theoretical is satisfactory.

Properties of $Ta(NH_2)_2Cl_3$.—The diamido trichloride of tantalum obtained in this manner is a light yellow solid which decomposes on heating above 170° in vacuum. It is decomposed rapidly by moisture and reacts vigorously with water with evolution of hydrogen chloride and precipitation of hydrated tantalic oxide. That this precipitate contained only negligible quantities of nitrogen was demonstrated by ammonia analysis of its solution in concentrated sulfuric acid. Hence, the hydrolysis can be represented by the equation $2Ta(NH_2)_2Cl_3 + (x + 5)H_2O \longrightarrow Ta_2O_5 \cdot xH_2O + 2HCl + 4NH_4Cl$. When fused with potassium hydroxide, ammonia is evolved and the melt is totally soluble in water. On gentle heating, the diamido trichloride dissolves in concentrated sulfuric acid with liberation of hydrogen chloride. Both of these reactions are in accordance with the above hydrolysis and known properties of tantalic oxide.

Conversion of $Ta(NH_2)_2Cl_3$ to Ta_3N_5.—The more easily prepared ammine–ammonium chlo-

---

ride mixture was employed in one experiment. It was heated continuously in the ammonia current at 750° for six days, at which time the sublimation of ammonium chloride to the cooler parts of the tube had ceased. The non-volatile residue remaining in the boat was red with a few purple spots. It was analyzed by the methods described for the diamide. Chlorine was not present. The data are summarized in Table VI.

TABLE VI

			Calcd. for Ta_3N_5

Average % Ta	87.39		
Average % N	11.06		
Total % found	98.45		
Atomic ratio of N/Ta	1.640		1.667

The pure diamide gave similar results. At 650–670° the product obtained was brighter red, more homogeneous in appearance and contained no dark spots. The variation of the analytical results among themselves is due to lack of homogeneity as the product was not ground up before analysis. The sum of the percentages of tantalum and nitrogen lacks 1.55% of being 100. Oxide formed from unavoidable reaction of the initial reactants with moisture of the air during experimental manipulation before the conversion is doubtless partly the cause of this discrepancy. The ratio N/Ta is somewhat better than the only other value found in the literature. Joly[13] prepared tantalum pentanitride directly by the action of gaseous ammonia on tantalum pentachloride at elevated temperature and found the corresponding ratio in his product to be 1.61.

It is to be concluded that when the diamido trichloride of tantalum, or its ammine, is heated in a current of ammonia, all of its chlorine is evolved as ammonium chloride which sublimes off and leaves a residue consisting essentially of the red pentanitride of tantalum. Its formation is accounted for by the equation

$$3Ta(NH_2)_2Cl_3 + 8NH_3 \longrightarrow Ta_3N_5 + 9NH_4Cl$$

Physical Properties of Ta_3N_5.—Although the X-ray spectrum of tantalum mononitride is known and the compound has been found to be crystalline,[14] the corresponding data for the pentanitride are lacking. On submitting the latter to X-ray analysis, it showed several well-defined, characteristic lines which were different from those of the mononitride later prepared. Hence, it is to be concluded that the pentanitride is also crystalline. Its density was found to be 8.5 and it was slightly diamagnetic.

Conversion of $Ta(NH_2)_2Cl_3$ **to TaN.**—Joly[13] found that the pentanitride was converted to the black mononitride by heating in a current of ammonia to red heat. The same conversion takes place as an intermediate step if the diamido trichloride or its ammine be treated similarly as we have already shown in the previous paper.[2] We have evidence that this step consists merely in the decomposition of the pentanitride, the presence of ammonia having no essential bearing on the reaction, which goes according to the equation

$$Ta_3N_5 \longrightarrow 3TaN + N_2$$

The conversion from the ammine was carried out in the same manner as for the pentanitride but at a higher temperature. A 2.1-g. sample of the mixture obtained by the action of liquid ammonia on tantalum pentachloride was heated in a current of dry ammonia gas at 1190° for twenty-four hours. Even under these conditions the conversion was not complete for the black residue obtained still contained more than theoretical nitrogen as shown by the following analysis which was carried out in the manner described for the pentanitride. No chlorine was found to be present.

	Found		Calcd. for TaN
Tantalum, %	91.61	91.75	92.81
Nitrogen, %	8.34	8.11	7.18

When heated in a vacuum the red pentanitride, made from $Ta(NH_2)_2Cl_3$ by heating in a current of ammonia at 750°, evolved nitrogen at 730°. A certain amount of hydrogen, however, was given off simultaneously (0.218 mole per mole of Ta_3N_5), indicating that the initial material contained a hydrogen compound, perhaps a small quantity of an imide, which underwent a decomposition similar to that observed by Moureu and Wetroff[15] in the case of phosphorus compounds. On the other hand, analysis of the black product obtained showed it to contain 8.01% nitrogen and the amount of nitrogen evolved corresponded to only 78% of the theoretical amount for formation of TaN even after six hundred hours of heating in vacuum at 800–850°. It appears that at these temperatures transformation of the pentanitride in vacuum is very slow.

Thermal Decomposition of $Ta(NH_2)_2Cl_3$ in Vacuum.—Due to the complicated character of this reaction it was not possible to arrive at any definite conclusions concerning its mechanism although it can be said with certainty that the two nitrides mentioned are among the products. The main reaction involved seems to be the following, although the change is evidently much more complicated.

$$3Ta(NH_2)_2Cl_3 \longrightarrow Ta_3N_5 + NH_4Cl + 8HCl$$

When heated in vacuum the first gaseous product, hydrogen chloride, commenced to be evolved at 170°. Ammonium chloride sublimed to the cooler parts of the apparatus along with a yellow to green tantalum compound which decomposed with evolution of hydrogen chloride and formation of a dark green to black compound on heating with a free flame. As shown by the data summarized in Table VII for experiments in which samples of the diamido trichloride were heated to various temperatures in vacuum and the residues obtained analyzed, temperatures as high as 800° are required to expel the chlorine completely.

TABLE VII

Experiment		(A)	(B)	(C)	(D)

			7.04		10.01
	Cl	16.5	5.90	3.4	0.0
			5.81		

The residue obtained varied from greenish brown to black as the temperature of decomposition was raised. In all cases, however, sulfur dioxide was liberated from concentrated sulfuric acid in the nitrogen analysis while the dissolving solid became bright red in experiments (B), (C) and (D), indicating that a superficial coating of mononitride hid the color of the pentanitride. That pentanitride actually was the chief component of the residue in experiment IV was confirmed by its X-ray spectrum. Although the other residues failed to show clearly defined lines, in the latter case well-defined lines corresponding in position to those previously obtained from the pentanitride were found.

The composition of the volatile tantalum compound could not be ascertained because of its small quantity and because of its rapid decomposition by the moisture of the atmosphere. Due to the fact that it underwent a color change on heating it could not have been tantalum pentachloride.

Magnetism of Tantalum Pentachloride.—It might be supposed that the difference in reactivity of the chlorine in tantalum pentachloride to liquid ammonia might be due to dissimilarity in bonding, for example the attachment of three chlorine atoms by doublets, while that of the remaining two by singlets with the formation of an octet structure around the tantalum. In this case it was to be expected that the pentachloride would be paramagnetic. Actual determination of the magnetism of iron-free pentachloride, however, showed it to be slightly diamagnetic. An average of three determinations made on a Curie balance in which the pentachloride was both packed and fused in the determination tube gave for x the value $-0.231 \pm 0.002 \times 10^{-6}$. Hence some other explanation must be sought for this difference in reactivity.

Discussion

Schwarz and Jeanmaire[11] found that with the normal valence halides of Group IV of the periodic classification those of the more metallic high atomic weight elements differed considerably from those of less metallic low atomic weight elements in the ease with which chlorine atoms were ammonolyzed by liquid ammonia. While the tetrahalides of silicon and germanium suffered complete ammonolysis, that of tin required special treatment to bring about complete replacement of chlorine and lead tetrachloride formed a stable chloramide, $Sn(NH_2)_3Cl$, which decomposed to a chloronitride, SnNCl. In the reactions of the chlorides of Group V with liquid ammonia there is an analogous behavior: the pentachloride of phosphorus suffers complete ammonolysis[16] while the halides of bismuth, BiX_3, form ammines but are not ammonolyzed.[17] The transitional element, tantalum, on the other hand, has intermediate properties between phosphorus and bismuth and its pentachloride undergoes only partial replacement of chlorine to form an ammoniated diamido trichloride.

(16) Moureu and Rocquet, *Compt. rend.*, **200**, 1407 (1935).

(17) Schwarz and Striebich, *Z. anorg. Chem.*, **223**, 399 (1935).

Summary

1. From equilibrium pressure–composition measurements it has been shown that the primary product of the action of liquid ammonia on tantalum pentachloride is soluble $Ta(NH_2)_2Cl_3 \cdot 7NH_3$ which is deposited from solution, along with the ammonium chloride simultaneously produced, in the form of a light yellow crystalline mass.

2. When heated in a vacuum this compound first loses its seven molecules of ammonia coördinatively bound to form the yellow diamido trichloride of tantalum. Study of this reaction revealed a slight discontinuity at the point where the total ammonia fixed by the solid material was nine moles per gram atom of tantalum present, indicating the formation of the pentammine of the diamido trichloride.

3. By repeated alternate heating and submission to the action of liquid ammonia more than three of the original five chlorine atoms in tantalum pentachloride can be ammonolyzed off to form a mixture the components of which were of undetermined character.

4. Some properties of $Ta(NH_2)_2Cl_3$ have been described and its thermal decomposition both in the presence of gaseous ammonia and in vacuum studied. In the presence of gaseous ammonia, the first product isolated was the pentanitride while in a vacuum at the same temperature the pentanitride is accompanied by some mononitride and a small amount of a volatile tantalum compound of undetermined composition.

5. At elevated temperature, in either an atmosphere of ammonia or in a vacuum, the pentanitride is found to decompose to the mononitride with the evolution of nitrogen.

6. Tantalum pentanitride has been shown to be crystalline from its X-ray spectrum and its density has been determined.

7. The magnetic constant of tantalum pentachloride has been measured.

The Separation of Gallium and its Colorimetric Determination by Means of Quinalizarin[1]

BY H. H. WILLARD AND H. C. FOGG[2]

Practically the only method available for the detection and estimation of small amounts of gallium is by means of the spectroscope. This furnishes a specific and sensitive method for detection, and one which in the hands of experienced manipulators is quite accurate for its determination. However, it has the disadvantages of requring an apparatus which not all laboratories possess, and a technique which everyone has not had an opportunity to develop.

Dennis and Bridgman[3] using a spark were able to detect, by means of a direct vision spectroscope, the gallium line, 4172, in a concentration of 3 mg. of gallium per 100 ml. when 0.15 ml. of the solution, corresponding to 0.0046 mg. of gallium, was placed in the small cup used to hold the solution. Approximately five times this amount of gallium was required for the line 4033 to be visible. The spectrograph has also been employed by Papish and Holt[4] for the direct detection and semi-quantitative estimation of gallium in certain minerals. Kimura, Nakamura and Kusibe[5] combined chemical concentration with the spectrographic method for the qualitative examination of a large number of Japanese minerals for gallium.

A colorimetric method, even if not as specific, is desirable and an investigation was, therefore, made to find a dye which would form with gallium, a suitable lake.

Experimental

Aurin tricarboxylic acid, alizarin red-S, titan yellow and quinalizarin (1,2,5,8-tetrahydroxyanthraquinone) were tried. Although the first dye gave a color with small amounts of gallium, as stated by Corey and Rogers,[6] no suitable experimental conditions could be established which would allow an accurate colorimetric determination.

Alizarin red-S gave a pink to salmon color in buffered solutions. However, the limits of *p*H range, from 4.0 to 4.5, were so narrow and the effect of varying concentrations of buffer salts so great that it was practically valueless as a reagent. Titan yellow gave no color with gallium. Quinalizarin gave a pink to amethyst color, depending upon the concentration of gallium and the *p*H of the solution. Kolthoff[7] has suggested this last reagent as a sensitive test for aluminum.

Preliminary Investigation of Quinalizarin.—This preliminary work showed that: (a) gallium produced a distinct color in the *p*H range of 4.5 to 6.0, and that the most favorable condition, considering the effect of aluminum, etc., was a *p*H of 5.0; (b) the addition of ammonium acetate or ammonium succinate increased the intensity of color of the dye alone and also of solutions containing gallium to about the same extent; (c) the presence of ammonium chloride made the difference in color between the blank and gallium solutions somewhat more pronounced; (d) in general the most uniform results could be obtained if the solutions had a *p*H of 5 and were normal in ammonium acetate and half normal in ammonium chloride.

Action of Quinalizarin with Other Ions.—Qualitative tests in a solution of *p*H 5.0, normal in ammonium acetate and half normal in ammonium chloride showed that: iron (Fe^{+++}), tin (Sn^{++}), antimony (Sb^{+++}), copper (Cu^{++}), lead (Pb^{++}), indium (In^{+++}), germanium (Ge^{++++}), vanadyl (VO^{++}), vanadate (VO_3^{-}) and molybdate (MoO_4^{--}) give colors which are not completely inhibited by fluoride. Iron (Fe^{+++}) and lead (Pb^{++}) cause a blue color while the others are pink. All are very sensitive. Zirconium (Zr^{++++}), thorium (Th^{++++}) and the rare earths give a blue, while tin (Sn^{++++}), beryllium (Be^{++}), aluminum (Al^{+++}), thallium (Tl^{+++}), titanium (Ti^{++++}), arsenite (AsO_3^{---}) and antimonate (SbO_4^{---}) cause a pink color which can be prevented by the addition of fluoride. The alkalies, alkaline earths, magnesium (Mg^{++}), manganese (Mn^{++}), iron (Fe^{++}), mercury (Hg^{++}), thallium (Tl^{+}), cadmium (Cd^{++}), uranyl (UO_2^{++}), tungstate (WO_4^{--}) and arsenate (AsO_4^{---}) give rise to no color. Silver (Ag^{+}), mercury (Hg^{+}), bismuth (Bi^{+++}), tantalum (Ta^{+++++}) and columbium (Cb^{+++++}), either precipitate as chlorides or hydrolyze out, thus causing no interference after removal by filtration. Cobalt (Co^{++}), nickel (Ni^{++}) and chromium (Cr^{+++}) do not interfere except for their own color. Zinc (Zn^{++}) can be present to the extent of 0.5 g. per liter before any color can be seen. More than that gives an amethyst to blue color.

Influence of Various Acid Radicals on the Color Produced by Gallium (Ga^{+++}), Iron (Fe^{+++}) and Aluminum (Al^{+++}).—Citrate, oxalate and tartrate effectively prevented the formation of color in all cases.

Phosphate had no effect on the color produced by aluminum but prevented the color due to ferric iron if added in sufficient concentration. However, it caused a very appreciable decrease in the color given by gallium.

Fluoride effectively prevented the color given by aluminum, while exerting only a relatively small influence in the case of iron and gallium. The only effect with gallium was a slight decrease in the intensity of color in all solutions, including the blank (see Table I). Experiments showed that 0.5 g. of sodium fluoride per liter, in excess of that required to form Na_3AlF_6, was necessary for the complete prevention of lake formation by aluminum. This was also about the maximum concentration of sodium fluoride permissible without seriously decreasing the color caused by gallium.

The Limit of Sensitivity for Gallium, Ferric Iron, Aluminum, Zinc and Indium.—This was determined by comparison of 50 ml. of solution in 50-ml. Nessler tubes, 125 mm. to the mark, the source of light being G. E. daylight bulbs, diffused by a ground glass plate. All solutions were *N* in ammonium acetate, 0.5 *N* in ammonium chloride and had a *p*H of 5.0 ± 0.1 determined with a quinhydrone electrode. One series contained no sodium fluoride while the other contained 0.5 g. per liter. One ml. of a 0.01% alcoholic solution of quinalizarin was added. The figures given below represent the concentrations of the ions which gave sufficient color to be distinguished with certainty from the blank upon repeated determinations.

TABLE I

LIMIT OF DETECTION OF Ga, Al, Fe^{+++}, Zn AND In WITH QUINALIZARIN

Metal	NaF, 0.5 g./l. metal mg./l.	No NaF, metal mg./l.
Ga	0.02	0.02
Al	20.00	.12
Fe (ic)	0.05	.02
Zn	800.00	400.00
In	10.00	2.00

Since it is obvious that a satisfactory colorimetric determination of gallium is possible only after a separation from many other metals, a study of such separations is described in the following pages. The most difficult and important separations, such as those from aluminum, iron and indium, are so different that they must be treated separately. The usefulness of the method is considerably reduced by the difficulty in removing iron, but many cases are encountered in which only very small amounts of iron are present.

The Determination of Gallium in the Presence of Aluminum

The Influence of Various Salts and *p*H on the Separation of Aluminum from Gallium by Means of Sodium Fluoride.—Qualitative and semi-quantitative tests showed that the presence of ammonium chloride, ammonium acetate, the *p*H of the solution at the time of addition of sodium fluoride, the excess of sodium fluoride and the presence of much sodium or potassium salt influenced the separation of aluminum and the recovery of gallium. Extensive experiments showed that the best separation of aluminum, by precipitation as Na_3AlF_6, was obtained when sodium fluoride was added as a saturated solution to the solution containing aluminum and gallium which was about half normal in ammonium chloride and buffered with ammonium acetate to a *p*H of around 5. The presence of more than a few milligrams of potassium or 100 mg. of sodium ion was detrimental to the above separation, although neither potassium nor sodium interfered with the colorimetric part of the determination.

Procedure.—The solution containing gallium and aluminum is neutralized to turbidity with ammonium hy-

---

[7] Kolthoff, *Chem. Weekblad*, **24**, 447 (1927); *J. Am. Pharm. Assoc.*, **17**, 360 (1928).

droxide, cleared with 6 *N* hydrochloric acid, and 4 ml. in excess added. This is followed by 7.7 g. of ammonium acetate and 2.7 g. of ammonium chloride. (This will make the solution *N* in ammonium acetate, 0.5 *N* in ammonium chloride, and give a *p*H of nearly 5.0 when finally diluted to 100 ml.) After diluting to 70–80 ml. and heating to 70–80°, enough saturated sodium fluoride solution is added, while stirring, to form Na_3AlF_6 and leave 0.5 g. per liter in excess. The resulting precipitate should be of a fine, crystalline nature. If it is of the opalescent, almost invisible type, some of the gallium is practically certain to be retained or else the aluminum may not be removed entirely. When it has stood for one to one and a half hours, with occasional stirring, paper pulp is added, the precipitate filtered off, the filtrate diluted to 100 ml. and adjusted to a *p*H of 5.0 using a quinhydrone electrode. Aliquot portions of such volume as to contain from 0.001 to 0.01 mg. of gallium are placed in 50-ml. Nessler tubes and filled to the mark with the stock solution from which the standards are made. A series of standards is prepared by adding to 50-ml. portions of this solution in Nessler tubes, definite volumes of a standard gallium chloride solution containing 0.01 mg. of gallium per ml. One ml. of a 0.01% alcoholic solution of quinalizarin is added to each tube, the contents stirred and the colors compared after one or two minutes.

Using 50-ml. Nessler tubes, the best concentration for comparison lies between 0.02 and 0.2 mg. of gallium per liter. Between 0.02 and 0.08 mg. per liter, a difference of 0.01 mg. per liter can be detected easily. Above that, it requires a difference of 0.02 mg. per liter.

The quinalizarin solution is not very stable and becomes practically useless after it has been prepared a week. Neither is it much good directly after preparation. It gives the best results from one to four days after preparation.

It is not necessary that the solutions have a *p*H of exactly 5.0, but it is necessary that both standards and unknown have the same *p*H. A very great deviation from 5 is not recommended, however, since at 4.5 the sensitivity of the gallium is much less, while at a higher *p*H the sensitivity of aluminum is greater.

The presence of 0.5 g. of sodium fluoride per liter is to be recommended in all cases, even if a separation of aluminum has not been made, since it will prevent any color due to traces of that element which are almost certain to be present.

The results shown in Table II, numbers 1 to 10, were obtained by the above method, while numbers 11 to 15 were obtained without preliminary separation of aluminum.

TABLE II

DETERMINATION OF GALLIUM IN THE PRESENCE OF ALUMINUM

No.	Al, mg.	Ga taken, mg.	Ga found, mg.	Error, mg.
1	10	0.000	0.000	±0.000
2	10	.005	.0047	− .0003
3	10	.010	.011	+ .001
4	10	.010	.012	+ .002
5	10	.010	.010	± .000
6	10	.020	.021	+ .001
7	10	.050	.047	− .003
8	20	.000	.000	± .000
9	20	.010	.0075	− .0025
10	20	.010	.006	− .004
	Al, mg./50 ml.	Ga taken, mg./50 ml.		
11	0.75	0.000	0.000	±0.000
12	.75	.0005[a]	.000	− .0005
13	.75	.001	.0011	+ .0001
14	.75	.0025	.0028	+ .0003
15	.75	.005	.005	± .000

[a] 0.0005 mg. of gallium in 50 ml. of solution is beyond the limit of sensitivity of the test.

From this it is seen that gallium can be separated accurately from aluminum if not more than 10 mg. of the latter is present. If the concentration of aluminum is not greater than 15 mg. per liter, the gallium can be determined directly without a preliminary precipitation of aluminum as Na_3AlF_6.

The Determination of Gallium in the Presence of Iron and Indium

Since quinalizarin gives a very sensitive color reaction with ferric iron, it is essential that every trace of this ion be removed before proceeding with the colorimetric determination of gallium. Experiments showed that it was not possible to convert the iron into ferrocyanide and determine the gallium directly, nor to collect quantitatively the latter from a solution by precipitating it along with cadmium sulfide. When the iron was reduced before adding quinalizarin, it was found that the reducing agents such as bisulfite, hydrazine sulfate and hydroxylamine hydrochloride failed to cause complete reduction. Others, like sodium hydrosulfite and phenylhydrazine hydrochloride, destroyed the dye.

The Separation of Iron and Indium from Gallium by Means of an Excess of Sodium Hydroxide.—Although this is a standard method of separation in ordinary analytical work, two serious difficulties were encountered in this instance. First, the adsorptive properties of ferric hydroxide proved to be so great that more than 1 mg. of iron prevented complete recovery of the gallium. Second, sufficient ferric hydroxide to give a color with the dye remained in the colloidal state and passed through the filter, even though the precipitate was settled by centrifuging, and removed by the method recommended by Cox, Schwartze, Hahn, Unangst and Neal,[8] for the separation of iron and aluminum. However, the use of hydrated manganese dioxide as a collector according to the method of Stokes and Cain[9] was found to give entirely satisfactory results for both iron and indium.

Procedure.—The solution containing the iron and gallium in 25 ml. or less, was heated nearly to boiling and enough approximately 3 *N* sodium hydroxide added to make the final concentration between half normal and normal. The heating was continued until the ferric hydroxide had coagulated. Paper pulp was added, the precipitate filtered off and washed with a hot 1% sodium chloride solution made alkaline with sodium hydroxide.

---

(8) Cox, Schwartze, Hahn, Unangst and Neal, *Ind. Eng. Chem.*, **24**, 403 (1932).

(9) Stokes and Cain, THIS JOURNAL, **29**, 409 (1907).

The paper pulp and filter paper used in this, and the next, filtration had been treated with hot 1.5 *N* sodium hydroxide solution and then washed with water. The filtrate was heated nearly to boiling, eight to ten drops of a 1% potassium permanganate solution added, and this followed in a minute or two by enough alcohol (5 to 10 drops) to cause reduction. The heating was continued until all green color had disappeared, and the brown precipitate of hydrated manganese dioxide had formed. This was filtered off and washed as before. The filtrate was neutralized to litmus with hydrochloric acid and enough ammonium chloride, ammonium acetate and sodium fluoride introduced so that the *p*H of the solution and the salt concentration would have the values previously recommended, when the whole was diluted to the desired volume (100 or 250 ml.). This was most conveniently done by adding the sodium fluoride as a saturated solution, and the other two salts as a stock solution with a *p*H of 5, which was 1.5 *N* in the former and 3 *N* in the latter.

In the case of indium the precipitate need not be filtered off before adding the permanganate.

The gallium was then determined as described under "The Determination of Gallium in the Presence of Aluminum." Table III shows the results obtained using the above procedure.

TABLE III

THE SEPARATION OF GALLIUM FROM IRON AND INDIUM

No.	Fe, mg.	Ga taken, mg.	Ga found, mg.	Error, mg.
1	0.5	0.010	0.009	−0.001
2	.5	.020	.018	− .002
3	1.0	.000	.000	± .000

	In, mg.			
16	100	.000	.000	± .000
17	100	.010	.011	+ .001
18	100	.025	.028	+ .003
19	100	.050	.052	+ .002
20	100	.060	.058	− .002

In numbers 10 to 20 the precipitate of ferric hydroxide, or indium hydroxide, was not filtered off before adding the potassium permanganate and reducing.

From this it can be seen that gallium can be determined accurately in the presence of iron, using the method given, only when not more than 1 mg. of the latter is present; otherwise a very appreciable amount of the gallium will be lost. Determinations 10 to 15 show that if not more than 0.2 mg. of iron is present, it is unnecessary to filter off the ferric hydroxide before adding the permanganate. With larger amounts of iron, it was found that it was removed incompletely unless filtered off as recommended in the procedure. Indium gives no difficulty even when 100 mg. is present.

Data obtained, but not included in the table, showed that if the concentration of indium did not exceed 8 mg. per liter, accurate determinations of gallium could be made without a preliminary separation.

The Determination of Gallium in the Presence of Zinc and Aluminum or Iron

Since preliminary determinations, Table I, showed that nearly 600 mg. of zinc per liter gave no color with quinalizarin if 0.5 g. of sodium fluoride was present, no special procedure was necessary for determining gallium in the presence of this element.

With zinc alone, the gallium was determined directly in solutions having a *p*H and the salt concentrations previously given. (Results are shown in Table IV, numbers 1 to 5.) When zinc and aluminum were both present, the latter was separated by the procedure given under "The Determination of Gallium in the Presence of Aluminum," and the gallium determined as if zinc were absent. (Determinations from 6 to 11 show the results obtained.) With iron and zinc present the procedure given under "The Determination of Gallium in the Presence of Iron" was followed except that sufficient sodium hydroxide was added to dissolve the zinc hydroxide. (Determinations 12 to 15 are representative of the results obtained.)

TABLE IV

THE DETERMINATION OF GALLIUM IN THE PRESENCE OF ZINC AND IRON OR ALUMINUM

No.	Al, mg.	Zn, mg.	Ga taken, mg.	Ga found, mg.	Error, mg.
1		25.0	0.000	0.000	±0.000
2		25.0	.001	.0012	+ .0002
3		25.0	.005	.006	+ .001
4		50.0	.010	.010	± .000
5		50.0	.020	.020	± .000
6	10.0	20.0	.000	.000	± .000
7	10.0	10.0	.005	.006	± .001
8	10.0	20.0	.025	.023	− .002
9	0.25	12.5	.003	.0035	+ .0005
10	.25	12.5	.010	.009	− .001
11	.50	20.0	.030	.035	+ .005
	Fe, mg.				
12	1.0	20.0	.000	.000	± .000
13	1.0	20.0	.005	.004	− .001
14	1.0	100.0	.025	.024	− .001
15	1.0	200.0	.060	.065	+ .005

Numbers 4, 5, 10, 11, 14 and 15 were diluted to 100 ml. and aliquots taken for colorimetric comparison. In determinations 6, 7 and 8 the Na_3AlF_6 was filtered off before comparison, while in 9, 10 and 11 the comparison was made without prior filtration.

This shows that gallium can be determined in the presence of zinc if the ratio of zinc to gallium does not exceed 25,000 to 1, providing the solution contains 0.5 g. of sodium fluoride per liter. If the Na_3AlF_6 was not filtered off, as in determinations 9, 10 and 11, a color was produced if approximately the maximum amounts of both zinc and aluminum, which would give no color when alone, were present, but not when half that quantity of each element was present.

The Determination of Gallium in the Presence of Iron and Aluminum

It was not possible to precipitate the aluminum with sodium fluoride, after the separation of iron with an excess of sodium or potassium hydroxide, due to the interference of the large amount of alkali salts introduced. This made it necessary to acidify the solution after the removal of iron and precipitate the hydroxides of gallium and aluminum by ammonium hydroxide. If this precipitate was filtered on the best grade of filter paper it was found that traces of iron were extracted from the paper during the boiling with hydrochloric acid necessary to redissolve the hydroxides. To avoid this interference the solution was filtered through a Gooch crucible containing a mat of purified anthracene or phenanthrene.[10,11]

Procedure.—The iron was separated as described under "The Determination of Gallium in the Presence of Iron and Indium" and the filtrate acidified with hydrochloric acid. The aluminum and gallium hydroxides were precipitated with ammonium hydroxide according to Blum's method[12] and filtered through a Gooch crucible containing an anthracene or phenanthrene mat, supported on a perforated disk. The precipitate and mat were transferred to the original beaker and boiled with hydrochloric acid. The filtering medium was filtered off through a paper previously washed with 5 *N* hydrochloric acid. The aluminum was then separated by means of sodium fluoride and the gallium determination completed in the usual manner. If only a half milligram of aluminum or less was present, the gallium was determined directly without any separation from that element. The results are shown in Table V.

TABLE V

SEPARATION OF GALLIUM FROM ALUMINUM AND IRON

No.	Al, mg.	Fe, mg.	Ga taken, mg.	Ga found, mg.	Error, mg.
1	10.0	1.0	0.000	0.000	±0.000
2	10.0	1.0	.005	.006	+ .001
3	10.0	1.0	.020	.020	± .000
4	10.0	1.0	.050	.045	− .005
5	15.0	1.0	.010	.008	− .002
6	1.0	1.0	.010	.008	− .002
7	0.5	1.0	.000	.000	± .000
8	.5	1.0	.005	.0055	+ .0005
9	.5	1.0	.010	.008	− .002
10	.5	1.0	.050	.045	− .005
11	.5	1.0	.030	.030	± .000

In Nos. 1–6, the Na_3AlF_6 was filtered off. In Nos. 7–11 no separation of the aluminum was made. Nos. 3, 4, 5, 6, 9, 10 and 11 were diluted to 100 ml. and aliquots taken for comparison.

It is therefore possible to determine gallium in the presence of iron and aluminum when both of the latter are present in as large an amount as is permissible when either is present alone.

The Determination of Gallium in the Presence of Lead, Copper, Tin, Antimony, Germanium and Platinum

Procedure.—The strongly hydrochloric acid solution containing the above elements was distilled to remove germanium. The acidity of the remaining solution was adjusted so as just to prevent precipitation by hydrolysis, and stirred with a small excess of cadmium metal (40 to 60 mesh). The precipitated metals and excess of cadmium were filtered off, 2 to 3 ml. of concd. sulfuric acid added to the filtrate and evaporated to fumes to expel hydrochloric acid. Approximately 100 ml. of water was added and the cadmium removed by electrolysis. This was followed by treatment with hydrogen sulfide to remove the last traces of cadmium and any of the other metals which might be remaining. After filtration and washing, the filtrate was reduced in volume by evaporation, treated with an excess of sodium hydroxide, potassium permanganate, etc., and the determination completed as previously given.

By this method 0.01 mg. of gallium could be determined in the presence of 0.1 g. of each of the above metals either singly or as a mixture.

In numbers 22, 23 and 24 the germanium was separated by precipitation as the sulfide.

---

(10) Gooch, *Proc. Am. Acad. Arts Sci., New Series*, **12**, 390 (1884–85).

(11) These latter substances were purified by dissolving in hot acetone and pouring slowly with constant agitation into an equal volume of concentrated hydrochloric acid. The precipitated anthracene or phenanthrene was filtered off and washed first with hot dilute hydrochloric acid and then with hot water. It was then crystallized from acetone or toluene. If this product, when boiled with hydrochloric acid, gave an extract which produced a color with quinalizarin under the conditions of the colorimetric determination, the process was repeated.

(12) Blum, THIS JOURNAL, **38**, 1282 (1916).

A direct precipitation of more than a trace of the sulfide metals with hydrogen sulfide from a 0.3 *N* acid solution usually resulted in loss of gallium due to its being carried down with the sulfide precipitate, except with the small amount of germanium which was present. In this case, a quantitative separation was obtained by precipitating this element with hydrogen sulfide from 6 to 8 *N* hydrochloric acid. Results obtained are shown in Table VI.

General Procedure.—Obtain the substance in a hydrochloric acid solution and filter off any silver, lead and mercurous mercury which may have precipitated as chloride. Follow this by the procedure given under "The determination of Gallium in the presence of Lead, Copper, Tin, Antimony, Germanium and Platinum." Next separate iron, indium and aluminum, and determine gallium according to the procedure given under "The determination of Gallium in the presence of Iron and Aluminum." This will remove all interfering elements except vanadium and molybdenum, for which no satisfactory separation was found. As much as 100 mg. of lead, copper, antimony, tin, zinc, indium and doubtless that much platinum and germanium may be present, but more than 10 mg. of aluminum and one milligram of iron cause difficulty.

Summary

1. A method for the colorimetric determination of gallium has been developed, based upon the formation of a pink to amethyst colored lake with quinalizarin. The optimum condition is a solution which is normal in ammonium acetate, 0.5 *N* in ammonium chloride, of *p*H 5.0 and containing 0.5 g. of sodium fluoride per liter. Under these conditions 0.02 mg. of gallium per liter can be distinguished. The best concentrations for comparison, using 50-ml. Nessler tubes, lie between 0.02 and 0.2 mg. of gallium per liter.

2. Methods have been developed for separating minute amounts of gallium from 100 mg. of those metals which interfere by giving colored lakes under the same conditions, namely, lead, copper, tin, antimony, indium, platinum and germanium, except that not more than 10 mg. of aluminum, nor 1 mg. of iron should be present, while vanadium and molybdenum must be absent.

The Hydration of Unsaturated Compounds. IV. The Rate of Hydration of Isobutene in the Presence of Silver Ion. The Nature of the Isobutene–Silver Complex[1]

BY W. F. EBERZ, H. J. WELGE, DON M. YOST AND H. J. LUCAS

It has been shown that certain soluble metallic salts, such as those of copper, nickel, manganese, etc., have little or no effect upon the rate with which dilute nitric acid catalyzes the hydration of isobutene,[2] whereas in the presence of mercuric nitrate only the isobutene which is not combined with the mercury undergoes hydration. A similar study of the hydration of isobutene in the presence of silver ion is of interest, not only from the theoretical but also from the practical point of view, since silver salts are often added to acids in order to aid the absorption of olefins.

In order to interpret the experimental data obtained from the hydration of isobutene in the presence of silver ion, it is necessary to know the nature of the silver–isobutene complex and the value of the hydration constant of isobutene in the absence of silver ion. The latter is already known.[2]

Nature of the Silver–Isobutene Complex.—This was determined by measuring the distribution ratio of isobutene between, first, carbon tetrachloride and aqueous potassium nitrate, and, second, between carbon tetrachloride and aqueous silver nitrate. In these measurements the ionic strength was maintained constant at 1 *N* by adjusting the concentration of potassium nitrate. In addition to these data, the distribution ratios of isobutene between carbon tetrachloride and pure water, and between carbon tetrachloride and 2 *N* potassium nitrate were also determined. The experimental results are shown in Tables I and II. All concentrations are expressed in moles per liter of solution.

In developing the expressions for the formation of the complex between butene and silver ion,

and for the hydration rate in silver nitrate solution, the following notation is used:

(Bt) = Total isobutene concentration, moles per liter, at time t
(B) = Free isobutene concentration, moles per liter, at time t
(BAg) = Complexed isobutene concentration, moles per liter, at time t
$(Ag)^+$ = Free silver concentration, moles per liter, at time t
(Agt) = Total silver concentration, moles per liter, at any time
$(B)_c$ = Butene concentration, moles per liter, in carbon tetrachloride
K_D = Distribution constant of isobutene between carbon tetrachloride and 1 N potassium nitrate = 830
K_C = Equilibrium constant for the formation of the isobutene–silver complex
$-S$ = The observed specific rate of disappearance of isobutene
k' = The reaction rate constant for the hydration of free butene under the conditions of the run under consideration
k'' = Same, of the complexed butene
k'_e = The expected rate constant for free butene, under the same conditions

$$K_D = (B)_c/(B) \qquad (1)$$

$$K_C = (BAg)/(B)(Ag^+) \qquad (2)$$

Equation (2) is true if the complex is made up of one mole of isobutene and one of silver ion.

Combining (1) and (2)

$$K_C = K_D(BAg)/(B)_c(Ag^+) \qquad (3)$$

and, by the proper substitutions, it is possible to obtain K_C in terms of quantities which can be determined experimentally, that is

$$K_C = K_D[(Bt) - (B)_c/K_D]/(B)_c[(Agt) - (Bt) + (B)_c/K_D] \qquad (4)$$

The values of K_C calculated by the use of equation (4), are shown in Table II. There seems to be a slight trend in these values, for they are smallest at the lowest silver concentrations. But since K_C is quite sensitive to variations in (Bt), especially when the latter has a small value, the trend is probably less significant than it appears to be. The fact that K_C is fairly constant over a four-fold change in the silver ion concentration shows that the correct ratio of butene to silver in the complex is 1:1. This ratio raises the question of the nature of the bond or bonds between the silver ion and the isobutene molecule, for generally the coördination number of silver is two. In order to gain a better understanding of compounds of this type, complexes of silver ion with other olefins, and complexes of isobutene with other metallic ions are being investigated.

Hydration in the Presence of Silver Ion.—The amount of isobutene hydrated in unit time at a given total butene concentration is very much decreased on the addition of silver nitrate, but the amount which actually hydrates exceeds that expected from the calculated free butene concentration. Because this relationship holds in the five experiments where the silver nitrate concentration is substantial (0.24 to 0.74 N), it was thought at first that possibly the complexed, as well as the free, butene hydrates. On this assumption reaction rate constants were calculated for the hydration of the complex. These were found not to be constant, but to vary substantially inversely as the concentration of silver ion. This led to the conclusion that only the free butene hydrates.

The following relations between observed and derived quantities were used. The expressions developed are rigorous, as no simplifying assumptions were made in deriving them. The concentration of silver ion, which can also be obtained from a second, somewhat complicated, expression, results more simply by using the concentration of free butene. For that reason, the derivation of the expression for the butene concentration (equation 12) is given.

Expressions for (B) and (Ag$^+$), the Concentrations of Free Butene and of Silver Ion.—

$$(\mathrm{Ag}t) = (\mathrm{Ag}^+) + (\mathrm{BAg}) \tag{5}$$

$$(\mathrm{B}t) = (\mathrm{B}) + (\mathrm{BAg}) \tag{6}$$

Combining (5) and (6)

$$(\mathrm{Ag}^+) = (\mathrm{Ag}t) - (\mathrm{B}t) + (\mathrm{B}) \tag{7}$$

From (2), (6) and (7)

$$K_\mathrm{C} = \frac{(\mathrm{B}t) - (\mathrm{B})}{(\mathrm{B})[(\mathrm{Ag}t) - (\mathrm{B}t) + (\mathrm{B})]} \tag{8}$$

$$K_\mathrm{C}(\mathrm{B})(\mathrm{Ag}t) - K_\mathrm{C}(\mathrm{B})(\mathrm{B}t) + K_\mathrm{C}(\mathrm{B})^2 = (\mathrm{B}t) - (\mathrm{B}) \tag{9}$$

$$K_\mathrm{C}(\mathrm{B})^2 - (\mathrm{B})[K_\mathrm{C}(\mathrm{B}t) - K_\mathrm{C}(\mathrm{Ag}t) + 1] - (\mathrm{B}t) = 0 \tag{10}$$

Let

$$K_\mathrm{C}(\mathrm{B}t) - K_\mathrm{C}(\mathrm{Ag}t) + 1 = \mathrm{U} \tag{11}$$

then

$$(\mathrm{B}) = \frac{\mathrm{U} \pm \sqrt{\mathrm{U}^2 + 4K_\mathrm{C}(\mathrm{B}t)}}{2K_\mathrm{C}} \tag{12}$$

Derivation of the Rate Expression.—Assuming that only the free butene hydrates, the rate of disappearance is given by equation (13)

$$-\,\mathrm{d}(\mathrm{B}t)/\mathrm{d}t = k'(\mathrm{B}) \tag{13}$$

Combining (2) and (6)

$$(\mathrm{B}) = (\mathrm{B}t)/1 + K_\mathrm{C}(\mathrm{Ag}^+) \tag{14}$$

Combining (13) and (14)

$$-\frac{\mathrm{d}(\mathrm{B}t)}{\mathrm{d}t} = \frac{k'(\mathrm{B}t)}{1 + K_\mathrm{C}(\mathrm{Ag}^+)} \tag{15}$$

$$-S = -\frac{\mathrm{d}\ln(\mathrm{B}t)}{\mathrm{d}t} = \frac{k'}{1 + \mathrm{K_C}(\mathrm{Ag}^+)} \tag{16}$$

That is, the slope of the plot of ln (Bt) against t, which is the observed specific rate of disappearance of isobutene in silver nitrate solution, is related to k', the rate constant of hydration of free isobutene; equations 16, 12 and 7 permit the calculation of k'.

In case the complexed butene also is assumed to hydrate, the rate expression is

$$-\,\mathrm{d}(\mathrm{B}t)/\mathrm{d}t = k'_e(\mathrm{B}) + k''(\mathrm{BAg}) \tag{17}$$

and it may be shown that

$$k'' = -\frac{S\{1 + K_\mathrm{C}[(\mathrm{Ag}t) - (\mathrm{B}t) + (\mathrm{B})]\} - k'_e}{K_\mathrm{C}[(\mathrm{Ag}t) - (\mathrm{B}t) + (\mathrm{B})]} \tag{18}$$

Materials and Analytical Methods.—The isobutene was prepared in the manner previously described;[2] the carbon tetrachloride was purified with dichromate and sulfuric acid,[3] and the other chemicals used were of C. P. grade. Silver ion was precipitated by the addition of potassium bromide before adding the standard bromate solution. The precipitate of silver bromide did not interfere with the analytical procedure previously described.[2]

Distribution Measurements.—In a 2-liter flask provided with a mechanical stirrer was placed about 150 ml. of carbon tetrachloride; isobutene was passed through until a sufficient amount was dissolved. In those measurements involving aqueous solutions not containing silver nitrate, the flask was nearly filled with the aqueous phase and the two phase system, immersed in a thermostat at 25.00 ± 0.03°, was agitated for one and one-half hours. After standing for two hours the drops of carbon tetrachloride clinging to the surface were shaken down and samples of each phase were removed under pressure, using a pipet with three-way stopcock, as previously described.[2] The sample of the aqueous phase measured 100 ml., and of the carbon tetrachloride phase, either 3.149 ml. or 10.40 ml. When the aqueous phase contained silver nitrate, a smaller flask containing a smaller volume of the aqueous phase was used, and a smaller sample of this was taken for analysis.

Reaction Rate Measurements.—The solutions were prepared by nearly saturating an aqueous solution of silver nitrate and potassium nitrate with isobutene, and then adding the desired amount of standardized nitric acid to yield the final solution of known concentration of silver nitrate, nitric acid and potassium nitrate. The ionic strength was kept at 1 *N*. The rate measurements were carried out at 25° in the apparatus and according to the procedure previously described. The experimental data and calculated constants are shown in Table III. Two sets of data and constants are given for each run, *viz.*, a set of initial values and a set of subsequent values. These last are either the final ones for the run, or else, in case the final slope is not the best one, intermediate values. In all cases there is a marked decrease in butene concentration between the initial and later values.

The Rate Constants.—In Table III, in the eighth column under $-S$, are given the values of the observed rate constants. These were obtained by multiplying by 2.303 the slopes of the curves of runs 1 to 5 inclusive in Fig. 1; these are the plots of $\log_{10}(\mathrm{B}t) + 2$ against the time in hours. In the ninth column under k', are the

values of the reaction rate constant calculated by means of equation (16), and in the tenth column, under k_e', the values of the reaction rate constant which would be expected from the known rate of hydration of isobutene[2] in the absence of silver ion, at the same acidity and ionic strength. It is assumed, in calculating k_e', that silver ion and potassium ion are equivalent in regard to ionic strength.

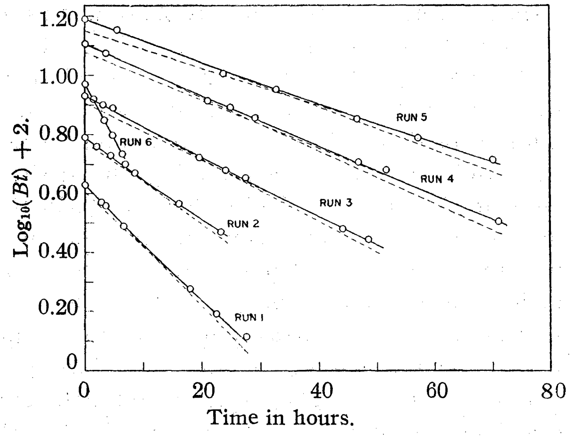

Fig. 1.

The fair constancy of k' at constant acidity and practically constant ionic strength (expts. 1 to 5), over a five-fold change in (B) and a three-fold change in (Ag^+), shows that the rate is first order with respect to uncomplexed butene. Because of the errors involved in taking slopes, the variations in k' are not significant. However, the average value of k', in experiments 1 to 5, is 0.652, whereas 0.499 is the average value of k_e'. Inspection of equation (16) shows that when (Ag^+) becomes zero, k' should be the rate constant in the absence of silver nitrate.

Equation (16) accounts for the observation that $-S$ is substantially inversely proportional to the silver concentration when (Ag*t*) exceeds (B*t*) by a factor of five or more. Also, in any given experiment, $-S$ gradually decreases because (Ag^+) is slowly increasing as the butene undergoes hydration.

The discrepancy between k' and k_e' (expts. 1 to 5) is not due to the hydration of the butene complex since the values of k'', eleventh column, Table III are not constant, but bear an inverse relationship to the concentration of silver ion. In calculating k'' by the use of equation (18), the value of k_e' shown in Table III were used. The discrepancy might be due to an error in K_C. In order for k' to agree with k_e', K_C would have to be smaller by about 25%. This is possible, for there is a slight trend in the values of K_C (Table II). They decrease slightly with a decrease in the ratio of (Ag*t*) to (B*t*). Since this ratio lies between 85 and 188 in the distribution experiments, and between 4.7 and 19 in the rate experiments 1 to 5, the trend in the values of K_C, if there is a trend, would tend to decrease the values of k'. This might account for the discrepancy between k' and k_e' when (Ag*t*)/(B*t*) is large, especially since, in experiment 6, where this ratio lies between 1.2 and 2.3, there is good agreement between k' and k_e'.

Summary

Isobutene and silver ion in aqueous solution form a complex ion for which the formula $C_4H_8Ag^+$ and the equilibrium constant $(C_4H_8Ag^+)/(C_4H_8)(Ag^+) = 61.7$, were determined by distribution measurements.

In 0.25 *N* nitric acid containing silver nitrate the amount of isobutene which hydrates in unit time, at a given concentration of total butene,

is much less than in the absence of silver nitrate, but is greater than corresponds to the amount of free butene. However, satisfactory rate constants were found when it was assumed that only the free butene present in the silver nitrate solution hydrates. The average value of the constants is greater than the known constant in the absence of silver ion. It is concluded that complexed butene does not hydrate.

The Analysis of Gamma-Fructoside Mixtures by Means of Invertase. V. Methylated and Acetylated Derivatives of Crystalline α-Methyl- and α-Benzylfructofuranoside[1]

BY C. B. PURVES AND C. S. HUDSON

The products obtained by the action of chemical reagents on fructose are in most instances complex mixtures not easily separable into their constituents by crystallization or by other methods. This circumstance adds greatly to the experimental difficulty of studying the chemistry of the ketose and in consequence also adds to the value of the few crystalline derivatives which have been prepared from it. The very readily hydrolyzed or gamma-methylfructoside isolated two years ago[2b] was a pure crystalline individual[3] and therefore provided a welcome new starting material for such studies, some of which are recorded in this article.

When the highly dextrorotatory tetramethyl derivative of the glycoside was hydrolyzed with aqueous acid, the less dextrorotatory liquid product was found to be tetramethyl fructofuranose.[4] These facts proved that the "crystalline gamma-methylfructoside" or the "glycoside c" of earlier articles[2b,5a,5b] was in reality α-methylfructofuranoside. The methylation of this substance was not easy. Silver oxide and methyl iodide with anhydrous dioxane as an initial solvent yielded fully methylated products with low and variable specific rotations in water (112, 118°) even after the removal of the methylated methyl esters which they contained (up to 17.6%). Dipotassium and tetrapotassium derivatives reacted very slowly and incompletely with methyl iodide even in the absence of liquid ammonia.[6] The satisfactory methylations, carried out with the help of thallous ethylate by a special method adapted from the work of Menzies,[7] gave tetramethyl α-methylfructofuranoside as a mobile liquid free from esters and with a specific rotation of 129.4° in water. An interesting liquid dimethylfructose, whose optical rotation passed through a minimum near 10° and whose methoxyl groups perhaps occupied the 3,4 positions, was prepared from the corresponding dimethyl α-methylfuranoside. The latter was an intermediate product in the thallous ethylate methylations.

A brief search for derivatives of the glycoside which might be of use in its separation from mixtures resulted in the discovery of tetraacetyl α-methylfructofuranoside in the form of crystals melting at 48–48.5° and having a specific dextrorotation of 88.1° in chloroform. The first crystals were obtained after long delay by acetylating the carefully purified glycoside with Liebermann's reagents but were subsequently prepared from sucrose. The fructofuranoside failed to form a sparingly soluble derivative with barium hydroxide or methylate and yielded no crystalline addition compound with alcoholic potassium acetate.[8] When equimolecular amounts of α-methylfructofuranoside and of hydrogen chloride were mixed in concentrated anhydrous dioxane solution, however, a white, gelatinous carbohydrate–hydrogen chloride addition compound immediately separated and at once began to decompose to a dark, copper reducing tar. Although this ill-defined and highly unstable complex was of a type new to sugar chemistry, such compounds have been inferred to exist as transitory inter-

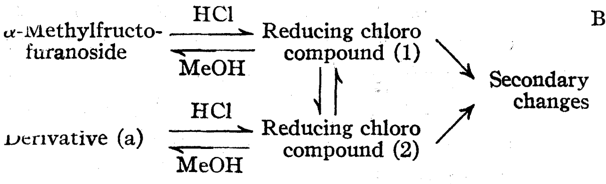
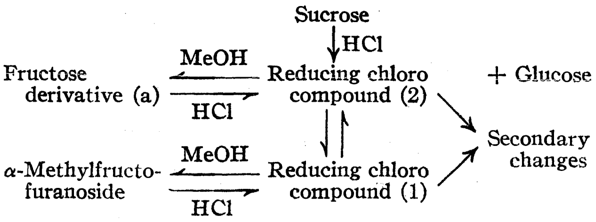
mediates in the transformations of glycosides dissolved in acid alcohols. Voss and Wachs[9] recently studied some aspects of the subject and discussed the relevant literature.

In the present case, no precipitate appeared when the dioxane solution was 0.0263 molar with respect to the glycoside and 0.025 normal with hydrogen chloride. The change with time both in the specific rotation (Fig. 1 Curve A) and in the copper reducing power of the solution (Fig. 1 Curve B) pointed to the occurrence of a complicated sequence of reactions. The maximum reduction attained, 49% of that theoretically possible, suggested that about half of the hydrogen chloride existed at this point as a copper-reducing chloro addition or substitution compound. After twenty-two hours at 20° almost half of the carbohydrate had been destroyed. The entire data supported the conclusion that a very rapid addition of hydrogen chloride to the fructofuranoside was followed by the formation of a highly unstable, copper reducing chloro compound. This partly decomposed and partly recombined with hydroxyl groups in the fructose molecule, thereby liberating hydrogen chloride which united with more of the glycosidic residues. These ideas supply an attractive explanation of the behavior of α-methylfructofuranoside in methyl alcoholic hydrogen chloride, when the starting material very rapidly attained an equilibrium with a second non-reducing gamma-fructose derivative (a) which was hydrolyzed by invertase[5a]

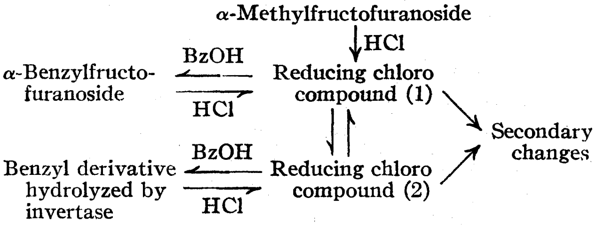


In this reaction the reduction was negligible throughout and the secondary changes were inappreciable for several hours. The concentration of intermediate chloro compounds was apparently restricted to a minute figure by an extremely rapid recombination with the large excess of methyl alcohol present. As shown in the scheme, this partial transformation of the glycoside suggested the nature of the primary equilibrium supposed to exist between the chloro compounds (1) and (2). Another example was drawn from the research already published[5b] concerning the scission of sucrose in methyl alcohol containing hydrogen chloride. The experimental data were consistent with the following set of reactions



A distinct optical exaltation was displayed by the sucrose–acid methyl alcoholic solution during the first few minutes. This was due possibly to the formation of a sucrose–hydrogen chloride addition compound.

If the above views on the mechanism of the interaction between α-methylfructofuranoside and methyl alcohol containing hydrogen chloride were correct, it was possible to use the fructoside in synthetical operations by substituting another hydroxylic compound for the methyl alcohol. Benzyl alcohol was chosen because it was expected to give crystalline derivatives of convenient solubility from which it might eventually be removed quantitatively, as toluene, by hydrogenation with palladium.[10] The following reactions were predicted in acid benzyl alcohol



The specific rotation of α-methylfructofuranoside in the new, acid solvent first decreased very rapidly and then much more slowly (Fig. 1, Curve C), the break in the curve (region C) signalizing the end of the primary change. The product isolated at this time included reducing substances (8 mol. % as fructose) and a new, non-reducing benzyl derivative (28 mol. %) which had a calculated specific levorotation of −27° in water and was hydrolyzed to fructose by the enzyme invertase. These two constituents were removed by a fermentation with yeast and α-benzylfructofuranoside (26.5 mol. %) was recovered as a crystalline tetraacetate from the unfermented portion of the product. By the end of the primary reaction, therefore, the origi-

nal gamma-methylglycoside had been largely replaced by a mixture of gamma-benzylglycosides.

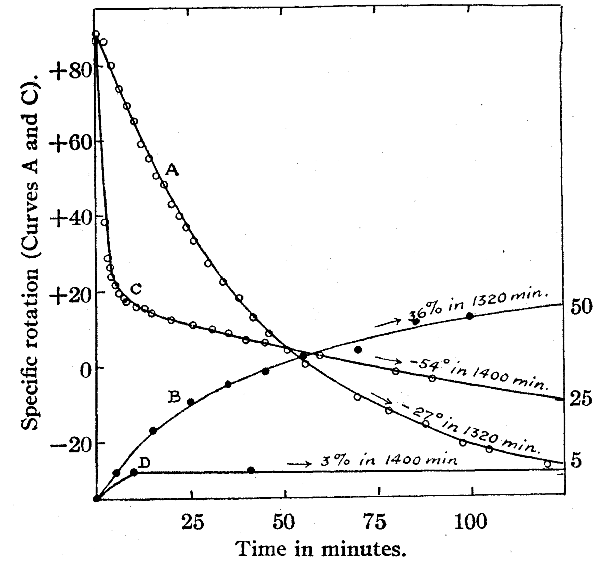

Fig. 1.—Action of hydrogen chloride on α-methylfructofuranoside: (A), specific rotation in dioxane; (B), copper reduction in dioxane; (C), specific rotation in benzyl alcohol; (D), copper reduction in benzyl alcohol.

The facts that the secondary optical change was fairly rapid and that a maximum copper reduction of 8 mol. % developed in the solution (Fig. 1, Curve D) suggested that labile chloro compounds accumulated as such in considerable amount and had time to undergo secondary transformations prior to recombination with the solvent.

Tetraacetyl α-benzylfructofuranoside was a beautifully crystalline substance melting at 84.5–85° and with a specific dextrorotation of 64.7° in chloroform. Deacetylation yielded α-benzylfructofuranoside as stout, rectangular tablets with a melting point of 89° and specific dextrorotations of 45.7 and 47.6° in water and dioxane, respectively. The new glycoside was hydrolyzed to fructose by aqueous acid 16.5 times more rapidly than sucrose but was unaffected by invertase or by yeast fermentation. When methylated with thallous ethylate it gave first a liquid dimethyl derivative and finally liquid tetramethyl α-benzylfructofuranoside with dextrorotations of 78.4° in dioxane and of 83.3° in chloroform. Scission of the latter with methyl alcoholic followed by aqueous hydrogen chloride resulted in an 80% yield of tetramethyl fructofuranose.[4] The isolation of the latter established the constitutions assigned to this series of benzyl derivatives.

The behavior of pure α-benzylfructofuranoside in benzyl alcoholic hydrogen chloride was similar to that of its methyl homolog in the same solvent. A very rapid primary decrease in specific rotation was followed by a fairly rapid secondary change (Fig. 2, Curve A) and was accompanied by the development of a substantial copper reduction (not plotted). The product isolated by arresting the reaction in the region A was submitted to the action of a powerful solution of invertase, which caused the copper reducing power of the mixture to increase from 12.4 mol. % to a final constant value of 44.8 mol. % as fructose. In Fig. 2, Curve C, the increase in the reduction at each time was plotted as a percentage of the total *enzymotic* increase, and from the curve the rate of hydrolysis was found to be about 5.1 times slower at each stage than the rate observed in an equivalent inversion of sucrose. A small initial exaltation in the optical rotatory power (Fig. 2, Curve B) paralleled the similar observation made during the partial hydrolysis of a gamma-methylfructoside mixture with invertase.[2a] The polarimetric and copper-reduction data enabled a specific levorotation of −27 ± 2° in water to be assigned to the non-reducing benzyl derivative unstable to the enzyme and the stable glycoside, with a dextrorotation of 41°, was mostly α-benzylfructofuranoside. The substrate hydrolyzed by

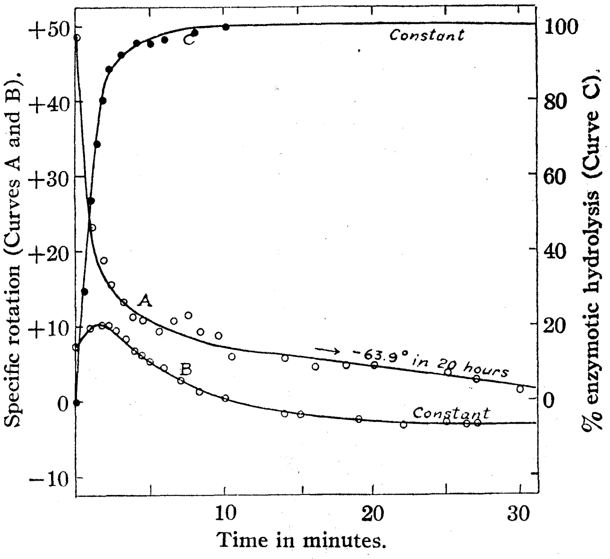

Fig. 2.—(A), Specific rotation of α-benzylfructofuranoside in acid benzyl alcohol; (B), hydrolysis of a gamma-benzyl fructoside mixture with invertase, specific rotation; (C), hydrolysis of the same gamma-benzy fructoside mixture with invertase, copper reduction, %.

invertase consisted of the benzyl and fructoside radicals because these alone were present during its preparation and the calculation assumed it to be a true benzylfructoside of molecular weight 270.

Experimental

Sodium light and a saccharimeter with a conversion factor of 0.3462° circular = 1° V. were used in the optical observations, which were made at 20° in a 2-dm. tube unless otherwise stated. Copper reducing power was expressed throughout as fructose. Previous articles[2,5] stressed the necessity of employing redistilled, anhydrous, acid-free solvents and of avoiding elevated temperatures whenever possible in the preparative work. They also described the method adopted in making up solutions containing hydrogen chloride and gave details of the analytical technique.

Preparation of a Liquid Dimethyl α-Methylfructofuranoside.—Fifteen grams of the pure, recrystallized α-methylfructofuranoside, dissolved in 50 ml. of 100% ethyl alcohol, were shaken vigorously for a few seconds with 100 ml. of 1.615 *N* ethereal thallous ethylate[11] (2 equivalents). The round-bottomed flask used was then attached to a ground-in reflux condenser through the top of which the solvents were thoroughly removed, finally in high vacuum. Access of atmospheric carbon dioxide was minimized during these operations, and the temperature restricted to that of the room or less. The dithallium derivative remaining in the flask as a pale yellow, friable powder was incorporated with 100 ml. of ether containing 15 ml. of methyl iodide (50% excess) before the mixture was warmed under the reflux condenser for six hours, or until a sample was no longer alkaline to moist litmus paper. Sometimes it was necessary to renew the methyl iodide, and to continue the heating. Four 50-ml. portions of ether extracted the product from the insoluble thallous iodide and when the solvent was removed from the combined extracts, finally at 40° in high vacuum, a nearly quantitative yield of a liquid dimethyl α-methylfructofuranoside remained.

Anal. Calcd. for dimethyl methylfructoside, $C_9H_{18}O_6$: C, 48.7; H, 8.1; OCH_3, 41.9. Found: C, 48.5; H, 8.3; OCH_3, 41.5.

The colorless dimethyl methylglycoside had a refractive index of $n^{20}D$ 1.4632 and the following specific dextrorotations: in chloroform, +94.0° (*C*, 1.565; V., +8.50°); in water, +111.4° (*C*, 1.6; V., +10.30°); in dioxane, +95.3° (*C*, 1.508; V., +8.30°). The aqueous solution was quite clear.

A Liquid Dimethyl Fructose.—A solution containing 3.78 g. of the above dimethyl methylglycoside in 0.1 *N* hydrochloric acid was hydrolyzed completely by fifteen minutes of heating at 100°. The product, 3.6 g., isolated by standard methods, had a refractive index of $n^{19}D$ 1.4768 and a methoxyl content of 29.3% (calcd. for dimethyl fructose, $C_8H_{16}O_6$: OCH_3, 29.8%). A 2.061% aqueous solution had a levorotation of −1.30° V. five minutes after solution, changing to a final constant value of −2.05° V. within two hours. These data corresponded to a mutarotation from $[\alpha]^{20}D$ −10.9° to $[\alpha]^{20}D$ −17.2°. At temperatures of 4, 10, 17, 30 and 45° the same solution displayed specific rotations of −16.8, −18.9, −18.1, −15.5 and −11.3°, respectively. The rotation therefore passed through a minimum in the neighborhood of 10°.

Tetramethyl α-Methylfructofuranoside.—The methylation of the dimethyl α-methyl derivative, 12.63 g., was carried out with 2 equivalents of ethereal thallous ethylate and 2.7 mols of methyl iodide in the way already described. Ether, 100 ml., was used in place of absolute alcohol as the initial solvent. The reaction was not quite complete (found: OCH_3, 58.0%) and a single treatment with silver oxide and methyl iodide was necessary before the product was distilled with high vacuum into a very well cooled receiver. The yield was 11.68 g. with a refractive index of $n^{20}D$ 1.4417 which was identical with that of the last drop.

Anal. Calcd. for tetramethyl methylfructoside, $C_{11}H_{22}O_6$: C, 52.8; H, 8.8; OCH_3, 62.0. Found: C, 52.9; H, 8.9; OCH_3, 61.4.

Tetramethyl α-methylfructofuranoside was a mobile, colorless liquid which gave a clear aqueous solution taking up no alkali and therefore containing no esters. Its specific dextrorotation was: +115.9° in chloroform (*C*, 2.279; V., +15.26°); +113.1° in dioxane (*C*, 2.120; V., +13.85°); and +129.4° in water (C, 2.6; V., +19.45°).

The methylated fructofuranoside, 4.45 g., was hydrolyzed and the tetramethyl fructofuranose produced was isolated and distilled by standard methods; yield 3.88 g. or 92%.

Anal. Calcd. for tetramethylfructose, $C_{10}H_{20}O_6$: C, 50.9; H, 8.5; OCH_3, 52.5. Found: C, 50.9; H, 8.7; OCH_3, 51.9.

Its refractive index, $n^{20}D$ 1.4517, and specific rotation in water, +28.1° initially to +29.8° finally, were in agreement with the accepted constants for this compound ($n^{13}D$ 1.4513; $[\alpha]D$ +31.3°).[4]

Preparation of Tetraacetyl α-Methylfructofuranoside from Sucrose.—A fermented, aqueous solution of α-methylfructofuranoside contaminated with glucofuranosides was prepared from 180 g. of sucrose by the method already published.[5b] A cautious evaporation of the neutralized solution (*p*H 8) without the addition of butyl alcohol left 65 g. of a thick sirup. This was acetylated by shaking at room temperature with 20 g. of anhydrous sodium acetate and 320 ml. of acetic anhydride and by heating the resulting solution for ninety minutes on the steam-bath. The water-soluble product, recovered by standard methods in a total of 600 ml. of neutral, dry benzene, was a thick, orange colored sirup weighing 100 g. Crude, nearly colorless tetraacetyl α-methylfructofuranoside, 92 g., passed into the receiver when this sirup was fractionated in high vacuum; bath 200–230°. A more accurate fractionation than that carried out would probably have rendered the following crystallization less difficult. Two volumes of water were added to one volume of a 20% solution of the distillate in methyl alcohol, the solution was cooled until it was definitely opalescent and the clear supernatant liquid was copiously nucleated in a separate vessel which was kept for three days at 0–5°; yield 35 g., increased to 40 g. by working up and redistilling the mother liquors and residues. A similar but easy re-

---

[11] Menzies, *J. Chem. Soc.*, 1571 (1930). Crude, moist thallous hydroxide was first prepared by adding the equivalent of baryta to a hot 15% thallous sulfate solution and by cautiously evaporating the filtrate.

crystallization left 36 g. or 38% of the calculated amount of the product in a pure condition. The sample for the rotations and analyses was dried in a vacuum over soda lime.

Anal. Calcd. for tetraacetyl methylfructoside, $C_{15}H_{22}O_{10}$: C, 49.7; H, 6.1; OCH_3, 8.6. Found: C, 49.5; H, 6.1; OCH_3, 8.6, 8.5.

In an acetyl estimation (Kunz' method)[12] 0.2043 g. required 22.6 ml. of 0.1 *N* alkali; calcd. 22.6 ml. The deacetylation of 2.64 g. by 100 ml. of anhydrous, 0.00068 normal methyl alcoholic barium methylate left 1.38 g. of pure α-methylfructofuranoside, with the correct specific rotation of +91.7° in methyl alcohol; calcd. 1.416 g.

The matted fine needles or large, well-built stout prisms of tetraacetyl α-methylfructofuranoside melted at 48–48.5°, dissolved in water and petroleum ether and were very soluble in the other common organic solvents. The compound had the following specific dextrorotations observed at 19°: +88.1° in chloroform (*C*, 4; V., +20.35°); +84.4° in dioxane (*C*, 4; V., +19.50°); +91.3° in methyl alcohol (*C*, 2.069; V., +10.92°); and +84.0° in water (*C*, 1; V., +9.70° observed in a 4-dm. tube).

The Carbohydrate–Hydrogen Chloride Addition Compound.—A 12.76% solution of α-methylfructofuranoside in warm dioxane was cooled to room temperature before 10 ml. was mixed quickly with 2 ml. of dioxane made 2.63 *N* with hydrogen chloride. The mixture was therefore 0.526 *M* with respect to both constituents. The white gelatinous fluid rapidly darkened in color as a difficult filtration gave a colorless filtrate the first portion of which, 4.7 ml., was diluted immediately to 25 ml. with water and analyzed. Found in the dioxane filtrate: HCl, 0.106 *M* by titration, 0.106 *M* as silver chloride; copper reduction as fructose, 0.038 *M*, increased to 0.052 *M* by a Herzfeld hydrolysis. By difference, the precipitate contained carbohydrate and hydrogen chloride in the molar ratio of 0.474:0.420 or of 1.13:1. The apparent deviation from an exact equimolecular ratio was probably due to the destruction of fructose in the filtrate prior to dilution with water.

Behavior of α-Methylfructofuranoside in Dioxane Containing Hydrogen Chloride.—The solution described in the caption to Table I was prepared and examined by usual methods. After 5, 15, 25, 35, 45, 55, 70, 85, 100, 125, 150, 175, 204 and 1320 minutes its copper reducing power was 6.3, 18.0, 25.4, 30.0, 33.8, 37.4, 39.1, 47.6, 48.6, 50.7, 47.6, 50.7, 47.6 and 36.0%, respectively, of the maximum possible (Fig. 1, Curve B). After 1320 minutes only 52.8% of the original fructose was estimated in a Herzfeld hydrolysis. The polarimetric observations given in Table I were made in a 4-dm. tube.

Action of Anhydrous Benzyl Alcoholic Hydrogen Chloride on α-Methylfructofuranoside.—Samples, 0.5 ml., of the solution described in the caption to Table II were prepared for the estimations of copper reducing power by discharge into 50-ml. volumes of 0.0003 *N* aqueous caustic soda containing 3% of methyl alcohol. After 0, 9.5, 41, 134, 204, 366, 488 and 1400 minutes these reductions were 0.0, 6.9, 7.9, 6.4, 5.9, 4.8, 4.6 and 3.0%, respectively, of the maximum calculated from the fructoside present (see Fig. 1, Curve D). The specific rotations in Table II were calculated as due throughout to methyl glycoside.

Preparation of Tetraacetyl α-Benzyl- from α-Methylfructofuranoside.—Ten grams of the finely divided methyl glycoside dissolved almost entirely when vigorously shaken for six minutes at 20° with 100 ml. of benzyl alcohol made 0.03 *N* with hydrogen chloride gas. After six minutes, the acid was neutralized quickly and completely with 2 g. of silver oxide and the pale yellow, silver-free filtrate was diluted with 200 ml. of benzene and 800 ml. of light petroleum. This dilution made it possible to recover 94% of the product from the mixed solvents by three extractions with 100 ml. volumes of water. The combined aqueous extracts were shaken once with ether and prepared for fermentation. Analysis: reduction 0.208%, increased to 0.900% by invertase and to 2.50% by a Herzfeld hydrolysis. Starch-free yeast, 1 g., fermented two components of the mixture and left unfermented 7.92 g. of gamma-benzyl

---

[12] Kunz and Hudson, THIS JOURNAL, **48**, 1982 (1926).

fructosides with a specific dextrorotation of 46.2° in water. Cold pyridine, 50 ml., and acetic anhydride, 50 ml., acetylated this sirup overnight. A recrystallization of the product from ether yielded 6.9 g. of sticky crystals with a specific rotation of +64.4° in methyl alcohol. A final recrystallization from 20 ml. of methyl alcohol gave 6.0 g. of pure tetraacetyl α-benzylfructofuranoside, corresponding to 26.5% of the methylfructoside used.

Anal. (Sample dried at 0.1 mm. and 55° for ten hours.) Calcd. for tetraacetyl benzylfructoside, $C_{21}H_{26}O_{10}$: C, 57.5; H, 5.9. Found: C, 57.4; H, 5.9. In an acetyl estimation, 0.2822 g. took 25.9 ml. of 0.1 *N* alkali. Calcd. for four acetyl groups, 25.8 ml.

The glycoside melted sharply at 84.5–85°, was insoluble in water, sparingly soluble in petroleum ether and soluble in other organic solvents. It separated from ether or hot methyl alcohol as stout flat prisms and occasionally as clusters of long needles from a cold dilute solution of the latter solvent. The following specific dextrorotations refer to 4% solutions: in methyl alcohol, +65.65° (V., +15.17°); in chloroform, +64.7° (V., +14.95°) and in dioxane +58.42° (V., +13.50°).

Preparation of α-Benzylfructofuranoside from its Tetraacetate.—Absolute barium methylate, 1.5 ml. of 2 *N*, added to 20 g. of the pure tetraacetate dissolved in 400 ml. of ice-cold, anhydrous methyl alcohol, was just sufficient to render the mixture definitely alkaline to phenol red. After standing overnight at 0°, the faintly yellow solution was evaporated at 0° (30 mm.) to a thick sirup which still contained the trace of unneutralized barium. This was removed by diluting the sirup with 400 ml. of boiling ether and filtering the warm solution through absorbent carbon. The filtrate quickly deposited 9.6 g. of stout, well-built rectangular tablets which adhered to the bottom and sides of the beaker. A further 0.9 g. obtained from the concentrated mother liquor brought the total yield of α-benzylfructofuranoside up to 85% of the theoretical.

Anal. Calcd. for a benzylfructoside, $C_{13}H_{18}O_6$: C, 57.8; H, 6.7. Found: C, 58.0; H, 6.8. A 1.50% solution in 0.25 *N* aqueous acid at 20° had, after complete hydrolysis, a reduction of 0.98% and a levorotation of −5.35°. Calcd. for fructose 1.00% and −5.34° V.

The compound was quite pure when isolated because fractional recrystallizations made by adding ether to a concentrated dioxane solution failed to change the following constants: melting point, 89°; specific dextrorotation in dioxane, +47.60° (*C*, 2; V., +5.50°) and in water, +45.70° (*C*, 2.5; V., +6.60°). α-Benzylfructofuranoside was almost insoluble in petroleum ether, was soluble in benzene and ether and dissolved freely in alcohols, water, and dioxane. Its reduction of the Shaffer–Hartmann alkaline copper reagent was inappreciable. A 1.25% solution of the benzyl gamma-fructoside in 1% aqueous acid sodium phosphate was mixed with a powerful invertase preparation. After twenty hours the mixture still inverted added sucrose rapidly but retained the original rotation and a zero reduction in measurements precise enough to have detected a hydrolysis of 2% with ease. Invertase therefore neither hydrolyzed the glycoside nor was inactivated by it.

Hydrolysis of α-Benzylfructofuranoside by Aqueous Acid.—The changes in the rotation and copper reducing power of a 1.5% solution in 0.25 *N* hydrochloric acid at 20° were followed as described in the case of the α-methyl glycoside.[5a] A unimolecular velocity constant of $10^4K = 72 \pm 1$ (in minutes and decimal logarithms), calculated from reduction data ranging from 8 to 92% hydrolysis, showed the hydrolysis to be 16.5 times more rapid than that determined for sucrose in the equivalent conditions (10^4K for sucrose = 4.3 ± 0.04). The optical observations simultaneously made on the α-benzylfructofuranoside solution corresponded to unimolecular coefficients which rose uniformly from $10^4K = 65.2$ (4.5% Hy.) to $10^4K = 76.8$ (13.8% Hy.). They then diminished steadily to $10^4K = 66.3 \pm 1$ (66.4–95.7% Hy.).

A Liquid Dimethyl α-Benzylfructofuranoside.—Four grams of the pure benzyl glycoside, m. p. 89°, dissolved at room temperature in 25 ml. of 100% ethyl alcohol, gave an immediate, amorphous, pale yellow precipitate of the dithallium derivative when 18.5 ml. of 1.66 *N* ethereal thallous ethylate was added (2 equivalents + 4% excess). The methylation was completed as in the case of the α-methyl glycoside and a nearly theoretical yield of a viscid, dimethyl α-benzylfructofuranoside, $n^{19}\text{D}$ 1.5145, was isolated.

Anal. (Sample heated at 30° in high vacuum.) Calcd. for a dimethyl benzylfructoside, $C_{15}H_{22}O_6$: C, 60.4; H, 7.4; OCH_3, 20.8. Found: C, 60.2; H, 7.6; OCH_3, 21.0.

The substance had a specific dextrorotation of $[\alpha]^{19}\text{D}$ +57.1° in dioxane (*C*, 1.243; V., +2.05°; L = 1).

Tetramethyl α-Benzylfructofuranoside.—The dithallium derivative of the above dimethyl α-benzyl glycoside was prepared as an amorphous white precipitate by adding 2.1 equivalents of ethereal thallous ethylate to 4.1 g. dissolved in 30 ml. of ether. After methylation the product was remethylated with 7 g. of silver oxide and 4 ml. of methyl iodide. Tetramethyl α-benzylfructofuranoside (yield 88%) was a somewhat viscid liquid with a refractive index of $n^{19}\text{D}$ 1.4900 after drying at 35° in a high vacuum.

Anal. Calcd. for tetramethyl benzylfructoside, $C_{17}H_{26}O_6$: C, 62.5; H, 8.0; OCH_3, 38.0. Found: C, 62.5; H, 8.2; OCH_3, 38.2. *Subs.* 0.1215 g. took 0.0 ml. of 0.1 *N* alkali so that esters were absent.

The substance had specific dextrorotations at 19° of +78.4° in dioxane (*C*, 2.134; V., +9.67°), of +83.3° in chloroform (*C*, 2.162; V., +10.40°) and of +78.8° in methyl alcohol (*C*, 1.29; V., +5.87°). It was insoluble in water but dissolved readily in organic solvents.

Hydrolysis of Tetramethyl α-Benzylfructofuranoside.—The benzyl group of the water-insoluble glycoside was first replaced by the methoxyl radical by solution (3.1 g.) in 72 ml. of 0.03 *N* methyl alcoholic hydrogen chloride at 19°. Fifteen hours later, when the specific rotation had diminished to a steady dextro value of 33.7°, calculated as benzyl fructoside, the resultant mixture of water-soluble tetramethyl gamma-methylfructosides and benzyl alcohol was isolated and hydrolyzed by aqueous acid in the usual way. Ether, 50 ml., extracted most of the benzyl alcohol (and 5% of the product) from the neutralized hydrolysate (80 ml.) and chloroform subsequently extracted crude tetramethyl fructofuranose; yield 91.3% after distillation. The product still contained some benzyl alcohol (found, OCH_3, 46.4%; $n^{19}\text{D}$ 1.4585) and was fractionated in high vacuum. The first fraction containing the alcohol was rejected (0.70 g.; n^{20}_D 1.4735) and the second fraction was practically pure tetramethyl fructofuranose (1.23 g. or 49%).

Anal. Calcd. for tetramethyl fructose, $C_{10}H_{20}O_6$: C, 50.9; H, 8.5; OCH_3, 52.5. Found: C, 51.0; H, 8.6; OCH_3, 50.3.

The refractive index and the specific rotation in water, n^{19}_D 1.4508 and $[\alpha]^{20}_D$ +29.8° (final value), respectively, were in good agreement with the constants accepted for tetramethyl fructofuranose (n^{13}_D 1.4513, $[\alpha]_D$ +31.3°).[4]

Behavior of α-Benzylfructofuranoside in Benzyl Alcoholic Hydrogen Chloride.—After 0, 1.3, 2, 2.5, 12.7, and 1560 minutes the copper reducing power of the solution described in the caption to Table III was 0, 4.4, 6.5, 7.8, 22.1 and 5.1%, respectively, of the maximum possible from the fructose glycoside present. These reductions were determined by discharging 0.5-ml. samples into Shaffer–Hartmann boiling tubes each containing 1 ml. of a mixture of purified dioxane (5 parts) and 0.1 *N* aqueous caustic soda (1 part). Water, 3.5 ml., was added to each before the estimation, which was of less than usual accuracy. A 1-dm. polarimeter tube was used in the optical observations.

[a] See Fig. 2, Curve A. [b] See Table I, note *b*.

Partial Hydrolysis of a Benzyl-furanoside Mixture with Invertase.—A solution consisting of 2.00 g. of α-benzylfructofuranoside dissolved in 25 ml. of anhydrous 0.01 *N* benzyl alcoholic hydrogen chloride was observed at 23° for twelve minutes on the saccharimeter or until its specific dextrorotation had decreased to +9.5° (Fig. 2, Curve A, region A). The acid was neutralized thoroughly with silver oxide after fourteen minutes, and the product recovered in 40 ml. of water containing 4 ml. of 2% sodium hydrogen phosphate.[13] This faintly acid solution (*p*H 4.5) had an observed dextrorotation of +1.98° and a copper reduction of 0.392%, increased to 3.15% by a Herzfeld hydrolysis. These values were unchanged after twenty hours at 23°. An equal volume of powerful invertase solution was then added and the consequent changes in optical rotation observed in a 4-dm. tube (Table IV). The specific rotations were calculated as entirely due to $[(3.15/2) \times (3/2)]$ or 2.36% of benzylfructoside and the increase in the copper reductions was expressed as a percentage of the maximum hydrolysis *caused by the enzyme.* After 0.5, 1, 1.4, 1.75, 2.25, 3, 4, 5, 6, 8 and 10 minutes the hydrolysis was 29.6, 53.8, 68.9, 80.9, 88.7, 92.2, 95.5, 95.5, 96.7, 98.4 and 100%, respectively (Fig. 2, Curve C). The corresponding velocity coefficients, calculated for a unimolecular reaction, increased from $10^4K = 50.8$ (0.5 min.) to $10^4K = 70.1$ (2.25 min.) and subsequently diminished.[13]

TABLE IV

PARTIAL ENZYMOTIC HYDROLYSIS OF A GAMMA-BENZYL FRUCTOSIDE MIXTURE. OPTICAL ROTATIONS AT 23°[a]

Min.	V.°, obsd.	$[\alpha]^{23}_D$	Min.	V.°, obsd.	$[\alpha]^{23}_D$
0	+1.98[b]	+7.3	8.2	0.36	1.3
1	2.71	9.9	10	+ .06	+0.2
1.7	2.76	10.1	14	− .43	−1.6
2.2	2.76	10.1	15	− .50	−1.9
2.7	2.58	9.5	19	− .69	−2.5
3.3	2.26	8.3	22	− .86	−3.1
4	1.96	6.9	25	− .79	−2.9
4.4	1.68	6.1	26.3	− .84	−3.1
5	1.48	5.4	27	− .84	−3.1
5.7	1.16	4.3	35	− .89	−3.3
7	0.73	2.7	1200[c]	− .87	−3.2

[a] See Fig. 2, Curve B. [b] Observed separately in absence of enzyme. [c] The solution had an acidity of *p*H 4.4 and the enzyme still actively hydrolyzed added sucrose.

Specific Rotations of the Benzyl Derivatives Hydrolyzed and Unhydrolyzed by Invertase.—The initial solution after dilution with an equal volume of enzyme had a dextrorotation of +1.98° in a 4-dm. tube and a reduction of 0.195% as fructose. At the end of the enzymotic hydrolysis the levorotation was −0.87°, observed in a 4-dm. tube, and the corresponding reduction was 0.705%. Further hydrolysis with 0.33 *N* hydrochloric acid at 23° reduced the rotation to −16.49° (L = 4) and increased the reduction to 1.575%, corresponding to a correct specific rotation of −90.6° for the fructose produced. These data, in conjunction with the fact that a 1% solution of the ketose in water at 23° had a levorotation of −10.40° (L = 4), made it possible to calculate[2a] that the specific rotation of the benzyl derivative hydrolyzed by invertase was −27.7° in water while a rotation of +41.0° could be assigned to the non-reducing benzylfructofuranosides stable to the enzyme. These specific rotations were found to be −27.4° and +40.0°, respectively, in an independent experiment carried out at 20°.

The molar composition of the gamma-benzyl fructoside mixture isolated from the acid benzyl alcohol near point A (Fig. 2, Curve A) was also calculated to be approximately: fructose in a reducing condition, 12.4%; non-reducing derivative hydrolyzed by invertase, 32.4% and non-reducing derivatives stable to invertase, 55.2%. The derivative hydrolyzed by invertase was 0.0283 molar in the solution examined.

Comparative Enzymotic Hydrolysis of Sucrose.—The same invertase solution as used above was mixed at 23°

---

(13) See preparation of tetraacetyl α-benzyl- from α-methylfructofuranoside.

with an equal volume of an aqueous 1.938% sucrose solution carefully buffered to *p*H 4.4. The copper reduction of the resulting 0.0283 *M* mixture was plotted against time and the unimolecular velocity constants were calculated for 30, 40, 50, 60, 70, 80, and 90% inversion. These constants were, respectively, 5.31, 5.50, 5.31, 4.89, 4.74, 4.72, and 5.39 times greater than those determined at similar stages in the enzymotic hydrolysis of the gamma benzylfructoside mixture. Invertase therefore hydrolyzed a constituent in the latter approximately 5.1 times more slowly than sucrose.

One of the authors (C. B. P.) desires to thank the Chemical Foundation of New York for a Research Associateship.

Summary

1. Crystalline α-methylfructofuranoside, m. p. 80.5–81° and $[\alpha]^{20}\text{D}$ +93.0° in water, gave a new crystalline tetraacetate, m. p. 48–48.5° and $[\alpha]^{20}\text{D}$ +88.1° in chloroform, which was also prepared directly from sucrose.

2. An unstable, amorphous α-methyl glycoside–hydrogen chloride addition compound was precipitated when the constituents were mixed in anhydrous dioxane. The course of the subsequent decomposition was followed in more dilute solution both polarimetrically and by means of the copper reducing power. The behavior of gamma-fructosides dissolved in acid alcohols was in consequence assumed to depend on the formation of reducing, chlorine-containing substances which underwent change prior to their re-condensation with the solvent.

3. α-Methylfructofuranoside, when dissolved in benzyl alcoholic hydrogen chloride, was replaced very rapidly by a mixture of benzyl gammafructosides. Pure α-benzylfructofuranoside, m. p. 89°, $[\alpha]^{20}\text{D}$ +45.7° in water, was isolated from this mixture in the form of its crystalline tetraacetate, m. p. 84.5–85°, $[\alpha]^{20}\text{D}$ +64.7° in chloroform. Aqueous acid hydrolyzed the unsubstituted α-benzyl glycoside 16.5 times more rapidly than sucrose but it was unaffected by invertase.

4. Benzyl alcoholic hydrogen chloride partially converted α-benzylfructofuranoside into another non-reducing benzyl derivative of gammafructose which was not isolated. This benzyl derivative was hydrolyzed by invertase 5.1 times more slowly than sucrose. It had a specific levorotation of $[\alpha]^{20}\text{D}$ $-27 \pm 2°$ in water, calculated on the assumption that it possessed the molecular weight of a true benzylfructoside.

5. The constitutions of the crystalline α-methyl- and α-benzylglycosides described above were established by the methylation method. Tetramethyl α-benzyl- and α-methylfructofuranosides were liquids with refractive indices of $n^{19}\text{D}$ 1.4900 and $n^{20}\text{D}$ 1.4417, respectively, and with specific dextrorotations in chloroform of $[\alpha]^{19}\text{D}$ +83.3° and $[\alpha]^{20}\text{D}$ +115.9°, respectively. Both gave tetramethyl fructofuranose when hydrolyzed with aqueous acid.

6. Fear and Menzies' method of methylation with thallous ethylate and methyl iodide gave satisfactory results in the preparations described in (5).

The Cleavage of Side Chains in Aromatic Hydrocarbons in the Form of Paraffins by Means of Aluminum Chloride[1]

BY V. N. IPATIEFF AND HERMAN PINES

In the course of the study of polymerization of olefins,[2] alkylation[3] and depolyalkylation[4] of aromatic hydrocarbons, one of the chief difficulties in the identification of the reaction products was the lack of an adequate method for determining the structure of the alkyl group attached to the aromatic ring. It was tried[5] by a destructive hydrogenation method to convert the alkyl group to the corresponding paraffinic hydrocarbon. It was possible by this method to obtain methane and benzene from toluene; ethane and benzene from mono- and polyethylbenzene. However, in the case of propyl and butylbenzenes, the alkyl group was decomposed yielding methane, ethane and some propane. The

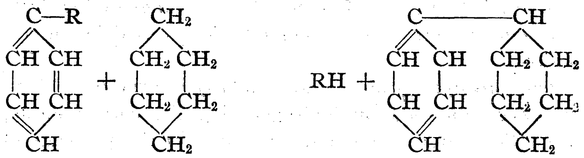
[5] Ipatieff and Pines, in publication.

destructive hydrogenation method, therefore, could not be used for the identification of alkylated aromatic hydrocarbons.

During the study of the behavior of different hydrocarbons in the presence of aluminum chloride, it was decided to investigate whether an alkyl group in an alkylated benzene could migrate and attach itself to cyclohexane to give alkylcyclohexane. The migration of alkyl groups from aromatics to naphthenes was not observed to take place. An interesting fact, however, was noticed, namely, when an alkylbenzene is heated with cyclohexane, the alkyl group is split off to yield the corresponding paraffin. Propyl-, *s*-butyl-, *t*-butyl- and *t*-amylbenzene when heated with cyclohexane in the presence of aluminum chloride yield, respectively, propane, butane, isobutane and isopentane. The hydrogen necessary to hydrogenate the alkyl group to the corresponding paraffin comes from the interaction of the two cyclic compounds: aromatic and naphthenic. This could be written schematically as follows



Isopropylbenzene alone does not yield propane under similar conditions; tertiary butylbenzene, however, yields isobutane and high boiling products.

The reaction written above is not the only one which occurs. In the case of isopropylbenzene and cyclohexane, besides propane and phenylcyclohexane, the following products were identified: methylcyclopentane, benzene, *p*-diisopropylbenzene and a product corresponding to cyclohexylisopropylbenzene or methylcyclopentylisopropylbenzene.

The yield of paraffin gases formed from the cleavage of aromatic side chains depends on two factors: (1) the structure of the alkyl group, and (2) the ease with which the cycloparaffin gives off hydrogen.

It was found that the alkyl group of isopropylbenzene splits off with more difficulty in the presence of monosubstituted cyclohexane than in the presence of cyclohexane; disubstituted cyclohexanes such as *p*-methylisopropylcyclohexane do not cause the cleavage of the alkyl groups in isopropylbenzene. Semi-quantitative determinations have shown that the ease of cleaving the isopropyl group from isopropylbenzene decreases with the substitution in the cyclohexane ring.

It was found that decahydronaphthalene facilitates the cleavage of the alkyl group in alkylated benzene. The product obtained from this reaction contains among others a compound corresponding to decahydronaphthylbenzene, which shows the origin of the hydrogen necessary to reduce the alkyl groups to paraffin.

The following tabulation gives the approximate yield of paraffin formed from the reaction between alkylated aromatics with cyclohexane and decahydronaphthalene.

		Naphthene hydrocarbon used	
		Cyclohexane	Decahydronaphthalene
	Paraffin formed		
Aromatic hydrocarbon used	Kind	Yield, %	Yield, %
Toluene	None	0	0
Ethylbenzene	None	0	0
Isopropylbenzene	Propane	33	53
s-Butylbenzene	Butane	35	71
t-Butylbenzene	Isobutene	61	94
s-Amylbenzene	Isopentane	60	..

The above tabulation shows that a tertiary butyl group splits off more easily than a secondary butyl group and that the latter splits off still more easily than an isopropyl group. Ethyl and methyl groups do not split off under the same conditions. The relative instability of the alkyl groups attached to the benzene ring is the same as that which we would predict from Kharasch's table of the relative electro-negativity of organic radicals.[6]

The method of cleaving alkyl groups from aromatic hydrocarbons could serve as a means for a direct measurement of the relative stability of the bond between the alkyl and phenyl radicals in alkylated aromatic hydrocarbons; it would also be possible to determine by this method the effect of different substituents on the relative stability of this bond. This method could also be used for direct measurement of the relative stability of the carbon–hydrogen bond in cyclic compounds like cyclohexane, decahydronaphthalene and possibly in some paraffinic hydrocarbons. By this method it was found that substitution increases the stability of the carbon–hydrogen bond in the cyclohexyl ring. The tabulation given above has also demonstrated that the carbon–hydrogen bond in decahydronaphthalene is less stable than in cyclohexane.

(6) (a) Kharasch and Grafflin, THIS JOURNAL, **47**, 1948 (1925); (b) Kharasch and Marker, *ibid.*, **48**, 3130 (1926); (c) Kharasch and Flenner, *ibid.*, **54**, 674 (1932).

An important application of the above mentioned reaction is its use in determining the structure of alkyl groups attached to an aromatic nucleus. It is important to keep the temperature of the reaction below 80°, since at higher temperatures partial decomposition of the hexamethylene ring to isobutane takes place.

It is worth while to mention here that alkylated cyclohexane when treated under similar conditions with cyclohexane or benzene does not yield paraffinic hydrocarbons. It seems that alkyl groups are much more strongly attached to a hexamethylene ring than to a phenyl ring.

In order to split the side chains from alkylnaphthenes, it is necessary to raise the temperature to 90° or higher; under these conditions, however, the hexamethylene ring decomposes, yielding isobutane.

The same type of reaction as mentioned above takes place when olefins are treated with benzene in the presence of cyclohexane or decahydronaphthalene and aluminum chloride. It seems that alkylation of aromatic hydrocarbons takes place first, which in the presence of cyclohexane dealkylate to give paraffins. *n*-Butene under these conditions yielded *n*-butane, while diisobutene or di-*n*-butene yielded isobutane. The last two experiments show that under these conditions depolyalkylation has taken place. In the case of di-*n*-butene, the depolyalkylation was accompanied by isomerization. The detailed results obtained from the action of olefins on cyclic hydrocarbons will be reported in another paper.

The reactions described in this paper are intended to be studied with other alkylating and polymerizing catalysts.

Apparatus and Procedure.—The apparatus consisted of a 250-cc. flask provided with a dropping funnel, mercury sealed stirrer, reflux condenser and an inlet tube for the hydrogen chloride. Ground glass joints were used throughout. The gases formed were collected in a calibrated trap (100-cc. capacity) cooled to −78° by means of a mixture of carbon dioxide and acetone. The non-condensable gases, if any, were collected in a gas bottle over salt water.

Aluminum chloride and the naphthene or decahydronaphthalene were placed in the flask, and a stream of nitrogen was passed to sweep out the air; a slow stream of hydrogen chloride was passed in and the flask was heated to the desired temperature by means of a water-bath. The aromatic hydrocarbons were then introduced. The gases evolved were submitted to a fractional distillation in a low temperature Podbielniak apparatus. The contents of the flask after the reaction consisted, in most cases, of two layers; the upper hydrocarbon layer was washed with 10% solution of sodium hydroxide followed by water, dried over calcium chloride and distilled. The lower aluminum chloride layer was decomposed with ice, neutralized with sodium hydroxide solution, dried and distilled.

Materials.—Toluene, xylenes, ethylbenzene and cyclohexane were obtained from the Eastman Kodak Company.

Isopropylbenzene, *s*-butylbenzene, *t*-butylbenzene and *s*-amylbenzene were obtained by treating propene, *n*-butene, isobutene and isopropylethylene, respectively, with benzene using 96% sulfuric acid as the catalyst.[7] In the case of alkylation of benzene with the last two olefins, the chief product formed was the dialkylbenzene which was dealkylated to the mono-substituted benzene by treating it with benzene in the presence of ferric chloride.[8] The aromatic hydrocarbons used had the following boiling ranges and indices of refraction:

Hydrocarbon	B. p., °C.	n^{20}D
Isopropylbenzene	151–152	1.4922
s-Butylbenzene	170–171	1.4901
t-Butylbenzene	168–169	1.4912
s-Amylbenzene	188–190	1.4932

Decahydronaphthalene was obtained from the Eastman Kodak Co. This product was stable toward a nitrating mixture, indicating the absence of naphthalene or tetrahydronaphthalene. The product was redistilled several times and the fraction having a boiling range of 187–189° and index of refraction n^{20}D of 1.4745 was used for the reaction.

Isopropylcyclohexane and *p*-methylisopropylcyclohexane were obtained by hydrogenating the corresponding aromatic hydrocarbons under pressure in the presence of nickel.

Experimental Data.—The conditions under which the experiments were carried out and the results obtained are given in Table I.

As an example of the type of products which are obtained, two experiments will be discussed in detail.

Experiment No. 4. Isopropylbenzene-Cyclohexane-Aluminum Chloride-Hydrogen Chloride. Hydrocarbon Layer.—The boiling range of the hydrocarbon layer was as follows:

B. p., °C.	% by weight
76–80	54
150–200	14
200–250	20
250–285	8
Above 285	3

The different products were redistilled and the following fractions isolated.

Fraction 76–80° contains 13.5% of benzene. This was determined by treating the fraction with fuming sulfuric acid (15% SO_3). The remaining compounds consisted of cyclohexane with pure methyl cyclopentane.

Fraction 140–166°, n^{20}D 1.4909, was completely soluble in 15% fuming sulfuric acid. This indicates the absence of alkyl cyclohexane.

Fraction 202–204°, n^{20}D 1.4907, corresponds to *p*-diisopropylbenzene. Calcd. for $C_{12}H_{18}$: C, 88.89; H, 11.11; mol. wt., 161. Found: C, 88.77; H, 11.18; mol. wt., 162.

10	*s*-Butylbenzene	40	62	15	80	3:00	4790	*n*-Butane	98	69.4	38.6
11	*i*-Butylbenzene	40	62	15	60–78	1:15	6450	*i*-Butane	98	57.9	46.4

[a] Negligible amount of methane and ethane was formed.

The oxidation of the fraction by means of dilute nitric acid (1:2.5) yielded terephthalic acid, which when converted to dimethyl terephthalate yielded a crystalline product with a melting point of 138°.

Fraction 239–245°, $n^{20}D$ 1.5191, probably contains a mixture consisting of triisopropylbenzene and phenylcyclohexane or phenylmethylcyclopentane. Calcd. for C_6H_5-C_6H_{11}: C, 90.0; H, 10.0; mol. wt., 184; $n^{20}D$, 1.5275. Calcd. for $C_6H_3(C_3H_7)_3$: C, 87.9; H, 12.1; mol. wt., 204; $n^{20}D$, 1.4929. Found: C, 89.3; H, 10.42; mol. wt., 174. On the basis of organic analysis and molecular weight determinations and index of refraction, it seems that the product consists of a mixture composed of 30% triisopropylbenzene and 70% of phenylcyclohexane.

Use of the dehydrogenation method, conversion of phenylcyclohexane to diphenyl is contemplated for proving the presence of the latter.

Fraction 275–280°, $n^{20}D$ 1.5170, corresponds to isopropylcyclohexylbenzene. Calcd. for $C_3H_7C_6H_4C_6H_{11}$: C, 89.11; H, 10.89; mol. wt., 202. Found: C, 89.19; H, 10.92; mol. wt., 207.

Catalyst Layer.—The aluminum chloride layer after being decomposed, washed and dried, weighed 11 g. It was submitted to a fractional distillation.

B. p., °C.	% by weight
75–78	27
78–148	6
148–250	19
250–315	21
315–360	10
Above 360	12

The index of refraction of the different fractions corresponded very closely to the index of refraction of the hydrocarbon layer.

Fraction 275–285°, $n^{20}D$ 1.5232, corresponds to isopropylcyclohexylbenzene. Calcd. for $C_3H_7C_6H_4C_6H_{11}$: C, 89.11; H, 10.89; mol. wt., 202. Found: C, 89.50; H, 10.42; mol. wt., 206.

Experiment 11. *t*-Butylbenzene-Decahydronaphthalene-Aluminum Chloride-Hydrogen Chloride. Hydrocarbon Layer.—After washing and drying it weighed 51.05 g. The following is the distillation range of the product.

B. p., °C.	% by weight
82–94	9.6
94–160	1.5
160–200	54.5
200–250	6.0
250–320	20.0
Bottoms	8.4

On redistillation the several fractions were separated.

Fraction 82–94° consisted of benzene.

Fraction 185–190°, $n^{20}D$ 1.4697, stable toward a nitrating mixture; organic analysis shows that it corresponds to decahydronaphthalene. Calcd. for $C_{10}H_{18}$: C, 86.97; H, 13.04; mol. wt., 138. Found: C, 87.14; H, 13.14; mol. wt., 136.

The index of refraction of this fraction was lower than that of the original product. This indicates that isomerization has taken place. Whether this is the case of *cis-trans* isomerization or whether the six-membered rings isomerize into five-membered rings as in the case of cyclohexane, is being investigated.

Fraction 300–310°, $n^{20}D$ 1.5330. This product corresponds to decahydronaphthylbenzene. Calcd. for $C_{10}H_{17}$-C_6H_5: C, 89.72; H, 10.28; mol. wt., 214. Found: C, 89.38; H, 10.62; mol. wt., 205; d^{20}_4, 0.9696.

Aluminum Chloride Layer.—The catalyst layer was decomposed, washed, dried and distilled.

B. p., °C.	% by weight
80–90	10.5
90–180	5.0
180–230	15.5
230–330	7.4
Bottoms	62.1

The product was redistilled and the index of refraction of the different fractions is the same as for the corresponding ones of the upper layer.

Acknowledgment.—The authors thank Mr. Bruno Kvetinskas for assistance in the experimental work.

Summary

When alkylbenzenes are heated with cyclohex-

ane or decahydronaphthalene in the presence of aluminum chloride catalyst, the alkyl groups are split off to yield the corresponding paraffins.

The relative stability of different alkylbenzenes is reported.

Various applications of this reaction are proposed.

The Thermal Decomposition of Gaseous Silicon Tetramethyl

BY DAVID F. HELM AND EDWARD MACK, JR.

In a previous paper[1] a study was made of the thermal decomposition of gaseous germanium tetraethyl. In the present paper the same type of study has been made of silicon tetramethyl. We have found that silicon tetramethyl gives a homogeneous decomposition which is unimolecular down to pressures of about 10 cm. In the case of germanium tetraethyl, over the temperature range employed, 420–450°, the products of the decomposition were a bright mirror-like deposit of germanium on the walls of the reaction vessel and a gas phase of essentially the same composition as the products obtained from the pyrolysis of *butane* at these temperatures. Whereas in the case of the more stable silicon tetramethyl it was necessary, to obtain a conveniently measurable rate of decomposition, to work at a much higher temperature, 660–720°, a sooty deposit was formed, consisting of silicon *and carbon*, and the gaseous products resembled closely those obtained from the pyrolysis of *ethane* at these temperatures.

Experimental

Silicon tetramethyl was prepared with the Grignard reaction by a method analogous to that employed[2] by Dennis and Hance for making germanium tetramethyl. The fraction of the purified product saved for use had a boiling point of 26.30 ± 0.05°.

The course of the decomposition was followed by three different manometer techniques, all of which gave substantially the same results. These included (1) a direct manometric method which was later abandoned in favor of (2) pointer membrane manometers and (3) clicker type null pressure gages. The pointer manometers were used in the same way as those described by Geddes[1] and Mack. Clicker gages were mounted outside the furnace and connected to the reaction vessel and the manometer line in the usual manner.

In the fairly high temperature range, 660–720°, it was necessary that fuzed quartz reaction chambers be used rather than Pyrex. Constant temperature inside a heavily lagged electric furnace was maintained within 0.3° with a platinum resistance thermometer wound near the heating coils and with an automatic controlling mechanism similar to that described by Scott and Brickwedde.[3]

Treatment of Data

The data for a typical run (No. 33) are given in Table I. This decomposition was carried

through at 678.7° with a membrane manometer. Inspection of the velocity constants computed from the time intervals shows that, after temperature equilibrium had been established, deviations are reasonably small. There is a small but definite drift downward in the value of the velocity constant toward the end, as is usually observed in such reactions. It is probably to be ascribed, at least in part, to the effect of the relatively large proportion of products on the small fraction of remaining silicon tetramethyl.

It was our uniform practice to compute the velocity constant for the interval from 0.4 to 0.8 completed and to consider this the constant for the run. The velocity constant for run No. 33 in Table I consequently is taken as 0.00133 sec.$^{-1}$. The ratio of the pressures (room temperature) before and after the decomposition was found to be 3.01; its close equivalent, P_∞/P_0, was 2.95.

Table II gives data for decompositions, at various pressures, all carried out at 689°. The method employed is given as (P) for pointer membrane and (C) for clicker system.

TABLE II

DATA FOR DECOMPOSITIONS AT 689°

Run	Method	P_0, cm.	P_∞/P_0	k, sec.$^{-1}$	
2	P	43.8	2.98	0.00188	Av. 0.00198
4	P	27.0	2.61	.00203	
8	P	25.1	3.00	.00210	
9	P	36.8	2.87	.00180	
10	P	32.5	2.92	.00193

16	P	23.1	3.03	.00202	
52	P	35.5	2.90	.00188	
51	P	15.3	3.20	.00212	
47	P	13.5	2.98	.00220	
75	C	12.6	..	.00182	
46	P	7.8	3.45	.00215	
76	C	7.7	..	.00188	
77	C	7.5	..	.00193	
45	P	7.4	3.25	.00222	
78	C	6.9	..	.00205	
50	P	5.8	2.79	.00217	
44	P	4.0	3.89	.00232	
79	C	3.68	..	.00200	
42	P	3.58	3.95	.00245	
80	C	3.3	..	.00198	
43	P	3.12	3.39	.00233	
81	C	1.48	..	.00210	
82	C	1.22	..	.00215	
49	P	0.85	..	.00225	
83	C	.44	..	.00207	
13	P	27.3	2.93	.00195	Av. 0.00204 (Surface increased 40–50 times)
14	P	25.7	3.46	.00212	
15	P	33.8	3.42	.00205	

The separate velocity constants calculated over short time intervals during any one decomposition are in fairly good agreement if the initial pressure, P_0, is high, and show a falling off only in the last quarter of the run. When the initial pressure is low the constants show a rapid falling off during the run, indicating that a unimolecular reaction is not being followed strictly. This second type of behavior begins to be apparent in the vicinity of 10 cm. initial pressure. A final average for the unimolecular constant is taken for P greater than 13 cm. (Below 10 cm. initial pressure the average k for a run was close to that for higher pressures but it was the mean of a rapidly descending series of values.) No critical pressure could be found below which the specific reaction rate was even reasonably constant throughout the run and lower than that secured at high pressures. The break predicted by the Lindemann theory seems lost as the unimolecular rate fades gradually into a higher order reaction with decreasing pressure.

At the bottom of Table II, the complete homogeneity of the reaction is shown by the results of Runs 13, 14, 15, in which the exposed surface area in the reaction vessel was increased 40–50 times by addition of quartz fibers, without a significant change in the velocity constant. A wall reaction may well play a significant role at low pressures, however.

The data for a typical low pressure run are

TABLE III

TYPICAL DECOMPOSITION AT LOW PRESSURE (689°)

Time, min.	Pressure, P	$P_\infty - P$	k, sec.$^{-1}$ Unimolecular	k', sec.$^{-1}$ Bimolecular

43.50	43.60			
54.00	43.97			
74.42	44.35			
97.0	44.60 = P_∞			

given in Table III. The data were secured with a clicker system and a heavy walled quartz reaction vessel to avoid appreciable loss of hydrogen by diffusion. Pressures were measured in cm. of ethyl phthalate and the initial pressure (P_0) is taken as $^1/_3\ P_\infty$ or 14.9 cm. ethyl phthalate or 1.22 cm. of mercury.

Velocity constants when computed on both a uni- and a bimolecular basis are about equally unsatisfactory, and indicate an order of reaction between the two.

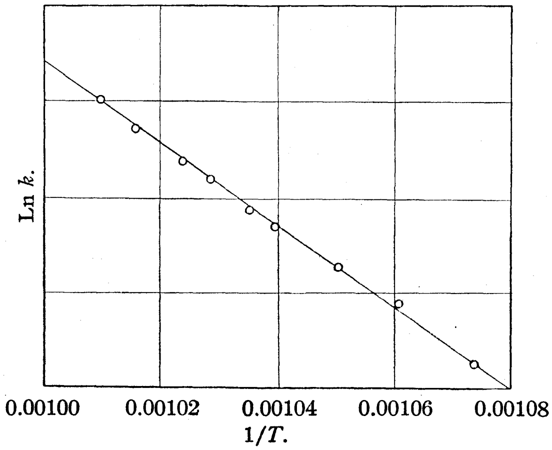

Fig. 1.

The variation of the velocity constant with temperature is shown in Table IV, and the plot of ln k against $1/T$ is given in Fig. 1.

Table IV

Temperature Coefficient Data

No. of runs	Temp., °C.	Av. k, sec.$^{-1}$
3	717	0.00672
3	711	.00520
3	704.6	.00380
10	700	.00320
13	693	.00233
10	689	.00198
6	679	.00134
5	669.2	.000847
3	659	.000527

The velocity constant as a function of temperature is given by the equation

$$\ln k = 35.03 - 78{,}800/RT$$

The energy of activation for the reaction is hence 79,000 cal. with a possible error of several thousand calories.

Analysis of Gaseous Products

In three cases after decomposition had been completed the vapor phase was pumped off and analyzed in a modified Bone–Wheeler apparatus. The results are given in Table V.

Table V

Analysis of Products

Compound	Temp., of decp., °C.	Acetylenes	Olefins	Hydrogen	Methane	Ethane	Time, min.
Si(Me)$_4$	659	0.75	1.5	39.2	58.4	0.0	180
Si(Me)$_4$	689	.13	1.0	40.0	58.8	.0	70
Si(Me)$_4$	689	.52	0.0	39.1	60.4	.0	70
Ethane	675	1.9	.7	40.9	54.5	2.0	360
Ethane	810	0.5	.75	34.10	65.65	0.0	15

For comparison the table includes the analyses of Bone and Coward[4] on the products resulting from the pyrolysis of ethane. If Si(Me)$_4$ decomposes through the agency of free methyl radicals, these short-lived molecules would come out of the reaction energy-loaded and in a highly reactive condition. It appears plausible that they might unite to form ethane but only momentarily, for ethane is known to decompose rapidly at these temperatures. The similarity of the products from ethane and Si(Me)$_4$ suggests that such a mechanism may be possible.

Summary

The thermal decomposition of silicon tetramethyl has been studied in the temperature range 659–717° and found to be homogeneous and unimolecular at pressures above 10 cm., and to fade into a higher order reaction at lower pressures.

The energy of activation is about 79,000 cal. and the velocity constant is given by the equation

$$\ln k = 35.03 - 78{,}800/RT$$

(In the case of germanium tetraethyl, the equation is $\ln k = 28.79 - 51{,}000/RT$, when k is expressed in reciprocal seconds.)

The decomposition produces a deposit of carbon and silicon and a gas phase essentially that secured upon pyrolysis of ethane.

No Lindemann critical pressure between uni- and bi-molecular rates could be located.

The Rate of Dissolution of Magnesium in Acids

BY CECIL V. KING AND WILLIAM H. CATHCART

As the result of previous studies in this Laboratory, the conclusion was reached that the rate of dissolution of magnesium in acids which are neither extremely weak nor form slightly soluble magnesium salts, is controlled by the rate of convection (stirring) and by the rate of diffusion of the acid.[1-3] It has been pointed out that the theory of Nernst[4] must be modified, in that the "diffusion layer" cannot be a stagnant layer (or even a layer in which flow is laminar only), and that the thickness of this layer must vary with the diffusion coefficient of the reagent, increasing as the latter increases. Investigators in related fields have concluded that in such processes the concentration gradient near the surface is not even linear, and that there may be a wide zone in which both diffusion and convection aid in the transport of material to and from the surface.

An entirely different picture of the dissolution process has been proposed by Kilpatrick and Rushton.[5] These authors have tried to show that the rates are dependent on the acid strength, in the same manner as in homogeneous acid–base catalysis; *i. e.*, that

$$k_{\mathrm{A}} = GK_{\mathrm{A}}^{x}$$

where k_{A} is the dissolution rate constant, K_{A} the acid dissociation constant, G and x are numerical constants, the latter a proper fraction. This assumes that the rate is controlled by the chemical reaction velocity and is entirely independent of diffusion rates.

This viewpoint has been criticized before,[1-3] but it is true, as Kilpatrick and Rushton pointed out, that it has been impossible to make a satisfactory comparison of the dissolution rate constants and the meager list of diffusion coefficients to be found in the literature. For this reason it was decided to determine the diffusion coefficients of a number of weak and strong acids, in the presence of their magnesium salts (when possible), and make the comparison with dissolution rate constants determined, so far as practical, under the same conditions of reagent and salt concentration.

It was found impossible to use the dissolution rate data of Kilpatrick and Rushton in this comparison, for several reasons. First, the great variation in diffusion coefficient with salt concentration in the case of strong acids makes it necessary to know the coefficient and rate constant in the presence of sufficient salt so that the salt formed in the reaction has little or no further effect. Second, Kilpatrick and Rushton do not report the actual rate constants obtained with certain acids (tartaric, citric, bisulfate, sulfuric) but hypothetical constants calculated for the undissociated acids in these solutions. Third, consistently lower dissolution rates were found in all acids than by these authors, although every effort was made to use comparable conditions.

Consequently, dissolution rate measurements were made in the same acids whose diffusion coefficients were measured, in the presence of the same salts. With the exception of benzoic, all the acids were ones used by Kilpatrick and Rushton.

Experimental

Diffusion Rates.—Measurements were made in porous glass disk cells of the type described by McBain and Dawson;[6] in a few cases the rotating cells described by Mouquin and Cathcart[7] were used. In general, the stationary and rotating cells gave nearly the same values in the critical concentration range. Diffusion coefficients (D) were calculated as described in another paper.[8] All measurements were made at 25 ± 0.02°. Most of the measurements have an estimated accuracy of about ±1%.

In all experiments the acid concentration was near 0.05 N initially except in the case of benzoic acid. The exact concentration before and after a twenty-four- to sixty-hour run was determined in terms of a standard alkali solution, and sometimes the acid diffusing through the cell disk was determined as well. The added salt had the same concentration on both sides of the disk initially; no attempt was made to follow its movement. Conditions within the "diffusion layer" of the dissolution rate experiments can only be approximated within the cell disk at best; but, as will be seen below, certain salt concentrations allow the best comparison available.

The results of the diffusion rate measurements are summarized in Table I and shown graphically in Fig. 1. The values of D are given in cm.^{2}/min. since the dissolution rate constants were calculated in cm./min. The effect of

added salt is seen to divide the acids roughly into two groups: (a) the diffusion coefficients of strong acids are greatly increased by the magnesium salts and (b) the diffusion coefficients of weak to moderately strong acids are either little affected, slightly decreased or slightly increased by salt addition. Three points are worthy of note: magnesium chloride does not increase the diffusion coefficient of hydrochloric acid nearly as much as sodium chloride does;[8] sodium bisulfate and sulfuric acid have practically the same coefficients in the presence of magnesium sulfate; and some of the organic acids used have such slightly soluble (acid?) magnesium salts that sodium chloride was used as the added salt.

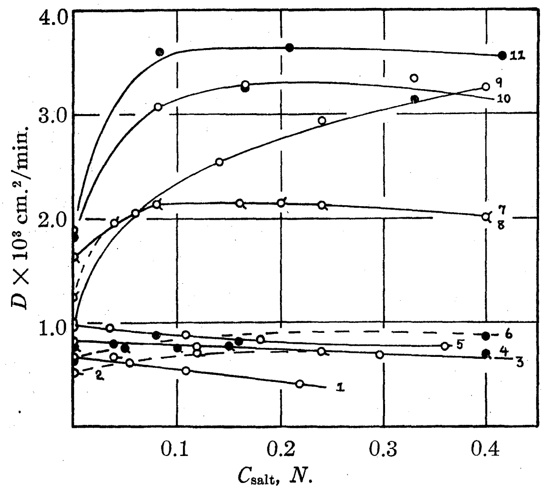

Fig. 1.—Diffusion coefficients *vs.* salt concentration. Acids: 1, benzoic; 2, citric (ɋ); 3, chloroacetic (○); 4, acetic (●); 5, formic; 6, tartaric; 7, bisulfate; 8, sulfuric; 9, benzene-sulfonic; 10, hydrochloric; 11, perchloric.

Dissolution Rates.—Magnesium cylinders approximately 2.6 cm. long and 1.8–2.0 cm. in diameter were rotated in 250 cc. of the acid solution contained in a 400-cc. beaker. The temperature of the solution was kept at 25 ± 0.5°, during the five- to fifteen-minute runs. The magnesium cylinders were carefully sanded to a smooth, clean surface before each series, and weighed before and after each run to the nearest 0.5 mg.

[a] In rotating cell.

Velocity constants were calculated from the equation

$$k = \frac{2.3V}{At}\log\frac{a}{a - x}$$

where V = volume of solution in cc., A = area of surface in sq. cm., t = time of run in minutes, a = dissolving capacity of the solution in any units and x = amount dissolved in the same units as a. The values of k should thus be comparable with constants obtained by Kilpatrick and Rushton.

Since the latter authors either ran their experiments at, or calculated the constants to a surface (peripheral) speed of 2000 cm./min., all our experiments were run at this peripheral speed. For instance, a cylinder 2.54 cm. long, 1.99 cm. in diameter was rotated at 320 r. p. m. (=2000 cm./min.) for five minutes in 0.0516 *N* perchloric acid, and 24.0 mg. of magnesium was dissolved. The dissolving capacity of the solution was 157 mg. of magnesium. Then

$$k = \frac{2.3 \times 250}{15.8 \times 5} \log \frac{157}{157 - 24} = 0.524$$

As the cylinder diameter decreased, the rotational speed was increased to keep the peripheral speed at 2000 cm./min. A cylinder 2.64 cm. long and 1.86 cm. in diameter was rotated at 340 r. p. m. for five minutes in 0.0562 *N* sodium bisulfate and 22.5, 23.5 mg. of magnesium was dissolved. The dissolving capacity of the solution was 171 mg. of magnesium. Then as an average

$$k = \frac{2.3 \times 250}{15.4 \times 5} \log \frac{171}{171 - 23} = 0.468$$

No attempt was made to obtain greater accuracy than ±5%. The method of obtaining rates and calculating constants is given in detail because all our values of *k* are only one-third to one-half as large as those obtained by Kilpatrick and Rushton under presumably comparable conditions. We have found, as they also state, that *k* is independent of length or diameter of cylinder, volume of solution and concentration of acid. Hence we can only conclude that some "apparatus constant" was different in the two cases.

The results of the rate experiments are summarized in Table II and shown graphically in Fig. 2. Several points are worthy of note.

(1) There was no loss in weight in solutions of benzoic acid containing sodium benzoate, and the cylinder acquired a visible white film. With hydrogen peroxide present hydrogen evolution was partly suppressed, the rate was somewhat increased in the acid alone and was normal in acid +0.2 *N* benzoate, but fell off in the presence of more concentrated sodium benzoate.

(2) The same rate was found in sodium bisulfate and sulfuric acid solutions, within experimental error, and this is true in the presence of magnesium sulfate. The rate decreases as sulfate is added while in the other stronger acids the rate increases when salt is added. The cylinder ac-

quired a thin brown film, slowly in the acid or bisulfate solutions, more rapidly the more concentrated the magnesium sulfate.

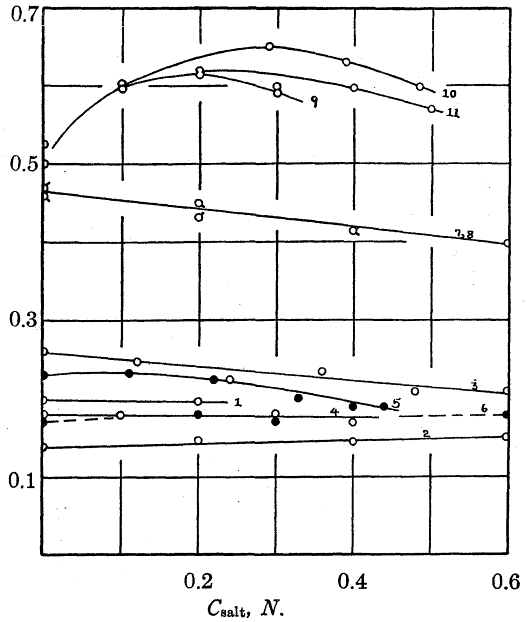

Fig. 2.—Dissolution rate constants *vs.* salt concentration. Acids: numbered as in Fig. 1.

(3) The rate in pyridinium chloride is higher than would be expected from the diffusion coefficient of Table I, but it decreases tremendously in the presence of excess pyridine. This was not known when the diffusion coefficients were measured, and it must be concluded that the measurements were not made under comparable conditions. This system is therefore omitted in further comparison.

(4) In every case except that of sulfuric acid and the bisulfate, the dissolution rates and diffusion coefficients change in the same direction on addition of salt. The magnitude of the change in dissolution rates is less than in diffusion coefficients, as would be expected from the diffusion theory; for even if pure acid is present initially, the magnesium salt is formed next the surface immediately.

Comparison of Diffusion and Dissolution Rates.—Values of D and k considered to be most nearly comparable were selected and are tabulated in Table III. The method of selection of most of the values is obvious; if the diffusion coefficient and the rate constant reach a maximum or a plateau near the same salt concentration, these values were chosen. In the case of sulfuric acid and the bisulfate, it seemed better to take the rate constant for the pure acid, but the maximum diffusion coefficient in the presence of salt.

TABLE III

COMPARISON OF DIFFUSION COEFFICIENTS AND DISSOLUTION RATE CONSTANTS

Acid	$D \times 10^3$, cm.²/min.	k, cm./min.
Benzoic	0.65	0.20
Citric	.70	.15
Monochloroacetic	.70	.23
Acetic	.76	.18
Formic	.85	.22
Tartaric	.85	.18
Sodium bisulfate	2.10	.46
Sulfuric	2.10	.46
Benzenesulfonic	3.00	.61
Hydrochloric	3.30	.64
Perchloric	3.60	.62

Discussion

While the dissolution rates do not fall in exactly the same order as the diffusion coefficients, the general trend is striking. Part of the lack of uniformity among the weaker acids undoubtedly is due to the fact that acids having salts of low solubility give low dissolution rates because of film formation. We cannot, however, account for the discrepancies among chloroacetic, formic and acetic acids, nor among benzenesulfonic, hydrochloric and perchloric acids.

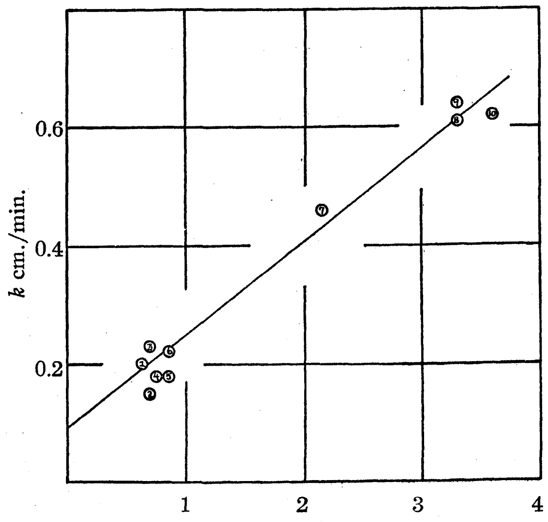

Fig. 3.—Dissolution rate constants *vs.* diffusion coefficients. Acids: 1, benzoic; 2, citric; 3, chloroacetic; 4, acetic; 5, tartaric; 6, formic; 7, sulfuric and bisulfate; 8, benzenesulfonic; 9, hydrochloric; 10, perchloric.

As shown in Fig. 3, the relation between k and D is reasonably well represented by a straight line which, however, does not pass through the origin. This type of relation was found before for dissolution rates in experiments with metal and other cylinders rotating at a higher speed in appropriate reagents.[2] Explanations of this extrapolation to a finite rate constant at zero diffusion coefficient are unsatisfactory, and as shown elsewhere[9] it is more probable that the true relation is of an exponential type

$$k = \alpha D^x$$

being nearly linear over the range of values plotted in Fig. 3. This exponential relation is consistent with a diffusion layer whose thickness increases with increasing diffusion coefficient, as is necessary from a consideration of turbulence in the solution near the metal surface.[2] Such a relation is also predicted from the expressions of Colburn[10] and Chilton and Colburn[11] derived to correlate heat and mass transfer in gas–liquid and gas–solid systems. The exponent x is given as $^2/_3$ by these authors.

From a log–log plot of k *vs.* D, the best value of x for these data is found to be approximately 0.70. In Fig. 4, values of k are plotted *vs.* $D^{0.70}$; the linear relation is at least as good as that of Fig. 3. The straight line is represented by the equation

$$k = 0.36D^{0.70}$$

A similar exponential relation holds for the data of ref. 2 and also of ref. 9. In the latter case, values for heat transfer are represented by the same equation as values for dissolution rates.

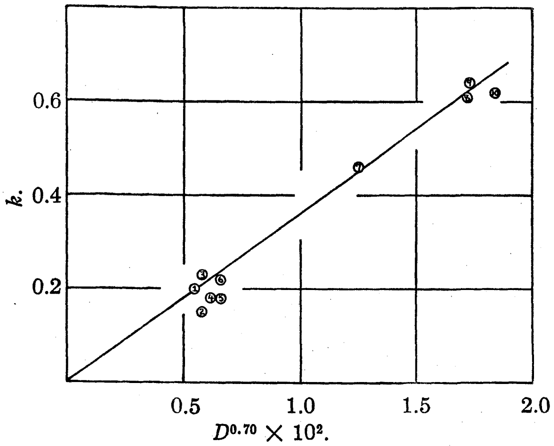

Fig. 4.—Dissolution rate constants *vs.* diffusion coefficients to the 0.70 power. Acids: numbered as in Fig. 3.

Summary

The diffusion coefficients of twelve acids have been measured in the porous glass disk type of diffusion cell, alone and in the presence of their magnesium salts when possible, otherwise with other salts present.

The dissolution rate of magnesium from cylinders rotating with a peripheral speed of 2000 cm./min. has been measured in the same acids in the presence of the same salts.

A comparison of diffusion coefficients and dissolution rate constants shows that they can be correlated fairly satisfactorily. The correlation is in agreement with a modification of the Nernst theory for such dissolution rates, and also with the Chilton–Colburn relations for heat and mass transfer at a phase boundary.

Studies in the Cyanine Dye Series. VII. New Dyes Containing Three Heterocyclic Nuclei

BY L. G. S. BROOKER AND L. A. SMITH

Cyanine dyes have been described in which a quinoline nucleus is linked through either the 2- or 4-position to a second heterocyclic nucleus. In the present paper, dyes of a new type are described in which a quinoline nucleus is linked through both of these positions to two other nuclei. These dyes differ from the previously known trinuclear dyes of the neocyanine type[1] since in the latter two nuclei are linked together by a three-carbon chain, the third nucleus forming part of a group attached to one of the carbon atoms of this chain.[2–5]

If 2,4-dimethylquinoline ethiodide (I) is treated with an excess of 2-iodoquinoline ethiodide in the presence of triethylamine, both methyl groups take part in the reaction, and a

new cyanine dye, 2,4-di-[(1-ethyl - 2(1) - quinolylidene) - methyl]-quinoline ethiodide (II) is formed. With equimolecular proportions of the two quaternary salts, however, a mixture of dyes is produced, the less soluble component of which, isolated as the perchlorate, was found to be identical with the perchlorate corresponding to 1,1′-diethyl-4-methyl-2,2′-cyanine iodide (III) made by condensing 2-iodolepidine ethiodide (V) with quinaldine ethiodide (VI). The second component of the mixture was not isolated in a pure state, but was without doubt the isomeric 1,1′-diethyl-2′-methyl-2,4′-cyanine iodide (IV). The absorption curve of the mixture of dyes was in complete agreement with this assumption, there being present distinct maxima corresponding to III and IV. The latter has been prepared by the action of potassium hydroxide on quinaldine ethiodide.[6]

It is reasonable to ascribe a certain reactivity to the methyl groups in III and IV and to regard these dyes as intermediate steps in the synthesis of II from I. This is substantiated by the fact that II was prepared from IV by interaction with a further proportion of 2-iodoquinoline ethiodide. In an attempted preparation of II from III, not enough of the desired dye was obtained for analysis, but there was sufficient to give the characteristically colored solution of II (see below).

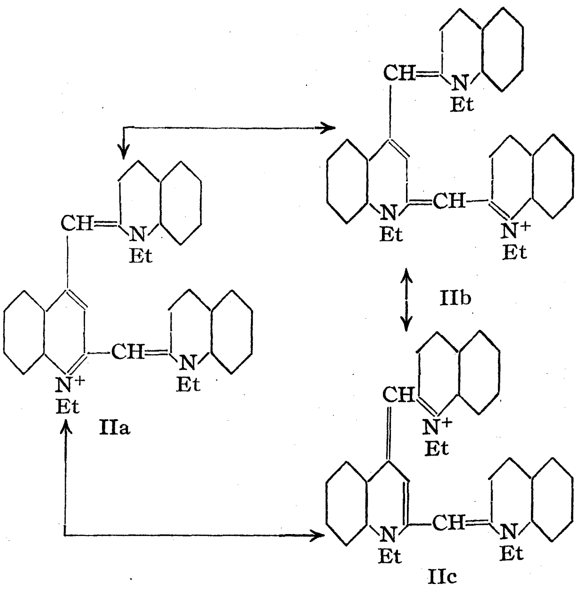
A further preparation of II was carried out as follows:

---

[6] Kaufmann and Vonderwahl, *Ber.*, **45**, 1413 (1912).

2,4-diiodoquinoline ethiodide (VII) was prepared from 2,4-dichloroquinoline (VIII) by heating the latter with an excess of ethyl iodide in a sealed tube at 100°. In VII the iodine atoms in positions 2 and 4 were both found to be reactive, since II was prepared by condensing it with VI, using triethylamine, it being best to use an excess of VI.

As obtained by any of the methods given, II consists of rather dark bronze crystals which dissolve in methyl alcohol to give a solution which is dull greenish-blue when sufficiently dilute but which develops a reddish color as the concentration is increased. The absorption curve of the dye (Fig. 1, A) is remarkable and differs in character from that ever previously described for a cyanine dye. There are two principal bands with maxima at 4800 and 6150 Å., respectively, that at the shorter wave length being narrower and somewhat stronger than the other. Between these bands there is a region of almost complete transmission with minimum absorption at about 5150 Å. In addition to the two principal bands, there is a weaker band with a distinct maximum at 4550 Å. The general appearance of the absorption curve is reminiscent of that of a mixture of two distinct cyanine dyes, the individual absorption curves of which overlap but very slightly.



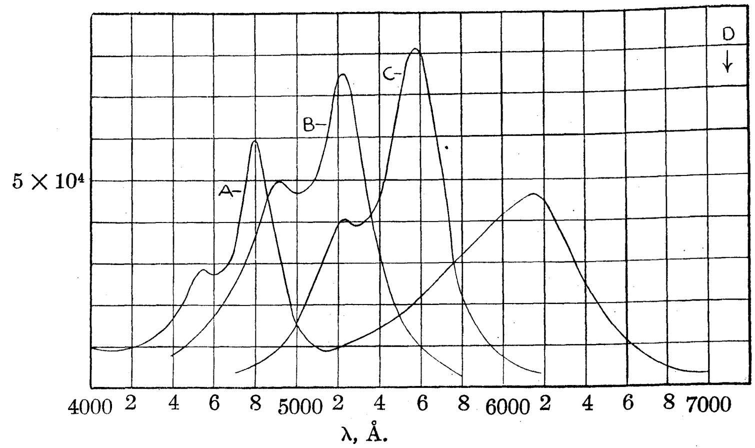


Fig. 1.—Absorption curves. A = 2,4-di[(1-ethyl-2(1)quinolylidene)methyl] quinoline ethiodide (II); B = 1,1′-diethyl-2,2′-cyanine iodide; C = 1,1′-diethyl-2,4′-cyanine iodide; D indicates maximum absorption of 1,1′-diethyl-2,2′-dicarbocyanine iodide (XII).

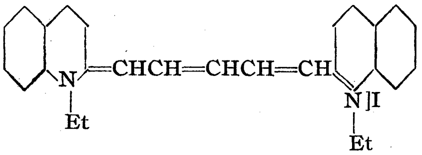
There is much direct and indirect evidence for the tautomerism of the cyanine dyes[7-9] and furthermore, it is plausible to assume that the color of these dyes is due to this tautomerism or, more precisely, to resonance within the conjugated chain (or chains) connecting the nitrogen atoms.[10] In the case of II this resonance may be represented as shown.

Now, the modes of resonance involved in IIa ↔ IIb and IIa ↔ IIc are those which are characteristic of 2,2′-cyanines and 2,4′-cyanines, respectively, while that of IIb ↔ IIc resembles that characteristic of 1,1′-diethyl-2,2′-dicarbocyanine iodide (XII),[11] but there is this difference, that whereas in XII the two nuclei are linked together by a simple pentamethenyl chain, in II a portion of the 5-carbon chain linking the two quinoline nuclei forms a part of the third quinoline nucleus.



XII

For purposes of comparison the absorption curves of 1,1′-diethyl-2,2′-cyanine iodide (Fig. 1, B) and of 1,1′-diethyl-2,4′-cyanine iodide (Fig. 1, C) are shown, these being the simple dyes the

characteristic linkages of which are simultaneously present in II. The absorption maximum of XII at 7080 Å., is indicated by the arrow (Fig. 1, D). The dye has a secondary maximum at 6510 Å.

It is reasonable to ascribe the unusual absorption of II to its unusual structure and specifically to the presence in the molecule of linkages characteristic of several distinct cyanine dye types. A point to be considered, however, is that whereas in a simple 2,2′-cyanine the conjugation between the two nitrogen atoms is complete in both the resonance formulas, in II the conjugation between the two nitrogen atoms of the 2,2′-cyanine linkage is interrupted in IIc. Similarly, the conjugation of the 2,4′-cyanine linkage is interrupted in IIb while the 2,2′-dicarbocyanine linkage is interrupted in IIa. Thus, although II contains conjugated linkages characteristic of three distinct cyanine dye types, in each of the three cases there is a further way of writing the formula of the dye in which the conjugation of these linkages is broken.

In the case of the meriquinoid dye Michler's Hydrol, it has been found that introducing a substituent (NH_2 or OH) in such a position that the molecule is no longer permanently quinonoid (giving Auramine or Michler's ketone, respectively) markedly lightens the color.[12] In the present case if it be assumed that that portion of the absorption curve of II which has its maximum at 6150 Å. is related to the modified dicarbocyanine system represented by IIb $\longleftrightarrow$ IIc, it follows that the effect of incorporating part of the polymethine chain of XII in a third quinoline nucleus, giving II, is to shift the absorption maximum 930 Å. toward the blue, and this marked hypsochromic effect may be due, in part at least, to the breaking of the conjugated dicarbocyanine system in IIa.

The relationship of the remainder of the absorption curve of II to the 3- and 5-carbon nitrogen–nitrogen linkages present in the dye remains obscure, although it is again noteworthy that the band at 4800 Å. lies at shorter wave length even than the absorption of the simple 2,2′-cyanine.

Two dyes closely related to II have also been prepared, these being 2,4-di-[(1-methyl-2(1)-quinolylidene)-methyl]-quinoline methiodide and 2,4-di-[(1-ethyl-2(1)-quinolylidene)-methyl]-quinoline methiodide. The absorption curves of these dyes are very similar to that of II, but the three differ considerably in their sensitizing action, that containing the three methyl groups being by far the strongest, although it is weaker than some of the cyanine dyes discovered in recent times. This dye sensitizes a bromide emulsion out to about 6700 Å. for a moderate exposure, with its maximum effect at 5550 Å., there being a weaker band with its head at about 6200 Å. The other two dyes sensitize over approximately the same range, but are weaker and show some desensitization.

It has long been known that IV is greatly inferior to 1,1′-diethyl-2,4′-cyanine iodide (Ethyl Red) as a sensitizer,[13] and Mills and Pope suggested that the presence of the substituent group in the chain of ethylenic linkages joining the two nitrogen atoms decreased the ability of the system to interact with light waves.[14] However, III is similarly greatly inferior as a sensitizer to 1,1′-diethyl-2,2′-cyanine iodide, although in this case the methyl substituent does not lie on the shortest chain connecting the two nitrogen atoms. That the depressant effect of a methyl group in the 4-(or 4-′)-position varies within wide limits, however, is demonstrated by the fact that 1′,2-diethyl-4′-methylthia-2′-cyanine iodide (IX), prepared from V, is inferior to 1′,2-diethylthia-2′-cyanine iodide to a much smaller extent, whilst 1′,2-diethyl-4′-methyl-3,4-benzothia-2′-cyanine iodide (X) is only very slightly weaker than the related unsubstituted dye.[15,16]

The absorption curves of the three dyes derived from 2-iodolepidine ethiodide were similar to those of the corresponding unsubstituted dyes, introduction of the 4′-methyl group either not affecting the position of the maximum (X) or else shifting it somewhat toward the blue (IX, 50 Å.) (III, 25 Å.).

The formation of a bluish-red impurity was observed in the preparation from V of III, IX and X, and was difficult to remove in the case of III. This impurity is doubtless due to the condensation of two molecules of V giving 1,1′-diethyl-2′-iodo-4-methyl-2,4′-cyanine iodide (XI) and a bluish-red dye, the composition of which corresponded to XI was obtained by the action of tri-

[16] Brooker, U. S. Patents 1,861,836, 1,969,444.

ethylamine on V alone. The combined action of the two substituents in XI on the absorption is very slight, the maxima coinciding with those of the unsubstituted dye within the limits of error, but their effect on the sensitizing action is profound, XI giving no trace of a sensitizing band for ordinary exposures.

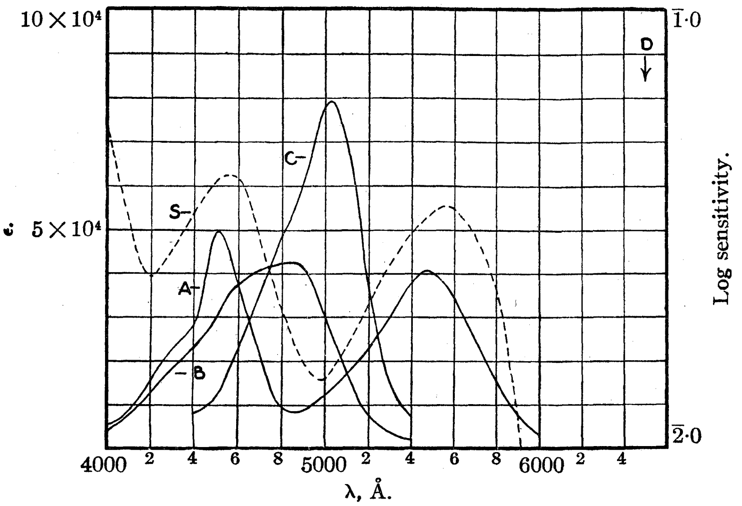

Fig. 2.—Absorption curves: A = 2,4-di[(2-ethyl-1(2)benzothiazolylidene)methyl]quinoline ethiodide (XIII); B = 1′,2-diethylthia-2′-cyanine iodide; C = 1′,2-diethylthia-4′-cyanine iodide; D indicates maximum absorption of 2,2′-diethylthiadicarbocyanine iodide (XVI). S = sensitizing curve of XIII in a chloride emulsion.

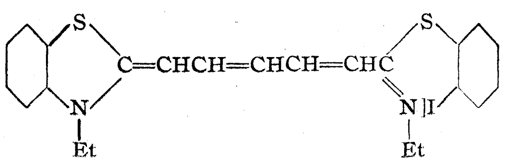
By the interaction of VII and 1-methylbenzothiazole ethiodide (in excess) using triethylamine, there was obtained 2,4-di-[(2-ethyl-1(2)-benzothiazolylidene)-methyl]-quinoline ethiodide (XIII). The dull reddish solution of this dye gives an absorption curve of the same general shape as that of II, the maxima being at 4515 and 5475 Å. and the minimum at 4875 Å. (Fig. 2, A). There is a further band at about 4300 Å., but it is ill defined.

The absorption curves of 1′,2-diethylthia-2′-cyanine iodide (Fig. 2, B) and 1′,2-diethylthia-4′-cyanine iodide (Fig. 2, C) are included for comparison, since the linkages characteristic of these dyes are simultaneously present in XIII. The third type of linkage present in XIII is a modification of that also present in 2,2′-diethylthiadicarbocyanine iodide (XVI), the absorption maximum of which is at 6500 Å.[11] (Fig. 2, arrow at D).



XVI

On the assumption already made, the effect of incorporating part of the polyene chain of XVI in a quinoline nucleus, giving XIII, is to move the maximum of absorption 1025 Å. nearer to the blue. It will also be noticed that the disposition of the B and C curves relative to the A curves is much the same in Figs. 1 and 2.

Dye XIII is a distinctly better photographic sensitizer than II. In a chloride emulsion there are two bands with maxima at about 4575 and 5575 Å., separated by a trough with its minimum at about 4975 Å. (Fig. 2, S). There is, in fact, a remarkably close resemblance between the absorption and sensitizing curves of XIII, and although similar cases have been noted since the earliest studies of the subject,[17,18] the present illustration is particularly striking on account of the unusual character of the curves. Compared with the absorption curve, the sensitizing curve appears to have been shifted bodily toward the red, but the extent of that shift is less than in many reported instances.[19]

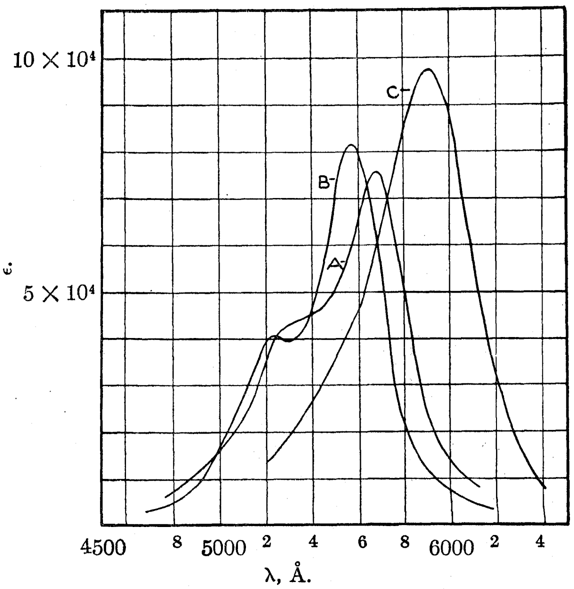


Fig. 3.—Absorption curves: A is 1,1′-diethyl-4-iodo-2,4′-cyanine iodide (XIV) or 1,1′-diethyl-2-iodo-4,4′-cyanine iodide (XV); B is 1,1′-diethyl-2,4′-cyanine iodide; C is 1,1′-diethyl-4,4′-cyanine iodide.

The dye similar to XIII but containing three methyl groups attached to the nitrogen atoms was also prepared. This was similar in its sensitizing action but somewhat stronger.

An attempt to prepare a dye containing three quinoline nuclei by condensing VII with two molecules of lepidine ethiodide was unsuccessful, the composition of a dye which was isolated corresponding to either 1,1′-diethyl-4-iodo-2,4′-cyanine iodide (XIV) or 1,1′-diethyl-2-iodo-4,4′-cyanine iodide (XV). The absorption curve of the dye (Fig. 3, A) has its maximum at 5675 Å. and accordingly XIV is considered to be the more likely formula since the strong hypsochromic effect that must be ascribed to the 2-iodine atom in XV, if this is held to be the correct formula, is at variance with the results observed in the case of XI, in which the 2′-iodine atom appears to counteract the, if anything, weakly hypsochromic effect of the 4-methyl group (compare III, IX and X). The sensitizing action of the dye resembles that of 1,1′-diethyl-2,4′-cyanine iodide more than it does that of 1,1′-diethyl-4,4′-cyanine iodide, but it is weaker than either of these. It gives an almost uniform extension of the spectrum to 6200 Å., with some desensitization.

The absorptions of the dyes were all determined for methyl alcoholic solutions and in the curves the molecular extinction coefficient, ϵ, is plotted against wave length. We are indebted to Dr. L. A. Jones and to Mr. E. E. Richardson for these results, to Dr. L. T. Hallett for the analyses, to Mr. G. Silberstein for the sensitizing curve, and to several other colleagues for the other photographic data.

Experimental

Intermediates

2,4-Dimethylquinoline Methiodide.[20]—The base (157 g.; 1 mol) was heated under reflux with methyl iodide (180 g.; 1.25 mols) for two days. The solid cake was ground with acetone and the yellow powder recrystallized from methyl alcohol (12 cc. per g.); yield of first crop 65%, increased to 93% by further crops. After a further recrystallization the pale yellow tables had m. p. 271–272°.

Anal. Calcd. for $C_{12}H_{14}IN$: I, 42.44. Found: I, 42.52.

2,4-Dimethylquinoline ethiodide (I)[20] was prepared similarly; yield 77% before and 73% after recrystallization (two crops). After a further recrystallization, the pale yellow crystals had m. p. 231–233°.

Anal. Calcd. for $C_{13}H_{16}IN$: I, 40.55. Found: I, 40.71.

2-Iodolepidine Ethiodide (V).—2-Chlorolepidine (50 g.; 1 mol) was heated under reflux with ethyl iodide (110 g.; 1.5 mols) for eight days in darkness.[8] The product was ground with acetone and weighed 64.6 g. (54%) and had m. p. 216–218° dec. After two recrystallizations from water (200 cc. per g.) (charcoal) the minute yellow crystals had m. p. 218–219° dec.

Anal. Calcd. for $C_{12}H_{13}I_2N$: I, 59.73. Found: I, 59.75.

2,4-Dihydroxyquinoline was made by the method of Ashley, Perkin and Robinson,[21] by treating methyl acetylanthranilate with sodium in toluene. These authors do not specify the time of heating nor do they give yields. We found that by refluxing for four hours the yield of purified product varied between 28 and 31%.

Anal. Calcd. for $C_9H_7NO_2$: C, 67.04; H, 4.38. Found: C, 67.38; H, 4.30.

2,4-Dichloroquinoline (VIII) was prepared from 2,4-dihydroxyquinoline by a modification of the method of Friedländer and Weinberg.[22] Contrary to the experience of Koller,[23] we were able to carry out the preparation satisfactorily using phosphorus pentachloride. In one experiment 2,4-dihydroxyquinoline (38.4 g.; 1 mol) was heated with phosphorus pentachloride (100 g.; 2 mols) and phosphorus oxychloride (80 cc.) at 100° for two hours. The excess of phosphorus oxychloride was removed under reduced pressure and the residue poured on ice. The solid was ground with ice water and filtered after neutralizing with sodium carbonate. It was then distilled *in vacuo;* yield 35 g. (74%). After recrystallization from methyl alcohol (2.5 cc. per g.) the yield (32.7 g.) was 69% (two crops). The colorless crystals melted at 66–67°.

Anal. Calcd. for $C_9H_5NCl_2$: C, 54.54; H, 2.55. Found: C, 54.39; H, 2.56.

2,4-Diiodoquinoline Methiodide.—2,4-Dichloroquinoline (4 g.; 1 mol) and methyl iodide (14.4 g.; 5 mols) were heated at 100° in a sealed tube for three days. The product was ground with acetone; yield 5.1 g. (49%). After two recrystallizations from nitromethane (1 liter per g.) the yellow crystals had m. p. 236–237°, dec.

Anal. Calcd. for $C_{10}H_8I_3N$: I, 72.80. Found: I, 72.45.

2,4-Diiodoquinoline ethiodide (VII) was prepared similarly by heating at 100° for three weeks; crude yield 47%. After one recrystallization from nitromethane (500 cc. per g.) the yellow crystals had m. p. 235–236°, dec.

Anal. Calcd. for $C_{11}H_{10}I_3N$: I, 70.91. Found: I, 70.80.

Dyes

In all cases methyl alcohol was used for recrystallizing the dyes.

1,1′-Diethyl-4-methyl-2,2′-cyanine Perchlorate (cf. III).—Quinaldine ethiodide (3 g.; 1 mol), 2-iodolepidine ethiodide (4.25 g.; 1 mol) and triethylamine 2.9 cc.; 2.1 mols) were refluxed with absolute ethyl alcohol (25 cc.) for twenty minutes. Dye separated (62% yield) and after two recrystallizations was converted into the

perchlorate by treatment with potassium perchlorate and given two further recrystallizations (500 cc. per g.). The characteristic brownish spheroidal crystal aggregates had m. p. 279–280° dec. The maximum absorption of the dye is at 5200 Å. A well-marked secondary band has its maximum at 4900 Å.

Anal. Calcd. for $C_{24}H_{25}ClN_2O_4$: C, 65.33; H, 5.72. Found: C, 65.00; H, 5.48.

When 2,4-dimethylquinoline ethiodide (3.1 g.; 1 mol) and 2-iodoquinoline ethiodide (4.1 g.; 1 mol) were similarly condensed using triethylamine (2.9 cc.; 2.1 mols) the yield of the mixed dyes was 86%. The absorption curve of the product at this stage showed two maxima of nearly equal strength at 5200 and 5550 Å. with a weaker one at 4900 Å. The mixture was converted into the perchlorates and extracted with boiling methyl alcohol (250 cc.). This removed most of the purplish-red dye (2,4′-cyanine) and after three recrystallizations the residue was identical (appearance; mixed m. p.; absorption) with the specimen obtained above. Found: C, 65.34; H, 5.64.

1,1′-Diethyl-2′-methyl-2,4′-cyanine Iodide (IV).—The earlier method was modified. A boiling solution of quinaldine ethiodide (29.9 g.; 2 mols) in ethyl alcohol (150 cc.) was treated with powdered potassium hydroxide (3.1 g.; 1 mol) with constant shaking and the whole refluxed for twenty minutes; yield after washing 66%, being 31% after two recrystallizations (25 cc. per g.); m. p. 191–192°.

Anal. Calcd. for $C_{24}H_{25}IN_2$: I, 27.11. Found: I, 27.11.

This dye has its maximum absorption at 5550 Å. with a secondary maximum at about 5225 Å.

2,4-Di-[(1-ethyl-2(1)-quinolylidene)-methyl]-quinoline Ethiodide (II). (A) From 2,4-Dimethylquinoline Ethiodide.—This salt (3.1 g.; 1 mol), 2-iodoquinoline ethiodide (16.4 g.; 4 mols), triethylamine (8.7 cc.; 6.2 mols) and ethyl alcohol (40 cc.) were refluxed for forty minutes. Dye separated on cooling and was washed (acetone, then water). After three recrystallizations (140 cc. per g.) the yield was 0.15 g. (2%). The dye formed minute dull bronze crystals, m. p. 291–292°, dec.

Anal. Calcd. for $C_{35}H_{34}IN_3$: C, 67.39; H, 5.50; I, 20.36; N, 6.74. Found: C, 66.72; H, 5.41; I, 20.39; N, 6.84.

(B) From 2,4-Diiodoquinoline Ethiodide.—This salt (2.7 g.; 1 mol), quinaldine ethiodide (6 g.; 4 mols), triethylamine (4.32 cc.; 6.2 mols) and ethyl alcohol (50 cc.) were refluxed for forty minutes. Dye separated on chilling and after washing was extracted with boiling methyl alcohol (75 cc. × 2). The first extract contained much purplish-red dye and was rejected, but the second extract deposited moderately pure product; wt. 0.4 g. (13%). After a further recrystallization (6.5%) the dye was analytically pure. Found: I, 20.32.

(C) From 1,1′-Diethyl-2′-methyl-2,4′-cyanine Iodide (IV).—This dye (2.34 g.; 1 mol) and 2-iodoquinoline ethiodide (8.24 g.; 4 mols) were refluxed for forty minutes with ethyl alcohol (30 cc.) and triethylamine (4.2 cc.; 6.2 mols). The dye which separated was washed, extracted with hot methyl alcohol (15 cc.) and the residue twice recrystallized; yield 4.5%. Found: I, 20.35.

The specimens prepared by the three methods were identical (appearance; mixed m. p.; absorption; sensitizing).

2,4-Di-[(1-methyl-2(1)-quinolylidene)-methyl]-quinoline methiodide was prepared similarly, using method B (above). Some unused 2,4-diiodoquinoline methiodide was removed by filtration from the hot reaction mixture together with some dye which apparently consisted of 2,2′- and 2,4′-cyanine. The hot filtrate deposited the desired dye on cooling (15% yield). Dull brownish crystals from methyl alcohol (225 cc. per g.); yield 10%; m. p. above 310° dec., with shrinking from about 300°.

Anal. Calcd. for $C_{32}H_{28}IN_3$: C, 66.07; H, 4.86; I, 21.84; N, 7.23. Found: C, 65.40; H, 4.94; I, 21.64; N, 7.23.

This dye has absorption maxima at 4775 and 6050 Å. The third band is not so clearly defined in this case, but appears to be at about 4500 Å.

2,4-(Di-[(1-ethyl-2(1)-quinolylidene)-methyl]-quinoline methiodide was prepared using method A (above). Dye separated during the reaction and was filtered from the hot liquor and given three recrystallizations (700 cc. per g.); yield 6%. The minute crystals had a coppery luster; m. p. 302–303° dec.

Anal. Calcd. for $C_{34}H_{32}IN_3$: I, 20.83; N, 6.90. Found: I, 20.84; N, 7.09.

In a later experiment better results were obtained using *n*-propyl alcohol as solvent, and refluxing for forty minutes, the yields being 31% before and 15% after recrystallization. The absorption of this dye was like that of II.

2,4-Di-[(2-ethyl-1(2)-benzothiazolylidene)-methyl]-quinoline Ethiodide (XIII).—2,4-Diiodoquinoline ethiodide (1.34 g.; 1 mol), 1-methylbenzothiazole etho-*p*-toluenesulfonate (3.5 g.; 4 mols), triethylamine (2.15 cc.; 6.2 mols) and ethyl alcohol (50 cc.) were refluxed for forty minutes. Solid separated on cooling but this was not the dye sought for and was removed. Ether was added to the filtrate and the dye separated; yield 0.25 g. (15%). After two recrystallizations (50 cc. per g.) the yield was 3%. The minute brownish crystals with greenish reflex had m. p. 274–276° dec.

Anal. Calcd. for $C_{31}H_{30}IN_3S_2$: I, 19.97. Found: I, 19.88.

The sensitizing curve was determined on the monochromatic sensitometer described by Jones and Sandvik,[24] the sensitivity being the reciprocal of the exposure (in ergs/sq. cm.) necessary to produce a density of 1.0.

2,4-Di-[(2-methyl-1(2)-benzothiazolylidene)-methyl]-quinoline methiodide was prepared similarly. Dye separated in the hot reaction mixture; yield 33% (17% after two recrystallizations; 1200 cc. per g.). The dye formed a brown felt of minute crystals with a greenish reflex and had m. p. 301–302° dec.

Anal. Calcd. for $C_{28}H_{24}IN_3S_2$: I, 21.39. Found: I, 21.42.

1,1′-Diethyl-4-iodo-2,4′-cyanine Iodide (XIV), or 1,1′-Diethyl-2(or 2′)-iodo-4,4′-cyanine Iodide (XV).—Lepidine ethiodide (3 g.; 4 mols), 2,4-diiodoquinoline ethiodide (1.34 g.; 1 mol), ethyl alcohol (40 cc.) and triethylamine (2.15 cc.; 6.2 mols) were refluxed for forty minutes. Dye (0.7 g.) separated on cooling and was purified by several

---

[24] Jones and Sandvik, *J. Opt. Soc. Am.*, **12**, 401 (1926).

recrystallizations (200 cc. per g.). The dye formed beautiful prisms with a greenish-bronze reflex; m. p. above 300°, dec., with sintering from 275°.

Anal. Calcd. for $C_{23}H_{22}I_2N_2$: I, 43.76. Found: I, 43.56.

1′,2 - Diethyl - 4′ - methylthia - 2′ - cyanine iodide (IX) was obtained from V in similar fashion to III, using 1-methylbenzothiazole etho-*p*-toluenesulfonate. The yield of crude product was 84%, and 45% after two recrystallizations (125 cc. per g.). The orange-yellow needles had m. p. 276–277.5°, dec.

Anal. Calcd. for $C_{22}H_{23}IN_2S$: I, 26.76. Found: I, 26.86.

The maximum absorption is at 4800 Å.

1′,2 - Diethyl - 4′- methyl - 3,4 - benzothia - 2′ - cyanine iodide (X) was obtained similarly using 2-methyl-β-naphthothiazole etho-*p*-toluenesulfonate. The yield of product was 57% before and 42% after recrystallization (325 cc. per g.). The minute reddish-orange needles had m. p. 272–274°, dec.

Anal. Calcd. for $C_{26}H_{25}IN_2S$: I, 24.21. Found: I, 24.19.

The dye has its maximum absorption at 5000 Å. There is an indefinite secondary band with its head at about 4800 Å.

1,1′ - Diethyl - 2′ - iodo - 4 - methyl - 2,4′ - cyanine Iodide (XI).—2-Iodolepidine ethiodide (4.25 g.; 2 mols), triethylamine (1.5 cc.; 2.1 mols) and ethyl alcohol (25 cc.) were refluxed for twenty minutes. Dye separated from the hot reaction mixture; yield 71% (44%; 140 cc. per g.). After a further recrystallization (yield 20%) the greenish-bronze crystals had m. p. 231–232°, dec.

Anal. Calcd. for $C_{24}H_{24}I_2N_2$: C, 48.49; H, 4.07; I, 42.73. Found: C, 48.65; H, 4.10; I, 42.37.

Summary

1. Both the methyl groups in 2,4-dimethylquinoline ethiodide can undergo condensation with 2-iodoquinoline ethiodide and there results a cyanine dye of a new type containing three quinoline nuclei. The same dye is formed when 2,4-diiodoquinoline ethiodide is condensed with quinaldine ethiodide and also when 1,1′-diethyl-2′-methyl-2,4′-cyanine iodide is condensed with 2-iodoquinoline ethiodide.

2. The absorption curve of the new dye is unusual. It consists of two distinct bands separated by a trough of almost complete transmission. This is probably due to the unusual structure of the dye, for the molecule contains linkages characteristic of three distinct cyanine dye types.

3. 2,4-Diiodoquinoline ethiodide condenses with 1-methylbenzothiazole etho-*p*-toluenesulfonate to give a trinuclear dye containing one quinoline and two benzothiazole nuclei. The absorption curve of this dye likewise consists of two distinct bands and bears a very close resemblance to the sensitizing curve of the dye for silver chloride, thus affording a particularly striking example of this relationship.

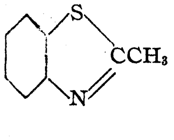
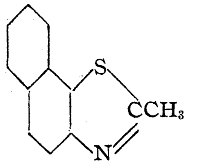
Studies in the Cyanine Dye Series. VIII. Dyes Derived from 2-Methylphenanthro-[9,10]-thiazole

BY G. H. KEYES AND L. G. S. BROOKER

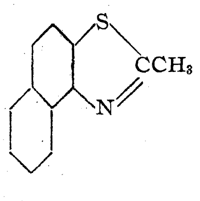
Certain cyanine dyes derived from 1-methylbenzothiazole (I) are well known, and in the search for effective photographic sensitizers, cyanines have been prepared from the methyl-α- and β-naphthothiazoles (II and III, respectively)[1,2,3] some of which dyes proved to be of considerable value. It was accordingly felt to be of interest to attempt to prepare dyes from 2-methylphenanthro-[9,10]-thiazole (IV), since this base may be considered to bear a similar relationship to II (or III) as III (or II) bears to I.



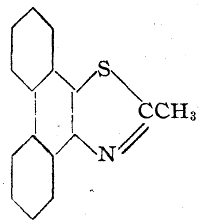
I



II



III



IV

The method used for preparing IV was a modi-

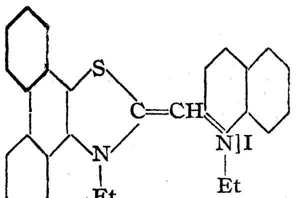
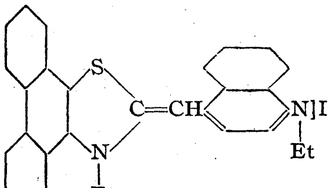
fication of that used by Jacobson[4] for the preparation of 2-methyl-β-naphthothiazole, 9-acetaminophenanthrene[5] being converted into the thioacetamino compound by treatment with phosphorus pentasulfide in hot dry toluene, and this being oxidized to the base by potassium ferricyanide in cold dilute alkaline solution. The pure base was obtained as nearly colorless needles with m. p. 145–147°, but the yield was only about 0.25%, calculated from the phenanthrene used as starting material.

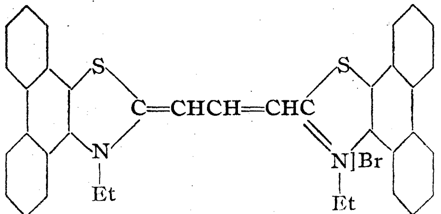
The metho- and etho-*p*-toluenesulfonates of the base were prepared by heating with the appropriate sulfonic esters, but the base reacted with these even more slowly than 2-methyl-β-naphthothiazole. Heating at high temperatures, too, had to be avoided on account of the tendency to decompose on the part of the esters, particularly the ethyl ester. From the appropriate *p*-toluenesulfonates the methiodide and ethiodide of the base were obtained and analyzed, but these salts were sparingly soluble and the *p*-toluenesulfonates themselves were chosen for submitting to certain dye condensations. From the etho-*p*-toluenesulfonate there was thus obtained 1′,2-diethyl-3,4,5,6-dibenzothia-2′-cyanine iodide (V), 1′,2-diethyl-3,4,5,6-dibenzothia-4′-cyanine iodide (VI) and 2,2′-diethyl-3,4,3′,4′,5,6,5′,6′-tetrabenzothiacarbocyanine bromide (VII) by condensation with 2-iodoquinoline ethiodide, quinoline ethiodide and ethyl orthoformate, respectively. In no case was the yield of dye high, and this is probably due in part to the presence in the ether-washed etho-*p*-toluenesulfonate employed of hydro-*p*-toluenesulfonate, formed by the union of the base with *p*-toluenesulfonic acid resulting from the decomposition of the sulfonic ester by elimination of ethylene.



V



VI



VII

It is interesting to compare dyes V, VI and VII with the related simpler dyes derived from I, II and III. In the thia-2′-cyanine series, the 1′,2-diethyl dyes derived from I, II and III are all known,[1,2] but in the present work the yields of those derived from II and III have been improved by the use of triethylamine.[6]

In the thia-4′-cyanine series, the dye derived from I, 1′,2-diethylthia-4′-cyanine iodide, was first described by Braunholtz and Mills[7] but we have obtained it in greatly increased yield by using excess of quinoline ethiodide and of potassium hydroxide in its preparation. High yields of the dyes from II and III were similarly obtained.

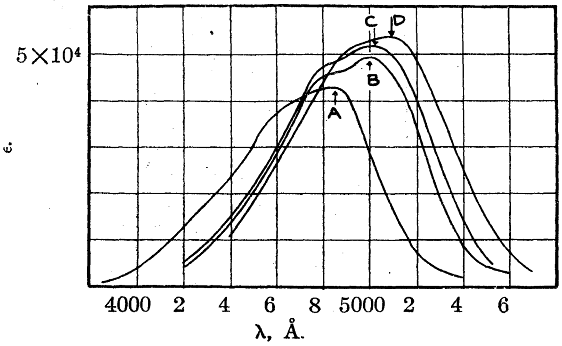


Fig. 1.—Absorption curves: A, 1′,2-diethylthia-2′-cyanine iodide; B, 1′,2-diethyl-5,6-benzothia-2′-cyanine iodide; C, 1′,2-diethyl-3,4-benzothia-2′-cyanine iodide; D, 1′,2-diethyl-3,4,5,6-dibenzothia-2′-cyanine iodide (V).

The absorption curves of the thia-2′-cyanines are given in Fig. 1, those of the thia-4′-cyanines in Fig. 2, and those of the thiacarbocyanines in Fig. 3. In all cases the molecular extinction coefficient, ε, is plotted against the wave length, λ, in Å. In all three series, A, B, C and D indicate the curves of the dyes derived from I, II, III and IV, respectively, and the maxima are indicated by arrows.

The wave lengths of maximum absorption of the

dyes are given in the table, the differences between adjacent values being given also.

Table of Absorption Maxima, in Å.

	A		B		C		D
Fig. 1	4850		5000		5025		5100
		150		25		75	
Fig. 2	5025		5215		5225		5300
		190		10		75	
Fig. 3	5575		5925		5950		6125
		350		25		175	

It has been shown previously that, in the thiacarbocyanine series, dyes derived from β-naphthothiazole have their maximum absorption nearer the red, in general, than the corresponding dyes derived from α-naphthothiazole,[3] and this rule is now seen to hold in the thia-2′-cyanine and thia-4′-cyanine series also.

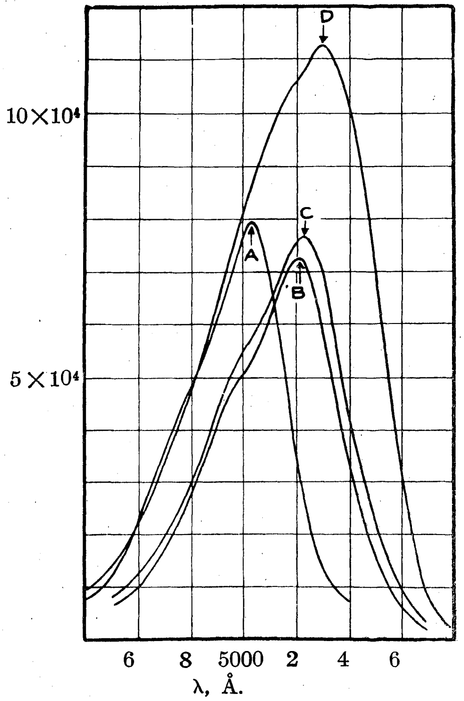

Fig. 2.—Absorption curves: A, 1′,2-diethylthia-4′-cyanine iodide; B, 2′,2-diethyl-5,6-benzothia-4′-cyanine iodide; C, 1′,2-diethyl-3,4-benzothia-4′-cyanine iodide; D, 1′,2-diethyl-3,4,5,6-dibenzothia-4′-cyanine iodide (VI).

A second generalization is that in every case a dye containing the phenanthro-[9,10]-thiazole nucleus has its absorption band nearer the red end of the spectrum than either of the corresponding dyes derived from a naphthothiazole. It is worthy of notice, however, that the shift produced when the benzothiazole nucleus (or nuclei) of a dye is replaced by α-naphthothiazole is at least twice as great as that produced when the β-naphthothiazole nucleus (or nuclei) of the dye in the same series is replaced by phenanthro-[9,10]-thiazole, although in both these processes the lighter nuclei of the two pairs have been weighted in the same way.

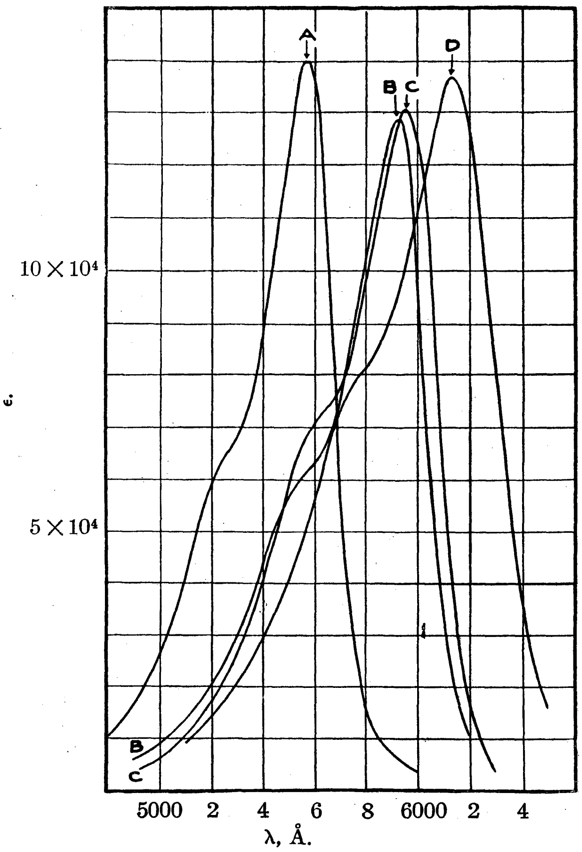

Fig. 3.—Absorption curves: A, 2,2′-diethylthiacarbocyanine iodide; B, 2,2′-diethyl-5,6,5′,6′-dibenzothiacarbocyanine bromide; C, 2,2′-diethyl-3,4,3′,4′-dibenzothiacarbocyanine bromide; D, 2,2′-diethyl-3,4,3′,4′,5,6,5′,6′-tetrabenzothiacarbocyanine bromide (VII).

Within each series the curves show a very marked resemblance to one another. Thus the four curves in Fig. 1 are all of the same general shape, there being in each case a principal band with a pronounced secondary band nearer the region of shorter wave length. The maximum values for ε lie very close together, also, and the same holds true, with one exception, for the curves in the other two figures. In Fig. 2 there is again a secondary band nearer the blue in each case, and curves A, B and C have maximum values of ε which are close together, but the value for D is considerably higher. The maximum value of ε for a thia-4′-cyanine is markedly higher than for the corresponding thia-2′-cyanine, and is highest of all for the corresponding thiacarbocyanine (Fig. 3). The curves in Fig. 3 have sharp maxima and there are again secondary bands nearer the blue.

The dyes were tested photographically after incorporation in a bromide emulsion. In the thia-2′-cyanine series (as in the thiacarbocyanine series[3]) the β-naphthothiazole derivative was a stronger sensitizer than the α-derivative but V is weaker than either of these. The thia-4′-cyanines which are derivatives of II and III are sensitizers for the green portion of the spectrum[8] with maxima at about 5400 Å., and each gives a second, less well-defined maximum nearer the blue. Here again the β-naphthothiazole derivative is the stronger sensitizer of the two. Dye VI sensitizes to about 6400 Å. for a moderate exposure, but the band is very flat and it is difficult to find a maximum.

The sensitizing action of the thiacarbocyanine dyes derived from II and III has already been described.[2,3] The dye VII is a relatively poor sensitizer. Its action extends to 6900 Å., but there is a decided gap between the regions of ordinary and of extra-sensitivity. The maximum effect is at 6550 Å., but even at this wave length VII is markedly inferior to either of the 2,2′-diethylthiacarbocyanines derived from the methyl naphthothiazoles, although their sensitizing maxima lie nearer to the blue.

We again wish to thank Dr. L. A. Jones and Mr. E. E. Richardson for the absorptions (which were all determined for methyl alcoholic solutions) and Dr. L. T. Hallett for the analyses except those marked by an asterisk which were kindly provided by Dr. S. F. Darling.

Experimental

9-Nitrophenanthrene, m. p. constant at 112.5–114.5°, was prepared by the method of Schmidt and Heinle[9] who give m. p. 116–117°. The yield of pure product was 4.5%.

9-Aminophenanthrene, m. p. 132–133°, was obtained in a yield of 27% using Schmidt and Strobel's method.[5] These authors claim a yield of 93–99% of product with m. p. 135–136°. They also state that the base darkens in air, but we find it to be quite stable when pure.

Anal. Calcd. for $C_{14}H_{11}N$: C, 87.00; H, 5.74; N, 7.25. Found: C, 86.75*; H, 5.45*; N, 7.24.

9-Acetaminophenanthrene was obtained by the following modification of Schmidt and Strobel's method, which avoids using a large excess of acetic anhydride. The 9-amino compound (4.8 g.; 1 mol) was dissolved in glacial acetic acid (60 cc.), heated on a steam-bath, acetic anhydride (3 g.; 1.2 mols) added, and the whole heated at 100° for forty-five minutes. The product separated on cooling (5 g.; 86%) and was a nearly colorless crystalline powder with m. p. 204–208° which was sufficiently pure for the next stage. On recrystallization from methyl alcohol (75 cc. per g.) the m. p. was raised to 213–215° (Schmidt and Strobel give m. p. 207–208° with sintering from 205°).

Anal. Calcd. for $C_{16}H_{13}NO$: C, 81.66; H, 5.57; N, 5.96. Found: C, 81.5*; H, 5.6*; N, 6.02.

9-Thioacetaminophenanthrene.—Jacobson[4] prepared thioacetyl-α-naphthylamine by fusing acetyl-α-naphthylamine with phosphorus pentasulfide. Hantzsch[10] improved on Hofmann's similar method for the preparation of thioacetamide[11] by using benzene in the reaction and in the following we used toluene.

9-Acetaminophenanthrene (5 g.; 1 mol) was dissolved in gently refluxing dry toluene (300 cc.), pyridine (1 cc.) was added (this improved the yield markedly) followed by finely powdered phosphorus pentasulfide (4.7 g.; 1 mol) with good mechanical stirring. Heating and stirring were continued for two hours, and the toluene was decanted from the sticky residue and extracted with hot 5% caustic soda solution. The chilled extract was acidified carefully with acetic acid and the thioacetyl compound separated as a brownish solid. This was redissolved in alkali and reprecipitated in the cold. (The moist product at this stage was sufficiently pure for conversion to IV.) After drying the yield was 61%. It was recrystallized from methyl alcohol (charcoal) (yield 20%) and formed buff-colored crystals with m. p. 181–182°, dec., not raised by further recrystallization.

Anal. Calcd. for $C_{16}H_{13}NS$: C, 76.45; H, 5.22; N, 5.58. Found: C, 76.4*; H, 5.1*; N, 5.56.

2-Methylphenanthro-[9,10]-thiazole.—A run of crude 9-thioacetaminophenanthrene was dissolved in dilute caustic soda and the solution chilled and aqueous potassium ferricyanide added until an excess was present as indicated by a permanent yellow color. The base which separated as a solid was extracted with ether, the extract dried over anhydrous potassium carbonate and the solvent removed; yield 53%, calculated from the acetyl compound. The base was recrystallized from methyl alcohol (yield 29%).

Anal. Calcd. for $C_{16}H_{11}NS$: C, 77.05; H, 4.45; N, 5.62. Found: C, 77.0*; H, 4.6*; N, 5.59.

2-Methylphenanthro-[9,10]-thiazole Methiodide.—The base (0.5 g.; 1 mol) and methyl *p*-toluenesulfonate (0.37 g.; 1 mol) were heated at 120–130° for one week. The solid product was dissolved in boiling methyl alcohol (30 cc.) and potassium iodide (0.66 g.; 2 mols) in water (10 cc.) was added to the filtered solution. The methiodide separated and was washed with acetone and dried; yield 0.4 g. (46%). The salt separated from methyl alcohol (25 cc.) as a nearly colorless crystalline powder with m. p. 206–208°, dec., after two further recrystallizations.

Anal. Calcd. for $C_{17}H_{14}INS$: I, 32.45. Found: I, 32.51.

2-Methylphenanthro-[9,10]-thiazole Ethiodide.—Equimolecular proportions of base (1 g.) and ethyl *p*-toluenesulfonate (0.8 g.) were heated at 130–140° for ten days. A hot aqueous extract (40 cc.) of the solid product was treated with hot aqueous potassium iodide (1.4 g. in 10 cc.). The ethiodide was precipitated (0.4 g.; 24%) and was recrystallized from methyl alcohol (10 cc.; charcoal); yield 18.5%. The melting point, 202–204°, dec., of the cream-colored crystalline powder was unaltered after a second recrystallization.

Anal. Calcd. for $C_{18}H_{16}INS$: I, 31.32. Found: I, 30.86.

In the dye condensations the crude etho-*p*-toluenesulfonate of the base was washed with ether and then used without further purification.

1′,2-Diethyl-5,6-benzothia-2′-cyanine iodide was obtained in a yield of 86% before and 70% after recrystallization when triethylamine was used to effect the condensation. The corresponding yields given by Hamer,[2] who used potassium hydroxide, are 44 and 30%. We find that the m. p. is 287–289°, dec.

1′,2-Diethyl-3,4-benzothia-2′-cyanine iodide was obtained similarly in a yield of 70% before and 55% after recrystallization; Hamer gives 36 and 24%.

1′,2-Diethylthia-4′-cyanine iodide was obtained by the interaction of 1-methylbenzothiazole ethiodide (1 mol), quinoline ethiodide (1 mol) and sodium ethylate (1.2 mols) by Braunholtz and Mills[7] who obtained the pure dye in a yield of 9–13%. By using potassium hydroxide (1 mol) for the condensation our yields were 19.5% before and 15.5% after recrystallization from methyl alcohol (55 cc. per g.). Kaufmann and Vonderwahl[12] have shown that in a very similar preparation, that of Ethyl Red (1,1′-diethyl-2,4′-cyanine iodide), the yield of dye was much improved by using 100% excess of quinoline ethiodide. In the present case, use of 2 mols of quinoline ethiodide resulted in the yield of pure dye being raised to 19%, but by using 2 mols of potassium hydroxide also, the much more marked increase of yield to 59% was obtained. Use of 3 mols of quinoline ethiodide and of potassium hydroxide gave a yield of 63% of pure dye, the yield being calculated in all cases from the 1-methylbenzothiazole ethiodide.

1′,2-Diethyl-5,6-benzothia-4′-cyanine iodide was obtained similarly from 1-methyl-α-naphthothiazole etho-*p*-toluenesulfonate (1 mol) using 100% excess of quinoline ethiodide and of potassium hydroxide; yield 51% before and 45% after recrystallization from methyl alcohol (350 cc. per g.). After a further recrystallization (yield 39%) the scarlet needles had m. p. 285–288°, dec.

Anal. Calcd. for $C_{25}H_{23}IN_2S$: I, 24.87. Found: I, 24.76.

1′,2-Diethyl-3,4-benzothia-4′-cyanine iodide was obtained similarly, yield 33% before and 27% after recrystallization. After two further recrystallizations (yield 21%) from methyl alcohol (175 cc. per g.) the dye formed beautiful reddish-brown needles (transmitted light) with a metallic green reflex; m. p. 248–250°, dec.

Anal. Calcd. for $C_{25}H_{23}IN_2S$: I, 24.87. Found: I, 24.76.

1′,2 - Diethyl - 3,4,5,6 - dibenzothia - 2′ - cyanine Iodide (V).—2 - Methylphenanthro - [9,10] - thiazole etho-*p*-toluenesulfonate (0.9 g.; 1 mol) was condensed with 2-iodoquinoline ethiodide (0.82 g.; 1 mol) in absolute ethyl alcohol (30 cc.) using triethylamine (0.4 g.; 2 mols), the mixture being refluxed for one-half hour; yield 0.15 g. (13%) and 0.09 g. (8%) after recrystallization from methyl alcohol (180 cc.). The dull-red crystals had m. p. 248–250°, dec.

Anal. Calcd. for $C_{29}H_{25}IN_2S$: I, 22.66. Found: I, 22.28.

1′ - Ethyl - 2 - methyl - 3,4,5,6 - dibenzothia - 2′ - cyanine iodide was prepared similarly; yield 45% before and 18% after recrystallization from methyl alcohol (1800 cc. per g.). The bright red crystalline powder had m. p. 244–246°, dec.

Anal. Calcd. for $C_{28}H_{23}IN_2S$: I, 23.24. Found: I, 22.91.

The absorption of this dye resembles that of V, but the maximum lies at 5050 Å.

1′,2 - Diethyl - 3,4,5,6 - dibenzothia - 4′ - cyanine Iodide (VI).—2 - Methylphenanthro - [9,10] - thiazole etho - *p* - toluenesulfonate (1.1 g.; 1 mol) was condensed with quinoline ethiodide (0.7 g.; 1 mol) in absolute ethyl alcohol (25 cc.) using potassium hydroxide (0.14 g.; 1 mol) and refluxing for forty-five minutes; yield 10% before and 7% after recrystallization from methyl alcohol (1130 cc. per g.). The dull reddish-brown crystals had m. p. 244–247°, dec.

Anal. Calcd. for $C_{29}H_{25}IN_2S$: I, 22.66. Found: I, 22.43.

This reaction was carried out before the advantage of using excess of quinoline ethiodide and potassium hydroxide in thia-4′-cyanine condensations was discovered, but the experiment was not repeated owing to lack of material.

2,2′ - Diethyl - 3,4,3′,4′,5,6,5′,6′ - tetrabenzothiacarbocyanine Bromide (VII).—2-Methylphenanthro-[9,10]-thiazole etho-*p*-toluenesulfonate (1.75 g.; 2 mols) was refluxed with pyridine (25 cc.) and ethyl orthoformate (1.2 g.; 2 mols) for forty-five minutes. The dye was precipitated as the bromide; yield 0.077 g. (6%). After recrystallization from dichloroethylene (Soxhlet) the yield was 4%. The minute dark bronze crystals had m. p. 200–202°, dec.

Anal. Calcd. for $C_{37}H_{29}BrN_2S_2$: C, 68.80; H, 4.53. Found: C, 68.97; H, 4.34.

Summary

1. Weighting the benzothiazole nucleus with a fused-on benzene residue gives α- or β-naphthothiazole nuclei, and these are present in photographic sensitizers of value. Repetition of the weighting process leads to the phenanthro-[9,10]-thiazole nucleus, and dyes containing this nucleus have been prepared in the hope that they would also be effective sensitizers.

2. 2-Methylphenanthro-[9,10]-thiazole has

Carbonyl Sulfide. The Heat Capacity, Vapor Pressure, and Heats of Fusion and Vaporization. The Third Law of Thermodynamics and Orientation Equilibrium in the Solid

BY J. D. KEMP AND W. F. GIAUQUE

At the present time the most important problem in connection with the third law of thermodynamics relates to the circumstances under which false equilibrium complicates the practical application of this law. When either the third or the second law of thermodynamics is combined with experimental data to permit the evaluation of some desired quantity, it is implied that the observations were made under conditions of true equilibrium with respect to all processes under consideration.

Recent low temperature investigations have shown that lack of equilibrium exists in the cases of hydrogen, water and their deuterium analogs, carbon monoxide, nitric and nitrous oxides. For each of the above substances the entropy may be accurately calculated from spectroscopic data and it has been possible to give a satisfactory quantitative explanation of the discrepancy between the calorimetric and the spectroscopic values. Carbon monoxide, nitrous oxide (NNO) and nitric oxide (N_2O_2) enter the crystalline state without discrimination between the molecular orientation positions of carbon, nitrogen or oxygen in the crystal lattice. These neighboring atoms in the periodic system are very similar in size and it seems desirable to carry out experiments in which the possibility of lack of discrimination is investigated with more dissimilar atoms.

Linear, unsymmetrical, polyatomic molecules offer a particularly simple case since it is evident that only the two positions corresponding to a rotation of 180° are possible within a crystal lattice. The substance selected for investigation was the linear molecule, carbonyl sulfide (SCO). The measurements to be presented show that the practical application of the third law gives the correct entropy. However, thermal equilibrium was obtained with great difficulty in a considerable region below the melting point, as might be expected if the molecules were beginning to acquire random orientation in the equilibrium state at these temperatures.

Carbonyl Sulfide.—Carbonyl sulfide was made by dropping C. P. concentrated sulfuric acid into a saturated water solution of C. P. potassium sulfocyanate. All solutions were boiled and the preparation line was evacuated with a mercury diffusion pump to eliminate air. The gas was bubbled through a 33% sodium hydroxide solution and collected in a bulb cooled by liquid air. The last traces of water were removed by passing the gas through a tower containing phosphorus pentoxide. Generous first and last fractions were discarded, leaving about 425 cc. of liquid carbonyl sulfide. The gas was then bubbled through some of its own liquid for further purification, a procedure similar to that employed by Gray[1] and by Johnston and Giauque.[2] The final purification was effected by the use of a vacuum jacketed fractionating column; 135 cc. of purified liquid carbonyl sulfide remained after these treatments.

By means of the premelting effects which are superimposed on the heat capacity just below the melting point, it was possible to estimate that the final preparation contained less than one part in twenty thousand of liquid-soluble solid-insoluble impurity.

Apparatus.—A vacuum calorimeter assembly similar to that described by Giauque and Wiebe[3] was used for the measurements. A full description of a similar calorimeter has been given by Giauque and Egan.[4] The calorimeter, which has been given the laboratory designation Gold Calorimeter IV, weighed 443 g. It was 4 cm. in

diameter and 12.5 cm. in length. In order to assure rapid distribution of thermal energy twelve radial vanes of gold, 0.2 mm. in thickness, were welded lengthwise to the inside wall of the calorimeter. The walls of the calorimeter were 1 mm. thick. A platinum inlet tube 2 cm. long and 2 mm. in diameter was welded to the top of the calorimeter and connected to a soda glass tube by means of a cobalt glass seal. Double silk covered, B. and S. gage No. 40, gold wire was wound on the calorimeter to serve as a thermometer heater; 0.175% of silver was added to the gold to increase the heater resistance at low temperatures. Other details of apparatus and procedure including the calibration of the standard thermocouples are given by Giauque and Egan.[4]

A copper-constantan thermocouple, of laboratory designation W-21, was wound around the calorimeter and one junction soldered into the platinum thermocouple well with Wood's metal. Thermocouple W-21 previously had been compared with thermocouple W-22, the present laboratory standard, which was calibrated against the laboratory helium gas thermometer. As the calorimeter could be used as a vapor pressure thermometer, comparisons of W-21 were made against oxygen and hydrogen vapor pressures. The calibration was found to agree within 0.05 degree. Below 20°K. the resistance thermometer was calibrated directly in terms of the vapor pressure of hydrogen. In conformity with other investigations carried out in this Laboratory, 0°C. was taken as 273.10°K.

Vapor Pressure.—As the calorimeter is well suited to maintaining a constant temperature for long periods of time, it was convenient to measure the vapor pressure of the carbonyl sulfide using a large diameter manometer which was connected to the calorimeter for that purpose. A Société Génevoise cathetometer with a precision of 0.002 cm. was used to compare the mercury levels with a standard meter hanging beside the manometer. The pressures were corrected to International centimeters of mercury, using data from the "I. C. T." for all the corrections with the exception of the meniscus height corrections which were taken from the work of Cawood and Patterson.[5] The standard acceleration of gravity was taken as 980.665 cm./sec.^{2} Sternwarte[6] has given 979.973 cm. sec.^{2} as the acceleration of gravity for this location.

The observations on the vapor pressure of liquid carbonyl sulfide have been represented by the following equation for the temperature region between 161.8 and 223.8°K.:

$$\log_{10} P(\text{int. cm. Hg}) = -(1318.260/T) + 10.15309 - 0.0147784T + 0.000018838T^2 \qquad (1)$$

The results are summarized in Table I.

TABLE I

VAPOR PRESSURE OF CARBONYL SULFIDE

Boiling point, 222.87°K.; 0°C. = 273.10°K.

T, °K.	$P_{\text{obs.}}$ Int. cm. Hg	$P_{\text{obsd.}} - P_{\text{calcd.}}$	$T_{\text{obsd.}} - T_{\text{calcd.}}$
161.797	1.282	+0.001	−0.009
161.809	1.283	+ .001	− .005
166.097	1.913	+ .001	− .006
170.560	2.826	− .002	+ .009
175.404	4.219	+ .003	− .009
180.073	6.055	+ .001	− 002
185.100	8.733	.000	.000
190.205	12.388	+ .001	− .002
195.714	17.652	+ .004	− .004
201.401	24.851	− .001	+ .001
211.832	44.134	+ .005	− .002
216.628	56.266	− .010	+ .005
220.522	67.969	.000	.000
223.791	79.189	− .002	.000

The calculated pressure differences given in column three were obtained by assuming the temperature observations to be correct. In column four, the calculated temperature differences were obtained by assuming the observed pressures to be correct. Although the absolute values of the temperatures may be in error by several hundredths of a degree, the observed temperatures are given to 0.001° because of the high relative accuracy.

Melting Point.—The melting point was observed as a function of the percentage melted. Table II gives the results of these observations.

TABLE II

MELTING POINT OF CARBONYL SULFIDE

0°C. = 273.10°K.

Date and time	% Melted	T, °K. resistance thermometer	T, °K. thermocouple
12/2/35 11:10 A.M.	Heated into melting point		
1:05 P.M.	10	134.283	134.29
4:25 P.M.	10	134.275	134.27
5:05 P.M.	Supplied heat		
12/3/35 10:30 A.M.	25	134.298	134.29
1:30 P.M.	25	134.295	134.30
2:00 P.M.	Supplied heat		
5:35 P.M.	50	134.304	134.31
12/4/35 11:00 A.M.	50	134.303	134.30
		Accepted value	134.31 ± 0.05

In obtaining the accepted value, it was recognized that the small amount of impurity present caused an appreciable melting point lowering.

Table III contains a comparison of the melting and boiling points obtained in this research with those obtained by other observers.

Measurement of the Amount of Carbonyl Sulfide.—The method of measuring the amount of carbonyl sulfide depended upon the fact that carbonyl sulfide is soluble in ethyl alcohol. By using liquid air, it was possible to condense the carbonyl sulfide in an ordinary glass bulb containing enough alcohol to lower the pressure of the carbonyl sulfide to about 2.5 atmospheres when it was warmed to room temperature. A bulb containing about 140 cc. of alcohol sufficed for weighing about 13.5 g. of carbonyl sulfide. Each bulb was fitted with a stopcock and one end of an interchangeable ground glass joint. A constriction was made in the stem of each bulb so that it could be sealed by fusing the glass, as it was considered unwise to subject the stopcocks to the pressure which was developed when the carbonyl sulfide was warmed to room temperature.

In order to measure heats of vaporization at a constant pressure, the gas was allowed to vaporize into a carefully calibrated five-liter bulb which was connected to a manometer and a constant pressure regulating device which has been described by Giauque and Johnston.[9] The five-liter bulb was thermostated at 25.00°C. The pressures were measured with the Société Génévoise cathetometer used as a comparison instrument in connection with a standard meter. The line volume outside of the thermostat was carefully determined and only amounted to 165 cc.

The procedure in determining the amount of carbonyl sulfide was as follows. After filling the large measuring bulb, the carbonyl sulfide was condensed in a weighed, evacuated bulb immersed in liquid air. The bulb was then taken off the line and its stem fused at the constriction. Although it was not necessary to use the measuring bulb after completing measurements of the heat of vaporization, its use was continued as a precaution against any accident which might have occurred to any of the weighing bulbs. Twelve weighing bulbs were required to complete the measurement of the amount of carbonyl sulfide.

The above procedure led incidentally to a value, 2.4849 ± 0.0005 g./l., of the density of carbonyl sulfide gas at 25°C. and one atmosphere. This value was derived from an average of eleven determinations at about one atmosphere.

The Heat Capacity of Carbonyl Sulfide.—The heat capacity measurements were made using the method fully described in previous papers from this Laboratory.[3,9] Calibrations of the resistance thermometer against thermocouple W-21 were taken simultaneously with the heat capacity measurements. From these data, a smooth table of resistance against temperature was constructed for use as a temperature scale for the heat capacity measurements. This procedure was followed because of the high precision of the resistance thermometer in measuring small temperature increments.

100	10.53	210	16.98
110	10.95	220	17.03
120	11.40		

Two series of heat capacity measurements were taken on solid carbonyl sulfide. For Series II, the carbonyl sulfide was cooled very slowly, forty-eight hours being required to complete solidification and another forty-eight hours to cool it to 60°K. In Series III, the carbonyl sulfide was cooled rapidly. It required about twelve minutes to complete solidification and about forty minutes more to cool it to 60°K. Further cooling to 15°K. required about two hours.

In both series, when 60°K. was approached in warming from 15°K., it became difficult to obtain thermal equilibrium due to some disturbance in the solid after the period of energy input. Normally, thermal equilibrium is obtained in the calorimeter in about five minutes after the period of energy input, but for the measurements from 60°K. to the melting point, 134.31°K., it required about an hour before thermal equilibrium was obtained.

The point of Series II at T = 61.08°K. is high by about 1% due probably to this lack of thermal equilibrium. The points of Series III are slightly lower than the points of Series II in the region of poor equilibrium. We believe that the slow attainment of thermal equilibrium was due to the difficult process of molecular rearrangement to give the equilibrium number of random end for end orientations.

Heat of Fusion.—Table VI gives a summary of the measurements on the heat of fusion. Each measurement started a short interval below the melting point and ended somewhat above the melting point. Correction was made for the $\int C_p dT$ and the premelting effect.

TABLE VI

HEAT OF FUSION OF CARBONYL SULFIDE

Molecular weight, 60.065

Temperature interval	Corrected heat input/mole	$\int C_p dT$ + premelting heat effect	ΔH cal./mole
132.477–138.090	1246.5	117.0	1129.5
133.730–138.186	1223.9	94.5	1129.4
132.054–137.807	1248.2	117.8	1130.4
		Mean	1129.8 ± 1.0 cal.

Heat of Vaporization.—The heat of vaporization was measured using the constant pressure regulator mentioned in the paragraph under the measurement of amount of carbonyl sulfide. Table VII contains a summary of the heat of vaporization measurements.

TABLE VII

HEAT OF VAPORIZATION OF CARBONYL SULFIDE

Boiling point, 222.87°K.; molecular weight, 60.065

Moles vaporized	Time of energy input, minutes	ΔH at 760 mm. cal./mole
0.21247	40	4424
.20469	40	4422
.20050	40	4423
.20396	40	4421
	Mean	4423 ± 4 cal.
From vapor pressure Equation 1, assuming a Berthelot gas		4415

The heat of vaporization may be calculated using the vapor pressure data and Berthelot's equation of state of the gas in connection with the equation $\Delta H = (dP/dT)(T\Delta V)$. The expression for ΔH finally takes the form

$$\Delta H = \frac{dP}{dT}\frac{RT^2}{P}\left[1 + \frac{9PT_c}{128P_cT}\left(1 - 6\frac{T_c^2}{T^2}\right) - \frac{PV}{RT}\text{liq.}\right]$$

$T_c = 378.1$°K., $P_c = 61$ atmospheres.[10]

The resulting value for ΔH is 4415 cal./mole. The heat of vaporization, assuming an ideal gas, is 141 cal./mole greater than that calculated on the basis of Berthelot's equation.

The Entropy from Calorimetric Data.—A summary of the calculation of the entropy of carbonyl sulfide at its boiling point, 222.87°K., is given in Table VIII.

The close agreement between the calculated value and the calorimetric value of the heat of vaporization lends plausibility to the use of Berthelot's equation in making a small entropy correction for the change from the actual to the ideal gas state. Berthelot's equation with the thermodynamic equation $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ gives the following expression for the correction:

$$\Delta S = 27RT_c^3P/32T^3P_c$$

$\Delta S = S_{\text{ideal}} - S_{\text{actual}} = 0.13$ E. U. at the boiling point.

TABLE VIII

CALCULATION OF ENTROPY OF CARBONYL SULFIDE

0–15°K., Debye function $hc\nu/k = 95$	0.55
15–134.31°K., graphical	14.96
Fusion, 1129.8/134.31	8.41
134.31–222.87°K., graphical	8.66
Vaporization 4423/222.87	19.85
Entropy of actual gas at boiling point	52.43 ± 0.10 E. U.
Correction for gas imperfection	0.13
Entropy of ideal gas at boiling point	52.56 E. U.

Entropy from Molecular Data.—The entropy of carbonyl sulfide has been calculated from band spectra data and electron diffraction measurements, using the following well-known equations

$$S_{\text{Trans.}} = 3/2R \ln M + 5/2R \ln T - R \ln P - 2.300$$

$$S_{\text{Rot.}} = R \ln IT + 177.676$$

$$S = R\sum_{\nu_1, \nu_2, \nu_3}\left[\frac{x}{1 - e^x} - \ln(e^x - 1)\right]$$

where $x = hc\nu/kT$ and ν_2 has a weight of two in the summation.

The moment of inertia of carbonyl sulfide, 137×10^{-40} g. cm.^{2}, has been obtained from the electron diffraction experiments of Brockway and Cross,[11] who give as the C=O and C=S distances 1.16 ± 0.02 Å. and 1.56 ± 0.03 Å., respectively. The uncertainty in this value leads to an uncertainty of ± 0.1 E. U. in the calculated entropy. Bartunek and Barker[12] have given the following equation summarizing the vibrational energy levels.

$$E_{\text{vib.}} = 863.4V_1 + 518.95V_2 + 2050.5V_3 - 4.2V_1^2 - 0.10V_2^2 - 2.35V_1V_2 + 9.3V_1V_3 + 3V_2V_3 + 2.65l^2\text{cm.}^{-1}$$

In making the calculation, the anharmonic terms were ignored as they do not contribute appreciably to the entropy at room temperature or lower. With this approximation, the equation gives the following vibrational frequencies: $\nu_1 = 859.2$, $\nu_2 = 521.50$, $\nu_3 = 2050.5$ (in cm.$^{-1}$).

A summary of the calculation with a comparison of the experimental and spectroscopic entropies is given in Table IX.

---

[10] "Int. Crit. Tables," **3**, 231 (1928).

[12] Bartunek and Barker, *Phys. Rev.*, **48**, 516 (1935).

TABLE IX

ENTROPY OF CARBONYL SULFIDE FROM MOLECULAR DATA

		222.87°K.	298.1°K.
Translation		36.761	38.206
Rotation		15.19	15.77
Vibration		0.711	1.389
Calculated entropy		52.66 E. U.	55.37 E. U.
Experimental entropy	Actual gas	52.43 E. U.	......
	Ideal gas	52.56 E. U.	55.27 E. U.

Cross[13] has also calculated the entropy at 298.1° K. His value is 0.03 E. U. higher than the calculated value given above. The difference is due to his use of slightly different vibrational constants.

The good agreement between the entropy value obtained from the third law of thermodynamics and that calculated from molecular data and quantum statistics proves that no random molecular orientation exists in carbonyl sulfide at low temperatures.

Summary

The heat capacity of liquid and solid carbonyl sulfide has been determined from 15°K. to the boiling point.

The melting point is 134.31°K., the boiling point, 222.87°K. (0°C. = 273.1°K.). The heat of fusion is 1129.8 cal. per mole and the heat of vaporization at the boiling point, 4423 cal. per mole.

The vapor pressure of liquid carbonyl sulfide has been measured and the data are represented very closely by the equation: liquid carbonyl sulfide 161.8 to 223.8°K.

$$\log_{10}P(\text{int. cm. Hg}) = -(1318.260/T) + 10.15309 - 0.0147784T + 0.000018838T^2$$

The density of carbonyl sulfide gas at 25°C. and 1 atm. is 2.4849 ± 0.0005 g./l.

From the experimental data the entropy of the ideal gas at the boiling point was found to be 52.56 cal./deg. per mole. This may be compared with the value 52.66 cal./deg. per mole, calculated from electron diffraction measurements and spectroscopic data.

The good agreement between the experimental and calculated values of the entropy indicates that the difference in size between the oxygen and sulfur ends of the carbonyl sulfide molecule suffices to prevent random orientation of the type found in carbon monoxide and nitrous and nitric oxides at low temperatures.

The Osmotic and Activity Coefficient Data of Some Aqueous Salt Solutions from Vapor Pressure Measurements

BY ROBERT A. ROBINSON

The isopiestic vapor pressure method has been[1] applied to the determination of the activity coefficients of some alkali halides, nitrates, acetates and *p*-toluenesulfonates and of some bivalent metal sulfates. The object of this communication is to describe: (1) the determination of the activity coefficients of some thallous salts; (2) the completion of the data for the nitrates and acetates by the inclusion of figures for the rubidium and cesium salts; (3) a redetermination on some rubidium and cesium halides and (4) the extension of measurements to polyvalent electrolytes, namely, barium chloride, lanthanum chloride, aluminum sulfate and potassium ferrocyanide.

All data in this paper refer to 25°.

I. Thallous Salts.—Thallous nitrate, perchlorate and acetate were prepared by interaction between the carbonate and the corresponding acid, the first salt being recrystallized five times and the other two salts four times. They were balanced against isopiestic solutions of potassium chloride and thence the osmotic and activity coefficients calculated in the manner described previously.[1c] The densities of aqueous solutions of the perchlorate and acetate, not hitherto recorded, have also been measured. Table I gives the data relevant to these salts, γ(D. H.) being the activity coefficient calculated on the limiting Debye–Hückel equation. Eleven determinations were made on the nitrate and twelve on the perchlorate. Twenty-nine measure-

ments on the acetate were necessary to cover the concentration range up to 6 *M*, this being one of the few thallous salts which gives concentrated solutions. The activity coefficients are plotted against $\sqrt{m}$ in Fig. 1.

From the density determinations, together with the data for thallous nitrate in the "International Critical Tables,"[2] the apparent molal volumes, Φ have been calculated. If Φ is plotted against $\sqrt{m}$, the points lie on a straight line within the limit of experimental error and consequently Φ can be represented by the equation[3]

$$\Phi = a\sqrt{m} + b$$

using the following values of the constants

$TlNO_3$	$a = 5.9$	$b = 39.5$
$TlClO_4$	$a = 5.3$	$b = 53.55$
$TlC_2H_3O_2$	$a = 4.3$	$b = 50.9$

The partial molal volume of salt will be given by

$$\overline{V}_s = (3a\sqrt{m}/2) + b$$

and the partial molal volume of water by

$$55.51\overline{V}_w = 18.07 - (am^{1/2}/2)$$

These formulas reproduce the experimental data for the nitrate and perchlorate within approximately 0.1 cc. The equation for the acetate is valid up to 3 *M* within approximately the same limit; there is no trend in the observations from the calculated curve, so that any error is probably experimental.

Thallous nitrate is remarkable in that it has a lower activity coefficient than any other uniunivalent salt at the same concentration; the values of the activity coefficient are so low that the limiting Debye–Hückel equation reproduces the experimental data at concentrations at which it would be expected that the finite radius and the variation of the dielectric constant would invalidate the limiting law. The Gronwall–La Mer–Sandved equation[4] is no more satisfactory, because in order to reproduce the experimental data it is necessary to choose a value of $a = 1.3$ Å., which is a most improbable figure.

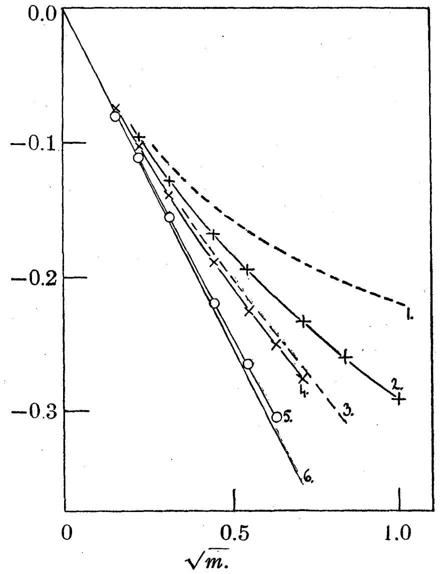

Fig. 1.—Activity coefficients of thallous salts: 1, KCl; 2, $TlC_2H_3O_2$; 3, KNO_3; 4, $TlClO_4$; 5, $TlNO_3$; 6, limiting Debye–Hückel slope.

The activity coefficient of thallous perchlorate is slightly less than that of rubidium nitrate at the same concentration and comparable with that of cesium nitrate. The data for the acetate lie between those for sodium and potassium nitrate. Thus the analogy with the heavier alkali metals exhibited by thallous nitrate and perchlorate does not extend to the acetate, for the alkali acetates are characterized by the very high values of their activity coefficients.

II. The Nitrate and Acetate of Rubidium and Cesium.—Rubidium carbonate of good quality was converted into the dichloroiodide and recrystallized twice in this form.[5] It was then converted into carbonate and the nitrate, acetate,

bromide and iodide prepared. Halogen analysis gave concordant values of the equivalent weight of the metal, namely, 85.38 (Rb = 85.44). Similarly cesium chloride was purified by the method described by Harned and Schupp.[6] It gave an equivalent weight of 132.75 (Cs = 132.91). From the purified material the nitrate, acetate, bromide and iodide were prepared.

The solutions of the nitrate and acetate were balanced against isopiestic solutions of potassium chloride, the number of determinations being: $RbNO_3$, 20; $RbC_2H_3O_2$, 22; $CsNO_3$ 18; $CsC_2H_3O_2$, 26. The osmotic and activity coefficients recorded in Table II were calculated. The activity coefficients of these four salts are of the magnitude which would be expected from an inspection of the data for the salts of the other alkali metals, the curves for rubidium and cesium nitrate lying close below that for potassium nitrate, while cesium acetate gives a curve above that for rubidium acetate which in turn lies above that for potassium acetate. The order of acetates, Cs > Rb > K > Na > Li is, therefore, the reverse of that which holds for alkali nitrates, chlorides, bromides and iodides.

Densities of solutions of the two acetates were also measured, but as only small quantities of material were available, small pycnometers had to be used, with a larger margin of error. The determinations should, however, be sufficient to transfer molality data to volume concentrations and to give approximate values of the coefficients in Masson's equation for the apparent molal volume. They are recorded in this manner, together with the corresponding figures for the nitrates and the remaining acetates, using data in the "International Critical Tables."[7] Similar data for the alkali halides have already been calculated by Scott.[8]

b	...	39.8	47.2	53.5	61.3

III. Halides of Rubidium and Cesium.—As few measurements have been made on rubidium chloride, it was felt desirable to make another determination of the activity coefficient of this salt, using a purer specimen than was available in the previous investigation.[1a] In this work, moreover, trouble was experienced by the decomposition of the iodides of rubidium and cesium[1b] and by corrosion of the silver dishes by the more concentrated solutions. Better results have now been obtained by using chromium plated boxes of "staybrite" steel. These boxes were also used to redetermine the data for the bromides. As far as can be judged, corrosion has been eliminated, for the full amount of halogen was recoverable and there was no detectable loss in weight of the dishes even after a lengthy run. Nevertheless, a minute error assumes importance in the case of such salts whose coefficients are so close together and it is still desirable that an independent determination by another method should be made. The redetermined data are not substantially different, except in the case of rubidium iodide whose activity coefficient is slightly higher

than that of the bromide in concentrated solutions and in the case of cesium iodide, the previous data for which differ considerably from the redetermined values. The latter are considered more reliable. This redetermination does not alter the order of the curves of γ against $\sqrt{m}$.

IV. Polyvalent Electrolytes.—Barium chloride of A. R. purity was used, analysis showing it to be of good quality. Lanthanum chloride was recrystallized three times; aluminum sulfate was prepared from A. R. potash alum and potassium ferrocyanide recrystallized once from Kahlbaum material. Table V gives the osmotic and activity coefficients derived from measurements on these four salts, numbering 36, 33, 36 and 24, respectively.

The activity coefficient of barium chloride at 0.05 M has been put equal to the value at this concentration calculated by Scatchard;[9] the present values at high concentrations are about 2% lower than those calculated by Scatchard and somewhat lower still than those derived from the measurements of Lucasse.[10] The agreement with the determinations of Pearce and Gelbach[11] is not good. For lanthanum chloride it is more difficult to select an initial value; as a temporary expedient, the activity coefficient at 0.05 M was taken as 0.380, the value for lanthanum nitrate at this concentration.[12] Similarly the value at 0.05 M for potassium ferrocyanide was taken from freezing point data.[12]

The osmotic coefficients of these salts are shown in Fig. 2 in the form of a plot of $(1 - \varphi)/z_1z_2\sqrt{\mu}$ against $\sqrt{\mu}$, z_1, z_2 being the ionic valences and μ the ionic strength. The limiting value of this function is 0.387 at 25°.

Discussion

The experimental results which have been described in this and the previous papers, may be summarized qualitatively as follows. (1) The curves of γ against $\sqrt{m}$ lie in the order of I > Br > Cl for the lithium, sodium and potassium salts. This order is reversed for the rubidium and cesium salts. (2) All lithium salts have high activity coefficients, the lowest recorded being those of the *p*-toluenesulfonate. (3) With the exception of lithium nitrate, the alkali nitrates are characterized by very low activity coefficients. This is also true of sodium and potassium *p*-toluenesulfonate. (4) The alkali acetates are characterized by a reversal of the order Li > Na > K > Rb > Cs, which holds for other alkali salts. In addition, the values are all high and comparable with those of lithium salts in general. (5) Thallous salts have low activity coefficients, the nitrate having the lowest activity coefficient of any uni-univalent salt; another characteristic is to be found in the acetate which does not reproduce the behavior of the alkali acetates but has a low activity coefficient.

In another publication Professor Scatchard will discuss on the basis of his equation[13] the osmotic coefficients of the alkali halides and he will show that this equation will not only predict the magnitude of the activity coefficients within the limits anticipated but will also explain the reversal of the order I > Br > Cl for the cesium salts. Consequently I shall not enter into a discussion of these halides. It is important, however, to point out that both the constants in Scatchard's equation, which determine the variation of polarization with concentration and the non-ionic effect, respectively, are related to the molal volume of the salts.

Turning now to the thallous salts, it has been shown that the activity coefficient of the nitrate cannot be reconciled either with the limiting Debye–Hückel equation or with the Gronwall–La Mer–Sandved equation. The molal volume of thallous nitrate lies between those of rubidium chloride and bromide (39.5, 25.2 and 41.8, respectively) and its ionic radii are probably comparable with those of rubidium bromide. The disparity between the osmotic coefficients (0.800 for thallous nitrate and 0.898 for rubidium bromide at 0.3 *M*) is therefore remarkable. While an explanation in terms of a physical difference between the nitrate and halogen ions, such as the increased possibility of polarization of the latter by oppositely charged ions, cannot be excluded, it seems improbable since a like disparity between lithium nitrate and lithium bromide with osmotic coefficients of 0.941 and 0.951 at 0.3 *M*, is not found. This leaves the possibility of the incomplete dissociation of thallous nitrate to be considered. Onsager[14] has already shown that conductivity data in very dilute solutions agree with the hypothesis of incomplete dissociation in the case of potassium nitrate, thallous nitrate and thallous chloride, with dissociation constants of 1.3, 0.55 and 0.31, respectively. Similarly Redlich and Rosenfeld[15] assign a dissociation constant of 1.2 to nitric acid and Cowperthwaite, La Mer and Barksdale[16] have also used this hypothesis to account for some anomalous e. m. f. data for thallous chloride, which otherwise lead to impossibly

low values for the ionic radii. Unfortunately the data for thallous nitrate apply to concentrations too high to be dealt with by Onsager's method but Davies[17] has devised an extension of the conductivity equation to which many uni-univalent salts conform up to molar concentration, *viz.*

$$\lambda_{\text{calcd.}} \sqrt{\eta} = \lambda_0 - (0.2238\ \lambda_0 + 50.49)f(c)$$

where η is the viscosity and $f(c)$ is an empirical function of the concentration. This equation applies at 18° but it can be used at 25° if suitable alteration is made in the numerical magnitude of the constants. In spite of its empirical nature, this theory deserves consideration for it satisfies the available data for all the alkali chlorides, bromides and iodides using the same values of $f(c)$ for each salt and indeed can be extended to even higher concentrations than were originally considered by Davies. In the case of an incompletely dissociated salt Davies assumes that the degree of dissociation is given by $\alpha = \lambda_{\text{obsd.}}/\lambda_{\text{calcd.}}$ and thence the dissociation constant by

$$K = \gamma^2\alpha^2c/(1 - \alpha)$$

The conductivity data for thallous nitrate are not as extensive as could be desired but they give the following values of the dissociation constant.

m	0.01	0.02	0.05	0.1	0.2	0.25
α	.983	.972	.946	.911	.870	.848
K	.45	.48	.48	.44	.38	.36

The values of K are as constant as can be expected in view of the large variation in $(1 - \alpha)$ caused by a slight error in α. It remains now to be shown that such incomplete dissociation accords with the anomalous osmotic coefficients. The vapor pressure lowering, from which the osmotic coefficient was calculated, may be assumed to be due to two factors, one due to the ions and the other to the undissociated molecules. The relative lowering of the vapor pressure due to the latter may be taken as 0.018 m_v, m_v being the molality of the undissociated molecules, provided they can be assumed to act as a perfect solute. The osmotic coefficient of the solution in the absence of these undissociated molecules would therefore be given by

$$\varphi' = -55.51/2m_{\pm} \ln\left[(p + 0.018m_vp_0)/p_0\right]$$

where $m_{\pm}$ is the ionic molality. Calculating φ' in this manner we obtain the following values

m	0.01	0.02	0.05	0.1	0.2	0.25
φ'	.969	.959	.938	.918	.882	.871

These values are of the right order; they can not be regarded as quantitatively reliable but it is nevertheless significant that Davies' method of computing the degree of dissociation leads to osmotic coefficients which correspond to reasonable ionic dimensions.

In the case of cesium, rubidium, potassium and sodium nitrate, although their activity coefficients are not as low as in the case of thallous nitrate, yet it would be anticipated from a comparison of their molal volumes with the data for the bromides that their activity coefficients would be of the same order as those of the corresponding bromides. From this point of view the anomalies are most pronounced, especially as lithium nitrate has an activity coefficient not greatly different from that of lithium bromide. The ratios of the activity coefficient of the bromide to that of the corresponding nitrate at 1 *M* concentration are as follows

Li	Na	K	Rb	Cs
1.09	1.27	1.40	1.35	1.28

Moreover, it may be significant that conductivity data, interpreted on the basis of Davies' equation, correspond to complete dissociation of lithium nitrate; on the other hand, incomplete dissociation is indicated in the case of the nitrates of sodium, potassium and cesium (the necessary data for the rubidium salt are lacking). It is therefore tempting to ascribe the anomalous activity coefficients of these nitrates to incomplete dissociation, the most powerful argument against this hypothesis being found in the work of Rao[18] who showed that the Raman spectrum from a solution of sodium nitrate showed no lines which could be ascribed to the undissociated molecule. The argument, however, cannot be held to be conclusive until much further work has been done, for Woodward[19] has found an example in hydrofluoric acid of an electrolyte which is certainly incompletely dissociated but gives no Raman lines for the undissociated molecule. Applying Davies' equation to these three nitrates, the following results are obtained.

Molality	0.01	0.05	0.1	0.5	1
			$NaNO_3$		
α	0.996	0.985	0.982	0.947	0.913

K	.87	.85	.91	.86	.66
φ'	.978	.950	.924	.839	.784

Whilst these osmotic coefficients can have little quantitative significance, especially for more concentrated solutions, the purpose of the calculation is achieved by showing that the effect of incomplete dissociation is such as to lead to osmotic coefficients of a more reasonable order.

The osmotic coefficients of the alkali acetates are much higher than one would expect from a consideration of their molal volumes. Davies' equation, however, gives no indication of incomplete dissociation and it is probable that the abnormally high values for all but the lithium salt as well as the reversal in the normal order Li > Na > K > Rb > Cs will find an explanation in the asymmetrical distribution of charge in the acetate ion.

There seems to be no purpose at present in attempting a theoretical explanation of the coefficients of the polyvalent salts. It may, however, be pointed out that, as Fig. 2 shows, the departure from the limiting Debye–Hückel equation at high concentrations is no more marked for polyvalent electrolytes in general than it is for a typical uni-univalent salt such as potassium chloride.

Finally I wish to record my thanks to Professor G. Scatchard, who has helped me with much information regarding his theory and to the Chemical Society for a grant which assisted in the purchase of rubidium and cesium salts.

Summary

1. Osmotic and activity coefficients have been determined by the isopiestic vapor pressure method for thallous nitrate, perchlorate and acetate, rubidium and cesium nitrate and acetate, barium chloride, lanthanum chloride, potassium ferrocyanide and aluminum sulfate. The data for rubidium chloride, bromide and iodide and cesium bromide and iodide have been redetermined.

2. The possibility of incomplete dissociation of sodium, potassium, cesium and thallous nitrate has been discussed and it is shown that not only is this hypothesis consistent with Davies' extension of the conductivity equation but it also explains the abnormally low values found for the osmotic and activity coefficients of these salts.

The Use of Crotonaldehyde to Reduce the Postprecipitation of Zinc on Copper Sulfide

BY JOHN R. CALDWELL[1] AND HARVEY V. MOYER

It has been known for many years that copper sulfide, precipitated in the presence of zinc, will carry down appreciable quantities of zinc even when the precipitation is made in a normal acid solution. Various theories of mixed crystal formation, of solid solution and of coprecipitation have been proposed as explanations. Comparatively recent studies have been made by Kolthoff and Pearson,[2] Knowles and Martin,[3] Balarew[4] and Kolthoff and Moltzau.[5]

Kolthoff has presented evidence which seems to indicate that an adsorbed layer of hydrogen sulfide on the surface of the copper sulfide causes the postprecipitation of the zinc as sulfide.

Recently we have found that certain organic compounds may be used to alter the nature of analytical precipitates.[6–9] In a study of the separation of zinc and cobalt, it was found that if zinc sulfide was precipitated in the presence of a small amount of certain aldehydes, acrolein in particular, the quantity of cobalt carried down is

so small that it is possible to make a quantitative separation of the metals in one precipitation. It seemed quite probable that this same procedure could be applied to the separation of copper and zinc.

Although a number of aldehydes were found to be effective in reducing the postprecipitation of zinc on copper sulfide, the unsaturated aldehydes containing the structure, RCH=CHCHO, proved superior to all others tried. Acrolein, cinnamic aldehyde and crotonaldehyde contain this structure and all were found to reduce greatly the quantity of zinc carried down. Acrolein is probably the best but it is troublesome to prepare and polymerizes so readily that it is difficult to keep. Cinnamic aldehyde tends to form an insoluble resinous product which interferes with filtration. Crotonaldehyde does not have these objectionable properties and was chosen for this investigation although it is not as effective as acrolein in the separation of zinc from cobalt. Benzaldehyde and formaldehyde were tried but were not as satisfactory as the unsaturated aldehydes. It was found that formaldehyde was quite effective in reducing the quantity of zinc carried down, but it seemed to prevent the quantitative precipitation of the copper. A few tenths of a milligram of copper always remained in solution after saturation with hydrogen sulfide.

Experimental

Materials.—The benzaldehyde and crotonaldehyde were distilled through a small laboratory fractionating column. Formaldehyde was used in the usual 40% solution.

A reagent grade of copper sulfate was recrystallized twice.

A reagent grade of zinc sulfate was recrystallized once.

Procedure.—A solution containing 0.125 g. of zinc and 0.125 g. of copper as sulfates with varying quantities of sulfuric acid was diluted to 100 ml. in a 250-ml. Erlenmeyer flask. Precipitations were made in pairs, one without aldehyde and the other containing approximately 0.05 ml. of an aldehyde. The flasks were connected to the same source of hydrogen sulfide through a Y-tube to ensure an equal supply of gas to each solution. A mechanical shaker kept the solutions in constant agitation during precipitation. Hydrogen sulfide was passed into the open flasks for five minutes to remove the air, then the flasks were stoppered and the gas was kept in contact with the solutions for fifteen minutes at the pressure of about 15 cm. of water. The flasks were removed, stoppered and allowed to stand for different lengths of time varying from thirty minutes to six hours.

In order to determine the quantity of zinc carried down, the solution was filtered through filter paper, washed with hot water and then five 10-ml. portions of 6 N hydrochloric acid were poured through the filter. This procedure was carried out in a hood since the aldehyde and hydrogen sulfide react to form a compound with a very unpleasant odor. The zinc was extracted by the hydrochloric acid and it was observed that if more than 10 mg. of zinc was present, there was a vigorous evolution of hydrogen sulfide. A few milligrams of copper always dissolved and this was removed before the zinc was determined. The solution was evaporated to dryness, moistened with nitric acid and again brought to dryness to destroy organic matter. The residue was dissolved in 100 ml. of water which was made normal with hydrochloric acid and the trace of copper precipitated with hydrogen sulfide. After filtration, the solution was evaporated to dryness and the zinc was determined turbidimetrically with potassium ferrocyanide according to the method described by Yoe.[10] In order to be certain that all the zinc was extracted from the copper sulfide, several precipitates, some formed in the presence of aldehyde and some formed in its absence, were dissolved in nitric acid and reprecipitated in the presence of crotonaldehyde. No zinc was found in any of the filtrates.

Benzaldehyde was tried in the first quantitative experiments. Although copper sulfide is usually precipitated in a solution 0.5 to 1 N in sulfuric acid, a lower normality was chosen in order to bring out the protective action of the aldehydes to the fullest extent. In the presence of 0.05 ml. of benzaldehyde, the zinc carried down with the copper sulfide varied from 0.2 to 1.2 mg., whereas, in the absence of the aldehyde, the quantity of zinc varied from 1.5 to 15 mg. Although considerable reduction in the zinc carried down was brought about by the benzaldehyde, it was not considered a satisfactory protective agent because of rather large variations in the results.

Crotonaldehyde was found to be effective in reducing the post-precipitation of zinc even in 0.36 N acid. In a series of determinations carried out as described above, approximately seventy times as much zinc was found on an average in the copper sulfide precipitates which were formed in the absence of the aldehyde. In four determinations in which filtration was made immediately after precipitation, an average of 0.07 mg. of zinc was found in those precipitated with aldehyde and an average of 4.0 mg. was found in the blanks. In ten determinations in which the precipitates were allowed to stand from two to three hours, an average of 0.11 mg. of zinc was found in those treated with aldehyde and an average of 8.0 mg. was found in the untreated ones. Five determinations on standing from four to six hours showed an average of 0.25 mg. of zinc when precipitated with aldehyde and an average of 18.0 mg. in its absence. A change of acid concentration from 0.36 to 0.5 N caused no significant difference in the results.

Discussion

The study of the postprecipitation of zinc on copper sulfide is complicated by the fact that the precipitate of copper sulfide is variable in composition and its true chemical nature is still unknown. Feigl[11] believes the initial precipitate

---

[10] Yoe, "Photometric Chemical Analysis," John Wiley and Sons, Inc., New York, 1928, p. 397.

[11] Feigl, *Z. anal. Chem.*, **72**, 32 (1927).

contains free sulfur because boiling with sodium sulfite gives a considerable quantity of sodium thiosulfate. Recent work by Sauer and Steiner[12] lends support to this view. There is a definite cycle of changes which take place during the precipitation and aging of copper sulfide. During early stages of the precipitation, copper sulfide separates as a fine black sol which remains in suspension in the solution. After three or four minutes the particles begin to clump together and settle. In another five minutes the loose clumps become more compact and dense and assume a brownish color. If the flask is stoppered and allowed to stand, a definite aging process takes place. In two or three hours, the dense brownish-black aggregations begin to disperse and become greenish-black in color. In about ten hours the peptization has reached a point where secondary aggregates are so reduced in size as to be almost invisible to the unaided eye. Microscopic examination shows that minute primary particles predominate. An extremely small concentration of crotonaldehyde exerts a profound influence upon this aging process. When formed in the presence of crotonaldehyde, the precipitate does not peptize to give small primary particles, but on the contrary tends to coagulate into clumps that are even larger than those formed in the beginning. Microscopic examination shows that the clumps consist of many primary particles closely packed into opaque dense masses which show no tendency to disintegrate, even after standing for several days.

Summary

If copper sulfide is precipitated in the presence of a very small concentration of crotonaldehyde, the quantity of zinc carried down is reduced greatly. Apparently the crotonaldehyde reacts with the adsorbed hydrogen sulfide and reduces its value on the surface of the copper sulfide so that it will not cause the postprecipitation of the zinc.

The Conductivity of Various Salts in *n*-Propyl and Isopropyl Alcohols

BY FRANK HOVORKA AND JOHN COLBERT SIMMS[1]

Introduction

The conductivity of various salts has been determined in methyl and ethyl alcohols by many workers during the last few years. Since only a comparatively few measurements were made in *n*-propyl and isopropyl alcohols, it seemed desirable to carry out a series of conductivity determinations of the more common uni-univalent salts in these two solvents. The dielectric constant of the alcohols gradually decreases as they increase in molecular weight. Therefore, a study of the alcohols as a series ought to give the effect of the solvent as well as that of the dielectric constant on the nature of the electrolytic solutions.

Apparatus.—The assembly comprised a Leeds and Northrup Kohlrausch bridge and dial box type coils of low induction. All the resistances were checked against coils calibrated by the Bureau of Standards. The balance point was detected by Baldwin type telephones using two stage amplification. The other parts used in this "set up" were of the standard type generally used in accurate conductivity measurements.

The cell used in this investigation was of borosilicate glass and was made after a design of Hartley and Barrett.[2]

The thermostat was a large vacuum jar. The temperature was kept constant at 25 ± 0.005°.

Materials and Procedure.—Each of the alcohols containing a little water was refluxed for several hours over barium oxide and then distilled into a Pyrex fractionating flask and column without coming in contact with air. Each was fractionated to a boiling point of 0.05° and then treated with metallic sodium. After two further distillations they were fractionated directly into the conductivity cell which was dried previously by passing dry warm air through it. Usually about 100 g. of alcohol was distilled into the cell. The specific resistance of the *n*-propyl alcohol was 2×10^8 mhos. and of the isopropyl alcohol 9×10^9 mhos. These values were determined by using a direct current of 135 volts and were used in making the solvent correction.

The C. P. salts were recrystallized from water at least three times, dried, and analyzed for final purity. A known amount of each salt was transferred to a 100-cc. Pyrex bottle which had been baked out with a free flame. All of the handling of salts as well as of the alcohols was car-

ried out in an atmosphere of dry air. Enough alcohol from the final purification was distilled into this bottle to give about a thirtieth normal solution. A small weight pipet was filled from this bottle and introduced through the cap of the cell while dry air was passing through the cell. The addition of about one gram of this solution to about 100 g. of the alcohol gave a solution approximately 0.0001 *N*.

The electrodes finally used were coated with a medium layer of platinum black and ignited to redness. This gave a dull gray coating. The balance was quite easily obtained and no oxidation seemed to occur as the conductivity of the solutions did not change on standing.

The value of the cell constant was determined several times during the work and no variation greater than the experimental error could be noted. The measurements were made over the same range of concentration as that of the alcohol solutions. Water was weighed in the cell and an aqueous solution of potassium chloride was added through the weight pipet. The conductivity values found compared with those calculated by the Kohlrausch and Maltby equation as corrected by Kraus and Parker:[3] $\Lambda_c = 129.91 - 80.75\sqrt{c}$.

Before the measurements on propyl alcohol were begun Frazer and Hartley's[4] measurements on potassium chloride were repeated. The results obtained checked their conductivity curve well within the experimental error.

Results

In Tables I and II C is the equivalent concentration; Λ_c the experimental equivalent conductivity; K_1, the dissociation constant as calculated from the Ostwald dilution law; and K_2, the dissociation constant as computed by the Fuoss and Kraus[5] method where

$$K_2 = c\gamma^2 f^2/1 - \gamma$$

c is the equivalent concentration, γ is equal to the average fraction of solute free to carry the current and f is the activity coefficient of the ions expressed by

$$-\ln f = \beta\sqrt{c\gamma}/(1 - \delta\sqrt{c\gamma})$$

$$\text{where } \beta = \frac{e}{2DkT}\left(\frac{8\,Ne^2}{1000\,DkT}\right)^{1/2}$$

$$\text{and } \delta = \left(\frac{8\,Ne^2}{1000\,DkT}\right)^{1/2}\alpha$$

Sodium bromide	98.28	4.612	4.351	2.989
Potassium bromide	101.23	4.612	4.034	2.772

In Table IV Λ_0 is the limiting conductivity obtained by extrapolating $\Lambda_c - \sqrt{c}$ experimental curves. Λ_0' was obtained by using the Fuoss and Kraus[5] equation

$$\gamma' = \frac{\Lambda/\Lambda_0}{1 - \alpha\Lambda_0^{-3/2}\sqrt{C\Lambda}}$$

and determining for what value of Λ_0, γ will converge to a constant value as successive substitutions are made. α in the last expression is computed by Onsager[11] as $\alpha = \frac{8.18 \times 10^5}{(DT)^{3/2}}\Lambda_0 + \frac{82}{\eta(DT)^{1/2}}$

This is probably the best method for obtaining accurately the limiting equivalent conductivity. A greatly simplified method for estimating γ suggested later by Fuoss[12] was found to be very useful but was not as accurate for the determination of Λ_0 as the original method which was used in all of the calculations in this paper. K_1 and K_2 are the averages of those given in Tables I and II. K_3 is a dissociation constant obtained by plotting $f\sqrt{c} - \sqrt{1 - \gamma}/\gamma$ for various values of Λ_0 until a straight line is obtained which passes through the origin. The slope of this line is equal to K_3.

Discussion

When $\Lambda_c - \sqrt{c}$ curves are plotted the points fall quite well on a straight line up to a concentration of about 0.0003 *N*. Above this concentration region the equivalent conductivity decreases at a considerably lower rate with the increase in concentration. Many of the curves intersect, illustrating rather marked differences between the electrolytes. These differences become more evident with the increasing molecular weight of the alcohols. In methyl alcohol, for instance,

[12] Fuoss, THIS JOURNAL, **57**, 488 (1935).

which resembles water in its behavior, the curves are almost parallel.

The experimental slopes of the conductivity curves are greater in every case than those predicted by Onsager. The deviation is in the neighborhood of 100% or more indicating a rather incomplete dissociation. The comparison of the values of experimental Λ_c (Tables I and II) with those calculated from the Debye–Hückel–Onsager equation show differences of about 5 to 10% in the more dilute regions.

The limiting equivalent conductivity (Table IV) of each salt is considerably less than its conductivity in ethyl alcohol. However, if methyl, ethyl, and the propyl alcohols are considered as a series, the values obtained cannot be explained on the ground of viscosity and the dielectric constant differences. Further, there seems to exist no relation in the order of conductivities of the salts in propyl and isopropyl alcohols, nor does the principle of additivity apply in either alcohol. Either the chemical nature of the solvent plays an important part or the viscosity and the dielectric constant are not accounted for correctly or both. It is of interest to note that the values of Λ_0 obtained by the extrapolation of $\Lambda_c - \sqrt{c}$ curves and those obtained by the Fuoss and Kraus method differ in some cases by as much as 3%. The importance, of course, of obtaining correct Λ_0 for various calculations cannot be overemphasized.

TABLE IV

LIMITING CONDUCTIVITY AND DISSOCIATION CONSTANTS

Solute	Alcohol solvent	Λ_0	Λ_0'	$K_1 \times 10^3$	$K_2 \times 10^3$	$K_3 \times 10^3$
KI	*n*-Propyl	25.42	25.16	2.378	4.107	4.053
NaI	*n*-Propyl	24.12	23.94	3.046	7.010	7.039
NaBr	*n*-Propyl	18.58	18.31	3.054	9.582	9.140
KBr	*n*-Propyl	23.54	22.93	1.518	2.343	2.373
KI	Isopropyl	23.64	23.45	1.220	1.461	1.461
NaI	Isopropyl	18.96	18.58	1.811	3.846	3.798
NaBr	Isopropyl	18.08	18.65	1.354	1.835	1.853
KBr	Isopropyl	19.50	19.81	0.352	0.357	0.354

There seem to be data available only for sodium iodide in propyl[13] and isopropyl alcohols.[14] The value of 18.87 obtained for Λ_0 by Brown for sodium iodide in isopropyl alcohol is in good agreement with the value obtained here. However, the value of 21.04 for Λ_0 obtained by Keyes and Winninghoff for sodium iodide in propyl alcohol is in considerable disagreement with the value found here.

The dissociation constants (Table IV) show that all of the salts used here may be considered as weak electrolytes in propyl and isopropyl alcohol. The values of these constants fit in rather well with those recorded for the lower and higher alcohols as well as for related solvents.[15]

The variation of the dissociation constant with concentration is shown in Tables I and II. The method of Fuoss and Kraus yields much greater but quite constant values. The Ostwald dilution law gives values for dissociation constants that increase considerably with the increase in concentration. The former is expected while the latter is inconsistent for weak electrolytes.

Summary

The conductivities of potassium iodide and bromide and of sodium iodide and bromide have been determined in propyl and isopropyl alcohols.

The limiting equivalent conductivities were calculated by the Fuoss and Kraus method and were compared with those obtained by extrapolation of $\Lambda_0 - \sqrt{C}$ curves.

The dissociation constants were calculated by the Fuoss and Kraus, and Ostwald methods for each electrolyte. It was shown that the former method yields greater but quite constant values. Furthermore, the values of the dissociation constants indicate that all of the salts used here may be considered as weak electrolytes in propyl and isopropyl alcohols.

There seems to exist no relation in the order of conductivities of the salts in these two alcohols nor does the principle of additivity apply in either alcohol.

The Effect of Structure upon the Reactions of Organic Compounds. Benzene Derivatives

BY LOUIS P. HAMMETT

The effect of a substituent in the meta or para position of the benzene ring upon the rate or upon the equilibrium of a reaction in which the reacting group is in a side chain attached to the ring may be represented by a simple formula which is valid within a reasonable precision in a surprising variety of cases. The formula is

$$-RT \ln K + RT \ln K^0 = \Delta F = A/d^2 \left(\frac{B_1}{D} + B_2\right)$$

K is a rate constant or an equilibrium constant for a substituted reactant, K^0 is the corresponding quantity for the unsubstituted reactant, ΔF is a free energy change or its kinetic analog, d is the distance from the substituent to the reacting group, D is the dielectric constant of the medium in which the reaction occurs, and the quantities A, B_1 and B_2 are constants independent of temperature and solvent. Of these A depends only upon the substituent and its position in the ring relative to the reacting group (with one exception, the two values necessary for the para nitro group), while B_1 and B_2 depend only upon the reaction.

The most important practical feature of equation (1) is the separation of the effect of a substituent into two constants, one of which depends on the substituent, the other upon the reaction. For this corollary of the equation the linear logarithmic relationships between equilibrium and rate constants which have been noted by myself[1] and in wider variety by Burkhardt, Ford and Singleton[2] offer a verification which has so far been made only qualitatively and by graphical methods. A more significant test may be made by obtaining a set of values of the constant A for various substituents from some suitable reaction or reactions, and determining quantitatively the precision with which these constants may be made to fit the data for all available reactions. For this purpose equation (1) may be rearranged to the form

$$\log K = \log K^0 + \sigma\rho \qquad (2)$$

$$\text{where } \sigma = -A/2.303\ R$$

$$\rho = \frac{1}{d^2 T}\left(\frac{B_1}{D} + B_2\right)$$

σ is a substituent constant, dependent upon the substituent; ρ is a reaction constant, dependent upon the reaction, the medium and the temperature. Since the only data available consist of values of the $\sigma\rho$ product, it is necessary to assign an arbitrary value to some one σ or ρ. The choice of a value of unity for the ρ constant in the ionization equilibrium of substituted benzoic acids in water solution at 25° was determined by the large amount of accurate data availabe from the recent work of Dippy and co-workers.[3] On this basis the difference between the logarithm of the ionization constant of a substituted benzoic acid and the logarithm of the ionization constant of benzoic acid gives the value of the σ constant for that substituent. With the nucleus of σ values thus provided, ρ values have been derived by least squares methods for other reactions, and from these in turn σ values have been obtained for substituents whose effects upon the ionization constant of benzoic acid are unknown or inaccurately known. After any new σ value was obtained it was used for the calculation of subsequent ρ values, so that the order of the calculations, which is that of the key numbers in the Tables, is of some significance. The criterion of the validity of equations (1) or (2) for any reaction is the precision with which the previously determined values of σ together with the experimental values of log K satisfy the linear equation (2). As a measure of this precision I have used the median deviation of the experimental points from the best straight line, the "probable error" of a point.[4]

The results of such calculations for all the reactions I have been able to find are given in Tables I, II and III. Table I contains the values of the substituent constants σ together with the symbol of the substituent, a key number to indicate the reaction from which the value was obtained, the number of reactions n for which data on the effect of this substituent are available, and the probable

error r of the log K values calculated for this substituent for these reactions. The data on reactions 28, 35, 36, 37 and 38 were not included in calculating the probable error because there was reason in these cases to doubt the accuracy of the measurement or the theoretical applicability of equation (1). Table II contains the ρ values for the various reactions together with a key number for the reaction, the best value of log K^0 in equation (2), the number of substituents n for which data are available, and the probable error r of the calculated values of log K. Table III contains brief descriptions of the reactions and literature references under the key numbers previously used. In the descriptions E means that the data used are the equilibrium constants of the reaction described, R that they are rate constants.

TABLE I

SUBSTITUENT CONSTANTS

38	+0.167	+0.785	.078	11
39	-0.018	+2.240	.079	9

The verification of equation (3) is satisfactory. Out of thirty-eight reactions involving derivatives of benzoic acid, of phenol, of aniline, of benzenesulfonic acid, of phenylboric acid, and of phenylphosphine, and including both equilibrium and rate constants, there are only six for which the probable error is greater than 0.1, one only for which it is greater than 0.2, and the mean value of the probable error for the whole series of reactions is 0.067. These figures compare well with a total range in the value of log K between p-nitro and p-amino substituted derivatives which may in an extreme case (reaction 16) amount to as much as 7. Figure 1 visualizes the magnitude of the deviations because the four reactions for which log K values are plotted against the σ values from Table I show probable errors not far from the mean value.

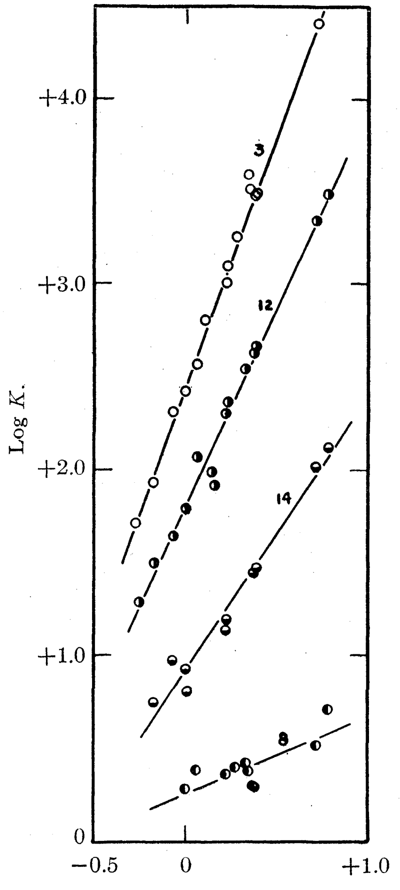

Fig. 1.—Relationship between log K and σ for various reactions (see Table III). The position of the scale of ordinates is arbitrary.

TABLE III

1. E. Ionization of substituted benzoic acids in water at 25°.[3]
2. R. Alkaline hydrolysis of substituted benzoic esters in 87.83% ethyl alcohol at 30°.[5]
3. E. Acidity constants of substituted anilinium ions in water at 25°.[6]
4. E. Ionization of substituted phenols in water at 25°.[7]
5. R. Hydrolysis of substituted cinnamic esters, conditions as in reaction 2.[5b]

33. R. Acid catalyzed hydrolysis of substituted aryl sulfuric acids in water solution at 48.6°.[2]
34. R. Addition of hydrogen sulfide to substituted benzonitriles in alkaline alcoholic solution at 60.6°.[5a]
35. R. Alkaline hydrolysis of substituted phenylacetic esters, conditions as in 2.[5b]
36. E. Ionization of substituted phenylacetic acids in water at 25°.[3,29]
37. R. Hydrolysis of substituted benzyl chlorides in acetone–water medium at 69.8°.[30]
38. R. Reaction of substituted benzyl chlorides with potassium iodide in acetone at 20°.[30]
39. R. Reaction of substituted ald-chlorimines with sodium hydroxide in 92.5% alcohol at 0°.[31]

The deviations from equation (1) are undoubtedly larger than those to be expected from any reasonable error in the actual measurement of rate or equilibrium as Dippy and Watson[32] have pointed out in connection with reaction 2. It is by no means so certain that they do not in some cases result from insufficient purity of reactants. The preparation and proper purification of the numerous substituted compounds is by no means an easy task, even for a skilled organic chemist, a fact which is strongly emphasized by the discovery of Bennett and Jones[33] that the data in the previous literature on the reaction rate of substituted benzyl chlorides with iodide ion were in error by two orders of magnitude because of the presence of extremely reactive impurities. Another source of danger in the study of any organic reaction is the possibility that the product analyzed for may be produced by more than one reaction, as in the case noted by Baker,[34] or even that the same over-all reaction may result from either or both of two competing reactions which are differently affected by substituents. Thus the hydrolysis of a halide may proceed either by a reaction with water or by a reaction with hydroxyl ion.[35] It seems hardly likely that these difficulties should account for all of the deviations noted, but they may very well be responsible for some of the worst cases.

The errors show no tendency to be larger for reactions with a large value of ρ. Consequently the probable percentage error in the prediction of an equilibrium or rate constant from Tables I and II is no greater in the case of reactions in which a substituent produces a large change in constant than it is with reactions in which a substituent has very little effect. This rather distorts the effect one gets from a graphical test, as can be seen in Fig. 1, in which all four reactions have nearly the same value of r.

In most cases the distribution of errors for a given substituent is a random one. In a few cases, notably those of the fluorine derivatives, of *m*-methoxy derivatives and the naphthalene compounds, there are indications that a somewhat better choice of σ values could be made, but there are hardly enough data in any of these cases to justify such a refinement.

In one case only, that of the *p*-nitro substituent, it has been impossible to represent all reactions with one value of σ. Even here, however, it is not a question of a range of values but of two widely different ones. One of these, listed as *p*-NO_2(a) with a value of +1.27 in Table I gives satisfactory agreement with all reactions of aniline or phenol derivatives; the other, listed as *p*-NO_2(b) with the value +0.778, applies to the reactions of all other compounds.

In addition to providing a test of equation (2), Tables I and II perform the function of compressing into a small space a large amount of experimental data, and of providing the material for a wide variety of predictions of unknown equilibrium and rate constants.

The factor $1/d^2$ or some closely related function of the distance from substituent to reacting group is demanded by an important relationship noted by Kindler.[5b] This is to the effect that the quantity K/K^0 for the alkaline hydrolysis of a series of meta and para substituted cinnamic esters varies as the square root of the corresponding quantity for the similarly substituted benzoic esters. This relationship is shown in the lower

plot in Fig. 2, in which the abscissa of each point is given by the logarithm of the hydrolysis rate constant of a substituted benzoic ester, and the ordinate by the constant for a cinnamic ester carrying the same substituent. The straight line is a plot of the equation, obtained by least squares methods.

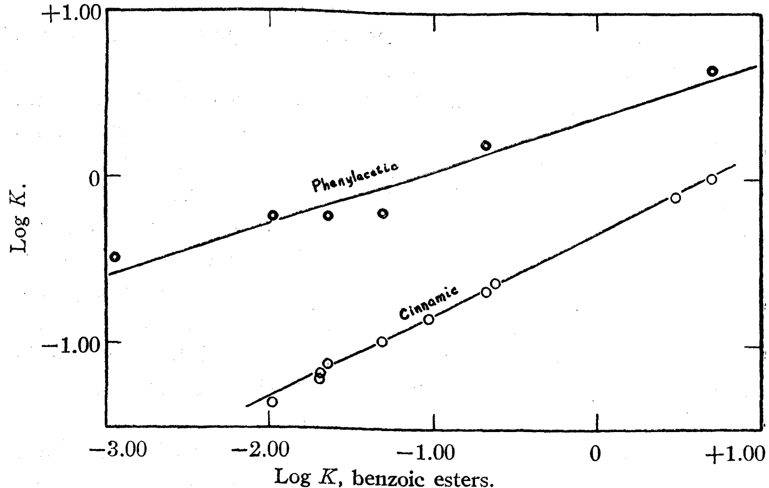

Fig. 2.—Relationships between hydrolysis constants.

$$\log K_c = -0.331 + 0.502 \log K_b \qquad (3)$$

and the median deviation or probable error of the points is only 0.014. The slope 0.502 agrees excellently with Kindler's relationship which requires a slope of 0.5 for the logarithmic plot.

If equation (1) applies to the hydrolysis constants of both sets of esters

$$-RT \ln K_c + RT \ln K_c^0 = \frac{A}{d_c^2}\left(\frac{B_1}{D} + B_2\right)$$

$$-RT \ln K_b + RT \ln K_b^0 = \frac{A}{d_b^2}\left(\frac{B_1}{D} + B_2\right)$$

it follows that

$$\log K_c = \text{constant} + (d_b/d_c)^2 \log K_b \qquad (4)$$

that is to say, equation (1) predicts a linear plot in Fig. 2 with a slope equal to $(d_b/d_c)^2$. If we estimate the value of d_b to be 5 Å. and that of d_c to be 7 Å., we obtain for the slope the value of 0.51 which is in satisfactory agreement with equation 3.

The agreement vanishes when, as in the upper plot in Fig. 2, Kindler's values for the hydrolysis constants of phenylacetic esters are plotted against the benzoic ester values. The median deviation of the points from the best straight line is 0.069, five times greater than in the cinnamic ester case, and the line has a slope of 0.325, smaller than the slope for the cinnamic esters, instead of larger, as would be expected. The scantier data available for hydrocinnamic esters suffice to show that the same complicating influence which appears in the phenylacetic case is present with these compounds also. It seems probable therefore that the simple relationship of equation (1) applies only when a continuous system of conjugated double bonds exists between substituent and reacting group.

The $1/D$ factor in equation (1) is in agreement with Wynne-Jones'[36] observation that, in the case of the ionization of organic acids, the quantity $\log K - \log K^0$ is linear in $1/D$, a relationship which applies to all organic acids, and not merely to those here under discussion. Data are not available for a test of the corresponding relationship on other reactions. It is a further corollary of the presence of this factor that a plot of the $\log K$ values obtained in a medium of dielectric constant D_1 against the values for the same reaction in a medium of dielectric constant D_2 should be linear with the slope $D_2(B_1 + B_2D_1)/D_1(B_1 + B_2D_2)$. The linearity is satisfactorily verified by comparison of the results of Wooten and Hammett[37] on ionization constants in butyl alcohol with the ionization constants of the same acids in water.[3] From data on eight substituents a slope of 1.48 with a median deviation of 0.025 is obtained. As was explained in a previous paper[38] the magnitude of the slope is not predictable because of the high salt concentration in the butyl alcohol experiments.

The effect of temperature upon the relative strengths of carboxylic acids has been discussed in a previous paper,[38] but the treatment needs minor modifications. In terms of equation (1) the quantity ΔF varies with temperature only because of the temperature dependence of the dielectric constant. Consequently ΔS, the difference between the entropies of reaction or of activation for the substituted and for the unsubstituted reactants, is given by

$$\Delta S = -\frac{\delta \Delta F}{\delta T} = \frac{AB_1}{d^2 D^2}\frac{\delta D}{\delta T}$$

---

[36] Wynne-Jones, *Proc. Roy. Soc.* (London), **A140**, 440 (1933).

[37] Wooten and Hammett, THIS JOURNAL, **57**, 2289 (1935).

[38] Hammett, *J. Chem. Phys.*, **4**, 613 (1936).

If the constant B_2 is negligible, this becomes

$$\Delta S = \Delta F\, \delta \ln D/\delta T \qquad (6)$$

a result with which the available data on the ionization of meta and para substituted benzoic acids are in agreement.[38] The quantity $\delta \ln D/\delta T$ is in general negative in sign, is equal to -0.005 for the solvent water, and is of the same order of magnitude for many organic liquids. If, on the other hand, the quantity B_1 is negligible, ΔF should be independent of temperature. This is very nearly the case for the alkaline hydrolysis of esters, for which the work of Ingold and Nathan[39] leads to a mean value of the ratio $\Delta S/\Delta F$ equal to only 0.00028 ± 0.00007.

In any case there should be a direct proportionality between ΔS and the quantity $\delta \Delta F/\delta D$, the change in ΔF per unit change in dielectric constant, since

$$\Delta S = -\frac{\delta \Delta F}{\delta D}\frac{\delta D}{\delta T} \qquad (7)$$

The existence of this proportionality has been demonstrated for the ionization of benzoic acids, but data are not available for the comparison of observed and calculated values of the proportionality constant.[38]

The existence of the relationships embodied in equation (1) must to a considerable extent determine the nature of any theory which may be adopted to account for the effect of substituents upon rates and equilibria. The theory of a dipole field transmitted through the medium can, as previously indicated,[38] account for the observed dependence of ΔF for the ionization of benzoic acids upon dielectric constant and temperature, but fails by an order of magnitude to account for the actual values of ΔF in this reaction or for the fact that a given substituent may have a several times larger ΔF in other reactions. If the latter difficulty is avoided by the hypothesis that there is an internally transmitted effect as well as the one transmitted through the medium, it becomes necessary to admit that this additional effect is of an entirely different sort, and not merely an internally transmitted dipole field, because such a field could have no greater effect in the hydrolysis of a benzoic ester than in the ionization of benzoic acid. It then becomes quite inconceivable that the two effects should be linearly related in different reactions, as equation (2) demands, and especially that they should show so exactly the same dependence upon distance as Kindler's observations on the hydrolysis of cinnamic and benzoic esters demand. It is therefore an unavoidable conclusion that a substituent affects rates and equilibria essentially by a single internally transmitted mechanism.

The only reasonable theory of such an internal effect seems to be the one of an internal displacement of electrons which has been much discussed by Ingold[40] and to which Wheland and Pauling[41] have given a more definite mechanism and description in terms of quantum mechanical ideas. According to this theory a substituent alters the average density of electron charge in every part of the molecule. This may be either because the substituent directly attracts or repels electrons more than does the hydrogen atom it replaces, or because the substituent permits the construction of alternative electronic distributions of a highly polar nature which resonate with the non-polar one, or from some combination of these effects. In any case the altered concentration of electrons on the atom by which the substituted molecule enters into the reaction under consideration must alter both equilibrium and rate constant for the reaction because both depend upon an energy of bond formation which is itself a function of the electron density. Consider the reaction

$$XC_6H_4NH_2 + HA \rightleftharpoons XC_6H_4NH_3^+ + A^- \qquad (8)$$

by which aniline derivatives act as bases. When the reaction proceeds to the right a new bond between hydrogen and nitrogen is formed, which depends upon electrons originally present on the nitrogen. This bond will be more stable the greater the concentration of available electrons, consequently a substituent which increases the electron density on the nitrogen atom must increase the equilibrium constant of the reaction, that is to say, it must increase the basicity of the aniline.

The reaction rate problem is most satisfactorily treated in terms of the illuminating idea of Eyring[42] and of Evans and Polanyi[43] according to which the rate of a reaction is proportional to the concentration of a transition state of maximum energy, which concentration can be calculated by the same statistical mechanical methods as if there were reversible chemical equilibrium between reactants and transition state. In the reaction

$$XC_6H_4NH_2 + CH_3I \longrightarrow XC_6H_4NH_2CH_3^+ + I^- \qquad (9)$$

---

[40] See for instance Ingold, *Chem. Rev.*, **15**, 225 (1934).

[41] Wheland and Pauling, THIS JOURNAL, **57**, 2086 (1935).

[42] Eyring, *J. Chem. Phys.*, **3**, 107 (1935).

[43] Evans and Polanyi, *Trans. Faraday Soc.*, **31**, 875 (1935).

for instance the transition state is a half-reacted state in which the methyl group has not completely let loose from the iodide ion, but is already partly attached to the nitrogen atom by electrons whose source is the aniline molecule. Obviously the probability of such a transition state and hence the rate of reaction will be increased by a substituent which increases the density of electrons on the nitrogen atom.

Clearly this picture is qualitatively in agreement with the effect represented by the second term in equation (1), although it does not immediately suggest the simplicity of the actual relationship. The factor A measures the tendency of the substituent to displace electrons, the factor B_2/d^2 measures both the displaceability of the electrons on the reacting group and the dependence of the free energy of reaction or of activation upon the change in electron density.

The first term in equation (1), AB_1/d^2D, may be accounted for in terms of the energy of a charged body in a dielectric medium, $e^2/2Da$ where e is the charge and a the radius of the body. By far the greater part of this energy in the case of a substance like benzoate ion must derive from that portion of the charge which is concentrated on the carboxylic group. Any charge distributed over the benzene nucleus can contribute little to the energy because of the large dimensions of the structure over which it is distributed. A substituent like the nitro group which attracts electrons must draw some of the charge off the carboxylic group, and even though this charge is again concentrated on a small structure, the nitro group, the electrostatic energy must decrease, because the effect depends upon the square of the charge. Thus if the energy due to the charge on the CO_2^- group in benzoate ion is given by $e^2/2Da$ and if the NO_2 group shares the charge equally with the CO_2^- in nitrobenzoate ion, the energy of the latter becomes

$$2(e/2)^2/2Da = 1/2(e^2/2Da)$$

which is one-half as great as the energy of the benzoate ion. This effect alone would make the free energy change negative in the reaction

$$NO_2C_6H_4CO_2H + C_6H_5CO_2^- \rightleftharpoons NO_2C_6H_4CO_2^- + C_6H_5CO_2H \quad (10)$$

and increase the equilibrium constant above unity. An additional favorable factor is the fact that the wave function for nitrobenzoic acid must contain a considerable contribution from a dipolar configuration with a negative charge on the NO_2 group and a positive charge on the CO_2H, whose electrostatic energy would also contribute to increasing the energy of the left-hand side of equation (10). Both of these energy changes will have a magnitude proportional to $1/D$, in agreement with equation (1).

Since the quantities B_1 and B_2 depend upon quite different phenomena, they are independently variable from reaction to reaction, and may even differ in sign. This is the case in the hydrolysis of aryl sulfuric acids (reaction 33) studied by Burkhardt, Ford and Singleton.[2] Here the mean value of the ratio $\Delta S/\Delta F$ is found to be 0.0035 ± 0.0001, and from equations (1) and (5) we have, using $\delta \ln D/\delta T = -0.005$

$$AB_1/d^2D = -0.7\Delta F$$
$$AB_2/d^2 = 1.7\Delta F$$

B_1 presumably will have its largest values when reactants, products or transition state contain electrically charged molecular species, it need not however be zero in the absence of these because of the possible presence of dipoles with widely separated charges. The sensitivity to structure of reactants exhibited by ρ of equation (2), which represents the total effect of the B_1 and B_2 terms is surprisingly large. Thus the value of ρ for reaction 30, the reaction of a series of substituted phenolate ions with ethylene oxide is -0.946, while the value for the reaction of the same substances with propylene oxide (reaction 31) is -0.771.

The relationships contained in equation (1) are applicable only to meta and para substituted benzene derivatives; the situation is more complicated both with ortho substituted benzene derivatives and with aliphatic or mixed aromatic-aliphatic compounds. A substituent in the ortho position to the reacting group exerts an influence upon both equilibrium and rate of reaction, which is frequently but not always of great magnitude, and whose governing laws and mechanism are evidently entirely different from those concerned in the effect of more distant substituents.[1,5,22,44,45] One corollary only of equation (1) remains valid in the case of an ortho substituent, namely, that represented by equation (7).[38] Consequently the temperature effect upon ΔF may be described as the result of the temperature dependence of the dielectric constant even in the case of an ortho substituent.

[44] Schwarzenbach and Egli, *Helv. Chim. Acta*, **17**, 1184 (1934).

[45] Hammett and Pfluger, THIS JOURNAL, **55**, 4079 (1933).

In the case of aliphatic compounds equation (7) also fails, even as the crudest approximation.[38] It seems probable that in this case factors appear in the partition functions whose ratio determines the value of ΔF which are dependent upon the internal motions of the reacting molecules and which fail to cancel out between numerator and denominator. As a result the free energy change is not equal to the difference in potential energy between products and reactants and is dependent upon temperature.[38] On this basis the applicability of equation (1) is dependent upon a rigidity of structure which is indeed inherent in most of the reactants to which we have applied the equation, and whose absence in other cases results in some of the most striking failures of the equation.

Pauling[46] has recently pointed out that the freedom of rotation of any side chain attached to the benzene ring is limited or destroyed whenever the classical formula with a single link between side chain and ring resonates with another configuration with a double link in the same position. Thus the actual structure of phenol partakes sufficiently of such structures as

to prevent rotation around the carbon-oxygen link. The same effect must exist in the various derivatives of phenol, aniline and benzoic acid which we have considered, and it should notably ossify the structure of cinnamic ester and its derivatives, but not those of the phenylacetic and hydrocinnamic esters. The striking contrast shown in Fig. 2 between the exact correlation of the hydrolysis rates of cinnamic esters with those of benzoic esters, and the poor correlation of the rates for phenylacetic esters is therefore entirely in agreement with this hypothesis.

Since the benzyl halides are incapable of this kind of resonance, there should be free rotation of the side chain. In agreement with this prediction we find very poor correlation between our σ constants and the reaction rates of benzyl halides. This is notably true for the hydrolysis (reaction 37) for which $r = 0.15$, but the reaction with iodide (reaction 38) has an r greater than the average, and a direct comparison of the iodide reaction with the hydrolysis gives a very poor correlation, the probable error in log K for the hydrolysis predicted from the iodide reaction being 0.20. On the other hand, there is excellent correlation between hydrolysis rate and rate of reaction with a tertiary amine.[47]

Clearly, then, linear logarithmic relationships between equilibrium or rate constants of different reactions are not limited to cases to which equation (1) is directly applicable. This fact appears indeed in the prototype of all such relationships, the relation between acid or base strength and catalytic effect discovered by Brönsted and Pedersen.[48] This applies both to aliphatic and aromatic acids, to ortho substituted as well as to meta and para substituted compounds. The same thing is true of Hammett and Pfluger's[45] relationship between the rate of alkylation of an amine by the methyl ester of an acid and the strength of the acid. Evidently the factors which cause the deviations from equation (1) may have linearly related effects upon two different reactions, provided these reactions are sufficiently closely related. Yet even in the case of general basic catalysis, Pfluger[49] has found significant deviations from a straight line plot when the alterations in structure take place in the reacting group itself as when diethylaniline is substituted for dimethylaniline.

Summary

A simple formula is proposed to represent the effect of a substituent in the meta or para position of the benzene ring upon the rate or equilibrium of a reaction in which the reacting group is in a side chain attached to the ring. This formula represents not only the total effect of the substituent but also the influence of changing length of side chain, of dielectric constant of the medium, and of temperature within a satisfactory precision in a wide variety of cases. The theory that a substituent acts by internal electron displacement is in complete agreement with this formula, including the temperature and medium effects embodied in it, and accounts also for the large deviations observed in the case of non-rigid structures.

A table of substituent constants and one of reaction constants has been calculated from which the effect of many substituents upon a large number of reaction rates and equilibria may be obtained by multiplication of the constants.

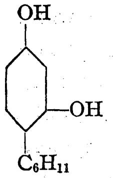
The Pentenyl-, Hexenyl- and Heptenylresorcinols

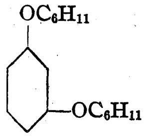
BY CHARLES D. HURD AND RAYMOND W. MCNAMEE[1]

Hexylresorcinol has been studied considerably in recent years but no attention has been given to its unsaturated analogs. The allylresorcinols[2] are the only alkenylresorcinols to have been investigated although the hexenyl- and heptenylpyrogallols have been described recently.[3]

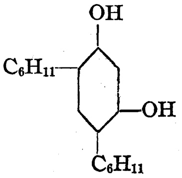
In the synthesis of 4-hexenylresorcinol (A), 1-bromo-2-hexene was reacted with resorcinol and potassium carbonate in acetone solution. Concurrently, there was formed resorcinol hexenyl diether (B), which was separated by insolubility in alkali, and 4,6-dihexenylresorcinol (C) which was separated from (A) by its lower volatility. The pentenyl- and heptenylresorcinols were prepared analogously. A molecular still was advantageous for the distillation of these substances. The alkenylresorcinols were characterized by solid derivatives (D) with chloroacetic acid. The methyl diethers (E) were also synthesized.



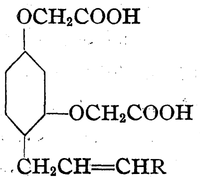
(A)



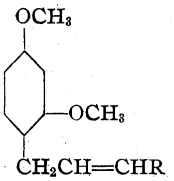
(B)



(C)



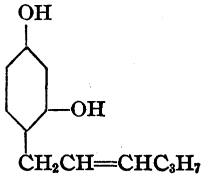
(D)



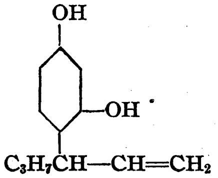
(E)

The structure of the alkenyl group in these compounds is a matter of some interest. Obviously, it is related to the structure of the alkenyl bromide used in the synthesis. Instead of regarding this as pure 1-bromo-2-alkene as has been done in the past,[4] it should be regarded as an equilibrium mixture of 1-bromo-2-alkene and 3-bromo-1-alkene, the former predominating. This aligns the structure with that of "crotyl" bromide, which has been proved[5] to be an equilibrium mixture of 1-bromo-2-butene and 3-bromo-1-butene, with the former in considerable excess.

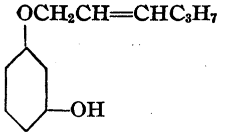
On this basis, (A) should be regarded as a mixture of F + G. It is reasonably certain that (A) was formed from resorcinol by direct substitution. Therefore, the F:G ratio should approximate the ratio of the two substances in hexenyl bromide. Hydrogenation of the (F + G) mixture yielded a mixture of hexylresorcinols from which *n*-hexylresorcinol crystallized.



(F)



(G)



(H)

Structure (G) might be regarded as coming from the ether (H) by pyrolysis. On heating, (H) should rearrange into (G) but temperatures of 200–220° would be required whereas 100° was the maximum temperature in this work. Both (B) and (H)[6] have been shown to be stable at 100°.

The position of the hexenyl group in hexenylresorcinol was established by oxidizing the methyl diether (E) to 2,4-dimethylbenzoic acid.

Bactericidal data on the resorcinol derivatives were obtained through the courtesy of the Parke, Davis and Company Laboratories. The phenol coefficients toward three test organisms are listed in Table I. The values of two related compounds are included for comparison.

Experimental Part

Reagents.—The syntheses of 1-bromo-2-hexene and 1-bromo-1-heptene have been described.[3] That for 1-bromo-2-pentene was as follows. 1-Pentene-3-ol, b. p. 35–37° (20 mm.), was prepared in 78% yield by dropping a solution of acrolein in ether into an excess of ethylmagnesium bromide at −5°. Then a mixture of 121 g. of this alcohol, 350 g. of 48% hydrobromic acid and 100 g. of concd. sulfuric acid was stirred for twenty-four hours.

4-Pentenylresorcinol	20	...	..

[a] Klarmann, Gatyas and Shternov, THIS JOURNAL, **53**, 3402 (1931). The temperature was 37°.

After dilution with water, the pentenyl bromide layer was separated, washed, dried and distilled. It boiled at 38–41° (19 mm.); n^{21}D 1.4757. The yield was 169 g. or 80%. It was chiefly 1-bromo-2-pentene but was probably in equilibrium with 3-bromo-1-pentene.

The Alkenylresorcinols

4-Hexenylresorcinol.—Forty-nine grams (0.3 mole) of 1-bromo-2-hexene was added during three hours to a well-stirred mixture of 66 g. of resorcinol (0.6 mole), 300 cc. of acetone and 40 g. of anhydrous potassium carbonate. The mixture was then refluxed for three hours. The acetone was removed by distillation and the residue was extracted with carbon tetrachloride. The resulting solution was washed free of resorcinol by many extractions with water. The alkali-soluble material was then separated from the mixture by use of a dilute solution of sodium hydroxide.

The alkaline solution was acidified with hydrochloric acid and the solution was extracted with ether. The extract was washed with water, dried and distilled from a Hickman molecular still[3] (p. 1732) at 0.003–0.005 mm. The bottom of the still was heated by a steam-bath. Thirty grams of distillate accumulated. It was redistilled. The first 23 cc. to come over (collected in several fractions) possessed a uniform index of refraction, n^{25}D 1.5388. That for the next 7 cc. was 1.5416. The 23-cc. portion, d^{25}_4 1.0481, was hexenylresorcinol.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 75.0; H, 8.32. Found: C, 74.5; H, 8.32.

4-Pentenylresorcinol.—This was prepared similarly from 66 g. of resorcinol, 45 g. of 1-bromo-2-pentene, 40 g. of potassium carbonate and 300 cc. of acetone. Several arbitrary fractions were collected in the Hickman still and the index of refraction taken. Those of similar constants were combined and refractionated thrice. In this way, 7 g. of pentenylresorcinol, n^{25}D 1.5461, d^{25}_4 1.0671, was obtained.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.1; H, 7.92. Found: C, 73.9; H, 7.99.

4-Heptenylresorcinol.—The general details were similar, these quantities of reagents being used: 85.5 g. of 1-bromo-2-heptene (0.5 mole), 110 g. of resorcinol (1 mole), 60 g. of potassium carbonate and one liter of acetone. The preliminary fractionation was by vacuum distillation at 1 mm. There was 17 cc. at 138–143°, 11 cc. at 143–150°, 7 cc. at 150–170° and 3.5 cc. of residue. The 17-cc. fraction contained the bulk of the heptenylresorcinol, and the 7-cc. fraction contained some diheptenylresorcinol (see below). Subsequent fractionations were performed in the Hickman still (at 100°) and 14 cc. of product, n^{25}D 1.5360, was obtained.

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 75.7; H, 8.80. Found: C, 75.5; H, 8.79.

The Diethers

Resorcinol Hexenyl Diether, $C_6H_4(OC_6H_{11})_2$.—The carbon tetrachloride solution from which 4-hexenylresorcinol had been extracted was distilled in a Hickman still at 100° after it was washed free of alkali and dried. Seven grams of a mobile liquid was obtained, n^{25}D 1.5172, d^{25}_4 0.9634.

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.8; H, 9.48. Found: C, 78.4; H, 9.50.

Resorcinol Pentenyl Diether.—This diether was obtained similarly from the carbon tetrachloride solution from which 4-pentenylresorcinol had been extracted. The distillate from the Hickman still weighed 3.5 g.; n^{25}D 1.5227, d^{25}_4 0.973.

Anal. Calcd. for $C_{16}H_{22}O_2$: C, 78.0; H, 9.01. Found: C, 78.3; H, 9.01.

Chloroacetic Derivatives of the 4-Alkenylresorcinols

2,4-Di-(carboxymethoxy)-1-hexenylbenzene (Structure D).—One gram of 4-hexenylresorcinol, 3.5 g. of chloroacetic acid and an excess of 10% sodium hydroxide solution were heated on a steam-bath for an hour. The solution was cooled, acidified and extracted with ether. The extract was washed with water and extracted with a solution of sodium bicarbonate. On acidification of the bicarbonate extract, the desired acid precipitated. After several crystallizations from 50% methanol it melted at 159–160°; yield 0.5 g.

Anal. Calcd. neut. equiv. for $C_6H_{11}C_6H_3(OCH_2COOH)_2$, 154. Found: 157.

2,4 - Di - (carboxymethoxy) - 1 - pentenylbenzene.—The m. p. of this derivative, prepared similarly from 4-pentenylresorcinol, was 164–165°.

Anal. Calcd. neut. equiv. for $C_5H_9C_6H_3(OCH_2COOH)_2$, 147. Found: 150.

2,4 - Di - (carboxymethoxy) - 1 - heptenylbenzene.—This acid, similarly prepared, melted at 144–145°.

Anal. Calcd. neut. equiv. for $C_7H_{13}C_6H_3(OCH_2COOH)_2$, 161. Found: 162.

Hydrogenation of the Hexenylresorcinol.—Four grams of 4-hexenylresorcinol was hydrogenated catalytically using 0.15 g. of the Adams platinum oxide catalyst, 200 cc. of ethyl alcohol, and hydrogen. The hydrogenation took an hour, but most of the hydrogen was absorbed in the first fifteen minutes. After filtration, the material was distilled at 3 mm. Two cc. of distillate (b. p. 130–135°, n^{25}D 1.5320, d^{25}_4 1.056) remained as an oil, but 0.6 cc. (b. p. 135–140°) solidified on standing. The latter melted at 67–68° which is the m. p. of 4-hexylresorcinol.[7] The 2-cc. fraction also analyzed correctly for hexylresorcinol but the fact that it would not crystallize, even

---

(7) Dohme, Cox and Miller, THIS JOURNAL, **48**, 1688 (1926).

when seeded, indicated that the material was a mixture of *n*-hexylresorcinol and isomers, presumably 4-(α-ethylbutyl)-resorcinol and resorcinol *n*-hexyl monoether (formed via the hexenyl monoether). The phenol coefficient of this fraction was determined (Table I).

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.2; H, 9.28. Found: C, 74.1; H, 9.33.

Methylation of the Alkenylresorcinols

4-Hexenylresorcinol Methyl Diether, $C_6H_{11}C_6H_3(OCH_3)_2$.—A mixture of 4.5 g. of 4-hexenylresorcinol, 50 cc. of 10% sodium hydroxide solution and 20 g. of methyl sulfate was stirred vigorously for an hour. The insoluble layer was drawn off, the aqueous layer was extracted with ether and the combined insoluble layers were washed with water, dried and distilled in a Hickman still at 100° and 0.12–0.15 mm.; yield 4.5 g. When redistilled at 10 mm. the material boiled at 150–152°; $n^{7}\mathrm{D}$ 1.5233, $n^{25}\mathrm{D}$ 1.5154, $d^{25}{}_4$ 0.9865.

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.4; H, 9.09. Found: C, 76.3; H, 9.02.

4-Pentenylresorcinol Methyl Diether.—4-Pentenylresorcinol (2.7 g.) was dissolved in 35 cc. of 10% sodium hydroxide solution and an excess of methyl sulfate was added. The mixture was stirred for one hour. The methylated compound was separated and distilled in a Hickman still. At 0.0005 mm. and 100° the material distilled at the rate of 20–25 drops per minute. The yield was 2.5 g.; $n^{25}\mathrm{D}$ 1.5192, $d^{25}{}_4$ 0.986.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.7; H, 8.79. Found: C, 75.6; H, 8.72.

Oxidation to 2,4-Dimethoxybenzoic Acid.—Twenty grams of powdered potassium permanganate was added to a solution of 4.0 g. of 4-hexenylresorcinol methyl diether in 200 cc. of acetone (distilled from potassium permanganate). The mixture was heated on the water-bath and stirred mechanically. At the end of one hour the manganese dioxide was removed by filtration, 100 cc. of water was added and the acetone was removed by distillation. The solution became cloudy due to the precipitation of unoxidized material. This (0.35 g.) was removed by ether extraction. The water solution was made slightly acid with sulfuric acid and 1.3 g. of 2,4-dimethoxybenzoic acid[8] precipitated; m. p. after one crystallization, 108°.

4,6-Dihexenylresorcinol (Structure C).—Resorcinol (55 g., 0.5 mole) was added to a solution of sodium (6.9 g., 0.3 mole) in 400 cc. of absolute alcohol. Then, during two hours, 49 g. (0.3 mole) of 1-bromo-2-hexene was dropped into the stirred mixture. It was stirred for ten hours more and then refluxed for two hours. The solvent was distilled off, the residue extracted with carbon tetrachloride (100 cc.) and the extract washed repeatedly with water until free of resorcinol. It was dried and distilled at 3 mm. Forty grams was collected at 135–155°; residue, 4 g. It was redistilled at 3 mm. through a 15-cm. column, whereupon 25 g. of monohexenyl derivatives were removed in the first fractions. Then, 7.5 g. of dihexenylresorcinol was collected at 155–180°. The latter was redistilled in a Hickman still. The fraction thus obtained was analyzed; $n^{25}\mathrm{D}$ 1.5310, $d^{25}{}_4$ 0.9971.

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.82; H, 9.48. Found: C, 79.07; H, 9.46.

This compound was also prepared in work with Mr. Louis Schmerling as follows. A suspension was made of sodium resorcinolate (from 5.5 g. of resorcinol and 2.3 g. of sodium) in benzene (25 g.). Eight grams of 1-bromo-2-hexene in 35 cc. of benzene was added and the mixture stirred for ten hours. Then another 8 g. was added and the mixture refluxed for nine hours. The benzene solution was decanted from the sodium bromide and washed repeatedly with water. After evaporation of the benzene under diminished pressure the residue was treated with 175 cc. of Claisen's aqueous–alcoholic potash (a mixture of 53 g. of potassium hydroxide and 44 cc. of water, made up to 175 cc. with methanol). A 2-g. fraction of resorcinol hexenyl diether was separated.

The alkaline solution was acidified with dilute sulfuric acid. The resulting oil was ether extracted, washed, dried and distilled in a Hickman still at 100°. About 2 g. of hexenylresorcinol was collected first, then 3.5 g. of dihexenylresorcinol (mol. wt., 265; calcd. for $C_{18}H_{26}O_2$, 274).

4,6-Dihexenylresorcinol Methyl Diether, $(C_6H_{11})_2C_6H_2(OCH_3)_2$.—The dihexenylresorcinol (3.5 g.) was dissolved in 10% sodium hydroxide solution after which it was stirred for an hour with an excess of methyl sulfate. The oil which separated was taken up in ether, washed, dried and distilled. Three grams of the diether was obtained; b. p. 158–163° at 10 mm., $n^{25}\mathrm{D}$ 1.5145, $d^{25}{}_4$ 0.957.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.4; H, 9.93. Found: C, 78.8; H, 10.0.

4,6-Diheptenylresorcinol, $(C_7H_{13})_2C_6H_2(OH)_2$.—This was a high-boiling by-product in the preparation of 4-heptenylresorcinol (see above). Its low volatility was witnessed by its slow rate of distillation from the Hickman still, namely, about one drop per minute at 100° and 0.0005 mm. Thus, from the less-volatile fractions there was finally obtained 2.5 cc. of oil which appeared to be 4,6-diheptenylresorcinol, $n^{25}\mathrm{D}$ 1.5265.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.4; H, 9.93. Found: C, 79.1; H, 10.1.

Summary

This paper describes the preparation of hexenylresorcinol, pentenylresorcinol and heptenylresorcinol by direct substitution of resorcinol with the corresponding alkenyl bromide. Concurrent reaction products were the dialkenylresorcinols and the resorcinol alkenyl diethers. The use of a molecular still greatly facilitated the separation and purification of these compounds. Chloroacetic acid derivatives and methyl ethers of the alkenylresorcinols were prepared.

From the hexenylresorcinol some *n*-hexylresorcinol was prepared by hydrogenation. Oxidation of hexenylresorcinol methyl diether gave rise to 2,4-dimethoxybenzoic acid.

Bactericidal data are included.

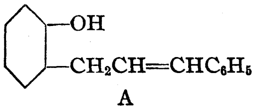
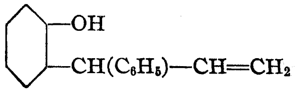
Observations on the Rearrangement of Allyl Aryl Ethers

BY CHARLES D. HURD AND LOUIS SCHMERLING[1]

In studying the cinnamyl derivatives of phenol, Claisen[2] found that the *o*-cinnamylphenol obtained by direct alkylation was different from the product obtained by pyrolysis of cinnamyl phenyl ether. To the former he assigned structure (A) and to the latter (B). Although this conclusion is not doubted from a qualitative standpoint, it has never been established whether or not (B) was formed exclusively or whether it was admixed to a small extent with (A). Since this is a matter of considerable importance in regard to the mechanism of rearrangement of allyl aryl ethers, it was decided to study this and other related questions.



A



B

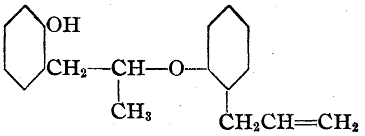
Accordingly, Claisen's two compounds were synthesized and subjected to ozonolysis. The ozonide from (A) should yield benzaldehyde but no formaldehyde on hydrolysis, whereas that from (B) should yield formaldehyde and no benzaldehyde. This was found to be the case, thus confirming Claisen's conclusion.

To determine whether the allyl aryl ether rearrangement is intra- or intermolecular, a mixture of cinnamyl phenyl ether, $C_6H_5—O—CH_2CH═CHC_6H_5$, and allyl β-naphthyl ether, $C_{10}H_7—O—CH_2CH═CH_2$ was heated. If intermolecular, some *o*-allylphenol should be formed. Since this is relatively low boiling (104° at 14 mm.) compared to 1-allyl-2-naphthol (177° at 12 mm.) or *o*-(α-phenylallyl)-phenol (190° at 13 mm.), its isolation from the reaction mixture would be accomplished easily. 1-Allyl-2-naphthol and *o*-(α-phenylallyl)-phenol were found but no *o*-allylphenol.

Similar evidence for the intramolecular nature of this rearrangement was obtained by studying a mixture of allyl β-naphthyl ether and 2-hexenyl phenyl ether.

In connection with this work, some of the hexenylresorcinols were synthesized. Resorcinol hexenyl monoether, $HOC_6H_4OCH_2CH═CHC_3H_7$, was isolated for the first time. It was insoluble in alkali and was stable at 100°.

The rearrangement of allyl phenyl ether into *o*-allylphenol was also studied. Claisen[3] obtained an 80% yield on heating at the reflux temperature for six hours. Our yields were only about half. The bulk of the product was a polymer from which a dimer and trimer were separated by distilling the tar from a molecular still. The dimer was soluble in dilute alkali, was unsaturated toward bromine, was unaffected[4] by hot formic acid, and had a molecular refraction of 80.5. These data are in harmony with *o*-(2-(*o*-allylphenoxy)-propyl)-phenol



which has a calculated molecular refraction of 81.1.

Experimental Part

Cinnamyl Phenyl Ether.—A mixture of cinnamyl bromide (80 g.), acetone (200 cc.), phenol (50 g.) and potassium carbonate (75 g.) was refluxed for four hours, then 200 cc. of water was added. The ether separated and solidified. It was washed with dilute alkali and water, and the yield was 78 g. or 92%. It melted at 67°. This is preferable to Claisen and Tietze's[5] method wherein sodium phenoxide reacted with cinnamyl bromide in methanol.

***o*-(α-Phenylallyl)-phenol.**—The rearrangement of cinnamyl phenyl ether by refluxing for four hours in diethylaniline was performed essentially as described by Claisen and Tietze. The reaction product boiled at 186–189° (18 mm.); phenylurethan, m. p. 93–94° (Claisen and Tietze reported 91°).

o-Cinnamylphenol (m. p. 55°, phenylurethan, m. p. 132°) was prepared according to Claisen's directions.[6] The essential feature of this synthesis was the gradual addition of cinnamyl bromide in benzene to a suspension of an equivalent quantity of sodium phenoxide in benzene followed by refluxing for five hours. Likewise, Claisen's directions[7] were followed in the preparation of allyl β-naphthyl ether, namely, the heating of a mixture of 0.1 molar quantities of β-naphthol, allyl bromide and potassium carbonate in 200 cc. of acetone. The refractive index at 25° was found to be 1.600. The synthesis of hexenyl phenyl ether (from 0.1 molar quantities of 1-bromo-2-

hexene, phenol, potassium carbonate and 200 cc. of acetone) and its pyrolysis to *o*-(α-*n*-propylallyl)-phenol followed the directions of Hurd and McNamee.[8]

Pyrolysis of Mixtures of Ethers.—A mixture of 7.5 g. of allyl β-naphthyl ether and 4.5 g. of cinnamyl phenyl ether was heated under a reflux condenser for four hours by a bath at 240°. An exothermic rearrangement was observed. The volume of the alkali-soluble portion was 3 cc. The only low-boiling material collected during distillation at 15 mm. was one drop of phenol. There was no evidence for *o*-allylphenol. One cc. of 1-allyl-2-naphthol was collected at 160–180°; n^{20}D 1.6170. It solidified on seeding with a crystal of 1-allyl-2-naphthol. At 180–190° there was obtained about 0.3 cc. of *o*-(phenylallyl)-phenol.

A mixture of 4.2 g. of allyl β-naphthyl ether and 4 g. of 2-hexenyl phenyl ether was heated similarly for six hours at a bath temperature of 250°. An exothermic reaction was noticed at 224° (temperature of mixture itself).

On working up the product (by alkali extraction and vacuum distillation) there was obtained 0.4 cc. of phenol which solidified and melted at 30°; bromination yielded tribromophenol, m. p. 96°. About 0.5 cc. of *o*-hexenylphenol, n^{22}D 1.5250, was collected at 128–148° (18 mm.), and 1.1 cc. of 1-allyl-2-naphthol, n^{16}D 1.6167, at 165–180°. The latter solidified. After crystallization from 50% alcohol it melted at 55°. No *o*-allylphenol, b. p. 104 (14 mm.), was observed.

Ozonolysis of *o*-Cinnamylphenol and *o*-(α-Phenylallyl)-phenol.—A 3% ozone stream was conducted through a solution of 3 g. of *o*-cinnamylphenol in 100 cc. of carbon tetrachloride for four hours. Some of the ozonide separated but the bulk of it was soluble. The solvent was removed under reduced pressure and the residual ozonide hydrolyzed with water. The aqueous layer (even on boiling) was free from any odor of formaldehyde. Also, formaldehyde was proved absent by the resorcinol ring test. The water-insoluble oil was taken up in ether, washed with dilute sodium bicarbonate and dilute sodium carbonate and evaporated. The residual benzaldehyde weighed 0.75 g.; its phenylhydrazone melted correctly at 155°.

Four grams of the isomeric *o*-(α-phenylallyl)-phenol, ozonized as before, yielded an oily ozonide which was hydrolyzed by shaking it with water and zinc dust. Formaldehyde was present in quantity as indicated by the strong odor and by the resorcinol ring test. The viscous, insoluble oil was taken up in ether and washed with sodium bicarbonate solution. Acidification of the wash solution gave no water-insoluble (benzoic) acid. The ether layer was then washed with sodium carbonate solution before evaporating the ether. The residue, a thick oil, gave no phenylhydrazone and yielded no benzoic acid on oxidation with potassium permanganate.

Resorcinol 2-Hexenyl Monoether.—Resorcinol (16.5 g.) was converted to its sodium salt by interaction with the calculated amount of sodium ethoxide in 400 cc. of absolute alcohol. This solution was added with stirring during three hours into 49 g. of 1-bromo-2-hexene. Stirring was continued overnight and then the solution was refluxed for two hours. The alcohol was removed and the residue extracted with carbon tetrachloride (125 cc.). The extract was washed with water to remove unreacted resorcinol. Then the solution was extracted with a 10% solution of sodium hydroxide. This process removed hexenylresorcinol but did not dissolve resorcinol hexenyl monoether or diether. From the alkaline extract by acidification, ether extraction and distillation in a Hickman still[9] at 100° and 0.001 mm. was obtained 6 cc. of 4-hexenylresorcinol,[10] n^{22}D 1.5398.

Anal. (Zerewitinoff) Calcd. for C_6H_{11}-$C_6H_3(OH)_2$: OH, 2.00. Found: OH, 1.99.

The alkali-insoluble portion was freed from the carbon tetrachloride and distilled in the Hickman still (100°, 0.001 mm.). Five fractions totaling 12.5 cc. were collected, all possessing nearly identical n^{23}D values of 1.5210. All five fractions were alkali-insoluble. Analysis proved this material to be resorcinol hexenyl monoether.

Anal. (Zerewitinoff) Calcd. for HO-C_6H_4-OC_6H_{11}: OH, 1.00. Found: OH, 1.00, 0.97.

The residue in the Hickman still contained resorcinol hexenyl diether. It was volatilized by raising the temperature of the still to 160° with an air-bath. Five grams of the diether[10] was collected, n^{23}D 1.5160.

Polymers of *o*-Allylphenol.—Allyl phenyl ether, b. p. 112–113° (34 mm.), n^{21}D 1.5208, n^{26}D 1.5190, was prepared in 82% yields according to Claisen's[11] directions. This ether (67 g.) was heated by a bath at 210–240° to maintain refluxing for five and a half hours. The temperature of the liquid rose from 190 to 220°. On working it up according to Claisen's directions there was obtained 23 g. of *o*-allylphenol (a 42% yield), and 3 g. of α-methylcumarane. A considerable quantity of dark, viscous tar remained in the distilling flask.

This tar was distilled from a Hickman still at 0.01 mm. With a bath temperature of 145° two 1-cc. fractions were collected which appeared to be a mixture of diallylphenol[12] and triallylphenol. The bath temperature was then raised to 245°, whereupon 10.5 cc. of an apparently uniform product, the dimer, distilled. The next 0.5-cc. fraction, collected at a bath temperature of 270°, set to a clear amber glass on cooling. Its molecular weight (calcd. for $C_{27}H_{30}O_3$, 402; found, 384) indicated that it was chiefly the trimer of *o*-allylphenol.

Properties of the Dimer.—The dimer was a liquid, n^{21}D 1.5825, d^{25}_{25} 1.11, easily soluble in 10% sodium hydroxide but almost insoluble in 20% alkali. The acetyl and benzoyl derivatives were oils. The substance absorbed bromine (in carbon tetrachloride) without the evolution of hydrogen bromide, and it was unaffected when heated with concentrated formic acid.[13] The molecular weight, determined cryoscopically in benzene, was satisfactory for the dimer.

Mol. wt. Calcd. for $C_{18}H_{20}O_2$, 268. Found: mol. wt., 270.

Summary

It was established by ozonolysis that the product of rearrangement of cinnamyl phenyl ether is

o-(*α*-phenylallyl)-phenol, unadmixed with any *o*-cinnamylphenol. Similarly, *o*-cinnamylphenol, prepared by direct alkylation of phenol, was free from *o*-(*α*-phenylallyl)-phenol.

Study of the rearrangement behavior of mixtures of allyl *β*-naphthyl ether with cinnamyl phenyl ether or 2-hexenyl phenyl ether showed that the rearrangement of allyl aryl ethers is intramolecular.

Resorcinol 2-hexenyl monoether and other hexenylresorcinols were prepared.

By use of a molecular still the polymeric products formed during pyrolysis of phenyl allyl ether were separated into a dimer and trimer of *o*-allylphenol. Considerable evidence supports *o*-(2-(*o*-allylphenoxy)-propyl)-phenol as the structure of the dimer.

A Series of N-Methyl Amides[1]

BY G. F. D'ALELIO[2] AND E. EMMET REID

In order to bring out the analogies of the N-monomethyl amides to the acids we have prepared the series from the normal acids, formic to stearic. Although some of these are recorded in the literature the data on all except the acetyl are fragmentary. We have compared a number of preparation methods which have been proposed for N-alkyl amides and have investigated some of their reactions. The physical properties of our compounds are given in Tables I and II and their melting points, along with those of the corresponding acids are plotted in Fig. 1. Using Swietoslawski's[3] values for the other elements the average value for the atomic refraction of nitro-

gen in these amides is 2.76. The curves for the melting points of these amides and of the acids are strikingly alike. The liquid N-methyl amides resemble the acids in viscosity. The lower members of the series are practically tasteless, but a peppery taste appears with the fourth and reaches a maximum value with the tenth, which has an intense burning taste and numbs the tongue. The toxicities increase likewise. Nos. 7, 8 and 9 are local anesthetics.[4]

Chemical Reactions

The mono-methyl amides, like acetamide,[5] form two types of hydrochlorides (a) $RCONHCH_3 \cdot HCl$ and (b) $(RCONHCH_3)_2 \cdot HCl$. In a non-polar solvent type (a) salts are formed, while in the absence of any solvent, type (b) result. Melting points and analyses of our preparations appear in Table III.

Table III

Sodium reacts readily with formamide[6] but hardly at all with its N-methyl derivative or with other N-methyl amides at room temperature. It does react with their solutions in boiling toluene. Amides form mercury derivatives[7] but the N-methylamides do not. Treatment of N-methyl acetamide with nitrous acid converts it into its nitroso compound, b. p. 116.3°, m. p. −8.5°, $n^{25}\text{D}$ 1.4415, d^{0}_{4} 1.1007, d^{25}_{4} 1.0709, mol. refr. 25.10, calcd. 25.32. Refluxing N-methyl acetamide with acetic anhydride gives N-methyldiacetamide,[3] b. p. 194.2°, m. p. −46.8°, $n^{25}\text{D}$ 1.4502, d^{0}_{4} 1.0904, d^{25}_{4} 1.0663, mol. refr. 28.9, calcd. 27.9. With phosphorus pentoxide a complicated reaction occurs: N-methyldiacetamide is formed in 19% yield. N-Bromo-N-methyl acetamide is obtained readily as light yellow prisms, m. p. 123.5° but is very unstable, readily giving up its bromine. It does not undergo the Hofmann[8] degradation which accords with the prediction of Stieglitz.[9]

Experimental

Preparation of N-Methyl Amides.—The most generally useful method was to drop the acid chloride very slowly, with constant stirring, into three moles of amine[10] in concentrated aqueous solution. For the first nine members the temperature was kept at −20 to −10° during the addition. The methyl amides were caused to separate by the addition of solid caustic potash to the mixture. The separated amide was dried over caustic potash, and distilled. For the higher members a large excess of amine was used, and cooling was effected by tap water. Troublesome emulsions result unless the acid chloride is added at an extremely slow rate. At the completion of the reaction the mixture was placed in a separatory funnel, the aqueous layer drawn off, and the amide taken up in benzene or ether. The solution was dried and the amide recovered by evaporation of the solvent and then recrystallized from anhydrous methanol. The yields run from 85 to 95%. Similar yields of the lower amides were obtained when the amine was passed into a solution of the acid chloride in dry toluene at −10° followed by the addition of 20% sodium hydroxide solution.

For comparison various other methods of preparing amides were tried. The reaction of dry methylamine on esters proved to be very slow but with an excess of the aqueous amine 68% of the heptamide was obtained after several days. From the sodium salt of an acid and methylamine hydrochloride as recommended by Verley[11] and Menschutkin[12] a good yield of the crude amide was obtained but it was difficult to purify. Acetamide[13] and its sodium salt[14] were methylated, yields 50–60%. The methyl amides of formic and acetic were obtained by passing the amine through the heated acids.[15]

N-Nitroso-N-methyl Acetamide.—To one mole of methyl acetamide and three moles of sodium nitrite dissolved in a minimum amount of water, concentrated hydrochloric acid was added slowly. When the reaction was complete the mixture was cooled, the oily layer separated, dried and distilled. On five runs the yields varied from 74–80%. *Anal.* % N calcd. 27.45; found 27.41.

N-Methyl Diacetamide.—N-Methyl acetamide was refluxed with 2.8 moles of acetic anhydride and the product fractionated in a precision still, yield 68%. *Anal.* % N calcd. 12.17; found 12.14.

N-Bromo-N-methyl Acetamide.—To 0.1 mole of N-methyl acetamide in 25 cc. of anhydrous ethyl acetate, 0.15 mole of bromine was added. Silver oxide was added slowly with rapid stirring until the bromine color disap-

peared, the temperature being kept below 50°. The silver bromide was filtered off and the solution evaporated *in vacuo*. The resulting oil crystallized on standing in a vacuum desiccator. The crystals were washed free of bromine with carbon tetrachloride. *Anal.* % Br calcd. 52.58; found 52.60.

Thanks are due to Dr. John R. Ruhoff and Dr. Jane Dick Mayer for samples of the higher acids and esters.

Summary

N-Methyl amides of the acids from formic to stearic have been prepared and some of their physical and pharmacological properties determined. Some of them are local anesthetics and possess a peppery taste. Derivatives of some of them have been made.

Three Series of N-Substituted Aliphatic Amides[1]

BY G. F. D'ALELIO AND E. EMMET REID

In a previous article,[2] a series of N-methyl amides has been described. This investigation considers three series involving the same normal aliphatic acids, their hydroxyls being replaced by the groups (a) —$NHCH_2CH_2OH$, (b) —$N(CH_2CH_2OH)_2$ and (c) —$NHCH_2CH(OH)CH_3$. Some acyl derivatives of aminoethanol have been described[3,4] and since the completion of our work, a communication describing the first three ethanol amides has appeared.[5]

All of our compounds were prepared by heating the ethyl esters of the acids, already reported,[6,7] with the amine.[8] For the first six members of series (a), the ester was refluxed with a 25% excess of ethanolamine for six hours and the product fractionated. For the remainder of this series, 2 g. of the ester with a 3% excess of the amine was heated at 160° for six to ten hours. The higher ethanol amides were washed with dilute hydrochloric acid and recrystallized from 95% ethanol or from anhydrous methanol.

The diethanol amides gave the most trouble; the lower members melt too low for crystallization, boil too high for fractionation and are too soluble in organic solvents and water With the higher members the reaction products solidified to waxes. These were dissolved in the minimum amount of methanol, 5 volumes of water added and the mixture saturated with sodium chloride. The precipitated amides were filtered off and kept four months in a vacuum desiccator over sulfuric acid. They could then be crystallized from methanol–ether mixtures; average yield 70%.

The higher isopropanol amides were readily prepared from the amine and the ester. The solids were recrystallized from methanol, average yield 85%.

N-Ethanol benzamide was prepared by heating equivalent quantities of ethyl benzoate and ethanolamine in a flask in an oil-bath at 150° until the calculated amount of alcohol had distilled off. The solidified product was spread on a porous plate, desiccated over sulfuric acid and recrystallized from acetone, yield 95%, m. p. 67.6°, N calcd. 8.48; found 8.39%. This compound was made by Fränkel[3] who gave 67° as m. p. and by Wenker[5] who obtained it as an uncrystallizable liquid. The melting points are given in Tables I and II and plotted in Fig. 1.

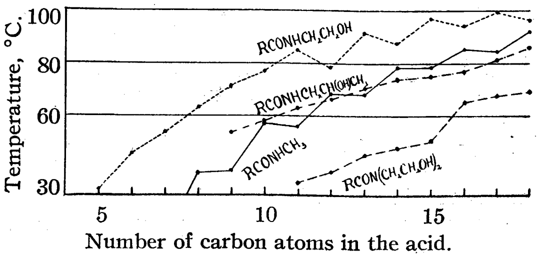

Fig. 1.—Melting points of the N-substituted amides.

The N-ethanol amides show slight alternation up to no. 11 where it suddenly becomes pronounced and then diminishes. This curve is the inverse of that of the N-methyl amides which is shown for comparison. The alternation is slight with the N-isopropanol amides and seems to

invert at no. 14. The melting points of the N-diethanol amides appear to rise in groups of three. Pharmacological results have been published.[9] For the ninth members of the four series of N-substituted amides the activities are in the order: $RCONHCH_3 > RCONHCH_2CH_2OH > RCON(CH_2CH_2OH)_2 > RCONHCH_2CH(OH)CH_3$.

Summary

The N-ethanol amides of the normal acids from formic to stearic have been prepared and characterized. The corresponding N-diethanol and N-isopropanol amides have been made of the higher acids. Comparative pharmacological effects are also reported.

Surprisingly few O-alkylated derivatives of fluorescein have been prepared. Only the methyl and ethyl derivatives are reported in the literature, but they have been investigated by many workers[2] chiefly because of the confusion arising from difficulties involved in their purification. In the present study, the allyl, pentenyl and hexenyl derivatives were synthesized. The various types involved are the "ether ester" (A), the "diether" (B), the "monoether" (C) and the "monoester" (D).

Two general methods of synthesis were used. In the first, fluorescein was reacted with the

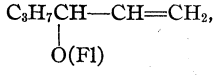
alkenyl bromide in acetone solution in the presence of potassium carbonate. All four type compounds were obtained in the reaction mixture. The first step in separating them was based on the fact that A and B are alkali-insoluble, whereas C, D and unreacted fluorescein are alkali-soluble. Separation of orange colored A from colorless B was accomplished by virtue of the fact that the latter is more soluble in carbon tetrachloride and less soluble in ethyl alcohol. The monoether and the monoester were separated from the fluorescein by precipitation from the alkaline solution with carbon dioxide. The amount of material so obtained was usually very small. The dark-red monoallyl ester was found to be less soluble in cold alcohol than the nearly colorless monoether and was separated from it by use of this property.

The second method, which has the advantage of being much more rapid than the first, was applied to phenols as well as to fluorescein types. It involves the reaction of the alkenyl bromide with the sodium phenolate in an aqueous acetone solution. The proportions of water and acetone were so adjusted as to give a clear solution. With this procedure, there were higher yields of C, lower yields of B, and approximately the same yields of A, as in the first method. Since little unreacted fluorescein remained, the monoether (C) could be obtained in a pure state by acidifying the alkaline solution and recrystallizing the precipitate from ethyl alcohol. It was not found possible to isolate any of the monoester by this second method.

It was found as expected that the various allyl and alkenyl ethers (types A, B and C) rearranged on heating to form C-substituted fluoresceins. When, for example, the allyl diether was heated to 210°, an exothermic reaction occurred, and most of the material became alkali-soluble. The product consisted chiefly of 2,7-diallylfluorescein with some 2-allylfluorescein and fluorescein. The presence of the latter compounds is analogous to the formation of phenol[3] from phenyl allyl ether. In the present study, fluorescein and the C-alkylated rearrangement products were found to be too similar in physical and chemical properties to permit the complete separation of the latter from the former.

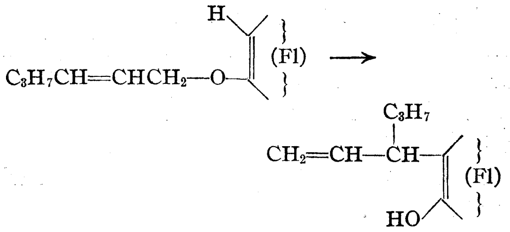
The structure of the hexenyl portion of fluorescein hexenyl diether was determined by ozonolysis. It was found that the volatile acid obtained from the ozonide was a mixture of formic and butyric acids, with butyric considerably in excess. The butyric acid would come from $C_3H_7CH{=}CHCH_2{-}O{-}(Fl)$ and the formic from



$$\underset{\displaystyle O(Fl)}{C_3H_7CH}{-}CH{=}CH_2,$$

wherein (Fl) represents the fluorescein residue. Such a result indicates that the hexenyl bromide used in the synthesis of the ether was an equilibrium mixture of 1-bromo-2-hexene and 3-bromo-1-hexene.

Ozonolysis of the rearrangement product of the diether gave evidence which supported the idea



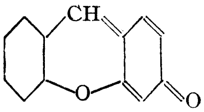
---

(3) Hurd and McNamee, THIS JOURNAL, **54**, 1648 (1932).

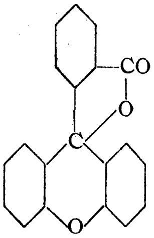
that the "wandering" group undergoes inversion of an allylic type. Formic and butyric acids were indicated as before, but this time it was the formic which was in excess.

The saponification of the diallyl ether ester led to some very interesting results. It was found that the solvent used during the reaction was a determining factor. Thus, it was shown that either fluorescein, or its monomethyl, ethyl or allyl ethers could be obtained by using, respectively, water, methanol, ethanol or allyl alcohol (or aqueous acetone) as the solvent. A similar observation was made by von Liebig[4] who obtained the monoethyl ether of fluorescein in an attempt to prepare the monomethyl ether by saponifying the dimethyl ether ester with ethyl alcoholic potash.

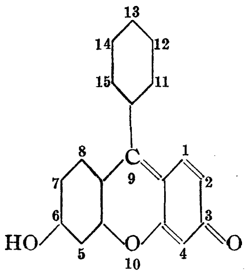
The O-alkenyl compounds studied are listed in Table I. The systematic names are derived from the following nuclei: fluorone (E), fluoran (F) and resorcinolbenzein (G).



(E)



(F)



(G)

The allyl ether ester (I) and pentenyl ether ester (VI) were tested bactericidally in the Parke, Davis and Company Laboratories, but were found to be ineffective (phenol coefficients less than 50 toward *Staph. aureus*). Their extreme insolubility may have been a contributing factor.

Two new reactions of fluorescein are also recorded. One is the production of diacetylfluorescein by addition of ketene, and the other is the formation of 3,6-dichlorofluoran by reaction with thionyl chloride.

Experimental Part

Diacetylfluorescein.—Ketene, generated at the rate of 0.1 mole per hour, by passing acetone vapors over a hot platinum filament,[5] was passed through a suspension of 1.66 g. of red fluorescein in 50 cc. of acetone. The calculated time to obtain the diacetate was six minutes. In five minutes, it was noticed that the fluorescein was beginning to dissolve. In seven minutes, solution was complete and the flow of ketene was stopped. The acetone was evaporated. The residual oil solidified on the addition of ethanol The first crystallization from 100 cc. of hot alcohol gave crystals which melted at 204° (the same as that observed with material prepared from fluorescein and acetic anhydride). A second recrystallization raised the m. p.[6] to 205°; yield, 1.9 g., or 91%.

3,6-Dichlorofluoran.—Ten cc. (16.5 g.) of thionyl chloride was added to 5 g. of red fluorescein. A yellow color was imparted to the mass. It turned red and dissolved after an hour of refluxing. The heating was continued for another hour and the excess of thionyl chloride was distilled off. The red-brown residue was digested with water, then treated with dilute sodium hydroxide, and finally crystallized from hot toluene. White crystals of 3,6-dichlorofluoran, m. p. 262°, uncorr., were obtained; yield 5.4 g., or 90%. The m. p. was unchanged by recrystallization from acetic anhydride or from alcohol. When dissolved in hot toluene and precipitated therefrom by one to two volumes of alcohol, the m. p. changed to 256°.

3,6-Dichlorofluoran, prepared from fluorescein and phosphorus pentachloride according to Baeyer's direction,[7] melted at 255°. Baeyer reported 252°. When reduced with zinc dust and alcohol,[8] both products yielded fluorescein dichloride, m. p. 229°.

Preparation of Ethers

Allyl *p*-Cresyl Ether.—This ether was prepared by a new method. An aqueous solution of sodium *p*-cresolate was prepared from 5.4 g. of *p*-cresol, 2.0 g. of sodium hydroxide and 30 cc. of water. To this were added 6.1 g. of allyl bromide and sufficient acetone (30 cc.) to give a single clear solution. The solution was allowed to stand at room temperature for four hours during which there separated an oily supernatant layer. The oil was extracted with petroleum ether, washed with water, dried over potassium carbonate, and distilled. Allyl *p*-cresyl ether was obtained as a colorless oil boiling at 96–98° (15 mm.); n^{24}_D 1.5157. These constants agree with those in the literature.[9] The yield was 5.3 g., which is 72%.

Hexenyl *p*-Cresyl Ether.—A solution was made of 4.4 g. of *p*-cresol and 1.6 g. of sodium hydroxide in 50 cc. of water. Then 6.5 g. of 1-bromo-2-hexene in 100 cc. of acetone was added. In four hours the mixture had separated in two layers which were separated by extraction with petroleum ether. After washing, drying and

[a] All analyses except XI were performed by Mr. M. A. Pollack.

The Allyl Ether Ester of Fluorescein (I)

First Method.—Thirty-three grams (0.1 mole) of fluorescein was mixed with 28 g. (0.2 mole) of potassium carbonate. A solution of 24 g. (0.2 mole) of allyl bromide in 300 cc. of acetone was added. After refluxing with stirring for twelve hours, the mixture was poured into 500 cc. of cold water. The allyl ether ester and the allyl diether of fluorescein precipitated, while the unreacted fluorescein as well as a small amount of the monoallyl ether and the monallyl ester dissolved, giving rise to a deep red solution which exhibited a green fluorescence. The orange precipitate was filtered off, washed with water, and dried in a desiccator. On recrystallizing the 30 g. of crude material from 350 cc. of carbon tetrachloride, there was obtained 16 g. of the orange-colored ether ester, m. p. 155°. Concentration of the mother liquor to 75 cc. yielded an additional 1.2 g. of the compound, bringing the total yield to 17.2 g. or 42%. On complete evaporation of the solvent, there was left a brown gummy residue from which the allyl diether could be obtained.

Second Method.—Thirty-eight grams (0.1 mole) of the disodium salt of fluorescein was dissolved in 250 cc. of water and a solution of 24 g. (0.2 mole) of allyl bromide in 150 cc. of acetone was added, giving a single clear solution. (The sodium salt was prepared by adding an excess of fluorescein to a solution of sodium hydroxide, filtering, and evaporating the filtrate to dryness.) The aqueous acetone solution was refluxed for two hours during which time the allyl ether ester and the monoallyl ether separated as a dark red oil. On pouring the supernatant solution into water, an orange, colloidal solution was obtained. Dilute alkali was added to dissolve the monoallyl ether and cause the precipitation of the ether ester as a flocculent orange precipitate. The dark red oil was dissolved in 50 cc. of acetone, poured into water, and the resulting colloidal solution treated similarly with alkali. After filtering and washing the precipitates, the combined yield of crude alkali-insoluble material was 25 g. On recrystallizing from carbon tetrachloride there was obtained 18 g. of (I), m. p. 155°. This is 43.5% of the theoretical.

The second method is not only more rapid than the first, but it is also to be preferred since a 30% yield of the monoallyl ether rather than unreacted fluorescein was obtained from the alkaline filtrate. It was found that the yield of ether ester could be made practically quantitative by using a 25% excess of allyl bromide and by adding sufficient acetone during the refluxing to maintain a clear solution.

The Allyl Diether of Fluorescein (II).—The brown, gummy residue from the final mother liquor from the recrystallization of (I), prepared by the first method, was dissolved in 30 cc. of hot 95% ethanol. Dark brown crystals began to separate on cooling. These were filtered and washed with alcohol to remove most of the brown impurity. On recrystallizing from 20 cc. of hot alcohol there was obtained 3.6 g. of pale yellow crystals which melted sharply at 124°.

The Allyl Ether of Fluorescein (III).—The alkaline filtrates from the synthesis of (I) by the second method were combined and acidified with hydrochloric acid. There was obtained a yellow precipitate which coagulated to form a tan gum on warming. (This serves to distinguish the monoether from unreacted fluorescein, the yellow form of which coagulates as red granules on warming in hydrochloric acid solution.) The coagulated precipitate was washed by decantation and then dissolved in 75 cc. of hot alcohol. On standing overnight 9.2 g. of the pale yellow allyl ether of fluorescein, m. p. 205°, separated. An additional 2.1 g. of the compound was obtained by evaporating the mother liquor and treating the resulting tar with a solution of 0.5 cc. of acetone in 10 cc. of alcohol which removed the impurities, leaving the ether undissolved. The total yield of (III) was 30% of the theoretical.

Acetate of (III).—This derivative was prepared by dissolving 0.5 g. of (III) in 2 cc. of acetic anhydride and heating for five minutes. After several recrystallizations from ethanol, the acetate was obtained colorless, m. p. 143°.

The Allyl Ester of Fluorescein (V).—The alkaline filtrate from the synthesis of (I) by the first method was acidified with hydrochloric acid and the yellow precipitate filtered and washed. This gave 10.8 g. of material which was dissolved in a solution of 4 g. of sodium carbonate in 200 cc. of water. Carbon dioxide was bubbled through the solution for several hours, at the end of which time 2.4 g. of orange-red solid had separated. This was a mixture of the allyl ether and the allyl ester. The former was extracted by washing the mixture with several 10-cc. portions of warm ethanol. The residue was dissolved in 4 cc. of hot ethanol. The solution was intensely fluorescent. On cooling, (V) slowly crystallized in small clusters of dark red crystals, m. p. 233°.

The pentenyl ether ester (VI) and the pentenyl diether of fluorescein (VII) were obtained in essentially the same

TABLE III

Substance heated	Compound formed Symbol	Compound formed Name	M.p., °C.	Analyses Calcd. C	Analyses Calcd. H	Analyses Found C	Analyses Found H
III	XIV	2-Allylfluorescein	168–176	74.17	4.32	73.57	4.46
II	XV	2,7-Diallylfluorescein	158–161	75.69	4.89	74.99	4.78
I	XVI	Allyl 2-allylresorcinolbenzein-11-carboxylate (Allyl ester of 2-allylfluorescein)	137–143	75.69	4.89	74.40	4.84
VIII	XVII	2-Pentenylfluorescein	156–160	75.00	5.00	74.25	4.86
XI	XVIII	2,7-Dihexenylfluorescein	135–140	77.42	6.45	75.28	6.52

way as the corresponding allyl derivatives, (I) and (II), using the first method. The mixture of 1-bromo-2-pentene[10] (0.1 mole), fluorescein (0.05 mole) and potassium carbonate (0.1 mole) in acetone (50 cc.) was refluxed for twelve hours over a period of two days. On pouring into water, an oily layer separated. The oil solidified after four hours in the ice box. It was filtered, washed with a 1% solution of sodium hydroxide, then water and finally dried. In this case, it was found that a better separation of the two isomers could be obtained by dissolving the ether ester in cold ethanol, which procedure left the diether undissolved. Recrystallized from hot ethanol, the pentenyl diether of fluorescein was obtained as pale yellow needles, m. p. 131°.

The pentenyl ether ester was obtained as orange-colored flakes, m. p. 118°, by precipitation from the alcoholic solution with water and recrystallization from carbon tetrachloride. The yields of diether and ether ester, respectively, were 23 and 17%.

The pentenyl ether of fluorescein (VIII) was obtained in 32% yield by the same method as that used to prepare the allyl ether (III). Its melting point, 220°, was found to depend somewhat on the rate of heating, for rearrangement takes place on melting. **Its acetyl derivative (IX)**, prepared analogously to IV, melted at 108°. The crystallization from alcohol required several hours.

The hexenyl ether ester (X) and the hexenyl diether of fluorescein (XI) were prepared in the same manner as the pentenyl compounds. It was necessary to reflux with stirring the mixture of 1-bromo-2-hexene[11] (0.2 mole) fluorescein (0.1 mole), and potassium carbonate (0.2 mole) in acetone (120 cc.) for sixty hours over a period of eight days. The first sign of reaction (*i. e.*, the formation of alkali-insoluble material) was not observed until the fifth day, after thirty-six hours of refluxing. The yields of diether and of ether ester, respectively, were 22 and 12%.

The Hexenyl Ether of Fluorescein (XII).—This compound and its acetyl derivative (XIII) were obtained by the same methods as for the allyl and pentenyl compounds. Like the other monoethers, the impure yellow crystals of the monohexenyl ether tended to turn orange when exposed to air and alcohol. It was only after three crystallizations from ethanol that it was obtained as pale yellow crystals, m. p. 187°; yield 12%.

Pyrolysis of the Ethers

General Procedure.—The compound (2–5 g.) was heated in a test-tube immersed in an oil-bath. Inner and outer temperatures were recorded. In all cases an exothermic reaction occurred at 210–220°, at which time the melt became viscous and darkened in color. The temperature was maintained at 210–220° for about one hour. The material was cooled, and the friable, dark red glass so obtained was crushed and extracted with a hot 5% solution of sodium bicarbonate. (In the case of the product from (I) it was necessary to use a 0.5% solution of sodium hydroxide.) The alkaline solutions were strongly fluorescent. The filtered alkaline solution was acidified, thereby precipitating the substituted fluorescein as a yellow-orange precipitate (yields, 50%) which formed a dark red glass on drying in an oven at 115°. The compounds were readily soluble in alcohol, acetone, ethyl acetate, glacial acetic acid or dioxane but insoluble in petroleum ether. In no case was it found possible to recrystallize the product from an organic solvent or combination of solvents.

The compounds treated in this manner were the allyl ether (III), the allyl ether ester (I), the allyl diether (II), the pentenyl ether (VIII), and the hexenyl diether (XI). Data regarding the substances formed are collected in Table III. Since purification was only by bicarbonate extraction and subsequent acidification, high purity for the compounds could not be expected. Analyses were fairly satisfactory in most cases, however. Small amounts of fluorescein or other by-products of the pyrolysis were undoubtedly present.

The material insoluble in sodium bicarbonate was washed with 10% sodium hydroxide, dissolved in alcohol and precipitated therefrom by water. About 0.3–0.6 g. of orange-yellow solid was obtained in each case. These were probably the cumarane analogs of XIV–XVIII.

Ozonolysis of Fluorescein Hexenyl Diether.—One gram (0.002 mole) of XI in 60 cc. of dry carbon tetrachloride was ozonized, the ozonide hydrolyzed with warm water and the aldehydes liberated were oxidized to acids by warming for four hours with a mixture of sodium hydroxide (1 g.) and silver oxide (from 3 g. of silver nitrate). After filtration, acidification with dilute sulfuric acid and refiltration, the filtrate was distilled to obtain the volatile acids. Both formic and butyric acids were identified, the former by permanganate titration and the latter (via the sodium salt and *p*-bromophenacyl bromide) as *p*-bromophenacyl butyrate, m. p. 61–63°. On the assumption that these were the only two volatile acids, they were analyzed by the Duclaux method and found to be in the ratio of 30:70 (formic:butyric). This assumption may not be wholly justified but the answer is valuable at least qualitatively.

Ozonolysis of 2,7-Dihexenylfluorescein.—Ozonolysis of XVIII (0.5 g.) and subsequent treatment as before yielded a mixture of volatile acids which was high in formic acid as revealed by permanganate titration.

---

[10] Hurd and McNamee, THIS JOURNAL, **59**, 104 (1937).

[11] Hurd and Parrish, *ibid.*, **57**, 1732 (1935).

Duclaux analysis seemed to show 85% formic and 15% butyric acids, but here again the possible presence of other volatile acids limits the reliability of this quantitative figure. It does serve to demonstrate the preponderance of formic acid in the mixture, however.

Hydrolysis and Alcoholysis of (I)

In Water.—Three grams of the allyl ether ester was refluxed with a solution of 2 g. of potassium hydroxide in 100 cc. of water. The compound slowly dissolved, giving an intensely fluorescent solution. Saponification was complete after thirty minutes. Acetic acid was added to the clear solution until incipient precipitation. Filtration yielded 0.35 g. of the allyl ether (III); m. p. 204° after crystallization from ethyl alcohol. Complete acidification of the filtrate yielded 1.4 g. of material which was shown to be fluorescein; m. p. of the diacetate, 203–204°.

In Allyl Alcohol.—Two grams of the allyl ether ester was dissolved in 20 cc. of dry allyl alcohol. One gram of crushed sodium hydroxide was added, and the mixture was refluxed for one hour. The completeness of the reaction was determined by pouring a test portion into water; a clear solution indicated that the saponification was complete. Part of the alcohol was then distilled off and the residue poured into 100 cc. of water, filtered to remove traces of insoluble impurities, and acidified with hydrochloric acid. There was obtained 1.8 g. of (III), m. p. 205° (recrystallized from ethyl alcohol); a mixed m. p. with an authentic sample showed no depression.

In Aqueous Acetone.—One gram of the allyl ether ester was dissolved in 50 cc. of acetone and 1.5 g. of sodium hydroxide dissolved in 10 cc. of water was added. Two layers were formed. Refluxing for two hours resulted in very little reaction. When, however, sufficient water to give a single, clear solution was added, the solution almost immediately showed a green fluorescence and after ten minutes saponification was complete. The solution was poured into 100 cc. of water and acidified. The tan precipitate thus obtained melted at 197–200°. One recrystallization from alcohol yielded 0.5 g. of the pure allyl ether, m. p. 205°.

This procedure was found to be quite satisfactory for obtaining the allyl monoether (III), using the crude ether ester prepared by the second method described above. The yield of (III) was 55–65%, with fluorescein formed as a by-product.

In Methanol.—The procedure and quantity of materials were the same as in the case of allyl alcohol. The product formed on acidifying the alkaline solution melted at 262–265°; yield 1.3 g. On recrystallization from 95% ethyl alcohol, very pale yellow crystals, m. p. 266°, were obtained. The melting point given in the literature for fluorescein methyl monoether[12] is 262, 265 or 266°. The identity of the monoether was confirmed by converting it to the dimethyl ether ester by refluxing 0.8 g. of the compound and 2 cc. of concentrated sulfuric acid in 20 cc. of methanol for eight hours. The solution was poured into dilute alkali and the orange precipitate filtered off. Recrystallized from ethyl acetate, it melted at 208°; yield 0.6 g.

3-Methoxy-6-acetoxyfluoran (Acetate of Fluorescein Methyl Ether).—This new ester was obtained by heating 0.5 g. of fluorescein methyl monoether in 2 cc. of acetic anhydride and working up the product in the usual manner: m. p. 141° (recrystallized from ethyl alcohol).

Anal. (By Mr. M. A. Pollack) Calcd. for $C_{23}H_{16}O_6$: C, 71.13; H, 4.12. Found: C, 70.95; H, 4.10.

In Ethanol.—The method and results were similar to those in the experiments with the other two alcohols. Acidification of the alkaline solution yielded 1.35 g. of tan material. It was purified from 95% ethyl alcohol from which it crystallized in nearly colorlesss crystals, m. p. 250°. This is correct for fluorescein ethyl monoether.[13] Its identity was confirmed by preparing the monoacetyl derivative, m. p. 222°.

Summary

β,γ-Unsaturated ethers of fluorescein have been synthesized. These include the allyl, pentenyl and hexenyl monoethers, diethers and ether esters. The monoallyl ester also has been prepared.

The behavior of these ethers toward heat is analogous to that of the other allyl aryl ethers. Rearrangement gives rise to C-alkenylated fluoresceins with attachment to the nucleus taking place at the gamma-carbon atom of the allyl chain.

The hydrolysis or alcoholysis of the diallyl ether ester of fluorescein has been shown to yield fluorescein, the monomethyl ether, the monoethyl ether, or the monoallyl ether when water, methanol, ethanol or allyl alcohol (or aqueous acetone), respectively, are used as solvent. The acetate of fluorescein methyl ether was prepared.

It was shown that diacetylfluorescein may be made very readily from fluorescein and ketene. 3,6-Dichlorofluoran was suitably prepared from fluorescein and thionyl chloride.

A rapid, new method of synthesis of alkenyl aryl ethers was presented.

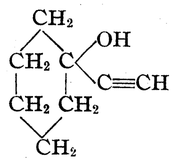
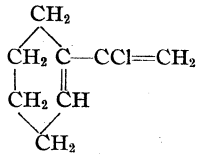
The Rearrangement of Ethynylcarbinols

BY CHARLES D. HURD AND ROBERT E. CHRIST

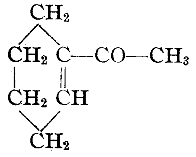
Recently, it was established[1] that 1-ethynyl-1-cyclohexanol (I) was converted by thionyl chloride and pyridine into 1-α-chlorovinyl-1-cyclohexene (II). Some years earlier, Rupe[2] had announced the transformation of (I) by formic acid into cyclohexylideneacetaldehyde, $(CH_2)_5$-C=CHCHO, not 1-acetyl-1-cyclohexene (III). In its enolized form (III) would be analogous to (II). The improbability that two acidic reagents should influence the ethynylcarbinol by essentially different mechanisms caused us to inspect Rupe's evidence. Curiously, it all supported the ketone (III), yet the aldehyde structure was assigned on the basis of delicate color reactions (Schiff's reagent and Angeli's reagent).



(I)



(II)



(III)

Evidence against the aldehyde formula was the non-formation of cyclohexylideneacetic acid with silver oxide. Ozonization supported (III) inasmuch as adipic acid was the reaction product instead of cyclohexanone. Excellent evidence for (III) was its behavior on catalytic hydrogenation. The material obtained boiled at 69° (12 mm.) and gave a semicarbazone of m. p. 171–172°. These are the constants for cyclohexyl methyl ketone[3] and its semicarbazone, rather than for cyclohexylacetaldehyde[4] (b. p. 79–80° (10 mm.); semicarbazone, m. p. 132–134°). Fischer and Löwenberg[5] had occasion to doubt the conclusion of Rupe and, in repeating the work, found that the hydrogenated product was actually cyclohexyl methyl ketone.

Rupe has also studied the rearrangement of about a dozen other ethynylcarbinols. In a few cases, namely, 1-ethynyl-3-(and 4-)-methyl-1-cyclohexanol and 1-ethynyl-2-methyl-5-isopropyl-1-cyclohexanol, rearrangement was reported[6] to yield unsaturated ketones of type III. The majority of the reactions, however, have been stated to yield the unsaturated aldehydes. No suggestion was included to explain why ketones were formed in a few cases and aldehydes in others. The aldehyde-forming carbinols included[7] ethynylmethylalkylcarbinol (alkyl = isohexyl, *t*-butyl, phenyl, isobutyl, β-phenylethyl), 1-ethynyl-2-(or 5)-isopropyl-5-(or 2)-methyl-1-cyclohexanol, and ethynylfenchyl alcohol. In these cases, as with 1-ethynyl-1-cyclohexanol, the interpretation of the evidence seemed questionable. Hence this matter was investigated and ethynylmethylphenylcarbinol, 1-ethynyl-1-cyclohexanol, and ethynylbornyl alcohol, a new compound, were selected for study. In none of these cases was any evidence found for the aldehyde structures postulated by Rupe. The evidence for ketones as rearrangement products was very convincing.

That (III) was the rearrangement product of (I) was confirmed by synthesizing 1-acetyl-1-cyclohexene from cyclohexene,[8] acetyl chloride, and aluminum chloride, preparing its semicarbazone (m. p. 220–221°), and proving its identity to the semicarbazone of (III), from (I), by a mixed melting point determination.

Ethynylmethylphenylcarbinol,
$C_6H_5\underset{CH_3}{C}(OH)$—C≡CH, was prepared according to Rupe's directions, but the oil (b. p. 122–130° (12 mm.); semicarbazone, m. p. 201°) which was obtained in small yield during reaction with formic acid was not β-phenylcrotonaldehyde (IV) as stated by Rupe and Giesler[9] but was simply acetophenone.

$$C_6H_5C(CH_3){=}CHCHO \quad (IV)$$
$$CH_2{=}C(C_6H_5)COCH_3 \quad (V)$$

The bulk of the reaction product was a tar which

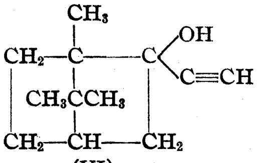
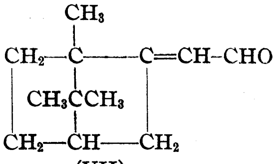
probably came *via* phenylbutenone (V). Both IV and V possess conjugated systems but V, with its unsubstituted methylene carbon, represents a type which is particularly susceptible to polymerization.

Ethynylbornyl alcohol (VI) was synthesized from camphor, acetylene and metallic sodium. A smooth rearrangement occurred with formic acid. The product, however, was not the aldehyde (VII) but was the ketone (IX).

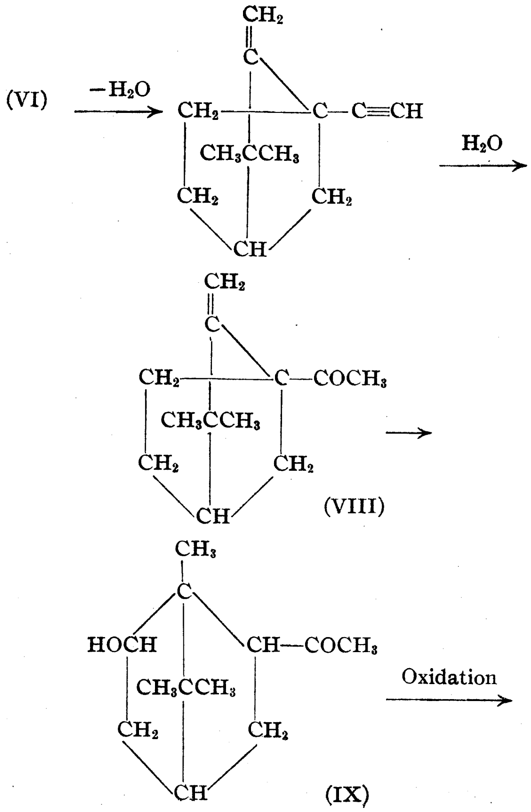


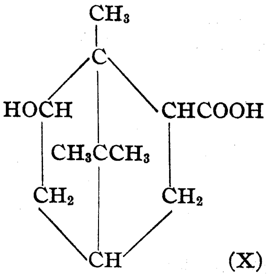
(VI)



(VII)

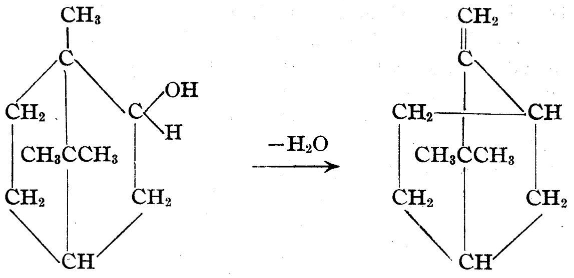
In the first place, no acid was obtainable by the prolonged action of silver oxide. Secondly, analysis corresponded to $C_{12}H_{20}O_2$ rather than $C_{12}H_{18}O$. Finally, oxidation by ozone yielded 6-hydroxy-2-camphanecarboxylic acid (X). From these data, it is apparent that the product of rearrangement is 2-acetyl-6-hydroxycamphane (IX). Since the latter is a γ-hydroxy ketone it may undergo cyclization into a hemi-acetal configuration. The mechanism for the transformation of VI to IX involves two Wagner rearrangements



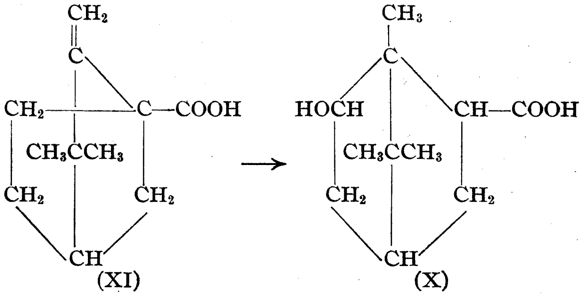


(X)

The dehydration of (VI) into (VIII) resembles the transformation of borneol into camphene



whereas that of (VIII) into (IX) is strictly analogous to the transformation[10] of camphenecarboxylic acid (XI) into (X).



Our hydroxycamphanecarboxylic acid (X), prepared by oxidation of (IX), was identical with Houben's acid (X), prepared from (XI).

Since these several cases have proven that ketones are the important rearrangement products of ethynylcarbinols, rather than aldehydes, serious doubt is cast on other similar cases wherein aldehydes are stated to be formed but wherein definite proof for the assertion is lacking. Obviously, the various non-discriminatory reactions of the "aldehydes" which appear in the literature (such as with the Grignard reagent, reducing agents, hydroxylamine or semicarbazide) should be reinterpreted on the basis of ketones.

Experimental Part

Preparation of Reagents.—Ethynylcyclohexanol, b. p. 74–76° (12 mm.), was prepared in 30% yield by Rupe's method, as modified by Hurd and Jones.[1] In the prepara-

---

[10] Houben, *Ber.*, **59**, 2285 (1926).

tion of ethynylmethylphenylcarbinol, the directions of Rupe and Geisler[9] were modified by using benzene instead of ether. Instead of keeping the solution at ice temperature during the addition of the acetylene, it was kept refluxing gently. Also, the acetylene was led in before the sodium had dissolved. The yield of this carbinol, b. p. 85–90° (4 mm.) and m. p. 49°, was 13.5%. It was accompanied by about thrice the quantity of the pinacol of acetophenone.

Ethynylbornyl Alcohol VI.—One hundred grams of camphor dissolved in 600 cc. of dry benzene was placed in a 3-necked, liter flask to which was attached a long spiral reflux condenser, mercury stirrer and an inlet for acetylene. To this was added 16 g. of finely cut sodium. Then, while the solution was kept gently refluxing, acetylene was passed through for fifteen hours. After standing overnight, the solution was hydrolyzed with water and neutralized with hydrochloric acid. The solution was then steam distilled. The benzene layer was separated and treated with alcoholic silver nitrate, whereupon an abundant white crystalline precipitate formed. Its weight was 37 g. This was filtered, washed with alcohol and dried.

The silver salt was treated with an equal weight of ammonium thiocyanate in water solution. The insoluble layer was extracted with benzene, dried over calcium chloride and the benzene was evaporated. Sublimation attended efforts to distil the residue *in vacuo:* hence, the material was sublimed under reduced pressure. In all, 15.3 g. of ethynylbornyl alcohol was obtained having a m. p.[11] of 97–98°. This is a 13% yield.

Anal. (by Maxwell Pollack). Calcd. for $C_{12}H_{18}O$: C, 80.84; H, 10.18. Found: C, 80.42; H, 10.00.

Ethynylfenchyl Alcohol.—Similar directions were adapted for this synthesis. The chief difference from Rupe and Kuenzy's[12] published directions is the use of hot benzene instead of cold ether as the reaction medium, but it brought about a greatly improved yield. With their directions, reported to yield 8–10%, we obtained about a 7% yield. The modified directions listed below gave about a 29% yield.

Forty grams of finely cut sodium and 600 cc. of benzene were placed in the apparatus and the mixture was saturated with acetylene after which 200 g. of fenchone was added gradually. The solution warmed up to reflux temperature as the stream of acetylene was passed through. The total period of addition was forty-eight hours.

After standing for twelve hours, the solution was hydrolyzed with water and neutralized with hydrochloric acid. The solution was then steam distilled. The benzene layer was separated, dried and evaporated to a small volume under reduced pressure. (No difficulty due to sublimation was observed in this case.) The residue was treated with silver nitrate in alcoholic solution. An abundant white crystalline precipitate formed. This salt was filtered, washed with alcohol, dried, treated with an equal weight of ammonium thiocyanate (in water) and then steam distilled. The insoluble layer was separated, dried over sodium sulfate and distilled. A total of 67.4 g. of ethynylfenchyl alcohol, b. p. 90° (12 mm.), was obtained.

Rearrangements

Ethynylcyclohexanol.—Rupe's procedure, that of heating the compound with formic acid, was followed except for minor variations. The product of rearrangement (57% yield) boiled at 60–64° (4 mm.). As reported by Rupe, this material gave a positive test with Schiff's reagent. Its semicarbazone melted at 220–221° after three crystallizations from alcohol.

1-Acetyl-1-cyclohexene (III).—This compound was made from cyclohexene (86 g.), acetyl chloride (78 g.), carbon disulfide (600 cc.) and aluminum chloride (133 g.) by Darzens' method.[13] The yield of (III), b. p. 195–202°, was 26 g. or 21%. Its semicarbazone melted at 220–221°. A mixed melting point determination of this semicarbazone and that of the previous paragraph was 220–221°.

Behavior of Ethynylmethylphenylcarbinol toward Formic Acid.—Analogous to the yield of 1 g. of product, b. p. 122–130° (12 mm.), from 10 g. of the carbinol which was reported by Rupe and Giesler,[9] we obtained 1.7 g. (b. p. 100–110° at 6 mm.) from 12 g. The residue was a dark red tar. The liquid product reacted positively toward Schiff's reagent. Its semicarbazone melted at 201° (Rupe and Giesler reported 201–202°). A mixed melting point determination with authentic acetophenone semicarbazone, m. p. 201°, was 201°.

Further evidence that this material was acetophenone, not β-phenylcrotonaldehyde (IV) as postulated by Rupe and Giesler, was its behavior on ozonolysis. Acetophenone (unused) and benzoic acid, m. p. 121°, were the products obtained. The latter would not be expected from (IV).

To make sure that acetophenone did not preëxist in the carbinol taken for rearrangement, more of the carbinol was prepared and purified rigorously. A portion of the product, collected at 83–86° (6 mm.), was treated with alcoholic silver nitrate solution. The yellow precipitate was collected on a filter, washed repeatedly with alcohol, then dried. Part of the salt was lost when it exploded violently. Equal weights of the salt and of ammonium thiocyanate were warmed in a flask with water to recover the ethynylcarbinol. The insoluble layer was extracted with benzene, dried, distilled, and twice recrystallized from petroleum ether. The m. p. was 49° and no semicarbazone was obtainable from it.

This pure ethynylmethylphenylcarbinol (4.4 g.) was heated with 50 cc. of 90% formic acid until spontaneous reaction occurred. When this had subsided it was refluxed for thirty minutes. Then the solution was neutralized with alkali and the insoluble layer extracted with benzene. Distillation yielded 0.5 g. at 100–110° (6 mm.) which, as before, was acetophenone; semicarbazone, m. p. and mixed m. p., 201°.

Rearrangement of Ethynylbornyl Alcohol (VI).—Ten grams of (VI) was placed in an all-glass refluxing apparatus with 60 cc. of 90% formic acid. The mixture was heated until a spontaneous reaction took place. The solution turned first to a red then to a deep brown color. Heating was continued for an additional hour. The solution was

---

[11] After the completion of the present study notice appeared of the synthesis of this compound by Dulou, *Bull. inst. pin*, **178**, 197 (1934); *C. A.*, **29**, 2945 (1935). Dulou's compound melted at 85° whereas ours was 98°.

[12] Rupe and Kuenzy, *Helv. Chim. Acta*, **14**, 708 (1931).

[13] Darzens, *Compt. rend.*, **150**, 707 (1910); Wallach, *Ann.*, **360**, 46 (1908).

neutralized with sodium hydroxide. The insoluble layer was extracted with benzene, dried over calcium chloride and then distilled under reduced pressure. A total of 7.5 g. (75% yield) of the rearranged product was obtained; b. p. 96–98° (6 mm.); $n^{24}D$ 1.4733. The substance gave a positive iodoform reaction, indicative of the $-COCH_3$ group. Schiff's reagent required considerable time for a slight color change. When 0.5 g. of this material in 50 cc. of alcohol was refluxed for five hours with freshly prepared silver oxide, no acid was obtainable on working up the products. Crystallization of this material was a difficult matter but it was found that solidification set in after about two weeks at room temperature. Recrystallization of this product from petroleum ether yielded crystals which melted at 77–78°. Analysis was satisfactory for 2-acetyl-6-hydroxycamphane (IX).

Anal. (by M. Pollack). Calcd. for $C_{12}H_{20}O_2$: C, 73.41; H, 10.27. Found: C, 73.43; H, 10.03.

Ozonization of 2-Acetyl-6-hydroxycamphane.—Eighty cc. of carbon tetrachloride was used as solvent for 4.14 g. (0.021 mole) of (IX) and 62.3 liters of an 8–10% ozone mixture was run in during twenty hours. The ozonide was hydrolyzed by warming on the steam-bath with an equal volume of water. There was formed 0.040 mole of acidic material (97.0 cc. of 0.4170 *N* sodium hydroxide solution was required). The neutral aqueous solution was extracted twice with carbon tetrachloride, then concentrated and acidified with hydrochloric acid. A brown, viscous mass separated which, after three crystallizations from alcohol–water, yielded 2.8 g. (0.014 mole) of white, crystalline 6-hydroxy-2-camphanecarboxylic acid[14] (X), m. p. 221°.

Neut. eq. Calcd. for $C_{11}H_{18}O_3$, 198.2. Found: 198.8 (0.2649 g. required 12.20 cc. of 0.1091 *N* NaOH).

Anal. (semi-micro). Calcd.: C, 66.62; H, 9.15. Found: C, 66.62, 66.40; H, 9.07, 9.16. *Anal.* (macro, by M. Pollack). Found: C, 66.64; H, 9.02.

Semicarbazone.—This derivative, prepared in the usual manner from IX, melted at 202°. That it was the semicarbazide of 1-acetylcamphene (VIII), rather than of IX, was shown by analysis. Evidently a dehydration process occurs during semicarbazone formation.

Anal. Calcd. for $C_{13}H_{21}ON_3$: N, 17.88. Calcd. for $C_{13}H_{23}O_2N_3$: N, 16.60. Found (Dumas): N, 17.84, 17.81.

Summary

Rearrangement of ethynylcyclohexanol by hot formic acid yields 1-acetyl-1-cyclohexene, not cyclohexylideneacetaldehyde, since it is identical to the substance prepared from cyclohexene, acetyl chloride and aluminum chloride. Other evidence for the structure of the product is cited also.

No evidence could be found to support the statement in the literature that an isomeric aldehyde is produced from ethynylmethylphenylcarbinol by rearrangement with formic acid. Instead of β-phenylcrotonaldehyde, the product formed is acetophenone. The bulk of the product is a tar which probably arises *via* 2-phenylbutenone.

Ethynylbornyl alcohol, prepared from camphor, acetylene and sodium, undergoes rearrangement to 2-acetyl-6-hydroxycamphane. On oxidation, this substance yields 6-hydroxy-2-camphanecarboxylic acid. Improved directions are given for the synthesis of ethynylfenchyl alcohol.

The Removal of HX from Organic Compounds by Means of Bases. III. The Rates of Removal of Hydrogen Bromide from Substituted N-Bromobenzamides and their Relative Ease of Rearrangement in the Presence of Alkali. The Hofmann Rearrangement

BY CHARLES R. HAUSER AND W. B. RENFROW, JR.

According to the most generally accepted mechanism for the Hofmann rearrangement of a bromoamide in the presence of alkali,[1] hydrogen bromide is removed to form an unstable univalent nitrogen compound which undergoes the rearrangement to give an isocyanate. Since it is possible to isolate the alkali salts, (RCONBr)Na, of certain bromoamides, the reaction apparently involves first, the removal of the hydrogen as a proton, followed by the release of bromide ion and rearrangement of the molecule; this might be represented as follows

$$\mathrm{RCONHBr} \xrightarrow{+\mathrm{OH}^\ominus} \mathrm{RCONBr}^\ominus \xrightarrow{-\mathrm{Br}^\ominus} (\mathrm{RCON}) \longrightarrow \mathrm{RCNO}$$

We have taken the view that the rate determining step of this process is the release of bromide ion from the negative ion of the salt, and that the rearrangement, if it is a separate step, occurs rela-

---

[1] See especially Porter, "Molecular Rearrangements," The Chemical Catalog Co., New York, 1928, pp. 13–30.

tively rapidly as the molecule is stabilized.[2] On this basis the ease of rearrangement[3] of a bromoamide in the presence of alkali would be dependent upon the rate of removal of bromide ion. As a possible test for this hypothesis, a study has been made of the rates of decomposition of the sodium salts of a series of meta and para substituted bromobenzamides. It seemed reasonable to expect that if this view were correct then an inverse relationship should exist between the rates of decomposition of these salts and the dissociation constants of the corresponding carboxylic acids. Linear relationships have been reported recently between the rates of certain reactions and the dissociation constants of the corresponding acids.[4] An inverse relationship should be expected in the case of the bromoamide salts since, in their decomposition, bromine is released as a negative bromide ion, whereas, in the dissociation of an acid, hydrogen is removed as a positive ion, *i. e.*, as a proton; this relationship has been verified for certain meta and para substituted bromobenzamides.

Experimental

Preparation of Bromobenzamides.—These compounds were prepared by a modification of the method by which Hoogewerff and van Dorp[5] prepared bromobenzamide and certain of its derivatives. Ten grams of pure, finely pulverized amide was added to 150 cc. of an ice-cold solution of sodium hypobromite, freshly prepared from 14.4 g. (0.09 mole) of bromine, and 9.0 g. (0.23 mole) of sodium hydroxide. After shaking for ten minutes, the mixture was filtered rapidly with suction into a cold solution of 9 cc. of glacial acetic acid in 25 cc. of water containing crushed ice. The bromoamide which precipitated was filtered off and washed thoroughly with water. The following conditions were found best for recrystallizing the various bromobenzamides used in this work. Bromobenzamide and the *p*-methyl derivative were dissolved in boiling chloroform, petroleum ether (b. p. 60–70°) added until turbidity just disappeared, and the solution cooled; the *m*-bromo and *m*-chloro derivatives were dissolved in glacial acetic acid at 50–60°, water added until cloudiness just disappeared, and the solution cooled; the *m*-nitro derivative was dissolved in acetic acid at 80–85°, water or petroleum ether added and the solution cooled; the *p*-chloro derivative was recrystallized from hot (70–80°) 50% aqueous acetic acid, the *p*-nitro derivative from boiling glacial acetic acid, and the *o*-chloro derivative from a boiling mixture of two parts of carbon tetrachloride to one of chloroform. The *p*-methoxy derivative was dissolved in a 5% solution of sodium hydroxide containing ice, and filtered into dilute acetic acid and ice. The yields of pure products obtained were 40–70% of the theoretical quantities. They should be kept cold, away from light.

For analysis the bromobenzamides were dissolved in glacial acetic acid, excess potassium iodide added, the solution diluted with water to about 150 cc., and the liberated iodine titrated with sodium thiosulfate to the starch–iodide end-point. The analytical data for the bromobenzamides used in this work are given in Table I. These compounds melted with decomposition. Their approximate melting or decomposition points are given in Table I. These values were determined by immersing samples in a bath which was previously heated to within 5–10° of these temperatures and gradually heating the bath in the usual manner.

Products of Reactions of Bromobenzamides with Alkali.—Bromoamides readily dissolve in sodium hydroxide to form sodium salts[1,5] which release bromide ion and undergo rearrangement to isocyanates. In the presence of alkali, the latter are hydrolyzed to primary amines. Bromoamides may also undergo hydrolysis to form the corresponding acids. These reactions may be represented by the following scheme.

At 30° in the presence of a large excess of alkali, the yields of amine obtained from the bromobenzamides studied in this investigation, with the exception of the nitro derivatives, were 90% or better, whereas the yields of the corresponding acids were less than 5% (see Table IV). The meta and para nitro derivatives, however, gave 25 and 46% yields of the corresponding acid, those of the

[2] In this connection see especially, Whitmore, THIS JOURNAL, **54** 3281 (1932); Wallis and Whitmore, *ibid.*, **56**, 1427 (1934).

[3] Jones and co-workers[1] assumed that the ease of rearrangement of this type is dependent upon the tendency for the radical R, in the univalent nitrogen derivative, to exist as a free radical, and they presented certain evidence to support this hypothesis. Recently, Wallis and co-workers [THIS JOURNAL, **55**, 1701, 2598 (1933); and Bell, *J. Soc. Chem. Ind.*, **52**, 584 (1933)], have presented evidence that R does not actually exist as a free radical during the Hofmann rearrangement.

[4] (a) Hammett and Pfluger, THIS JOURNAL, **55**, 4079 (1933); Hammett, *Chem. Rev.*, **17**, 125 (1935); (b) Dippy and Watson, *J. Chem. Soc.*, 436 (1936).

[5] Hoogewerff and van Dorp, *Rec. trav. chim.*, **8**, 173 (1889); see also, *ibid.*, **6**, 373 (1887). In agreement with our results these workers have shown that the potassium salts of *m*- and *p*-nitrobromobenzamides are more stable than the salt of bromobenzamide.

amines being correspondingly smaller. The relatively low yields of amines obtained in these cases may be explained by the fact that the rate of rearrangement of these compounds is greatly retarded by the presence of the nitro group (see Table IV), whereas the rate of hydrolysis is probably accelerated. It is of interest that the rearrangement apparently has a higher temperature coefficient than the hydrolysis. A 90% yield of *p*-nitroaniline was obtained when *p*-nitrobromobenzamide was dissolved in alkali solution at the temperature of the boiling water-bath (96–100°), whereas a yield of amine of only 48% was obtained at 30°. This point should be considered in the preparation of amines by this reaction.

The yields of amine and acid given in Table IV have been determined under the conditions used in the rate measurements described below. These products were isolated according to the following procedure.

The pure bromoamide (0.005 mole) was dissolved in 100 cc. of 1.0 molar carbonate-free sodium hydroxide solution at 30 ± 0.02°, and kept at this temperature until the mixture no longer contained active bromine. In order to convert any unchanged isocyanate into primary amine, the mixture was acidified with hydrochloric acid and heated on the water-bath for an hour. It was then cooled and extracted with three 25-cc. portions of ether. Organic acid mixed with a very small amount of neutral tarry material was obtained from the dried[6] ether extracts by evaporation of the solvent. The primary amine was obtained from the aqueous solution by making it alkaline and extracting it with three portions of ether. Liquid amines were isolated as their hydrochlorides by passing dry hydrogen chloride into their dried ether solutions. The organic acids and solid amines were identified by their melting points and in most cases by mixed melting points with authentic specimens.

Relative Stabilities of the Sodium Salts of Bromobenzamides.—Van Dam and Aberson[7] have studied the rate of decomposition of bromobenzamide in various concentrations of alkali. With an equivalent of alkali a colored precipitate formed within a short time, interfering with the titration; benzoylphenylurea was isolated from the reaction mixture. Under these conditions we have been able to obtain a yield of aniline of only 30% of the theoretical amount. Van Dam and Aberson[7] showed that in the presence of an excess of alkali the rate was dependent not only on the concentration of bromobenzamide but also on that of the alkali, being approximately proportional to the concentration of alkali when twenty to forty equivalents of the latter to one of the bromoamide were used.[8] We have obtained 94–95% yields of aniline using 10, 20 or 40 equivalents of alkali to one of bromobenzamide. In this investigation therefore, the rates of decomposition of substituted bromobenzamides were determined in the presence of a large excess (20 to 1) of alkali, using the same molar concentrations of reactants in all cases.

The course of the reaction of a 0.05 molar bromoamide solution in 1.0 molar sodium hydroxide at 30 ± 0.02° was followed by titrating samples for active bromine in the usual manner. Since the reaction is first order with respect to the bromoamides, velocity constants have been calculated from the first order rate of reaction equation

$$K = \frac{2.303}{t} \log \frac{a}{a - x}$$

where t is in minutes. Two sets of measurements have been made with each bromoamide, the data and velocity constants with a representative compound being given in Table II. The average values of velocity constants K, calculated for 25–95% decomposition of the bromoamides are arranged in decreasing order in Table IV. With the exceptions of the *p*-methoxy and the nitro derivatives, these values are reproducible to within 1–3%. Under the conditions used the *p*-methoxy compound[9] decomposed too rapidly (95% within five minutes) to measure accurately. The values of K calculated for the *o*-, *m*- and *p*-nitro derivatives were not constant but increased steadily from 0.00105–0.00174, 0.000556–0.000988 and 0.000823–0.000974, respectively. Mean values are recorded in Table IV merely to illustrate their relative stabilities. It is to be noted that in these cases considerable hydrolysis occurred.

Velocity constants for the sodium salts of bromobenzamide and of *p*-methyl- and *m*-chlorobromobenzamides have been measured at two or three temperatures, and the heats of activation

[6] Anhydrous calcium sulfate (Drierite) was used.

[7] Van Dam and Aberson, *Rec. trav. chim.*, **19**, 318 (1900); Van Dam, *ibid.*, **18**, 408 (1899).

[8] It does not seem possible that this alkali effect could be due only to a shift in the equilibrium of the acid–base reaction between the bromoamide and alkali. Further studies in this connection are planned.

[9] This was the most unstable compound prepared. A product 90% pure was used for an approximate rate determination.

calculated. The results are given in Table III. It can be seen that the heat of activation for the *p*-methyl derivative is about one thousand calories less than that for bromobenzamide, whereas the value obtained for the *m*-chloro derivative is 400 cal. greater; this latter difference might be within the experimental error. This phase of the problem is being studied further.

TABLE III

HEATS OF ACTIVATION OF THE SODIUM SALTS OF BROMOBENZAMIDE AND CERTAIN OF ITS DERIVATIVES

Derivative	T_1	K_1	T_2	K_2	Q
p-Methyl	30	0.138	20	0.0301	27,000

o-NO_2	.0013[c]	(700.)	....	....
m-NO_2	.0008[c]	32.1	70	25
p-NO_2	.0008[c]	37.6	48	46

[a] The dissociation constants listed here, with the exception of the one for *o*-nitrobenzoic acid, have been taken from the recent papers of Dippy and co-workers, see note 13. [b] An approximate value for the constant. In qualitative agreement with our results, Van Dam has previously reported that in the presence of potassium hypobromite, *p*-methoxybenzamide is decomposed more readily than benzamide; see ref. 7. [c] Not a constant; an average value only.

It can be seen from Table IV that the rates of decomposition of the salts of the meta and para substituted bromobenzamides at 30°, and presumably their ease of rearrangement,[10] are in general in the inverse order to the dissociation constants of the corresponding carboxylic acids.[11] When the logarithms of the rate constants[12] are plotted against the logarithms of the dissociation constants of the corresponding acids an approximately linear relationship is exhibited as shown in Fig. 1; the equation for the straight line is $\log K_v = -11.81 - 2.50 \log K_A$. The dissociation constants used here are the thermodynamic values recently reported by Dippy and co-workers.[13] If the values given in the "International Critical Tables" are used, the discrepancy between the *m*-chloro and *m*-bromo derivatives disappears but, on the whole, the linear relationship is not quite as good as that represented in Fig. 1.

It is considered that these results are in agreement with the hypothesis that the ease of rearrangement of a bromoamide in the presence of alkali is dependent upon the ease of release of bromide ion from the negative ion of the salt. It can be seen from Table IV that the *o*-chloro and *o*-nitro derivatives are more unstable than would be anticipated from the dissociation constants of the corresponding acids; however, such lack of agreement between theory and experiment with ortho substituted compounds has been observed in other cases.[14]

---

(10) This does not necessarily mean that the ease of rearrangement of the corresponding univalent nitrogen compounds, if they have an independent existence, would be in the same order; see note 3.

(11) In this connection it should be mentioned that certain hydroxy bromobenzamide derivatives are very unstable. McCoy, *Am. Chem. J.*, **21**, 116 (1899); see also ref. 7.

(12) See note (c) Table IV.

(13) Dippy and co-workers, *J. Chem. Soc.*, 1888 (1934); 343 (1935); 645 (1936).

(14) In this connection it is of interest to note that although the calculated dipole moments of *m*-, and *p*-chlorobenzoic acids can be correlated with their dissociation constants, apparently no correlation is found in the case of *o*-chlorobenzoic acid; dipole moment calculations seem to indicate that the latter should be weaker than benzoic acid, whereas actually it is much stronger; see Smallwood, THIS JOURNAL, **54**, 3048 (1932); see also ref. 4b.

The writers wish to thank Dr. Douglas G. Hill for suggestions on the kinetics of these reactions.

Summary

1. The rates of decomposition of the sodium salts of a series of substituted bromobenzamides have been measured at 30°.

2. The rates of decomposition of the sodium salts of bromobenzamide and of *m*-chloro- and *p*-methylbromobenzamides have been measured at two or three temperatures and their heats of activation calculated.

3. It has been found that the relative rates of decomposition of certain meta and para substituted bromobenzamides at 30°, and presumably their relative ease of rearrangement in the presence of alkali, are inversely related to the dissociation constants of the corresponding carboxylic acids.

4. These results are considered to be in agreement with the hypothesis that the ease of rearrangement of a bromoamide in the presence of alkali is dependent upon the ease of release of bromide ion from the negative ion of the alkali salt.

5. It has been found that in the presence of excess alkali at 30°, *p*-nitrobromobenzamide gives approximately as much *p*-nitrobenzoic acid by hydrolysis as *p*-nitroaniline by rearrangement; at 96–100°, however, a 90% yield of *p*-nitroaniline is obtained.

Studies on Lignin and Related Compounds. XXVI. The Properties of Spruce Lignin Extracted with Formic Acid

BY GEORGE F. WRIGHT AND HAROLD HIBBERT

The recent publications by Freudenberg and co-workers[1] and by Staudinger and Dreher,[2] in which they describe the extraction of spruce wood meal with formic acid, anticipate a current investigation in this Laboratory. Although this study is not yet complete it seems advisable to present a preliminary account of the work.

Considerable doubt exists as to the reliability of any known extraction process for isolating *unchanged* lignin from wood, and it seems preferable to consider an extractant as the first reagent in a series of reactions intended to prove structure. As one of a series of such extractants, so regarded, it has been found that boiling formic acid removes from resin- and soluble-carbohydrate-free spruce wood meal 17% of its weight in the form of methoxyl-containing material. Because of partial demethoxylation this process yields lignins of comparatively low methoxyl content (12–14%) but it possesses the advantages of: (a) rapidity and convenience of extraction, and (b) isolation of extracts readily soluble in many organic solvents. Thanks to this ease of solubility, it has been found possible to effect a separation of the isolated lignin into five fractions by precipitation of chloroform, acetone and aqueous acetone solutions into ether and also petroleum ether (Table I). This fractionation is undoubtedly incomplete; indeed, subsequent experiments show that the fractions are still complex. Nevertheless, examination of these partially separated products shows a definite trend in chemical and physical properties undoubtedly characteristic of the individual substances that comprise the isolated mixture called lignin.

The behavior of two functional groups has been examined in this study, namely, (a) reactions of the hydroxyl and (b) reactions of the carbonyl group. The suitable solubility of formic acid lignin has permitted the use of the Grignard machine[3] for simultaneous determination of both groups. These analyses have been supplemented by appropriate methoxylations and tosylations. The results (Table I) show two interesting facts: (i) the native lignins contain small amounts of non-enolizable carbonyl groups; (ii) the more soluble, and therefore simplest, fractions, have *higher hydroxyl* and *lower methoxyl* values than their more complex, insoluble analogs. This decrease in hydroxyl value with decreasing solubility suggests that increasing aggregation of

Total water insoluble extract	7.10	...	7.64	...	3.11	...	...	...

[a] It should be noted that complete extraction of the lignin is favored by increased strength of formic acid and by longer heating; on the other hand, the amount of acetone–water insoluble extract decreases during the course of the extraction. An absolutely anhydrous medium should be avoided because of secondary reactions (presumably formylation) occurring during the extraction.

the lignin complex is associated with loss of hydroxyl. The question as to whether these more complex molecules exist pre-formed in the wood[1] or, alternatively, arise from some simpler type during the extraction process[4] would, at this time, seem to be of secondary importance as compared with elucidation of the structure of lignin as it comes to hand.

The small but consistent amount of Grignard reagent added by both native and substituted formic acid lignins confirms the previous claim[5] that lignin contains a carbonyl linkage. That this small value (about one-half carbonyl group per kilogram) is real is shown by treatment of the lignin with phenylmagnesium bromide; the phenylated lignin, thus produced, is no longer capable of adding methyl-magnesium iodide (Table II, expt. 8).

Analyses in the Grignard machine indicate that the *unfractionated* formic acid lignin contains about four hydroxyl groups per kilogram (Table I). This was confirmed by tosylation of the same material, four tosyl groups per kilogram being introduced. These four have been differentiated into phenolic and non-phenolic hydroxyl groups by methoxylation of the unfractionated lignin with diazomethane. Both the gas evolution and the final methoxyl value indicate that two out of the four hydroxyl groups per kilogram are phenolic in character. While the reaction with diazomethane provides inconclusive evidence for distinguishing phenolic, enolic and carboxylic hydroxyls, the presence of labile enol is considered improbable because of the constancy of the carbonyl value found in all of the formic acid lignin derivatives; a keto-enolic equilibrium undoubtedly would be disturbed in the several methoxylation processes which were employed. With regard to a carboxylic linkage, methoxylation would increase the carbonyl value, since methyl esters usually react with two equivalents of Grignard reagent. Since no change in the carbonyl value was found (Table II, expt. 7) it would seem that the hydroxyl groups, reactive toward diazomethane, are phenolic in character.[6]

This amount of phenolic hydroxyl is rather larger than that observed with other lignins.[7] It is, however, significant that this increase corresponds closely with the difference in methoxyl value between the spruce lignin isolated by the Klason method[8] (17%) and the formic acid method (14%). This evidence indicates that the labile methoxyl (which is liberated as methyl formate) is attached in the lignin to phenolic hydroxyl.

It was somewhat surprising to find that native formic acid lignin contained only four hydroxyl groups per kilogram, since complete methoxylation should yield, correspondingly, a lignin containing only 24.6% methoxyl, while it has been found by many investigators[7,8] that "completely methoxylated lignin" contains about 32% OCH_3. Actually a single methoxylation of the formic acid lignin with dimethyl sulfate and sodium hydroxide gave a product containing 24–27% OCH_3 (Table II, expts. 3, 4, 5, 6). Furthermore,

analyses of these methoxylated products in the Grignard machine showed that the lignin still contained from 4 to 3 free hydroxyl groups per kg. (Table II, expts. 3, 4, 6). Calculations from these figures indicate that complete methoxylation should yield lignin containing 34.6–35.2% OCH_3. Accordingly, two further methoxylations were effected with dimethyl sulfate followed by treatment with diazomethane (Table II, expt. 4), the final methoxyl value being 30%. Further attempts are being made to increase the methoxyl content of this product containing 30% OCH_3 and 2.3 hydroxyl groups per kg. However, the futility of alkaline methoxylation as a criterion for the detection and estimation of hydroxyl groups can be seen from the fact that this lignin (OCH_3 30%) still contains sufficient free hydroxyl groups to yield methoxylated lignin containing 36% methoxyl, assuming these groups to be capable of methoxylation. It is thus apparent that repeated methoxylation increases the *potential* methoxyl number by about 1% (34.6–35.2 to 36%). An explanation of this peculiar behavior is furnished in the analysis of the native lignin which had been allowed to stand for forty-five days in 1% sodium hydroxide solution (Table II, expt. 13), during which period there was no absorption of atmospheric oxygen. The original hydroxyl number increased from 4 to 12.5 per kg. with an accompanying decrease of methoxyl from 12.86 to 11.98%. The calculated methoxyl value, upon addition of 4.25 moles of water per kilogram of lignin, is 11.96%, *viz.* 12.86 (10)/[1000 + (12.5–4)18/2]. In short, hydroxyl groups appear *de novo* upon treatment of the native lignin with alkali.[8a] It is noteworthy that if the entire non-methoxyl oxygen content of the formic acid lignin were converted to hydroxyl (by ring opening) the hydroxyl number as deduced from ultimate analysis[2] would likewise be 12.5 per kg.

In view of these surprising results, other lignins were examined for their hydroxyl content. The chloroform soluble fraction of glycol lignin[9] (OCH_3, 16.68%) was found to contain 4.1 hydroxyl groups per kg. (Table II, expt. 12) corresponding to a fully methoxylated value of 27.3%. Repeated treatment of this with diazomethane, followed by subsequent acetylation and dimethyl sulfate methoxylation gave a product containing 31.7% OCH_3 and this "completely methoxylated" derivative still contained two free hydroxyl groups. On the other hand, a methanol lignin (OCH_3, 24.7%) which had been methoxylated only with diazomethane and, therefore, had not been subjected to an alkaline treatment was found to contain three free hydroxyl groups per kilogram (Table II, expt. 9). A sample of the fully methoxylated methanol lignin (OCH_3, 32%) was not available but a methoxylated methanol lignin prepared from methoxylated wood meal[10] and further methoxylated with dimethyl sulfate and sodium hydroxide, followed by treatment with diazomethane, gave a product with 35.4% OCH_3 but still containing 0.9 free hydroxyl group per kilogram (Table II, expt. 10). All of these methoxylated lignins were free from sulfur.

It thus appears that *alkaline methoxylation is unreliable both as a measure of the hydroxyl groups originally present in the lignin and of complete methoxylation.* A few attempts to methoxylate formic acid lignin with dimethyl sulfate at controlled *p*H (Table II, expts. 1, 2) resulted in incomplete reaction; the work is being continued. The possibility that the active hydrogen determination gives false values, either because of demethoxylation or enolization, is improbable. Firstly, no type of demethoxylation involving gas formation with Grignard reagent under these conditions is known, although what may be a typical compound, pentamethylquercetin, was examined (Table III, expt. 1). Secondly, the appearance of enolic methoxyl must necessarily be accompanied by a corresponding decrease in carbonyl value, while actually the carbonyl value is constant within experimental error. Consequently the Grignard analysis is considered reliable for the estimation of hydroxyl groups in lignin.

Extended speculation concerning these newly synthesized hydroxyl groups must await additional experimental evidence. Obviously they could be formed either by addition of the elements of water to double bonds, or by splitting of oxygen rings. It is improbable that all such oxygen rings could be pyrones because of the

---

(8a) The authors find it necessary to point out that additional work has failed to confirm the *quantitative* values thus obtained, although *qualitatively* the evidence supports the conclusions drawn. They are likewise in harmony with previous experimental work carried out by Jack Compton in these laboratories and to appear in the *Canadian Journal of Research*, January, 1937.

TABLE III

ANALYSES OF RELATED COMPOUNDS

Expt. no.	Substance	Solvent	Active hydrogen	RMgX added
1	Pentamethylquercetin, m. p. 148°	Xylene	0.1 per mole	0.8 per mole
2	Cellulose prepared from wood meal (extracted twice with phenol containing 1% concd. HCl and dried at 60° (20 mm.) for 3 hr.	Quinoline (suspension)	1.2 per kg.	0.6 per kg.
3	Oleic acid	Xylene	1.1 per mole	1.0 per mole
4	Isosafrole	Xylene	0.1 per mole	0.0 per mole

low carbonyl value found in the lignin. This does not exclude the presence of the more probable chromanol grouping.[11] The experimental results are contradictory concerning this possibility. Since the splitting of a chromanol ring necessitates formation of a phenolic hydroxyl group, an attempt was made to determine this by treating the previously dimethyl sulfate-alkali methoxylated lignin with diazomethane (Table II, expt. 3a) but no phenolic group was detected. On the other hand, when the same lignin, thrice dimethyl sulfate-alkali methoxylated, was treated with diazomethane an increase of about 1.5% OCH_3 was observed (expt. 4d). The reason for this discrepancy is being investigated. It is certain that hydroxyl formation takes place under exceedingly mild conditions (1% sodium hydroxide) but ethylene oxide or lactone rings cannot be involved because they would have been detected in the Grignard analysis of the native lignin in amounts corresponding to the subsequent hydroxyl increase, resulting from ring fission.

Likewise from the evidence submitted here it is not possible to designate the type of carbonyl function found in this lignin except that it probably is not an acyl group (lignin-OCOR) which would have been removed during methoxylation. Also the carbonyl group is probably not of an enolizable type. The latter reservation follows from its constant value throughout the methoxylation experiments. The carbonyl function is, however, destroyed by prolonged treatment with alkali (Table II, expt. 13). Finally it must be emphasized that this is a preliminary report of work in progress, the methods of which are to be refined in the interest of accuracy.

The authors wish to thank Dr. Saul M. Trister for aid in the experimental work.

Experimental

Preparation of Formic Acid Lignin.—A suspension of 40 g. of spruce wood meal (75 mesh) (previously extracted successively with a 1:1 alcohol–benzene mixture, then with water, and dried at 55° (30 mm.))[12] in 300 cc. of formic acid of various concentrations (Table I) was refluxed in different experiments for six to thirteen hours. After cooling the mixture was filtered by suction and washed with 100 cc. of cold 90% formic acid. The residual moist wood meal (vacuum dried, wt. 23–15 g. depending on duration of boiling) was further extracted for twenty-four hours with 100 cc. of dioxane and another twenty-four hours with 100 cc. of dioxane containing 1% concd. hydrochloric acid. Although this latter treatment decreased the weight of wood meal from 23 g. (vacuum dried at 55°) to 14.6 g., the evaporated extracts yielded only 0.23 g. of lignin. Evidently a large part of the cellulose is hydrolyzed in the process. The reflux condenser was maintained at 40° during the extraction and the uncondensed gases from the condenser were conducted through a dry-ice trap. The condensate was identified as methyl formate (b. p. 31.5°) and by test for methanol following alkaline hydrolysis.

The original formic acid solution, obtained by filtration from the residual wood meal, was evaporated almost to dryness at 25 mm. pressure and the residue washed with water to remove soluble carbohydrates[13] and filtered by suction. After thorough washing with water on the filter and drying by prolonged suction under a rubber dam, the water-insoluble portion was dissolved in 300 cc. of a 3:17 water–acetone mixture leaving a residue[13] which was removed either by suction filtration or centrifuging. The solution was evaporated to dryness (25 mm.), the drying process being facilitated by addition of chloroform. The residue was extracted with three 100-cc. portions of chloroform and the extract concentrated to 40 cc. (30 mm.) (solution A). The chloroform-insoluble residue was further extracted with three 50-cc. portions of acetone and then concentrated to 50 cc. (30 mm.) (solution B). Finally the acetone insoluble residue was dissolved completely in 110 cc. of the 3:17 water–acetone mixture (solution C). These three solutions (A, B and C) were each precipitated into tenfold volumes of ether and the precipitates removed by centrifuging. The chloroform–ether and acetone–ether solutions, containing some lignin, were concentrated to 20 cc. and precipitated into 200 cc. of petroleum ether (b. p. 30–50°). Evaporation of the centrifuged chloroform–ether–petroleum ether solution left a slight residue of odoriferous material. The results of this separation are shown in Table I.

Methoxylation of Lignin with Diazomethane.—One gram of lignin was dissolved in 15 cc. of dry dioxane. To

---

[11] Russell, *Chem. Rev.*, **17**, 155 (1935).

[12] As could have been predicted by King and Hibbert, *Can. J. Research*, **B14**, 12 (1936), a fourfold extraction of the wood meal with 5% alkali had no effect on methoxyl, active hydrogen or carbonyl content of the extracted lignin.

[13] At present undergoing investigation.

this solution at 25° was added, at one time, 4 cc. of an ether solution of diazomethane prepared from 0.5 cc. of nitrosomethylurethan. After five hours the gas evolution according to second order reaction rate ceased, about 48 cc. having been evolved. The solution was allowed to stand overnight, evaporated to dryness (30 mm.) and redissolved in benzene or acetone according to its solubility. The solution was centrifuged to remove diazomethane polymer and then precipitated into a tenfold volume of ether, the yield of centrifuged, ether-washed lignin dried at 60° (20 mm.) being 0.9–1.0 g.

Methoxylation of Lignin with Dimethyl Sulfate.—One gram of lignin was dissolved in a mixture of 40 cc. of acetone and 10 cc. of water. The solution was stirred under nitrogen while 3.8 cc. (0.09 mole) of dimethyl sulfate and 0.05 mole of the desired alkaline reagent were added simultaneously, the alkali being maintained constantly in excess during a period of ninety minutes and the solution stirred for a further thirty minutes. It was then diluted to 200 cc. with water, and acetic acid added until the suspension gave an acid reaction to litmus paper. At this point precipitation always occurred. The precipitated product was removed by extraction with chloroform, and the chloroform solution washed with 1% sodium hydroxide. In some cases it was found advisable to supplement this alkaline wash with an acid wash using 1% acetic or hydrochloric acid since chloroform soluble sodium lignates have been encountered. The washed chloroform solution was dried by evaporation at 25° (30 mm.) and the dried solution precipitated subsequently into a tenfold volume of ether or petroleum ether (b. p. 30–50°). The precipitated lignin was washed with a fresh portion of the precipitating reagent and dried at 60° (20 mm.). Yields were 0.9–1.0 g. as compared with yields of 0.8–0.9 for similar reactions carried out in air.

Tosylation of Lignin.—A solution of 3 g. of lignin and 5 g. of tosyl chloride in 50 cc. of dry pyridine was allowed to react for three days at room temperature and then added in a fine stream to 800 cc. of water containing 20 g. of potassium bicarbonate. After five hours' subsequent stirring, the precipitate was filtered by suction and dried (30 mm.). It was insoluble in alkali. A solution of the crude material in 100 cc. of chloroform was precipitated into 800 cc. of ether. The centrifuged, ether washed product was dried at 60° (20 mm.); weight, 4.47 g. The calculated yield, assuming esterification of four hydroxyl groups and addition of two molecules of water per kilogram is 4.96 g. The methoxyl content of this assumed compound would be 7.9% OCH_3. Found: OCH_3, 7.8%. One gram of the product when treated with phenylmagnesium bromide and subsequently oxidized with 1% potassium permanganate yielded 0.02 g. of sublimed benzoic acid.

Grignardization of Formic Acid Lignin.—A solution of 1 g. of chloroform–ether soluble lignin (containing 12.17% OCH_3 and 4.4 active hydrogen per kg.) in a mixture of 50 cc. ether and 50 cc. of dioxane was stirred under nitrogen while 20 cc. (0.021 mole) of phenylmagnesium bromide solution in ether was added over a ten-minute period. The reaction mixture was refluxed for two hours and allowed to stand overnight. Next day a solution of 4.75 cc. (0.05 mole) of dimethyl sulfate in 10 cc. of ether was added dropwise to the stirred reaction mixture in order to increase the lignin solubility by methoxylation. After three hours of refluxing the reaction was left overnight. Next morning the mixture was poured into 0.5% hydrochloric acid. The ether layer was diluted with chloroform, separated from the aqueous layer, and washed once with sodium bicarbonate solution and thrice with 1% sodium hydroxide in water. The acidified aqueous solutions were extracted thrice with chloroform. These solutions after drying by vacuum evaporation were precipitated into a tenfold volume of petroleum ether (b. p. 30–50°): yield of vacuum-dried product from the bicarbonate extract, 0.05 g.; OCH_3, 14.75%; yield of vacuum-dried product from the sodium hydroxide extract, 0.56 g.; OCH_3, 18.31%.

The reaction products so obtained were analyzed for methoxyl content (micro)[14] and for active hydrogen and carbonyl in the Grignard machine. The solution medium for this latter determination was either xylene, quinoline or dioxane (5 cc. in quantity), the latter two being conveniently purified by distillation from methylmagnesium chloride or sodium–benzophenone. Because of the volatility of dioxane on the boiling water-bath it was necessary to cool the outlet of the reaction flask during the heating period of fifteen minutes. The analyses together with yield and differentiating solubilities of the reaction products are summarized in Tables II and III.

Summary

1. The extraction of spruce wood meal with boiling formic acid is described.

2. A comparison of active hydrogen determinations with the results of alkaline methoxylation throws doubt on the hitherto assumed reliability of the latter as an agent for the proof of lignin structure.

3. The presence of carbonyl in lignin is confirmed.

MONTREAL, CANADA RECEIVED NOVEMBER 10, 1936

---

[14] The micromethoxyl method is admirably suited for the methoxyl determination of lignin because the divergence of duplicate analyses informs the experienced analyst as to the homogeneity of his sample. One-tenth of the amount of phenol recommended by Clark [THIS JOURNAL, **51**, 1979 (1929)] for the semi-micromethoxyl determination is employed.

Derivatives of Quinoline. I. Nupercaine Analogs. I

BY M. E. SMITH AND C. B. POLLARD

During the last few years, as a result of attempts to find new local anesthetics, a number of substituted 2-alkoxycinchoninamides have been prepared, of which nupercaine, N-diethyl-N′-(2-*n*-butoxycinchoninyl) ethylenediamine, is perhaps the best known. It has seemed advisable to extend this work to include certain piperazine and morpholine compounds.

In this investigation, 2-chlorocinchoninyl chloride was prepared by the method of Mulert,[1] except that purified commercial heptane (b. p. 93–97°) was used instead of ligroin to extract the product, and the hot heptane solution was filtered through a suction filter instead of being used in a Soxhlet extraction apparatus. 2-Chlorocinchoninyl chloride was treated with piperazine, N-phenylpiperazine, and morpholine to give N,N′-bis-(2-chlorocinchoninyl)-piperazine, N-phenyl-N′-(2-chlorocinchoninyl)-piperazine, and N-(2-chlorocinchoninyl)-morpholine, respectively. N-Phenyl-N′-(2-chlorocinchoninyl)-piperazine was treated with a number of sodium alcoholates to give several N-phenyl-N′-(2-alkoxycinchoninyl)-piperazines. The methoxy and ethoxy derivatives of N-(2-chlorocinchoninyl)-morpholine were prepared similarly.

The N-(2-ethoxycinchoninyl)-morpholine compound exhibited pronounced anesthetic action when tested on the tongue.

Pharmacological studies of these compounds are now being made under the direction of Dr. James C. Munch of John Wyeth and Brother. A report of these studies will appear at a later date.

Experimental

N,N′-Bis-(2-Chlorocinchoninyl)-piperazine.—A hot benzene solution of 22.6 g. (0.1 mole) of 2-chlorocinchoninyl chloride was added with stirring to 19.4 g. (0.1 mole) of melted piperazine hexahydrate. A white precipitate settled out. After this product had been washed well with water, acetone, alcohol and ether, it weighed 19.8 g. This compound was not appreciably soluble in any of the common organic solvents.

N-Phenyl-N′-(2-chlorocinchoninyl)-piperazine.—A hot benzene solution of 22.6 g. (0.1 mole) of 2-chlorocinchoninyl chloride was added with stirring to a mixture of 16.2 g. (0.1 mole) of N-phenylpiperazine in an aqueous solution of 5.3 g. (0.05 mole) of sodium carbonate. The resulting mixture was stirred for fifteen minutes and then allowed to stand for several hours. The product was filtered and washed with several portions of warm water, followed by a very small amount of acetone. The yield was 33.3 g. The compound was recrystallized twice from acetone before the melting point was determined. This compound is fairly soluble in alcohol and benzene, but is insoluble in water.

N-(2-Chlorocinchoninyl)-morpholine.—A hot benzene solution of 11.3 g. (0.05 mole) of 2-chlorocinchoninyl chloride was added while stirring to a mixture of 4.3 g. (0.05 mole) of morpholine in an aqueous solution of 2.7 g. (0.025 mole) of sodium carbonate. The resulting mixture was stirred for half an hour and then allowed to stand for several hours. The product was then filtered and washed with several portions of water, followed by a very small amount of acetone. The yield was 13.5 g. The product was recrystallized twice from 95% ethanol before the final

---

[1] Mulert, *Ber.*, **39**, 1901–1908 (1906).

melting point was determined. This compound is fairly soluble in acetone and benzene, but is insoluble in water.

N-Phenyl-N′-(2-alkoxycinchoninyl)-piperazines.—A hot solution of 8.8 g. (0.025 mole) of N-phenyl-N′-(2-chlorocinchoninyl)-piperazine in 140 ml. of benzene was added to a solution of 1.0 g. of sodium dissolved in 25 ml. of the appropriate alcohol, and the resulting mixture was refluxed four to fifty hours, after which it was filtered free from sodium chloride. In the cases of the methyl, ethyl, propyl and allyl compounds, the filtrate was evaporated to dryness, washed with water and recrystallized from 95% ethanol. In the cases of the others, the filtrate was washed with water and then evaporated to an oil, which was then dissolved in ethanol. Crystals eventually appeared from these alcoholic solutions, although with difficulty in some cases. All of the compounds were crystallized again from ethanol before their melting points were determined. These compounds are fairly soluble in acetone and benzene, but are insoluble in water.

N-(2-Alkoxycinchoninyl)-morpholines.—A hot solution of 5.5 g. (0.02 mole) of N-(2-chlorocinchoninyl)-morpholine in 50 ml. of benzene was added to a solution of 1.0 g. of sodium dissolved in 50 ml. of the appropriate alcohol. This mixture was refluxed for four hours, filtered and then evaporated to a solid. This was washed with water and then dissolved in ethanol. The crystals which later appeared were again crystallized before the melting points were determined.

A summary of the new nupercaine analogs is shown in Table I.

Summary

1. Thirteen new quinoline compounds analogous to nupercaine have been prepared and characterized.

2. At least one of these compounds has anesthetic properties.

3. Pharmacological studies of these compounds are now under way under the direction of Dr. James C. Munch of John Wyeth and Brother.

4. Work on these series of compounds is being continued in this Laboratory.

GAINESVILLE, FLA.

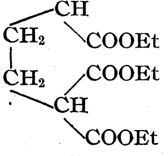
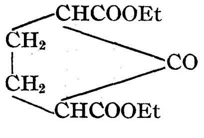
The Reaction of Certain Monosubstituted Malonic Esters and Methylene Dimalonic Esters with Sodium Ethoxide

BY J. R. ROLAND AND S. M. MCELVAIN

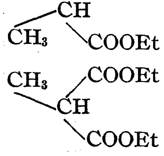
The fact that ethylene dimalonic ester (I) undergoes intramolecular condensation to give a dicarbethoxycyclopentanone[1] (II), led to the expectation that two molecules of methylmalonic ester (III), on account of their similarity to I in structure, should condense intermolecularly. As a matter of fact, such an intermolecular condensation of monosubstituted malonic esters had been predicted by Dieckmann[2] on the basis of his interpretation of the mechanism of the acetoacetic ester condensation. Later, however, Dieckmann and Kron[3] mentioned briefly in a footnote the failure of methylmalonic ester to undergo this condensation.



I



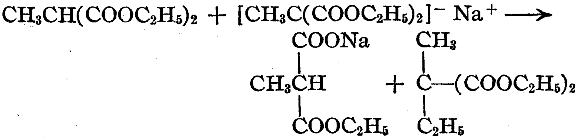
II



III

In view of this reported failure to realize an intermolecular condensation of III, it seemed worth while to ascertain what products, if any, result from the reaction of sodium ethoxide and methylmalonic ester. Of course the first product formed from these reactants is the sodium enolate of methylmalonic ester and an equivalent of alcohol. When the latter is removed by distillation the reactants remaining are this enolate and the excess methylmalonic ester. Such enolates are, therefore, the real condensing agents when such an ester as I is condensed.

When the sodium enolate of methylmalonic ester was heated at 140–160° with an excess of the ester, the reaction products isolated were monoethylmethylmalonate, methylethylmalonic ester and α-methylbutyric ester. The first two of these products are the result of the alkylation of the enolate by methylmalonic ester,[4] thus



$$CH_3CH(COOC_2H_5)_2 + [CH_3C(COOC_2H_5)_2]^- Na^+ \longrightarrow \underset{COOC_2H_5}{\overset{COONa}{CH_3CH}} + \underset{C_2H_5}{\overset{CH_3}{C}}\text{—}(COOC_2H_5)_2$$

---

[1] Meincke, Cox and McElvain, THIS JOURNAL, **57**, 1133 (1935). *Cf.* also the condensation of the homologous trimethylene dimalonic ester [Guha and Seshadriengar, *Current Sci.*, **3**, 20 (1934)].

[2] Dieckmann, *Ber.*, **33**, 2678 (1900).

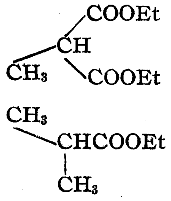
[3] Dieckmann and Kron, *ibid.*, **41**, 1260 (footnote 1) (1908).

[4] *Cf.* Walter and McElvain, THIS JOURNAL, **57**, 1891 (1935).

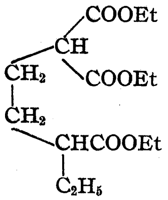
The α-methyl butyric ester results from the decarboxylation of the methylethylmalonic ester. At lower temperatures (100–120° and 50–60°) this alkylation reaction did not occur and the only product under these conditions was due to the hydrolysis of the enolate[5] when the reaction mixture was worked up, since none of it was obtained when the reaction mixture was decomposed with dry hydrogen chloride. Apparently, therefore, the only reaction which methylmalonic ester shows with sodium ethoxide at 140–160° is self alkylation, and this reaction takes place to the extent of 72% of the theoretical.

It seemed necessary to determine whether or not this alkylation reaction was preventing any acetoacetic ester condensation of the malonic ester from taking place. This was done by using isopropylmalonic ester instead of methylmalonic ester. The isopropyl group has been shown[6] to be effective in blocking certain alkylations. With this group present, the alkylation amounted to only 45% of the theoretical at 140–160°, but no trace of any condensation product could be isolated from the reaction.

Just as methylmalonic ester failed to undergo an acetoacetic ester condensation with itself, it also failed to condense with ethyl isobutyrate. This intermolecular condensation would be expected from the similarity in structure between these esters (IV) and ethyl α-ethyl-α′-carbethoxyadipate (V) which has been shown[7] to undergo intramolecular condensation with the formation of 2-ethyl-2,5-dicarbethoxycyclopentanone.



IV

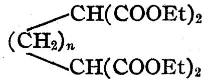


V

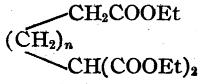
These esters (IV) failed to enter into any intermolecular condensation. The only product, besides the starting materials, which was isolated from the reaction was a small amount of monoethyl methylmalonate.

On the basis of our present knowledge no reasonable explanation is available to account for the ready intramolecular condensation of such esters as I and V and the failure of such esters as III and IV to undergo an intermolecular condensation. This failure, however, by emphasizing the necessity of a structure that permits an intramolecular condensation, suggested the investigation of the behavior of some other methylene dimalonic esters, the intramolecular condensation of which would yield cyclic products containing cycles other than those of conventional five or six members.

In this connection methylene dimalonic ester (VI, $n = 1$), pentamethylene dimalonic ester (VI, $n = 5$) and decamethylene dimalonic ester (VI, $n = 10$) were investigated. These esters, if they condensed intramolecularly in the manner of I, would yield products containing four, eight and thirteen membered rings, respectively.



VI



VII

None of these dimalonic esters gave any evidence of intramolecular condensation when heated with sodium ethoxide. Methylene dimalonic ester yielded ethyl acrylate, malonic ester, ethyl α-carbethoxyglutarate (VII, $n = 1$) and a relatively large amount of an undistillable tar. The first two of the products are probably the result of a retrograde Michael reaction on VII ($n = 1$). The best explanation for the unusually large amount of tar is from the polymerization of methylene malonic ester which, along with malonic ester, would result from a retrograde Michael reaction on the starting ester (VI, $n = 1$). Pentamethylene dimalonic ester yielded only de-carboxylated products, ethyl azelate and ethyl α-carbethoxyazelate (VII, $n = 5$). Decamethylene dimalonic ester yielded no product boiling lower than itself. The reaction product was a viscous liquid which could not be distilled and appeared to be an intermolecular condensation product.

Experimental

Methylmalonic ester was prepared by the Wislicenus[8] procedure, in yields of 60–70% of the theoretical. The product obtained boiled at 194–196°.

Reaction of Methylmalonic Ester with Sodium Ethoxide.—One mole (174 g.) of methylmalonic ester was heated with 0.5 mole of sodium ethoxide at 160° for eight hours. The apparatus was arranged so that any distillate could be collected. The distillate on fractionation yielded the following fractions: (a) alcohol, b. p. 75–78°, 25.8 g.; (b) ethyl propionate, b. p. 98–104°, 7.0 g.; (c) ethyl α-

methylbutyrate, b. p. 125–132°, sap. equiv. 129 (calcd. 130), 2.2 g.

The reaction mixture, after cooling, was treated with a cold solution of 35% sulfuric acid, the precipitated $Na_2SO_4 \cdot 10H_2O$ filtered off, and the filtrate fractionated. The following fractions were collected from this filtrate: (d) ethyl propionate, b. p. 98–100°, 4 g.; (e) ethyl α-methylbutyrate, b. p., 130–131°, 10.7 g.; (f) methylmalonic ester, b. p. 194–196°, 53.4 g.; (g) ethyl methylethylmalonate, b. p. 205–208°, sap. equiv., 102 (calcd. 101), 57.0 g.; (h) monoethyl methylmalonate, b. p. 100–102° (2 mm.), 13.0 g., sap. equiv. 71 (calcd. 73), n^{25}_{D} 1.4235, d^{25}_{25} 1.1192.[9] Analyses calcd. for $C_6H_{10}O_4$: C, 49.3, H, 6.85; OC_2H_5, 30.8. Found: 49.4, 6.84, 30.2.

The total quantity of alkylated products, methylethylmalonic ester and α-methylbutyric ester from the above run amounted to 72.1% of the theoretical.

When methylmalonic ester was allowed to react with sodium ethoxide at 50–60° and also at 120° for six hours and the product worked up in the same manner as described above, the only product which was isolated was the mono-ethyl methylmalonate. If, however, dry hydrogen chloride instead of 35% sulfuric acid was used to decompose the reaction mixture, unchanged methylmalonic ester was the only product recovered.

Isopropylmalonic Ester.—This ester was prepared in 56% yield by alkylation of sodiomalonic ester suspended in alcohol with isopropyl bromide. The product, washed free of unreacted malonic ester with 25% potassium hydroxide, boiled 211–212°.[10]

Reaction of Isopropyl Malonic Ester with Sodium Ethoxide.—One-half mole (101 g.) of isopropylmalonic ester was allowed to react with 0.25 mole of sodium ethoxide for eighteen hours at 150–160°. During this time 8.5 g. of alcohol distilled from the reaction mixture. When the reaction mixture was worked up as described above, the following fractions were collected: (a) ethyl isovalerate, b. p. 132–134°, sap. equiv. 133 (calcd. 130), 11.0 g.; (b) ethyl α-isopropylbutyrate, b. p. 158–162°, 4.7 g., derived acid, b. p. 203°,[11] neut. equiv. 130 (calcd. 130); (c) isopropylmalonic ester, b. p. 91–92° (8 mm.), 29.8 g.; (d) ethylisopropylmalonic ester, b. p. 81–82° (2 mm.), 15.5 g., derived acid, m. p. 132–133°;[11] (e) b. p., 100–110° (2 mm.), 5.0 g.

Fraction e was heated to 140° in order to decarboxylate any mono-ethyl ester. Only 75 cc. of carbon dioxide was obtained from a 4-g. sample, the theoretical amount being 560 cc., had the sample been pure half ester. This amount of carbon dioxide corresponds to 0.67 g. of half ester. The remainder boiled 134–136° (10 mm.) and was found to be identical with ethylisopropylmalonic ester (fraction d).

The alkylated products, fractions b, d, and e, are equivalent to 23.4 g. of starting material and represent a yield of 45% of the theoretical.

Attempted Condensation of Ethyl Isobutyrate with Methylmalonic Ester.—To one-half mole of sodium ethoxide was added one mole (174 g.) of methylmalonic ester. (The alcohol formed was removed at 50° under diminished pressure.) To this was added two moles (232 g.) of ethyl isobutyrate and the mixture refluxed for ten hours. The amounts of the various products isolated were: 195 g. of ethyl isobutyrate (107–110°); 126 g. of methylmalonic ester (194–196°); 7 g. of monoethyl methylmalonate [100–110° (2 mm.)].

Reaction of Methylene Dimalonic Ester with Sodium Ethoxide.—A mixture of one-half mole of sodium ethoxide and one-half mole (166 g.) methylene dimalonic ester, prepared according to Welch,[12] was heated at 110–115° for eight hours. During this period of heating 11.6 g. of alcohol distilled out. The pressure was then reduced to 400 mm. and 2.8 g. of ethyl carbonate distilled over. The reaction mixture was decomposed with 35% sulfuric acid, cooled, and the $Na_2SO_4 \cdot 10H_2O$ filtered off. Fractionation of the filtrate yielded (a) 21.2 g. of a fraction, b. p. 80–110°, composed of a mixture of alcohol and ethyl acrylate which from saponification values contained 7.6 g. of ethyl acrylate; (b) 12.2 g. of malonic ester, b. p. 195–198°; (c) 13.2 g. α-carbethoxyglutaric ester, b. p. 149–151° (7 mm.);[13] (d) 15.2 g. of starting ester, methylene dimalonic ester, b. p. 150–153° (2 mm.). The undistilled residue from this run amounted to 78 g.

Preparation of Pentamethylene Dimalonic Ester.—This was prepared according to the method of Perkin[14] except that the sodiomalonic ester was prepared in benzene. The ester, boiling 194–199° (1 mm.), was obtained in 24% yield.

Reaction of Pentamethylene Dimalonic Ester with Sodium Ethoxide.—Sixty two grams (0.14 mole) of pentamethylene dimalonic ester was heated with 0.08 mole of sodium ethoxide at 120–130° for eight hours. During this time 2.2 g. of alcohol distilled from the reaction. The reaction mixture was treated with 35% sulfuric acid and after filtering off the $Na_2SO_4 \cdot 10H_2O$ the filtrate fractionated. Fraction (a) 5 g., b. p. 115–125°, was ethyl azelate; sap. equiv. 131 (calcd. 122), m. p. of derived azelaic acid 105–106° and its *p*-phenylphenacyl ester 145–146°;[15] fraction (b) 10 g., b. p., 125–150°; fraction (c) 17.8 g., b. p. 150–165°; fraction (d) 12.2 g., b. p. 165–170°.

The acids derived from (d) were decarboxylated to determine the amount of α-carboxyazelaic acid, a compound which has not been described previously. The carbon dioxide obtained when the acids from (d) were heated indicated that the mixed acids from (d) contained 67% α-carboxyazelaic acid. The acid remaining after the evolution of the carbon dioxide was azelaic acid.

Considerable evolution of carbon dioxide was observed during the isolation of the acids from fractions (b) and (c). This indicates that these fractions were also mixtures of ethyl azelate and ethyl α-carbethoxyazelate.

Decamethylene dimalonic ester was prepared by reaction of decamethylene bromide with a benzene suspension of sodiomalonic ester.[16] All material boiling below 160° (0.2 mm.) was removed. The residue, which could not be readily distilled, amounted to 36% of the theoretical yield.

Reaction of Decamethylene Dimalonic Ester with Sodium Ethoxide.—Two hundred twenty-nine grams of the residue obtained above was heated with one-half mole

of sodium ethoxide at 130° for six hours. During this time, only 3.2 g. of alcohol distilled from the reaction. On working up the reaction mixture in the manner described for the other dimalonic esters nothing could be distilled from the reaction product even at 230° and under 0.4 mm. pressure. This product, which was much more viscous than the starting material, was probably an intermolecular condensation product, and was not investigated further.

Summary

A study of the behavior of methylmalonic ester, isopropylmalonic ester, methylene dimalonic ester, pentamethylene dimalonic ester and decamethylene dimalonic ester with sodium ethoxide has been made. The main reaction product in the cases of the monosubstituted malonic esters was the dialkylmalonic ester resulting from self-alkylation of the starting esters. There was no evidence of an intermolecular condensation product in either case.

With the methylene dimalonic esters no intramolecular condensation could be effected. When the reaction products could be identified they were found to be decomposition products, resulting from retrograde Michael reactions and decarboxylation, of the starting esters.

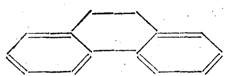
[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

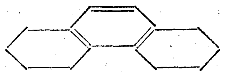
Hydrogenation of Phenanthrene

BY JOHN R. DURLAND AND HOMER ADKINS

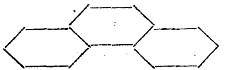
Three substances, 9,10-dihydrophenanthrene[1,3] (I), 1,2,3,4,5,6,7,8-octahydrophenanthrene[2,3,4] (II), and tetradecahydrophenanthrene[5] (III), have been made by the catalytic hydrogenation of phenanthrene. Incidental to an investigation of the relation of structure to the hydrogenation of certain phenanthrene derivatives we have developed procedures for the preparation of these compounds which may be of immediate value to others.



I



II



III

Burger and Mosettig took advantage of the greater activity of copper–chromium oxide[6] toward olefinic double bonds as compared with benzenoid nuclei[7] and selectively hydrogenated phenanthrene at 220°, obtaining 9,10-dihydrophenanthrene in yields of about 80%. We have duplicated their results. However, with a purer sample of phenanthrene we have obtained no dihydrophenanthrene at 220°. With this purer sample of phenanthrene we have been able to hydrogenate in the 9,10-position with copper–chromium oxide at 130° within four hours, as compared with the eight to ten hours at 220° reported by Burger and Mosettig. The best temperature for the production of 9,10-dihydrophenanthrene with copper–chromium oxide appears to be about 150°, the yield being 87%. At 180° a little octahydrophenanthrene was produced, while at 220° the latter is produced to the exclusion of the dihydro compound.

The fact that phenanthrene may be hydrogenated in the 9,10-position over copper–chromium oxide at 130° is rather striking evidence of the olefinic character of the double bond in that position. Copper–chromium oxide is not usually active toward any type of unsaturation at temperatures much below 130°.

With pure phenanthrene, Raney nickel may also be used for the preparation of dihydrophenanthrene. When the reaction was carried out at 96°, a 61% yield was obtained after five hours. However, nickel is not so satisfactory as copper–chromium oxide for this selective hydrogenation. With copper–chromium oxide there is a difference of about 50° between the temperature at which hydrogenation begins in the 9,10-position and the temperature required for further hydrogenation. With Raney nickel the temperature differential for these two types of reaction is no more than 10°. These facts are indicated by a com-

parison of the data for experiments 1 and 5 (Ni) and 2, 4 and 8 (CuCrO).

Either Raney nickel or copper–chromium oxide may be used for the preparation of octa- or tetradecahydrophenanthrene, but nickel is to be preferred. Octahydrophenanthrene is best made at 120°, the time for pure phenanthrene with Raney nickel being only four or five hours instead of two to eight days at 120 to 140° as with less pure material.[2] Tetradecahydrophenanthrene is best made at about 200° with Raney nickel, the time required being three or four hours.

The copper–chromium oxide catalyst usually has been found to be inactive toward phenyl groups. However, as Folkers has pointed out,[8] this inactivity is merely relative and under certain drastic conditions even phenyl groups may be hydrogenated. In this Laboratory cyclohexyl derivatives have been produced over copper–chromium oxide from ethyl salcylate,[9] N-substituted phthalimides[10] and N-phenyl pyrrole.[11] The conversion of 9,10-dihydrophenanthrene to 1,2,3,4,5,6,7,8-octahydrophenanthrene is not a clear cut indication of the activity of copper–chromium oxide for the hydrogenation of a benzoid nucleus since this transformation apparently involves intramolecular rearrangement. However, the conversion of the octahydrophenanthrene to tetradecahydrophenanthrene at 300° is fairly clear evidence for the activity of copper–chromium oxide in catalyzing the hydrogenation of a benzenoid nucleus in a hydrocarbon.

Experimental Part

Crude phenanthrene was purified by a combination and modification of the procedures used by Bachmann[12] and by Schroeter.[3] The former used an oxidizing agent but no sodium, the latter sodium but no oxidizing agent. One kilogram of "70% phenanthrene" (Eastman) was heated with six liters of 95% alcohol and the hot solution decanted from the insoluble portion (discarded) and cooled. The crystallized phenanthrene was dissolved in 2400 ml. of glacial acetic acid. To the boiling solution was added gradually a solution of 100 g. of sodium dichromate dihydrate in 20 ml. of sulfuric acid and 150 ml. of 50% acetic acid. Thirty ml. of sulfuric acid was then added slowly and the solution refluxed for fifteen minutes. After pouring the hot solution into an equal volume of cracked ice and water, the mixture was filtered and the phenanthrene washed with water until a colorless filtrate was obtained. After drying at 80° the product was fractionated carefully through a Widmer column, b. p. 181–183° (15 mm.). (The yield but not the purity of the final product was increased about 20 g. by one crystallization of this distillate from ethyl alcohol.) The distillate was heated for four hours at 200° with 10% of its weight of metallic sodium, the mixture being *stirred vigorously during the entire period.* The phenanthrene was distilled with care in a Claisen flask with a thin plug of glass wool in the side neck. The colorless product was fractionated over 5 to 10 g. of metallic sodium through a Widmer column, the low boiling fractions (diphenyl) being discarded. The pure product weighed 480–530 g., melted at 97–98°, and was perfectly colorless even in the liquid state. An additional 70–80 g. of impure phenanthrene was recovered by subliming all residues from the sodium treatment.

The reaction mixtures after hydrogenation were fractionated through a Widmer column having a glass spiral 15 cm. in length. The fractions considered to be dihydrophenanthrene were taken at 176–178° (20 mm.) or 140–142° (6 mm.). The octahydrophenanthrene fractions were taken at 172–173° (20 mm.) or 135–136° (6 mm.). Tetradecahydrophenanthrene was taken at 147–149° (20 mm.) or 142–144° (15 mm.). The best indication of the purity of the hydrogenated phenanthrenes so obtained is given by a comparison of the refractive indices of the products as given in Table I with those of more thoroughly purified products, and with those previously reported. Dihydrophenanthrene after one crystallization from methanol melted 33.8 to 34.4° and the supercooled material showed a $n^{25}\mathrm{D}$ of 1.6406. Octahydrophenanthrene was purified through the sulfonic acid as described by Schroeter. The pure compound so obtained, b. p. 134–135° (5 mm.), m. p. 16.6°, showed a $n^{25}\mathrm{D}$ of 1.5640, a figure almost identical with that of material purified only by a careful frac-

tionation. Rehydrogenation and refractionation of the tetradecahydrophenanthrene gave a product, b. p. 155–157° (27 mm.), having $n^{25}D$ of 1.5003 which agrees with the value given by Pinkney and Marvel.[5]

In the fractionation of the reaction mixtures there were intermediate fractions which are not reported in the table. Their amounts in most cases represented only a few per cent. of the weight of phenanthrene originally used. However, with copper–chromium oxide at temperatures of 200–300° these unidentified products amounted to about 30% of the weight of phenanthrene submitted to hydrogenation.

Summary

Methods have been given for the preparation of 9,10-dihydrophenanthrene, 1,2,3,4,5,6,7,8-octahydrophenanthrene, and tetradecahydrophenanthrene from "70% phenanthrene."

Molecular Rearrangements in the Sterols. I. The Action of Anhydrous Potassium Acetate on Cholesteryl *p*-Toluenesulfonate in Acetic Anhydride Solution

BY EVERETT S. WALLIS, E. FERNHOLZ AND F. T. GEPHART

The epimerization of the hydroxyl group of cholesterol and other unsaturated sterols has become of great interest since Ruzicka[1] showed that the male hormone, androsterone, is a derivative of *epi*-dihydrocholesterol, and that its physiological activity is much greater than the corresponding epimer.

This difference in the activity of the two isomers stimulated our interest in the preparation of the epimer of dehydroandrosterone. In order to find a satisfactory method for the preparation of this latter compound we first thought it advisable to study possible methods for the epimerization of cholesterol, since the previous attempts of Stoll[2] to prepare *epi*-cholesterol had failed.

During the course of this investigation three papers have appeared which have an important bearing on this problem. Evans and Schoenheimer[3] have reported the preparation of *epi*-allocholesterol, which differs from *epi*-cholesterol only in the position of the double bond. Marker, Oakwood and Crooks[4] have described the preparation of *epi*-cholesterol by the action of oxygen on the Grignard reagent obtained from cholesteryl chloride. Beynon, Heilbron and Spring[5] have published experimental results obtained in an investigation of some reactions of the isomeric ethers of cholesterol.

These publications make it advisable to report certain experiments we have carried out on the problem of obtaining *epi*-cholesterol in good yields, and which also have interest regarding the constitution of the two series of isomeric ethers of cholesterol, discovered by Stoll.[2]

Stoll[2] found that when cholesteryl *p*-toluene sulfonate is boiled with an alcohol it reacts easily to form a normal levorotatory ether, but that an isomeric dextrorotatory ether is formed when the reaction is carried out in the presence of potassium acetate. Stoll[2] expressed the opinion that this new ether was a derivative of *epi*-cholesterol or of *epi*-allocholesterol.

In the same year Wagner-Jauregg and Werner[6] reported that cholesteryl chloride and bromide behaved in a similar manner, that is, when heated alone with alcohols the normal levorotatory ether is formed, but in the presence of potassium acetate the isomeric dextrorotatory ether is produced. They further observed that the isomeric methyl ether is converted into the normal ether when heated with hydrogen chloride in methyl alcohol at 130°. From this fact they concluded that in the formation of ethers from either cholesteryl halides or the *p*-toluene sulfonate the isomeric ethers are first formed, but that the acid produced in the reaction converts them into the so-called "normal" form. These investigators also attempted to hydrogenate the isomeric ether. Although they found that this reaction did not proceed smoothly, it is important to note in view of certain of our experiments about to be described that a small amount of the normal dihydrocholesteryl methyl ether was isolated.

In this connection the observations of Beynon, Heilbron and Spring[5] are also of special interest.

---

[5] Beynon, Heilbron and Spring, *J. Chem. Soc.*, 907 (1936).

[6] Wagner-Jauregg and Werner, *J. physiol. Chem.*, **213**, 119 (1932).

These authors made a study of the hydrolysis of the two series of cholesteryl ethers with the idea in mind that the "abnormal" ethers might be derivatives of *epi*-cholesterol. They found that whereas the normal ethers are not hydrolyzed by halogen acids in acetic acid solution the isomeric ethers react quite readily with halogen acids to produce the normal cholesteryl halides. They also observed that by the action of bromine the alkoxyl group in the isomeric ethers is replaced by bromine. In each case studied 3,5,6-tribromocholestane was produced. The normal ethers reacted normally to give a stable dibromide.

In this paper we wish to report certain experimental results obtained by us in a search for a satisfactory method for the preparation in good yields of the epimeric modifications of certain unsaturated sterols. Our method of attack was also based upon certain experiments of Phillips[7] carried out on alcohols containing only one asymmetric carbon atom, and it involved an investigation of the action of potassium acetate on cholesteryl *p*-toluene sulfonate. But in order to avoid the complication of the formation of ethers, and since we had observed that in acetic acid solution the normal cholesteryl acetate is formed, the reaction was carried out with anhydrous potassium acetate in acetic anhydride solution. This indeed yielded a new acetate, isomeric with cholesteryl acetate, which at first we were inclined to believe was *epi*-cholesteryl acetate. Experiments soon showed, however, that this was not the case.

This new acetate which we shall now call *i*-cholesteryl acetate is *strongly dextrorotatory*, $[\alpha]^{20}\text{D}$ +47.8°, and melts at 73°. Hydrolysis yields *i*-cholesterol. This compound crystallizes from alcohol in long needles which melt at room temperature. The substance resolidifies and passes into another crystalline form which melts at 74–75°. *i*-Cholesterol is strongly *dextrorotatory*, $[\alpha]^{20}\text{D}$ +23.9°. It is not precipitated by digitonin. Reacetylation yields the above *i*-cholesteryl acetate.

Experimental results obtained in a study of the catalytic hydrogenation of this new acetate are of special interest. Palladium black was found to be entirely ineffective in bringing about the hydrogenation. Platinum black brought about a very slow reaction. On working up the products there was isolated, besides the starting material, some cholestane. The Adams platinum oxide catalyst produced an entirely different result. When the platinum oxide was reduced in presence of the *i*-cholesteryl acetate a rapid hydrogenation took place and dihydrocholesteryl acetate was formed in good yield. This fact strongly indicates that an inversion of the hydroxyl group does not occur during the formation of *i*-cholesterol. It also suggests a close relationship to the "abnormal" ethers discussed above since, as has already been pointed out, Wagner-Jauregg and Werner[6] isolated dihydrocholesteryl methyl ether from the hydrogenation products of the "abnormal" ether.

There are other important facts which should be recorded. *i*-Cholesteryl acetate does not react with perbenzoic acid. Neither does it decolorize readily a solution of bromine in carbon tetrachloride. The Liebermann reaction, however, is quite strong. This inertness toward bromine and perbenzoic acid, and the relatively great stability toward catalytic hydrogenation, suggest that a double bond as such is not present in *i*-cholesteryl acetate and *i*-cholesterol.

Experiments were carried out to determine the nature of the hydroxyl group in *i*-cholesterol. It was found that *i*-cholesterol could be oxidized easily with chromic acid in acetic acid solution. From the products formed we were able to isolate an oxime in a 20% yield. This leads to the conclusion that *i*-cholesterol is a secondary alcohol.

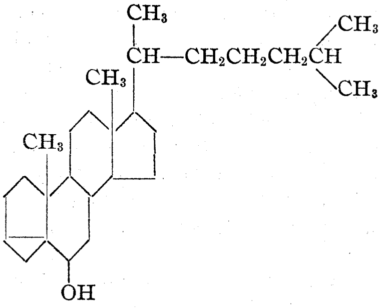
In certain reactions a conversion of *i*-cholesterol to cholesterol was observed. For example, in the course of the preparation of the 3,5-dinitrobenzoate of *i*-cholesterol the interesting observation was made that when the reaction was carried out by heating the mixture of pyridine, dinitrobenzoyl chloride and *i*-cholesterol for one hour on the water-bath it was possible to isolate in a yield of 18% the normal cholesteryl dinitrobenzoate (m. p. 193° $[\alpha]^{18}\text{D}$ −14.6°). If, however, the reaction was carried out at room temperature only small amounts of the normal cholesteryl dinitrobenzoate were produced. In another experiment *i*-cholesteryl acetate was dissolved in acetic acid, and after the addition of two drops of sulfuric acid the mixture was heated on the water-bath for one hour. Partial conversion to cholesteryl acetate took place, and hydrolysis gave a product precipitable with digitonin.

All these facts lead to the conclusion that the reaction of anhydrous potassium acetate on

---

[7] Phillips, *J. Chem. Soc.*, **123**, 44 (1925). Other papers by Phillips and co-workers have appeared since this time.

cholesteryl *p*-toluene sulfonate in acetic anhydride solution is accompanied by a molecular rearrangement. The exact nature of this rearrangement is still obscure. At the present time, however, we believe that in *i*-cholesterol and its derivatives the carbon skeleton is different, and that the reaction may involve a type of rearrangement common in certain terpenes, but until now unknown in sterol chemistry. Such a rearrangement would produce a compound whose structure could be represented in the following manner.



This type of formulation would explain the apparent non-reactivity of the double bond, since it is not present as such in the molecule. The assumed structure represents the molecule as a secondary alcohol, and therefore explains the formation of a ketone on oxidation with chromic acid. It also accounts for the conversion of *i*-cholesterol and its acetate under suitable conditions into cholesterol and its derivatives.

In conclusion we wish to state that regardless of the true nature of the structure of *i*-cholesterol, the experimental facts above described strongly suggest that a close relationship exists between this new compound and the so-called "abnormal" ethers of Stoll. This relationship is being investigated further.

Experimental Part

Preparation of Cholesteryl *p*-Toluene Sulfonate.—This compound was prepared by the method of Freudenberg[8] with the following modifications. After dissolving by gentle warming 58.2 g. of dried cholesterol in 70 cc. of dried pyridine, 58.2 g. of *p*-toluenesulfonyl chloride was added. Within five minutes a white crystalline precipitate began to form. After the mixture had stood overnight, the product was taken up in ether, worked up in the usual manner, and finally recrystallized from dry ether; yield, 72.1 g. (89.3%); m. p. 131.5–132.5°.

Preparation of *i*-Cholesteryl Acetate.—One hundred grams of anhydrous potassium acetate was dissolved in 1500 cc. of boiling acetic anhydride (pure). The solution was cooled to 50° whereupon potassium acetate crystallized in a finely divided state. To this mixture was added 35 g. of cholesteryl *p*-toluenesulfonate. The flask was then placed on the steam-bath, and stirred for approximately thirty-six hours. During this time the temperature inside the flask varied from 70–80°. The dark brown mixture was poured into cold water; 800 cc. of ether was added and the ether layer was washed repeatedly with a cold aqueous solution of potassium carbonate. (In a later experiment the acetic anhydride was removed by distillation under diminished pressure.) After complete removal of the acetic anhydride and acetic acid the ether layer was dried with anhydrous sodium sulfate, decolorized with animal charcoal and the ether removed by distillation. An oily product was obtained. This material was dissolved in alcohol, and small amounts of ether were added. Crystallization was carried out in such a manner as to obtain four crops of crystals: 3.6 g., m. p. 71.5°; 0.5 g., m. p. 70–71°; 4.7 g., m. p. 64–66°; 7.2 g., m. p. 59–62°. Several recrystallizations of the third and fourth fractions gave 0.4 g. of material, m. p. 71°, and 7.5 g., m. p. 67–68°. The combined weight of fractions of m. p. 68–71.5° was 12.0 g. (43.2%). The other products of the reaction consisted mainly of an unsaturated hydrocarbon and cholesteryl acetate.

It was found to be impossible to free the *i*-cholesteryl acetate from cholesteryl acetate by the process of recrystallization. Therefore, 7.5 g. of the above acetate of m. p. 67–68° was dissolved in 100 cc. of alcohol, and treated with 8 g. of potassium hydroxide. The solution was refluxed for one-half hour on the water-bath, poured into water and the product extracted with ether. The dried ether solution was evaporated to dryness and taken up in a small amount of 90% alcohol. A solution of 6 g. of digitonin in 500 cc. of 90% alcohol was then added. The mixture was cooled to room temperature and the digitonide was filtered and dried; weight 4.8 g. (corresponding to 1.2 g. of cholesterol).

The filtrate was evaporated to dryness, the residue was digested with ether, and, after removing the solvent, it was crystallized from alcohol. After thorough cooling in an ice–salt mixture the *i*-cholesterol which separated was collected rapidly, and placed in a vacuum desiccator where it melted and resolidified. The product weighed 3.5 g. and melted constantly at 74–75°, $[\alpha]^{20}_D$ +23.9° (22.6 mg. dissolved in 2 cc. of chloroform solution gave an α_D +0.27°, 100-mm. tube).

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.85; H, 11.92. Found. C, 83.75; H, 11.87.

The acetate was prepared by heating 1.5 g. of *i*-cholesterol with 10 cc. of acetic anhydride for one hour on the water-bath. The crystalline product which separated on cooling was recrystallized from alcohol; yield 1.4 g., m. p. 73°, $[\alpha]^{20}_D$ +47.8° (25.1 mg. in 2 cc. chloroform solution gave α_D +0.60).

Anal. Calcd. for $C_{29}H_{48}O_2$: C, 81.23; H, 11.29. Found: C, 81.32; H, 11.39.

Catalytic Hydrogenation of *i*-Cholesteryl Acetate.—(a) After reducing 1.07 g. of platinum oxide suspended in 50 cc. of acetic acid with hydrogen, 1 g. of *i*-cholesteryl acetate was added. Hydrogen was absorbed slowly and after five hours the reaction was stopped. After removal of the solvent the material was crystallized from alcohol. This

---

[8] Freudenberg and Hess, *Ann.*, **448**, 128 (1926).

gave 0.29 g. of starting material, m. p. 70°. The material remaining in the mother liquor was hydrolyzed with alcoholic potassium hydroxide and on crystallization from acetone there was obtained a substance, m. p. 78°, which did not depress the melting point of authentic cholestane; $[\alpha]^{20}_D$ +22.5° (22.2 mg. in 2 cc. chloroform solution gave $[\alpha]^{20}_D$ +0.25 1 dm. tube; lit. +24.7°).

(b) In a second experiment 1.332 g. of *i*-cholesteryl acetate was shaken with 1.30 g. of PtO_2 and 50 cc. of glacial acetic acid in an atmosphere of hydrogen, at room temperature, and at ordinary pressure. In fifteen minutes 310 cc. of hydrogen was absorbed. After hydrolysis with alcoholic potassium hydroxide, there was obtained a crystalline product which after thorough drying melted at 140°, and was identified by mixed melting point determination as dihydrocholesterol (cholestanol); yield, 1.1 g., or 85%.

Titration of *i*-Cholesteryl Acetate with Perbenzoic Acid.—Two samples of *i*-cholesteryl acetate were dissolved in chloroform, an excess of perbenzoic acid dissolved in the same solvent was added and the solutions were kept at 0°. Blanks were also run for comparison. Sample 1: 39.6 mg. consumed 0.079 mg. oxygen in forty-eight hours. Theoretical for 1 atom of oxygen 1.64 mg. oxygen. Sample 2: 56.0 mg. consumed 0.198 mg. oxygen in six days. Theoretical for 1 atom of oxygen 2.32 mg. of oxygen. It readily can be seen from these results that practically no reaction took place.

It was also observed that both *i*-cholesterol and *i*-cholesteryl acetate would not decolorize a dilute solution of bromine in carbon tetrachloride.

Oxidation with Chromic Acid.—To a solution of 0.93 g. of *i*-cholesterol in 30 cc. of specially purified acetic acid (potassium permanganate method), a solution of 0.64 g. of chromic acid in 20 cc. acetic acid was added drop by drop. The solution became temporarily cloudy and a slight rise in temperature was observed. After standing overnight at room temperature the mixture was extracted with ether. The ether was shaken with an aqueous solution of 2 *N* sodium hydroxide to remove the acidic material. Attempts to obtain a crystalline material from this acidic portion were unsuccessful. The neutral part crystallized but had an unsharp melting point; yield 0.33 g.

This crude ketone was boiled for two hours with 0.3 g. of hydroxylamine hydrochloride and 0.5 g. of sodium acetate in 30 cc. of ethyl alcohol. The product was precipitated with water. Recrystallizations from dilute alcohol gave small leaflets which when thoroughly dried melted at 143–144°; yield 0.2 g.

Anal. Calcd. for $C_{27}H_{45}NO$: C, 81.12; H, 11.35; N, 3.51. Found: C, 80.95; H, 11.58; N, 3.88.

Conversion of *i*-Cholesterol into Normal Cholesteryl *m*-Dinitrobenzoate.—A mixture of 0.574 g. of *i*-cholesterol (m. p. 74–75°), freed from cholesterol by means of digitonin, 0.6 g. of *m*-dinitrobenzoyl chloride, and 5 cc. of pyridine was heated for one hour in the water-bath. The material was taken up in ether and recrystallized from a mixture of acetone and alcohol; yield 0.16 g., m. p. 193°; $[\alpha]^{18}_D$ −14.5°. The product was identified by a mixed melting point determination as cholesteryl *m*-dinitrobenzoate.

Anal. Calcd. for $C_{34}H_{48}O_6N_2$: C, 70.30; H, 8.34. Found: C, 70.28; H, 8.37.

Conversion of *i*-Cholesteryl Acetate into Normal Cholesteryl Acetate.—After dissolving 0.1 g. of pure *i*-cholesteryl acetate (m. p. 73°) in 10 cc. of acetic acid, two drops of sulfuric acid were added, and the solution was heated on the water-bath for one hour. The solution was then worked up in the usual manner and a crystalline material was obtained which melted unsharply at 95–103°. Two recrystallizations from alcohol gave 0.03 g. of material which melted at 112–114° and showed no depression of the melting point when mixed with cholesteryl acetate (m. p. 114°).

Hydrolysis with alcoholic potassium hydroxide gave a product precipitable with digitonin.

We wish to take this opportunity to express our thanks to Merck & Company, Inc., Rahway, N. J., for all analyses published in this article, and for a grant-in-aid for this work.

Summary

The action of anhydrous potassium acetate on cholesteryl *p*-toluenesulfonate in acetic anhydride solution has been studied.

A new acetate and a new alcohol isomeric with cholesterol have been isolated. Certain properties of these two compounds, designated as *i*-cholesterol and *i*-cholesteryl acetate, have been described.

Evidence is submitted which leads to the conclusion that the reaction is accompanied by a molecular rearrangement.

It is further pointed out that the properties of this new alcohol suggest that a close relationship exists between it and the isomeric ethers of cholesterol discovered by Stoll.

Oxidation–Reduction Potentials of β-Hydroxyphenazine and N-Methyl-β-oxyphenazine[1]

BY PAUL W. PREISLER AND LOUIS H. HEMPELMANN

The rapidly increasing number of type oxidation–reduction systems[2] shown to follow the mathematical formulations of the potentials of the two-step oxidation–reduction process[3] suggest that all electromotively active reversible oxidation–reduction systems are probably of this same general character. To gain further evidence on the important questions of the nature of the two-step process and of the effect on the potentials of the structure of the molecule and of substitution, a survey of the various types of systems is being conducted.

The potentials of β-hydroxyphenazine and of N-methyl-β-oxyphenazine (methyl aposafranone), because of their structural relation to the natural pigment pyocyanine, are of particular interest and are reported here. The oxidation–reduction reactions of β-hydroxyphenazine appear to involve both nitrogens of the phenazine nucleus, while those of N-methyl-β-oxyphenazine involve the oxygen and its para-position nitrogen. Both systems show clearly the two-step process in solutions more acid than *p*H 3 and a transformation into an apparent one-step process in solutions less acid. They illustrate the fundamental characteristics of their respective type systems and the effects of the ionizations of the components upon the oxidation–reduction potentials.

Experimental

β-Hydroxyphenazine was prepared[4] by condensing *o*-phenylenediamine and 2-hydroxy-1,4-quinone.[5] The resulting dark brown material was extracted repeatedly with boiling water and the extract was filtered off and allowed to cool slowly. The dark red hydrated crystals which were obtained were changed to the golden yellow anhydrous compound by heating to 110°.

N-Methyl-β-oxyphenazine was prepared by treating the acetyl derivative[4] of this yellow compound with methyl sulfate, decomposing the addition compounds so formed, and separating the desired material from isomeric substances. Recrystallization from water gave the characteristic dark red needle-like crystals.

The potentials of two platinum electrodes, immersed in the buffer containing the oxidant and its reduction products, were measured against a saturated calomel half-cell connected to the solution by a 5% agar-saturated potassium chloride bridge. Electrodes usually agreed to within 0.0002 volt and equilibrium conditions were attained rapidly. The calomel cell was standardized against a hydrogen electrode in 0.05 *M* potassium hydrogen phthalate. The *p*H values of the buffers were determined by a hydrogen electrode.

The substances used for buffers were: citrates from *p*H 1.48 to 4.73, phosphates from *p*H 5.79 to 6.71 and 10.69 to 11.69, carbonates from *p*H 9.13 to 9.54, and veronal from *p*H 7.48 to 8.52. Hydrochloric acid or sodium hydroxide was used to make up the more acid or more alkaline solutions.

The buffers were 0.05 to 0.10 *M* in buffering ion and the reactants about 0.0005 to 0.0001 *M*, as indicated. No corrections were made for the *p*H changes accompanying the reduction. An equivalent amount of sodium hydroxide was added to the titanous chloride titrating solutions to compensate for the excess of hydrochloric acid (7.493 *N*) in the commercial titanous chloride (1.29 *M*) preparations. Titanous chloride was used as reducing agent in buffers from *p*H 0.04 to 4.73 and sodium hydrosulfite in buffers less acid.

Commercial tank nitrogen, deoxygenated by passing over heated copper, was used to deoxygenate and stir the solutions. Temperature was maintained to within 0.1° of 30.0° by immersing the electrode vessels in a suitable bath.

The mixture of oxidant and its reduction products was made by titrating the deoxygenated, buffered oxidant solution with reducing agent similarly prepared. The solutions of N-methyl-β-oxyphenazine consisted of 50 cc. of buffer and 5 cc. of water containing 5 mg. of compound. The solutions of β-hydroxyphenazine consisted of 50 cc. of buffer, and 4 cc. of water and 1 cc. of an alcoholic solution containing 5 mg. for all buffers *p*H 0.04 to 1.48 and 8.40 to 9.54; 4.9 cc. water and 0.1 cc. for *p*H 2.05 to 5.79; and 4.8 cc. water and 0.2 cc. for *p*H 6.71 to 7.48. From 10 to 15 cc. of titrating solution was usually added.

Titrations of β-hydroxyphenazine by reducing agents, in buffers of higher *p*H than 9.54, and the alternative of reductions at lower *p*H and subsequent titrations at higher *p*H by oxidizing agents, did not give satisfactory results, probably because of the relatively high reducing intensity or the low solubility of the compounds.

The titration curves obtained for solutions at or below *p*H 2.05 show partial merging of the second step of the titrated system with the titanic–titanous system, however,

by employing the proper geometrical method, a close estimation of the mid-point of the second step was attained.

The colors of the oxidants and the reductants in the hydrochloric acid solutions are various shades of yellow and the semiquinones are yellow-green. N-Methyl-β-oxyphenazine is red in solutions more alkaline than *p*H 5; a colorimetric determination of the ionization constant gave $pK = 3.05$, in close agreement with the electrometrically determined value of 3.0. Although the ionized forms of the oxidant and the reductant of β-hydroxyphenazine are deeper yellow than the un-ionized, the low solubility of the un-ionized forms prevent the accurate estimation of the ionization constants by visual methods.

Discussion

The characteristic points of the titration curves are given in the table and figures, $E'_{0\text{oxid-red}}$ being the mid-point or the 50% reduction point and $E'_{0\text{oxid-semi}}$ and $E'_{0\text{semi-red}}$ being the 25 and 75% reduction points of the curves of E'_0 against per cent. of reduction at the respective *p*H values. The quantities in parentheses were calculated[3] from the "index potentials," $(E_{1/4} - E_{3/4})/2$, and represent the mid-points of the separate one-equivalent curves, which in this region overlap or merge into each other.

POTENTIALS OF MIXTURES OF EQUIVALENT AMOUNTS OF OXIDANTS AND OF REDUCTANTS IN BUFFERS AT VARIOUS *p*H

[a] Calculated.

By plotting the E'_0 values of the three systems against *p*H and projecting the straight line portions of the curves, intersections are formed which represent the ionization constants of the various species. Each essentially straight-line portion represents a region in which particular ionic or molecular species predominate and each intermediary curved portion represents a region of transition mixtures. The chemical reactions which probably predominate in these straight line portions reveal that the slope of any curve of E'_0 against *p*H is apparently determined by the number of hydrogen ions and electrons involved in the equilibria, being at 30° where $RT/F = 0.06$ volt

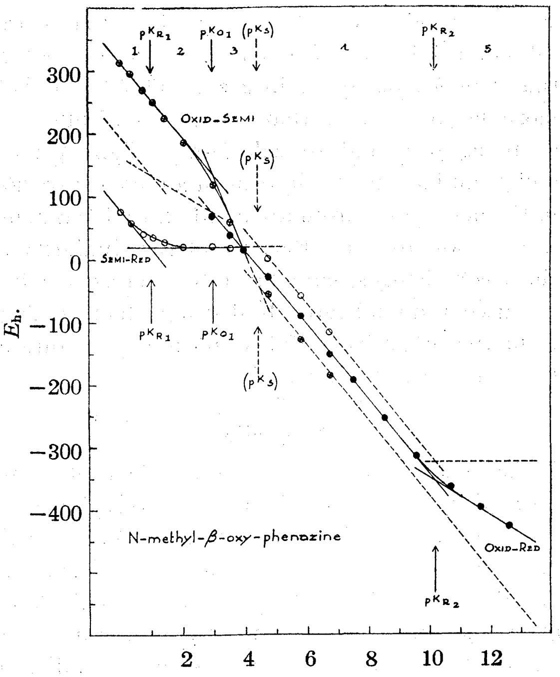
$$\frac{E'_0}{p\text{H}} = 0.06 \text{ volt} \times \frac{(\text{number of H}^+)}{(\text{number of electrons})}$$

The chemical equations for β-hydroxyphenazine for the sections as numbered at the top of Fig. 1, using "(pz)" to indicate the two phenylene nuclei connected by two nitrogen atoms without designating the positions of the double bonds or the unusual valencies or configurations of the semiquinone, are as follows:

The first equation of each pair represents the oxidant–semiquinone system and the second the semiquinone–reductant system: the sum of both would represent the oxidant–reductant system whose slope would be the mean value of the other two.

1. $\text{HO(pz)H}^+ + \text{e} + \text{H}^+ = \text{HO(pz)H}^+\cdot\text{H}$
(slope = 0.06 × 1/1 = 0.06)
$\text{HO(pz)H}^+\cdot\text{H} + \text{e} + \text{H}^+ = \text{HO(pz)H}^+\cdot\text{HH}$
(slope = 0.06 × 1/1 = 0.06)

2. $HO(pz)H^+ + e + H^+ = HO(pz)H^+ \cdot H$
(slope = 0.06 × 1/1 = 0.06)
$HO(pz)H^+ \cdot H + e = HO(pz) \cdot HH$
(slope = 0.06 × 0/1 = 0.00)
3. $HO(pz) + e + 2H^+ = HO(pz)H^+ \cdot H$
(slope = 0.06 × 2/1 = 0.12)
$HO(pz)H^+ \cdot H + e = HO(pz) \cdot HH$
(slope = 0.06 × 0/1 = 0.00)
4. $HO(pz) + e + H^+ = HO(pz) \cdot H$
(slope = 0.06 × 1/1 = 0.06)
$HO(pz) \cdot H + e + H^+ = HO(pz) \cdot HH$
(slope = 0.06 × 1/1 = 0.06)
5. $^-O(pz) + e + 2H^+ = HO(pz) \cdot H$
slope = 0.06 × 2/1 = 0.12)
$HO(pz) \cdot H + e + H^+ = HO(pz) \cdot HH$
(slope = 0.06 × 1/1 = 0.06)



pH.

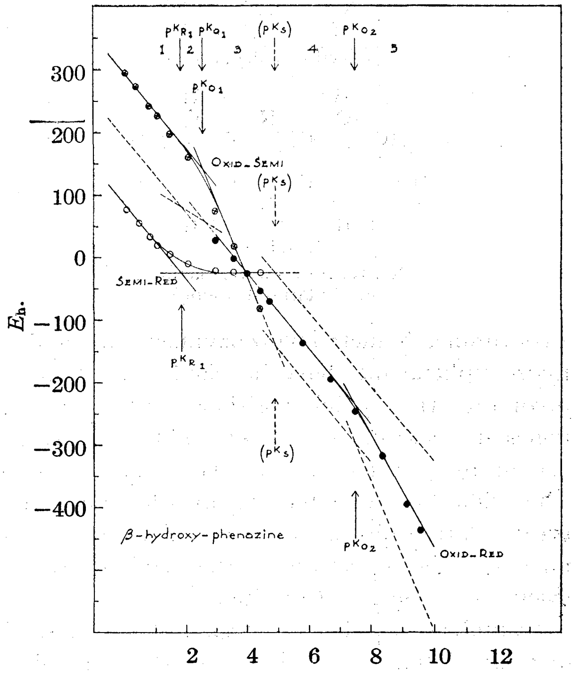
Fig. 1.

The ionization constants are: pK_{O_1} = 2.6 cation to free base; pK_{O_2} = 7.5, free base to anion; pK_S = (4.9) (approximate) cation to free base; pK_{R_1} = 1.8, cation to free base. The ionizations are accompanied by a noticeable change in color and an increase in solubility. The one additional anionic ionization in the semiquinone and the two in the reductant, which might occur at the hydrogens added in the reduction process, and the anionic ionization of the H from the OH group of the semiquinone and of the reductant are not evident in the pH regions studied.

The equations for N-methyl-β-oxyphenazine are of the same general character for the first four sections shown in Fig. 2, with the exception that the HO–group is replaced by an O= with consequent rearrangement of the double bonds and loss of one point of ionization, and the addition of a CH_3– group to the nitrogen atom meta to the oxygen. The equations for section 5 are

5. $(pzCH_3) + e + H^+ = (pzCH_3) \cdot H$
(slope = 0.06 × 1/1 = 0.06)
$(pzCH_3) \cdot H + e = (pzCH_3) \cdot {}^-H$
(slope = 0.06 × 0/1 = 0.00)

The ionization constants are: pK_O = 3.0, cation to free base; pK_S = (4.4) (approximate) cation to free base; pK_{R_1} = 1.0, cation to free base; pK_{R_2} = 10.1, free base to anion. The one anionic ionization of the semiquinone and the second in the reductant, which might occur at the hydrogens added by the reduction, were not evident in the pH regions investigated.

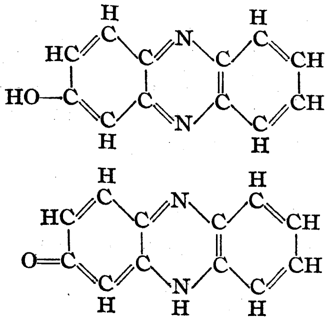


pH.

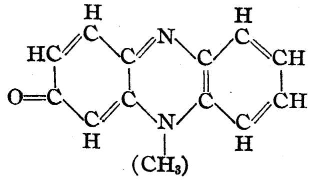
Fig. 2.

Only approximate values for the ionization constants for the semiquinones could be estimated, because the titration curves did not show a sufficiently high "index potential" to locate precisely the E_0' againts pH curves for the systems involving semiquinones. The effect of an ionization of a semiquinone is to change the solpe of the oxidant–semiquinone curve exactly to the same amount and in the opposite direction as the slope of the semiquinone-reductant curve, thereby causing no change in the slope of the resultant oxidant–reductant curve and preventing the detection there of any semiquinone ionizations.

The structure of β-hydroxyphenazine indicates that the oxidation–reduction system could involve either the two nitrogens or the oxygen and the nitrogen para to it. In the case of the N-methyl derivative, only one structure is possible, assuming that the methyl group does not have the power to shift its position.



β-Hydroxyphenazine



N-Methyl-β-oxyphenazine
(methylaposafranone)

Pyocyanine, N-methoxyl-α-oxyphenazine, and α-hydroxyphenazine have a similar relationship involving the ortho positions. The semiquinones in these cases have one additional hydrogen atom or electron, and the reductants two. The oxidants and reductants have the same structural relationship as quinone-imine to aminophenol; the structure of the semiquinones is discussed in the literature cited.[2,3]

In buffers at *p*H 6, the region of lowest semiquinone formation and where the un-ionized forms predominate, the E_0' of N-methyl-α-oxyphenazine is about 0.125 volt more positive than the E_0' of N-methyl-β-oxyphenazine. This amount is greater than the separation, 0.088 volt, of the ortho-quinone and the para-quinone systems, indicating that they are probably related as ortho–para isomers. The difference between the α- and the β-hydroxyphenazine is only 0.030 volt and they lie in the same general region where the E_0' of phenazine[6] would be expected, so that they are probably behaving as hydroxy substituted phenazines.

The low solubility and lack of contrasting color changes makes β-hydroxyphenazine unsuitable as a colorimetric indicator of oxidation–reduction potential. N-Methyl-β-oxyphenazine is useful as an indicator of oxidation–reduction potential from *p*H 5.5 to 12 in a zone about 0.05 volt more negative than that of indigo disulfonate, changing from red to colorless or light yellow, and as an indicator of hydrogen ion concentration in the acid region from about *p*H 2 to 4, changing from yellow to red. Because of the similarity of the color changes, care must be exercised, when it is used as an indicator, to distinguish one change from the other by suitably adjusting conditions in the material to be tested.

Summary

The oxidation–reduction potentials of β-hydroxyphenazine and N-methyl-β-oxyphenazine have been determined by an electrometric method and the ionization constants of the oxidants and of the reductants have been calculated from the data. The N-methyl-β-oxyphenazine has properties suggesting its use as an indicator for oxidation–reduction potential and for hydrogen ion concentration. The chemical structure of the compounds and certain theoretical aspects of semiquinone formation and oxidation–reduction potentials are discussed.

The Heat Capacity and Entropy of Rhombic and Monoclinic Sulfur

BY E. D. EASTMAN AND W. C. MCGAVOCK

The only data at present available in the literature on the heat capacity at low temperatures of the two crystalline forms of sulfur are early measurements made in Nernst's laboratory.[1] As these are insufficient for the determination of entropy with the certainty now desirable, we have made a more complete investigation, the results of which are presented here.

Experimental Details

The method of measurement of heat capacity was the standard one of electrical heating in vacuum now universally employed for such measurements at low temperatures, and conformed, in general practice, with that of numerous other investigations in this Laboratory at the date of these measurements, 1932–1933.

The calorimeter was constructed of gold, to enable measurements to be made near the transition temperature without danger of reaction of the metal with sulfur. It was welded from gold sheet of 1 mm. thickness in the form of a cylinder 7 cm. long and 5 cm. in diameter. Eleven radial vanes 0.2 mm. thick and extending nearly to the center were welded to the interior wall to promote thermal conduction. The opening to the calorimeter was provided by a tube of *einschmilzungsglas* sealed to a platinum tube which in turn was welded to the calorimeter. The materials of the calorimeter comprised 306 g. of gold, 3.66 g. of platinum and 5.52 g. of glass, together with small amounts of Bakelite lacquer and lens paper used in cementing and insulating the heater.

The calorimeter heater, which also served as a resistance thermometer, was of No. 40 B. and S. gage double silk insulated wire of gold alloyed with 0.1% silver, drawn in the manner described by Onnes and Clay.[2] Its resistance was 13.9 ohms at 15°K. and 248 ohms at 298°K. The procedure in attaching the heater-thermometer to the calorimeter was as follows. The surface of the calorimeter was first given a "hair" finish with fine emery paper. Two very thin coats of Bakelite lacquer were next applied, each dried in air and heated slowly in the course of a day or more up to 140–150°. This temperature was maintained until the color was a dark reddish-brown. A thickness of lens paper was then applied, the heater wound on, another thickness of lens paper applied and the whole soaked with Bakelite lacquer. This was baked as described above, and two or three more very thin coats of Bakelite applied. The surface was then covered with gold beaters leaf to cut down radiation interchange during the measurements.

The resistance thermometer on the calorimeter was standardized by comparison with a thermocouple which had been calibrated by Dr. R. T. Milner by comparison with laboratory standards, the temperature scale being that established by Giauque, Buffington and Schulze.[3] For the extension of this scale to higher temperatures the couple was calibrated at the transition temperature of sodium sulfate decahydrate and at the boiling point of water.

The timer described by Johnston[4] was used to measure the heating interval to less than one hundredth of a sec. The time of heating was from six to twenty minutes, the temperature increments varying from 1° at the lowest temperature to 6 or 8° near the transition.

A lead block of large heat capacity surrounded the calorimeter, making it possible to stabilize temperatures at points intermediate between those of the outer baths employed in different temperature ranges. For work above room temperature the metal can enclosing the block was provided with a heating coil for regulation of its temperature.

Helium at 75 cm. pressure at 20° was employed in the calorimeter to promote heat conduction to the sample. Measurements of the temperature head between the calorimeter wall and the sulfur showed it to be less than one-fifth the head between the heater and the wall (0.2 to 0.5°) under the same conditions.

Thermal equilibrium, except for a second order drift apparent between 200 and 300°K.,[5] was complete in the full calorimeter within ten or fifteen minutes after the heating period.

The calorimeter contained 113.41 ± 0.01 g. of sulfur prepared as follows. A pure crystallized commercial product was melted and maintained at 120° for several hours. It was then distilled in Pyrex glass and the distillate dissolved in freshly distilled carbon disulfide and recrystallized. Unbroken crystals, which passed a sieve opening of 3.5 mm. and were retained on a 2.0-mm. screen, were selected. These were freed of carbon disulfide by heating at 85 ± 5° at 1-mm. pressure for eight days. After this period, a test made by boiling a sample in a high vacuum resulted in the liberation of an amount of gas corresponding to less than 0.001% CS_2. All determinations on rhombic sulfur were made with this material. Monoclinic sulfur was obtained by holding the sample in the calorimeter at temperatures between the transition and melting points for a long period, as described later. The sample was never melted after the treatment above and could therefore have contained none of the "insoluble" sulfur, which differs considerably in heat capacity from monoclinic and is present in small amounts in material prepared by crystallization of the melt.

The data given below are based on the following constants: atomic weight of sulfur = 32.06, 1 cal. = 4.1833 int. joule, and 0 = 273.1°K.

(5) We suspect the glass sealing tube, because of its low thermal conductivity, to have been in part responsible for this drift. The large radiating and absorbing power is an additional unfavorable property of this material. We now consider all metal construction preferable.

Heat Capacity of Rhombic Sulfur

The results of the heat capacity measurements for rhombic sulfur are listed in Table I and shown graphically in Fig. 1. The figure also includes certain points from Table V, to be explained later.

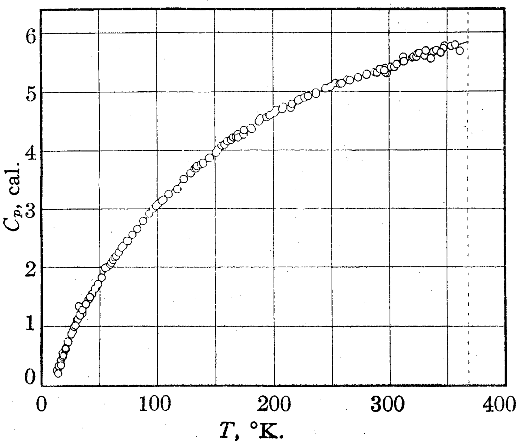

Fig. 1.—Atomic heat capacity of rhombic sulfur.

[a] In each of these runs the average temperature of the heater on the calorimeter was above the transition point of sulfur during a portion of the run. These points are not plotted in Fig. 1.

The individual measurements show fluctuations larger than can be attributed to instrumental errors, which in general were of the order of 0.1%. The very large differences among the points at the lowest temperatures result from inaccuracies in three separate calibrations[6] of the resistance thermometer in different series of experiments. These calibrations permit measurements of temperature differences in very close agreement over most of their range but deviate in the region of extremely small resistances. The remaining variations we believe to be due to imperfect drift and heat exchange corrections. At the highest temperatures employed, the method of measurement is inherently defective in this regard for precise work. In the intermediate range the difficulty attributed above to the glass tube on the calorimeter is important. To ensure the absence of constant errors from these sources in the final results, the conditions of approach to thermal equilibrium were varied systematically in making measurements. This, together with the large number of observations, gives us confidence in the accuracy of the averaged results, within the limits estimated below.

Representative values of the heat capacity read from the smoothed curve of Fig. 1 are given in Table II. The uncertainty connected with these smoothed values varies with the temperature. We estimate it to be about 8% at 15°K., 1.5% at 20°K., 1.0% at 30°K., and 0.5% at 40°K. From 60 to 290°K. it is of the order of 0.3%. Above 290°K. it averages about 0.5%. These figures are limits of error, which we think should not be exceeded in any values listed in Table II, with the possible exception of those very near the extremes of the temperature range.

---

(6) Necessitated by changes in resistance resulting from the thermal treatment.

170	4.269	360	5.783
180	4.404	368.6	(5.837)
190	4.526		

Comparison with the data of Nernst[1] shows our results in Table II to be lower by amounts varying from 6 to 28% between 20 and 30°K. and from 1 to 5% between 70 and 90°K. and near 200°K. The remaining data in the literature are all mean specific heats over large temperature intervals above room temperature due to Regnault,[7] Kopp,[8] Bunsen,[9] Wigand,[10] Koref,[1,11] Lindemann,[1] and Mondain-Monval.[12]

Our values are higher by amounts averaging about 2% than those of Kopp, Bunsen, and Mondain-Monval, and lower by about the same amount than those of the other observers.

The heat capacity at constant volume as a function of temperature is of some interest, and is approximately calculable in the case of rhombic sulfur. For this purpose the thermodynamic relation

$$C_p - C_v = \alpha^2 VT/\beta \qquad (1)$$

is employed. Based on the work of Kopp,[13] Russner,[14] and Schrauf,[15] we take the cubic coefficient of expansion at 20° as $\alpha = (18.1 \pm 1) \times 10^{-5}$ deg.$^{-1}$. The compressibility, β, from the work of Richards[16] and an extrapolation of Bridgman's data,[17] is $(13.0 \pm 0.2) \times 10^{-6}$ cm.^{2}/kg. at 20°. The atomic volume is 15.60 ± 0.05 cc. These values substituted in equation 1 give $C_p - C_v = 0.270 \pm 0.03$ cal./deg. at 20°. The value of C_p at this temperature from the smoothed curve of Fig. 1 is 5.37 ± 0.03. C_v at 293.1°K. is therefore 5.10 ± 0.05. Data required for application of equation 1 at lower temperatures are lacking. We have therefore resorted to an approximate empirical equation proposed and discussed by Grüneisen,[18] namely

$$C_p - C_v = kTC_p^2 \qquad (2)$$

From the datum above, k in this equation is found to be 3.20×10^{-5}. Employing this constant with figures for C_p from our work we obtain values of $C_p - C_v$ and C_v shown at regular intervals in log T in Table III.

TABLE III

CALCULATED ATOMIC HEAT CAPACITY AT CONSTANT VOLUME OF RHOMBIC SULFUR

Log T	$C_p - C_v$ cal./deg.	C_v cal./deg.
2.500	0.308	5.21
(2.4672)	(.270)	(5.10)
2.400	.208	4.88
2.300	.137	4.49
2.200	.085	4.00
2.100	.051	3.50
2.000	.0297	3.02
1.900	.0170	2.56
1.800	.0095	2.16
1.700	.0050	1.77
1.600	.0027	1.45

We may mention at this point that the values of C_v in Table III (and at lower temperatures where C_v is nearly identical with C_p) may be represented approximately up to $C_v = 3.0$ by the function

$$C_v = f(T/\Theta)^n \qquad (3)$$

proposed by Lewis and Gibson,[19] if $\log \Theta = 1.992$ and $n = 0.5025$. Above $C_v = 3.0$ deviations begin, C_v at 293°K. falling about 0.45 cal./deg. above the typical curve of these authors. Applying the values of n and Θ adopted by Lewis and Gibson to our data, we find that the experimental points fall above their curve at low temperatures and below it in the upper range by amounts much greater than the experimental error. No values of the constants applied to our

data will reproduce this curve over the full range of our investigation.

Heat Capacity of Monoclinic Sulfur

After completion of the runs with rhombic sulfur, the sample was transformed to monoclinic by maintaining the temperature of the calorimeter between 96 and 100° for a period of twenty-four hours. The first measurement recorded in column 4 of Table IV was then made, the calorimeter held for an additional twenty-four hours above the transition point and the second measurement made. During these runs the conditions appeared as nearly ideal as could be obtained, and they were therefore considered sufficient to establish the heat capacity of the monoclinic form in the rather narrow range of temperature within which it is stable. After the second run, the calorimeter was cooled as rapidly as possible to 60°K. The initial rate of cooling was 10° per minute, and in thirty minutes the temperature was reduced to 200°K., below which transition is very slow. Runs numbered 3 to 16 in Table IV were then made in sequence. The total time elapsing from the beginning of the initial cooling to the start of the run is shown in each case in the second column of the table. After completion of run 15 the temperature was raised to about 218°K. and maintained there for fifty-three hours before the start of run 16. Following this the calorimeter was again cooled, and run 17 completed at 92°K. Immediately before run 18 the calorimeter was heated from this temperature to about 153°K.

18	334	154.91	4.158	.1136	7.33

The results shown in Table IV lie consistently above the smoothed curve for the rhombic form. Runs 18 and 19, at 92 and 155°K., respectively, which were made after the calorimeter had been held for a long period at 220°K., agree within the experimental error with the preceding runs near these temperatures. We have taken this as evidence that no appreciable reversion to the rhombic form occurred in this series after the initial cooling. Run 17 at 220° appears to be rather lower than should correspond to the monoclinic form at this temperature. We have indications from later runs, however, that this is due to an unusually large fluctuation rather than to transition, and consequently attach less weight to this point than to the others.

In an attempt to confirm and extend the data on the monoclinic form, the sample, which had been allowed to warm and stand for some days at room temperature, was again heated and held above the transition point, and then cooled rapidly, this time to 12°K. A second series of measurements ranging from 13.5 to 205°K. was then made. At temperatures where the two forms differ appreciably in heat capacity, as shown by the earlier measurements, this series gave results only a little higher than those with rhombic. We believe that the repetition of the transformation had produced more reactive crystals, in which the transformation could not be so completely inhibited on cooling as with those which had undergone only the single change. (It should be mentioned that during the "annealing" period preceding the cooling an accidental drop below the transition temperature occurred, which may have had some influence on the subsequent behavior.) In connection with this point, the appearance of the sample after removal from the calorimeter may be noted. The crystals, which had been subjected to several transitions, had maintained their original form, but had become opaque, indicating the presence of small crystals in mosaic form.

Of the measurements of this series, only those below 65°K., which are useful in supplementing the data on rhombic sulfur, with which they are identical within the errors in this range, will be recorded here. These are given in Table V, and plotted in Fig. 1.

A third "annealing" above the transition tem-

perature was next made, followed by a series of runs extending from 110 to 345°K. The results of these measurements in the lower temperature range fell consistently between the rhombic curve and the first series of points for the monoclinic. From their position relative to these two, it appeared that the sample consisted in this case of about 60% of the monoclinic form. The corresponding difference in heat capacity persisted up to 255°K. Within the period of ten hours intervening between the run at this temperature and the next at 268°K., the sample was apparently entirely transformed to rhombic, since its heat capacity fell to the rhombic curve and remained there in all succeeding runs. No further attempts to secure measurements on monoclinic sulfur were made.

The evidence cited above convinces us that no appreciable conversion of monoclinic to rhombic occurred after the initial cooling in any of the three series of experiments at temperatures below about 250°K. During the cooling itself there was marked conversion in the second and third series. We believe that if any such effect occurred in the first series it could have affected only a small fraction of the sample. The approximate agreement of our results, discussed below, for the difference in heat capacity of the two forms with those of Nernst near 200°K. supports this belief, since Nernst's observations were made on relatively large crystals of monoclinic sulfur which were known not to transform appreciably on cooling.

We consider it advantageous for the present purposes in dealing with the data on monoclinic to treat the difference, ΔC_p, of monoclinic from rhombic, rather than C_p itself. Values of ΔC_p (and of $\Delta C_p/T$) from our work are therefore included in Table IV. These are computed from the difference in heat capacity of the full calorimeter in individual runs with monoclinic sulfur from the smoothed curve for the full calorimeter containing rhombic sulfur at the same temperature. We have secured smoothed values of ΔC_p, and at the same time obtained a plot for use in a later calculation, by treating $\Delta C_p/T$ as a function of temperature.

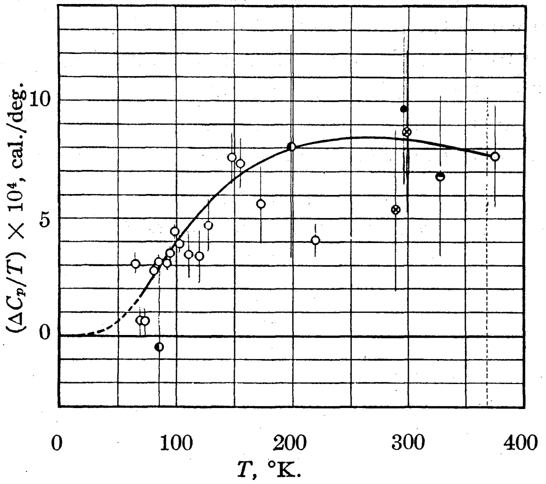

Fig. 2.—Difference of atomic heat capacities of monoclinic and rhombic sulfur: Regnault, ⊖; Wigand, ⊗; Nernst, ◐; Koref, ●; this research, ○.

In Fig. 2, $\Delta C_p/T$ is plotted against T. The vertical strokes attached to points representing our measurements are intended to give an idea of the experimental uncertainty. They represent the average deviation of three or four determinations on rhombic sulfur from the smoothed curve for rhombic immediately above and below the temperature of the monoclinic run in question. The uncertainty in particular cases may therefore exceed considerably that indicated as normal. For comparison with our results, and to supplement them, values of ΔC_p obtainable from the work of other observers are also plotted in Fig. 2. These data represent small groups of points at neighboring temperatures for the two forms which have been corrected to a common mean temperature, averaged separately, and the difference of the averages plotted against the mean temperature. Our estimate of the uncertainty is also indicated for these points in the plot.

The curve shown in Fig. 2 fits all of the points within the experimental uncertainty, and is correct in general form. The approximate position and shape of the theoretically required maximum in the curve we have inferred from the position of our points above the transition temperature relative to the fairly well defined course of the curve at low temperatures, and also from the points of the third series of measurements mentioned above. From the curve as shown we have obtained smoothed values of ΔC_p. These, in conjunction with the data of Table II on rhombic, yield smoothed values of C_p for monoclinic sulfur shown in Table VI over the temperature range in which the difference in heat capacity of the two forms is significant. The uncertainty in C_p in this table is of the order of 1.5% in the upper temperature range, and approaches that previously estimated for rhombic at lower temperatures.

Calculations of Entropy

The entropy difference between 15°K. and any higher temperature up to the transition point for rhombic sulfur is obtainable by graphic integration on a suitable plot of the data of Table II. For the entropy difference between 0 and 15°K., we find by similar integration under an extrapolated curve of C_p/T against T, and by calculation from a Debye function fitted to our points up to 40°K., 0.12 ± 0.02 e. u. For the total entropy of rhombic sulfur we obtain 7.624 ± 0.05 e. u. at 298.1°K. and 8.827 ± 0.06 at the transition point (368.6°K.).

The entropy of transition of rhombic to monoclinic sulfur is determined by integration under the curve in Fig. 2 to be 0.157 ± 0.04 e. u. at 298.1°K. and 0.215 ± 0.05 at 368.6°K. By combination of these figures with the values for the rhombic form, the entropy of monoclinic sulfur is 7.78 ± 0.1 e. u. at 298.1°K. and 9.04 ± 0.1 e. u. at 368.6°K.

These results are in agreement with those of Lewis and Gibson,[19] 7.6 and 7.8 e. u. at 298.1°K., for the two forms. The closeness of this agreement is in part fortuitous, in view of our earlier remarks in the discussion of C_v. Equally well justified calculations of the type of Lewis and Gibson's might introduce discrepancies of the order of 0.5 e. u. To this degree of approximation, however, their method is justified in the case of sulfur.

For comparison of the above value of ΔS obtained by application of the third law with one based solely on the second law, existing data on the heat of transition may be employed. Numerous measurements of ΔH, by widely different direct and indirect methods, due to Mitscherlich,[20] Reicher,[21] Tammann,[22] Brönsted,[23] Mondain-Monval,[12] and Neumann[24] are available. After a critical review of the work of these investigators, into which we cannot enter here, we have adopted 95 ± 10 cal. as the value of ΔH at the transition point. This corresponds to 0.258 ± 0.027 e. u., compared with the value based on the third law of 0.215 ± 0.05 at the same temperature.

It appears from this comparison that the third law is accurately applicable, without complications of the types that sometimes occur, to the sulfur transition. The uncertainty of 0.05–0.1 e. u. in this "check" of the law is smaller[25] than that in many others, and permits the assumption of no significant discrepancy. This case, as is well known, has often been cited in support of the third law. The experimental basis for this claim is greatly strengthened by the data discussed here.

Summary

Measurements of the heat capacity of rhombic and monoclinic sulfur have been made over the temperature range 15–375°K., and from them the

[25] It is, of course, the absolute rather than the percentage figure which is important in such tests.

entropy of both forms determined. The entropy difference of the two forms obtained from the heat capacities agrees, within the small experimental uncertainty, with that from the heat of transition, as expected from the third law.

The heat capacity at constant volume has been calculated for rhombic sulfur, and its variation with temperature compared with the "*n* formula" of Lewis and Gibson.

The Reaction of Titanium Tetrachloride with Hydrogen Peroxide in Dry Ethyl Acetate

BY DOUGLAS G. NICHOLSON AND M. ANTOINE REITER

Several references concerning addition compounds of titanium tetrachloride and neutral molecules have appeared in recent chemical literature.[1–4] In view of these references, it seemed quite probable that titanium tetrachloride would unite with hydrogen peroxide in a non-aqueous medium to form a similar addition compound. Since both substances have an appreciable solubility in dry ethyl acetate, this material was selected as the solvent in the investigation.

Experimental

The solution of hydrogen peroxide in dry ethyl acetate was prepared in a manner previously described.[5] This peroxide solution was added slowly to an ice cold solution of titanium tetrachloride in ethyl acetate. As it was added, the titanium solution became orange to orange-red in color, and, with continued addition of the peroxide, a white crystalline precipitate formed. After thoroughly washing this precipitate with cold dry ethyl acetate, samples were analyzed in an effort to determine the chlorine to titanium, as well as the hydrogen peroxide to titanium, ratios present. Efforts to determine the actual composition of the white precipitated material proved unsatisfactory, because of its extremely unstable nature.

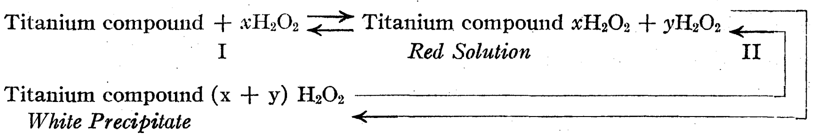
Data

Analysis of fourteen different samples of the material showed the average ratio of chlorine to titanium content to be 1 to 1.05 with an average deviation of 0.01 and a maximum deviation of 0.03. The average hydrogen peroxide to titanium ratio obtained from the same sample was 1 to 1.01 with an average deviation of 0.022 and a maximum deviation of 0.05.

Discussion

The color change encountered, as the solution of hydrogen peroxide in acetate was added to the titanium tetrachloride solution, followed by the formation of the white precipitate, seemed to indicate that more than one compound of these two substances had been formed. If some of the red colored solution was allowed to remain in an open vessel for some time the intensity of the color gradually faded.

In view of these facts the following equilibria are postulated:



The presence of a trace of moisture caused the white precipitate to become orange-red in color. Thus, it seems quite probable that moisture tends to shift the right-hand equilibrium (II) toward the left. All attempts to remove the last traces of acetate solution from the white precipitate resulted in its partial decomposition, in which the surface of the material became yellow to orange in color. This white precipitate was very soluble in water, producing the yellow to orange typical peroxytitanate solutions.

Analysis of the titanium tetrachloride used showed it to be very pure. The apparent loss of three atoms of chlorine per molecule of titanium tetrachloride can be attributed to either or both of two factors: namely, (1) oxidation to free chlorine by the hydrogen peroxide present, and

(5) Nicholson, THIS JOURNAL, **58**, 2525 (1936).

(2) partial decomposition of the ethyl acetate, producing ethyl chloride and titanium acetate. The second factor seems more probable, since refluxing a solution of titanium tetrachloride in ethyl acetate resulted in a partial loss of chlorine. No explanation is made concerning the fact that but three of the chlorine atoms had been replaced.

Summary

The reaction between titanium tetrachloride and hydrogen peroxide in dry ethyl acetate has been studied in some detail. A white compound containing titanium, chlorine and hydrogen peroxide in the approximate ratio of 1:1:1 can be prepared. This material is unstable toward water, as well as slightly elevated temperatures. In decomposing, it becomes yellow-orange in color. It is very soluble in water, producing orange-red clear solutions.

The Use of Iodine and of Potassium Iodate as Volumetric Oxidizing Agents in Solutions Containing Mercuric Salts. I. The Effect of Mercuric Salts upon the Stoichiometry of Various Oxidation–Reduction Reactions. New Procedures for the Titration of Arsenite and Antimonite with Standard Solutions of Iodine or of Potassium Iodate

BY N. HOWELL FURMAN AND CLARK O. MILLER[1]

Introduction

The stoichiometry of certain reactions between powerful oxidizing agents and halides, or between the halogens or their oxy acids and reducing agents, is modified when mercuric salts are present in excess. Several situations may arise, depending upon particular halide that is present, the total acidity and the relative concentrations of mercuric salt, halide and acid. There are two principal kinds of behavior which are of interest here: (a) the failure of free halogen to appear when a limited quantity of a halide, an excess of mercuric ion and an excess of nitric, sulfuric or perchloric acid is treated with a powerful oxidizing agent, as for example, potassium bromate or permanganate; (b) the reduction of bromate to bromide, of iodate to iodide and of iodine to iodide by various reducing agents in the presence of an excess of mercuric salt and acid. The former case will be reviewed briefly with presentation of some experimental observations, and the latter will be treated more fully, especially with regard to the reactions of potassium iodate and of iodine and the application of these reactions in volumetric analysis.

(a) The Non-appearance of Free Halogen when Mercuric Salt is Present in Excess.—G. F. Smith[2] described a series of experiments in which solutions of bromides, chlorides or iodides containing mercuric nitrate or perchlorate and the corresponding free acid were heated with an excess of potassium bromate solution. He reported that no reaction was observed and that the solution after the heating liberated an amount of iodine equivalent to the original potassium bromate when an excess of potassium iodide was added to the cold solution. He found similar results for mixtures of a bromide, mercuric salt, potassium permanganate and acid, and attributed this "preventive effect" to the formation of slightly ionized mercuric halides.

We have repeated experiments of the type described by Smith upon mixtures containing potassium iodide, excess of mercuric sulfate and sulfuric acid. Potassium bromate or permanganate was added. After heating there was no loss of oxidizing power toward potassium iodide. Reactions had occurred, however, for the potassium bromate had been reduced and an equivalent amount of iodate had been formed, as was indicated by the presence of bromide and iodate in mixtures that were examined qualitatively and by quantitative experiments. The potassium permanganate was decolorized and iodate was formed. Smith's explanation[2] of the "protective action" of mercuric salts is contradicted by these qualitative experiments.

In the case of iodide, which is of principal inter-

[2] G. F. Smith, THIS JOURNAL, **45**, 1417 (1923).

est in this paper, the oxidation proceeds to the iodate stage without visual evidence of the intermediate formation of free iodine when mercuric salts are present in sufficient excess. In the absence of mercuric salts the oxidation of iodide usually leads to the quantitative liberation of iodine in solutions that are 1–2 *N* in acid. The explanation of the effect of mercuric salts seems clear from the evidence that is available in the literature. In the oxidation of iodide to higher states we are concerned with the effect of mercuric ion and acidity upon the equilibria

$$2I^- + 2e \rightleftharpoons I_2 \quad (1)$$
$$I_2 + H_2O \rightleftharpoons I^- + IO^- + 2H^+ \quad (2)$$
$$3IO^- \rightleftharpoons IO_3^- + 2I^- \quad (3)$$

Measurements are presented in this paper regarding the effect of mercuric ions and acidity upon process (1). Mercuric ions tend to bind iodide ions in the form of complex and undissociated molecules. It is thus more difficult to liberate iodine from an iodide in the presence of a mercuric salt than in its absence. Mercuric ions tend to aid processes (2, 3) by removing one of the products of the reaction, namely, iodide. Some of the evidence previously published regarding processes (2, 3) in the presence of mercury will be summarized briefly. Brückner[3] found that iodine in the presence of mercuric oxide undergoes autoxidation

$$6HgO + 6I_2 = 5HgI_2 + Hg(IO_3)_2 \quad (4)$$

A similar autoxidation occurs if mercuric sulfate is added to a solution of iodine. A complex white precipitate that contains mercuric sulfate, iodide and iodate, is formed. Hovorka[4] observed a similar process when mercuric perchlorate was used.

$$6Hg(ClO_4)_2 + 6I_2 + 6H_2O = 5HgI_2 + Hg(IO_3)_2 + 12HClO_4 \quad (5)$$

This type of autoxidation is not limited to iodine, for Chateau[5] has demonstrated similar autoxidation of bromine and chlorine, respectively, in the presence of mercuric mercury, to form hypochlorite or hypobromite. The change of hypoiodous acid to an equivalent mixture of iodate and iodide (equation 3) is rapid according to Skrabal.[6] Reaction (2) is also rapid, for a solution of iodine is rapidly decolorized when added to a solution of mercuric sulfate.

The binding or removal of iodide ions is the important factor in promoting the change of iodine to iodate. A similar autoxidation occurs when silver is used instead of mercuric ion[7] and the mechanism has been shown to involve reactions (2, 3).

We have shown qualitatively that the presence of an excess of a mercuric salt does not inhibit the oxidation of a limited quantity of halide ion by a powerful oxidizing agent like potassium permanganate or potassium bromate. Evidence from the literature has been cited to show the mechanism of the formation of oxy-halogen acids by spontaneous autoxidation of the halogens in the presence of mercuric or silver ions. In a particular case such as the reaction between bromate and iodide, the presence of mercuric salt tends to establish an equilibrium between iodate, iodide, bromate and bromide such that the total oxidizing power of the solution toward a powerful reductant remains constant.

(b) **The Action of Reducing Agents upon Bromate and Iodate in the Presence of Mercuric Salts.** (1) **In the Presence of Mercuric Sulfate, Perchlorate or Nitrate and the Corresponding Acid.**—Under these conditions bromate is reduced to bromide or iodate to iodide by a reductant that is sufficiently powerful. The following are some typical reactions

$$6Mn^{++} + 2BrO_3^- + 6H_2O + Hg^{++} = 6MnO_2 + HgBr_2 + 12H^+ \quad (6)$$
$$4Cr^{+++} + 2BrO_3^- + 10H_2O + Hg^{++} = 4HCrO_4^- + HgBr_2 + 16H^+ \quad (7)$$
$$6NO_2^- + 2BrO_3^- + Hg^{++} = 6NO_3^- + HgBr_2 \quad (8)$$
$$6C_2O_4^= + 2BrO_3^- + Hg^{++} + 12H^+ = 12CO_2 + HgBr_2 + 6H_2O \quad (9)$$

In the absence of mercuric ion, the bromate is reduced to free bromine in each instance (6–9).

Hovorka[4] determined the lower acids of phosphorus and also certain hydrazine derivatives by adding a measured excessive quantity of standard potassium iodate, mercuric perchlorate and acid. After oxidation was complete the excess of oxidant was determined.

(2) **Reactions in the Presence of Mercuric Chloride.**—When chloride is present in excess, and mercuric ion is present, there is competition between iodide and chloride ion for association with mercuric ion in the form of complexes or nonionized molecules. There is also a distribution of any elementary iodine that may be present be-

tween combination with iodide ion and mercuric chloride, respectively. The net result of these various tendencies is that iodate tends to be reduced to iodide and iodine to iodide by the majority of reductants (those of E_0 values less than 0.5–0.6 volt). Iodine under these conditions shows no tendency to undergo autoxidation to form iodate and iodide. Mercuric iodide is readily soluble in a sufficient excess of hydrochloric acid, and it dissolves without decomposition according to Kohler.[8]

In the absence of chloride ion, mercuric salts such as the sulfate tend to form complex basic salts, most of which are insoluble.[9]

The presence of chloride ion and acid tends to diminish the "protective effect" that Smith[2] observed. The following table indicates the extent to which loss of halogen occurs under various conditions.

TABLE I

THE EFFECT OF CHLORIDES UPON THE REACTION BETWEEN IODIDE AND BROMATE IN THE PRESENCE OF MERCURIC NITRATE

20.00 ml. of approximately 0.1 *N* $KBrO_3$ used, equivalent to 23.15 ml. of approximately 0.1 *N* $Na_2S_2O_3$. Mercury added as HgO dissolved in HNO_3. Time of boiling five minutes. Dilution 100 ml. 10.0 ml. 0.1 *N* KI added. 2.0 g. of mercury in soln.

Expt.	NaCl added, g.	Nitric acid, *N*	Iodine value of boiled solns., ml. of $Na_2S_2O_3$	Difference ml. of $Na_2S_2O_3$
1	0.0	1.0	23.13	−0.02
2	.1	1.0	23.05	− .10
3	.2	1.0	22.95	− .20
4	.7	0.5	22.60	− .55
5	1.0	1.0	22.90	− .25
6	1.5	2.0	17.90	−5.25
7	2.0	1.0	20.25	−2.90
8	5 ml. 6 *N* HCl	0.5	20.20	−2.95
9	10 ml. 6 *N* HCl	1.0	17.75	−5.40

In expts. 1–5 there was insufficient chloride to bind the mercury completely as mercuric chloride (2 g. mercury is equivalent to 1.17 g. sodium chloride). The formation of a mercuric iodate precipitate was noted in expts. 1–3. Solutions 6–9 became brown showing the liberation of iodine.

If error were introduced by the action of nitric acid upon the iodide to liberate iodine it would be in the direction opposite to that found by experiment. After the heating, the solution was cooled and diluted to 250 ml. before the addition of excess of potassium iodide to avoid the liberation of excess iodine by the action of nitric acid after the protective action of the mercuric ion had been removed. Experiment 1 indicates that this procedure is adequate.

We attribute the loss in oxidizing power (expts. 2–8, Table I) to the fact that the iodine does not undergo immediate autoxidation in such solutions, and hence escapes as vapor.

The following differences between the behavior of iodine in neutral and acidified mercuric chloride solutions are rather striking, and confirm the view that hydrochloric acid prevents autoxidation of iodine.

(a) Concentrated mercuric chloride solution plus iodine.	(b) A mixture of 5 ml. saturated iodine solution, 10 ml. saturated $HgCl_2$ soln. and 40 ml. of 6 *N* HCl.
1. The color of iodine disappears, unless a rather large amount is added.	1. The iodine color is evident, but faint.
2. No iodine is extracted from the colorless solution by carbon tetrachloride.	2. Iodine is extracted, but with much greater difficulty than from water. After 4 extractions with 5 ml. portions of CCl_4 only half of the iodine had been removed from the soln.
3. Upon addition of HCl, iodine is liberated.	3. After extraction, no iodide could be detected in the aqueous layer. (Evidence of non-formation of ICl which should leave iodide in the aqueous layer, $I_2 + Cl^- = ICl + I^-$)
4. After the removal of iodide from the aqueous layer by silver ion, the remaining solution[a] was able to oxidize iodide when acidified with HCl.	4.[a] The iodine that remained in the aqueous layer could be titrated to iodine monochloride with standard iodate.
[a] At this point the solution contained iodate.	[a] At this point the solution contained iodine and not iodate.

In both cases (a, b) we are concerned with the gross process

$$6I_2 + 6H_2O + 6HgCl_2 = 5HgI_2 + Hg(IO_3)_2 + 12HCl \tag{10}$$

but in case (a) the equilibrium conditions are such that the formation of iodate is favored, whereas with excess of acid (case b) the interaction of iodate and iodide to form free iodine is favored. There is a further competing reaction that must be considered

$$HgCl_2 + I_2 \rightleftharpoons HgCl_2I_2 \tag{11}$$

as was found in distribution experiments by Herz and Paul.[10] This process accounts for the great difficulty with which iodine is extracted from solutions containing mercuric chloride and hydrochloric acid.

---

(8) Kohler, *Ber.*, **12**, 608 (1879).

(9) In Gmelin-Kraut, "Handbuch der anorganische Chemie," Vol. V^2, pp. 804–805, many compounds of the type $(3HgO\cdot 2SO_3)_x\cdot HgI_2\cdot yH_2O$ are reported.

(10) Herz and Paul, *Z. anorg. Chem.*, **85**, 214 (1914).

In the foregoing considerations the formation of iodine monochloride has been neglected, although it might be an intermediate step in certain of the autoxidations that occur.[11]

Explanation of the Varied Stoichiometry of Iodate Reactions in the Presence of Mercuric Chloride and Hydrochloric Acid.—It has been demonstrated by Schoonover and Furman[12] that in addition to the customary iodate processes

$$IO_3^- + 6H^+ + Cl^- + 4e = ICl + 3H_2O \quad (12)$$

(In 4–6 *N* HCl; Hg may be either present or absent)

and

$$IO_3^- + 6H^+ + 5e = {}^1/_2I_2 + 3H_2O \quad (13)$$

(dilute acid, 1–3 *N*; Hg^{++} absent)

a third type of stoichiometry may be realized in the oxidation of arsenite by iodate ion

$$IO_3^- + 6H^+ + 6e = I^- + 3H_2O \quad (14)$$

The last process (14) occurs in the presence of a sufficient excess of mercuric chloride and at acidities between 1 and 3 *N*. In the subsequent section an attempt will be made to explain the latter type of stoichiometry upon the basis of electrode potential measurements.

The Effect of Mercuric Salts upon the Iodine–Iodide Potential

We now present measurements of the effect of mercuric salts upon the iodine–iodide potential, and make application of the effect to the titration of arsenite and antimonite by iodine at acidities not used hitherto.

In the measurements of potentials an attempt has been made to reproduce the conditions that prevail during titrations and to obtain data showing how the potentials of the various systems change relative to each other as a function of acidity. From such data it is possible to choose the most favorable range of acidity. No attempt has been made to correct for liquid junction potentials, since the calculation of the corrections at the high concentrations in question presents difficulties,[13,14] and for the present purposes relative potential values are adequate. As has been pointed out by Brönsted and Pedersen[15] high precision in measuring relative potentials is obtained when the concentration of the oxidation–reduction system is small relative to that of the other electrolytes.

As a test of our technique we have repeated the determination of the potential of the arsenate–arsenite systems as a function of acidity and have obtained good agreement with the data of Foerster and Pressprich[16] as is shown by the graph of the values on Fig. 1, curve 2, where points from both sets of measurements are plotted.

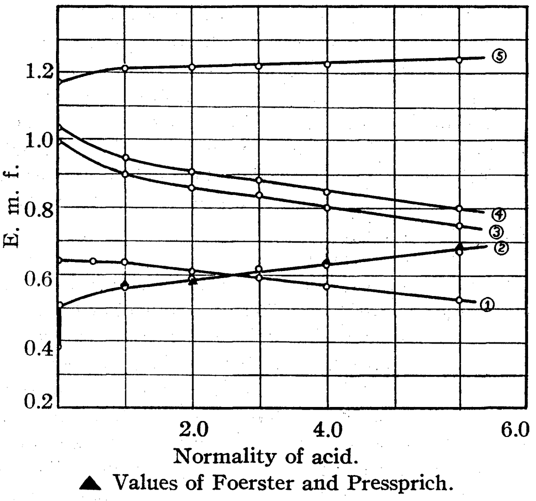

Fig. 1.—The abscissas represent normalities of hydrochloric acid, curves 1–5, or of sulfuric acid, curve 6. The ordinates represent oxidation–reduction potentials relative to the normal hydrogen electrode as zero, without correction for liquid junctions: (1), oxidation–reduction potentials of solutions 0.01 *N* in both iodine and iodide; (2), data for the arsenic system; solutions 0.01 *N* or 0.005 *M* in both forms of arsenic. The solid triangles are from measurements of Foerster and Pressprich:[7] (3), graph of potentials for the solutions used in (1) after adding 2 g. of mercuric chloride per 50 ml; (4), graph of potential values after adding 2 g. of mercuric chloride per 50 ml. of the solutions used in (3); (5), graph of potential values obtained upon adding 2 to 4 g. of solid mercuric sulfate to 50-ml. portions of solutions approx. 0.01 *N* in both iodine and potassium iodide and containing sulfuric acid as given on the abscissa axis.

Experimental

Apparatus and Materials.—Potentials were measured with a student-type assembly. Two spirals of bright platinum were used and averages of concordant readings of these relative to a saturated calomel electrode have been recorded. The side arm of the electrode terminated in a sintered porcelain plate. The cell was maintained at 25 ± 0.1° in a thermostat.

Potentiometric titrations were made by the classical

---

[11] Faull and Forbes, THIS JOURNAL, **55**, 1809 (1933), postulate the formation of iodine monochloride in 6 *N* HCl solution by the action of air and light upon iodine. Hübl (cited in Beckurts "Methoden der Massanalyse," F. Vieweg and Sohn Braunschweig, 1931, p. 162) inferred that iodine monochloride was formed by the interaction of mercuric chloride and iodine in alcoholic solution.

[12] Schoonover and Furman, *ibid.*, **55**, 3123 (1933).

[13] Taylor, *J. Phys. Chem.*, **31**, 1478 (1927).

[14] Guggenheim, *ibid.*, **33**, 842 (1929).

[15] Brönsted and Pedersen, *Z. physik. Chem.*, **103**, 307 (1922).

[16] Foerster and Pressprich, *Z. Elektrochem.*, **33**, 176 (1927).

method[17] or by the Furman and Wilson[18] continuous reading method. The calibrations of measuring vessels, standard cells and weights were checked against the secondary laboratory standards. Arsenious oxide from the Bureau of Standards was the basis of standardization of the volumetric solutions.

A solution approximately 0.02 *N* in iodine and in potassium iodide was prepared by dissolving 2.8806 g. of resublimed iodine and an equivalent amount (3.7678 g.) of dried reagent grade potassium iodide and diluting to 1 liter. An arsenate-arsenite solution of similar concentration was prepared from 1.0682 g. of reagent grade arsenious oxide dissolved in a minimum amount of sodium hydroxide, plus an equivalent amount (4.337 g.) of recrystallized sodium arsenate ($Na_2HAsO_4 \cdot 12H_2O$). The solution was made faintly acid to phenolphthalein and diluted to 1 liter.

Solutions of arsenite and antimonite for testing new titration procedures were prepared from Merck reagent grade arsenious oxide or from tartar emetic from the J. T. Baker Chemical Co., and analyzed iodometrically. Mercuric chloride was added in the form of a saturated solution in *N* hydrochloric acid.

Potential Measurements.—Twenty-five-ml. portions of the iodine–iodide solution were pipetted into the cell and the solution was diluted to 50 ml. with acid of the proper concentration to make the final concentrations as indicated in Table II. No attempt has been made to introduce corrections for triiodide ion formation because mercuric chloride is capable of binding both iodide ion and free iodine (or triiodide) to varying extents at various acidities. After making measurements on various mixtures of iodine–potassium iodide–acid, in each case 2 g. of solid mercuric chloride was added, and the mixture was stirred to constant composition and potential. The process was then repeated with the addition of 2 g. more of mercuric chloride. The data are recorded in Table II.

Table II

The Effect of Hydrochloric Acid and of Mercuric Chloride upon the Iodine–Iodide System at 25°

	Potential, Pt *vs.* satd. calomel, v.		
HCl, *N*	1 Soln. 0.01 *N* in I_2 & KI	2 As in 1 plus 2 g. $HgCl_2$ per 50 ml.	3 As in 2 plus 2 g. $HgCl_2$ per 50 ml.
0.0	0.400	0.760[a]	0.787[a]
.5	.400	.687[a]	.721[a]
1.0	.395	.662	.692

4.0	.345	.586	.604
6.0	.294	.531	.546

[a] In these instances a little solid iodine was observed. To each of the values (col. 1–3) 0.246 volt has been added in plotting Fig. 1.

A similar series of measurements was made upon solutions containing mercuric sulfate and sulfuric acid. Under these conditions mercuric iodide was first precipitated, but dissolved upon the addition of more mercuric sulfate. A fine white precipitate that separated was known to contain mercuric iodate bound in a complex compound.

Table III

The Effect of Sulfuric Acid and Mercuric Sulfate upon the Oxidation–Reduction Potential of Equivalent Mixtures of Iodine and Iodide at 25°

	Potential, pt. *vs.* satd. calomel, v.		
H_2SO_4 *N*	1 Soln. approx. 0.01 *N* in I_2 and KI	2 Soln. as in 1 plus 2 g. $HgSO_4$ per 50 ml.	3 As in 2 plus 2. g. $HgSO_4$
0.0	0.404	0.939	0.937
1.0	.404	.971	.966
2.0	.397	.980	.977
4.0	.379	.994	.996
6.0	.351	1.008	1.006

In this case it is evident that a reaction has occurred that has produced a system of very high potential (*iodate–iodide* system). The values are somewhat higher than the normal potential of the iodate–iodide–acid system because iodide ions are bound in the form of undissociated or complex substances. A mixture of mercuric sulfate, potassium iodide, potassium iodate and sulfuric acid of composition within the range of the measurements gave a potential in the measured range.

Foerster and Pressprich[16] have shown that arsenate–arsenite mixtures approach equilibrium potentials slowly and that a small quantity of iodide hastens the process. They observed that the iodine–iodide potential did not interfere with the measurements as long as the amount of this system added was equivalent to less than 10% of the arsenate–arsenite system. In our measurements a very minute crystal of potassium iodide was added to each solution so that the ratio of the two forms of arsenic was practically 1:1 at 0.01 *N* for each form.

Discussion

The graphs (1, 2, Fig. 1) for the arsenic and iodine systems represent the oxidizing power of equivalent mixtures of the two forms in each case. At the beginning of the titration of a solution 0.01 N in arsenite and 1–2 N hydrochloric acid, the arsenate–arsenite ratio would be small and the potential would lie about 0.0885 volt below curve 2, while the potential of an iodine–iodide system, formed by the momentary *liberation of iodine* by interaction of iodate and the small amount of iodide derived from the iodate that had been added up to this point, would lie 2 or 3 times 0.059 volt above curve 1, Fig. 1. The iodine would be immediately reduced by the arsenite. This simple explanation in terms of oxidation–reduction potentials seems to account more adequately for the non-appearance of iodine in the early stages of such a titration than the qualitative interpretation in terms of relative reaction rates that were given by Schoonover and Furman.[12] In the latter a slow rate was attributed to the interaction of iodate, iodide and acid. As the titration proceeds, the relative positions of the two systems on the potential scale are reversed, and there is a sharp equivalence point corresponding to the oxidation of arsenite to arsenate and the reduction of iodate to iodine.

Figure 1 also indicates that the iodine–iodide system with mercuric chloride added is above the arsenate–arsenite system over the range of acidity that was studied. An increase in the concentration of mercury tends to bind the iodide more completely and the potential of a 1:1 mixture is raised still further by the increase.

The considerations that have been presented indicate clearly that new applications of iodine as an oxidizing agent may be made if mercuric chloride is added to the acidified solution that is to be titrated. Hitherto iodine has been used to titrate only the more powerful reductants such as stannous tin in acid solution. The latter may be titrated with iodate, which is reduced to iodide.[19] The steadiness of potentials at the end-points indicates that the presence of mercuric chloride tends to eliminate the troublesome autoxidation of iodide by air, which is catalyzed by many ions.

The potentials measured for the iodine–iodide system in the presence of mercuric sulfate and sulfuric acid are very much higher than for mixtures containing comparable amounts of mercuric chloride and hydrochloric acid. In contrast with the latter, doubling of the quantity of mercuric sulfate had practically no effect upon the potential. The iodine color disappeared in the sulfate case, and both electrical and chemical evidence points to the formation of iodate and iodide. It is difficult to make use of this high potential for titration purposes because of the appearance of insoluble products containing iodate.

The Iodometric Determination of Arsenic and Antimony in Acid Solution in the Presence of Mercuric Chloride

The preceding sections have indicated that the determination of trivalent arsenic or antimony may be made with standard iodine in a new range of acidity if mercuric chloride is added. The obvious advantages are the elimination of buffer mixtures and the possibility of operating in the presence of substances which would give undesirable precipitates or undergo oxidation at the pH which prevails in the usual iodometric method. It is necessary to use an excess of mercuric chloride that is sufficient to bind both the iodide introduced as potassium iodide in the standard solution and that which is formed by reduction of iodine.

The end-points of the oxidations may be determined either potentiometrically or with the aid of a suitable organic solvent for iodine, like carbon tetrachloride. The interference of mercuric chloride with the starch–iodide indicator for iodine is well known, and is probably to be attributed to binding of iodide and iodine by mercuric ion.[20] Mylius[21] proved that an iodide concentration of at least 10^{-6} g. is necessary. If an excess of potassium iodide is added, mercuric salts no longer interfere.[22] The early explanation by Millon[23] that mercuric chloride caused iodine to rearrange to iodine monochloride and iodide appears untenable because iodine may be extracted by carbon tetrachloride from solutions which fail to develop the color with starch.

Titration of Known Solutions.—Solutions of arsenite and antimonite were titrated with standard iodine solution in bicarbonate medium using starch as indicator. The titrations were repeated in solutions of various acidities with mercuric chloride present. In the latter case excel-

24.96	33.37	33.32	50	3.0[a]
20.00	26.80	26.70	25	2.8

[a] Indicates that the reaction was too slow to be practical at the acidity in question.

There are several factors which determine the range of acid concentration that is permissible. At low acidities mercuric iodide tends to precipitate, and at high acidities the rate of reaction diminishes. At high acidities the potentials of the two systems tend to converge. The best condition is the lowest acidity that prevents the precipitation of mercuric iodide. An increase in the amount of mercuric chloride often permits the use of less acid.

The range of acidity is more restricted for antimony than for arsenic. The oxidation–reduction potential of the antimony system lies higher throughout the range than that of the arsenic system although exact data are not available. Latimer and Hildebrand[24] give 0.75 volt as the E_0 value for the antimony system.

If carbon tetrachloride is used as an indicating medium the mixture must be stirred quite vigorously as there is a tendency for iodine to accumulate in this solvent prior to the end-point. In the potentiometric titration there is no tendency for the potential to drift to lower values at the end-point after violent stirring for several minutes.

Applications.—The new method was further tested upon weighed samples of pure arsenious oxide. End-points were found with good concordance both potentiometrically[18] and with carbon tetrachloride. The solutions contained 50 ml. of saturated mercuric chloride solution and were 1.2–1.7 *N* in hydrochloric acid.

	1	2	3	4
As_2O_3 present, g.	0.0453	0.0739	0.0697	0.1203
As_2O_3 found, g.	$.0453_5$	.0740	.0696	.1202

Substances of antimony content unknown to the operator (M) were examined. Weighed samples of tartar emetic were dissolved in 20 ml. of water and 50 ml. of *N* hydrochloric acid saturated with mercuric chloride. Found: 37.48, 37.52 and 37.57% Sb. Value established by other investigators and other methods, av. 37.54% Sb.

One-gram samples of an alloy were dissolved in sulfuric acid (10 ml. concn.) with the usual precautions to remove sulfur dioxide and to prevent oxidation by air. After addition of 2 g. of sodium and potassium tartrate and 10 ml. of concd. hydrochloric acid and 50 ml. of the mercuric chloride, and proper dilution, potentiometric titrations were made. Found: 7.29 and 7.27% Sb, Bureau of Standards Certificate value 7.31% Sb. Owing to the presence of copper and other ions the use of carbon tetrachloride is not recommended for indication in the analysis of antimony alloys.

THE DETERMINATION OF ANTIMONY WITH STANDARD POTASSIUM IODATE

Introduction

Potassium iodate was first used by Andrews[25] for the determination of trivalent antimony, and the application of the method was extended by Jamieson.[26] The conditions employed were concentrated hydrochloric acid medium 4–6 *N*, in which the iodate is reduced to iodine monochloride. Lang[27] also used potassium iodate for the determination of antimony, but under conditions that result in the formation of iodine cyanide in a solution 1.2 *N* in hydrochloric acid; this method has the advantage that starch indicator may be used.

In the present investigation the reaction between antimonite and iodate has been studied with the object of testing the various stoichiometric processes that are possible, particularly at low acidities, with or without the addition of mercuric chloride.

The Effect of the Concentration of Hydrochloric Acid upon the Stoichiometry of the Reaction between Antimonite and Iodate.—The acidity is the important factor in determining the stoichiometry of this reaction, as was observed by Schoonover and Furman[12] in the analogous reaction between arsenite and iodate. At a low range of acidities a definite equivalence point was detected corresponding to the reduction of iodate to iodine

$$5H_3SbO_3 + 2KIO_3 + 2HCl = I_2 + 5H_3SbO_4 + 2KCl + H_2O \quad (15)$$

In the absence of tartrates this "iodine" end-point is obtained over the narrow range of 2.4–3.5 *N* acid; with tartrates present the acidity may be as low as 1 *N*. Theoretically it might be possible to realize the stoichiometry of reaction (15) at somewhat higher acidities. The change in potential at the end-point would depend upon a transition from the iodine–iodide level to the iodine–iodine monochloride level which is less favorable for observation than a change to the iodine–iodate level.

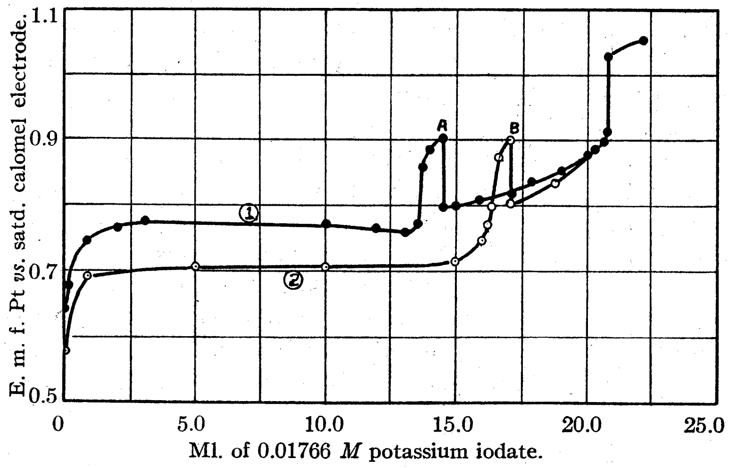

Fig. 2.—Curve 1: Graph of e. m. f. during titration of 0.0889 g. of antimony with 0.01766 *M* KIO_3 in the presence of mercuric chloride. Initial HCl concentration 2.7 *N*. At point A, HCl is added to bring its concentration above 5 *N*. Curve 2: repetition of titration as given in 1, with no mercuric chloride present.

The change in potential at the latter transition is only of the order of 0.03–0.07 volt per 0.05 ml. of 0.1 *N* potassium iodate. The classical potentiometric method rather than simplified methods was used for this small change. At acidities of 4–6 *N* the iodine that is liberated in the first reaction (15) is oxidized to iodine monochloride

$$2I_2 + KIO_3 + 6HCl = 5ICl + KCl + 3H_2O \quad (16)$$

and a second end-point is realized by adding hydrochloric acid and titrating to a second break in potential. The addition of the acid produces a drop in potential point B, curve 2, Fig. 2. At the latter end-point 0.05 ml. of 0.1 *N* iodate produces a rise of 0.07–0.12 volt. The presence of tartrate does not interfere with the detection of either end-point.

It was observed[12] that the presence of an immiscible organic solvent for iodine increases the potential change at the iodine equivalence point. Benzene is more effective than carbon tetrachloride and is to be recommended if the iodine end-point alone is to be determined. If the iodine monochloride end-point is also to be found, carbon tetrachloride offers mechanical advantages: ease of stirring from its position below the aqueous layer, and prevention of loss of iodine by volatilization.

The potassium iodate was 0.01766 *M*. The normalities for the iodide, iodine or iodine monochloride end-points are, respectively, 6, 5 or 4 times the molarity.

The iodine end-point was also obtained by titrating antimonite with iodate in sulfuric acid solutions from 2.7 to 6.0 *N*. In twelve determinations the maximum error was 0.2%. Only the iodine end-point is obtained in this medium.

The Oxidation of Trivalent Antimony in Hydrochloric Acid Solution with Mercuric Chloride Present.—In the presence of mercuric chloride there is a sharp end-point at the completion of the reduction of the iodate to iodide

$$3H_3SbO_3 + KIO_3 \xrightarrow[(HgCl_2)]{(HCl)} 3H_3SbO_4 + KI \quad (17)$$

[a] The few experiments that have been selected include a fair sampling of the most and least accurate results of the whole series.

[b] Low initial acidity possible because tartrate was present.

We have explained the mechanism of this process on the basis of the formation of undissociated mercuric iodide which is soluble in hydrochloric acid. The iodine–iodide potential is so far increased by this process that iodine formed momentarily during the reaction is immediately reduced to iodide by the antimonite. The relative levels of the iodine and antimony systems under these conditions have been discussed (p. 158).

The first small increment of standard iodate beyond the iodide end-point produces free iodine which may be detected readily by extraction to a layer of carbon tetrachloride, and this simple visible indication agrees with the potentiometric end-point within about 0.02 ml. of 0.1 *N* solution. At acidities below 3.5 *N* the change in e. m. f. is of the order of 0.25 volt per 0.05 ml. of 0.1 *N* iodate at the end-point. The continuous-reading circuit was used for most of the determinations that are represented in Table VII. In many cases carbon tetrachloride was also present and a double indication was obtained. After the finding of this first end-point, increase of hydrochloric acid concentration to 4–6 *N* again causes a drop in potential (A, curve 1, Fig. 2) and the titration may be carried to the iodine monochloride point.

Discussion

The general conclusions of these studies of the stoichiometry of the antimony reactions are similar to those in the investigation of the determination of arsenic;[12] the rather obvious conclusion that both arsenic and antimony if present together would be determined simultaneously according to any of the three possible reactions, has been verified by experiments which need not be detailed here.

The possibility of visual estimation of the iodide end-point has been pointed out; this applies to the determination of arsenic as well, although it was not noted in the former investigation.[12] We believe the mechanism of the oxidations by iodate in the presence of mercuric chloride to be essentially the same as those by iodine. The use of iodate rather than iodine offers the advantage of detecting the iodine monochloride end-point if the first end-point is overstepped.

Summary

1. The fact that the addition of iodine to solutions of mercuric salts in sulfuric, perchloric and nitric acids produces an immediate rearrangement into equivalent quantities of iodide and iodate has been confirmed.

2. The apparent failure of strong oxidizing agents to oxidize halides in the presence of highly ionized mercuric salts has been explained by showing that an oxidation does occur, but that the total oxidizing power of the solution toward a strong reducing agent like potassium iodide is preserved due to the autoxidation of the halogen under these conditions.

3. The effect of chlorides upon mixtures of bromate, iodide and mercuric nitrate has been observed, and the peculiar properties of solutions of iodine in mercuric chloride have been pointed out.

4. The ability to obtain the iodide equivalence point in the reaction between iodate and arsenite in the presence of mercuric chloride and hydrochloric acid has been attributed to an increase in the iodine–iodide potential due to the removal of iodide ions from solution as un-ionized mercuric iodide which is soluble in hydrochloric acid.

5. The oxidation–reduction potentials of equivalent mixtures of arsenate and arsenite and of iodine and iodide have been measured at various concentrations of hydrochloric and sulfuric acids. The very marked effect of mercuric chloride and mercuric sulfate upon the potentials of the iodine–iodide mixtures has been determined, and the increase has been attributed to binding of iodide by mercuric ions when chlorides are present and to the formation of iodate in the solutions containing sulfates.

6. It has been shown that a standard iodine solution may be used to titrate arsenite in solutions 1.2–3.8 *N* in hydrochloric acid, or antimonite in solutions 2–2.8 *N* in the acid, provided mercuric chloride is added to increase the iodine–iodide potential to a sufficient extent. This new

mode of titrations has been applied to the determination of arsenic and antimony in a few of the materials that are encountered in practice.

7. It is possible to determine antimony with standard potassium iodate under conditions such that the iodate may be reduced, as desired, to iodide, iodine or iodine monochloride. The first and third, or the second and third of the possible stoichiometric processes may be realized to give two end-points in a single titration. The new procedures involving the reduction of iodate to iodine at low acidities, or to iodide at low acidities in the presence of mercuric chloride, give results which compare favorably in accuracy with those obtained by other procedures.

The Use of Iodine and of Potassium Iodate as Volumetric Oxidizing Agents in Solutions Containing Mercuric Salts. II. The Oxidation of Phenylhydrazine and of Semicarbazide by Means of Potassium Iodate

BY CLARK O. MILLER AND N. HOWELL FURMAN

Introduction

The nature and proportions of the end-products of the oxidation of hydrazine and its derivatives vary with the specific nature and the oxidation–reduction potential of the oxidizing system and with the *p*H of the medium. These facts have been established by various investigators.[1] It is a striking fact that hydrazine is oxidized quantitatively to nitrogen and water only by iodine, bromine or certain halogen oxyacids or salts;[1a,c] in other cases variable amounts of hydrazoic acid and ammonium salts are formed.

The determination with iodine must be made in buffered neutral or alkaline solutions since the reaction is too slow in acid medium for direct titrations. Hydrazine and its derivatives, especially phenylhydrazine, are readily oxidized by air under these conditions and hence the iodine method is of limited applicability.

We have shown[2] that the addition of mercuric chloride to the acidified solution that is to be titrated makes it possible to realize the stoichiometry of the reduction of iodate to iodide or of iodine to iodide smoothly in a range of acidity that would not be possible in the absence of the mercuric salt. This development increases the scope of iodine and iodate methods. We have chosen the oxidation of phenylhydrazine and of semicarbazide, respectively, as further illustrations of the application of potassium iodate under the new conditions of titration.

Phenylhydrazine.—Emil Fischer[3] stated that an emulsion of phenylhydrazine and water reacted as follows with iodine

$$2C_6H_5NHNH_2 + 2I_2 = 3HI + C_6H_5NH_2{\cdot}HI + C_6H_5N_3 \quad (1)$$

If an excess of hydrazine is used (2 moles per mole of $C_6H_5NHNH_2$) the reaction that occurs is

$$C_6H_5NHNH_2 + 2I_2 = 3HI + C_6H_5I + N_2 \quad (2)$$

according to von Meyer.[4] A volumetric process was based upon reaction (2) by adding a measured excess of standard iodine to the slightly alkaline solution, followed by back-titration with standard thiosulfate.

Fehling's solution oxidizes phenylhydrazine to nitrogen, water and benzene, and the nitrometric method of Watson Smith[5] is based on this reaction.

Seide, Scherlin and Bras[6] state that iodic acid reacts with phenylhydrazine in benzene–water emulsion to give a 25% yield of monoiodobenzene. Rimini[7] noted that hydrazine was oxidized by iodic acid, and Kurtenacker and Kubina[8] stated that direct titration of phenylhydrazine and semicarbazide with iodate to the iodine monochloride end-point is possible, but gave experimental evidence only for the latter compound. They also studied the determination of both substances with standard potassium bromate.

Mechanism of the Oxidation.—In our studies, two observations were made which do not seem in

[3] Fischer, *Ber.*, **10**, 1335 (1887).

[4] E. von Meyer, *J. prakt. Chem.*, **36**, 115 (1887).

[5] Watson Smith, *Chem. News*, **93**, 83 (1906).

[6] Seide, Scherlin and Bras, *J. prakt. Chem.*, **138**, 225 (1933).

[7] Rimini, *Gazz. chim. ital.*, **35**, I, 267 (1905).

[8] Kurtenacker and Kubina, *Z. anal. Chem.*, **64**, 388 (1924).

accord with the equation of von Meyer.[4] First, no liberation of nitrogen was observed in the early stages of the reaction, and second, no monoiodobenzene was detected. Nitrogen was evolved slowly toward the end of the titration. Upon treatment of the partially oxidized solution with alkaline beta-naphthol, a red dye was formed, indicating the presence of a diazonium salt. Equations for the three types of iodate processes may then be written:

(a) In 1–3 *N* HCl with mercuric chloride present

$$3C_6H_5NHNH_2 + 2KIO_3 + 3HCl = 3C_6H_5NNCL + \underset{\underset{HgI_2}{\downarrow}}{2KI} + 6H_2O \quad (3)$$

(b) In 1–3 N HCl

$$5C_6H_5NHNH_2 + 4KIO_3 + 9HCl = 5C_6H_5NNCl + 2I_2 + 12H_2O \quad (4)$$

(c) In 4–6 *N* HCl

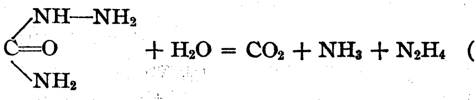
$$C_6H_5NHNH_2 + KIO_3 + 3HCl = C_6H_5NNCl + ICl + KCl + 3H_2O \quad (5)$$

The quantitative oxidation appears to be concerned with the formation of the diazonium salt, and the reaction of the latter with the medium to give nitrogen and phenol is a secondary process. The presence of phenol was confirmed by evaporating the solution to a small volume and coupling with phthalic anhydride.

The formation of the diazonium salt was also observed when phenylhydrazine was titrated with iodine. If a large excess of iodine–potassium iodide solution were used, both phenol and iodobenzene probably would be formed.

Chattaway[9] has shown that primary aromatic amines are transformed into diazonium salts by the action of other halogens (Cl_2 or Br_2) in glacial acetic acid solution.

Semicarbazide.—Prior studies of the determination of semicarbazide have been along the same lines as in the case of hydrazine. It was shown by Maselli[10] that semicarbazide is hydrolyzed with the formation of hydrazine by boiling in dilute sulfuric acid solution



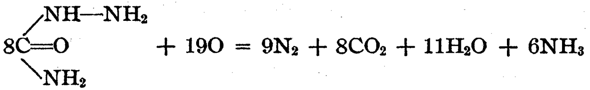
$$C{=}O\begin{smallmatrix}\diagup NH{-}NH_2\\ \diagdown NH_2\end{smallmatrix} + H_2O = CO_2 + NH_3 + N_2H_4 \quad (6)$$

The general concept that the hydrolysis of the compound must precede its oxidation apparently persists.[11]

Kurtenacker and Kubina[8] suggested two procedures for the determination of semicarbazide with potassium iodate. One consisted in adding a measured excess of standard potassium iodate, boiling to expel iodine and back-titration of the excess of the iodate. The other method was the conventional direct titration to the iodine monochloride end-point; few test analyses were given.

Hovorka[12] devised an indirect procedure for the determination of semicarbazide, using mercuric perchlorate and iodate. Thirty minutes are usually required for the oxidation to reach completion, after which the excess of iodate is determined by adding an excess of potassium iodide and titrating the iodine with standard thiosulfate solution. The chief advantage that this method offers is that the necessity of boiling iodine out of the solution is eliminated.

The oxidation of semicarbazide with either chlorate, bromate or iodate was investigated by Datta and Choudhury[13,14] with the object of developing a gasometric method for estimating the compound. The equation that was given for the reaction is

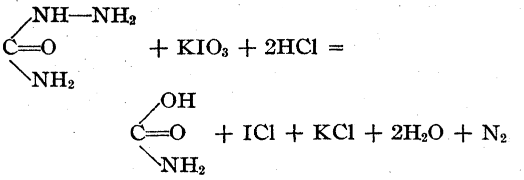


$$8C{=}O\begin{smallmatrix}\diagup NH{-}NH_2\\ \diagdown NH_2\end{smallmatrix} + 19O = 9N_2 + 8CO_2 + 11H_2O + 6NH_3 \quad (7)$$

The results deviate as much as 3.0% from the theoretical. The carbon dioxide must be absorbed. The fact that a functional group, $-NH_2$, is partially oxidized seems to make this type of procedure uncertain.

Bartlett[15] reported that 99.9% of the semicarbazide present was oxidized by excess of iodine in three seconds in a phosphate buffer of *p*H 7.

From a consideration of the various facts, the rapid reaction of semicarbazide with iodine in neutral solution or with iodate in acid solution is not due to hydrolysis, but depends upon direct attack of the hydrazine group with intermediate formation of unstable carbamic acid, which immediately breaks down to give carbon dioxide and ammonia



$$C{=}O\begin{smallmatrix}\diagup NH{-}NH_2\\ \diagdown NH_2\end{smallmatrix} + KIO_3 + 2HCl = C{=}O\begin{smallmatrix}\diagup OH\\ \diagdown NH_2\end{smallmatrix} + ICl + KCl + 2H_2O + N_2 \quad (8)$$

In solutions that are lower than 3 N in hydrochloric acid the iodate is reduced to iodine if mercuric salt is absent, or to iodide if mercuric chloride is present in concentration sufficient to bind the iodide. The latter stoichiometry has not been realized hitherto in a direct titration.

Experimental

Since the researches of Ardagh, *et al.*[16] have shown that solutions of phenylhydrazine are relatively unstable, even when acidified, and must be preserved under an inert atmosphere, it was found desirable in our work to weigh samples of purified phenylhydrazine hydrochloride for each experiment. Samples of an Eastman product were recrystallized from hot water after decolorizing them with charcoal. The crystals were washed thoroughly with alcohol, then with ether and were dried by vacuum desiccation overnight. Drying for short intervals at 100° is also permissible, but at higher temperatures discoloration occurs and partial rearrangement to *p*-phenylenediamine takes place.

The purity of the crystals was tested by titration of samples with sodium hydroxide that had been standardized against pure benzoic acid, using phenolphthalein indicator. At the equivalence point the solution contains sodium chloride and free phenylhydrazine, $K_b = 1.6 \times 10^{-9}$. Hence for solutions between 0.1 and 0.01 N the *p*H at the end-point is from 9.1–8.6. In a series of nine titrations the maximum error was ±0.25% and the average was +0.03%, on the assumption of a pure product.

The standard potassium iodate and the mercuric chloride solutions were prepared as in the preceding investigation,[2] where the nature of the electrical apparatus is also mentioned.

Semicarbazide hydrochloride, from the G. F. Kahlbaum Co., was purified by dissolving in distilled water, filtering, and precipitating by the addition of 1–2 volumes of ethyl alcohol. The crystals were filtered, washed repeatedly with 95% alcohol, then with ether. After vacuum desiccation overnight the material was suitable for weighing. The tested technique of purification together with the titrations to the iodine monochloride point with iodate served to establish the purity of the material.

The Titration of Phenylhydrazine Hydrochloride with Standard Potassium Iodate in the Presence of Hg^{++}.—Portions of the purified substance ranging from 0.08 to 0.26 g. were titrated in solutions of various acidities as shown in Table I. In each case 15–25 ml. of saturated mercuric chloride was present, and the final volume after titration was about 150 ml. In neutral or feebly acid solution phenylhydrazine reduces mercuric ion; it is therefore desirable to acidify the solution before adding the phenylhydrazine. No reduction occurred when the acidity was at least 2 N. If only a small amount of mercurous chloride is formed, the solution need not be discarded because the iodate oxidizes the mercurous chloride to mercuric, during the titration.

At the end of the titration to the first end-point (iodide) the potential jump is 0.06 to 0.08 volt per 0.05 ml. of 0.1 N KIO_3; either classical or simplified methods may be used. The use of carbon tetrachloride for the "iodide" end-point is not very satisfactory.

TABLE I

POTENTIOMETRIC TITRATION OF PHENYLHYDRAZINE WITH POTASSIUM IODATE SOLUTION IN THE PRESENCE OF MERCURIC CHLORIDE

1 Sample, g.	2 KIO_3 to iodide end-pt., ml.	3 $C_6H_5N_2H_3HCl$ found from 2, g.	4 KIO_3 to ICl end-pt., ml.	5 Subst. found from 4	6 Concentration of HCl, N	7
					Init.	Final
0.1831	35.55	0.1833	53.30	0.1832	1.1	3.6
.1119	21.73	.1120	32.53	.1118	2.8	4.0
.1447	28.05	.1446	42.05	.1446	2.6	4.2
.1328	25.70	.1325	38.59	.1326	2.8	3.9
.1590	30.77	.1587	46.08	.1584	1.6	5.0
.1099*	21.28	.1098	32.05	.1101	3.2	4.1
.1219*	23.63	.1218	35.50	.1220	3.6	4.2
.1159*	22.45	.1158	33.66	.1157	2.4	3.9

The KIO_3 solution was 0.02378 M and the normality is, respectively, 6 or 4 times molarity for the iodide and iodine monochloride end-points. In the last three determinations, marked (*), from 0.5 to 1 ml. of aniline was present.

After finding the first end-point, the stoichiometry of equation (5) may be realized by continuing the titration after adding hydrochloric acid to 4–6 M concentration. Potential break: 0.12–0.16 volt per 0.05 ml. of 0.1 N KIO_3. Care must be taken to avoid the accumulation of nitrogen bubbles on the platinum indicator electrode.

It is of interest that potassium iodate oxidizes the hydrazine group selectively in the presence of an aromatic amine (aniline), whereas more powerful oxidants attack the latter under similar conditions.

A series of eight determinations under conditions similar to those indicated in Table I, but with omission of the mercuric salt, proved that it was possible to realize the stoichiometry of equation (4); after adding hydrochloric acid to 4–6 M concentration the titration may be continued to a second end-point corresponding to equation (5). The maximum errors were +0.20 and −0.30%. Only three determinations were in error by more than 0.2%.

A critical experimental study of the conventional iodine method yielded the following conclusions: low results are obtained in alkaline solution; the reaction is incomplete in strongly acid solution; correct results are obtained when the *p*H of the solution is between 2 and 5. We found the iodine method to be tedious due to the sluggishness of the reaction near the end-point. We regard the various iodate procedures that have been described as far superior to the titration with iodine.

The Oxidation of Semicarbazide in the Presence of Mercuric Chloride.—The weighed samples were dissolved in water and hydrochloric acid (see Table II) and 15–30 ml. of saturated mercuric chloride solution was added. The initial volume ranged from 40–80 ml. The progress of the reaction was followed potentiometrically or by noting the readings of a sensitive galvanometer in series with a high resistance. The reaction is slow near the "iodide" end-point, so that the last 0.2 ml. of reagent must be added in drops at about thirty-second intervals. Each drop produces a potential rise which diminishes rapidly prior to the end-point, but does not diminish at the end-point; change, 0.08 volt per 0.05 ml. of 0.1 N KIO_3. Up to a certain limit the addition of more mercuric chloride makes the process more rapid.

---

[16] Ardagh, *et al.*, THIS JOURNAL, **54**, 721 (1932).

The iodine monochloride equivalence point is very sharp and must be recommended as the most satisfactory for ordinary titrations. If a carbon tetrachloride layer is used for indication, very thorough stirring or shaking is necessary near the end-point. The break in e. m. f. is about 0.13 volt per 0.05 ml. of 0.1 N reagent. The data in Table II are fairly representative of 22 determinations that were made.

TABLE II

POTENTIOMETRIC TITRATION OF SEMICARBAZIDE HYDROCHLORIDE WITH STANDARD POTASSIUM IODATE IN THE PRESENCE OF MERCURIC CHLORIDE

1	2	3	4	5	6	7
Sample, g.	KIO_3 to "iodide" end-pt., ml.	Subst. found from 2 g.	KIO_3 to ICl end-point, g.	Subst. found from 4 g.	Concn. of HCl, N	
					Initial	Final
0.1263	31.80	0.1264	47.50	0.1266	1.1	6.1
.1026	25.76	.1025	38.68	.1026	0.8	3.7
.1362	34.73	.1362	52.04	.1361	.8	3.4
.1514	38.48	.1509	57.84	.1514	1.7	4.3
.0627	15.95	.0626	24.00	.0627	1.3	5.0
.1070	27.20	.1066	40.82	.1067	1.2	4.0
.0874*			33.42	.0874		4.65
.1612*			61.70	.1613		4.3
.1055			40.40	.1058		4.8

The potassium iodate solution was 0.02378 M for the first two determinations and 0.02344 for the others. The normalities for the iodide and iodine monochloride reactions are, respectively, 6 and 4 times the molarity. In the determinations marked (*) the solution contained 0.1 to 0.5 g. of urea. Potassium iodate oxidizes the aliphatic hydrazine derivative selectively in presence of the corresponding amino compound just as was the case with the aromatic substances.

A number of experiments proved that it was impractical to base a direct titration on the process involving the reduction of the iodate to iodine in dilute hydrochloric acid solution (less than 3 N) in the absence of mercuric chloride. The reaction was extremely slow in the neighborhood of the end-point.

Of the determinations made to the iodine monochloride point only four deviated as much as 0.21–0.27% from the theoretical value, and the average deviation was −0.05%. Semicarbazide could therefore serve as a standard substance since it is purified and preserved easily. The substance has suitable characteristics for the removal of an excess of an oxidizing agent that is not powerful enough to attack the amino group. The nature of the products (CO_2, N_2, ammonium salt and water) is favorable for such application.

Summary

1. The oxidation of phenylhydrazine in acidic solution by potassium iodate or by iodine has been shown to result in the formation of the diazonium salt which slowly hydrolyzes giving off nitrogen and forming phenol in the absence of an excess of potassium iodide.

2. The iodate procedures have been compared with the iodine method and they offer decided advantages of rapidity and ease of execution.

3. Potassium iodate does not attack aniline readily in cold acidified solutions and correct results are obtained for phenylhydrazine in the presence of the former.

4. The optimum conditions for the stoichiometric reduction of iodate to iodide, with mercury present, or to iodine monochloride in 3–6 N hydrochloric acid solution by both phenylhydrazine and semicarbazide have been investigated. In the case of phenylhydrazine it was also found possible to obtain an end-point corresponding to the reduction of the iodate to iodine, at low acid concentration.

5. The mechanism of the oxidation of semicarbazide has been considered and it has been pointed out that hydrolysis need not precede the oxidation process.

6. Potassium iodate attacks urea very slowly in cold acidified solutions and semicarbazide may therefore be titrated selectively in the presence of the former substance.

The Kinetics of Gaseous Addition of Halogen Acids to Isobutene

BY G. B. KISTIAKOWSKY AND C. H. STAUFFER

In a recent paper[1] the thermal decomposition of tertiary butyl chloride into hydrogen chloride and isobutene has been shown to be a clean gaseous unimolecular reaction. The present communication deals with some measurements of the tertiary butyl bromide decomposition, and with the study of the reverse reactions. These latter are of considerable interest because work on liquid phase reactions of this type has led to the discovery of peculiar effects, due supposedly to the presence of oxygen or peroxides,[2] and because Maass[3] has claimed that a discontinuity in reaction rates exists in the transition from the liquid to the gaseous state which cannot be explained by the concentration effect alone.

Equilibrium between halogen acids and olefinic hydrocarbons in the gaseous state has been investigated in the past infrequently. The work of Brunel[4] on isobutene and hydrogen bromide will be discussed later. Wibaut, Rutgers and Diekmann[5] reported an 84.4% yield of ethyl chloride at *ca.* 200° and atmospheric pressure, while Tilman[6] finds about 4% decomposition of ethyl chloride around 120°. These studies have been made with the aid of catalysts. While they possibly cannot be regarded as very accurate determination of equilibria, they indicate, as will be seen from comparison with the data here presented, that the free energies of formation of alkyl halides are not greatly dependent either on the alkyl or on the halogen constituent of the molecule.

The study of the decomposition of tertiary butyl bromide using technique developed earlier for the chloride presented no new difficulties, but repeated experiments made to study the addition of hydrogen chloride and bromide to ethylene, pentene-2 and isobutene[7] failed to discover any homogeneous reaction. This is in accord with the findings of Maass, but it does not mean that the gaseous kinetics of these reactions are in any way "abnormal." As will be seen later, the activation energies of the association reactions with isobutene are fairly high, causing slow rates at lower temperatures, while at higher temperatures the equilibria are too unfavorable for a study at and below atmospheric pressure.

It thus became necessary to determine their kinetics by combining rate expressions for the decomposition with equilibria data; the latter were obtained with the aid of catalyzed reactions. This procedure suffers, of course, from increased errors, but the over-all accuracy is sufficient, we believe, to draw the most essential conclusions.

Experimental

The decomposition of *t*-butyl bromide and the equilibrium composition in both reactions were studied in a static system by pressure measurements. For the decomposition experiments the system was the same as described previously;[1] it was used also for the equilibria studies, but in this case the containers of the halogen hydrides were separated from the reaction flask by a glass valve, whereas between the isobutene and the *t*-butyl halide containers and the flask were stopcocks followed by a glass valve. This latter communicated also, through a third stopcock, with the pumping system.

The same treatments of the flask, even perhaps somewhat more protracted, were necessary to obtain a homogeneous decomposition of *t*-butyl bromide as were described in the case of *t*-butyl chloride.

For the equilibria studies flasks of varying catalytic activity were used at the several temperatures studied. For the lowest temperature a one-liter flask filled with 100 g. of glass wool (soft glass) was prepared; the others were filled with broken glass (Pyrex) of about pea size and with pieces of 10-mm. tubing, while for the highest temperatures an empty flask was found to give the most convenient rates. The equilibrium was usually indicated by a complete cessation of pressure changes, but in some cases a very slow, steady decrease of pressure was observed, due, no doubt, to a polymerization reaction of the olefin. In these runs the equilibrium pressure was extrapolated to zero time assuming a constant rate of polymerization. The whole correction was small.

According to Brunel,[4] besides the *t*-butyl halide, considerable quantities of the isobutyl halide are formed at temperatures in the neighborhood of 270° (25% of isobutyl bromide), while at 100° their relative yield is negligible. If true, this finding would indicate that the heat of formation of the iso compound differs very considerably from that of the tertiary halide, while the free energies of their formation are nearly identical at 270°. Such a conclusion

[7] Hydrogen bromide and isobutene have a barely measurable homogeneous rate at 300°. About 2% reaction occurs in six minutes with little further change.

is not very plausible and Brunel's measurements were repeated avoiding his most probable source of error, a reaction between condensed isobutene and hydrogen bromide. The method consisted in passing a metered mixture of hydrogen chloride and isobutene through a flask packed with glass wool and maintained at 270°. The contact time was more than amply sufficient to establish equilibrium. After leaving the furnace the gases passed through several bubblers containing a 7.5% solution of sodium bicarbonate, to remove hydrogen chloride, then a calcium chloride tube and a trap at 0° in which the alkyl chlorides were collected; another trap, at −80°, collected the unreacted isobutene. About 13 cc. of butyl chlorides was obtained. This was distilled through a 3-ft. (91 cm.) Podbielniak-type column with a 10:1 reflux ratio. Less than 0.5 cc. came over before 50.4° and the rest boiled at 50.6° until the pot was dry. The hold-up in the column amounted to 1.5 cc. It had a refractive index of $n^{20}{}_D$ 1.3901, while the distillate had a (uniform) refractive index of 1.3839. If this entire difference is attributed to the presence of isobutyl chloride in the residues, its concentration in the initial mixture is found to be 7.8%. Considering all probable errors, such as the higher volatility of *t*-butyl chloride, the presence of polymers, etc., the real concentration is probably smaller. This experiment could not be repeated with hydrogen bromide because of rapid hydrolysis of *t*-butyl bromide by the bicarbonate solution, but we believe that essentially the same conditions prevail in that system also. Brunel's finding is accountable by a reaction between hydrogen bromide and isobutene when these were condensed to a liquid, which would probably give, since oxygen was not carefully excluded, mainly isobutyl bromide. In his experiments at 100°, on the other hand, only a little free hydrogen bromide remained upon establishment of gaseous equilibrium and thus the liquid phase reaction was insignificant.

Preparation of the Materials.—The *t*-butyl bromide was obtained from Eastman Kodak Co. and was purified by a slow crystallization with stirring. When approximately half of the material was frozen, the crystals were separated from the liquid, and used for the kinetic experiments. No difference in results was observable between different samples. The *t*-butyl chloride was made as described previously.[1]

The isobutene was part of the material prepared in this Laboratory for the calorimetric study of its heat of hydrogenation[8] and was used without further purification.

Hydrogen chloride was prepared by dropping concd. C. P. sulfuric acid on sodium chloride and concd. hydrochloric acid solution. It was dried over sulfuric acid, liquefied and distilled once from trap to trap *in vacuo*. The middle third was used.

Hydrogen bromide was prepared by dropping bromine on naphthalene. The evolved gases were led over naphthalene and copper turnings, to remove unreacted bromine. Hydrogen bromide was liquefied and distilled from trap to trap once. The middle third was used.

Results and Interpretation.—A summary of the rate constants and the experimental data for the thermal decomposition of the tertiary butyl bromide will be found in Table I. Run 95p was carried out in a packed flask having ten times the surface volume ratio of the unpacked flask. The packed flask had been given nine treatments to deactivate the glass surface. Each treatment consisted in allowing about 200 mm. of *t*-butyl bromide to decompose in the flask at a temperature of 500° for from five to ten hours. The comparison indicates quite clearly the homogeneity of the reaction.

TABLE I

DECOMPOSITION OF *t*-BUTYL BROMIDE

Run	T, °K	P, mm.	$k \times 10^4$, sec.$^{-1}$
87	508.9	97	0.836
95p	509.9	101	1.07
88	510.2	96	1.01
84	526.1	93	3.41
82	540.5	101	9.40
85	559.3	95	32.5

83	562.7	95	42.0
86	564.8	95	44.0

In Tables II and III will be found the equilibrium constants for the chloride and bromide, respectively. Runs whose numbers include an (a) are those in which the equilibrium was approached from the side of addition, while the letter (d) refers to an approach through the decomposition reaction. Those containing (ad) refer to runs in which the tertiary bromide was first decomposed at a rate too rapid to get an accurate initial pressure, and then the reaction was forced back by introducing a measured amount of hydrogen bromide and following the pressure until the equilibrium was again established. The usual plot of the decomposition rate constant of the bromide gives a good straight line and leads to an activation energy of 40,500 ±

38a	531.7	218.1	.438

1000 cal. Using this value, the expression for the rate constant can be cast into the form

$$\text{(Bromide) } k_{\text{d}} = 10^{13.3 \pm 0.4}\, e^{-(40,500 \pm 1000)/RT} \text{ sec.}^{-1}$$

To be compared with it is the expression for the decomposition of the chloride:[1]

$$\text{(Chloride) } k_{\text{d}} = 10^{13.9 \pm 0.7}\, e^{-(45,000 \pm 1900)/RT} \text{ sec.}^{-1}$$

It is apparent that while the activation energies of the two reactions are markedly different (see Fig. 1), the *A* factors, within experimental uncertainties, are identical. The lower activation energy of the bromide is in good accord with the lesser stability of this compound as is known from general chemical experience.

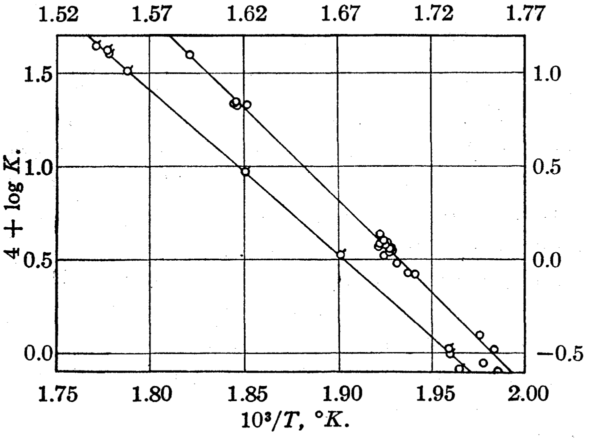

Fig. 1.—Plot of the reciprocal of the absolute temperature against the logarithm of the unimolecular rate constant. Upper curve refers to the decomposition of *t*-butyl chloride, and the lower curve to *t*-butyl bromide.

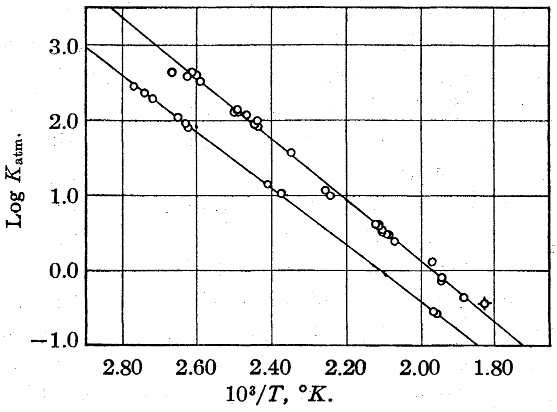

Fig. 2.—Plot of the reciprocal of the absolute temperature against the logarithm of the equilibrium constants expressed in atmospheres. The upper curve refers to the HBr, isobutane, and *t*-butyl bromide equilibrium, and the lower curve to the HCl, isobutane, and *t*-butyl chloride equilibrium. The crossed circle is a value found by Brunel.

The logarithmic plots of the two equilibrium constants will be found in Fig. 2 together with the values given by Brunel.[4] Both equilibria give good straight lines and the expressions for the constants can be cast into the forms

$$\text{(Chloride) } \log K = (17{,}100/4.58T) - 7.89$$
$$\Delta F^{\circ} = 17{,}100 + 36.1T \text{ (atmospheres standard)}$$

with an uncertainty of *ca.* 500 calories in the heat of reaction;

$$\text{(Bromide) } \log K = (18{,}900/4.58T) - 8.12$$
$$\Delta F^{\circ} = -18{,}900 + 37.2T$$

with an uncertainty of *ca.* 900 calories in the heat of reaction. The difference of the two heats of reaction exceeds the probable error, even when the uncertainty caused by the possible formation of isobutyl halides is included. As stated before, Brunel's finding of a large amount of iso compound at 270° could not be substantiated and a plausible explanation of his experimental data has been offered. A correction for 8% iso chloride found at 270° (and a negligible amount at low temperatures) would change the heat of reaction only by some 200 cal./mole and can thus be disregarded in the following calculations.

Changing the equilibrium constants to mole/cc.

as units, converting the heats of reactions to constant volume and utilizing the relation

$$K = k_{\text{ass.}}/k_{\text{dec.}}$$

the following expressions are obtained for the association rate constants

$$(\text{Chloride})\ k = 10^{11.0 \pm 1.0}\, e^{-(28{,}800 \pm 2400)/RT} \text{ cc./mole sec.}$$
$$(\text{Bromide})\ k = 10^{10.2 \pm 0.7}\, e^{-(22{,}500 \pm 1900)/RT} \text{ cc./mole sec.}$$

As before, the A factors can be considered as identical within experimental errors, while the activation energies are decidedly different. This difference is even more marked than in the decomposition reactions.

The A factors of these reactions are considerably smaller than the usual kinetic collision factors, but this is to be expected in association reactions of large molecules and the best method to investigate whether they are "normal" is to compare them to the theoretical expressions for the rates of such reactions, as developed recently in several publications. Use will be made of the Eyring[9] notation and concept of the activated complex but no attempt will be made to calculate the potential energy surface of the reaction. It will be assumed instead that the activated complex is identical in size and shape with the final molecule (*t*-butyl chloride), an assumption made by Rice and Gershinowitz[10] in their "exact orientation" theory. An estimate of the vibrational frequencies of the activated complex being uncertain, to say the least, these frequencies will be regarded as unknown and to be deduced from a comparison of the calculated and measured rate constants.

Two possibilities offer themselves for calculation. One may regard that CH_3 group, in the activated complex, which becomes $=CH_2$ group in isobutene as possessing free rotation. Then the activated complex is identical with *t*-butyl chloride in all degrees of freedom, but one, and the calculation conforms entirely to the "exact orientation" theory. Or, one may suppose that free rotation does not exist in the activated complex and that instead a torsional vibration (of low frequency) is present. The two methods of calculation lead to formally different equations. However, no decision is possible between them because numerically very similar results are obtained in both cases. This is due to the circumstance that the partition function of internal rotation of a CH_3 group (one degree of freedom) is almost equal numerically to the extra symmetry factor to be assigned to the activated complex when it is assumed to have free internal rotation of that group. If the activated complex has free rotation of all three (equivalent) methyl groups, its symmetry factor is taken at 3^4; if free rotation exists in only the non-reacting methyl groups, the factor is 3^2. The symmetry factor of the non-activated *t*-butyl chloride is 3^4, that of isobutene 18. The internal rotational partition function of CH_3 is calculated to be equal to 7.2 at 500°K. The other numerical data used are:

The product of the moments of inertia of isobutene is 6.6×10^{-115} g.^{3} cm.^{6}. The product of the moments of inertia of *t*-butyl chloride is 58×10^{-115} g.^{3} cm.^{6}. The moment of inertia of hydrogen chloride is 2.6×10^{-40} g. cm.^{2}. The former two have been calculated using Pauling's internuclear distances and tetrahedral angles. Using the internal free rotation model we find for the association reaction rate constant

$$k_{\text{ass.}} = 1.5 \times 10^9 \frac{F^*}{F_1 F_2} \frac{500}{T} e^{-(E_0 - RT)/RT} \text{ cc. mole}^{-1} \text{ sec.}^{-1} \quad (1)$$

The F's stand here for the vibrational partition functions, F^* containing three more of them than F_1 and F_2 together. The value before the exponential cannot be compared directly with the experimental figure because of differences in the activation energy. The following procedure which has been adopted to correct E_0 to the temperature of the experiments is not free from objections but it seems to us to be practically the most reasonable one. The rate constant for the decomposition reaction is calculated to

$$k_{\text{dec.}} = 2.8 \times 10^{13} \frac{F^*}{F_3} \frac{T}{500} e^{-(E_0 + RT)/RT} \text{ sec.}^{-1} \quad (2)$$

where F^* contains one less vibration than F_3. $E_0 + RT$ is the activation energy at the temperature of the experiments unless the vibrational heat capacities of the associated molecule and the activated complex are different. Comparing the numerical factor in (2) with the experimental values, one finds that they are practically identical for the *t*-bromide, while that of the *t*-chloride is about three times larger. This we are inclined to ascribe to experimental errors, in accord with the "exact orientation" theory which does not assume any loosening of the molecule on transition to the activated state and hence prescribes essentially identical vibrational partition functions for the reactant molecule and the activated

---

(10) Rice and Gershinowitz, *ibid.*, **3**, 479 (1935).

complex. Because the equilibria data can be regarded as quite accurate, the experimental association rate A-factor of the chloride must also be reduced by a factor three to make everything self-consistent. The ratio of the experimental value to the above calculated one is then equal to about nine. Assuming now that the difference between E_0 and the experimental activation energy is due to the T factor in equation (1) and the contribution of the three extra vibrations in F^*, one finds by trial that a factor four for the product of the three extra vibrational partition functions in F^* gives the correct answer. Hence, the average frequency of the new vibrations in the activated complex is *ca.* 340 cm.$^{-1}$.

For the model of the activated complex, in which the CH_2 group of the butene has not acquired free rotation, one finds

$$k_{\text{ass.}} = 1.1 \times 10^9 \frac{F^*}{F_1F_2}\left(\frac{500}{T}\right)^{3/2} e^{-(E_0-{}^3/_2RT)/RT} \text{ cc. mole}^{-1}\text{ sec.}^{-1} \quad (3)$$

and

$$k_{\text{dec.}} = 2.2 \times 10^{13} \frac{F^*}{F^3}\left(\frac{T}{500}\right)^{1/2} e^{-(E_0+{}^1/_2RT)/RT} \text{ sec.}^{-1} \quad (4)$$

where F^* contains four more vibrations than F_1 and F_2 together and the same number as F_3. Proceeding much in the same manner as outlined before, one arrives at an average frequency of vibrations formed in the association reaction of about 450 cm.$^{-1}$. In view of the experimental errors and the many approximations made in calculations it is impossible to make a selection between these two sets of data. Both are quite reasonable although, as in the case of Diels–Alder association reactions,[11] somewhat higher frequencies would have been even more acceptable. In any case it should be clear from the preceding calculations that the association of halogen hydrides and isobutene in the gas phase proceeds according to entirely normal kinetics, calculable, in the order of magnitude at least, by the statistical theory of reaction rates. Some details of the calculations and some experimental data are not as perfect as could be desired but the main purpose of this investigation—a demonstration that the kinetics of these associations are "normal"—has been achieved. They cannot be observed directly merely because of coöperation of a high energy of activation and an unfavorable equilibrium. This applies *a fortiori* to the formation of secondary and primary halides because their energies of activation are probably still higher. This may be deduced tentatively from the generalization that the stability of primary and secondary halides is greater than that of the tertiary ones,[12] coupled with the not greatly different free energy change in the reaction.

Some remarks concerning association reactions of halogen acids and ethylenic hydrocarbons in liquid media are, perhaps, in order here. Present work leaves no doubt that these reactions at and near room temperature proceed via some mechanism quite different kinetically from the one here discussed. This is inevitable since, even allowing for concentration changes, one finds vanishingly small reaction rates at room temperature, with the expressions here given, whereas rapid rates have been observed in several widely different solvents.[2,5] This latter circumstance would make it very improbable that the fast rate is due to some specific effect of solvent on the activity of the reactants, or on that of the activated complex. Hence, the most plausible mechanism accounting for the reaction rate in liquids is a chain mechanism. In the light of such interpretation the findings of Kharasch,[2] on the action of oxygen, may find a reasonable explanation, although on the whole the effect is puzzling. In this connection it may be added also that in the gas phase reaction the addition of small amounts of oxygen does nothing but accelerate the wall reaction.

Summary

The rate of gaseous thermal decomposition of *t*-butyl bromide has been investigated in the temperature region of 509–564°K., and it was found to be a homogeneous unimolecular reaction.

The reaction rate constant was found to be

$$k = 10^{13.3 \pm 0.4}\, e^{-(40,500 \pm 1000)/RT} \text{ sec.}^{-1}$$

The equilibrium of *t*-butyl bromide and *t*-butyl chloride with isobutene and the respective halogen acid was investigated in the temperature region 361–533°K.

The heats of reaction at constant pressure for the associations were found to be −17,100 ± 500 cal., and −18,900 ± 900 cal. per mole for the formation of the chloride and the bromide, respectively.

The free energy changes of the reactions were found to be expressed in the form

(Chloride) $\Delta F^\circ = -17{,}100 + 36.1T$ (atmospheres standard)

(Bromide) $\Delta F^\circ = -18{,}900 + 37.2T$

---

[11] Kistiakowsky and Lacher, THIS JOURNAL, **58**, 123 (1936).

[12] *Cf.* Vernon and Daniels, *ibid.*, **55**, 922 (1933).

The rate equations of the association reactions were calculated from these data and found to be:

$$(t\text{-Chloride})\quad k = 10^{11.0 \pm 1.0}\, e^{-(28{,}800 \pm 2400)/RT}$$
$$(t\text{-Bromide})\quad k = 10^{10.2 \pm 0.7}\, e^{-(22{,}500 \pm 1900)/RT}$$

The units are cc. moles^{-1} sec.$^{-1}$.

The isomerization of *t*-butyl chloride to isobutyl chloride at 270° was investigated, and found to be less than 7.8% at equilibrium.

The statistical mechanical explanation of slow reaction rates in the form developed by Eyring was applied, and reasonable agreement was found with the theory.

Some Chemical Properties of an Essential Growth Factor for Pathogenic Bacteria

BY FELIX SAUNDERS, I. I. FINKLE, LEON STERNFELD AND STEWART A. KOSER

Many bacteria which develop quite readily in a meat-infusion culture-medium are unable to grow in a simple synthetic medium composed of several amino acids, dextrose, and inorganic salts. This observation is particularly true of many of the pathogenic types and has given rise to considerable speculation concerning the nature of the substances in meat infusions which appear to be necessary for development. Several attempts have been made to fractionate meat infusions or other similar mediums in the hope of gaining an insight into the nature of the factors essential for growth of the more exacting bacteria.[1] The same method of study has also been applied to yeasts.[2]

In previous work of our own[3] it was found that a growth-stimulating fraction could be removed from veal infusion by adsorption on charcoal and subsequent elution with hot ethanol or acetone. When this fraction was added to a simple synthetic medium[4] it rendered the medium suitable for the growth of some, though not all, of the more exacting pathogenic bacteria. In certain instances very small amounts of this added factor were sufficient to permit development in a synthetic medium in which the organisms ordinarily refused to grow. The results of a representative experiment with three microörganisms belonging to different biological groups are given in Table I.

The luxuriance of growth, varying from very light to heavy turbidity, is shown by the number of + signs. Absence of visible turbidity is shown by 0. An occasional doubtful reading is recorded ?. Readings were also made after seven and fourteen days, but have been omitted from the table as in most instances they showed no change.

The strain of *C. diphtheriae* used was a culture of "Park 8," that of the Sonne dysentery bacillus was no. 268 of the British Type Collection, and the strain of *Staph. albus* was from our laboratory stock collection.

Here it is seen that two of the three microorganisms refused to develop in the synthetic medium alone. The third organism, the so-called Sonne type of dysentery bacillus, grew very sparsely in the synthetic medium. When the fraction from veal infusion was added all of the organisms developed very well and produced a heavy growth in a few days. Relatively small amounts of this added material were effective and it is evident that something quite essential for multiplication has been added.

Is the added material a foodstuff or something in the nature of an accessory growth factor? It is obvious that the fraction from veal infusion must consist of a mixture of compounds and one would expect some food materials to be carried over along with any accessory factor which might be present. The results with the inorganic salt solution shown in Table I indicate that only a negligible amount of actual food material was contained

[a] The amount of solution of growth factor (from veal infusion) added to each 5-cc. tube of either synthetic medium or inorganic salt solution. The total solids in each cc. of the preparation of growth factor was 3 mg.

in the fraction from veal infusion. Since the inorganic salt solution supplied no food material which could be used by the bacteria for growth, any development following addition of the fraction from veal infusion must have resulted from food material carried over in this fraction. When large amounts such as 0.1 cc. of this preparation were added to the inorganic salt mixture, a light growth of two of the cultures resulted but in no case was the development nearly as rapid or as luxuriant as when a similar amount was added to the synthetic medium. Nor was growth stimulated by such small amounts of the fraction as was evident in the case of the synthetic medium. The preparation alone evidently supplied only traces of food material but when added to a synthetic medium containing dextrose and a few amino acids, very small amounts were sufficient to serve as an "activator" and the amino acids and dextrose were then utilized with resultant good development of the cultures.

Later work[5] showed that a similar preparation could be obtained from a considerable number of animal and plant sources. Of over thirty such sources tested, calf spleen, calf liver, and yeast appeared to be the richest. The evidence accumulated so far indicates that the growth factor is widely distributed in living tissue whether of plant or animal origin, and is probably a single chemical entity. Additional study of this apparently essential growth factor seemed desirable and attempts were made to obtain the active substance in pure form. Although this objective has not been reached up to the present time, some progress has been made in the fractionation, and with the partially purified preparations obtained it has been possible to study some of the chemical properties of the active principle.

Experimental

Preparation of Crude Growth Factor.—For the preparation of the fractions used in the following studies usually beef spleen or liver were used.[6] The method for concentrating growth factor has undergone several modifications. The process given below is the one in use at present. One hundred pounds (45 kg.) of beef spleen or liver are ground and covered with 250 liters of distilled water. After standing overnight or longer in the refrigerator the mixture is heated to boiling and boiled for five minutes. It is filtered while hot and the residue is washed with 50 liters of boiling water. The *hot* filtrates are combined and a *hot* saturated solution of lead acetate is added until no more precipitate is formed. It is important that *both* solutions be hot, otherwise the next filtration is likely to be very slow. Fuller's earth and supercel (200 g. of each) are stirred in thoroughly. The lead precipitate and the earths are filtered off. Charcoal is suspended in the filtrate (about 1 g. for every liter of filtrate added in small portions) and stirred intermittently for ten minutes or more. The charcoal is filtered off under suction and washed until free from lead.

The wet charcoal is placed in a large continuous extractor and extracted with alcohol for two weeks or more if the

[6] We are indebted to Dr. David Klein of The Wilson Laboratories for generously supplying us with tissue and carrying out some of the preliminary steps of the purification.

alcohol still shows considerable color. The alcohol is changed every other day and the several portions of alcohol are combined. Every day 100 cc. of water is poured into the extractor through the condenser. When most of the color has been removed from the charcoal the extraction is discontinued and the charcoal discarded. The alcohol is removed from the combined extracts under reduced pressure. The residue is taken up in a minimum of water and any insoluble material is filtered off. The filtrate is again taken to dryness in a flask with a ground glass joint which can be fitted to a condenser.

The residue is extracted at least three times with 200-cc. portions of boiling absolute methanol. The methanol extracts are decanted or filtered from the residue in the flask. To the combined methanol extracts, 5 volumes of absolute ether are added. After standing a few minutes a gummy precipitate settles out leaving a clear supernatant fluid which can be decanted. The methanol–ether mixture is removed under reduced pressure. The residue is taken up in 100 cc. of water or more if necessary and any insoluble material is filtered off.

Fifty cc. of a 10% solution of chloroplatinic acid is added to the filtrate which is placed in the refrigerator and allowed to stand for a week or more. The precipitate which has formed is filtered off. The filtrate is allowed to stand overnight. If no more precipitate forms hydrogen sulfide is passed into the solution to remove the platinum. If a precipitate does form the filtrate is allowed to stand for a few days more and the second precipitate is removed.

After the platinum sulfide has been filtered off the filtrate is evaporated to dryness under reduced pressure. The residue is taken up in water and any insoluble material filtered off. The filtrate constitutes the crude material on which most of the tests described in this paper were performed. The solutions are straw colored or brownish and have a characteristic meat-extract odor. This odor is the same regardless of the source from which the material was prepared.

Method of Assay.—Four different organisms, *Staphylococcus albus*, *Corynebacterium diphtheriae* (Park 8), *Shigella dysenteriae* (Shiga), and *Brucella abortus*, were used for assay. These organisms show a wide range of sensitivity toward the growth factor but could always be arranged in the same order of sensitivity regardless of the source of the growth factor or the treatment to which it had been subjected. Throughout the experiments care was taken to avoid carrying over a heavy inoculum when testing for the presence of growth-promoting factor. Light suspensions of each of the four organisms were first made in 5 cc. of a buffered salt solution by transferring a small bit of growth from a twenty-four- or forty-eight-hour agar slant of the culture. These suspensions showed no evident turbidity. After thorough distribution, 0.1 cc. of the suspension was then pipetted aseptically into each tube of synthetic medium containing the added extract and also into controls of synthetic medium alone and of veal infusion broth. All tests were incubated at 37°. Throughout the work the purity of the cultures developing in the various tests was often checked by gram stains together with whatever other study appeared desirable.

Solubility in Organic Solvents.—A solution of growth factor was shaken with three separate portions of ether. The ether fractions were combined and the ether removed under diminished pressure. The slight residue was taken up in water and assayed but no activity could be detected. Similar results were obtained from the same procedures using benzene and chloroform. The higher alcohols appear to dissolve some growth factor but the growth factor is probably held in the small amount of water which the alcohols dissolve. The growth factor is soluble in absolute methanol and absolute ethanol but not as readily as in water. However, it is still too soluble in these alcohols to permit recrystallization from them. In one experiment a concentrated solution of growth factor in ethanol was prepared and chilled with solid carbon dioxide until it became sirupy but no solid was thrown out. Of course the growth factor is readily soluble in any aqueous mixture of the alcohols since it is extremely soluble in water.

Solubility in Phenol.—A growth-factor preparation was evaporated to dryness. Phenol was added and warmed until it liquefied. All of the material appeared to go into solution. The flask was washed out with another portion of liquefied phenol and the combined portions of phenol were filtered through a steam funnel. The phenol was removed from the filtrate by steam distillation. The liquid remaining in the flask after removing the phenol was evaporated to dryness under diminished pressure, taken up in the original amount of water and assayed. Little or none of the activity had been destroyed by the treatment described.

Effect of Oxidants on Growth-Factor Preparations.—Enough 30% hydrogen peroxide was added to 50 cc. of a solution of growth factor to give a final concentration of 3% and the solution heated on the steam-bath for forty-five minutes. The solution was evaporated to dryness under reduced pressure and the residue taken up in 50 cc. of water. Another sample of growth factor in aqueous solution was aerated by passing a vigorous stream of air through a flask containing the solution for twenty hours. Enough water was then added to restore the original volume. Assay showed that in neither of these samples was the activity appreciably diminished. Heating a sample of growth factor on the steam-bath under reflux for thirty-six hours or autoclaving for fifteen minutes at 1 atm. extra pressure had no detectable effect on the activity.

Action of Bromine on Growth Factor.—Bromine was added drop by drop to a solution of growth factor with vigorous shaking until the color persisted. The solution was allowed to stand overnight in a refrigerator. Excess bromine was removed by aeration and a gummy precipitate which had formed was filtered off. Silver acetate was added to remove bromide ions and the silver bromide removed by filtration. Hydrogen sulfide was passed into the solution and the silver sulfide formed was filtered off. The filtrate was concentrated under reduced pressure to dryness and then taken up in enough water to make up the original volume of the solution. The activity had been reduced by about one-fourth. In another experiment the bromine was added in solution in chloroform. The results were essentially the same as described above. When a large excess of liquid bromine is added to a dried growth-factor preparation and heated on the steam-bath the activity is destroyed completely.

Action of Ammoniacal Silver on Growth Factor.—Ammoniacal silver was added to a growth-factor preparation and the solution was warmed on the steam-bath for ten minutes. The calculated amount of hydrochloric acid was added and the silver chloride removed. There was no loss of activity. None of the preparations tested reduced Fehling's solution.

Action of Acetic Anhydride on Growth Factor.—A solution of growth factor was evaporated to complete dryness *in vacuo*. Seventy-five grams of acetic anhydride and 5 g. of fused sodium acetate were added. The mixture was heated on the steam-bath under reflux for twenty minutes and then poured into 500 cc. of iced water. A gummy precipitate formed which was removed by filtration. The filtrate was diluted to 2 liters and treated with 15 g. of charcoal in two steps to adsorb the growth factor. The charcoal was filtered off and extracted in a continuous extractor for twenty-four hours. The alcohol was removed under reduced pressure and the residue taken up in water. Assay showed that there had been only a slight loss of activity.

Action of Nitrous Acid on Growth Factor.—Fifty cc. of a preparation was diluted to 2 liters and 10 g. of sodium nitrite added. The solution was cooled to 10° and 25 cc. of glacial acetic acid added. The solution was stirred for thirty minutes and then allowed to stand overnight in the refrigerator. The growth factor was adsorbed on 8 g. of charcoal and eluted with alcohol. There was only a slight loss of activity.

Qualitative Elementary Tests.—Qualitative tests for nitrogen were run on several different samples. In every case the test was positive. Tests for sulfur run on the same samples were always negative. Since the preparations were impure no significance can be attached to the nitrogen tests but the growth factor is probably free from sulfur.

Discussion

All the experiments described above have been repeated and confirmed several times. They have also been repeated in many cases using growth factor from different sources. All the evidence at hand indicates that the growth factor is the same regardless of source and that it is a widely distributed if not universal constituent of living tissue. Many microörganisms are unable to utilize sources of energy unless this accessory substance is present. Others which are capable of developing in a synthetic medium apparently can either get along without it or can synthesize the small amount of growth factor that they need. For example, veal infusion from which the growth factor has been removed by adsorption on charcoal will still support the growth of airborne saprophytes and molds but will not permit the growth of certain pathogens. However, after saprophytes have been allowed to grow in the infusion which has been treated with charcoal the presence of growth factor can be demonstrated by the technique described above. Furthermore molds grown on Czapek-Dox medium will synthesize growth factor.

Because of the wide distribution of growth factor and the organisms capable of synthesizing it, it would be difficult or impossible to produce a diet deficient in this factor for higher forms, especially as the intestinal tract contains organisms capable of synthesizing this accessory. Growth factor requirements can be studied only under rigidly controlled conditions such as those prevailing in bacterial cultures in a synthetic medium. Perhaps organisms in the intestinal tract play an essential part in supplying this factor and are a part of a true symbiosis.

There is considerable variation among bacteria regarding their growth-factor requirements. Some require only a few micrograms of growth factor for each liter of medium in order to produce abundant growth while others grow much less vigorously even when the amount of growth factor has been increased as much as a hundred fold. Of course, many other factors such as amino acids, sugars, etc., may be involved. Cultures of *C. diphtheriae* have been grown on synthetic medium plus growth factor by transferring directly from one synthetic culture to another without any intermediate culturing on infusion. This culturing has been carried on for over fifty successive transfers.

In spite of its biological reactivity, growth factor is comparatively unreactive chemically. Although it has the stability generally associated with hydrocarbons it is extremely water soluble. Dried growth-factor preparation dissolves in water almost instantaneously but is not hygroscopic. It probably is not inorganic since it is destroyed by both wet and dry ashing. At present we feel that we have not enough positive chemical evidence at hand to warrant drawing any conclusions regarding its chemical constitution.

Acknowledgment.—This work has been aided by a grant from the Committee on Scientific Research of the American Medical Association. It is a pleasure to be able to thank the Committee for their generous support.

Summary

1. Many plant and animal tissues contain a substance which is essential for the growth of certain pathogenic bacteria. This substance has been purified partially and the chemical properties of the impure preparations studied.

2. Growth factor is soluble in water, metha-

nol, ethanol, and phenol, but it is insoluble in the higher alcohols, ether, benzene, and chloroform.

3. The activity is not appreciably affected by autoclaving, aeration, boiling, or by oxidizing agents such as 3% hydrogen peroxide, or ammoniacal silver, and is only slightly affected by bromine in the cold.

4. Treatment with acetic anhydride caused only slight loss of activity.

5. The growth factor probably does not contain sulfur.

6. It is not inorganic since it is destroyed by both wet and dry ashing.

Studies in Proteins. V. A Crystalline Globulin from the Paradise Nut, Lecythis Zabucayo

BY BIRGIT VENNESLAND, MARY B. BLAUCH AND FELIX SAUNDERS

Introduction

The Paradise nut, *Lecythis zabucayo*, is a rugose, fusiform nut resembling the Brazil nut in size and taste. It is grown in Brazil and Guiana where it is known as the sapucaya or monkey-pot nut. The natives consider the flavor of the Paradise nut to be superior to that of the Brazil nut, consequently few of them are exported but they can be obtained occasionally on the Chicago market.

Since the Brazil nut yields a crystalline globulin, excelsin, it was thought possible that the Paradise nut might also yield a crystalline globulin.

Method.—A protein was isolated from Paradise nuts by extracting the defatted seed-meal with a saturated solution of sodium chloride and precipitating the protein with ammonium sulfate. The precipitate formed by saturating the protein solution with ammonium sulfate was redissolved in water and dialyzed against running distilled water at about 5°. Details of the method have been given elsewhere.[1] During dialysis crystals of globulin formed in the viscose bags. The crystals were thick, hexagonal plates. The edges of the upper and lower surfaces appeared to be beveled. Three of the angles of the sides were slightly more acute than those of the other three.

Experimental

Determinations of nitrogen distribution were made in the usual way. The results given below represent an average of several determinations.

	Protein, % Paradise-nut globulin	Protein, % Excelsin[a]	Total N, % Paradise-nut globulin
Amide N	1.42	1.48	9.12
Humin N	0.33	0.17	2.10
Total N in phosphotungstic acid ppt.	5.54	5.76	35.60
α-Amino N in phosphotungstic acid ppt.	2.06		13.28
Total N in filtrate (Kjeldahl)	8.46	10.97	53.51
α-Amino N in filtrate (Van Slyke)	8.43		53.44
Total N	15.75	18.30	
Histidine N (colorimetric)			5.23
Cystine N (gravimetric)			0.47

[a] Osborne and Harris as quoted by Plimmer, "Chemical Constitution of the Proteins," 2nd ed., Longmans, Green and Co., New York, 1924, p. 131.

Summary

A crystalline globulin has been isolated from the Paradise nut (*Lecythis zabucayo*).

The nitrogen distribution of this protein has been determined and found to be the same as excelsin except for mono-amino nitrogen.

Nitrogen Compounds in Petroleum Distillates. IX. Nitrogen Bases from California Cracked Gasoline[1]

BY A. C. BRATTON AND J. R. BAILEY

The crude bases for this investigation, 242 cc., b. p. 115-240°,[2] were extracted from four barrels of pressure distillate, b. p. 36–171°, obtained in cracking *gas-oil*, from Los Angeles Basin petroleum, and *crude residuum* from San Joaquin Valley petroleum, at 454° and 54–58 atmospheres.

Nine bases, consisting of quinoline, quinaldine, and seven pyridine homologs, were isolated and there is no reason to suspect that any base, present beyond negligible amount, was overlooked. *Non-aromatic* types, which are present along with *aromatic* types in *straight-run* kero bases in a percentage ratio of approximately 85:15, respectively,[3] were not encountered among the *cracked* gasoline bases which obviously are pyrolysis products of more complex molecules, including aromatic and non-aromatic bases together with inert nitrogen compounds.[4] At the temperature of the cracking plant non-aromatic bases are evidently unstable and, it may be, undergo dehydrogenation and molecular rearrangement to more stable aromatic types. Whereas both quinoline and quinaldine occur in cracked gasoline, a careful search carried out in the Texas Laboratory has not revealed either of these products or any monoalkyl quinoline in straight-run distillates. Since a number of polymethylated quinolines have been identified in straight-run distillates, dealkylation may be assumed as at least one effect produced at high temperatures on aromatic bases and it is equally certain that, through pyrolytic degradation of polynuclear aromatics, there arise at times pyridine or its homologs.

Due to the limited supply (130 cc.) of bases available, it was impractical to fractionate this small volume exhaustively through an effective column by the usual procedure. To circumvent this difficulty, resort was had to the indirect micro method, termed Amplified Distillation,[5] which originated with the authors.

An inspection of Table I reveals that, because of the proximity of boiling points (144–145.3°, 157–158°, 170.3–171.6°) within three pairs of the gasoline bases, it was impractical to separate individual products, free of admixtures, through fractional distillation alone.

Experimental

Action of *p*-Toluenesulfonyl Chloride on the Bases.—The crude material (154.5 cc. or 139.3 g.) was added to 851 cc. of 3 *N* sodium hydroxide and 272 g. of *p*-toluenesulfonyl chloride was stirred in over a period of forty-five minutes with the temperature at 25–30°. A temperature of 60–70° was then maintained for fifteen minutes, after which the cooled solution (A) was extracted with several 200-cc. portions of ether (B), followed by withdrawal of the bases (112 cc.) from the latter with four 200-cc. portions of 1 *N* hydrochloric acid. Since there was no precipitation of sulfonamides on strong acidification of the ethered out solution (A), it was evaporated to dryness, 400 cc. of concentrated hydrochloric acid was added and the mixture was refluxed for thirty hours. After removal of the excess acid in steam, caustic soda was added and the free bases (18 cc.) were distilled out with steam. These bases proved to be exclusively tertiary and accordingly were combined with the 112 cc. of unchanged bases recovered from the toluenesulfonyl chloride treatment. The residue from evaporation of the ether solution (B) on being processed like solution (A) yielded no bases. From these results it is evident that the Hinsberg separation of amines is unreliable when applied to a complex mixture of petroleum bases.

Amplified Distillation.—To the 130 cc. of bases was added 2438 cc. of acid- and caustic-washed hydrocarbon oil boiling evenly over a 90–240° range. This mixture was distilled at a 10:1 reflux ratio through a 1 × 105-cm. spirally-indented, adiabatic column, cuts being made in 1° fractions (D). A second fractionation from a smaller still-pot was performed as follows: the still was charged with the lowest fraction, 1D, which was then topped in 1° cuts to the minimum temperature of 2D, when this second fraction was added. The procedure was repeated in ascending order of boiling points until all the D fractions were distilled. Finally a third distillation was carried out in like manner on the fractions from the second distillation. The final 1° cuts from multiple distillation boiled over a 35–260° range, with the bases segregated between 98–236°, *i. e.*, in 139 fractions, each with an average base content of around 1 cc.

The base-hydrocarbon fractions were agitated over three-minute periods with three successive 0.5–0.7 volumes of 4 *N* hydrochloric acid, followed by 0.5 volume of water. In order to withdraw *non-aromatic hydrochlorides* each of the acid extracts was agitated for thirty minutes with an equal volume of chloroform.[3] A very small amount of

[b] See below, "Treatment of Unresolved Bases."

bases recovered from the combined chloroform extracts proved to be *aromatic*. From this result, *the occurrence of non-aromatic bases in cracked gasoline, regardless of its source, is not to be expected;* in any event, so far as concerns the processing of the bases under investigation, chloroform extraction of their hydrochlorides was superfluous.

In order to remove chloroform, the separate acid fractions were steamed out and the bases were freed with caustic and distilled in steam. Sulfur dioxide was then run into the separate distillates to methyl orange acidity, excess picric acid solution was added and precipitation was allowed to proceed under thermostatic control over four-hour periods at 50, 35° and finally at the minimum temperature allowable without separation of picric acid.

Water saturated with sulfur dioxide will not precipitate picric acid from its aqueous solution saturated at the same temperature; so temperature–solubility curves of picric acid in water[6] made possible a regulation of the minimum temperature at which picration could be effected with avoidance of any separation of picric acid.

Where picrates were not freed of admixtures through recrystallization, they were converted to mercuric chloride salts and an exchange in the two types of salts was repeated as often as necessary for final purification. The confusion which often arises from the formation of different mercuric chloride salts of an individual base was eliminated by observance of specific conditions which led to definite products, usually of the formula $Base{\cdot}HCl{\cdot}2HgCl_2$. For conversion of a picrate to a mercuric chloride salt, the base was liberated, steam distilled and titrated to slight acidity (methyl orange) with 0.506 *N* hydrochloric acid. Through the use of a mercuric chloride solution saturated at 25°[6] (p. 409) it was possible to carry out precipitation with exactly 2 moles of mercuric chloride per mole of base-hydrochloride. Minimum allowable cooling curves were again used as controls in fractional precipitation of the salts over a maximum temperature range. Where a salt appeared with a mercury content greater than in the formula $Base{\cdot}HCl{\cdot}2HgCl_2$, an adjustment was made in the amount of the reagent, such as to ensure complete precipitation of the bases.

Table I summarizes the properties of the salts obtained from the amplified distillation fractions. In recombination of individual salts from various fractions, prior to their purification and identification, it is obvious from the wide overlap of the origin of the corresponding bases, that the salts were combined from broader bands of distillation fractions than might seem warranted.

Treatment of Unresolved Bases.—In order to rework the regained residual bases from the salts described above, they were dissolved in 1 liter of sulfurous acid solution, excess picric acid (15 liters) was added and the bases were liberated from both the precipitated (D) and dissolved (E) picrates. This material gave the following constants.

	Cc.	G.	B. p., °C.	n^{25}_{D}	Sp. gr. 28.5/25.6
Bases from D	29	26.6	116–225	1.5002	0.9172
Bases from E	27.5	25.1	116–200	1.4953	.9157

The bases from E, *without admixture with hydrocarbon oil*, were fractionated in the usual way into 5° cuts through a 1 × 105-cm. column with a 10:1 reflux ratio. Crystalline salts were obtained from all of the first seven fractions boiling up to 164°; the remainder yielded only smears. Final purification through an exchange in salt types was effected as follows: mercuric chloride salts ⟶ picrates ⟶ mercuric chloride salts ⟶ picrates. The products isolated and identified as picrates were 2,4-dimethylpyridine, 3,5-dimethylpyridine and 2,4,6-trimethylpyridine; in other words, the presence of only three of the nine bases (Table I) identified through amplified distillation could be confirmed. This comparison establishes beyond question the superiority of amplified distillation over straight distillation in the resolution of complex mixtures of petroleum bases.

The bases from (D) were processed similarly to those from (E) but no pure individual product was isolated.

Purification and Identification of Salts

Each of the salts listed below was synthesized for a comparison of the two samples by solubilities, crystalline form and mixed melting points.

2-Methylpyridine.—Picrate 1 was recrystallized from water in long (2 cm.) spear-like clusters of slender prisms melting at 165.5°.

Anal. Calcd. for $C_{12}H_{10}O_7N_4$: N, 17.39. Found: N, 17.51.

4-Methylpyridine.—Picrate 3 was recrystallized from water in clusters of flat feather-like needles (1.5 cm.) melting at 167°.

Anal. Calcd. for $C_{12}H_{10}O_7N_4$: N, 17.39. Found: N, 17.55.

2,6-Dimethylpyridine.—Picrate 2 was recrystallized from water in microscopic prisms melting at 163°.

Anal. Calcd. for $C_{13}H_{12}O_7N_4$: N, 16.67. Found: N, 16.45.

2,5-Dimethylpyridine.—The mercuric chloride salt 4 was converted to the picrate which crystallized from water in long (2 cm.) spear-shaped clusters of thin prisms melting at 168.5–169.5°. The synthetic picrate prepared by the method of Errera[9] (p. 3691) melted at 167.5–168.5° (Errera reported 165.5°).

Anal. Calcd. for $C_{13}H_{12}O_7N_4$: N, 16.67. Found: N, 16.43.

2,4-Dimethylpyridine.—Picrate 5 from water formed slender prisms melting at 182.5–183° in agreement with the synthetic product, m. p. 182.5°.[10] The picrate is far less easily purified than is the mercuric chloride salt.

Anal. Calcd. for $C_{13}H_{12}O_7N_4$: N, 16.67. Found: N, 16.49.

3,5-Dimethylpyridine.—Picrate 10 separated from water in single slender needles (5 mm.) melting at 245°.

Anal. Calcd. for $C_{13}H_{12}O_7N_4$: N, 16.67. Found: N, 16.91.

2,4,6-Trimethylpyridine.—Picrate 12 crystallized from water in short interlacing needles melting at 155.5–156°.

Anal. Calcd. for $C_{14}H_{14}O_7N_4$: N, 16.00. Found: N, 16.12.

Quinoline.—Picrate 13 crystallized from 50% alcohol in very short needles melting at 203–203.5°.

Anal. Calcd. for $C_{15}H_{10}O_7N_4$: N, 15.64. Found: N, 15.65.

Quinaldine.—The melting point of picrate 14 after several recrystallizations from acetone rose from 191–192° (reported in the literature) to 193–194°. This solvent is to be preferred to water or alcohol. Nitrogen determination on the lower melting sample ran 0.3–0.5% below the calculated per cent.

Anal. Calcd. for $C_{16}H_{12}O_7N_4$: N, 15.05. Found: N, 14.98.

Summary

Seven pyridine homologs, quinoline and quinaldine were isolated through *amplified distillation* of 130 cc. of California pressure distillate gasoline bases. In contrast to *straight run* distillates in the same temperature range, which contain in preponderant amount *non-aromatic* bases, only *aromatic* bases were encountered in the *cracked* gasoline.

The present investigation offers conclusive proof of the efficiency of amplified distillation as an indirect micro method in exhaustively fractionating small volumes of complex mixtures of petroleum bases.

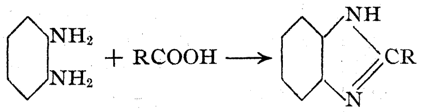
2-Alkylbenzimidazoles as Derivatives for the Identification of Aliphatic Acids

By W. O. Pool, H. J. Harwood and A. W. Ralston

In the course of work involving the identification of normal fatty acids the need of a complete series of satisfactory derivatives became apparent. Of the various derivatives described in the literature for the characterization of organic acids the 2-alkylbenzimidazoles of Seka and Müller[1] appeared most promising.

These 2-alkylbenzimidazoles were prepared by heating a mixture of the acid and *o*-phenylenediamine. The resulting compounds were comparatively high melting and the melting point range of the series was continuous and broad.



The series of 2-*n*-alkylbenzimidazoles through the *n*-heptadecyl derivative has now been completed. The procedure of Seka and Müller has been improved in that the time required for the preparation of a derivative has been greatly reduced and the compounds obtained by the present method have been found to possess higher melting points than those reported by Seka and Müller.

Experimental Part

Procedure.—A mixture of 1 to 3 g. of acid and a molecular equivalent of *o*-phenylenediamine was heated at the boiling temperature for thirty minutes. The mixture was then dissolved in hot alcohol and the unreacted acid neutralized by the addition of potassium hydroxide solution until just alkaline to phenolphthalein. In the case of capric and higher acids the 2-alkylbenzimidazole crystallized when this alcohol solution was cooled. In the case of pelargonic and lower acids ether was added to the alcohol solution and this ether solution then washed with successive portions of water. The 2-alkylbenzimidazole was obtained by evaporation of the ether. The products were purified by recrystallization from alcohol, dilute alcohol or water with the addition of decolorizing carbon.

Discussion

2-Alkylbenzimidazoles were easily and quickly prepared from small amounts of material. These derivatives crystallized well and possessed sharp melting points. With the lower members of the series the melting point interval between adjacent members was large and there was considerable depression in the melting point of mixtures of adjacent members. The 2-alkylbenzimidazoles of acids above lauric did not serve as a very good means of distinguishing these acids from one

---

[1] Seka and Müller, *Monatsh.*, **57**, 95–105 (1931).

another as the melting points of these derivatives lay closely together. In certain cases the compounds contained a colored impurity which was removed only after numerous crystallizations.

These 2-alkylbenzimidazoles form salts with acids (picric, sulfuric, etc.) which might be used in distinguishing the higher members of the series. This possibility has not yet been investigated.

Summary

1. A procedure for the preparation of 2-alkylbenzimidazoles from aliphatic acids and *o*-phenylenediamine has been described.

2. A series of 2-alkylbenzimidazoles has been prepared using normal aliphatic acids containing from one to eighteen carbon atoms.

The Liquidus Curve and Surface of the Systems Lithium and Calcium Nitrates and Calcium, Lithium and Potassium Nitrates

BY ALEXANDER LEHRMAN, EDWARD ADLER, JACOB FREIDUS AND MAX NEIMAND

This paper reports an investigation of the liquidus curve and surface of the systems lithium and calcium nitrates and calcium, lithium and potassium nitrates. The work was undertaken in order to be able ultimately to define the liquidus surfaces of the quaternary system composed of the nitrates of lithium, sodium, potassium and calcium. It is hoped that the quaternary system in mind will yield a salt-bath melting below 100°. Such a salt-bath would have distinct advantages.

Of the six binary and four ternary systems that should be known before the quaternary system is investigated, five binary and two ternary are described in the literature.[1]

The completion of the present work leaves uninvestigated only the ternary system lithium, sodium and calcium nitrates (although it seems necessary in the light of the work of Rostkovsky,[1f] of Laybourn and Magdin[1g] and the data presented here, that the ternary system composed of the nitrates of sodium, potassium and calcium as presented by Menzies and Dutt[1b] should be checked).

Experimental

The salts used were prepared from C. P. products by recrystallization followed by drying except the calcium nitrate which was the C. P. salt dissolved, treated with pure lime, filtered, neutralized with nitric acid, evaporated and dried.

Temperature Measurements.—Temperatures were measured with a copper–constantan thermocouple of No. 28 wire in conjunction with a Leeds and Northrup potentiometer indicator, the cold junction being cracked ice. The couple was protected from the molten nitrates by a narrow guard tube made by drawing out Pyrex tubing and sealing at one end. It was standardized by determining the e. m. fs. at the boiling point of water and melting points of U. S. Bureau of Standards tin (231.9°), C. P. cadmium (320.9°), and purified potassium dichromate (397.5°), and plotting the deviations from the standard table of Adams.[2] While the melting point of potassium dichromate is about 10° higher than the upper end of the standard table, it was considered justifiable to extrapolate through this short range.

Method.—Mixtures of the two salts (approximately 20 g.) were made in the 2.5 × 20-cm. Pyrex tubes used in the determinations. The couple in its guard tube was inserted into the salt mixture and held in place by a two-holed stopper. A stirrer made of Pyrex rod passed through a piece of Pyrex tubing in the second hole of the stopper. It was necessary to use Pyrex glassware throughout, as molten lithium nitrate attacks soft glass.

The tube holding the salts was suspended in a small resistance furnace and heated while stirring until the salts were completely molten, care being taken to avoid excessive temperatures. It was then transferred to a double-walled test-tube and held suspended there by an asbestos ring, and constantly stirred.

As the crystallization temperature was approached, crystals formed on the test-tube wall at the surface of the molten salt and were pushed into the liquid by the stirrer. The initial crystallization temperature was seen easily, as clouds of fine crystals suddenly appeared, while above this temperature the crystals when pushed into the melt by the stirrer rapidly dissolved. No supercooling was observed in any of the stirred melts, except in the calcium nitrate region of the ternary system, where it was necessary in some cases to inoculate with very fine crystals in order to prevent the formation of supercooled glasses which when formed did not crystallize on long standing. Crystallization temperature determinations were repeated until they agreed to within 1.0°. The reported values represent at least three determinations.

[2] "Pyrometric Practice," Bureau of Standards Technological Paper No. 170, p. 309.

The Binary System Lithium and Calcium Nitrates.—In order not to overlook any break in the liquidus curve, time–temperature and time–differential temperature cooling curves were made on a number of melts. No halt due to a transition or reaction was observed. These curves showed the eutectic temperature of the system to be at 235.2°. The apparatus used for the time–temperature and time–differential temperature cooling curves has been described previously.[3] It should be mentioned that when stirring is omitted as was the case in obtaining the cooling curves, supercooling takes place at the initial crystallization temperature and slight supercooling at the eutectic point.

Decomposition was not apparent in any of the melts until the concentration of calcium nitrate reached 60%. By slow and careful heating of this mixture decomposition was reduced to a negligible amount. The observed melting points are recorded in Table I and plotted in Fig. 1.

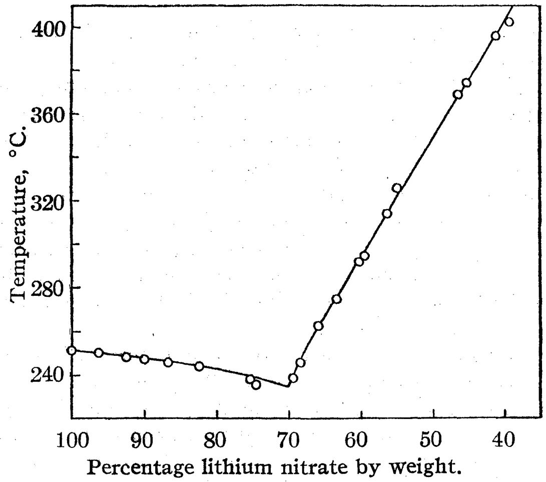

Fig. 1.—Liquidus of the lithium nitrate–calcium nitrate system.

The melting point of lithium nitrate found (251.4°) agrees well with that determined by Briscoe, Evans and Robinson (252°).[4]

TABLE I

CRYSTALLIZATION TEMPERATURES. LITHIUM NITRATE–CALCIUM NITRATE

68.4	246	39.4	403

The Ternary System Lithium, Potassium and Calcium Nitrates.—The region near the 100% calcium nitrate point was not investigated as calcium nitrate decomposes before it melts. In all cases care was taken not to heat the mixtures above 400° to avoid decomposition. Furthermore, no effort was made to find the boundaries of the region in which the compound $4KNO_3 \cdot Ca(NO_3)_2$ is formed from the melt. The determination of a few points in the binary system potassium and calcium nitrate showed that Rostkovsky's results[1f] are more reliable than those of Menzies and Dutt.[1b] In the region of high concentration of

calcium nitrate glasses were readily formed, and these showed no signs of further crystallization at room temperature even in the presence of large crystals of calcium nitrate. Cooling curves on melts of composition near that of the ternary eutectic showed a eutectic halt at 117.4°. No halt due to the inversion of potassium nitrate (128° in the pure substance[5]) was observed. This inversion of potassium nitrate should produce a slight break in the liquidus surface near the eutectic point.

The melting points of the ternary mixtures are given in Table II. The regions in which the three solid phases form (neglecting $4KNO_3 \cdot Ca(NO_3)_2$ and the low temperature form of potassium nitrate) and the eutectic points are shown in Fig. 2, the binary eutectics used being those of Rostkovsky[1f] and Carveth.[1a]

Summary

1. The liquidus curve of the binary system lithium nitrate–calcium nitrate has been determined. The eutectic temperature is 235.2°, the eutectic composition is at about 70% lithium nitrate.

2. The liquidus surface of the ternary system calcium, lithium and potassium nitrates has been explored partially. The ternary eutectic temperature is 117.4°, the eutectic composition is 15% calcium, 62% potassium and 23% lithium nitrates.

[A CONTRIBUTION FROM THE CHEMICAL LABORATORY OF NORTHWESTERN UNIVERSITY]

A Redetermination of the Deuterium–Protium Ratio in Normal Water

BY J. L. GABBARD AND MALCOLM DOLE

In the course of preparing some deuterium-free hydrogen for use in one of the researches on the isotopes of oxygen in progress in this Laboratory, it became possible to redetermine, by means of a method involving a knowledge of the oxygen isotope ratios in water and air, the deuterium–protium ratio in normal water. Limitations of space forbid a detailed discussion of the many previous measurements of this ratio; the reader is referred to the recent papers of Morita and Titani[1] and of Hall and Jones[2] for references and comments on earlier work. At present there seem to be three apparently accurate determinations of the deuterium–protium ratio in which the difficulties due to oxygen isotope fractionation on electrolysis were recognized and avoided, namely, those of Johnston ($-18.3\ \gamma$),[3] Morita and Titani ($-18.9\ \gamma$) and Hall and Jones ($-16.5\ \gamma$). The symbol γ represents in p. p. m. the density of deuterium-free water less the density of normal water; from the γ values the deuterium–protium ratio is calculated easily. The maximum difference in the above results ($2.4\ \gamma$) is greater than the experimental errors of density measurement and is due, we believe, to the different methods used by the above authors in bringing to normal or correcting for the oxygen isotope ratios in the waters under investigation.

Since the relative atomic weight of oxygen in air and in water has been determined recently[4] it is possible to solve the oxygen isotope problem by combining the deuterium-free hydrogen with oxygen of the air and after measuring the density of resulting water, the proper correction for the difference in the atomic weight of air and water oxygen can be applied, yielding what should be the correct density of water made of isotopically pure protium and the oxygen of normal water. From this latter value the D/H ratio in normal water is calculated readily.

Experimental

The electrolysis apparatus was very kindly constructed for us by Dr. P. W. Selwood who was able to give us frequently valuable advice and suggestions from his great store of electrolytic experience. The lengthy first and second fractionations were carried out by Mr. Stanley Cristol working under an NYA grant from the government. In the case of all electrolyses after the first two, sodium peroxide instead of sodium hydroxide was added to the water to make it conducting; sodium peroxide was used because it contains no deuterium, the excess oxygen was eliminated by boiling. Data for the preparation of deuterium-free water are given in Table I where the letters after the numbers are labels serving to distinguish and identify the various waters in order to clarify the table. All the different waters mentioned in this paper will be marked in this way so that the previous history of the water can be found readily by the reader (N signifies normal, or Lake Michigan, water).

Part of the water obtained from each electrolysis was decomposed electrolytically, the hydrogen passed over hot

copper; it was next dried and then combined with dried atmospheric oxygen over a hot copper catalyst with the hydrogen always slightly in excess to prevent fractionation of the oxygen isotopes. The resulting water was condensed in a water condenser; in one experiment the water condenser was supplemented by a dry ice–acetone condenser, but no difference in the density of the water due to the introduction of the dry ice condenser could be detected. Data for the preparation of this water are given in Table II.

TABLE I

DATA OBTAINED IN THE PREPARATION OF DEUTERIUM-FREE WATER

Fractionation	Water taken, cc.	Water collected, cc.	% collected	Residue, cc.	Lost, cc.	cc. retained for hydrogen analyis
1	72,000 (N)	23,600 (A)	32.79	47,000	1400	
2	23,600 (A)	9,440 (B)	40.00			800 (B)
3	8,640 (B)	4,579 (C)	52.99	3,782 (D)	739	590 (C)

TABLE II

DATA OBTAINED IN THE PREPARATION OF WATER MADE FROM DEUTERIUM-FREE HYDROGEN AND ATMOSPHERIC OXYGEN

Fractionation	Water taken, cc.	Product, cc.	Residue, cc.	Water lost, cc.
2	800 (B)	300 (H)	200 (I)	300
3	590 (C)	285 (J)	50	265
4	500 (E)	255 (K)	50	195
5	675 (F)	440 (L)	50	185

The purification of the various waters and the method of measuring the density were essentially the same as previously described.[5]

In order to prevent the "light" water from being contaminated with normal water, some wash water for use in rinsing the various glass receptacles, thermometers, floats, etc., was prepared by electrolyzing approximately half of the residue from the second fraction in the hydrogen separation cells and combining the liberated hydrogen with atmospheric oxygen. Two liters of wash water having a density only slightly greater than the lightest fractions (J, K, L) were obtained.

The ordinary laboratory distilled water which comes originally from Lake Michigan was the standard water chosen. The hydrogen and oxygen of this water were assumed to be normal in their isotopic composition.

The density data are collected in Table III.

After the density of the various fractions had been measured, waters H, J, K, L, were mixed, the density of the mixture taken and then a very careful electrolytic fractionation carried out by decomposing 60% of the mixture. In this final step the air supplying the atmospheric oxygen was passed through a drying tower of solid potassium hydroxide and then through concentrated sulfuric acid.

The water resulting from the combustion of the electrolytic hydrogen and the atmospheric oxygen was completely recovered in a dry ice–acetone trap. These extra precautions did not lower the density of the "light" water below -9.0γ.

TABLE III

DATA FOR THE DENSITY OF THE VARIOUS WATERS

	Fraction no.	Label	Δt,°C	γ
	3	(J)	−0.029	− 8.7
			− .029	− 8.7
	4	(K)	− .029	− 8.7
			− .032	− 9.6
	5	(L)	− .030	− 9.0
			− .030	− 9.0
Accepted value:			− .030	− 9.0
2, 3, 4, 5 (Waters H, J, K, L, mixed):				
			− .029	− 8.7
2, 3, 4, 5 Mixed and further fractionated:				
			− .030	− 9.0
Water G			− .062	−18.6
Water M			− .041	−12.6

The density of water G was measured in order to see whether the electrodes of the cells had fractionated the oxygen isotopes during all the electrolyses. This water is probably equivalent to Johnston's light fraction from his second or third electrolysis since it represents the residue after decomposing 53% of water E from the fourth fractionation. The ability of the electrodes of the cells to fractionate the hydrogen isotopes was tested at the conclusion of the experiments; 1200 cc. of normal distilled water was placed in the cells and electrolyzed, and 490 cc. of first fraction water resulted. This water, water M, had a γ value of -12.6, which proved that the electrodes had not lost their activity for hydrogen isotope separation.

We conclude from our measurements that the density of deuterium-free water containing atmospheric oxygen is 9.0 p. p. m. lighter than purified Lake Michigan water.

The close agreement between the densities of waters J, K and L, indicates that the hydrogen must have been brought to a constant isotopic composition which we assume is practically pure protium.

Discussion of the Data and Comparison with Previous Results

In order to calculate from our value of $-9.0\ \gamma$ the density of D-free water containing normal oxygen, it is necessary to know the exact value for the difference in density of waters made of normal oxygen and atmospheric oxygen. This value has been determined carefully by a number of workers using an electrolytic method with rather excellent agreement considering the different techniques involved and the geographical location of the standard waters. In Table IV we have summarized recently published results.

Accepting $6.4\ \gamma$ as the excess density of water containing atmospheric oxygen, we can subtract this number from our datum of $-9.0\ \gamma$ to obtain $-15.4\ \gamma$ as the difference in density between deuterium-free water and normal water, the oxygen of both waters being isotopically identical. In Table V we have summarized all published re-

sults for the γ-value of D-free water, and we have included also values of the D/H ratio (denominators rounded off to the nearest 100), calculated by the method of Morita and Titani,[1] using the accurate specific gravity value for heavy water given by Selwood, Taylor, Hipple and Bleakney.[6]

There is considerable discrepancy between these values for the D/H ratio. Christiansen, Crabtree and Laby,[7] Ingold, Ingold, Whitaker and Whytlaw-Gray,[8] and Tronstad, Nordhagen and Brun[9] do not state in their short "Letters to the Editor" whether or not they corrected for the electrolytic fractionation of the oxygen isotopes in their experiments. We are doubtful whether the D-free water prepared by Christiansen, Crabtree and Laby contained atmospheric oxygen as suggested by Morita and Titani,[1] inasmuch as the Australian workers stated that they burned the gases evolved. The data in Table V due to Edwards, Bell and Wolfenden,[10] and to Lewis and Macdonald[11] were obtained by measuring the rate at which deuterium concentrates on electrolysis. Knowing the fractionation factor for the cells, the D/H ratio in normal water can be calculated. Lewis and Macdonald made no attempt to correct for oxygen isotope fractionation. This method does not seem to be as accurate, however, as the method of measuring the density of D-free water.

TABLE V

DENSITY DIFFERENCES BETWEEN DEUTERIUM-FREE WATER AND NORMAL WATER FROM DIFFERENT INVESTIGATIONS

Investigation	Source of water	γ	D/H Ratio
This investigation	Lake Michigan	-15.4	1:6900

Edwards, Bell and Wolfenden	Oxford, England		1:6200
Hall and Jones	Lake Mendota	-16.5	1:6500
Ingold, Ingold, Whitaker and Whytlaw-Gray	London, England	-12.0	1:8900
Johnston	Columbus, Ohio	-18.3	1:5800
Lewis and Macdonald	Berkeley, Calif.		1:6500
Morita and Titani	Osaka, Japan	-18.9	1:5600
Tronstad, Nordhagen and Brun	Rjukan, Norway	-18.5	1:5800

Johnston[3] assumes in his work that the oxygen isotope fractionation factor is independent of the kind of hydrogen isotope present in the water. This assumption was also tacitly made by one of us in obtaining the data of Table IV. Selwood, Taylor, Hipple and Bleakney[6] have calculated with the aid of the theory given by Eyring and Sherman[12] that the separation ratio for the bonds D-O^{18}, D-O^{16} is slightly higher than that for the bonds H-O^{18}, H-O^{16}, but they state that even when the concentration of deuterium had reached the high percentage of 90%, the effect was too small to be detected experimentally. Unless there are some unknown influences at work in the region of low deuterium concentration, it would appear that the assumption of independence for the oxygen isotope fractionation factor is entirely justified. Probably a greater source of uncertainty in Johnston's work is the difficulty regarding the extrapolation. We have reëxtrapolated his data, drawing our straight line through all of his circles, but purposely sloping the line to yield an extrapolated value as near our datum of $-15.4\ \gamma$ as possible. The result of this extrapolation was $-15.9\ \gamma$, which indicates that Johnston's results are not entirely inconsistent with the work of this paper. We are not insisting, however, that our extrapolation is as reliable or more reliable than his.

It is more difficult to explain the discrepancy between the result of this investigation and that of Morita and Titani, which seems to have been carried out very carefully.[1] It is possible, of course, that Japanese water may contain more deuterium than the water of Lake Michigan, but it seems hardly likely that the difference will be great enough to cause a difference of 3 p. p. m. in the density, particularly since one of us has re-

cently found no measurable difference in the deuterium content of fresh and salt water.[13]

Hall and Jones' datum of $-16.5\ \gamma$, which differs from ours by 1.1 p. p. m., was obtained in two ways although both methods involved the normalization of the oxygen in the water by equilibration with carbon dioxide gas which had been equilibrated previously with normal water. Since carbon dioxide comes so slowly to equilibrium with water and since the equilibrium constant is a function of temperature, it would seem that this method is undesirable and difficult of application. The assumption is also made that the oxygen isotope equilibrium between carbon dioxide and water is the same irrespective of the deuterium content of the water. We examine this assumption below. Hall and Jones in a second series of experiments burned their cell hydrogen with atmospheric oxygen obtaining results which varied considerably, although their last measurements ($-8.9\ \gamma$) agreed almost exactly with ours ($-9.0\ \gamma$). However, on equilibration with carbon dioxide this water which was apparently exactly like ours, changed in density to $-16.5\ \gamma$, whereas our calculated result is $-15.4\ \gamma$. Thus the discrepancy between the work of Hall and Jones and our own is seen to be due to the two different ways in correcting for the oxygen isotope ratio. We believe that our method which consists essentially in measuring the oxygen isotope ratio in atmospheric oxygen gives a more reliable result than the method of Hall and Jones based on the carbon dioxide equilibration.

Calculation of Some Isotopic Exchange Equilibrium Constants.—Among the equilibrium constants of isotopic exchange reactions which Urey and Greiff[14] have calculated from spectroscopic data and statistical theory constants involving D_2O^{16} and D_2O^{18} are missing, because, undoubtedly, the supply of heavy water is so limited that no practical importance is attached to these constants, but in order to answer certain theoretical questions which have arisen we decided to calculate the equilibrium constants of the oxygen isotope reactions between carbon dioxide, oxygen and heavy water. If the distribution function ratio[15] $f_{D_2O^{18}}/f_{D_2O^{16}}$ is known, then the desired equilibrium constants can be calculated easily, making use of other distribution function ratios tabulated by Urey and Greiff. Frequencies for the D_2O^{16} and D_2O^{18} molecules were calculated using the equations of Van Vleck and Cross[16] after their force constants k_1, k_{12} and k_3 had been adjusted to give agreement between the calculated frequencies of the D_2O^{16} molecule (2666.0, 2785.0, 1176.6) and those (2666, 2784, 1179) observed by Barker and Sleator.[17] The results of the calculation are collected in Table VI.[18]

TABLE VI

MOLECULAR CONSTANTS

Molecule	ω_1	ω_2	ω_3	A_2/A_1	B_2/B_1
D_2O^{16}	2666.0	2785.0	1176.6	1.0083	1.0229
D_2O^{18}	2646.8	2770.3	1169.5		

DISTRIBUTION FUNCTION RATIOS

	273.1°A.	298.1°A.	600°A.
$\frac{f_{D_2O^{18}}}{f_{D_2O^{16}}}$	1.3043	1.2926	1.2316

EQUILIBRIUM CONSTANTS AND ENRICHMENT FACTORS

Reaction	$K_{298.1°}$	Enrichment factor
$CO_2^{16} + 2D_2O^{18}(g) \rightleftharpoons CO_2^{18} + 2D_2O^{16}(g)$	1.065	1.032
$O_2^{16} + 2D_2O^{18}(g) \rightleftharpoons O_2^{18} + 2D_2O^{16}(g)$	0.9990	0.9995

The distribution function ratio, $f_{D_2O^{18}}/f_{D_2O^{16}}$, is about 3% greater than the ratio $f_{H_2O^{18}}/f_{H_2O^{16}}$; hence the equilibrium constants of the reactions listed in Table VI are about 6% smaller than the constants for the normal water equilibria. Thus O^{18} tends to concentrate less in the gas phase and more in the aqueous phase; in the case of the oxygen–water equilibrium the new calculations show that the equilibrium concentrations of the reaction are shifted far enough so that O^{18} concentrates in the heavy water rather than in the gas. However, the difference in behavior between the carbon dioxide–water equilibrium and the carbon dioxide–heavy water equilibrium is not great enough to invalidate the equilibration method of Hall and Jones. In regard to the relative rate at which the carbon dioxide comes into equilibrium with the two kinds of water, nothing is known at the present time.

Summary

Deuterium-free hydrogen has been prepared and combined with atmospheric oxygen yielding

[17] E. F. Barker and W. W. Sleator, *ibid.*, **3**, 660 (1935).

[18] At the suggestion of the referee of this paper we give the values of the force constants calculated by us by arbitrarily setting the value of k_{13} at 0.05×10^5, and by solving simultaneously three independent equations, for k_1, k_{12} and k_3. These three equations were obtained by substituting known values for the a_{ij} constants into the three equations for λ_1^2, λ_2^2 and λ_3^2. These last three quantities were also known from the experimental data. The new values of the force constants for the D_2O^{16} molecule are k_1, 7.796×10^5; k_{12}, 0.4976×10^5; k_3, 0.3598×10^5; and k_{13} 0.05×10^5.

water lighter by 9 p. p. m. than Lake Michigan water. When 6.4 p. p. m. are added to 9 p. p. m. to correct for the difference in atomic weight of atmospheric oxygen and aqueous oxygen, the density of D-free water containing normal oxygen is 15.4 p. p. m. lighter than normal water. From this the ratio of deuterium atoms to hydrogen atoms in Lake Michigan water is calculated to be 1:6900. Our density value of $-15.4\ \gamma$ agrees within 1.1 p. p. m. with that of Hall and Jones, $-16.5\ \gamma$, and confirms their belief that the commonly accepted value for the D/H ratio is too high and should be revised downward. Our result indicates, however, that the downward revision should be somewhat more than that recommended by Hall and Jones.

Isotopic exchange equilibrium constants involving D_2O^{16} and D_2O^{18} have been calculated and tabulated.

The Solubilities of Potassium Chloride in Deuterium Water and in Ordinary Water from 0 to 180°

BY R. W. SHEARMAN AND ALAN W. C. MENZIES

Published measurements of solubility of salts in deuterium water[1] hitherto have been limited to a few determinations near room temperature. The present work is one of a series of studies over a wide temperature range undertaken in the hope of gaining insight into portions of the general subject of aqueous solubility.

Method and Materials.—For all our experiments with deuterium water, and for most of those with ordinary water, the method used was that described by Menzies.[2] A few experiments requiring much ordinary water in relation to the quantity of solute were carried out by the older synthetic method, where each experiment demands a separate sealed tube. Our method of securing and measuring steady temperatures has already been described;[2] and it may be added that about one-half of the measurements were carried out in the jacketed air-oven referred to in the earlier publication.

The deuterium water was similar to that described elsewhere,[3] with a content of 98.2% D_2O. The relative density of this water compared to ordinary water at 25° was taken as 1.1059 for the purposes of conversion of measured volumes to masses. In order to apply the small correction for the weight of water vapor present in the gas phase, values of the vapor pressure of saturated solutions of potassium chloride were derived, by extrapolation when necessary, from the work of Leopold and Johnston;[4] and these pressure values could, with adequate approximation, be adapted to suit the case of deuterium water solutions from a knowledge of solubility and of the vapor pressures of deuterium water relative to that of ordinary water.[3]

Potassium chloride is easily obtained of highest purity, and we estimate the impurity of our sample, other than water, as less than five parts per 10,000. Water was removed by slow heating to incipient fusion.[5]

Manner of Stating Solubility.—The solubility of potassium chloride in common water is reported in moles of solute per 1000 g. of water (55.51 moles H_2O), conformably to the practice of "International Critical Tables." To secure a comparable statement of solubility in deuterium water, we state the number of moles of solute per 1111.7 g. of solvent, which is 55.51 moles of D_2O. To arrive at this value from experiments made with 98.2% D_2O, we first computed, from the weights of solvent and solute used, the molal solubility in 1109.7 g. of our sample, which is the weight containing 55.51 moles of mixed D_2O and H_2O. By comparing the value so found with the molal solubility in ordinary water, we were able, by a short linear extrapolation, to arrive at the solubility per 55.51 moles of pure D_2O.

Experimental Results.—For all but the lower temperature experiments the identical solute material, 0.4086 g. of potassium chloride, was employed with both solvents. The total weight of 98.2% deuterium water employed was 1.39 g., and this was completely recovered in its original purity. In the case of deuterium water, the ratio of mass of solute to solvent was reduced for a few of the lower temperature experiments by using a smaller weight of solute in the apparatus described; and, in the case of ordinary water, by increasing the amount of solvent in separate sealed-tube experiments.

Table I records the results observed in ordinary water in the first two columns and in deuterium water in the third and fourth columns.

These observations were graphed in the manner described previously,[2] and solubility values read off for round values of temperature, as recorded in Table II, where, in the fourth column a comparison is made with the solubility values found in "International Critical Tables."

160	9.57	− .3	9.36	2.2
180	*10.24*	− .6	*10.06*	*1.8*

It will be seen from Table II that the solubility in ordinary water diverges most largely from the "I. C. T." values in the region near 60°. Since the latter values were compiled, new measurements have been made by Scott and Durham,[6] who report solubilities at 50.21, 67.91 and 92.23°. Their values, followed by our own in parentheses for these temperatures, are 5.73 (5.75), 6.35 (6.36) and 7.20 (7.24), respectively. The divergencies here are in the opposite direction from those of "I. C. T."

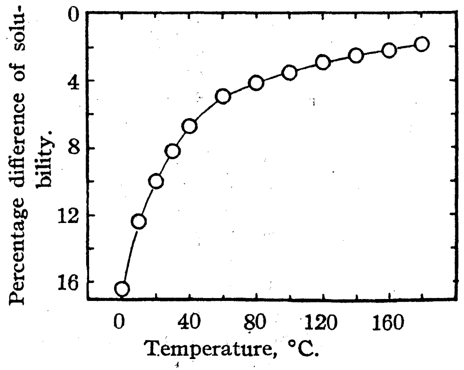

Fig. 1.—Comparison of solubility of potassium chloride in ordinary and in deuterium water.

The error in measurement by the method here used has been discussed elsewhere.[2] The average divergence of the experimentally determined points from our smooth curves was about 0.3% in the present work.

Graphical Comparison.—The diagram, Fig. 1, shows a plot of the values in Table II, column 5, against temperature.

Discussion.—The solubility of potassium chloride increases with temperature faster with deuterium water as solvent than with ordinary water. In addition to the nature of the solvent, another of the factors concerned in this is the heat of ion hydration. This in turn is influenced by the nature and the condition of the solvent.

Inspection of Fig. 1 makes it evident that, passing downward from 180 to about 60°, the change with temperature of the solubility difference is roughly rectilinear. From about 60° downward, the solubility difference increases at a much faster rate than before. This may perhaps be correlated with change with temperature of the average configurations in liquid water.[7] Recalling that the temperature of maximum density for deuterium water is 11.6° as compared with 4.0° for ordinary water, one is led to believe that the forms or structures present in water just above the melting point persist to higher temperatures in the case of deuterium water than of ordinary water.

Contrary to a prevalent belief,[8] in comparing deuterium water with ordinary water as a solvent for salts it must not be thought that the former is a poorer solvent under all circumstances, for such is not the case.[9] Because such facts must be taken into consideration, further discussion will find more appropriate place after the solubility results for other salts have been communicated.

Summary

Values for the solubility of potassium chloride in ordinary water and in deuterium water have been reported in the temperature range 0–180°. The differences in solubility have been briefly discussed.

The Surface Tension of Solutions of Electrolytes as a Function of the Concentration. I. A Differential Method for Measuring Relative Surface Tension

BY GRINNELL JONES AND WENDELL A. RAY

Introduction

Most salts may be classified among the "capillary-inactive substances" which give solutions having a surface tension slightly greater than that of pure water and which are negatively adsorbed in the surface layer within the range of concentration hitherto investigated. Measurements by many early investigators have shown that the surface tension–concentration curves are approximately linear and that the slope and curvature are less influenced by the individuality and valence type of the salt than the corresponding curves for most other properties of solutions of electrolytes.

The first careful work on dilute solutions (less than 0.2 N) appears to have been done under the supervision of Heydweiller by two of his pupils, Gradenwitz and Kleine, who used the capillary rise method. Heydweiller has assembled and critically analyzed the data available up to 1910.[1]

If Quincke's law, which may be expressed $\sigma_c/\sigma_0 = 1 + kc$, were really valid, then $(\sigma_c - \sigma_0)/\sigma_0 c = k$ should be a constant independent of the concentration. Heydweiller found, however, that for many salts $(\sigma_c - \sigma_0)/\sigma_0 c$ decreases rather sharply with rising concentration in the dilute range (below 0.2 N), passes through a flat minimum, and then rises slowly for concentrated (above about 2 N) solutions. Heydweiller suggests that the attractive forces between adjacent ions of opposite charge will cause an increase in the surface tension. He says, "The effect of ions n the surface tension is to be ascribed in greatest art to the electrical forces of their charges."

Schwenker[2] has measured the surface tension of ill more dilute (0.015 N up to 0.15–0.18 N) lutions of lithium, sodium and potassium chloles at 0° by measuring the vertical force necesy to pull a horizontal wire out of the solution. s surface tension–concentration curves for se three salts are identical at the lower concentions within his experimental error and have the same downward curvature at low concentrations which Heydweiller found to be characteristic of solutions of electrolytes. Schwenker regards this characteristic behavior to be in accord with Lenard's theory that the surface layer of water at a water–air interface is electrically negatively charged and that there is a positively charged layer at a lower depth.[3]

Wagner,[4] and later Onsager and Samaras,[5] have applied the Debye–Hückel theory of interionic attraction to the problem and reached the conclusion that the electric forces between the ions must cause a deficiency of ions in the surface layer and an increase of the surface tension. They derived the following equation for dilute aqueous solutions of uni-univalent electrolytes

$$\sigma_c/\sigma_0 = 1 + \frac{79.517}{D\sigma_0} c \log \frac{1.143 \times 10^{-3}(DT)^3}{c} \qquad (1)$$

where D is the dielectric constant of water and T the absolute temperature. It should be noted that this equation contains no parameters which are selected to fit the data, and also that it contains no quantities which are dependent on the particular salt or ions present. This equation, therefore, predicts that all uni-univalent salts should give identical surface tension–concentration curves, at least through the range of concentrations for which the authors would claim that their equation is valid. The available experimental data show that in the relatively high concentrations for which reliable data are available the curves are approximately, but not exactly, identical. The Onsager–Samaras equation predicts that the limiting slope at zero concentration should be plus infinity and have a very sharp negative curvature in the extremely dilute range. Data at sufficiently low concentrations to test this conclusion are not available. According to this equation, within the experimentally accessible range the surface tension–concentration curve should have a gentle positive but decreasing slope, which is qualitatively in accord with the data. The equation predicts that the relative surface

tension should reach a maximum at $c = 0.54$ with the low value of only 1.0033. The available data give no indication that there is a maximum in the surface tension curves near half normal, or at any other concentration, and values much above the computed maximum have been observed for many salts. It is, therefore, evident that there have been terms omitted in the derivation of this equation which become significant substantially below half normal. Although in the derivation of their equation Onsager and Samaras limited themselves to uni-univalent salts, the available data indicate that the influence of valence on the surface tension is much less than on most other properties of electrolytes.

The object of this investigation is to study the relative surface tension of solutions of electrolytes as a function of concentration and nature of the salt, with special attention to very dilute solutions. Since we are interested in the interpretation of the data from the point of view of the interionic attraction theory of Debye, we are interested primarily in the conditions after equilibrium between the thermal and electrical forces has been established. We, therefore, desire to measure the static rather than the dynamic surface tension. Since the surface tension of solutions of salts differs only slightly from that of pure water (less than 3% for normal solutions), a higher order of precision will be needed to secure significant results for dilute solutions than has hitherto been obtained with any of the methods. For the theoretical purposes which interest us an accurate knowledge of surface tension relative to that of pure water will suffice and absolute values are not needed. This simplifies the experimental problem greatly. The capillary rise method seemed to be the most promising. We undertook, therefore, to modify the technique of this method to make it a differential method of sufficient precision for our purposes.

A Differential Method of Determining the Surface Tension of Solutions Relative to that of the Pure Solvent

In its fundamentals the capillary rise method of determining the absolute surface tension of a liquid consists in measuring the vertical difference in height between a meniscus in a narrow cylindrical tube, whose radius is determined independently, and in a connecting tube which is so wide that it has a flat surface at the center, together with an independent determination of the density of the liquid. The surface tension is then computed from the equation

$$\sigma = \frac{rhg(D - \beta)}{2} \cos \theta \qquad (2)$$

where r is the radius of the narrow tube at the level of the meniscus, h is the capillary rise measured above a connecting free surface of infinite extent, g is the acceleration of gravity, D is the absolute density of the liquid, and β is the density of the gas phase (air plus water vapor) at the temperature and the barometric pressure prevailing when the experiment is made, and θ is the angle of contact. For water and aqueous solutions in glass or silica tubes θ is zero if the surfaces are really clean. An approximate value of the capillary rise is obtained by measuring the difference in elevation between the lowest points in the menisci in the narrow and wide tubes. The true capillary rise, h, is then obtained by applying a correction for the liquid in the upper and lower menisci by Rayleigh's[6] formula. When necessary, subscripts are used to distinguish between the capillary rise for a solution, h_c, and that of pure water, h_0.

The density can be determined easily within 0.001% and the value of the acceleration of gravity can be regarded as known, so that the accuracy of the result depends on the unavoidable experimental errors in determining r and h.

The radius of the capillary has usually been computed from measurements of the length of a weighed drop of mercury in the capillary. This requires the assumption that the capillary is a true right circular cylinder, whereas even the best capillary obtainable may be more or less elliptical and conical. Irregularities in the walls of the tube may cause optical distortion of the image and thus cause an error in the measurement. The capillary rise is found by measuring the elevation of the upper and lower meniscus on a vertical scale by means of a cathetometer. This reading on the meniscus in the capillary tube is comparatively easy, but it is much more difficult to obtain an accurate reading on the meniscus in the wide tube. The apparent readings are influenced by the adjustment of the illuminating device, the length of the focus, and the possible optical distortion of the image due to irregularities of the walls of the wide tube. Moreover, vibrations of the surface are apt to be disturbing.

Extreme care is required to reduce the combined effect of the errors in the radius and capillary rise to 0.1%, and it is doubtful if anyone has succeeded in reducing them below 0.05%.

We have devised a modification of the usual procedur
which makes it a differential method for measurements o
the surface tension of solutions relative to that of the pur
solvent and practically eliminates the two greatest sourc
of error in the older technique.

Errors due to deviation of the capillary tube from a tr
right circular cylinder and to inaccuracy in the determi
tion of the radius of the capillary are completely elimina
by bringing the meniscus of the solution and of pure wa
to the same part of the capillary tube, designated by a s
able permanent mark, and then determining the differe
in capillary rise in the wide tube.[7] By dividing the ex
sion for the surface tension of the solution, σ_c, by th
the pure solvent, σ_0, the radius of the capillary and
acceleration of gravity are eliminated entirely.

The difficulties of measuring the height of the me
in the wide tube by a cathetometer are avoided entir

[7] This device has been used by Gradenwitz and Kleine.

a modification of the procedure which permits the difference in capillary rise of solution and of solvent to be computed from data obtained by weighing.

The new differential capillarimeter is in principle suitable for any solvent, but up to the present time we have used it only with aqueous solutions and, since the properties of water influence or control some of the details, we shall in the following discussion assume that the solvent is water.

Derivation of the Equation for the Computation of the Relative Surface Tension of Solutions from the Experimental Data

The differential capillarimeter is shown in Fig. 1. It consists of a fine capillary tube of vitreous silica of radius r (r is 0.0136 cm. in our instrument) sealed to a wide tube which has been ground and polished internally to a true right circular cylinder of radius R (R is 2.1489 cm.). The empty instrument is weighed and then mounted vertically in a thermostat at 25.00°. Pure water is added to the instrument in an amount which will bring the meniscus in the capillary to the reference mark M. The volume of the water is then designated as V_0. The vertical height between the lowest point in the meniscus in the capillary and the lowest point of the meniscus in the wide tube is then measured by a cathetometer which, after applying two small meniscus corrections explained below, gives the true capillary rise for water, h_0. The instrument is then removed from the thermostat and weighed with its contents, which, after subtracting the weight of the empty instrument and adding the vacuum correction, gives the true weight of water W_0. Let D_0 represent the absolute density of water. It is obvious that $V_0 = W_0/D_0$.

Then the instrument is emptied, dried and remounted in the thermostat and filled with the proper amount of solution containing c gram equivalents of salt per liter to bring the meniscus in the capillary again to the mark, M. The capillary rise is $h_c = h_0 + \Delta h$. It is not necessary
determine h_c by making measurements with the
tometer and adding meniscus corrections,
this is sometimes done as a check. The
then removed from the thermostat,
nd weighed with its contents,
ng the weight of the empty
the vacuum correction,
lution W_c. The volume
volume of the solution
here D_c is the absolute
The density is determined independently in a suitable pycnometer. Then we may write

$$\sigma = \frac{\sigma_c}{\sigma_0} = \frac{rg\ (D_c - \beta_c)h_c}{rg\ (D_0 - \beta_0)h_0} = \frac{(D_c - \beta_c)(h_0 + \Delta h)}{(D_0 - \beta_0)h_0} = \frac{D_c - \beta_c}{D_0 - \beta_0} + \frac{(D_c - \beta_c)\Delta h}{(D_0 - \beta_0)h_0} \tag{3}$$

Since we bring the upper meniscus to the same part of the capillary for the solution and for water, the value of r cancels out and does not have to be known exactly.

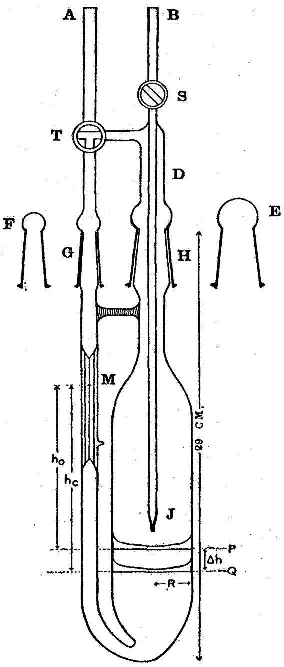

Fig. 1.—Silica capillarimeter.

Let W_0' and V_0' represent the weight and volume of water contained in the apparatus from the upper surface in the capillary to the level of a free surface of infinite extent which is assumed to be in hydrostatic equilibrium with the liquid in the instrument (P in the diagram), and let W_0'' and V_0'' represent the weight and volume between the meniscus in the wide tube and the level of the free surface (not the tangent to the lowest point of the meniscus). Then $W_0 = W_0' + W_0''$ and $V_0 = V_0' + V_0''$. The force of gravity on the liquid in the meniscus above the level of the free surface is balanced partly by the surface tension and partly by the buoyancy of the air. Therefore, we may write

$$W_0''g = D_0V_0''g = 2\pi R\sigma_0 + V_0''\beta_0 g \tag{4}$$

$$V_0'' = \frac{2\pi R\sigma_0}{g(D_0 - \beta_0)} \tag{5}$$

$$V_0' = V_0 - \frac{2\pi R\sigma_0}{g(D_0 - \beta_0)} = \frac{W_0}{D_0} - \frac{2\pi R\sigma_0}{g(D_0 - \beta_0)} \tag{6}$$

and in an exactly analogous manner we may write for the solution

$$V_c' = V_c - \frac{2\pi R\sigma_c}{g(D_c - \beta_c)} = \frac{W_c}{D_c} - \frac{2\pi R\sigma_c}{g(D_c - \beta_c)} \tag{7}$$

Since the wide tube is a true cylinder of radius, R, and is mounted vertically, we may write

$$\Delta V = V_0' - V' = \pi R^2 \Delta h \tag{8}$$

$$\Delta h = \frac{1}{\pi R^2}\left\{\frac{W_0}{D_0} - \frac{2\pi R\sigma_0}{g(D_0 - \beta_0)} - \frac{W_c}{D_c} + \frac{2\pi R\sigma_c}{g(D_c - \beta_c)}\right\} \tag{9}$$

Making this substitution in equation (3) gives

$$\sigma = \frac{\sigma_c}{\sigma_0} = \frac{D_c - \beta_c}{D_0 - \beta_0} + \frac{(D_c - \beta_c)}{(D_0 - \beta_0)}\frac{\Delta h}{h_0} = \frac{D_c - \beta_c}{D_0 - \beta_0} + \frac{(D_c - \beta_c)}{(D_0 - \beta_0)\,\pi R^2 h_0}\left\{\frac{W_0}{D_0} - \frac{2\pi R\sigma_0}{g(D_0 - \beta_c)} - \frac{W_c}{D_c} + \frac{2\pi R\sigma_c}{g(D_c - \beta_c)}\right\} \tag{10}$$

Then a purely algebraic and rigid transformation remembering that $r = 2\sigma_0/gh_0(D_0 - \beta_0)$ gives the equation

$$\sigma = \frac{\sigma_c}{\sigma_0} = \left\{\frac{D_c - \beta_c}{D_0 - \beta_0}\right\}\left\{1 + \frac{1}{\pi R^2 h_0 (1 - r/R)}\left(\frac{W_0}{D_0} - \frac{W_c}{D_c}\right)\right\} \tag{11}$$

It should be noted that this equation does not involve any assumption that the reservoir is so wide that the capillary rise in this tube is negligible, nor does it contain any assumption that the meniscus in the wide tube has the same shape for the solution and for water. If the derivation is carried through with these assumptions the result is the same, except that the factor $(1 - r/R)$ in the denominator of the second term is missing.

Precision Analysis

For the purpose of precision analysis it is more convenient to write equation (11) in the equivalent form

$$\sigma = \frac{\sigma_c}{\sigma_0} = \frac{D_c - \beta_c}{D_0 - \beta_0} + \frac{(D_c - \beta_c)}{(D_0 - \beta_0)}\frac{(W_0 D_c - W_c D_0)}{\pi R(R - r)h_0 D_0 D_c} \tag{12}$$

For all the cases reported below, the first term in equation (12), $(D_c - \beta_c)/(D_0 - \beta_0)$ is greater than 1 and less than 1.15. The second term is negative in all cases yet encountered and much smaller (the greatest numerical value so far experienced is 0.06338 for 3 N potassium chloride) and may, therefore, be regarded as a correcting term. It is, therefore, obvious that the accuracy of the final result will depend directly upon the accuracy of the determination of the densities of our solutions and that the quantities which are involved as factors of the second term do not have to be known with as great accuracy as the densities. Since in our instrument r/R is 0.00633, the final result will be very little influenced by an error in r.

D_0, β_c, β_0 and π may be regarded as known without significant error, but all of the other quantities appearing in the equation are determined by experiment and are subject to experimental errors which may influence the accuracy of the computed relative surface tension. From the principles of partial differentiation we may write

$$\Delta\sigma = \frac{\partial\sigma}{\partial D_c}\Delta D_c + \frac{\partial\sigma}{\partial W_0}\Delta W_0 + \frac{\partial\sigma}{\partial W_c}\Delta W_c + \frac{\partial\sigma}{\partial h_0}\Delta h_0 + \frac{\partial\sigma}{\partial R}\Delta R + \frac{\partial\sigma}{\partial r}\Delta r + \frac{\partial\sigma}{\partial T}\Delta T + \frac{\partial\sigma}{\partial(r_c/r_0)}\Delta\frac{(r_c)}{(r_0)} \tag{13}$$

Although equation (12) does not contain the temperature, T, explicitly, σ is a function of the temperature, and therefore to obtain a complete differential equation the term $\partial\sigma\Delta T/\partial T$ must be added. In the derivation of equation (12) it was assumed that the solution and water are brought to the same part of the capillary so that $r_c = r_0$. The error caused by a failure to meet this condition perfectly in the experiments is represented by the term $\partial\sigma\Delta(r_c/r_0)/\partial(r_c/r_0)$.

The problem now is to carry out the differentiation indicated in equation (13) and to substitute actual numerical data for each algebraic symbol in the total differential equation. In Table I we have used the data for three different solutions of potassium chloride selected to be typical of a dilute solution, an intermediate solution, and a very concentrated solution to compute the experimental errors in the measured quantities, D_c, W_0, W_c, h_0, R and r, which would each separately cause an error of 0.001% in the relative surface tension for an instrument for which h_0 = 10.834 cm., R = 2.1489 cm. and r = 0.0136 cm.

TABLE I

PRECISION ANALYSIS

	0.001 N KCl	0.1 N KCl	3 N KCl	
D_c	0.997116	1.001787	1.12808	G./ml.
W_0	84.9947	84.9947	84.9795	G.
W_c	85.0318	85.7047	106.1728	G.
D_c	+0.0000064	+0.0000064	+0.0000064	G./ml.
W_0	+ .00155	+ .00155	+ .00137	G.
W_c	− .00155	− .00155	− .00155	G.
h_0	+ .5	+ .055	+ .0038	Cm.
R	+ .05	+ .0054	+ .00017	Cm.
r	− .1	− .0108	− .00033	Cm

The foregoing table, interpreted in the our experience with the method, shows accuracy of the result will probably influenced by the errors in W_0 and W_c because it is difficult to determine them experimentally within 0.0015 g. It should, however, be noted that any systematic error in W_0 is likely to be duplicated in W_c and hence these errors are likely to compensate each other. The quantity D_c ranks next in its probable influence on the result because it is difficult to determine the density of a solution within 6 parts in a million, although by using large pycnometers (50 cc.) results can be duplicated within this limit. The combined effect of these errors should not exceed 0.003% with our apparatus. On the other hand, it is experimentally easy to determine h_0, R and r within the limits required of them except that for the most concentrated solutions the determination of R commences to become critical. The experimental error in R may be about 0.0001 cm. The radius of the capillary, r, is computed from the capillary rise with water, and the error in r depends mainly on the error in the value σ_0 selected from the literature for the calculation. An error of about 2.5% in the assumed value of σ_0 would be needed to cause an error of 0.00033 cm. in r and hence an error of 0.001% in the relative surface tension of a 3 N potassium chloride solution. Since σ_0 is probably known within 0.1%, errors due to r are insignificant in all the cases yet investigated.

The absolute surface tension of water at 25° changes 0.22% per degree, which would require that the temperature should be fixed within 0.0045° in order to fix the absolute surface tension within 0.001%. Since it is probable that the absolute surface tension of solutions varies with the temperature nearly the same as water, it follows that the temperature coefficient of the relative surface tension of solutions to that of water is presumably much smaller than the figure given above, so that a substantially greater error than 0.005° in our temperature scale could be tolerated. Since we had available a very good thermometer having a scale of 6 cm. per degree, which had been calibrated at the Bureau of Standards, we are confident that the working temperature of our thermostat was so near to 25.00° that no significant error is involved. A more dangerous source of error would be a variation of the temperature of the thermostat during the interval between the measurements on water and on the solutions. Our thermostat was good enough so that the maximum variation ever observed was safely within the tolerable limit of 0.004°.

The foregoing analysis also assumed that the radius of the tube is the same for the solution and for water. Since the position of the meniscus when the capillarimeter is filled may differ from the reference mark by ±0.001 cm., a variation of radius of 0.001% over a range of 0.002 cm. or 0.5% per cm. might cause an error of 0.001% in the relative surface tension. It is believed that our capillary is uniform within this tolerance (see page 192).

The advantages of our differential method over the old method are shown by a similar analysis of the formula

$$\sigma = \frac{\sigma_c}{\sigma_0} = \frac{g(D_c - \beta_c)h_c r_c}{g(D_0 - \beta_0)h_0 r_0}$$

On differentiating with respect to each of the experimentally determined quantities and substituting the numerical data for the 0.001, and 0.1 and 3 N potassium chloride solutions in this equation, it appears that the requirements for precision are nearly independent of the concentration and, therefore, a detailed table is omitted. These calculations show that an error of 0.000010 g./ml. in D_c, an error of 0.00011 cm. in either h_c or h_0 will each cause an error of 0.001% in the relative surface tension. Although D_c can be determined within this tolerance, the probable error in h_c and h_0 is many times the safe limit. By comparison with the table given above it will be noted that the new method is more dependent on errors in D_c than the old, but that is of minor importance because, if unlimited amounts of solutions are available, the densities can be determined with sufficient accuracy. On the other hand, the influence of errors in h_0 is reduced greatly in the new method, especially at low concentrations, and the necessity of determining h_c is eliminated. Moreover, the old method, in which no effort is made to bring the meniscus to exactly the same part of the capillary, requires the assumption that $r_c/r_0 =$ 1.00000 over the working range of the capillary which may amount to 2 cm., whereas the new method only requires that the radius of the capillary shall be constant within 0.001% over a range of only 0.002 cm.

The Capillarimeter and its Accessories.—The capillarimeter (Fig. 1) has graduation marks, 0.1 mm. apart, engraved on the capillary tube. A segment of this tube was ground off to give a flat polished strip and the marks were cut on this surface by the use of a fine diamond point operated by a dividing engine. These marks were so fine as to be invisible to the naked eye, but were correspondingly sharp when viewed under the microscope. They were not visible when the tube was immersed directly in the water of the thermostat; this was remedied by enclosing the capillary tube in another tube, the intervening space being filled with hydrogen for better thermal conductivity. The wide tube of the capillarimeter before fabrication was ground and polished inside and outside to true coaxial right circular cylinders in order to permit an accurately reproducible vertical mounting of the instrument and to avoid optical distortion. The external and internal diameters of this tube were measured with a micrometer before fabrication and found to be 5.0126 and 4.3004 cm., respectively, with a maximum variation at any place of ±0.00013 cm. After the construction of the complete instrument the external diameter was again measured by the micrometer and found to be unchanged within the working range.

A special holder, equipped with precision levels and leveling screws, was constructed which ensured that the capillarimeter could be mounted in a definite reproducible vertical position inside a water thermostat which was maintained at 25 ± 0.003°. The levels of the menisci were measured by observation through a window of optically plane glass by means of a special cathetometer, whose vertical scale was calibrated by comparison with a standard Invar scale provided with a Bureau of Standards certificate. To improve the definition of the menisci an adjustable blackened metal screen with horizontal slits as used by Richards and Coombs[8] was installed behind the menisci. A window of frosted glass in the back wall of the thermostat permitted adequate illumination.

The internal radius of the wide tube and of the capillary were determined after the construction of the instrument. The capillarimeter in its vertical mounting inside the thermostat was filled with sufficient water to bring the menisci within the working range. After waiting forty minutes for temperature equilibrium the heights of the menisci were measured. A weighed quantity of water of about 30 g. was then added and the measurements repeated. Three such independent determinations, covering approximately the same working range, gave as computed values of the radius of the wide tube 2.14882; 2.14892; and 2.14883; average 2.1489 cm. This figure is believed to be more reliable than the figure 2.1504 cm. obtained with a micrometer before the construction of the instrument.

As a result of many readings the observed or apparent capillary rise for water at 25° was taken as 10.8293 cm. between the lowest level of two menisci. This figure must be corrected[9] by +0.00453 cm. for the liquid in the upper meniscus; and by +0.00068 cm. for the elevation of the lowest part of the meniscus in the wide tube above the level of an infinite connecting surface; giving 10.8345 cm. as the true capillary rise. Hence the internal radius of the capillary at the point M (or more accurately at a level about 0.0045 cm. above M where the gas–liquid interface becomes vertical) is computed to be 0.01361 cm., by the use of equation (2), assuming[10] that $\sigma = 71.97$ for pure water at 25, and that at Cambridge the acceleration of gravity is 980.4.

Similar measurements, made at intervals along the capillary near the mark, M, show that the radius changes by 0.26% of itself per centimeter of length. If we always bring the water and solutions to be compared within 0.001 cm. of the mark, which is possible experimentally, the error in the relative surface tension due to conicality of the capillary tube would be less than 0.001%, which is negligible.

Purification of Materials and Preparation of Solutions.—The impurities most to be feared are capillary active substances, especially traces of grease and oils. Any relaxation in extreme care to maintain perfect cleanliness is apt to be followed promptly by erratic results. The capillarimeter, solution flasks, delivery tubes and all glassware were cleaned by exposure to a hot mixture of concentrated sulfuric and nitric acids, and finally thoroughly rinsed with water. This process was repeated whenever there was the slightest indication of imperfect drainage.

Richards and Carver[11] have published results indicating the effect of dissolved air is to lower the surface tension of water at 20° by about 0.03%. This difference, however, is about their limit of error and may not be significant. It seemed impractical to carry out all of our measurements *in vacuo*. Since we are interested in relative results and since the effect of dissolved air, if any, would probably be very nearly the same for solutions and for water, we decided to make all measurements on water and on solutions which were saturated with air.

The water used was freshly distilled conductivity water. It was collected in large bottles and shaken to saturate it with air, then blown by filtered compressed air through a sintered Jena Glass filter into a "water tower" which served as a storage reservoir. It was made of Pyrex, was 1 meter high, and 8 cm. in diameter. The water was stored here overnight to permit capillary active substances to rise to the surface and any dust particles to settle out. The water was then withdrawn when needed through a tube from the interior of the reservoir. The cock which controlled the outflow was ungreased and so well ground that no lubricant except water was needed. When water was withdrawn, suitable adapters were used to guide the water into the solution flasks or into other receptacles. The development of this device for protecting the water from capillary substances or dust greatly improved the reproducibility of the results.

The purest potassium chloride which could be purchased was recrystallized twice with centrifugal drainage and fused in platinum. A saturated solution of this salt gave no color with phenolphthalein. Potassium sulfate was prepared and tested in an exactly similar manner, except that it was not fused but was heated to redness in platinum. The cesium nitrate was made from the mineral pollucite by Professor Brainerd Mears and was a part of the same material already used for viscosity measurements in this Laboratory. Sucrose was obtained from "rock candy," since our previous experience showed that this variety contains less electrolyte than sucrose from any other source. The carefully selected crystals were then placed in platinum Gooch crucibles in a centrifuge

and washed with conductivity water to rinse off the surface and then dried in a vacuum at a temperature of 50°. The electrical conductivity of solutions of this sucrose was so low as to prove that the electrolyte present as an impurity was less than 0.001% and, therefore, negligible for our purposes.

All solutions were prepared by the weight method with extreme care to prevent contamination by capillary active substances. All weighings were corrected to vacuum, and the concentration in gram molecules per liter at 25° computed by the aid of the density which was determined for each solution. The density determinations were made by the use of three Ostwald pycnometers of slightly more than 50 cc. capacity. The results obtained with these three instruments usually checked within five parts in a million.

Capillarimetric Procedure.—Comparative measurements were made on the solutions and on water with every detail of manipulation, except the addition of salt, and of measurement as nearly identical as possible. The capillarimeter was cleaned, weighed, and hung in the thermostat in the proper position and the height of the reference mark on the fixed vertical scale measured. After standing for several hours to permit capillary-active substances, if present, to come to the surface, slightly less than the required amount (about 85 cc.) of water (or solution) was transferred to the capillarimeter through a tube containing a sintered Pyrex filter. The water (or solution) was brought to 25.00° before making the transfer to avoid condensation in the upper part of the capillarimeter and suitable precautions taken to deliver the water (or solution) to the lower part of the capillarimeter without spattering and the delivery tube was withdrawn without touching the neck of the capillarimeter and thereby wetting it. The cross head filled with water (or solution) from S to J was then placed in position, as shown in Fig. 1. After waiting about thirty minutes for temperature control, the liquid was sucked up into the capillary by opening the cock, T, and applying gentle suction at A. The meniscus was allowed to fall until it reached its position of rest and then observed through the telescope. Water (or solution) was then added drop by drop from J until the meniscus, when falling, came to rest within 0.001 cm. of the reference mark. Then, after the proper quantity of water had been added, the level of the lowest point of the meniscus in the capillary with reference to the mark, M, and to the fixed scale was measured and recorded. Then the level of the lowest point of the meniscus in the center of the wide tube was measured with reference to the fixed scale. The cross head of the capillarimeter was then removed, replaced by the caps (F and E, Fig. 1), and the capillarimeter removed from the thermostat, carefully dried externally, and weighed on a large Troemner balance against a suitable counterpoise. The balance was sensitive to 0.1 mg. but the results were not reproducible better than 1–2 mg.

The entire operation was then repeated as exactly as possible, using a solution instead of water. The measurement of the actual capillary rise for the solution is not needed for the calculations of the results, and was sometimes omitted when pressed for time, but often made as a check.

It is well known that solid surfaces become coated with a greasy film when exposed to air for a short time.[12] In order to allow all traces of capillary active substances which might be introduced in this manner to rise to the surface, all of the solutions were made up in much larger quantities than were required for the measurements and allowed to stand undisturbed in closed flasks for from six to eighteen hours before use. Only the interior fractions taken from near the bottom were employed in the actual surface tension measurements.

In order to test the effectiveness of this method, three solutions of approximately 0.001 molar potassium sulfate were made up in three different ways. The first solution was prepared from a sample of salt which was weighed in a platinum boat, then ignited to a red heat and dissolved as soon as it had cooled; the second solution was prepared from a sample which was exposed to the laboratory air for twenty-four hours without a cover; while the third solution was prepared from a sample of salt which was deliberately contaminated with olive oil, by wetting the salt with a solution of olive oil in ethyl ether. The ether was allowed to evaporate leaving about 0.2 mg. of oil on the surface of the crystals. The surface of this solution was obviously greasy. Two determinations of relative surface tension were made on each of these solutions, the first after standing for six hours, and the second after standing for eighteen hours. The results are shown in the following table.

	Soln. I	Soln. II	Soln. III
6 hours old	0.99983	0.99986	0.99986
18 hours old	.99983	.99987	.99985

All three solutions had the same surface tension within the experimental error, which proves that the technique of withdrawing the solution from the interior was adequate to prevent errors due to accidental contamination of the salt by dust carrying capillary active substances.

Experimental Data

In order to illustrate the concordance which can be obtained with the new differential method the data are given in full for 0.05 N potassium chloride. Two different solutions were prepared, as shown in the upper part of Table III. This also shows the values for h_0 and W_0 determined on the same day and with the same reference mark. Each solution was used for two entirely independent experiments in the capillarimeter as is shown in the lower part of the table. The following figures were used in computing the results: $D_0 = 0.997074$; $\beta_c = \beta_0 = 0.00117$; $R = 2.1489$ cm.; $r = 0.013607$ cm.; $1 - r/R = 0.993671$.

In order to save space in printing the data are given in more abbreviated form in Tables III, IV and V. The figures for the relative surface tension are the averages of at least two independent experiments. The greatest deviation for any solution was only 0.005% and the average deviation was only 0.002%.

Interpretation of the Data

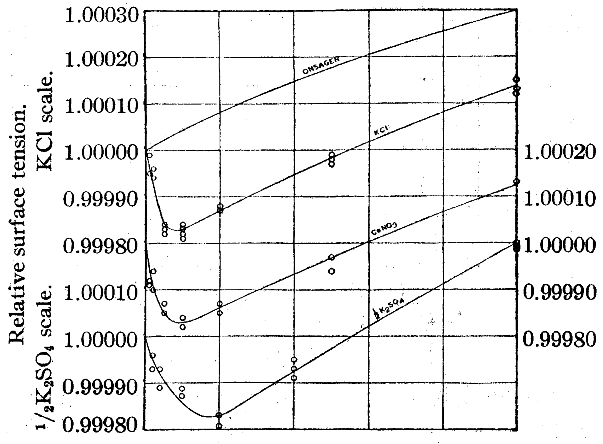
The densities of these three salts can be expressed over the entire range studied by equations having the form suggested by Root.[13]

---

(13) W. C. Root, THIS JOURNAL, 55, 850 (1933).

For KCl: $d^{25}{}_4 = 0.997074 + 0.0480688c - 0.002283c^{3/2}$
For K_2SO_4: $d^{25}{}_4 = 0.997074 + 0.070994c - 0.004240c^{3/2}$
For $CsNO_3$: $d^{25}{}_4 = 0.997074 + 0.143708c - 0.000477c^{3/2}$

These equations agree with our data over the entire range studied and with the average deviations of less than 0.001%. This confirms previous experience in this Laboratory as to the usefulness of the Root equation.



Concentration.

Fig. 2.

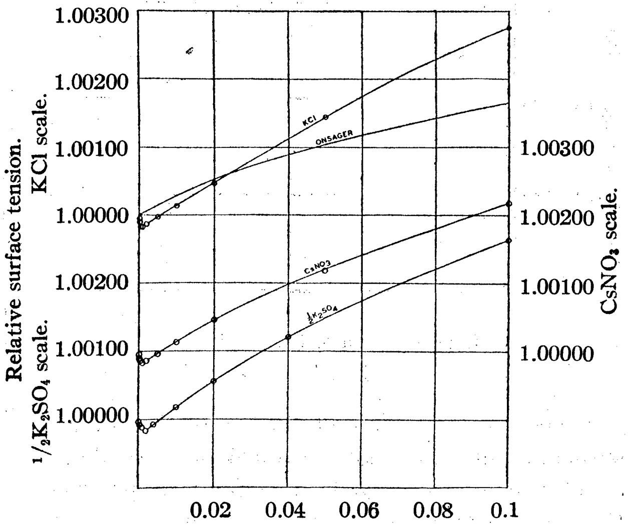
Within the ranges of concentration which have been studied by earlier experimenters, our data on the relative surface tension show the characteristics which Heydweiller has found to be typical of solutions of strong electrolytes; namely, $\sigma - c$ curves which are approximately linear with a gentle positive slope, but with a slight downward curvature which is especially pronounced in the dilute range (below 0.1 N), followed by an upward curvature in concentrated solutions (above 2 N) (see Figs. 3, 4 and 5). A comparison of the last column in our tables with the corresponding figures in the papers by Heydweiller and of Schwenker shows a marked similarity.

The most interesting and novel result of these measurements is that at extreme dilutions (less than about 0.006 N) the solutions of the three salts studied have a smaller surface tension than pure water, although above this lower limit the surface tension is greater than that of pure water and the surface tension–concentration curves show that these salts may be regarded as typical "capillary-inactive" substances.

The minimum surface tension which has been observed is not quite 0.02% less than that of pure water and occurs at about 0.001 N. In spite of the fact that the observed decrease is so small we believe that it is real and not due to experimental error. Figure 2 shows graphically the results of the separate experiments. Their averages only are given in the tables of numerical data. The concordance of the separate data, together with the precision analysis given above, make it seem probable that the error in the average for any concentration is not more than 0.002%. At the minimum in the surface tension the depression is, therefore, about nine times the probable error in the data. Moreover, the data give smooth curves which are similar for the three salts.

If the observed depression in surface tension is real, it follows from the well-known Gibbs theorem that at extreme dilutions these salts must be positively adsorbed in the surface layer, whereas above some lower limit of concentration (from 0.001 to 0.002 normal) there must be a deficiency in the surface layer or negative adsorption.

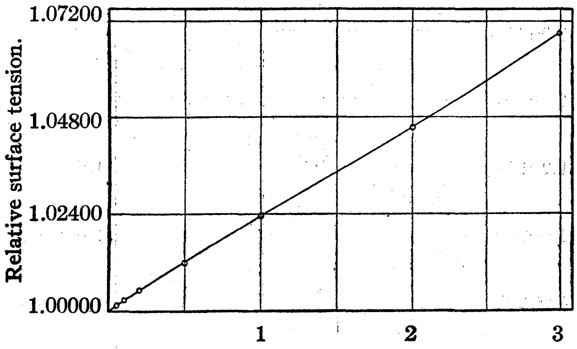
It would, of course, be premature to generalize from observations on three salts only that all salts will cause a diminution in surface tension and be positively adsorbed in the surface layer at sufficiently low concentrations. We intend to extend the experimental investigation to other salts of varied valence types and to study the influence of variations in the temperature and solvent. Since, however, the only three salts studied give similar curves, we shall assume tentatively that the phenomenon is general for aqueous solutions and discuss its implications on this assumption.



Concentration.

Fig. 3.

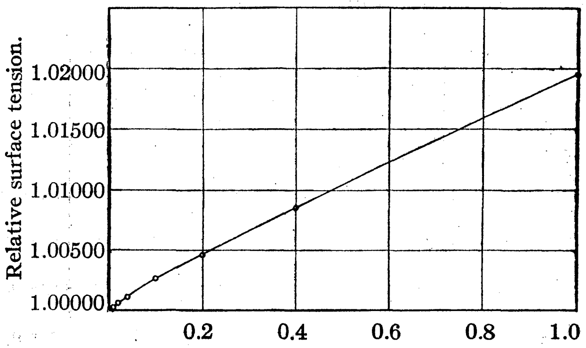
So far as we know this depression of the surface tension and positive adsorption at low concentrations has never been observed at a liquid–gas interface for any salt which gives increased surface tension at moderate concentrations and, therefore, can be classed as a "capillary-inactive" substance in the sense that this term has been used in the literature. An analogous phenomenon, however, has been observed at the interface between aqueous solutions of salts and organic liquids. Eversole and Dedrich, and Dedrich and Hanson,[14] who used a drop weight method, have measured the effect of sodium formate and of sodium acetate on the interfacial tension between aqueous solutions of these salts and mineral oil, or toluene, or benzene. They found a minimum in the curves for all of the cases studied, except for sodium acetate solutions against mineral oil. In the case of sodium formate solutions the minimum was found at high concentrations (above 1 *N*). The minimum for the sodium acetate solutions was not located very definitely, but was evidently much lower and was placed by the authors at around 0.1 to 0.15 *N*. "An attempt to explain the effect of these salts has been made on the basis of the Langmuir theory of molecular orientation and the increased interionic attraction in the interface due to the dielectric constant gradient in the interfacial layer."



Concentration of KCl at 25°.

Fig. 4.

McTaggart[15] has found that a bubble of air suspended in water moves toward the cathode in an electric field, which he interprets as proving that the surface film of water at the water–air interface is negatively charged. Lenard and his students[16] have reached the same conclusion from experiments on electrical effects in waterfalls and sprays. McTaggart then finds that by the addition of minute traces of salts containing positive ions of high valency (aluminum nitrate, lanthanum nitrate, thorium nitrate) to the water the air bubble will then move cataphoretically to the anode.



Concentration, $^1/_2K_2SO_4$ at 25°.

Fig. 5.

Freundlich, in a discussion of McTaggart's experiments on the cataphoresis of air bubbles says, "The fact that inorganic salts must here be assumed to be positively adsorbed does not appear to be in agreement with earlier experience. At all other interfaces, such as those of charcoal, glass, and oil, this assumption is justified, since they are actually positively adsorbed and lower the interfacial tension. At the interface water–air, however, they almost always raise the surface tension, and hence should be negatively adsorbed. This rise of σ refers, of course, to much more concentrated solutions. In such dilutions as come into question here a change in the surface tension cannot be established. It is not impossible that in this range of concentration the surface tension may be lowered by these electrolytes and positive adsorption take place, in accordance with the very general experience, that the first small amount of a foreign substance always causes a lowering of σ. The first gentle rise of the σ, c curve for inorganic salt solutions would thus be in the region of a minimum in the σ, c curve, only that this minimum, since it is very slight, cannot be measured."[17]

McTaggart's demonstration, however, that a trace of a salt containing a trivalent or tetravalent positive ion causes an air bubble to move to the anode merely proves that the surface film

(17) H. Freundlich, "Colloid and Capillary Chemistry," Methuen Co., London, 1926, pp. 75 and 279–280.

becomes positively charged. It does not necessarily prove that the salt as a whole, or even the positive ion, is positively adsorbed in the surface. There might be a deficiency of both ions in the surface layer (negative adsorption and increased surface tension), but if there were a partial separation of the ions in the process with the negative ion being drawn into the interior more than the positive ion, there would be established an electrostatic double layer which would account for McTaggart's results.

It next became of interest to determine whether the observed decrease in surface tension at great dilutions is caused by ions only, or whether it will also be found in dilute solutions of non-electrolytes which are capillary inactive in the sense that they give a slight increase in surface tension and are not adsorbed in the surface at moderate concentrations. Sucrose is known to cause a linear increase in surface tension within the lower part of the range of concentration hitherto investigated, but accurate measurements at extreme dilution are not available. We, therefore, made measurements on sucrose solutions from 0.0002 to 0.005 molar, as shown below.

TABLE VI

RELATIVE SURFACE TENSION OF SUCROSE SOLUTIONS AT 25°

c	D_c	σ_c/σ_0
0.000200	0.997093	0.99999
.000500	.997132	1.00002
.001000	.997202	1.00004
.002000	.997329	1.00008
.005000	.997726	1.00016

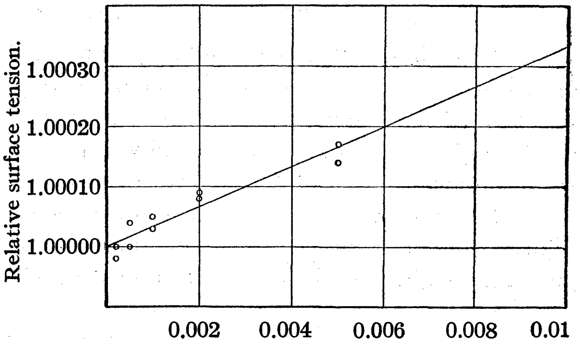
These results are shown in Fig. 6.

The slight indicated decrease at 0.0002 molar is within the limit of experimental error and is not significant. The data show a linear increase in surface tension and, therefore, show that sucrose is negatively adsorbed even at these extreme dilutions. It seems probable, therefore, that the influence which causes the decrease in surface tension and positive adsorption for salts is dependent on the electric charges of the ions.

Our results on the surface tension of salts are not in accord with the Onsager and Samaras equation, especially as to the sign of the limiting slope at infinite dilution. The Onsager–Samaras equation predicts that the limiting slope should be plus infinity, whereas the data show a large negative slope at extreme dilutions. The systematic differences between the data and the equation are shown in Figs. 2 and 3. The experimental and theoretical curves cross each other and there is no maximum in the experimental curve.

An inspection of our curves indicates that the influence which causes the diminution of surface tension is of such a nature that it reaches a limiting or saturation value at an extremely low concentration (perhaps under 0.002 N) and is maintained, but not appreciably increased, at higher concentrations.

The effect of the interionic attraction which is treated by Onsager and Samaras and which causes an increase in surface tension is of minor importance in the dilute range but increases approximately linearly with the concentration and becomes dominant above about 0.006 N.



Concentration of sucrose at 25°.

Fig. 6.

Onsager and Samaras in the derivation of their equation consider only the electric forces between the ions, but they do not consider the electric forces between the ions and the water molecules considered as electric dipoles. The electric forces between the dipolar water molecules must tend to maintain a systematic or ordered arrangement. A fairly detailed theory as to the nature of this ordered arrangement has been worked out by Bernal and Fowler.[18] If we add a salt to water in such great dilution that the interionic forces are negligible, there must nevertheless be a disturbance of the normal arrangement of the water molecules in the vicinity of the ions. The electric forces between the water dipoles would oppose this disturbance and tend to thrust the disturbing ions out into the surface, thus causing positive adsorption. In view of the electrically unsymmetrical character of the water molecules, this force may well be different for positive and negative ions, thus accounting for the effects described

---

(18) J. D. Bernal and R. H. Fowler, *J. Chem. Phys.*, **1**, 515 (1933).

by McTaggart and by Lenard and his students. Since the cohesion, and therefore also the surface tension, of water is probably largely due to the electric forces between the dipoles, a disturbance of the normal electric distribution may cause a diminution of the surface tension.

As the solution becomes more concentrated (about 0.01 N or above), the mutual attraction between ions of opposite polarity becomes stronger than the forces between the ions and the water molecules and causes negative adsorption and an increase in surface tension in the manner discussed by Onsager and Samaras. We may conclude, therefore, that the treatment of Onsager and Samaras is over simplified and thus fails to give a complete and accurate result.

Summary

1. A modification of the capillary rise method of measuring the surface tension of solutions relative to that of the pure solvent, which makes it a differential method and substantially improves the accuracy of the results, is described.

2. The relative surface tension of aqueous solutions of potassium chloride, potassium sulfate, and cesium nitrates has been determined at 25° from 0.0001 N up to 3, 1 and 0.1 N, respectively, and of sucrose solutions from 0.0002 molar up to 0.005 molar.

3. These three salts all increase the surface tension of water from 0.01 N up to the highest concentration studied and give surface tension–concentration curves which are typical of strong electrolytes that are capillary inactive and negatively adsorbed in the surface layer.

4. At extreme dilutions (below about 0.006 N) all three salts cause a decrease in surface tension and are, therefore, positively adsorbed in the surface layer at concentrations below that giving the minimum (about 0.001 N) of the surface tension.

5. Sucrose gives a linear surface tension–concentration curve with no change in the sign of the slope at extreme dilutions.

6. The data are not in accord with the Onsager–Samaras equation for the surface tension as a function of the concentration.

7. The influence which causes diminished surface tension and positive adsorption at extreme dilution is ionic in character and probably due to an interaction between the ions and polarized water molecules.

The Action of Elementary Fluorine upon Organic Compounds. III. The Vapor Phase Fluorination of Hexachloroethane

By William T. Miller, Jr., John D. Calfee and Lucius A. Bigelow

Previous papers in this series[1] have described the fluorination of certain organic compounds dissolved in carbon tetrachloride, using, however, an open type of generator as the source of the halogen. This earlier procedure had two disadvantages, since the fluorine produced was contaminated with other gases, and also reacted to a considerable extent with the solvent. More recently, we have designed a new closed generator[2] capable of delivering fluorine 94–99% pure, and in addition have considered it desirable to avoid the use of solvents altogether. The present paper describes the vapor phase fluorination of hexachloroethane over a copper gauze catalyst. It is probable, of course, that the reaction took place at the surface of the metal, which acquired a thin coating of copper salts during the process, and cupric fluoride may have been the immediate fluorinating agent. However, the change did not occur rapidly at ordinary temperatures, and the gauze was not greatly attacked over a considerable period of time, even when heated. So far as the writers are aware, no similar, direct, vapor phase fluorination of an organic compound containing more than one carbon atom has as yet been reported, in which definite chemical individuals have been formed.

The procedure employed in this fluorination was exceedingly simple. The sample was placed in a horizontal tube, between two copper gauze rolls, suitably heated. The fluorine, diluted with nitrogen, was introduced at the center of one of

---

[1] This Journal, 55, 4614 (1933); 56, 2773 (1934).

[2] Miller and Bigelow, *ibid.*, 58, 1985 (1936).

these rolls, in a manner somewhat similar to that described by Fredenhagen and Cadenbach.[3] Under appropriate conditions, a perfectly quiet, continuous reaction occurred, and the products were condensed at reduced temperatures. After purification and rectification in a Podbielniak still, the main product, which was *sym*-difluorotetrachloroethane, boiled at 92°, and melted at 24–25°, corresponding closely to the values previously reported by Locke, Bride and Henne,[4] who obtained the compound by another method. The yield of the pure haloethane was approximately 20%. A further study of this and similar reactions is contemplated.

Experimental

The fluorination was carried out in a Pyrex glass tube, diameter 2.8 cm., length 75 cm. The gas was introduced through a 6.3-mm. copper tube, closed at the end, but perforated irregularly along the last 4 cm. of its length. The perforations were surrounded by a tight roll of clean 20-mesh copper gauze, 6 cm. in length, which fitted snugly into the glass tube. The charge was placed in the 10-cm. space immediately following the gauze, and the total distance occupied by both of these was surrounded, on the outside, by a sliding metal air bath. Beyond the charge, the reaction tube was filled for a length of 25 cm. with another roll of gauze, surrounded by a second, independent air-bath. In this very simple set up, connections were made with ordinary stoppers, wrapped with copper foil and painted with Ceresin wax.

In operation, the tube was first swept out with nitrogen, and the second gauze heated to 160°. Then the fluorine, diluted with nitrogen in the ratio of 1:1.6, was passed in at a rate corresponding to a current of 3.8 amp. through the generator (roughly 1.5 liters per hour). Finally the first gauze was heated gradually to 125°, when a continuous reaction took place, the fluorine being always in excess. The products were condensed as a mixture of liquid and solid in a trap at about −40°. On warming to room temperature there remained a clear liquid, which was formed at the rate of about 1.6 g. per hour. For each 10 g. of hexachloroethane utilized, approximately 7.4 g. of this liquid was produced. The crude material was dissolved in ether, washed with 5% sodium carbonate solution and dried over calcium chloride, during which process a considerable portion of it dissolved. The ether solution was then fractionated directly in a Podbielniak still. The pure product, b. p. 92°, m. p. 24–25°, was obtained in approximately 20% yield. According to Locke, Bride and Henne[4] *sym*-difluorotetrachloroethane boils at 92.8° and melts at 24.7°.

Anal. Calcd. for $C_2F_2Cl_4$: F, 18.6; Cl, 69.6; mol. wt., 204. Found: F, 18.5, 18.7; Cl, 69.3, 69.5; mol. wt., 209, 210.

The fluorine analyses were made by the Willard and Winter method, after decomposing the sample in a Parr bomb.

When tetrachloroethylene, b. p. 119°, was fluorinated in a similar manner, with both gauzes at 130°, and the haloethylene in excess, *sym*-difluorotetrachloroethane, boiling at 92°, was also produced, in about 20% yield, and further identified by means of a mixed melting point. Considerable substitution took place at the same time, however. In this case, the sample was introduced by passing nitrogen through the refluxing liquid, heated in a bath at 135°.

Summary

Hexachloroethane has been fluorinated directly, in the vapor phase over a copper gauze catalyst. A 20% yield of pure *sym*-difluorotetrachloroethane was obtained. Tetrachloroethylene, under similar conditions, yielded the same product.

The Action of Formaldehyde upon Cysteine

BY SARAH RATNER[1] AND H. T. CLARKE

The reaction of mercaptans with carbonyl compounds has received extensive study, but little attention has, until recently, been paid to the case of cysteine. In a study of the effect of formaldehyde on the titration curves of amino acids, Birch and Harris[2] observed, on the addition of formaldehyde to cysteine, the disappearance of the buffering action typical of the sulfhydryl group. Shinohara[3] in an investigation of the action of cysteine upon phosphotungstic acid, noted that the reducing power is inhibited completely by addition of formaldehyde. During the progress of the present investigation, Schubert[4] has described the formation of compounds of cysteine with various aldehydes, among them formaldehyde, and has produced evidence that the latter reacts with cysteine to form a thiazolidinecarboxylic acid. The present report covers a more extended investigation of this compound, its reactions, and its manner of formation.

The reaction between formaldehyde and cysteine can take place over a wide range of hydrogen ion activity. The product, which is remarkably stable toward both acid and alkali, possesses amphoteric properties, as is shown by the titration curve (Fig. 3). The empirical formula, $C_4H_7O_2NS$, and the conditions of formation indicate that the compound is formed from equimolecular quantities of cysteine and formaldehyde; its simple molecular character is indicated by the observed molecular weight of the methyl ester.

The nitrogen exists in the form of a secondary amino group, as is shown by the formation of an acetyl derivative and by the behavior with nitrous acid in the Van Slyke procedure.[5] The product, moreover, displays no tendency to racemize when its sodium salt is treated with acetic anhydride by the method of du Vigneaud and Meyer[6]—a result characteristic of secondary, in contrast to primary, α-amino acids.

The sulfur is present as a thio ether, for the nitroprusside reaction is negative; oxidation of the acetyl derivative by hydrogen peroxide leads, according to the conditions, to a sulfoxide or a sulfone. The unsubstituted acid, on treatment with hydrogen peroxide or iodine, is converted, with loss of formaldehyde, into cystine; with bromine water, cysteic acid is produced.

Among the compounds described by Schubert[4] some are formed by addition and others by condensation. It therefore seems probable that the reaction of cysteine with formaldehyde occurs in two steps, firstly, addition of the aldehyde, and secondly, ring closure by removal of a molecule of water. The formaldehyde may, theoretically, react primarily with either the sulfhydryl or the amino group of cysteine. A decision between these alternative possibilities can be reached by noting the ease of reaction of formaldehyde with acetylcysteine on the one hand, and S-ethylcysteine on the other. Experiment shows that the rotation of S-ethylcysteine at *p*H 5.12[7] is not changed by the presence of formaldehyde, while that of acetylcysteine is. At this *p*H, the rate of change is extremely rapid, both with cysteine and with acetylcysteine, but can be measured at higher hydrogen ion concentrations (*p*H 1–4). With cysteine (Fig. 1) the rotation reaches the theoretical value; with acetylcysteine (Fig. 2), on the other hand, the levo-rotation is distinctly lower than that observed for pure acetylthiazolidinecarboxylic acid under the same conditions. This may be interpreted as indicating the formation of a less strongly levorotatory addition compound of the type $RSCH_2OH$. By analogy, the first stage in the reaction between cysteine and formaldehyde may be regarded as taking place at the sulfur atom.

In determining the rates of the reaction at different *p*H levels, advantage was taken of the small optical rotation of cysteine and the conveniently large one of thiazolidinecarboxylic acid by follow-

---

[1] This report is from a dissertation submitted by Sarah Ratner in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science of Columbia University.

[5] In this, 20 to 30%, according to the conditions, of the equivalent amount of nitrogen is set free, but this anomaly may be ascribed, as in the case of cystine [Laugh and Lewis, *ibid.*, **104**, 601 (1934)], to oxidative side reactions; under suitable conditions as much as 10% of the sulfur is converted into sulfuric acid by the reaction of nitrous acid.

[6] Du Vigneaud and Meyer, *ibid.*, **98**, 295 (1932); **99**, 143 (1932).

[7] Formaldehyde does not influence the titration curve at this point.

ing the change in rotation. Six buffered reaction mixtures between pH 1.5 and pH 12 were investigated at 25°. The velocity curves (Fig. 2) display a measurable rate of reaction which increases rapidly on raising the pH, and above 5 becomes too fast to follow.

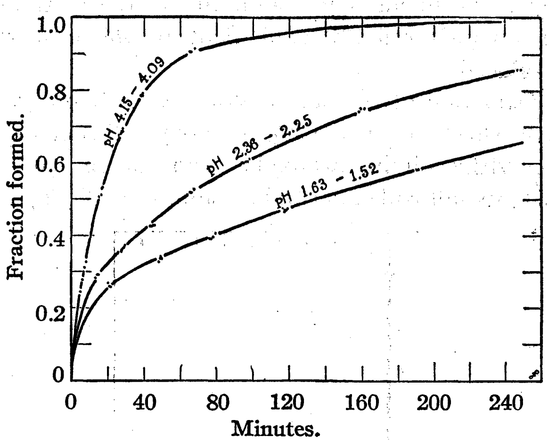

Fig. 1.—Rate of thiazolidinecarboxylic acid formation.

Thiazolidinecarboxylic acid behaves as an ampholyte (Fig. 3); the acidic dissociation (pK_1 1.51) is strong, but the basic dissociation (pK_2 6.21) extremely weak in comparison with those of α-amino acids in general, including proline (Table I).

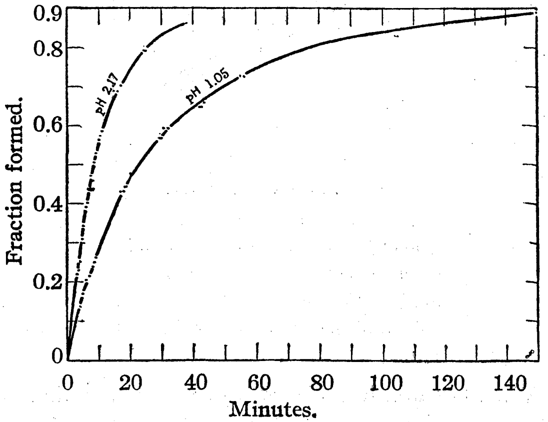

Fig. 2.—Rate of reaction of acetylcysteine and formaldehyde.

Replacement of the labile hydrogen atoms in thiazolidinecarboxylic acid produces changes in dissociation constants which are similar in direction to those which accompany similar substitutions in other amino acids.[8] The constants for the methyl ester and the acetyl derivative demonstrate the weakening effect, on both acidic and basic dissociation, of the inhibition of the ionizing function of one group (Figs. 5 and 6).

TABLE I

DISSOCIATION CONSTANTS OF AMINO ACIDS, THIAZOLIDINECARBOXYLIC ACID AND RELATED COMPOUNDS

	pK_1	pK_2

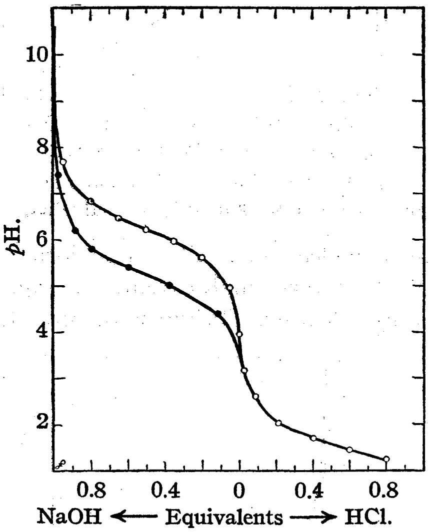

Fig. 3.—Titration of thiazolidinecarboxylic acid ○–○ in water and ●–● in 18% formaldehyde.

In the presence of a large amount of formaldehyde, the basic dissociation of thiazolidinecarboxylic acid is decreased (Fig. 3) but to a smaller extent than in proline and in S-ethylcysteine (Fig. 4). The presence of the $-CH_2S-$ group in the thiazolidine ring presumably exerts approximately the same effect on the basic dissociation constant as the introduction of a single hydroxymethyl group into a primary amino acid. The effect of formaldehyde upon the basic dissociation of thiazolidinecarboxylic acid, namely, depression by about one pK unit, is probably much the same as that of the second hydroxymethyl group in a compound of two molecules of formaldehyde with one of a primary amino acid.[9]

(9) Levy, *J. Biol. Chem.*, **79**, 767 (1933).

Acetylation or esterification of thiazolidinecarboxylic acid has no tendency to open the ring, and the corresponding derivatives are obtained in excellent yields.

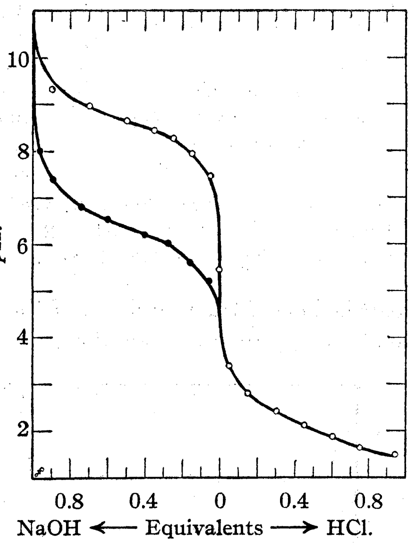

Fig. 4.—Titration of S-ethylcysteine ○–○ in water and ●–● in 18% formaldehyde.

Hydrolytic cleavage in *N* hydrochloric acid occurs only to a very small extent, and can be detected only when equilibrium is disturbed, as by removal of formaldehyde. A solution of thiazolidinecarboxylic acid in *N* hydrochloric acid was heated in a sealed tube at 100° for twenty-four hours; the rotation remained essentially unchanged. On the other hand, hydrolysis was detected by distilling the solution at constant volume. Formaldehyde was found in the distillate in amounts roughly equivalent to the cysteine produced.

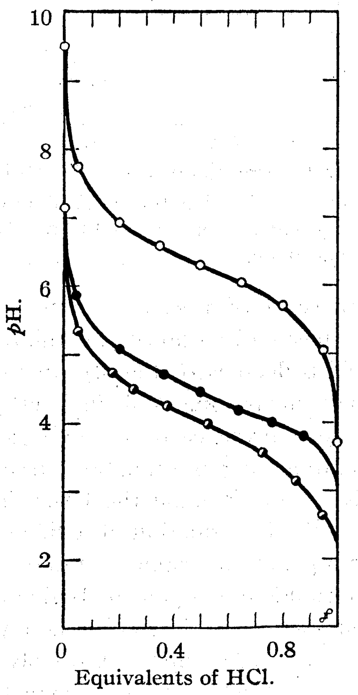

Fig. 5.—Titration of thiazolidine ○–○ in water, ●–● in 18% formaldehyde and ◐–◐ in methyl thiazolidinecarboxylate.

Oxidation of the sulfur atom exerts a progressive effect in increasing carboxyl dissociation. Acetylthiazolidinecarboxylic acid has a *pK* of 2.96, its sulfoxide 2.50 and its sulfone 2.23 (Fig. 6).

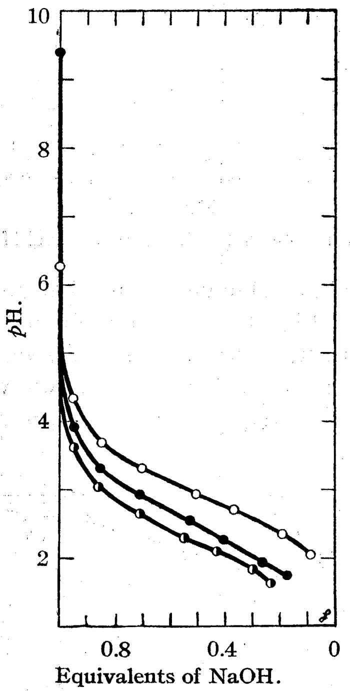

Fig. 6.—Titration of ○–○ acetylthiazolidinecarboxylic acid, ●–● acetylthiazolidinecarboxylic acid sulfoxide and ◐–◐ acetylthiazolidinecarboxylic acid sulfone.

With hot alkaline plumbite in an atmosphere of nitrogen, lead sulfide is formed from thiazolidinecarboxylic acid, but more slowly than from cysteine.[10] The first evidence of its formation was noticed after twenty-five minutes at 95°; after twenty-four hours 97.5% of the theoretical amount had precipitated.

With iodoacetic acid and benzyl chloride, which react with sulfhydryl groups,[11] the corresponding

---

(10) Fruton and Clarke, *J. Biol. Chem.*, **106**, 667 (1934); Blumenthal and Clarke, *ibid.*, **110**, 343 (1935).

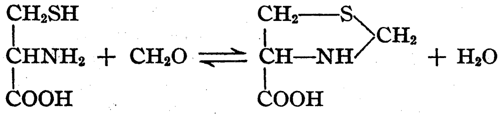
(11) Dickens, *Biochem. J.*, **27**, 1141 (1933); Michaelis and Schubert, *J. Biol. Chem.*, **106**, 331 (1934).

cysteine derivatives are formed from thiazolidinecarboxylic acid in alkaline solution (*p*H 10–11) at room temperature.

Ring opening may also be demonstrated at *p*H 10 by the action of air in the presence of a trace of ferric chloride; cystine is formed slowly. Other oxidizing agents bring about ring opening more readily: one equivalent of hydrogen peroxide or of iodine produces cystine and formaldehyde almost quantitatively. With bromine water, cysteic acid is formed, six equivalents of the halogen being consumed.

Thiazolidinecarboxylic acid reacts with sulfite apparently to form an equilibrium mixture. The progress of the reaction, which is rapid at *p*H 5 or above, can be measured at *p*H 4 by following the change in optical rotation. Sulfhydryl is formed in the process, for an increasing power to reduce phosphotungstic acid is observed. Thiazolidinecarboxylic acid alone does not reduce phosphotungstic acid at *p*H levels below 11.

All these observations may be interpreted as indicating the existence of an equilibrium



which lies so far to the right that sulfhydryl reactions are ordinarily imperceptible. Disturbance of this equilibrium by an irreversible process displaces it to the left.

Acetylation changes this behavior considerably. Iodine does not oxidize acetylthiazolidinecarboxylic acid, and hydrogen peroxide in suitable organic solvents yields the corresponding sulfoxide and sulfone, which are stable in aqueous solution. The sulfoxide is reduced by hydrogen iodide, with liberation of two equivalents of iodine; the sulfone is not affected in this way.

The parent thiazolidine, prepared for purposes of comparison by the condensation of β-aminoethyl mercaptan with formaldehyde, is a stable liquid of weakly basic character (Fig. 5 and Table I), and displays chemical properties analogous to those of the carboxylic acid. Its basic dissociation is depressed by formaldehyde (Fig. 5) to a greater extent than is the case with the carboxylic acid. With acetic anhydride it yields an acetyl derivative which is not oxidized by iodine but on treatment with two moles of hydrogen peroxide in glacial acetic acid yields a crystalline sulfone; the corresponding sulfoxide could not be obtained in crystalline form. The free base is oxidized by iodine to di-β-aminoethyl disulfide and by bromine to taurine. The boiling point, 164–165°, is notably higher than that of thiazole (117°); that of thiazoline (138–139°) occupies an intermediate position.

Experimental

Thiazolidine-4-carboxylic Acid.—The cysteine hydrochloride from 30 g. of cystine was dissolved in 100 cc. of water; 22 cc. of commercial 40% formaldehyde (1.1 mole) was added, and the mixture allowed to stand overnight at room temperature. On the addition of 25 cc. of pyridine, crystals soon separated. The whole was diluted with 50 cc. of alcohol and filtered. The product (28.2 g.) was recrystallized from hot water. The resulting long, colorless needles, which melt with decomposition at 196–197°, are insoluble in alcohol, somewhat soluble in cold water, readily soluble in hot water, in acid and in alkali.

Anal. Calcd. for $C_4H_7O_2NS$: C, 36.06; H, 5.26; N, 10.52; S, 24.05. Found: C, 35.93; H, 5.27; N,[12] 10.38; S, 24.09. $[\alpha]^{20}_D$ −141° in water; $[\alpha]^{22}_D$ −100° in *N* hydrochloric acid; $[\alpha]^{22}_D$ −203° in *N* sodium hydroxide.

The specific rotation was also determined at a series of *p*H levels in suitable buffered solutions, the *p*H values of which were determined potentiometrically.

TABLE II

*p*H	1.52	2.25	4.09	6.10	9.88
$[\alpha]^{25}_D$	−120	−135	−142	−173	−214

A solution in 10–15% hydrochloric acid, when allowed to evaporate at room temperature *in vacuo*, deposited the hydrochloride as large quadrangular prisms, m. p. 184–185° with decomposition, readily soluble in alcohol.

Anal. Calcd. for $C_4H_7O_2NS{\cdot}HCl$: N, 8.26; Cl, 20.91. Found: N, 8.08; Cl, 21.00.

When a concentrated aqueous solution is diluted with water, the free acid crystallizes out.

Thiazolidinecarboxylic Acid Methyl Ester Hydrochloride.—A solution of 10 g. of thiazolidinecarboxylic acid in 100 cc. of methanol which had been saturated with dry hydrogen chloride was warmed under reflux on a steam-bath for one hour. The solution was evaporated to a small volume *in vacuo*, ether was added, and the crystalline product chilled, filtered off and dried *in vacuo* over solid alkali; yield 13 g. (94%). It was recrystallized by dissolving in methanol and precipitating with ether, and appears as shiny plates which decompose at 164–165°; very soluble in water and alcohol, insoluble in ether.

Anal. Calcd. for $C_5H_9O_2NS{\cdot}HCl$: Cl, 19.31; S, 17.46; N, 7.63; CH_3O, 16.89. Found: Cl, 19.39; S, 17.74; N, 7.60; CH_3O, 16.76.

Methyl Thiazolidinecarboxylate.—To a suspension of 13 g. of ester hydrochloride in 3–4 cc. of water, covered with about 30 cc. of ether, anhydrous potassium carbonate was added slowly in excess. The ether was decanted

---

[12] As most of the compounds described in this paper gave low values for nitrogen by the micro-Dumas method, the micro-Kjeldahl process was employed throughout. Grateful acknowledgment is made to Mr. William Saschek for the analytical results here reported.

after shaking. Extraction with ether was repeated several times. The combined ethereal solution was dried with barium oxide and the ether removed; the residual crude oil was distilled *in vacuo;* b. p. 75° (1.0 mm.); yield 7.85 g. (75%).

Anal. Calcd. for $C_5H_9O_2NS$: CH_3O, 21.08; S, 21.79; mol. wt., 147. Found: CH_3O, 21.14; S, 21.82; mol. wt., 149.2, 146.6 (cryoscopic in C_6H_6). $[\alpha]^{23}\mathrm{D}$ -83.0 in water; $[\alpha]^{21}\mathrm{D}$ -106.3 in benzene; $[\alpha]^{21}\mathrm{D}$ $-94.7°$ in CH_3OH; d^{23}_4 1.324; $n^{25}\mathrm{D}$ 1.527.

The ester showed no tendency to condense with itself even on long standing.

Acetylthiazolidinecarboxylic Acid.—To a suspension of 9.3 g. of thiazolidinecarboxylic acid in 30 cc. of water, 30 cc. of acetic anhydride was added slowly at 90° with constant stirring over a twenty-minute period. The clear solution was heated for forty minutes longer. Water and acetic acid were removed *in vacuo*, the residue dissolved in 30 cc. of hot water. On cooling, crystals appeared as six-sided prisms which were filtered off after chilling; yield 10.0 g. (82%), m. p. 143.5–144.5°; very soluble in water, somewhat less so in alcohol, acetone and ether.

Anal. Calcd. for $C_6H_9O_3NS$: C, 41.11; H, 5.18; N, 8.00. Found: C, 40.92; H, 5.07; N, 7.85. $[\alpha]^{20}\mathrm{D}$ -133.5 in water (*p*H 2.1); $[\alpha]^{20}\mathrm{D}$ $-159.8°$ in an equivalent quantity of dilute sodium hydroxide.

Acetylation of Sodium Salt of Thiazolidinecarboxylic Acid.—Into a 10-cc. volumetric flask was weighed 0.875 g. of thiazolidinecarboxylic acid (5 mml.); 5 cc. of *N* sodium hydroxide and 3.0 cc. of acetic anhydride (30 mml.) was added and the volume made up to 10 cc. with water. The flask was kept at 37° and 2-cc. samples were withdrawn after 46, 92 and 168 hours. To each sample 12.7 cc. of *N* sodium hydroxide was added, followed after three hours by 6.85 cc. of 2 *N* sulfuric acid. The solution was taken to dryness *in vacuo;* the residue was extracted with 20 cc. of hot absolute ethyl alcohol, the alcohol was evaporated and the residue so obtained recrystallized from a small amount of water. $[\alpha]^{23}\mathrm{D}$ $-133.2°$ after 46 hours; $-134.4°$ after ninety-two hours; $-134.4°$ after one hundred and sixty-eight hours.

Phenylalanine when treated in exactly the same way was found to be completely racemized after twenty-four hours.

Effect of *p*H on Velocity of Formation (Figs. 1, 2).—All solutions were made up so that 25 cc. contained 1.70 mml. each of cysteine hydrochloride (or acetylcysteine) and formaldehyde, 15 cc. of the appropriate 0.1 *N* buffer (or sodium chloride solution of equivalent ionic strength) with appropriate amounts of acid or alkali. The initial rotation for each curve was determined by omitting formaldehyde from the solution, and the final values were determined from equimolar solutions of thiazolidinecarboxylic acid. The final value of the cysteine reaction mixture agreed with the rotation calculated for the end-product. The *p*H of all solutions were determined with the glass electrode. Despite buffering, a change in *p*H (about 0.1) occurs during the reaction owing to the large difference between the *pK*'s of cysteine and thiazolidinecarboxylic acid. The initial and final *p*H values are recorded on the curves. The concentrations of the acetylcysteine and cysteine hydrochloride stock solutions were calculated from Kjeldahl nitrogen determinations and the formaldehyde stock solution was analyzed by iodine titration.

The values plotted in the curves were those of X calculated from the formula

$$\alpha_0\,(1 - X) + \alpha_\infty X = \alpha_{\text{obsd.}}$$

In the experiments with acetylcysteine, the value for α_∞ was based upon the final steady value observed in the reaction mixture.

Titration Curves (Figs. 3–6).—Except in the formaldehyde titrations, 0.1 *M* solutions were titrated with *N* sodium hydroxide and hydrochloric acid. The *p*H measurements, made with a glass electrode,[13] are reliable to ±0.03. The values reported (pK_1 for the acid constants and $pK_2 = pK_b - pK_w$ for the basic constants) each represent the average of the values calculated from five points in the curve. In the formaldehyde titrations, 5 cc. quantities of 0.1 *M* solution were added to 100 cc. of 18% formaldehyde and titrated with 0.1 *N* sodium hydroxide. All curves were corrected for water blanks.

Hydrolysis of Thiazolidinecarboxylic Acid.—A solution of 0.3021 g. of the acid in 25 cc. of *N* hydrochloric acid was distilled slowly for nine hours with addition of water at the approximate rate of distillation. The distillate, which amounted to 100 cc., was collected under alcoholic dimedon solution; it yielded 65 mg. of the formaldehyde derivative, m. p. 187°.

The residual solution was made up to 25 cc.; it gave a strong reaction with nitroprusside. The observed rotation (2 dcm. tube) of the solution before distillation was $-2.47°$; after distillation $-2.04°$. The fall in rotation corresponds to a conversion of 15.3% of the thiazolidinecarboxylic acid into cysteine having[14] $[\alpha]\mathrm{D}$ $+7.6°$.[15] The cysteine content, determined by the Lugg modification[16] of the method of Folin and Marenzi, was 11.0%.

Reaction with Iodoacetic Acid.—A solution of 0.66 g. of thiazolidinecarboxylic acid (5 mml.), 0.93 g. of iodoacetic acid (5 mml.) and 1.04 g. of potassium carbonate (15 m. eq.) in 10 cc. of water was allowed to stand overnight at room temperature. Upon the addition of 10 cc. of *N* hydrochloric acid crystals slowly appeared. The yield of S-carboxymethyl cysteine[11] was 0.77 g. (87%); thin trapezoidal plates from water, m. p. 200° (dec.).

Anal. Calcd. for $C_5H_9O_4NS$: H, 5.06; C, 33.51; N, 7.82. Found: H, 4.88; C, 33.33; N, 7.87 (Van Slyke amino N).

Reaction with Benzyl Chloride.—A mixture of 0.66 g. of thiazolidinecarboxylic acid, 0.63 g. of benzyl chloride and 0.69 g. of potassium carbonate in 10 cc. of water was stirred for twenty-four hours at room temperature. S-Benzylcysteine crystallized out during the reaction; m. p. 210° (dec.), unchanged by admixture with an authentic sample;[17] $[\alpha]\mathrm{D}$ $+23.8°$ in *N* sodium hydroxide.

Action of Oxygen in Alkaline Solution.—A solution containing 0.266 g. of thiazolidinecarboxylic acid (2 mml.), 2 cc. of *N* sodium hydroxide, 5 cc. of half-neutralized 0.2 *M*

---

(13) A modification by F. Rosebury of the apparatus described by him in *Ind. Eng. Chem., Anal. Ed.*, **4**, 398 (1932).

(14) Assuming $[\alpha]\mathrm{D}$ $+15.9°$ [Vickery and Leavenworth, *J. Biol. Chem.*, **86**, 129 (1930)] the conversion would be 14.3%.

(15) Toennies and Bennet, *J. Biol. Chem.*, **112**, 499 (1936).

(17) Clarke and Inouye, *J. Biol. Chem.*, **94**, 549 (1932).

bicarbonate buffer and 0.1 cc. of 0.01 *M* ferric chloride was made up to a volume of 10 cc. Air was passed through the solution for twenty-four hours at room temperature. The *p*H (10.2) was then brought to 6.4 by the addition of 2 cc. of *N* hydrochloric acid. After several days hexagonal plates had separated. The product, weighing 8 mg. (3.3%), was identified as cystine.

Oxidation with Hydrogen Peroxide.—A solution of 0.266 g. of thiazolidinecarboxylic acid in 30 cc. of water and 0.12 cc. (1.05 equiv.) of 30% hydrogen peroxide was allowed to stand at room temperature for several days; regular hexagonal plates separated; yield 0.210 g. (87%) of cystine; $[\alpha]_D$ $-214.5°$ in *N* hydrochloric acid. The filtrate was distilled into alcoholic dimedon; 0.408 g. (70%) of the formaldehyde derivative was secured.

Oxidation with Iodine.—To 10 cc. of 0.1 molar thiazolidinecarboxylic acid was added 10 cc. of 0.1 *N* iodine in 2.5% potassium iodide. The iodine was decolorized rapidly and regular hexagonal plates soon separated. Pyridine (0.2 cc.) was added and after two days 0.100 g. (83%) of cystine was obtained; $[\alpha]^{22}_D$ $-212°$ in *N* hydrochloric acid.

The filtrate yielded 0.141 g. (50%) of the dimedon derivative of formaldehyde, m. p. 187°.

On titration with iodine, 1.6–1.7 equivalents were consumed by thiazolidinecarboxylic acid, 1.0–1.2 by its methyl ester. The consumption of iodine in excess of one equivalent is attributable to oxidation of cystine.[18]

Oxidation with Bromine.—A solution of 0.2896 g. (2.175 mml.) of thiazolidinecarboxylic acid in 10 cc. of water was titrated at 0° with *N* bromine in acetic acid. The end-point, taken when the yellow color persisted for thirty seconds, was reached with 6.45 mml. of bromine (5.94 equivalents). The resulting solution was evaporated to dryness *in vacuo*, and the crystalline residue purified by repeated precipitation from water by absolute alcohol. $[\alpha]^{24}_D$ $+7.7°$ in water. The cysteic acid was identified as the copper salt.

Anal. Calcd. for $C_3H_7O_6NSCu$: N, 5.63; S, 12.89; Cu, 25.56. Found: N, 5.57; S, 13.22; Cu, 25.77.

Action of Sulfite on Thiazolidinecarboxylic Acid.—To a solution of 1.5 mml. was added 15 mml. of sodium sulfite, suitably buffered and the volume made up to 25 cc. The optical rotation of the resulting solution was determined at intervals:

OBSERVED ROTATIONS (2 DCM.) AFTER SPECIFIED TIMES

*p*H	0	5 min.	15 min.	20 min.	30 min.	95 min.	8 hrs.
4.03	−2.26°	−2.02°		−1.80°		−1.66°	−1.66°
6.41	−2.80°		−0.96°		−0.92°		

The zero values, determined in the absence of sulfite, were obtained by interpolation from the *p*H dependence data (Table II).

Action of Phosphotungstic Acid and Sulfite on Thiazolidinecarboxylic Acid.—To 2 cc. of 0.00832 molar thiazolidinecarboxylic acid was added 2 cc. of phosphotungstic acid solution, buffered to *p*H 5.7, according to the directions of Lugg.[16] No appreciable color appeared. When 1 cc. of molar sodium sulfite was incorporated in an otherwise similar mixture, a blue color appeared; this continued to increase in intensity at a rate considerably less than that observed with cystine. Comparison with cystine standards showed after thirteen hours a color intensity equivalent to 43% of that observed with an equimolar quantity of cystine.

In another experiment, 50 cc. of 0.00832 molar thiazolidinecarboxylic acid was mixed with 20 cc. of molar sulfite, and diluted to 100 cc. The color developed with phosphotungstic acid was determined at intervals under the conditions described by Lugg. The color intensities, expressed as percentages of that of the equimolar cystine standard, were

Hours	0.1	4	10	22
Color	11	27	28	28

With twice the amount of sulfite, the maximum color developed after six hours was 47%; after ninety-three hours, it had fallen to 30%. No attempt was made further to investigate the effect of variations in the proportion of sulfite.

Sulfoxide of Acetylthiazolidinecarboxylic Acid.—A solution of 0.876 g. (5 mml.) of acetylthiazolidinecarboxylic acid in 40 cc. of acetone was treated with 0.6 cc. (5.25 mml.) of 30% hydrogen peroxide. After three days the solvent was evaporated under reduced pressure. The residue was recrystallized by adding acetone to its solution in the minimum quantity of hot alcohol: 0.690 g. of octagonal prisms, m. p. 188–190° (dec.); $[\alpha]^{26}_D$ $-118°$ in water.

Anal. Calcd. for $C_6H_9O_4NS$: C, 37.67; H, 4.75; N, 7.33; neut. eq., 191. Found: C, 37.57; H, 4.90; N, 7.32; neut. eq., 190.

The same product was obtained in substantially the same yield by the use of twice the above proportion of hydrogen peroxide in acetone.

A weighed amount (30.6 mg.) of the sulfoxide was added to a solution containing 1 cc. of 5 *N* KI and 0.5 cc. of 10 *N* HCl. After an hour 3 cc. of water was added and the solution quantitatively transferred to a separatory funnel with 5 cc. more water. The iodine extracted with peroxide-free ether and titrated with 0.1 *N* thiosulfate, required 3.23 cc. (2.02 equivalents).

Sulfone of Acetylthiazolidinecarboxylic Acid.—To a solution of 0.876 g. (5 mml.) of acetylthiazolidinecarboxylic acid in 20 cc. of glacial acetic acid (distilled over chromic anhydride) 1.5 cc. (11 mml.) of 30% hydrogen peroxide was added. After seven days the acetic acid was removed *in vacuo*. The crystalline residue (0.77 g.) was twice recrystallized from 10 cc. of hot alcohol; trilateral prisms, m. p. 190° (dec.); $[\alpha]^{25}_D$ $-90.8°$ in water.

Anal. Calcd. for $C_6H_9O_5NS$: C, 34.76; H, 4.38; N, 6.76; neut. eq., 207. Found: C, 35.10; H, 4.48; N, 6.70; neut. eq., 205.

The compound liberated practically no iodine from acidified potassium iodide solution.

Thiazolidine.—Twelve grams of phthalimidoethyl mercaptan[19] was hydrolyzed by boiling for twelve hours under reflux with a mixture of 120 cc. of 20% hydrochloric acid

---

(18) Simonsen, *J. Biol. Chem.*, **101**, 35 (1933); Shinohara, *ibid.*, **96**, 285 (1932).

(19) Gabriel, *Ber.*, **24**, 1110 (1891).

and 20 cc. of glacial acetic acid. After cooling, phthalic acid was filtered off, and the filtrate was concentrated *in vacuo*, filtered again, and finally taken to dryness in a vacuum desiccator over potassium hydroxide. The crude aminoethyl mercaptan hydrochloride[20] was dissolved in 20 cc. of water, treated with 4.6 cc. of formalin, allowed to stand overnight, and taken to dryness *in vacuo*. The residue was crystallized from alcohol; yield, 6.63 g. (91%) of long needles; m. p. 180° (dec.).

Anal. Calcd. for $C_3H_7NS{\cdot}HCl$: C, 28.66; H, 6.42; S, 25.53; N, 11.15; Cl, 28.24. Found: C, 28.86; H, 6.76; S, 25.77; N, 10.88; Cl, 28.1.

The free base, liberated from the above hydrochloride by potassium carbonate, is readily volatile with steam, miscible in all proportions with water, and can be salted out readily with potassium carbonate. It is a colorless liquid, b. p. 164–165°, d^{25}_4 1.131, n^{30}_D 1.551.

Anal. Calcd. for C_3H_7NS: N, 15.72; C, 40.39; H, 7.92. Found: N, 15.77; C, 40.40; H, 7.80.

Acetylthiazolidine.—An excess (2.5 cc.) of acetic anhydride was added to 1.51 g. of the free base; the acetic acid was removed *in vacuo*, and the residual liquid distilled under reduced pressure; b. p. 83–85° (0.7 mm.); yield 1.96 g. (88%).

Anal. Calcd. for C_5H_9ONS: C, 45.76; H, 6.91; N, 10.68. Found: C, 44.66; H, 6.74; N, 10.24.

Sulfone of Acetylthiazolidine.—To a solution of 0.712 g. of acetylthiazolidine in 10 cc. of glacial acetic acid, 1.5 cc. (2.3 mole) of hydrogen peroxide was added. After a week the solvent was removed *in vacuo* and the residue recrystallized from hot alcohol; stout hexagonal prisms or long plates, m. p. 122°.

Anal. Calcd. for $C_5H_9O_3NS$: C, 36.78; H, 5.56; N, 8.58. Found: C, 36.72; H, 5.33; N, 8.65.

Oxidation of Thiazolidine with Bromine.—*N* Bromine in acetic acid was added to 0.354 g. (4 mml.) of thiazolidine in 5 cc. of water to a faint permanent yellow (5.8 equivalents). The solution was taken to dryness *in vacuo*, and the residue recrystallized by adding alcohol to a concentrated solution in water. The product, taurine, formed fine needles, was neutral in reaction and did not melt below 260°; yield, 0.430 g. (86%).

Anal. Calcd. for $C_2H_7O_3NS$: N, 11.19. Found: N, 10.95.

Oxidation of Thiazolidine with Iodine.—To 0.3358 g. of free thiazolidine (3.77 mml.) in 5 cc. of water was added 37.7 cc. of 0.1 *N* iodine in 2.5% potassium iodide. A white solid appeared which redissolved slowly. After twenty hours the colorless solution was filtered to remove a small red precipitate, and 3.77 cc. of *N* sodium hydroxide was added. A colorless solid which precipitated was filtered off. Formaldehyde was identified in the filtrate. The colorless precipitate, apparently an aldehyde–ammonia, was dissolved in excess hydrochloric acid, when a strong odor of formaldehyde was evolved. The solution was taken to dryness *in vacuo* and the residue recrystallized from ethyl alcohol. The resulting needles, 0.250 g., m. p. 206°, were identified as di-β-aminoethyl disulfide hydrochloride, described by Gabriel.[21]

Anal. Calcd. for $C_4H_{12}N_2S_2{\cdot}2HCl$: N, 12.43. Found: N, 12.33.

Summary

Formaldehyde reacts with cysteine over a wide range of *p*H to form thiazolidine-4-carboxylic acid, the mode of formation, constitution and properties of which are here discussed.

Thiazolidine, similarly prepared from formaldehyde and β-aminoethyl mercaptan, is also described.

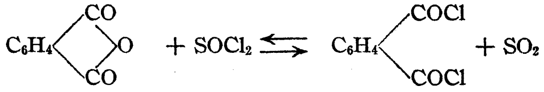
Phthalyl Chloride

BY L. P. KYRIDES

Phthalyl chloride has been prepared by the interaction of phthalic anhydride and phosphorus pentachloride.[1] Thionyl chloride converts phthalic acid into the anhydride, but is reported to have no action on the latter at refluxing temperatures even in presence of catalysts or pyridine.[2] We found that excellent yields of phthalyl chloride are readily obtained if the reaction is carried out at elevated temperatures in presence of very small amounts of anhydrous zinc chloride.[3] We also observed that the reaction is reversible, since thionyl chloride is obtained when sulfur dioxide and phthalyl chloride react at around 200°, also in presence of zinc chloride. The reaction is, therefore, expressed as



$$C_6H_4\left\langle\begin{matrix}CO\\ \ \ \ \ \ \ \rangle O\\ CO\end{matrix}\right. + SOCl_2 \rightleftarrows C_6H_4\left\langle\begin{matrix}COCl\\ \\ COCl\end{matrix}\right. + SO_2$$

If no zinc chloride is present and thionyl chloride

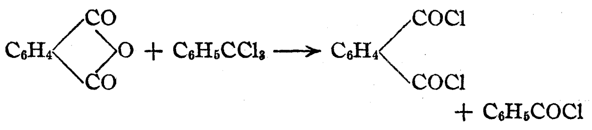
[3] U. S. Patent 1,951,364.

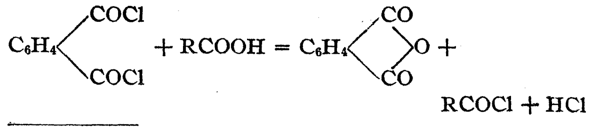
is dropped very slowly into phthalic anhydride at 220° over a period of forty hours, only about 70% of the anhydride is converted into phthalyl chloride. Meyer[2] had observed that thionyl chloride converts maleic and succinic acids into anhydrides but not into chlorides. Fumaryl and succinyl chlorides are obtained in good yields if the reaction is carried out in presence of zinc chloride.

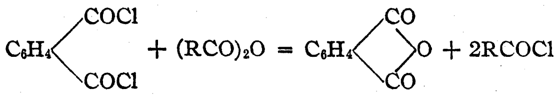
Benzotrichloride has been used in a limited number of cases for the preparation of chlorides from monocarboxylic acids and their anhydrides. Phthalic anhydride and benzotrichloride did not react at 200°; but the addition of a trace of zinc chloride induced a distinct reaction. By increasing the amount of zinc chloride, the conversion proceeded at a fairly rapid rate even as low as 100°.[4] The reaction products were separated easily by simple fractionation. This reaction takes place as follows



The phthalyl chloride obtained by all of the processes contains small amounts of dissolved anhydride, an observation which had also been made by Bruehl[1] in the phosphorus pentachloride reaction. The solubility of the anhydride in phthalyl chloride is of the order of 5–6% at 15°, so that it is easy to free it from an excessive amount of anhydride by filtration after cooling. The phthalyl chloride containing dissolved anhydride is perfectly satisfactory for most reactions.

Van Dorp and Van Dorp[5] found that phthalyl chloride and fumaric acid reacted at 120–160° to give a good yield of fumaryl chloride. We have used phthalyl chloride in many reactions and found it to be an excellent reagent for the nearly quantitative conversion of acids and anhydrides into acid chlorides. If the boiling points of these chlorides are not too close to those of phthalyl chloride and phthalic anhydride, they can be obtained in very pure form by direct fractionation. The reactions take place as follows





Maleic and succinic anhydrides are converted into chlorides with phthalyl chloride only in presence of zinc chloride as is the case with thionyl chloride.

Experimental

1. Phthalyl Chloride from Phthalic Anhydride and Thionyl Chloride.—The apparatus consisted of a three-necked flask, with an efficient reflux condenser, a dropping funnel and an agitator (the latter being used only in case large amounts of materials were to be made).

Three hundred grams of phthalic anhydride and 1.5 g. of technical anhydrous zinc chloride were charged into the flask and the mixture was heated over a wire gauze to 220°. The theoretical amount of thionyl chloride (241 g.) was dropped in over a period of about ten hours, at such a rate that the temperature could be maintained at about 220°. The reaction mass was distilled directly under a vacuum of 4.5 mm. and 380 g. of a liquid distillate was obtained boiling at 119–122°. After standing cold for some time, a small amount of phthalic anhydride separated out, which after isolation weighed 22 g. The filtered phthalyl chloride analyzed 94% by chlorine analysis, so that the conversion amounted to 86% and the yield was practically quantitative on the anhydride consumed.

2. Thionyl Chloride from Phthalyl Chloride and Sulfur Dioxide.—A mixture of 107 g. of phthalyl chloride (94%) and 2 g. of zinc chloride was heated at 200°. A slow current of sulfur dioxide was bubbled through the mixture and the distillate was condensed using running water. After a ten-hour reaction, 44.3 g. of a distillate had collected which upon redistillation gave 39 g. of thionyl chloride, which amounts to 66% of the theoretical yield from phthalyl chloride. No attempt was made to analyze the unreacted sulfur dioxide for its thionyl chloride content. Since, however, the residue from the reaction was practically chlorine free, it is presumed that a considerable portion of the thionyl chloride was lost with the uncondensed gas.

3. Phthalyl Chloride from Phthalic Anhydride and Benzotrichloride.—A mixture of 225 g. of phthalic anhydride, 290 g. of fractionated benzotrichloride (sp. gr. 1.38) and 20 g. of zinc chloride was heated in an oil-bath at 110–120° overnight (reaction time twenty hours) and the reaction mixture was fractionated carefully under a vacuum of about 23 mm. The fractions consisted of 201 g. of benzoyl chloride boiling at 90–95°; 8.8 g. boiling up to 138° and 287 g. of phthalyl chloride boiling mostly at 150–152°.

The phthalyl chloride fraction upon standing cold deposited a few crystals of phthalic anhydride, indicating that it was about 95% pure. The theoretically expected weight yields of phthalyl and benzoyl chlorides were 308 and 208 g., respectively.

The residue from the distillation containing the zinc chloride was found capable of promoting the reaction of fresh quantities of reactants. It was also found that zinc oxide and zinc dust can be used as catalysts in place of zinc chloride. The activity of these is, no doubt, due to their transformation to zinc chloride in the reaction mixture.

---

(4) U. S. Patent 1,963,748; 1,963,749.

(5) Van Dorp and Van Dorp, *Rec. trav. chim.*, **25**, 96 (1906).

If the amount of zinc chloride is reduced to one-tenth of that used in this experiment, the temperature has to be raised to about 200° in order that the reaction may proceed at a fairly rapid rate.

When *o*-chlorobenzotrichloride was used in place of benzotrichloride, the reaction products consisted, as was to be expected, of phthalyl and *o*-chlorobenzoyl chlorides.

4. **Butyryl Chloride from Phthalyl Chloride.**—A flask connected to a short fractionating column was charged with 340 g. of phthalyl chloride, heated at about 140° and treated slowly with 132 g. of *n*-butyric acid. Hydrogen chloride was evolved as the acid was added and part of the butyryl chloride distilled over. Finally, vacuum was applied and the remainder of the chloride recovered. Refractionation gave 146.5 g. of butyryl chloride which represents a 91.5% yield of the theoretical on butyric acid.

5. **Fumaryl Chloride from Maleic Anhydride.**—A mixture of 98 g. of maleic anhydride, 231 g. of 94% phthalyl chloride and about 0.5 g. of zinc chloride was heated overnight at about 140°. Vacuum was applied and the fumaryl chloride distilled until phthalic anhydride began to separate in the condenser. The distillate, amounting to 146 g., was found to contain 129 g. of fumaryl chloride and 15 g. of unreacted maleic anhydride. The yield, therefore, of the chloride on the anhydride which was consumed was nearly quantitative.

The writer is indebted to Messrs. M. N. Dvornikoff and O. J. Weinkauff for assistance in the experimental part of the investigation.

Summary

Phthalyl chloride can be made in good yields from thionyl chloride or benzotrichloride and phthalic anhydride at elevated temperatures using zinc chloride as catalyst and, reversibly, thionyl chloride is formed from the interaction of sulfur dioxide with phthalyl chloride under the same conditions.

Acid chlorides can be produced in excellent yields from the interaction of acids or their anhydrides with phthalyl chloride.

In the case of the anhydrides of acids, such as succinic and maleic acids, which do not react directly with phthalyl or thionyl chlorides, the reaction can be catalyzed with traces of zinc chloride to give good yields of the desired acid chlorides.

Mellitic Acid from Coals, Cokes and Graphites

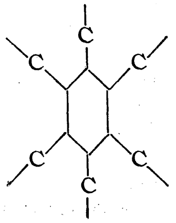
BY BERNARD JUETTNER

Carbonization of coal involves the loss of volatile decomposition products such as gas, tar and water, and the formation of a condensed, non-volatile residue. The more important factors influencing the degree of condensation of the residue are: the final temperature, the rate of heating and the nature of the coal. Another factor may be the speed at which the decomposition products are removed, which in turn depends largely on the thermal variables mentioned above, on the pressure in the retort during the carbonization, and on the particle size of the coal.[1,2] The ash of the coal may also exert an influence due to catalytic effects.

The purpose of this work is to determine the degree of condensation of various carbonaceous materials, by conversion of these high molecular weight condensed bodies into small identifiable units of structural significance. The development of such a method permits the evaluation of the relative importance of such variables as maximum temperature, heating rate and specific nature of the material.

To accomplish the purpose in view the oxidation reagent employed must be powerful enough to penetrate to the last skeletal nuclei, but should not result in complete breakdown to carbon dioxide.

Mellitic acid, the benzene hexacarboxylic acid, is known as an oxidation product of various carbonaceous materials. It forms a relatively insoluble ammonium salt and hence can be determined nearly quantitatively; it is very resistant to further oxidation, and is of definite structural significance, since it can only be formed from such structures as



or

[1] Lowry, *Ind. Eng. Chem.*, **26**, 321 (1934).

[2] Juettner and Howard, Coal Research Lab., Carnegie Inst. of Tech., Contrib. No. 8; Juettner and Howard, *Ind. Eng. Chem.*, **26**, 1115 (1934).

or more condensed bodies. It therefore appeared that a systematic study of the yields of this acid obtained from various condensed carbonaceous materials would contribute to the end in view.

There is wide disagreement in the literature as to the yield of mellitic acid obtainable by oxidation of carbonaceous materials. This is no doubt due to variation in the nature of the materials themselves, the oxidation reagent employed and to the technique used in isolating the acid. In many cases no mention of yields is made.[3] In the recent work of Meyer and Raudnitz,[4] carbons from various sources were oxidized by refluxing with nitric acid (sp. gr. 1.5–1.52) and 0.2% vanadic acid for eighty hours. If the solution was still dark after twenty hours, sulfuric acid was added and boiling continued. The crude mellitic acid was converted into the ammonium salt. This had to be purified through the copper salt. Their yields, which are the highest in the literature, are based on the crude ammonium salt. The yield of pure mellitic acid is not given.

The few references[5] in the literature to yields of mellitic acid obtained by the oxidation of coals and cokes report values of 1% or less, or do not make any quantitative statements. Nearly the same quantity, 0.6% of mellitic acid, was found in this Laboratory[6] by oxidizing Edenborn coal for thirty days with 1 *N* nitric acid. Even after two months of refluxing with the dilute nitric acid the oxidation was very incomplete, not reaching the skeletal nuclei. Therefore a search was made for a reagent that would attack the condensed structure and yet not destroy the mellitic acid formed. Under such conditions the maximum yield of this acid should be obtained. Mellitic acid is reported not to be oxidized by boiling concentrated nitric acid nor by alkaline permanganate. It therefore appeared that in this respect these reagents would meet our requirements.

Experimental

Characteristics of Coal, Cokes and Graphites.—In this work only one coal and the various cokes prepared from it were oxidized. This coal, a Pittsburgh seam coal from the Edenborn Mine, is described in detail in a Bureau of Mines publication.[7] The 500° coke was prepared in a rotating Fischer retort at a heating rate of 1.9° per minute. The temperature was held at 500° for one hour. All the other cokes were prepared in a small tube retort at varying heating rates.[8] The final temperature was maintained for one hour. The artificial graphite was an Acheson graphite electric furnace electrode. All these materials were ground to pass 200 mesh. Only the natural graphite was of smaller particle size. This graphite is known as "Dixon Micronized" No. 200–05.

Oxidation Procedures.—Since it was desirable that the oxidation method be applicable to a wide range of coals, cokes and other carbons, the 500° Edenborn coke was selected as a product of intermediate complexity suitable for evaluation of the various processes.

Alkaline Permanganate Oxidation.—Samples of 100 g. were oxidized with an excess of permanganate in three liters of water containing 200 g. of potassium hydroxide for one week. The oxidation was carried out in an iron vessel provided with water cooled lid and stirrer. Any excess permanganate still present at the end of the experiment was destroyed with formic acid. The manganese dioxide was filtered off and washed thoroughly.

The filtrate was concentrated and the following methods were used in an attempt to recover the free acids. (1) The concentrated filtrate was acidified with sulfuric acid and the salts recovered on evaporation were extracted with ether and acetone. This procedure was used by Bone.[9] The recovery was very poor. (2) The filtrate was acidified with hydrochloric acid and the solution poured into a large excess of methyl alcohol. The precipitate, potassium chloride, was filtered off and the filtrate evaporated to dryness. Again the recovery was incomplete and the acids high in inorganic residue. (3) The concentrated filtrate was placed in the middle cell of a three-compartment dialyzer with a parchment membrane on the acid and cellophane on the alkaline side. After electrolysis for four days with a current of 3–4 amp. the acids were found to have migrated completely to the anode compartment. Cathodic and anodic compartments were emptied and refilled with distilled water twice during twenty-four hours. No organic material was found in the cathode liquors, but in cases of incomplete oxidation the larger molecular weight compounds remained in the middle compartment. The combined anodic solutions were evaporated to dryness and the non-volatile acids weighed. The ash content of the free acids was usually less than 0.5% and never more than 1.0%.

The acids were dissolved in 300 cc. of warm water and poured into 1.5 liters of concentrated ammonium hydroxide. The ammonium hydroxide precipitate consisted, in the case of the alkaline permanganate oxidations, mainly of hydrated ammonium oxalate, which is only moderately soluble under these conditions. To obtain the free acids the ammonium hydroxide precipitate was electrolyzed.

The acids recovered by evaporation of the anodic solution to dryness were esterified with diazomethane. The

esters were placed in a molecular fractionating still. When the heating bath temperature was 100° dimethyl oxalate distilled over (0.001 mm.). The residue in the still was purified by recrystallization from methyl alcohol and water and found to be the hexamethyl ester of mellitic acid. *Anal.* Calcd.: C, 50.71; H, 4.23. Found: C, 50.81; H, 4.21. M. p. of authentic sample 187°; mixed m. p. 186°.

The dimethyl oxalate was recrystallized from chilled ether. *Anal.* Calcd.: C, 40.66; H, 5.12. Found: C, 40.77; H, 5.12.

The ammonium oxalate was also determined by titration with 0.1 *N* permanganate in sulfuric acid solution, mellitic acid not being oxidized under these conditions.

Oxidation with Nitric Acid (Sp. Gr. 1.5).—One hundred grams of the 500° coke was refluxed for fourteen days with 1500 cc. of fuming nitric acid to which 0.24 g. of ammonium vanadate was added. The whole mixture was then evaporated to dryness on a steam-bath under vacuum. The solid residue was weighed, dissolved in water, made alkaline and electrolyzed in the usual manner. Ammonium mellitate was precipitated as before. The use of nitric acid alone resulted in the formation of a large amount of complex oxidation products which on electrolysis remained in the center compartment, even in the presence of excess alkali.

Nitric Acid Followed by Alkaline Permanganate (Standard Procedure).—After drying and weighing, the residue from the nitric acid treatment was further oxidized with an excess of alkaline permanganate for seven days, and the excess permanganate destroyed with formic acid. The manganese dioxide was filtered off and washed thoroughly. The filtrate was concentrated and electrolyzed. The acids from the anode compartment were recovered by evaporation. After first drying and weighing the acids were redissolved in 300 cc. of warm water, filtered and poured into 1500 cc. of ammonium hydroxide (sp. gr. 0.9). The mixture was chilled to 0° under constant stirring and held there for one-half hour. This procedure has been used throughout our work and was found much more satisfactory than saturation with ammonia gas from the standpoint of reproducibility and pure precipitation. However, it should be kept in mind that 4 g. of mellitic acid remains in solution under these conditions and is lost. By using nitric acid first and then alkaline permanganate the highest yields of mellitic acid were obtained. The ammonium hydroxide precipitate was found to be pure ammonium mellitate, shown to be free from oxalic acid by failure to reduce 0.1 *N* permanganate in acid solution. This procedure was later adopted as standard.

Nitric Acid Followed by Acid Permanganate and then by Alkaline Permanganate.—After refluxing in the same manner with nitric acid, the acid was diluted with an equal volume of water and a solution of 50 g. of potassium permanganate was run into the boiling acid. The whole was then evaporated to dryness in vacuum on the water-bath. When all nitric acid had been eliminated, the residue was treated with excess potassium hydroxide solution and further oxidized with permanganate. The acid permanganate appears to oxidize the mellitic acid to some extent under these conditions.

Examination of Ammonium Precipitates from the Various Procedures.—The ammonium precipitate from the procedure using alkaline permanganate alone consisted mainly of ammonium oxalate monohydrate. The corresponding precipitates from the three other procedures did not consume any 0.1 *N* permanganate when titrated for oxalic acid. All these precipitates were white. The weight was taken after drying for forty-eight hours over sulfuric acid under reduced pressure. Under these conditions the precipitate had the approximate composition of a hexahydrate. *Anal.* Calcd.: C, 26.09; H, 6.52; N, 15.22. Found: C, 26.22; H, 6.20; N, 15.80; ash, 0.05. Ammonium mellitate is reported[10] to form a nonahydrate, $C_6(COONH_4)_6 \cdot 9H_2O$.

A suitable mixture for electrolysis was found to be 10 g. of ammonium precipitate, 14 g. of potassium hydroxide, and about 4 cc. of 85% formic acid. In one experiment, for example, 136.6 g. of ammonium mellitate was dissolved in 2000 cc. of water containing 200 g. of potassium hydroxide and 55 cc. of formic acid. The whole was split in two equal portions and electrolyzed in two dialyzers. The current was not allowed to exceed 4 amp. at 110 volts. The evaporation residue from the anodes was dried for eighteen hours on the steam-bath and then for four days in high vacuum over phosphoric anhydride at room temperature. The weight of the residue after that time was 86.82 g. There was still a slight weight change after four days' drying. Recoveries on smaller samples from individual oxidations were of the same order.

Anal. Calcd. for $C_{12}H_6O_{12}$: C, 42.10; H, 1.75. Found: C, 41.94; H, 1.95; ash, 0.17.

Identification by Means of the Neutral Methyl Ester.—The acid recovered by electrolysis was esterified with diazomethane. Recrystallization from methyl alcohol, to which hot water was added, yielded, on cooling, the colorless needles of the hexamethyl ester: m. p. 187°, giving no depression when mixed with an authentic sample of the ester. Determinations of the yield of ester were made on individual specimens and also on a composite sample representing the greater number of the experiments. The yield of the pure ester averaged 84% of the theoretical.

Amounts of Reagents Used.—In all cases a large excess of reagents was used: 1500 cc. of nitric acid, sp. gr. 1.50, was used per 100 g. An excess of potassium permanganate was also used. For the original coal the amount was about 2.0 g. of permanganate per g., in a week's oxidation; for the cokes the quantity used decreased with increasing carbonization temperature, about 3.5, 1.5 and 1.0 g. per gram of coke being used for the 500, 700 and 1000° cokes, respectively, in a one-week oxidation period; for the graphites about 9.0 g. per gram was used in a two-week period.

Carbon Balance.—In all cases the carbon was oxidized to carbon dioxide, mellitic acid, and acids soluble in ammonium hydroxide. Tests showed that 4 g. of mellitic acid remained dissolved in ammonium hydroxide under our conditions. By evaporating the residual liquid in the center compartment of the dialyzer only silica was found.

To determine whether any organic material was lost when the manganese dioxide was filtered off, it was dissolved in hydrochloric acid and filtered. With the cokes small amounts of silica were found, but no organic matter.

---

[10] Beilstein's "Handbuch der organ. Chemie."

With the artificial graphite, 9.0 g. of apparently unchanged graphite was obtained; with the natural graphite 7.6 g. No trace of graphitic acid or any other intermediate oxidation product was found.

Discussion

Effects of Reagents on Yields of Mellitic Acid.—Table I shows the yield of mellitic acid by the alkaline permanganate oxidation to be small and of little significance. From Table II it is evident that the oxidation procedure which gives the highest yield of mellitic acid from the 500° coke is nitric acid followed by alkaline permanganate, and that the yield is adversely affected by the use of the acid permanganate intermediate stage. This effect is much more marked in the case of the 1000° coke: when nitric acid and alkaline permanganate were used 22.5 g. of mellitic acid was recovered per 100 g. By the additional use of acid permanganate only 10.3 g. of mellitic acid was obtained. Nitric acid followed by alkaline permanganate was therefore chosen as the standard procedure.

TABLE I

OXIDATION OF COAL AND COKE WITH ALKALINE PERMANGANATE

Per 100 g.	Edenborn coal	500° Edenborn coke	500° Edenborn coke
C per 100 g.	78.27	80.17	80.17
Time of oxidation, hours	7	7	280
Non-volatile acids after electrolysis, g.	85.0	97	67.3
Oxalic acid, g. (calcd. from ammonium oxalate)	30	22	12.4
Mellitic acid, g. (calcd.)[a]	1.02	2.92	3.37
Hexamethyl ester of mellitic acid obtained, g.	0.61	0.81	1.78

[a] Calculated from yield of ammonium mellitate using an experimentally determined conversion factor of 0.636.

TABLE II

ACTION OF OTHER OXIDIZING AGENTS ON 500° EDENBORN COKE

100 g. coke	Mellitic acid recovered, g.
Alkaline permanganate for 280 hours	3.37[a]
Nitric acid	7.25
Nitric acid + alkaline permanganate	11.9
Nitric acid + acid permanganate + alkaline permanganate	10.9

[a] Calculated from ammonium mellitate.

Reproducibility and Losses of Standard Procedure.—In Table III the results of three parallel experiments with the 500° coke are given and show good agreement. The losses occurring, when mellitic acid was subjected to the standard procedure, are shown in the same table and probably can largely be attributed to manipulative losses rather than to oxidation of the mellitic acid itself.

TABLE III

REPRODUCIBILITY AND LOSSES IN STANDARD PROCEDURE

	Residue after nitric acid treatment, g.	Acids after alk. permanganate oxidation, g.	Mellitic acid recovered, g.
100 g. 500° Edenborn coke	95.5	29.7	11.9
	96.2	30.8	11.5
	96.3	28.8	11.5
100 g. mellitic acid	97.5	87.5	83.5

Effect of Carbonization Temperature on the Yield of Mellitic Acid.—From the data given in Table IV it is evident that condensation progresses rapidly up to 700°, where an apparent stability is reached. It should be emphasized that only up to a certain stage should the yield of mellitic acid be expected to increase as condensation takes place and that beyond this point a decrease would be expected, since in large C_6 ring structures a greater fraction of the carbon would necessarily appear as carbon dioxide. When it is taken into account that 4 g. of mellitic acid remained in the ammonium hydroxide during precipitation the ratio of the yields of mellitic acid from coal and coke is greatly increased over that calculated from the data in the table. To assist in the interpretation of the results on coal and coke, oxidations were also carried out, by the standardized procedure, on a natural and on an artificial graphite, where presumably a high degree of condensation is reached.

TABLE IV

EFFECT OF TEMPERATURE OF CARBONIZATION ON YIELD OF MELLITIC ACID

Edenborn 100 g.	Coal	500° Coke	540° Coke	700° Coke	1000° Coke
Heating rate, °C./min.	...	1.9	1.4	1.4	1.4
Carbon per 100 g.	78.27	80.17	79.47	79.80	86.74
Residue after nitric acid oxidation, g.	70.1	95.5	100.6	79.4	50.9
Acids after permanganate oxidation, g.	28.1	29.7	29.1	39.7	29.4
Mellitic acid recovered, g.	5.5	11.9	15.5	24.1	22.5

Oxidation of Artificial and Natural Graphites.—The standard procedure was applied, except that the oxidation period with alkaline permanganate was increased to two weeks. At the end of that time the permanganate was still being decolorized slowly. The material recovered after the nitric acid oxidation resembled ordinary graphite, in both cases, but when treated with alkaline permanganate the oxidizing agent was consumed at a rapid rate. In the case of the Acheson graphite the permanganate was reduced at a rate of about 9 g. per hour at first; after two weeks the rate fell to 1.7 g. per hour. A parallel experiment was made with the Acheson graphite not pre-oxidized with nitric acid. In this case the alkaline permanganate oxidation was very slow, the rate of reduction being 1–2 g. per hour at first and remaining constant for one week, when the experiment was discontinued. To study the effect of particle size, "Aquadag," a colloidal graphite, was also oxidized and unexpectedly gave a smaller yield of mellitic acid than the other graphites.

The data in Table V show that carbonic and mellitic acids are the principal oxidation products of natural and artificial graphite. From these figures we see that in the oxidation of a highly condensed cyclic substance, such as graphite, only a small portion of the carbon is utilized for mellitic acid formation; by far the largest part is converted to carbon dioxide, since large condensed structures have to be destroyed to get to the mellitic acid nucleus. This suggests that the structure which would give the optimum yield of mellitic acid would be one containing many small aromatic "islands," such "islands" being the results of a small crystal size in the case of certain graphites, or the interposition in the lattice of such atoms as oxygen, nitrogen or sulfur in the case of cokes. From a continuous cyclic system, such as graphite is generally believed to be, we had expected only carbon dioxide. For a better interpretation of highly condensed carbons by means of mellitic acid yields much more work is needed, especially the effect of the nature of the original carbon during carbonization and also the effect of particle size in the oxidation should be studied. Further work to that end is in progress.

TABLE V

OXIDATION OF GRAPHITES

100 g. samples	Acheson electrode graphite, −200 mesh	Natural graphite "Micronized Dixon Graphite"	"Aquadag" per 100 g. dry materia
Carbon per 100 g.	99.5	97.4	..
Residue after nitric acid oxidation, g.	71.0	78.5	21.5
Acids after permanganate oxidation, g.	23.7	26.9	14.5
Mellitic acid recovered, g.	19.1	21.7	8.3

Effect of Heating Rate on the Yield of Mellitic Acid from Cokes.—Cokes prepared at a maximum temperature of 540° but heated at a rate of 1.4°/minute and 21.8°/minute, and at maximum temperatures of 700 and 1000° with heating rates of 1.4, 5.5 and 21.8°/minute, respectively, were oxidized using the standard procedure. The yields of mellitic acid showed only slight variations for the cokes prepared at a given temperature, from which it follows that the final temperature of carbonization is the most important factor in determining the yields of mellitic acid obtained.

It should be mentioned that these yields of mellitic acid are the highest for any pure organic compound other than carbonic and oxalic acids obtained from coal or coke. The yields given in the tables are those actually recovered. Since it was shown that 4 g. is lost in the ammonia precipitation, the mellitic acid formed would be greater by this amount over the yields shown in the tables.

Acknowledgments.—The author wishes to thank H. C. Howard, F. C. Silbert and W. B. Warren of this Laboratory for assistance and cooperation in this work.

Summary

Alkaline permanganate, nitric acid, nitric acid followed by alkaline permanganate and nitric acid followed successively by acid permanganate and alkaline permanganate have been used in the oxidation of coal, cokes and graphites to mellitic acid. The action of nitric acid followed by alkaline permanganate is particularly effective in oxidizing a wide range of carbonaceous materials to mellitic acid. Neither reagent alone is satisfactory. With alkaline permanganate alone little mellitic acid is formed and large amounts of oxalic acid. With nitric acid alone mellitic acid is recovered and no oxalic acid, but the yield of mellitic acid is low due to the formation of intermediate oxidation products of high molecular weight. By subsequent alkaline permanganate treatment these intermediates are oxidized to mellitic acid. This is well illustrated by the behavior of graphite. Nitric acid or permanganate alone have no visible effect on graphite, but by oxidation with nitric acid first, followed by alkaline permanganate, 19.1 g. of mellitic acid was recovered per 100 g. of artificial graphite. This yield is of the same order as that from a natural

graphite and from the 700 and 1000° Edenborn cokes.

The effect of the carbonization temperature of the coke on the yield of mellitic acid was studied. From Edenborn coal, little mellitic acid was obtained. With increasing carbonization temperature the yield increased rapidly up to 700°. With the 1000° coke about the same quantity was recovered as with the 700° coke. With high temperature cokes the interpretation of our results becomes difficult. There is at present no satisfactory explanation for the uniformity of mellitic acid yields from such widely different carbons as 700 and 1000° cokes, artificial and natural graphites.

Cokes with the same final carbonization temperatures but widely different heating rates show small differences in the mellitic acid yield, which probably does not have important significance.

Some Ethers of 3-Butyn-1-ol[1]

By P. A. McCusker and J. W. Kroeger

In view of the commercial availability of certain derivatives of ethylene glycol commonly known as Cellosolves and Carbitols, it was proposed to investigate the preparation and properties of acetylenic compounds derived from these starting materials. This group of compounds, the 1-alkoxy-3-butynes, provides not only a new type of acetylene for investigation but also furnishes a starting point for further syntheses since the terminal hydrogen of the chain is quite labile, being attached to a triply bonded carbon atom.

Various types of acetylenic ethers are reported in the literature[2] the majority of which are ethers of propargyl alcohol. Of the group of compounds described herein, all are new with the exception of 1-methoxy-3-butyne which was prepared by Lespieau[3] by dehydrohalogenation.

The technique of the preparation of acetylenic compounds as originally described by Picon,[4] who treated sodium acetylide in liquid ammonia with alkyl iodides, has been modified in this Laboratory to apply to alkyl bromides. The Cellosolves and Carbitols were converted to the corresponding bromides by the method of Palomaa and Kenetti.[5] Of these, 2,2′-dibromodiethyl ether and ethyl 2-bromoethyl glycol ether, the bromides derived from diethylene glycol and diethylene glycol monoethyl ether, respectively, are new compounds. The acetylenes were obtained from these various bromides in yields of 60 to 75% according to the type reaction

$$\mathrm{R{-}O{-}CH_2{-}CH_2Br + NaC{\equiv}CH \longrightarrow R{-}O{-}CH_2{-}CH_2{-}C{\equiv}CH + NaBr}$$

These acetylenes are quite stable to light and air. Carefully purified samples were water-white after standing for three months. The characteristic odor of the 1-alkynes is unusually powerful in these acetylenic ethers.

Sodium acetylide does not react appreciably with 2,2′-dichlorodiethyl ether, under the experimental conditions used. Ethylene bromohydrin when treated with sodium acetylide is converted to acetaldehyde, principally.

Experimental

Preparation of Bromides.—Commercial samples of the various glycol derivatives were treated with phosphorus tribromide in the presence of pyridine.[4] Redistillation of the glycol ethers was usually unnecessary. The physical constants for 2,2′-dibromodiethyl ether, which has not previously been reported, are: b. p. 115° (32 mm.); $n^{27}\mathrm{D}$ 1.5131; $d^{27}{}_4$ 1.8222. The constants for ethyl, 2-bromoethyl glycol ether are: b. p. 100–101° (33 mm.); $n^{24}\mathrm{D}$ 1.4580; $d^{24}{}_4$ 1.3340.

Preparation of Acetylenes.—One liter of liquid ammonia was placed in a 3-liter three-necked flask and stirred vigorously while a rapid stream of acetylene was bubbled through. To this, 1.2 moles (excess) of sodium dissolved in liquid ammonia was added slowly. When all the sodium had been converted to sodium acetylide, one mole of bromide was slowly dropped in and the mixture was stirred for two to four hours. Five hundred milliliters of water was then added and the organic layer which separated was washed with dilute hydrochloric acid, then with saturated

NOTES

Concerning the Alleged Absorption of Gaseous Nitrogen by Benzene Solutions of Rubber and Guttapercha Hydrocarbons

BY LOUIS B. HOWARD[1] AND GUIDO E. HILBERT

Experiments described by De Jong[2] have been interpreted as indicating that dilute benzene solutions of rubber or guttapercha hydrocarbon from sheet balata, when exposed to sunlight for a few days in either quartz or ordinary glass vessels, absorb gaseous nitrogen in appreciable amounts.[3] If such a photochemical combination of rubber and nitrogen actually occurs, one might reasonably expect other unsaturated hydrocarbons containing isoprene units such as carotene and xanthophyll to behave similarly. These substances which always are found closely associated with chlorophyll in green plants possess physiological functions which, as yet, remain quite obscure. It therefore seemed of very great importance from both a theoretical and a practical standpoint to attempt to confirm these results of De Jong.

In the present study the experimental procedure of the original investigation was followed as closely as the description of the work allowed. Several variable factors, such as temperature, barometric pressure, vapor pressure of the benzene solutions and the heating effect of sealing the tubes, were controlled. In one experiment Pyrex tubes of 150-cc. capacity were filled with

---

[1] Now employed at the Whittier, Calif., station of the Bureau of Entomology and Plant Quarantine.

[2] De Jong, *Rec. trav. chim.*, **51**, 153 (1931).

[3] In one case a tube containing 54 cc. of a 1.05% solution of rubber in benzene under an atmosphere of nitrogen was found to draw in 11 cc. of water when opened under the surface of this liquid after six days of irradiation. This was considered to indicate an absorption of 12.8 mg. of nitrogen which according to his calculations represented 2.5% of the weight of the rubber.

100 cc. of nitrogen gas and 50 cc. of benzene solutions containing about 0.5% of either pale crepe rubber or balata. After sealing, these tubes and a benzene control were exposed to direct sunlight during the summer for various lengths of time up to five weeks. At the end of the tests the changes in volume of the nitrogen in the tubes containing the rubber solutions differed from that of the benzene control by a maximum of 0.5 cc. which was found to be about the limit of experimental error.

Another series of experiments was carried out in an apparatus which consisted of several volumetric reaction chambers in the form of glass tubes fitted with stopcocks and attached to a mercury leveling bulb. The tubes were charged with about 100 cc. of nitrogen and one, reserved for a control, with 50 cc. of pure benzene and the others with 50 cc. each of 1.1% benzene solutions of one of the following types of rubber: pale crepe (from a shipment just received), fine Para from South America, smoked sheet or balata. Even though the tubes were exposed to direct sunlight for three months during the summer the slight changes in volume of the gas were in every case less than 1 cc. and, in each of the rubber solutions, were actual *increases*.

It may be concluded that under the conditions described and with the specimens of rubber, nitrogen and benzene used, nitrogen gas is not absorbed to any appreciable extent.

The Formation of Atacamite by the Incorporation of Copper Powder in Magnesium Oxychloride Compositions

By Dean S. Hubbell[1]

When magnesium oxychloride compositions that contain copper harden in the presence of air, the formation of a new phase is indicated by the development of a blue-green color as well as by an increase in strength and a reduction in solubility.

The new blue-green phase was found by X-ray examinations to be identical with atacamite and also cupric oxychloride prepared by dissolving freshly precipitated cupric carbonate in a solution of cupric chloride. This is in harmony with the observations of other investigators[2] who have shown that copper is corroded by certain chloride solutions in the presence of air to form a basic chloride resembling atacamite.

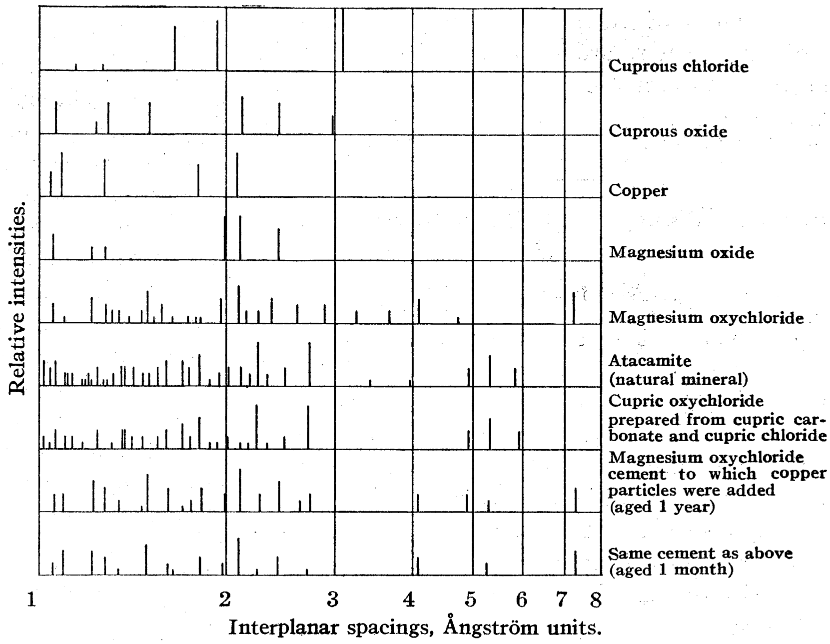

Fig. 1.—Diffraction data.

X-Ray diffraction analyses were made by the Debye–Scherrer method on a sample of the oxychloride cement after aging first for one month and then for one year. The radiation from an X-ray tube provided with a copper target was used, after filtering through nickel, in a camera of 57.3-mm. effective diameter. The specimens used were rods of 0.7-mm. diameter formed from the powdered samples with collodion as a binder. The interplanar spacings obtained from the photograms are shown in the accompanying figure, which includes data obtained in a similar way for cupric oxychloride, atacamite, magnesium oxychloride, copper, cupric chloride, cuprous chloride and magnesium oxide. The relative intensities of the corresponding diffraction lines were estimated visually.

Both unaged and aged oxychloride cements contain, as a major constituent, a material corresponding to magnesium oxychloride, as the similarity of the diffraction data indicates. Diffraction lines corresponding to the stronger

lines of cupric oxychloride, and of atacamite, but noticeably broad, were found for these cements, indicating that cupric oxychloride had been formed in appreciable amounts, but in very small, almost colloidal, particles. The amount of this compound is probably somewhat greater in the aged cement than in the unaged material. On the other hand, it is evident that cupric oxychloride has not formed a complex compound with magnesium oxychloride nor entered appreciably into solid solution in it.

It has been observed that the formation of the new phase takes place at the expense of the copper particles and that it cannot proceed in the absence of oxygen or of water vapor. Exposure to sunlight appears to retard and strong ultraviolet light prevents its formation.

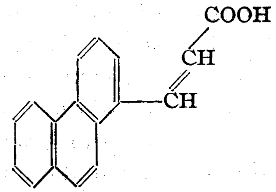
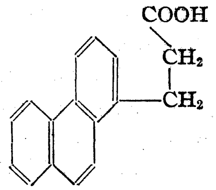
Rapid Synthesis of β-(1-Phenanthryl)-propionic Acid

By Samuel Natelson and Sidney P. Gottfried

1-Phenanthraldehyde, prepared by the method of Bachmann,[1] was converted rapidly in good yield to β-(1-phenanthryl)-propionic acid after the method described by the authors for a similar series.[2] 1-Phenanthraldehyde, which condenses with acetic anhydride and sodium acetate in extremely poor yield after the usual Perkin reaction, condenses almost quantitatively with malonic acid, with the elimination of carbon dioxide. The β-(1-phenanthryl)-acrylic acid formed (I) may be reduced to yield β-(1-phenanthryl)-propionic acid (II).[3] This acid has been prepared before by Bachmann[1] by a more tedious route in an attempt to synthesize 3′-keto-1,2-cyclopentenophenanthrene.



(I)



(II)

Ten grams of 1-phenanthraldehyde is mixed with 4 g. of malonic acid (excess) and 0.5 cc. of pyridine. The mixture is heated on a water-bath for thirty minutes, when effervescence ceases and the whole mass solidifies. The β-(1-phenanthryl)-acrylic acid, formed in almost quantitative yield, is washed with dilute acid to remove the pyridine and is recrystallized from acetone, m. p. 259°. This acid dissolved in dilute potassium hydroxide, is reduced with an excess of 3% sodium amalgam to yield 9–11 g. of β-(1-phenanthryl)-propionic acid (II), m. p. 187–188° (from acetone). It seems curious to the authors that reduction at the 9,10-positions of the phenanthrene nucleus was not brought about by the sodium amalgam.

COMMUNICATION TO THE EDITOR

SYNTHETIC VITAMIN B_1

Sir:

In our last communication [This Journal, **58,** 1504 (1936)] we reported synthetic vitamin B_1 chloride melting at 232–234° rather than at 246–250° as previously given for the natural product. We have, however, using our previous method but by a different choice of solvents for purification, obtained, in good yield, synthetic vitamin B_1 chloride which agrees in every particular with the natural vitamin. We owe thanks to Dr. G. A. Stein of the Merck Laboratories for his collaboration in this matter.

A low melting point has also been observed in the bromide. In both chloride and bromide the low melting point is associated with a much greater solubility in alcoholic solvents. Both low melting salts are obtained from methanol solutions by addition of ether. However, when recrystallized from methanol by addition of ethanol or from water by addition of ethanol, the higher melting forms have been obtained. The discrepancies in melting point and solubility are not paralleled by detectable discrepancies in composition, absorption spectra or physiological potency. Crystallographic and polarographic examinations have revealed a number of interesting features which, however, do not permit us to draw any final conclusions. The matter is still under investigation.

NEW BOOKS

The Chemistry of the Colloidal State. A Textbook for an Introductory Course. Second edition. By JOHN C. WARE, Sc.M., Ph.D., Consulting Chemist. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1936. xvi + 334 pp. 96 figs. 15.5 × 23.5 cm. Price, $3.75.

This second edition, like the first, is clearly written in a style suitable for students who are not interested in a too mathematical discussion of colloid chemistry, and it should therefore find a place in colleges where such courses are taught.

The following additions have been made: A new chapter of six pages on Intermediate Cases—Soaps; one-half page on Edible Jellies; three paragraphs on emulsions; four pages on the precipitation of substances in the colloidal state; two paragraphs on the electrical character of interfacial phenomena; nine lines on the plating of rubber; nine lines on the Donnan equilibrium, and two pages on surface tension lowering. There is an over-all increase of twenty-one pages.

One is at a loss, however, to see how the author's statement that the text has been largely rewritten is justified. Many of the chapters are practically unchanged and there is no change in the figures. Also, the statement in the Preface that the space given to adsorption has been doubled actually finds little support, as twenty-eight pages are devoted to this topic in the first edition and twenty-nine in the second edition.

A. L. ELDER

Principles of Biochemistry. By ALBERT P. MATHEWS, Andrew Carnegie Professor of Biochemistry, University of Cincinnati. William Wood and Company, Mt. Royal and Guilford Avenues, Baltimore, Maryland, 1936. x + 512 pp. 15.5 × 24 cm. Price, $4.50.

A teacher for forty years who has "a profound respect and affection" for the "earnest, hard working and lively young people" who are his pupils should know their needs. And when he has in addition carried on continuous productive research in the field in which he teaches, he should be in a position to write a textbook which gives his students the information they need in a form at once interesting, critically accurate and up-to-date. This, we believe, Professor Mathews has accomplished in his new book.

The material is treated under the usual headings of Glucides, Lipides and Protides (the newer names for the familiar Carbohydrates, Fats and Proteins; then the Special Chemistry of Important Tissues, Vitamins and Hormones; and Energy Metabolism. In each case, the material selected is such as to give a clear and accurate picture to the student of both the chemistry and physiology of the material under discussion with relatively little of that rounding off of debatable topics which is necessary in the interest of clearness.

In the opinion of the reviewer, it is to be regretted that the author has, after due consideration, omitted almost all references to the literature because the student has not time to consult the original literature. This is conceded; also that only a small percentage of the students would do so if they had the time, since it is easier to accept authority than to try to get at the truth of the matter from published work. Nevertheless, the medical school is the last place where the student will get formal assistance in arriving at a critical view of what is going on in his field of interest, and, if he wishes to keep up with the advance of medicine during his lifetime, he should acquire the technique of critical reading before he leaves school. However, this is a minor point and detracts little, if at all, from the general excellence of the book.

W. R. BLOOR

Analytische Chemie der Edelmetalle. (Analytical Chemistry of the Noble Metals.) By Dr. ALFRED WOGRINZ, Lecturer at the Technical Institute of Vienna. Ferdinand Enke Verlag, Hasenbergsteige 3, Stuttgart W, Germany, 1936. xi + 141 pp. 14 figs. 16.5 × 25.5 cm. Price, RM. 13; bound, RM. 14.80.

The above book is essentially a compilation of the scattered information on the analytical chemistry of the noble metals. Fifty pages are devoted to silver, thirty to gold, and forty-five to the platinum metals. Under each of these headings the subject matter is presented similarly, being divided into a brief introduction of history and occurrence, followed by a discussion of analytical reactions, methods of detection and of determination, and procedures of separation, including those applicable to certain technical products. In addition, six pages are given over to tables of a number of physical properties. The book also contains an author and a subject index, and a list of works consulted. It is clearly printed on a good grade of paper.

The sections dealing with silver and gold appear to be quite complete, but that dealing with the platinum metals leaves the analytical chemistry of the group some twenty years out-of-date, owing to the fact, unfortunately, that consideration is not given to work done in recent years, the aim of which has been to replace the traditional methods of separation and of determination with others more in keeping with modern requirements of accurate chemical analysis. The section on the platinum metals, therefore, is more of historical interest than of practical value.

Raleigh Gilchrist

Annual Survey of American Chemistry. Volume X, 1935. Edited by Clarence J. West, Director, Research Information Service, National Research Council. Published by Reinhold Publishing Corporation, 330 West 42d Street, New York, N. Y., 1936. 487 pp. 14 × 22 cm. Price, $5.00.

It is advisable to list the topics reviewed in the latest volume of the annual Survey of American Chemistry because lack of space and the growing output of American chemists have made necessary the limitation of the fields covered in any one volume. The subjects included in Volume X are as follows: Theories of solution, the kinetics of homogeneous gas reactions, molecular structure, thermodynamics and thermochemistry, contact catalysis, inorganic chemistry, 1933–1935, analytical chemistry, 1934 and 1935, applications of X-rays in metallurgy, ferrous metallurgy, the platinum metals, electroörganic chemistry, aliphatic compounds, carbocyclic compounds, heterocyclic compounds, alkaloids, food chemistry, insecticides and fungicides, gaseous fuels, 1934 and 1935, petroleum chemistry and technology, detergents and detergency, cellulose and paper, synthetic plastics, rubber, unit processes in organic synthesis, chemical economics (1931–1935).

The amount of space given to any one research is necessarily small, but it is possible to find any details desired through the use of the complete list of references appended to each Chapter. It is of interest to note that the book contains over 4800 references—a fact that indicates the productivity of American chemists.

The high standard of the past has been maintained. The writer joins the editor in the belief that "the success of the series is due to the cordial and unselfish coöperation of the authors who have given so freely of their knowledge and experience." The editor also deserves praise for the excellence with which he has done his work.

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

VOLUME 59 FEBRUARY 8, 1937 NUMBER 2

Seventh Report of the Committee on Atomic Weights of the International Union of Chemistry

BY G. P. BAXTER (*Chairman*), O. HÖNIGSCHMID AND P. LEBEAU

The following report of the Committee covers the twelve-month period, September 30, 1935, to September 30, 1936.[1]

The following changes in the table of atomic weights have been made:

Carbon, from 12.00 to 12.01
Rubidium, from 85.44 to 85.48
Gadolinium, from 157.3 to 156.9
Lead, from 207.22 to 207.21
Uranium, from 238.14 to 238.07

Oxygen.—Dole[2] reports a difference in isotopic composition between the oxygen of the air and that of the water of Lake Michigan, U. S., corresponding to 0.00008 atomic weight unit, and advocates some single isotope such as protium as atomic weight standard. Since analytical accuracy under the most favorable conditions does not surpass 0.001% and since the determination of atomic weights by chemical methods, no matter what standard is used, must in most cases involve reference to oxygen more or less directly, the Committee sees no reason to change the position taken in its Second Report,[3] that no advantage is to be gained by any change of standard at the present time.

Hydrogen.—Although no change in the atomic weight of hydrogen is made in this year's table, it seems increasingly probable from mass spectrographic measurements[4] that the atomic weight of hydrogen is 0.0002–0.0003 higher than the current value. As pointed out by Moles,[5] chemical determinations have ordinarily been made with electrolytic hydrogen which, owing to isotopic separation, has a less than normal proportion of deuterium.

Carbon.—Toral and Moles[6] have determined the density of carbon dioxide, made by pyrolysis of sodium bicarbonate, with the following average results. Individual results are not given.

1 atmosphere	1.97701
$^1/_2$ atmosphere	1.97014

Limiting density is then 1.96327 and the atomic weight of carbon 12.006 if gram molecular volume is taken as 22.4146. Using their own value for the limiting density of oxygen Toral and Moles obtain the value 12.007 for carbon.

Carbon.—Baxter and Hale[7] have determined the atomic weight of carbon by combustion of hydrocarbons. A weighed amount of hydrocarbon was burned in pure oxygen and both the carbon dioxide and the water formed were collected and weighed. From the weight of water the weight of hydrogen was calculated and subtracted from the weight of hydrocarbon to find

2.99639	1.58592	.17743	2.81896	10.33026	7.51130	.375296	12.009(5)
					Average	.375309	12.009(9)
			Anthracene				
2.99484	1.51453	0.16945	2.82539	10.35398	7.52859	0.375288	12.009(2)
2.04930	1.03682	.11600	1.93330	7.08554	5.15224	.375235	12.007(5)
					Average	.375262	12.008(4)
					Average of all		12.009(1)

the weight of carbon, from which, with the weight of carbon dioxide formed, the ratio of carbon to oxygen may be calculated.

Hydrocarbons were purified by chemical treatment, by crystallization from hydrocarbon solvents and by distillation or sublimation.

Combustion was effected by slowly evaporating weighed amounts of hydrocarbon into a stream of an excess of oxygen which passed over platinum catalysts in a quartz tube, first at 650°, but eventually at 800°. A short section of copper oxide provided for a possible deficiency of oxygen. Water was collected largely by condensation but partly by phosphorus pentoxide. Carbon dioxide was collected in ascarite (sodium hydroxide) and escape of water from the carbon dioxide absorber was prevented by phosphorus pentoxide. Vacuum corrections are applied.

Results with pyrene were inconsistent and differed from those with other hydrocarbons.

This result is in accord with recent gas density and mass spectrographic evidence that the atomic weight of carbon is not far from 12.01. Accordingly the International value has been altered to this figure.

Batuecas[8] recalculates his data on the densities of several gases and finds values for carbon from 11.999 to 12.007, and for nitrogen 14.011 and 14.009.

Neon.—Jungbluth-Ficht and Hoeppener[9] starting with neon containing 18% of helium, fractionated this gas by adsorption on active charcoal at low temperature. The products of the last three fractionations gave the following densities (volume of globe = 300 ml., g = 980.616)

A	0.8988
B	0.89949
C	0.89990

The density of the purest fraction (C) corresponds to the atomic weight of neon in current use.

Potassium.—Brewer[10] has measured the abundance ratio K^{39}/K^{41} in potassium from various sources. With minerals the ratio varied from 14.11 to 14.32 (except for one sample which gave 14.6). With plant ash a larger variation was found, from 12.63 (kelp) to 14.6 (potato sprouts). In sea water from different localities the ratio was constant at 14.20. The abundance ratio 14.20, with the packing fraction -7.0×10^{-4} and the conversion factor 1.00027, give 39.094 for the atomic weight of potassium. With the average abundance ratio from minerals, 14.25, the atomic weight is 39.093. The abundance ratio corresponding to the atomic weight 39.096 is 13.93.

Gallium.—Lundell and Hoffman[11] have determined the ratio of gallium to gallium oxide. Gallium of 99.999% purity was prepared by a combination of wet methods, electrolysis and fractional crystallization of the metal.[12] By chemical and optical examination the crystals were found to be free from oxide film. In one set of experiments weighed crystals were dissolved in a mixture of nitric, hydrochloric and

sulfuric acids and after removal of nitric and hydrochloric acids gallium hydroxide was precipitated with ammonia. The hydroxide was collected and ignited at 1200–1300° to constant weight (I). In another the gallium sulfate was evaporated to dryness and ignited at 1200–1300° (II). In a third, after solution in mixed nitric and hydrochloric acids, the hydrochloric acid was eliminated by evaporation with nitric acid, the solution of gallium nitrate was evaporated to dryness and the residue ignited at 1200–1300° (III). Oxide samples prepared by the three methods were found to be free from occluded gases. Weights are corrected to the vacuum standard.

The difference between the average value for gallium and that found earlier by Richards and Craig, though the analysis of $GaCl_3$, 69.72, warrants further investigation.

Germanium.—Hönigschmid, Wintersberger and Wittner[13] have determined the ratio of germanium tetrabromide to silver and silver bromide. The tetrabromide was synthesized from spectroscopically pure germanium and pure bromine and was fractionally distilled in exhausted glass systems. Glass bulbs were partially filled with material at various stages of the fractionation. After being weighed the bulbs were broken under sodium hydroxide and the glass was collected for weighing. The solution was then acidified and compared with silver in the usual way. Finally the silver bromide was collected. Weights are corrected to vacuum. Fractions are numbered in the order of decreasing volatility.

Hönigschmid and Wintersberger[14] have determined the ratio of germanium tetrachloride to silver and silver chloride. Germanium was recovered from the tetrabromide analyses by precipitation as hydroxide or sulfide and after conversion to oxide was reduced in hydrogen. The tetrachloride, which was synthesized from the

metal and chlorine prepared from pyrolusite and hydrochloric acid, was fractionally distilled in exhausted systems and collected in sealed glass bulbs. These were analyzed as described above. Weights are corrected to vacuum.

The average result, 72.59, is 0.01 unit lower than the International value, which depends upon the work of Baxter and Cooper.

Rubidium.—Archibald, Hooley and Phillips[15] have redetermined the ratio RbCl:Ag. Rubidium dichloroiodide was fractionally crystallized ten times from dilute hydrochloric acid. Conversion through the sulfate to the hydroxide by means of barium hydroxide was followed by neutralization with tartaric acid and five recrystallizations of the acid tartrate. After conversion of the tartrate to carbonate by ignition, the chloride was formed and recrystallized three times. Spectrographic analysis yielded no evidence of the presence of other alkalies.

Rubidium chloride was prepared for weighing by fusion in nitrogen, and was compared with pure silver by the "standard solution" method of Johnson. Weights are corrected to vacuum.

THE ATOMIC WEIGHT OF RUBIDIUM

RbCl, g.	Ag, g.	RbCl:Ag	At. wt. Rb
2.41226	2.15167	1.12111	85.488
2.77942	2.47848	1.12142	85.519

Average of last six analyses		1.12104	85.481

Archibald and Hooley[16] have continued the foregoing investigation by the determination of the ratio RbBr:Ag:AgBr. Rubidium nitrate resulting from the rubidium chloride analyses was freed from silver and converted to acid tartrate which was four times crystallized. Conversion to bromide followed. The first fraction of crystals formed Sample I. The remainder was converted to tribromide and twice recrystallized. The crystals after conversion to bromide formed Sample II, the mother liquors Sample III. Comparison of weighed amounts of rubidium bromide with silver was followed by gravimetric determination of the silver bromide formed. Weights are corrected to vacuum.

The average value from the three ratios, 85.48, is 0.04 unit higher than that found by Archibald over thirty years ago and has been adopted for the table.

Silver.—Hönigschmid and Schlee[17] have determined the ratio of silver nitrate to silver chloride in the dry way. Silver nitrate which had been prepared from the purest silver was crystallized from nitric acid and after being dried in pure air at 150° was fused at 220°. Conversion of the weighed nitrate to chloride was effected, first at 150° in hydrogen chloride diluted with nitrogen, later at higher temperatures in more concentrated hydrogen chloride, until finally the fusion temperature was passed. No loss of silver salt occurred during the conversion. Weights are corrected to vacuum.

THE RATIO OF SILVER NITRATE TO SILVER CHLORIDE

	$AgNO_3$, g.	AgCl, g.	$AgNO_3$:AgCl
	6.60708	5.57445	1.185244
	6.25586	5.27812	1.185244
	6.53756	5.51582	1.185238
	6.42000	5.41662	1.185241
	6.19269	5.22483	1.185242
	7.48847	6.31810	1.185241
	6.58954	5.55968	1.185237
	6.76512	5.70780	1.185241
Total	52.85632	44.59542	1.185241

This experimental value affords close confirmation of International atomic weights which give, as the value to be expected, 1.185235.

Cadmium.—Hönigschmid and Schlee[18] have analyzed cadmium chloride and bromide. Cadmium metal was fractionally distilled in vacuum until spectroscopic examination (Gerlach) showed no impurities. Cadmium chloride was prepared by solution of the metal in nitric acid and displacement of the nitric acid by hydrochloric acid. After crystallization the salt was dehydrated and twice sublimed in hydrogen chloride (Sample I). A second sample was made by heating the metal in dry hydrogen chloride, and twice subliming the product (Sample II). Preparatory to weighing the chloride was fused in nitrogen in a quartz system, since chlorine and hydrogen chloride are retained if the operation is conducted in these gases.

Cadmium bromide was synthesized by heating the metal in a current of nitrogen and bromide in a quartz apparatus and was twice resublimed in nitrogen and bromide before the final fusion in nitrogen. Analysis by comparison with silver followed the conventional lines. Weights are corrected to vacuum.

The average of all the individual values, 112.41, is identical with the present International value and is 0.2 unit higher than Aston's most recent mass spectroscopic determination, 112.2.

Gadolinium.—Naeser and Hopkins[19] have determined the ratio of gadolinium chloride to silver. Samarium–europium–gadolinium material was fractionally crystallized as double magnesium nitrates with and without bismuth as "separating element," and then as simple nitrates with bismuth nitrate as separator. Bismuth was eventually removed as sulfide and the gadolinium was five times alternately precipitated as hydroxide and oxalate. Of the eight final fractions, 7–14, the first six showed only gadolinium in their arc spectra.

Gadolinium chloride was prepared for weighing by evaporating to dryness a solution of the salt in a weighed quartz flask and cautious expulsion of the crystal water wholly by efflorescence, all in a current of hydrogen chloride. Fusion in hydrogen chloride followed. Comparison with silver followed conventional lines, by the equal opalescence method. Weights are corrected to vacuum.

THE ATOMIC WEIGHT OF GADOLINIUM

Fraction	$GdCl_3$, g.	Ag, g.	$GdCl_3$: 3Ag	At. wt. Gd

12	2.48952	3.06091	.81333	156.85
			.81332	156.85

Since this result is in accord with Aston's recent finding, the value 156.9 has been adopted for the International table.

---

[18] Hönigschmid and Schlee, *Z. anorg. allgem. Chem.*, **227**, 184 (1936).

[19] Naeser and Hopkins, THIS JOURNAL, **57**, 2183 (1935).

Erbium.—Hönigschmid[20] has redetermined, by analysis of the chloride, the atomic weight of an erbium preparation containing 0.37 atomic per cent. of yttrium and 0.42% of thulium. The value found was 166.96, which, when corrected for yttrium and thulium becomes 167.24. The material used earlier by Hönigschmid and Kapfenberger, which gave the value 165.2, was found to contain 2.9 atomic per cent. of yttrium, 2.9% of holmium, 2.9% of thulium and 2.7% of ytterbium. Correction for these impurities raises the observed value to 167.35. The discrepancy between the results of Hönigschmid and Kapfenberger, and that of Aston, 167.15, is thus largely removed. However, the Committee feel that it is advisable to defer any change in the value for erbium in the table until the details of Hönigschmid's work are available.

Tantalum.—Hönigschmid and Schlee[21] have continued their work on the atomic weight of tantalum by analysis of tantalum pentachloride. The purification of tantalum material consisted in recrystallization of the double potassium fluoride, conversion to tantalic acid by evaporation with sulfuric acid, extraction of potassium salt with hot water and ignition at 1000°. At this stage, columbium, thorium and zirconium had been eliminated but a trace of iron remained. This was removed by fusion with sodium hydroxide and precipitation of iron as sulfide. Precipitation of tantalic acid with sulfurous acid and ignition followed.

The pentachloride was prepared by first converting the oxide to sulfide by heating in a current of hydrogen sulfide and carbon disulfide and then heating the sulfide in chlorine. Removal of sulfur chloride was effected by distillation in a current of chlorine and by heating in a high vacuum. The product was distilled into small glass bulbs for weighing.

The weighed bulbs were broken under alcohol, and after dilution with water the glass was collected and weighed. Precipitation of tantalic acid with ammonia followed and after addition of a slight excess of nitric acid the solution was compared with weighed quantities of pure silver. Weights are corrected to vacuum.

The average result agrees exactly with that previously found by the authors from the analysis of the pentabromide.

THE ATOMIC WEIGHT OF TANTALUM

Lead.—Hecht and Kroupa[22] have determined the atomic weights of several radiogenic leads. Lead chloride from each specimen was purified by crystallization as nitrate, conversion to sulfate and to carbonate, recrystallization as nitrate and as chloride and distillation of the chloride in hydrogen chloride. The ratios of lead chloride to silver and silver chloride were found in the conventional way. Weights are corrected to vacuum.

The value for Great Bear Lake material is slightly higher than that found by Marble and by Baxter and Alter with a different sample. This difference is undoubtedly due to varying amounts of common lead which the mineral is known to contain. With a different specimen of Wilberforce uraninite Baxter and Bliss found 206.195, although the Th/U ratio of this specimen was lower. It is far from certain, however, that Wilberforce uraninite is free from common lead. The lead in the black insoluble portion of Katanga pitchblende appears to have a slightly higher atomic weight than that in the hydro-

chloric acid-soluble portion of the same specimen as determined by Hönigschmid, Sachtleben and Baudrexler, 206.03.

In the light of recent evidence (see preceding reports) the atomic weight of common lead appears to be nearer 207.21 than 207.22 and this change has been made in the table.

Uranium.—Hönigschmid and Wittner[23] have investigated the ratios UCl_4:4Ag:4AgCl and UBr_4:4Ag:4AgBr. Samples of uranium material from different mineral sources were purified by essentially similar methods, including removal of heavy metals with hydrogen sulfide, precipitation of uranyl carbonate and solution in excess ammonium carbonate, crystallization of uranyl nitrate, precipitation of uranyl oxalate and ignition, first to U_3O_8 and then to UO_2 in hydrogen.

The halides were obtained by heating the oxide mixed with sugar charcoal in an atmosphere of nitrogen and chlorine or bromine and the first sublimate obtained was resublimed into a weighed quartz tube, all in a quartz bottling system. In

many of the experiments the sublimed halide was fused in an atmosphere of the corresponding halogen before being weighed. Analysis followed by dissolving the salt, oxidizing with hydrogen peroxide in acid solution and comparison with silver. Afterward, in some cases the silver halides were collected. Weights are corrected to vacuum.

Within the experimental error there seem to be no differences in the isotopic composition of the samples of uranium, although the original minerals differ considerably in geologic age.

The authors believe the comparisons of the halides with silver to be more accurate than those with silver halides, and point out that, since material fused after sublimation seems to yield slightly higher and less consistent results than when final fusion is omitted, dissociation and loss of halogen may occur during fusion. Therefore they prefer the final value 238.07, which results from analyses of unfused chloride, to the average of all the determinations.

This result is materially lower than the value in use for some time, which depends on the work of Hönigschmid and of Hönigschmid and Schilz. The authors believe the difference to be due to the fact that in the earlier work the halides were finally sublimed and fused in nitrogen before weighing. Since there seems to be no doubt that this is the case, and since the value 238.07 best represents the evidence of the foregoing work, this new value has been adopted for the International table.

Molybdenum and Tungsten.—Hönigschmid and Wittmann[24] and Hönigschmid and Menn[25] have redetermined the atomic weights of molybdenum and tungsten by analysis of the pentachloride and hexachloride, respectively.[26] Their results, Mo = 95.95 and W = 183.92, agree closely with Aston's recent determinations, and are only slightly lower than the International values.

New measurements of doublets by Aston[27] with a perfected mass spectrograph include the following values for certain light isotopes.

O^{16} = 16.0000	(Factor = 1.00025) O = 16.0000
H = 1.00812	H = 1.0079
D = 2.01471	D = 2.0142
He = 4.00391	He = 4.0029
C^{12} = 12.0035	C^{12} = 12.0005
N^{14} = 14.0073	N^{14} = 14.0038

The value for C^{12} is slightly lower than that reported by Aston in 1935, and with an abundance ratio of 1/100 for C^{13} leads to an atomic weight of 12.010.

Cinchona Alkaloids in Pneumonia. IV. Derivatives of Ethylapocupreine[1]

BY C. L. BUTLER, ALICE G. RENFREW, LEONARD H. CRETCHER AND B. L. SOUTHER

The pneumococcus inhibiting action of various cupreine derivatives and reasons for renewing chemotherapeutic investigations in this field have been given in previous papers of this series.[2,3] In the present paper ethylapocupreine[4] and several of its derivatives are briefly discussed. A preliminary report of the high bacteriostatic activity, high protective action using mice, and lowered toxicity of ethylapocupreine compared to optochin was given at the September, 1934, meeting of the American Chemical Society at Cleveland, Ohio, and discussed in the medical literature[5] by the physicians associated with us. These valuable properties were thoroughly confirmed during the fall and winter of 1934–35. The results are in general agreement with those reported by others[6] although the rather large difference in favor of ethylapocupreine over optochin reported by the Japanese investigators[6b] was not confirmed here. It was later demonstrated by means of a newly developed method using dogs[7] that in large doses this ether as well as optochin had a decidedly damaging effect on the inner ganglionic layer of the retina. Extensive clinical investigation of the drug, therefore, was not carried out. A minor development was the successful use of ethylapocupreine without any unfavorable symptoms in the treatment of pneumococcic infections of the eyes and throat. In this connection the drug is believed to be at least as effective as optochin.

It was believed, on general grounds, and from past experience with hydroxyethylhydrocupreine[2] that the introduction of the hydroxyl group into the ethyl radical of ethylapocupreine would materially decrease its toxicity. The preparation of hydroxyethylapocupreine[8] is not as simple a matter as would at first appear. Ordinary methods, such as alkylation of apocupreine[2,10] in the form of sodium or potassium salt with ethylene chlorohydrin or hydroxyethyl toluenesulfonate yield the desired product but in amounts which are far from satisfactory. Further, the hydroxyethylapocupreine is so contaminated with by-products of uncertain constitution that isolation and purification are tedious and difficult. This result is no doubt due to the presence in the cinchona structure of several reactive groups, other than the phenolic hydroxyl, which is the only point we desire to attack; and to the rather high reactivity of these hydroxyethylating reagents. Various indirect methods such as alkylation of apocupreine N-oxides, and alkylations with toluenesulfonyl esters of glycol monocarboxy esters, either failed completely or gave results so low as to make them impractical.

Equation I

$$\begin{tikzcd}
 & (C_{19}H_{21}ON_2)OCH_2CH_2OCH{=}CH_2 \arrow[d] \\
(C_{19}H_{21}ON_2)OCH_2CH_2OCH_2CH_2Cl \arrow[r, "NaOC_2H_5"] \arrow[ur, "\text{desired}"] \arrow[dr, "\text{obtained}"'] & (C_{19}H_{21}ON_2)OCH_2CH_2OH \\
 & (C_{19}H_{21}ON_2)OCH_2CH_2OCH_2CH_2OC_2H_5
\end{tikzcd}$$

A further attempt consisted in the removal of hydrogen chloride from β-chlorethoxyethylapocupreine with the aim of preparing the vinoxyethyl derivative[2] which should hydrolyze readily to give the desired hydroxyethylapocupreine. However, the only substance which could be isolated under our conditions proved to be the carbitol ether of apocupreine. Equation I shows the desired course of reaction and the one actually obtained.

(4) We have had no desire to ignore the criticisms of the term "apocupreine" made by Henry and Solomon, *Chemistry and Industry*, **54**, 641 (1935). We still believe the name "apoquinine" to be unsuitable for the purified substances isolated from this crude reaction product. In order to avoid further confusion, however, we shall continue to apply the term "apocupreine" only to the purified base of $[\alpha]_D$ $-215°$, until we have the opportunity of going further into the matter of the uniformity of Suszko's base [*Rec. trav. chim.*, **52**, 839 (1933)]. Such opportunity has been denied us up to the present time by the press of more practical matters.

Butoxyethylapocupreine	1:200,000	..	...	...	25/30	15/15	...	...	Negative
Phenoxyethylapocupreine	1:300,000	2/5	20/20	15/15	...	...	...	...	......

This reaction product proved to have moderate bacteriostatic and protective activity against pneumococcus in mice.

Other special methods of preparing hydroxyethylapocupreine, which we hope may be considerably more useful, are being investigated at present.

As shown in Table I, the expected lowering of toxicity in hydroxyethylapocupreine was accomplished. The bacteriostatic activity of the drug as compared with ethylapocupreine also was diminished considerably. However, the protecting effect when tested against pneumococcus infected mice was maintained at a high level. A further finding of great importance to these investigations was the absence of any unfavorable eye effect in tests by the dog method referred to above.[7] The data shown in Table I as well as results of extensive clinical tests will be reported in detail elsewhere by the medical staff in charge of this phase of the work.

A study of various other alkoxy- and aryloxyethylapocupreines is also in progress. Judging by the examples herein reported, this type of alkylation takes place quite readily on reaction of apocupreine in alkaline alcoholic solution with the desired R-oxyethyltoluenesulfonate. The preparations were undertaken with the two-fold aim of determining their usefulness as pneumococcicidal agents and of investigating their possibilities as intermediates in the preparation of the hydroxyethyl ether.

Butoxyethylapocupreine, as shown in Table I, had moderate activity as a bacteriostatic agent against the pneumococcus. It was rather low in toxicity and showed no eye effect in a small number of trials when tested by the method mentioned above.[7] Phenoxyethylapocupreine also had moderately high bacteriostatic activity. It was, however, more toxic than any cinchona derivative thus far examined. Preliminary attempts at partial hydrolysis of these substances to hydroxyethylapocupreine according to the equation

$$(C_{19}H_{21}ON_2)OCH_2CH_2OR' \longrightarrow (C_{19}H_{21}ON_2)OCH_2\text{-}CH_2OH + R'OH$$

resulted in a complete breakdown of the ethers to apocupreine and presumably glycol and the corresponding alcohol or phenol. Other derivatives which may show a greater difference in stability of ether linkages are also being investigated and will be reported as soon as possible.

Experimental

Ethylapocupreine.—This ether was prepared by alkylation with ethyl *p*-toluenesulfonate or ethyl sulfate, $[\alpha]_D$ −198°.[9] Dihydrochloride from alcohol: $[\alpha]_D$ −237°.[10] *Anal.* Calcd. for $C_{21}H_{26}O_2N_2 \cdot 2HCl$: Cl, 17.2. Found: Cl, 16.8.

Hydroxyethylapocupreine.—Apocupreine in the form of its potassium salt was alkylated in alcoholic solution with one equivalent of ethylene chlorohydrin. The reaction product was worked up as dihydrochloride. On recrystallization from absolute alcohol containing a little ether a pure salt with $[\alpha]_D$ −229° was obtained. The base was recovered from this salt in amorphous condition, $[\alpha]_D$ −194°.

Anal. Base. Calcd. for $C_{21}H_{26}O_3N_2$: C, 71.1; H, 7.4. Found: C, 70.8, 70.6; H, 7.1. *Dihydrochloride.* Calcd. for $C_{21}H_{26}O_3N_2 \cdot 2HCl$: Cl, 16.6; N, 6.6. Found: Cl, 16.2; N, 6.3.

The demonstration of two hydroxyl groups in this substance was accomplished as follows. Two grams of the base was acetylated thoroughly by refluxing with 10 cc. of acetyl chloride for three hours; the base was recovered and again treated with acetyl chloride for two hours. The final amorphous base had $[\alpha]_D$ −51° in absolute alcohol.

Anal. Calcd. for $2CH_3CO$ in $C_{25}H_{30}O_5N_2$: CH_3CO, 19.6. Found: CH_3CO, 20.3, 19.0, 19.1.

β-Chloroethoxyethyl-*p*-toluenesulfonate.—One hundred and twenty-four grams (1 mole) of diethyleneglycol chlorohydrin was heated with 143 g. (0.75 mole) of *p*-toluenesulfonyl chloride in an oil-bath at 142° for ten hours. The product was diluted with benzene and the solution was washed with sodium hydroxide solution. After drying,

---

[9] l = 1; c = 1, for all specific rotations herein reported; bases in absolute alcohol, salts in water.

[10] Compare Henry and Solomon, *J. Chem. Soc.*, 1923 (1934).

the benzene was removed under reduced pressure. The yield of oily ester was 130 g. This product proved to be a satisfactory alkylating reagent without any further purification, even though a small sample distilled from a Hickman vacuum still gave low figures when analyzed for sulfur.

Anal. Calcd. for $C_{11}H_{15}O_5SCl$: S, 10.9. Found: S, 9.4, 9.6.

Butoxyethyl-*p*-toluenesulfonate.—This ester was prepared in 74% yield from ethylene glycol monobutyl ether and *p*-toluenesulfonyl chloride in the presence of pyridine by the method which was used in earlier work, for the preparation of ethoxyethyltoluenesulfonate.[2] The product was a heavy oil which could not be distilled readily. It was therefore analyzed after thorough washing and drying.

Anal. Calcd. for $C_{13}H_{20}O_4S$: S, 11.7. Found: S, 11.5.

Phenoxyethyl-*p*-toluenesulfonate.—This reagent was prepared similarly from ethylene glycol monophenyl ether and *p*-toluenesulfonyl chloride by the method described in the earlier paper.[2] The reaction mixture solidified on standing for a short time to a semi-solid crystalline mass which was separated by filtration into a solid and a liquid fraction. The solid material after several recrystallizations from alcohol was obtained in 42.5% yield with melting point 75°.

Anal. Calcd. for $C_{15}H_{16}O_4S$: S, 11.0. Found: S, 10.6.

The rather low yield is due to the fact that *p*-toluenesulfonyl chloride in this case acts, in part, as a chlorinating agent. This was shown by the isolation from the liquid fraction of the reaction product of a 30% yield of β-chloroethyl phenyl ether, m. p. 28°, b. p. 220° (740 mm.). These figures agree with the data given in the literature[11] for this compound.

β-Chloroethoxyethylapocupreine.—Twenty-five grams of apocupreine in form of potassium salt was refluxed in alcoholic solution with 21.7 g. of β-chloroethoxyethyl-*p*-toluenesulfonate for four and one-half hours. The product was worked up in the ordinary way and finally isolated as dihydrochloride; yield 12.5 g. of salt recrystallized from a mixture of alcohol and ether; $[\alpha]_D$ −195°.

Anal. Calcd. for $C_{23}H_{29}O_3N_2Cl{\cdot}2HCl$: Total Cl, 21.7; Cl ion, 14.5. Found: Total Cl, 21.6; Cl ion, 14.4.

Apocupreine Carbitol Ether.—This substance resulted from an attempt to prepare vinoxyethylapocupreine as follows: 4.9 g. (0.01 mole) of β-chloroethoxyethylapocupreine dihydrochloride was added to 30 cc. of absolute alcohol in which 0.75 g. (0.032 mole) of sodium had been dissolved. Sodium chloride was filtered off and the clear solution was heated in a sealed tube for eight hours at 96°. After cooling, a nearly quantitative yield of sodium chloride was filtered off and the alcohol was removed by distillation under reduced pressure. On warming the residue in dilute hydrochloric acid solution for about fifteen minutes, no odor of acetaldehyde could be detected. The product was then worked up as dihydrochloride. Since it could not be obtained crystalline, the salt was purified by several precipitations from alcoholic solution with ether; yield 3.7 g.; $[\alpha]_D$ −183°.

Anal. Calcd. for $C_{25}H_{34}O_4N_2{\cdot}2HCl$: Cl, 14.2; N, 5.6. Found: Cl, 14.3; N, 5.5.

Butoxyethylapocupreine.—Sixty-two grams of apocupreine, alkylated in the usual way with 54.4 g. of butoxyethyl-*p*-toluenesulfonate yielded 38 g. of crude product. Neither the crude base nor the hydrochlorides could be obtained in crystalline condition. The dihydrochloride was therefore partially purified by treating its tepid aqueous solution with nuchar, concentrating to dryness at reduced pressure, and precipitating several times from alcoholic solution with ether $[\alpha]_D$ −198°.

Anal. Calcd. for $C_{25}H_{36}O_3N_2Cl_2$: N, 5.8; Cl, 14.7. Found: N, 5.6; Cl, 14.7.

Phenoxyethylapocupreine.—Sixty-two grams of apocupreine, alkylated with 58.4 g. of phenoxyethyl-*p*-toluenesulfonate, yielded 24 g. of base crystallized from alcohol. A small sample of recrystallized material gave $[\alpha]_D$ −159°, m. p. 178°. The base gave a difficultly soluble dihydrochloride when treated with a slight excess of aqueous hydrochloric acid.

Anal. Base. Calcd. for $C_{27}H_{30}O_3N_2$: N, 6.5. Found: N, 6.4. *Dihydrochloride.* Calcd. for $C_{27}H_{30}O_3N_2{\cdot}2HCl$: Cl, 14.4. Found: Cl, 13.8.

Summary

Ethylapocupreine and several of its derivatives have been prepared. Results of pharmacological tests of importance in chemotherapeutic studies of pneumonia have been presented briefly.

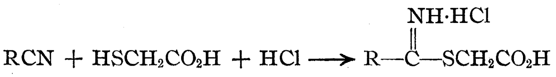
Identification of Nitriles. II. Addition Compounds of Nitriles with Mercaptoacetic Acid

BY F. E. CONDO, E. T. HINKEL, A. FASSERO AND R. L. SHRINER

Nitriles are usually characterized by (a) hydrolysis to the acid, (b) conversion to phenyl alkyl ketones by the action of the Grignard reagent,[1] and (c) formation of the 2,4,6-trihydroxyphenyl alkyl ketone by means of the Hoesch reaction.[2] Each of these methods has some disadvantages, and hence a further search has been made for easily prepared crystalline derivatives.

Nitriles react with alcohols in the presence of hydrogen chloride to form imido ester hydrochlorides. These are good crystalline compounds, but are rather sensitive to moisture, and many of them decompose at or near the same temperature. The analogous thiol compounds obtained by using mercaptans[3] appeared to be more stable. The lower mercaptans are rather disagreeable to use; hence a study was made of other thiol compounds. Thiophenol was found to add to acetonitrile, but the higher nitriles did not readily yield crystalline products.

The best reagent found was mercaptoacetic acid (thioglycolic acid) which readily added to nitriles in the presence of hydrogen chloride, forming α-iminoalkylmercaptoacetic acid hydrochlorides (I),[4] according to the equation



$$\mathrm{RCN + HSCH_2CO_2H + HCl \longrightarrow R{-}\overset{\overset{\displaystyle NH\cdot HCl}{\|}}{C}{-}SCH_2CO_2H}$$

I

By means of this reaction, stable crystalline derivatives could be prepared from both aliphatic and aromatic nitriles in good yields.

The reaction fails in the case of aromatic nitriles containing a group in a position ortho to the cyano group. This result parallels the observations of Pinner,[5] who noted that ortho substituted nitriles failed to form imino ester hydrochlorides when treated with an alcohol and hydrogen chloride.

Since these thioimino ester hydrochlorides are salts, they decompose upon attempting to determine their melting points. It was found, however, that the decomposition temperatures were sharp and reproducible, provided the determinations were made under the same conditions. Table I lists the derivatives of common nitriles, and shows the decomposition points of the compounds when determined by (a) placing the melting point sample in the bath at 20°, and (b) placing the sample in the bath 5° below the decomposition temperature observed by the first procedure.

These thioimino ester hydrochlorides also may be characterized by means of neutral equivalents. Electrometric titrations were carried out, using the glass electrode in order to determine the proper indicator to show the end-point. The curves obtained did not show very sharp breaks corresponding to one or two equivalents of alkali. This appeared to be due to the fact that an appreciable amount of time was necessary to obtain the readings, and so partial hydrolysis or reversal of the addition reaction took place. Hence, titrations were carried out as rapidly as possible, using phenolphthalein, thymol blue and thymolphthalein as indicators. In general, it was found that thymol blue gave the sharpest end-point, and neutral equivalents closely approximating the calculated values for reaction with two equivalents of alkali could be obtained. The data are shown in Table I.

Since many of these ester hydrochlorides decompose at nearly the same temperatures, it is necessary to consider also the boiling point of the nitrile and the neutral equivalent of the derivative in order to have sufficient data definitely to characterize a nitrile.

Previous investigators have shown that thioamides[3b,6] may be alkylated to produce thioimino ester hydrochlorides. In order to establish the

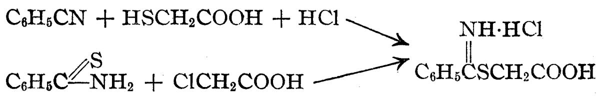
structure of the compounds prepared in the present work, α-iminobenzylmercaptoacetic acid hydrochloride (II), obtained by the addition of mercaptoacetic acid and hydrogen chloride to benzonitrile, was shown to be identical with that obtained from thiobenzamide and chloroacetic acid.



$$C_6H_5CN + HSCH_2COOH + HCl \rightarrow C_6H_5\overset{\overset{NH\cdot HCl}{\|}}{C}SCH_2COOH \leftarrow C_6H_5C{\overset{S}{\leqslant}}NH_2 + ClCH_2COOH$$

II

Experimental Part

Nitriles.—The aliphatic nitriles were prepared by the action of sodium cyanide on the alkyl halides.[7] The aryl nitriles were made by the Sandmeyer reaction.[8]

α-Iminoalkylmercaptoacetic Acid Hydrochlorides.—Three methods were used in the preparation of the addition compounds. (A) The nitrile and a slight excess of mercaptoacetic acid were mixed together, cooled in an ice-bath and saturated with hydrogen chloride. The tube was stoppered and kept in the ice-bath until crystallization was complete. (B) The nitrile and mercaptoacetic acid were dissolved in an equal volume of absolute ether, the solution cooled in an ice-bath and saturated with dry hydrogen chloride. The tube was stoppered and kept cold until crystallization was complete. (C) The mixture of nitrile (2 g.) and mercaptoacetic acid (4 g.) was treated with 50 cc. of absolute ether, which had been previously saturated with dry hydrogen chloride at 5–10°. The flask was stoppered and placed in a refrigerator until crystallization was complete.

In each case the crystals were removed by filtration and thoroughly washed with absolute ether. They were placed in a vacuum desiccator containing concentrated sulfuric acid, potassium hydroxide and paraffin wax in order to remove the last traces of hydrogen chloride and ether. Procedures (A) and (B) above gave the best yields, 80–90%. The yield depends on the length of time the mixture is allowed to stand. The aliphatic nitriles reacted more rapidly than those of the aromatic series. Crystallization of the addition compound derived from an aliphatic nitrile often started within fifteen minutes, and was usually complete in two to three hours, whereas with the aromatic nitriles the process sometimes required twelve to sixteen hours by procedure (A) or (B) and two to three days when procedure (C) was used. The yields by procedure (C) were lower than by (A) or (B), but the product was of higher purity, and was not sticky and hygroscopic as was sometimes the case when procedure (A) was used. For identification work, procedures (B) and (C) are preferred, and may be used with 0.2 to 0.5 g. of nitrile and proportional amounts of the other reagents, provided care is taken to exclude moisture.

Neutral Equivalents.—An accurately weighed sample was dissolved in 100 cc. of carbon dioxide-free distilled water and *rapidly* titrated with standard, carbonate-free, sodium hydroxide solution, using thymol blue (*p*H change, 8.0–9.6) as the indicator. In the case of derivatives of nitriles containing more than five carbon atoms, it was necessary to dissolve them in 50% alcohol. The end-point was the olive-green color intermediate between yellow and blue. The data are given in Table I.

Analyses.—Although the chlorine in these hydrochlorides is ionic, it was necessary to decompose the compound with sodium peroxide in a Parr bomb, and then determine the chlorine. Direct precipitation of silver chloride by addition of silver nitrate to the thioimido ester hydrochlorides gave erroneous results. In two cases as shown in Table I, namely, the compounds derived from *m*- and *p*-tolunitrile, the chlorine analyses are high. The preparation of these compounds has been repeated many times and various purification processes have been tried. Apparently a small amount of the chlorimide, formed by addition of hydrogen chloride to the nitrile, is occluded by the product, and this results in the high values for chlorine.

α-Iminobenzylmercaptoacetic Acid Hydrochloride.—Equivalent amounts of chloroacetic acid and thiobenzamide were dissolved in absolute ether and the solution allowed to stand for two weeks at room temperature. The crystals which had separated were removed by filtration and triturated with dry acetone. After thorough washing with dry acetone and absolute ether, the crystals decomposed at 124–125°.

[8] *Ibid.*, p. 500.

Anal. Calcd. for $C_9H_{10}O_2NSCl$: Cl, 15.32; neut. equiv., 115.7. Found: Cl, 15.39; neut. equiv., 115.9.

No depression in the decomposition point occurred when this product was mixed with the compound obtained by the addition of mercaptoacetic acid to benzonitrile in the presence of hydrogen chloride.

Summary

A series of α-iminoalkylmercaptoacetic acid hydrochlorides have been prepared by the addition of mercaptoacetic acid (thioglycolic acid) to nitriles in the presence of hydrogen chloride. These addition products are stable, possess characteristic decomposition points, and may be titrated as dibasic acids by the use of thymol blue as the indicator.

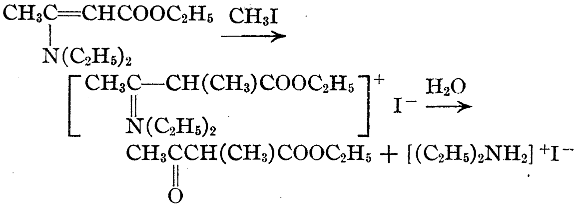
The Alkylation of Beta-Aminocrotonic Esters

BY WALTER M. LAUER AND GEORGE W. LONES

An important study of the alkylation of ethyl β-diethylaminocrotonate with methyl iodide has led Robinson[1] to formulate the reaction as follows

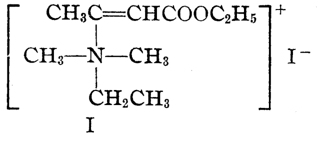


$$CH_3\underset{\displaystyle N(C_2H_5)_2}{\underset{|}{C}}{=}CHCOOC_2H_5 \xrightarrow{CH_3I} \left[CH_3\underset{\displaystyle N(C_2H_5)_2}{\underset{\|}{C}}{-}CH(CH_3)COOC_2H_5\right]^+ I^- \xrightarrow{H_2O} CH_3\underset{\displaystyle O}{\underset{\|}{C}}CH(CH_3)COOC_2H_5 + [(C_2H_5)_2NH_2]^+I^-$$

since diethylammonium iodide and ethyl α-methylacetoacetate were obtained after the reaction mixture was treated with water. An alternative view that the methyl group first attached itself to the nitrogen and subsequently rearranged from the nitrogen to carbon atom is still possible provided the methyl group is assigned a greater migratory aptitude than the ethyl group.

The present work was carried out in order to distinguish between these two mechanisms. The results definitely eliminate the second view and bring additional support to the formulation of Robinson.

Alkylation of ethyl β-dimethylaminocrotonate with ethyl iodide formed a product which on hydrolysis yielded ethyl α-*ethyl*acetoacetate. Now, if the initial step in the process involves the formation of a compound of structure (I)



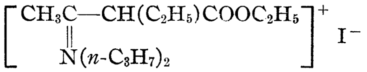
$$\left[\begin{array}{c} CH_3C{=}CHCOOC_2H_5 \\ | \\ CH_3{-}N{-}CH_3 \\ | \\ CH_2CH_3 \end{array}\right]^+ I^-$$

I

and we assign a greater migratory aptitude to the methyl group than to the ethyl group in order to account for the fact that alkylation of ethyl β-diethylaminocrotonate with methyl iodide yields ethyl α-methylacetoacetate, then the expected rearrangement product of I upon hydrolysis would give ethyl α-*methyl*acetoacetate. Instead ethyl α-*ethyl*acetoacetate was obtained.

Likewise, ethyl β-methylaminocrotonate and ethyl β-di-*n*-propylaminocrotonate upon treatment with ethyl iodide followed by hydrolysis yielded ethyl α-ethylacetoacetate. Thus, the substituent which is introduced in the α-position is determined by the alkyl halide used and is independent of the alkyl group or groups already joined to the nitrogen atom.

In the case of ethyl β-di-*n*-propylaminocrotonate it was possible to isolate the ethyl iodide addition product (II)



$$\left[CH_3\underset{\displaystyle N(n\text{-}C_3H_7)_2}{\underset{\|}{C}}{-}CH(C_2H_5)COOC_2H_5\right]^+ I^-$$

II

which upon hydrolysis gave ethyl α-ethylacetoacetate and di-*n*-propylammonium iodide.

Experimental

Ethyl β-aminocrotonate was prepared according to the method of Michaelis,[2] and alkylated with ethyl iodide following the procedure of Collie.[3] After refluxing for twenty hours, a solid which was identified by means of a Volhard titration as ammonium iodide had separated out even though attempts were made to exclude moisture. The reaction mixture, after filtration, was then allowed to stand overnight with 5% sodium hydroxide. After acidification with dilute sulfuric acid, hydrolysis was completed by refluxing. Methyl propyl ketone (identified as the 2,4-dinitrophenylhydrazone, m. p. 141–142°) was obtained upon distillation.

(2) Michaelis, *Ann.*, **366**, 337 (1909).

(3) Collie, *ibid.*, **226**, 316 (1884).

Ethyl β-methylaminocrotonate, prepared according to the directions of Kuckert,[4] was heated (100° for twelve hours) with ethyl iodide in a sealed tube. A crystalline solid appeared in the reaction mixture in small amounts. Part of this solid proved to be methylammonium iodide (Volhard titration and preparation of picrate, m. p. 208°). The main portion of the reaction mixture was refluxed with water for fifteen minutes and then allowed to stand overnight. Extraction with ether, after acidification, gave ethyl α-ethylacetoacetate (b. p. 195–198°), which was hydrolyzed to methyl propyl ketone (identified as the 2,4-dinitrophenylhydrazone).

Ethyl β-dimethylaminocrotonate (b. p. 120–121° at 10–11 mm.) was prepared in 66% yield by the action of dimethylamine on freshly distilled ethyl acetoacetate and *alkylated with ethyl iodide* in the following manner.

Ethyl β-dimethylaminocrotonate (15 g.) and ethyl iodide (50 g.) were heated on the steam-bath for forty-five hours. As the reaction proceeded a dark red oily supernatant layer formed. After removal of the excess ethyl iodide by heating on the steam-bath, water (50 ml.) was added and heating was continued for fifteen minutes. The reaction mixture was then cooled, acidified with dilute hydrochloric acid and extracted with ether. Distillation yielded ethyl α-ethylacetoacetate (10.3 g.); b. p. 82–84° at 14 mm.

The ethyl α-ethylacetoacetate was added to 75 ml. to aqueous sodium hydroxide (5%) and allowed to stand for three hours. Dilute sulfuric acid (1:2; 10 ml.) was then added and the mixture was refluxed. A 10-ml. distillate was collected. The upper layer (6.8 ml.), which consisted of methyl propyl ketone, was dried over sodium sulfate and redistilled (b. p. 99–100°). The methyl propyl ketone was characterized by means of its 2,4-dinitrophenylhydrazone (m. p. 140°).

Ethyl β-diethylaminocrotonate prepared in accordance with the directions of Kuckert[4] was alkylated with ethyl iodide. Ethyl α-ethylacetoacetate was obtained in agreement with the results reported by Robinson.[1]

Ethyl β-Di-*n*-propylaminocrotonate.—Di-*n*-propylamine (39 g.) and freshly distilled ethyl acetoacetate (50 g.) were mixed and allowed to stand at room temperature for six weeks. The mixture was then vacuum distilled, collecting the fraction (48 g.) boiling between 149 and 151° at 9 mm.

Anal. Calcd. for $C_{12}H_{23}O_2N$: C, 67.55; H, 10.87. Found: C, 67.65; H, 10.87.

Ethyl β-di-*n*-propylaminocrotonate (25 g.) and ethyl iodide (50 g.) were refluxed on the steam-bath for twenty-four hours. After cooling, the reaction mixture solidified. The solid mass was partially freed of oil by pressing on a porous plate and placing in a vacuum desiccator for one-half hour. The weight of the impure solid was 30 g. One gram of this solid was crystallized by dissolving in absolute alcohol (5 ml.) and adding anhydrous ether until a precipitate just began to form. Cooling in an ice–salt bath caused the separation of fine white crystals (0.56 g.; m. p. 114–116°), which rapidly became yellow on standing in the air.

Anal. Calcd. for $C_{14}H_{28}O_2NI$: C, 45.5; H, 7.6; I, 34.3. Found: C, 45.2; H, 8.0; I, 33.9.

The main portion of the impure solid (25 g.) was then purified in the above described manner and 18.5 g. of crystalline product was obtained.

The salt was then added to water (50 ml.) and boiled for one-half hour. After cooling, acidification with dilute hydrochloric acid, extraction with ether and drying over anhydrous calcium sulfate, a 70% yield of ethyl α-ethylacetoacetate (5.5 g.) was obtained. This ester was again converted to methyl propyl ketone which was identified as the 2,4-dinitrophenylhydrazone; m. p. 141–142°.

The aqueous acid solution from which the ethyl α-ethylacetoacetate had been extracted was concentrated to about one-fourth of its original volume. After cooling in an ice-bath, the solution was made strongly alkaline and extracted with ether. The ether extract, dried over solid potassium hydroxide and distilled, yielded 4 ml. of di-*n*-propylamine (b. p. 108°). The amine was identified as dipropylamine di-propyldithiocarbamate (m. p. 116–117°).[5]

Summary

Several substituted β-aminocrotonic esters were alkylated with ethyl iodide. The results obtained bring additional support for Robinson's views concerning the mechanism of this process.

Aromatization of Cellulose by Heat

BY R. C. SMITH AND H. C. HOWARD

Graphite is one of the ultimate products of thermal decomposition of all organic substances and thermodynamically can logically be considered the limiting member of the series of aromatic hydrocarbons.[1] Little information is available as to the temperature at which this C_6 ring structure begins to appear when a non-aromatic substance, such as cellulose, is subjected to increasingly severe thermal treatment although the subject is of great theoretical interest in connection with coalification and carbonization processes. Fischer and Schrader[2] regarded the fact that the bituminous coals yield significant amounts of aromatic acids on oxidation as evidence for the point of view that such coals are derived from lignin, since in parallel oxidation experiments on lignin and cellulose, aromatic acids were recovered from the former and not from the latter. Bone[3] confirmed the results of the German workers and reported that in quantitative oxidations with alkaline permanganate, 39–46% of the carbon of three British bituminous coals could be accounted for as benzene carboxylic acids; with cellulose 96.8% of the carbon was found in the simple acids carbonic, oxalic and acetic.[4] Obviously the recovery of aromatic acids by oxidation of coal does not prove that coal is derived exclusively from lignin if it is found that by heating cellulose to temperatures which may conceivably have been reached during coalification, substances are formed which yield aromatic compounds on oxidation.

In the present investigation samples of pure cotton cellulose were heated in a nitrogen atmosphere at temperatures ranging from 190 to 400°. The ultimate composition of the residues from the pyrolyses, with the theoretical composition of cellulose for comparison, are shown in Table I. The high carbon content of the product obtained at 250°, as compared with that at 190°, is very striking. A strong exothermic reaction was observed in this temperature range. The residues from pyrolysis at 190° were light brown in color and fibrous; all the others were black friable chars, but still retained some fiber structure. The gaseous products from a 250° pyrolysis, after correction for nitrogen, consisted of 74.6% carbon dioxide, 11.6% hydrogen, 12.1% carbon monoxide and 1.6% hydrocarbons.

TABLE I

ULTIMATE COMPOSITIONS

	C	H	O (diff.)	Ash[b]
Cellulose, %	44.44	6.17	49.39	..
190° Char[a]	45.34	6.21	47.81	0.64
250° Char	71.54	4.79	22.48	1.19
400° Char	85.58	4.51	9.42	0.49

[a] All chars dried at 100° in vacuum. [b] From corrosion of the bomb.

The residues from the pyrolyses were completely converted to water soluble acidic oxidation products by exhaustive oxidation with alkaline permanganate. The amounts of carbonic, oxalic and volatile acids, the latter calculated as acetic, formed were determined and the percentage distribution of the carbon among the various oxidation products calculated. The results are shown in Table II and data on the oxidation of the original cellulose are included for comparison. The column designated "aromatic carbon" was obtained by difference and gives the percentage of the total carbon in the soluble products unaccounted for by the simple acids, carbonic, acetic, and oxalic. Even in the case of the 250° char, significant amounts of the carbon are not so accounted for. The essentially aromatic character of the carbon assigned to aromatic acids was established by decarboxylation of the mixed acids. Benzene and diphenyl were the only condensable hydrocarbons recovered. With the 250° char the carbon appearing as aromatic acids is less than that found in similar oxidation experiments with a Pittsburgh seam bituminous coal for which an average figure of 30% has been obtained.[5] In the case of the 300° char, however, the aromatic carbon is of the same order as that from the Pittsburgh coal. The 2% "aromatic carbon" reported in the oxidation products of the original cellulose indicates the probable experi-

TABLE II

DISTRIBUTION OF CARBON IN OXIDATION PRODUCTS AND RESULTS OF DECARBOXYLATION

			Carbon					Steam volatile hydrocarbons	
Chars Temp., °C.	Chars Yield, %	$KMnO_4$ g./g. char	Total, g.	Carbonic, %	Oxalic %	Acetic %	Aromatic %	Yield, g.	% to 90°
Original cellulose[a]		6.7	46.9	63.9	32.3	1.7	2.1	..	..
190	89	8.4	43.7	93.7	1.1	0.5	4.7	Trace	..
250[b]	50	12.0	38.6	73.8	11.1	1.5	13.7	1.38	48.9
275	45	11.1	36.2	59.0	14.1	1.8	25.1	2.25	66.8
300	44	10.8	35.4	51.6	18.5	1.6	28.4	2.50	67.5
350	43	10.5	32.7	52.0	12.0	1.8	34.0	1.79	59.3
400[c]	38	10.8	34.3	53.3	12.9	1.0	32.8	4.95[d]	82[e]

[a] 75 g. used, computed on the basis of 100 g. [b] Average of two experiments. [c] Average of three experiments. [d] Three samples decarboxylated together, yield computed for 38 g. of char. [e] To 79.5°.

mental error of the method. The higher recovery of total carbon for cellulose as well as the products of pyrolysis, than calculated, is due to carbonate in the alkali and absorption of carbon dioxide from the air.

The actual recovery of steam volatile hydrocarbons by decarboxylation of the acids from oxidation of the 400° char is somewhat higher than that obtained by decarboxylation of acids from a Pittsburgh seam coal[6] and corresponds to 13 g. per 100 g. of cellulose char. This is equivalent to 5 g. per 100 g. of original cellulose linters.

Densities, d^{25}_4, and refractive indices, $n^{20}_{\rm D}$ of the hydrocarbons recovered from the 250, 275, 300, 350° chars were 0.92, 0.90, 0.91, 0.89, and 1.529, 1.538, 1.522, 1.526, respectively (benzene, d^{25}_4 0.873; $n^{20}_{\rm D}$ 1.501). Fractionation of the hydrocarbons from the 400° char yielded 82%, boiling 78–79.5°, $n^{20}_{\rm D}$ 1.500; 5% crude diphenyl and 13% of tarry residue. Densities and refractive indices prove the hydrocarbons to be aromatic and boiling points indicate a large proportion of benzene.

It is evident that during the thermal decomposition of cellulose, C_6 ring structures are formed rapidly above 200°. While there is wide disagreement as to the temperatures reached in the coalification process,[7] 200–300° appears possible, especially in view of the fact that strong exothermic reactions, such as cellulose exhibits at 150–200°, may have taken place. Hence it follows that the establishment of the presence of aromatic structures in bituminous coals does not necessarily exclude cellulose as a progenitor of such coals.

Experimental

Thermal Decomposition of the Cellulose.—One hundred-gram samples of cellulose linters[8] were packed into a one-liter bomb and flushed with nitrogen. The bomb was electrically heated at a rate of 2° per minute. Temperatures were measured by two thermocouples, one in the center of the bomb and the other between the furnace and the outer wall of the bomb; a temperature gradient of approximately 50° was found, and the temperatures reported correspond to the minimum values observed.

Oxidation and Determination of Carbon Balances.—The dried residue from pyrolysis of 100 g. of cellulose, after vacuum drying at 100°, was suspended in about 2500 cc. of potassium hydroxide solution (140 g. per liter of water) in an iron vessel provided with agitator, cover and reflux condenser. Potassium permanganate was added in small portions over several hours until an excess was present. The vessel was then closed and kept at the boiling point for the period required for discharge of the permanganate, usually several days. The manganese dioxide formed in the reaction was filtered off by suction and thoroughly washed. The combined filtrate and washings, golden yellow in color, were concentrated to less than 2000 cc., cooled, transferred to a 2000-cc. volumetric flask, made up to volume, thoroughly mixed and aliquots withdrawn for determination of the distribution of the carbon. Total carbon was determined in a 5-cc. aliquot by wet oxidation with a chromic–sulfuric acid mixture; carbonic acid in a 10-cc. aliquot by evolution with dilute hydrochloric acid. To determine volatile acids a large aliquot, 100 cc., was diluted to 500 cc., acidified with dilute sulfuric acid and distilled to a small volume. The distillate was titrated with 0.1 *N* alkali using phenolphthalein. To determine oxalic acid a 25-cc. aliquot was made acid with dilute hydrochloric acid, alkaline with potassium hydroxide and finally acid with acetic acid. Calcium acetate was added in excess and the precipitated calcium oxalate, after digestion, was filtered off, washed thoroughly, dissolved in dilute sulfuric acid and the oxalic acid titrated with 0.1 *N* permanganate. Contamination of the calcium oxalate precipitate with the calcium salts of benzene carboxylic acids could have little effect on the oxalate determinations since work on known

[8] Obtained through the courtesy of Dr. Charles Carpenter Carnegie Institute of Technology.

mixtures of oxalic and benzene carboxylic acids had shown that the former can be titrated quantitatively in the presence of the latter.

Decarboxylation.—Previous work with the oxidation products of coal had indicated the difficulty of recovering in good yields the individual pure aromatic acids present, so recourse was had to decarboxylation as a method of establishing aromatic character.[6] In some cases the solutions remaining, after the aliquots had been removed for analytical work, were concentrated until salts began to separate and placed in the middle compartment of a three-compartment cell, subjected to electrolysis, and the free acids recovered by vacuum evaporation of the anode liquors on the water-bath. The required amount of alkali was added and the decarboxylation carried out as previously described.[9] In other cases the alkali salts were evaporated to a small volume and decarboxylated directly.

Summary

The presence of C_6 ring structures in products obtained by pyrolyzing cellulose at temperatures up to 400° has been established by oxidation followed by decarboxylation and recovery of benzene and diphenyl. The yield of aromatic hydrocarbons, based on the pyrolyzed cellulose, is of the same order as that obtained by similar attack on a Pittsburgh seam bituminous coal. It has been pointed out that the presence of C_6 ring structure in bituminous coal does not exclude the possibility of such coals having been derived from cellulose.

Oxidation of a Pittsburgh Seam Bituminous Coal and Low Temperature Coke by Alkaline Permanganate

BY B. JUETTNER, R. C. SMITH AND H. C. HOWARD

The present generally accepted picture of the structure of bituminous coal as a system containing condensed rings is based largely on evidence from oxidation experiments.[1] Certain bituminous coals have been reported to yield as much as 46% of their carbon as benzene carboxylic acids on oxidation with alkaline permanganate.[2] Obviously such high yields of one type of compound are of great theoretical interest, and are of possible technical importance.

A study has been made of the nature of the products obtained by exhaustive alkaline permanganate oxidation of a Pittsburgh seam coal[3] and a 500° coke prepared from this coal. It has been found that 90–95% of the carbon of these materials can be recovered after oxidation as a solution of water soluble, non-colloidal acidic products, which vary in color from pale yellow to deep reddish-brown, depending upon the amount of permanganate employed and the oxidation period. Typical data showing the distribution of the carbon[4] among the chief oxidation products are given in Table I. The assumption that the carbon not found as carbonic, oxalic and acetic acids is in aromatic acids, is based upon the fact that the only condensable hydrocarbons recovered by decarboxylation were aromatic and consisted chiefly of benzene and diphenyl. On this basis it is evident that a significant fraction of the carbon in the Pittsburgh coal is in cyclic structures and that coking increases the proportion of cyclic carbon present. However, we have found no evidence that would justify a statement that any considerable fraction of the acids produced by the action of alkaline permanganate on this coal consists of benzene carboxylic acids.

TABLE I

CARBON DISTRIBUTION IN POTASSIUM SALTS

Soc.* (London), **A110**, 537–542 (1926); **A127**, 480–510 (1930); **A148**, 492–522 (1935). Recent hydrogenation work by Biggs, THIS JOURNAL, **58**, 1020 (1936), constitutes even more convincing evidence.

[2] Bone, Parsons, Sapiro and Groocock, *Proc. Roy. Soc.* (London), **A148**, 521 (1935).

[3] Described in detail in Bur. Mines Tech. Paper 525, 1932.

[4] The general procedure described in ref. 2 has been used. These authors do not reveal the method employed to determine the carbon reported as oxalic and benzene carboxylic acids in their carbon balances.

Recovery and Identification of Acids.—The recovery in good yields of the free acids from their potassium salts presented great difficulties, since all are readily soluble in water and have unfavorable distribution coefficients in solvent systems such as water and ether. The procedure described by Bone, Horton and Ward,[5] the addition of the theoretical amount of sulfuric acid, followed by evaporation to dryness and extraction of the dried residue with ether and acetone, gave poor recoveries and, indeed, on theoretical grounds it is difficult to see why complete metathesis to free acids and potassium sulfate should take place. Two methods have been developed which give satisfactory recoveries of the free acids. They are: (1) acidification of the solution of potassium salts with sulfuric acid followed by extraction of the solution with ether in a continuous extractor of the type described by Kester,[6] and (2) decomposition of the salts by electrolysis in a three-compartment cell. The recoveries of acids obtained by the two methods are illustrated in Table II. The data show that the recovery of the higher molecular weight acids is more complete by electrolysis than by extraction. In confirmation of this it has been observed that while the central compartment in the electrolytic cell ultimately becomes colorless, even very prolonged extraction fails to remove all the color from the aqueous layer in the extraction process. Secondary oxidation of the aromatic acids at the anode during electrolysis appears to be inconsiderable. Because of the high recoveries and the simplicity and convenience of the method, the separation by electrolysis has been used almost exclusively.

TABLE II

COMPARISON OF METHODS OF RECOVERY OF ACIDS

Material	K salts	Acids recov. by elect.	Acids recov. by 78-hr. ether extn.
Carbon as:			
Total, g.	100	45.5	40.7
Carbonic acid, g.	48.5		
Acetic acid, g.	2.3		
Oxalic acid, g.	15.9	13.7 86%	15.6 98%
Arom. acids (diff.), g.	33.3	31.8 96%	25.1 72%

The anode liquors containing the free acids were concentrated in vacuum on the water-bath, but it was found necessary to conduct the final drying operation at not over 50° to prevent discoloration. The acids so recovered are yellow to light buff in color, almost free from inorganic impurities, and completely soluble in water, alcohol and ethyl ether. Since they have all migrated through parchment, the color cannot be due to colloidal or high molecular weight impurities. They contain 30–40% oxalic acid; the carbonic and volatile organic acids are, of course, not recovered. The average yield from Edenborn coal has been 88 g. of these mixed acids per 100 g. of coal; the yield from the coke is higher, 98 g. per 100 g.

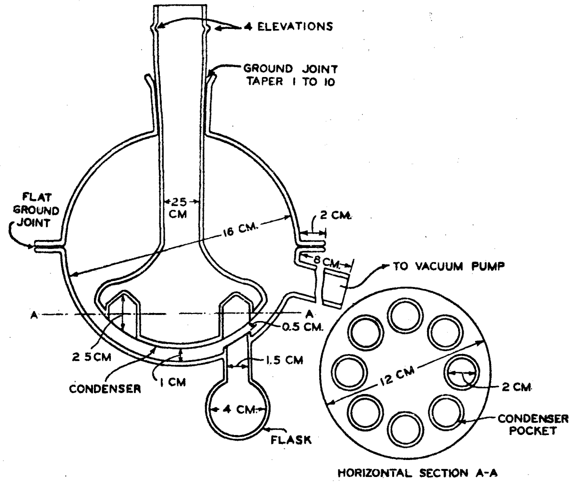

Fig. 1.

The first attempt to isolate pure compounds from the mixed acids was by esterification with diazomethane followed by fractionation in a high vacuum still, Fig. 1. Typical data from such a fractionation are shown in Table III. A significant part of these esters was not distillable even at 300° in a vacuum of 1 micron. From the low boiling fractions considerable amounts of crystalline dimethyl oxalate separated; higher fractions ranged from limpid oils to semi-solid resinous products, and in no case was any pure crystalline material other than dimethyl oxalate recovered. The non-distillable residue was a reddish-brown, brittle resin.

The next attempts at separation were by means of the formation of characteristic salts. By saturation of an aqueous solution of the mixed salts with ammonia at low temperature a copious crystalline precipitate resulted. Mellitic acid precipitates almost quantitatively under these conditions, as a hydrated ammonium mellitate, and a considerable amount of the oxalic acid also separates as the monohydrated ammonium salt. The free acids from the insoluble ammonium salts

were recovered by electrolysis, esterified and distilled. No difficulty was encountered in isolating the pure hexamethyl ester of mellitic acid. The yield of pure ester from the coal was 0.6 g. per 100 g. of coal; from the coke, 0.8 g.

The soluble ammonium salts in the filtrate from the ammonia precipitation were converted to barium salts by excess barium hydroxide and these fractionated into water insoluble and soluble, and the water insoluble barium salts were separated again into two fractions, insoluble and soluble in glacial acetic acid. In the first two experiments separation into an insoluble calcium salt fraction was also made, but this proved of little value and was omitted in later work. The amounts of acids recovered from the different salt fractions, yields of total esters, and pure esters isolated are shown in Table IV. Work with an authentic sample of the methyl ester of benzene pentacarboxylic acid had shown that this ester distilled rapidly in our still at 220° at 1 micron pressure. It had also been observed in the earlier experiments with the esters of acids from coal that temperatures above 220° resulted in little increase in condensate, but considerable thermal decomposition. Accordingly in all later fractionations the maximum temperature used was 220°.

The relatively small proportion of the methyl esters from the coal acids distilling in the range in which authentic samples of the esters of the higher benzene carboxylic acids were known to distil rapidly, led to the conclusion that oxidation had been incomplete. Hence a sample of acids prepared by the oxidation of coke was re-oxidized with further amounts of alkaline permanganate for a two-week period. The permanganate used in the first oxidation was 8.9 g. per g. of coke; in the reoxidation an additional 1.4 g. was necessary. The distribution of the carbon before and after this reoxidation is shown in Table V. It is evident that under these conditions the aromatic acids are attacked. As a result of the further oxidation, the color of the acids in aqueous solution changed from reddish-brown to golden-yellow. There is also definite indication of oxidation of oxalic acid.[7]

Recovery of the acids, fractionation of the acids by salt precipitation and fractionation of

[a] The reoxidized acids recovered by electrolysis weighed 55.5 g. and contained 12.6 g. oxalic and 42.9 g. aromatic acids.

the esters were carried out substantially as described for the products from coal. The data are collected in Table VI. As was found with the coal, a large fraction of these esters was not distillable at 220° and 1 micron pressure, and the same type of reddish-brown, resinous residue remained in the still. However, significantly greater amounts of hexamethyl mellitate and of the ester of the pentacarboxylic acid were isolated.

[a] From the condenser. [b] Almost pure oxalate. [c] Mixed crystals; no individuals isolated. [d] Prehnitate from this fraction. [e] Pentacarboxylate from this fraction; 1.66 g. per 100 g. coke. [f] Mellitate from this fraction; 1.78 g. per 100 g. coke.

Because of the small amounts of definite compounds isolated by the methods described, we were led to the use of a more general means of characterizing these acids. It has been pointed out[8] that decarboxylation to the nuclear hydrocarbons constitutes such a tool, and that method was applied. The average yield of steam volatile hydrocarbons recovered by decarboxylation of the acids from coal was 7.7 g. per 100 g. coal, and from the coke acids, 11 g. The higher yield of aromatic hydrocarbons from the coke is in accord with the previously expressed view that carbonization results in increased condensation to cyclic structures. Fractionation of the hydrocarbons obtained by decarboxylation showed 50–60% to be benzene, identified by boiling point and refractive index; 10–15% boiled between 82 and 150° and was not identified; and from the high boiling residue diphenyl was recovered, in some cases amounting to 20% of the total hydrocarbons. Some diphenyl was always formed in decarboxylation experiments with known benzene carboxylic acids, but usually in small amounts, less than 5% of the total steam volatile hydrocarbons.

There appears little doubt that a significant fraction, 50–60%, of the non-volatile acids formed by alkaline permanganate oxidation of this coal and a 500° coke is aromatic. We have, however, found no evidence that any considerable amount of simple benzenoid acids is present. The persistent color and the failure of a large part of the esters to distil under conditions where the esters of authentic samples of benzene carboxylic acids evaporate rapidly, indicate that we are dealing with acids of more complex structure. Although all attempts to isolate them by specific reactions have failed, it seems probable that ketonic aromatic acids are present. Diphenyl was always recovered from the decarboxylation experiments on the acids from coal in significantly greater amounts than obtained in the work with known benzene carboxylic acids. Failure to isolate hydrocarbons more complex than diphenyl, by heating the acids with alkali to elevated temperatures, is not necessarily decisive evidence for the absence of acids with condensed aromatic nuclei, since the drastic alkali treatment may have resulted in scission of the nuclei of ketonic acids. Bamberger and Hooker[9] showed that a diphenyl carboxylic acid, and ultimately diphenyl, resulted

from the fusion of a fluorenone carboxylic acid with alkali.[10]

Experimental

Oxidation.—Five hundred grams of the 200 mesh coal or coke[11] was suspended in about 35 liters of approximately 0.4 *N* potassium hydroxide solution, contained in an iron kettle which was provided with good mechanical agitation and heated by a large ring burner. The solid permanganate was added in small amounts over a period of several hours and such an excess used that about twelve hours of boiling was required for the discharge of the color. Under these conditions the coal consumed significantly greater amounts of permanganate than the coke; 11 g. per g. was used for the former and 8.9 for the latter. The ratio of grams of alkali per gram of coal or coke was 1.6.

The precipitated manganese dioxide was filtered off by suction on a 32-cm. Büchner funnel, thoroughly pressed, then returned to the kettle and agitated with a few liters of water. This operation was repeated three times. The combined filtrate and washings, approximately 50 liters, were concentrated until salts began to separate, diluted and then transferred to a volumetric flask of suitable size, 6500 cc. Aliquot portions of this solution were used for carbon balances and for the preparation of the free acids.

Carbon Balances.—Total carbon was determined by oxidation of a suitable sized aliquot, with chromic and sulfuric acids; carbonate carbon, by evolution with hydrochloric acid; volatile acids, by steam distillation, after acidification with dilute sulfuric acid, followed by titration of the distillate with standard alkali using phenolphthalein. Volatile acids were calculated as acetic. Oxalate carbon was determined by precipitation of the calcium salt with calcium acetate from an aliquot which was first acidified with hydrochloric acid, then made alkaline with potassium hydroxide, and finally acidified with glacial acetic acid. The calcium salt so obtained was never pure white in color and, on solution in dilute sulfuric acid and titration with standard permanganate, a much less stable end-point was obtained than with pure calcium oxalate. For this reason it is possible that the figures for oxalate carbon are high. The error is not thought to be appreciable. Experiments with mixtures of oxalic and authentic samples of benzene carboxylic acids showed that the former can be determined quantitatively, in the presence of the latter, by titration in acid solution with standard permanganate.

The difference between total carbon by oxidation with chromic and sulfuric acids, and the sum of the carbon found as carbonate, acetate and oxalate is reported as aromatic.

Recovery of Free Acids.—A suitable amount, 1000 cc., of the solution of potassium salts was placed in the middle compartment of a three compartment cell, such as is used for the purification of colloidal material by electrodialysis,[12] and electrolyzed between an anodic diaphragm of parchment and a cathodic diaphragm of cellophane, using a platinum gauze anode and a copper cathode, until the salts were completely decomposed. The acids were recovered by evaporation of the anode solutions in vacuum on the water-bath and the cathodic solutions, containing the potassium hydroxide formed by decomposition of the salts, were discarded. Anode and cathode compartments were emptied approximately twice every twenty-four hours and fresh distilled water added. At the close of the electrolysis the solution in the middle compartment was colorless and evaporation to dryness showed no significant amounts of inorganic or organic substances. In some cases the cathode liquors were pale yellow, indicating migration or diffusion of organic substances toward the negative electrode. The data of Table II show that the recovery of aromatic carbon is satisfactory.

The acids so recovered were relatively free from inorganic impurities; the residue on ignition was less than 1%. In the dry state they darkened and showed evidence of charring at temperatures as low as 100°; hence while the initial concentration was carried out on the water-bath, the final drying was at 50°. The anhydrous acids so prepared were yellow or tan in color, highly hygroscopic, very soluble in water, and soluble in ethyl ether. Analysis for oxalic acid by the method described showed it to be present in different preparations in amounts varying from 25–35%.

Esterification.—An appropriate amount, 20–40 g., of the mixed anhydrous acids, prepared as above, was dissolved in methyl alcohol or ether and subjected to exhaustive methylation, with diazomethane, by the method of Staudinger and Kupfer.[13] After the methylation the solvent was allowed to evaporate at room temperature and the yellow to reddish-brown sirupy mixture of esters was transferred to the molecular still for fractionation. The addition of silver powder to the sirupy mixture was found to facilitate its transfer to the still and eliminated spattering in the subsequent distillation A considerable part of the dimethyl oxalate was no doubt lost with the ether. After distillation the various ester fractions were removed mechanically as completely as possible from the pockets of the condenser. Any material still adhering to the condenser was removed by washing with acetone, and the amounts so recovered are shown in Table VI. The nonvolatile residue was separated from the silver powder by extraction with acetone. Total recoveries were usually above 90%, except in those cases where dimethyl oxalate was present in large amounts. The various ester fractions were crystallized from acetone and water mixtures and the identity of the pure esters established by analysis and mixed melting point with authentic samples, except in the case of the ester of prehnitic acid. None of this acid or its ester was available.

Decarboxylation.—This was carried out as described elsewhere[8] (p. 2326).

Summary

The exhaustive oxidation with alkaline permanganate of a Pittsburgh seam bituminous coal, Edenborn mine, and of a 500° coke from this coal has been studied. It is shown that 90–95% of the carbon can be recovered as the potassium salts of water soluble, non-colloidal acids. Ap-

[13] Staudinger and Kupfer, *Ber.*, **45**, 505 (1912).

proximately 30 and 35% of the carbon of the coal and coke, respectively, is found as aromatic acids.

It has been shown that good recoveries of oxalic and aromatic acids can be obtained by direct electrolytic decomposition, in a three compartment cell, of the potassium salts resulting from the oxidation. Oxalic plus aromatic acids recovered in this way were 88 and 98 g. per 100 g. of coal and coke, respectively.

Esterification followed by distillation of the esters in a special molecular fractionating still resulted in the isolation of no crystalline material other than dimethyl oxalate. Separation of the acids on the basis of varying salt solubilities, followed by liberation of the free acids from the salt fractions, and esterification and fractionation of the esters, resulted in the isolation of small amounts, usually less than 2 g. per 100 g. of coal or coke, of various benzene carboxylic acids. The presence of a large fraction, approximately 50%, of esters which are not distillable, under conditions where it was shown that the esters of known carboxylic acids distil rapidly, has led to the conclusion that a significant part of the acids from this coal and coke are more complex than benzene carboxylic acids. The persistent yellow color of the acids and low volatility of the esters indicate that they may be condensed aromatic acids containing carbonyl oxygen. It is pointed out that the failure to recover hydrocarbons more complex than diphenyl, by decarboxylation, does not necessarily preclude the possibility of the presence of acids with condensed aromatic nuclei containing carbonyl oxygen, since drastic alkaline decomposition is known to split the nuclei of such aromatic acids.

The Mechanism of Vinyl Polymerizations[1]

BY PAUL J. FLORY

Nearly all compounds containing non-benzenoid carbon–carbon double bonds are capable of undergoing polymerization when subjected to suitable conditions. High molecular weight polymers may be formed from many such compounds, notable examples of which are styrene, vinyl acetate, acrylic acid and its esters, butadiene, and chloroprene. The closely similar characteristics of the conversion of monomer to polymer in these vinyl polymerizations has led to the conclusion that all of them proceed by essentially the same mechanism.

An abundance of evidence has been accumulated to show that typical vinyl polymerizations are chain reactions.[2,3] Except in the presence of certain polymerization catalysts, it may be assumed that the chain is propagated through the successive addition of monomer molecules to a free radical, *i. e.*

$$---(CH_2{-}CHR)_x{-}CH_2{-}CHR{-} \xrightarrow{+\ CH_2{=}CHR}$$

$$---(CH_2{-}CHR)_{x+1}{-}CH_2{-}CHR{-} \xrightarrow{+\ CH_2{=}CHR}$$

etc.[4,5]

In support of this free radical chain mechanism Taylor and Jones[6] have found that ethylene is polymerized by free radicals released in the thermal decomposition of metal alkyls, and Rice and Sickman[7] induced the polymerization of ethylene with methyl radicals from decomposing azomethane. The mechanisms of the equally important processes of chain initiation and termination have remained more obscure. From the limited experimental results available at the present time it is possible to draw certain general conclusions pertaining to the mechanisms of these processes, and upon the basis of these conclusions the theoretical treatment of the kinetics of vinyl polymerizations presented in the following pages has been developed.

---

[1] The term "vinyl polymerizations" is used here to include not only polymerizations of derivatives of vinyl alcohol such as vinyl acetate or vinyl chloride, but all polymerizations involving olefinic double bonds and leading to products of high molecular weight.

General Discussion

There are two pertinent characteristics of vinyl polymerization which must be accounted for by an acceptable mechanism for the process: the apparent autocatalytic character of the conversion of monomer to polymer, *i. e.*, the increase in rate during the first stage of the process,[8] and the approximate constancy of the average molecular weight during the polymerization.[4,5,9] Dostal and Mark[10] have proposed a mechanism based on two processes, chain initiation brought about by a relatively slow "activation" of monomer, and subsequent rapid successive addition of monomers to the activated molecule as indicated above. It was originally assumed that activated molecules continue to "grow" (add on monomers) indefinitely. More recently Dostal[11] has appended to the equations derived on the basis of this mechanism a correction to allow for an "isomerization" reaction whereby the actively "growing" molecule reverts to an inactive polymer molecule incapable of adding on more monomers. The equations of Dostal and Mark are unnecessarily obscure due to their use of an abstract quantity, the "eigenzeit" ($= {}_0\int^t x \, dt$ where x is the fraction of the material which is monomeric at time t), instead of an explicit expression of time.[12] Although the theories of Dostal predict an increase in rate during the early stages of the polymerization in agreement with experiment, they also predict an increase in the molecular weight during the course of the polymerization, which is not in accord with observation.

Staudinger and Frost[4] conceive of the polymerization process as consisting of the three steps: chain initiation, chain propagation, and chain termination. The latter step, whereby an "active" polymer molecule is "deactivated," is incorporated as one of the main reactions. Schulz[13] concludes that inasmuch as according to this mechanism the average molecular weight must be proportional to the ratio of the rate of chain propagation to the rate of chain termination, the constancy of the average molecular weight throughout the course of the polymerization is to be explained by a constancy in this ratio. From this conclusion he derives size distribution equations which are in agreement with the approximate distribution of sizes which he found experimentally in polyisobutylene. This mechanism offers a satisfactory explanation of molecular weight constancy during the polymerization and of the distribution of molecular sizes, but fails to account for the acceleration of the rate at the outset of the polymerization.[14] Thus, neither the theory of Dostal nor that of Schulz is in satisfactory accord with experiment.

Before attempting to formulate a preferable mechanism, let us examine the facts pertaining to the formation and termination of the polymerization chains. Both the formation and annihilation of free radicals (active centers) in the polymerizing monomer, in the absence of extraneous substances such as (negative) catalysts, is subject to a highly significant restriction, namely, that *the free radicals can be formed or destroyed in pairs only.* For example, the free bond terminus of an "active" polymer molecule may be destroyed through saturation of the free bond with a univalent group or a hydrogen atom, or through the formation of a double bond in place of the free radical end group with concurrent loss of a univalent group or a hydrogen atom. In any case the disappearance of the free bond on the chain molecule would require the appearance of a free radical or hydrogen atom elsewhere. Thus, although the active centers can, in effect, be transferred from one molecule to another, they can be destroyed only in pairs by reaction with each other. Consequently, the destruction of active centers must be bimolecular. Furthermore the rate of destruction of active centers must be proportional to the *square* of their concentration, and the length of a particular chain from initiation to destruction must be inversely proportional to the first power of their concentration.

In photopolymerizations a manifold increase in the rate of production of active centers is brought about without directly affecting the other proc-

---

[8] See for example, Mark and Raff, *Z. physik. Chem.*, **B31**, 275 (1936).

[9] It has been found in this Laboratory recently that the average molecular weight of methyl methacrylate polymer at less than one per cent. conversion does not differ significantly from the average molecular weight of the polymer when polymerization is nearly complete.

[10] Dostal and Mark, *Z. physik. Chem.*, **B29**, 299 (1935).

[11] Dostal, *Monatsh.*, **67**, 1 (1935); **67**, 63 (1935).

[12] Gee, *Trans. Faraday Soc.*, **32**, 656 (1936), has simplified the abstract and approximate equations of Dostal and has shown the consequences of chain deactivation mechanisms of several sorts. He has attempted to apply his theories to polymerizations in general without differentiating between the various types [Carothers, *Chem. Rev.*, **8**, 378 (1931)] which involve unlike mechanisms. See Gee and Rideal, *Trans. Faraday Soc.*, **31**, 969 (1935), and **32**, 666 (1936).

[13] Schulz, *Z. physik. Chem.*, **B30**, 379 (1935).

[14] Schulz has mentioned in a footnote that perhaps an occasional "branching" of the chain to bring about initiation of one or two new chains at the moment of deactivation might explain the acceleration in rate.

esses involved. With the resultant increase in the concentration of active centers the chain length must decrease and so, according to the conventionally accepted identity of chain length and degree of polymerization, a decrease in molecular weight would be expected. In conflict with this latter deduction, photopolymerized methyl methacrylate[20] (methyl α-methyl acrylate) is not of appreciably lower molecular weight than polymer prepared in the absence of light at the same temperature. Staudinger and Schwalbach[15] obtained their highest molecular weight polyvinyl acetate by photopolymerization at 20°. Although no polymer was prepared by thermal polymerization at this temperature, extrapolation of data at higher temperatures (*cf. seq.*) indicates approximate equality of the molecular weights of photo and thermal polymers at 20°. Staudinger and Schwalbach also found that introduction of oxygen retarded the rate of the photopolymerization much more than it reduced the molecular weight.

It is evident from these results that an increase in the number of active centers does not decrease the molecular weight, nor does impedance of the reaction through the destruction of active centers by a negative catalyst necessitate a corresponding reduction in molecular weight. These facts suggest that the reaction which limits the growth of a particular molecule, *i. e.*, the reaction which determines the molecular weight, and the reaction which destroys active centers are not one and the same reaction, but are entirely independent processes. This concept has been embodied in the following scheme for the mechanism of vinyl polymerizations

$$M_1 + M_1 \longrightarrow 2M^* \qquad (1)$$
$$M^*_n + M_1 \longrightarrow M^*_{n+1} \qquad (2)$$
$$M^*_n + M \longrightarrow M_n + M^* \qquad (3)$$
$$M^*_n + M^*_m \longrightarrow M_n + M_m, \text{ or } M_{n+m} \qquad (4)$$

where M_1 denotes a monomer molecule, M_n a polymer molecule composed of n units, and M a molecule containing an unspecified number of units; a molecule bearing an active center is marked with an asterisk. Reaction (1) has been written to imply the simultaneous formation of two active centers; as will be shown later, both of them are very probably on the same molecule (dimer or trimer). The active centers created in (1) undergo the chain propagation reaction (2) repeatedly until at some stage the "chain transfer" reaction (3) intervenes, whereupon the polymer molecule loses the active center and ceases to grow. The molecule M* which inherits the active center grows by the repeated occurrence of reaction (2) until (3) again intervenes, etc. At a favorable collision of two of the active centers, which will be relatively rare since the active centers must be present in such minute concentrations, mutual deactivation (4) will occur. The production of each active center will, on the average, bring about the formation of many polymer molecules before the effect of the active center is finally ended by reaction (4). (It is assumed that the absolute rate of (3) is much greater than that of (4).)

The principal feature of the above mechanism in contrast to previous theories is the concept of distinctly separate processes for the interruption of the growth of a particular molecule and for the destruction of active centers. As the following discussion shows, this mechanism is capable of explaining in a quantitative manner the acceleration of the rate which occurs at the outset of the polymerization, the approximate constancy of molecular weight during the course of the process, and the molecular weight dependence on temperature and independence of rate of polymerization.

Kinetics of Conversion of Monomer to Polymer

The following analysis of polymerization kinetics will be restricted to non-catalytic and homogeneous processes, *i. e.*, to polymerizations carried out under catalytically aseptic conditions. It will be assumed that the rate constants of reactions (2), (3) and (4) are independent of the size of the polymer molecule bearing the active center. Hence, the probability either of chain transfer or of chain termination at any particular stage of growth of the polymer will be the same as for any other stage of growth. If the molecular weight of the polymer is disregarded and only the conversion of monomer to polymer is considered, then reactions (1), (2) and (4) will suffice as a basis for a kinetic interpretation of the process. As discussed above, it is apparent that both (2) and (4) must be second-order processes. Chain initiation (1) cannot be first order (in the absence of catalysts) because as shown in a following section the energy requirement for such a process is too great, but it may be either second or third order. In the following treatment (2) and (4) will be taken as second order, and equations will be derived for both a second order and a third order initiation process.

---

(15) Staudinger and Schwalbach, *Ann.*, **488**, 8 (1931).

Polymerization Kinetics Assuming Second Order Chain Initiation.—The following notation will be used

n = concentration of monomer
N = concentration of active centers
k_1, k_2 and k_4 = velocity constants of reactions (1), (2) and (4), respectively.

If (1), (2) and (4) are all second order[16]

$$\mathrm{d}N/\mathrm{d}t = k_1n^2 - k_4N^2 \qquad (5)$$

$$\mathrm{d}n/\mathrm{d}t = k_2Nn \qquad (6)$$

Dividing equation (5) by (6), integrating and supplying the boundary condition, $N = 0$ when $n = n_0$, gives

$$N = \left(\frac{k_1}{k_4 - k_2}\right)^{1/2} [n^2 - n_0^2(n/n_0)^{2r}]^{1/2} \qquad (7)$$

where $r = k_4/k_2$. Substituting (7) in (6) and letting $n/n_0 = x$ and $n_0(k_1k_2)^{1/2} = K$

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -Kx^2\left(\frac{1 - x^{2r-2}}{r - 1}\right)^{1/2} \qquad (8)$$

Equation (8) and some of the equations derived therefrom are indeterminate at the point $r = 1$.

The relation of x, the fraction of the original material which is unpolymerized, to t is completely determined according to (8) by two parameters, K and r. Since K occurs conjugate with t, a change in K merely has the same effect as an alteration of the time units; the fundamental characteristics of the variation of x with t are entirely determined by r. The solid curves in Fig. 1A represent solutions of (8) for the several values of r indicated above each curve, time being expressed in arbitrary units equal to $1/K$; in Fig. 1B a magnified scale has been used to show the initial portions of the curves. Inasmuch as no general solution of (8) has been obtained, these solutions have been obtained by the special methods discussed in the following paragraphs.

When $r = 0$, *i. e.*, when no destruction of active centers occurs ($k_4 = 0$), the mechanism presented above and the original Dostal and Mark[10] mechanism in which second order chain initiation is assumed are identical with respect to conversion of monomer to polymer (although the two mechanisms predict different molecular weights). In this case (8) becomes[17]

$$\mathrm{d}x/\mathrm{d}t = -Kx(1 - x^2)^{1/2} \qquad (8.1)$$

Integration of (8.1) gives

$$\ln\,[(1 + \sqrt{1 - x^2})/x] = Kt \qquad (9.1)$$

The $r = 0$ curve in Fig. 1A was obtained from equation (9.1), which corresponds to Dostal and Mark's[10] approximate equation (20). As they have shown, the rate of polymerization accelerates, reaches a maximum corresponding to the inflection in the curve, and then decreases continuously.

As r increases to large values, *i. e.*, as the rate of destruction of active centers becomes relatively more rapid, the duration of the rate acceleration period becomes shorter, and when $r \gg 1$, (8) approaches the simple second order equation[18]

$$\mathrm{d}x/\mathrm{d}t = -(K/r^{1/2})x^2 \qquad (8.2)$$

For $r = 2$, an intermediate case between these two extremes, equation (8) integrates to

$$Kt = (1 - x^2)^{1/2}/x \qquad (9.3)$$

from which the $r = 2$ curve has been derived. The curves for $r = 10$, 25 and 100, have been obtained by graphical integration using the first form of the equation

$$Kt = 1/2\,(r - 1)^{-1/2}\int_1^x \frac{1}{x}\,\mathrm{d}\ln\left[\frac{1 + (1 - x^{2r-2})^{1/2}}{1 - (1 - x^{2r-2})^{1/2}}\right]$$
$$= (r - 1)^{1/2}\int_1^x (1 - x^{2r-2})^{-1/2}\,\mathrm{d}(1/x)$$

for values of x near unity and the second form for all smaller values of x.

All of the curves meet at sufficiently small $1-x$ values, as shown in Figs. 1A and 1B. An increase in r retards the conversion and brings the inflection point, or point of the maximum rate, to a lower $1-x$ value; that is, a recession in the acceleration period occurs when r is increased.

The relation of x_m, the value of x at the inflection, to r can be derived from (8) as follows

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} = \frac{K^2x^3}{(r - 1)}\,[2 - (r + 1)x^{2r-2}] = 0$$
$$x_m = ((r + 1)/2)^{1/(2-2r)} \qquad (10)$$

Curve 2 of Fig. 2 expresses this relation graphically. Substituting (10) in (8) in order to obtain the rate at x_m

$$\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)_{\mathrm{max.}} = -Kx_m^2\,(r + 1)^{-1/2} = \frac{-K}{\sqrt{2}}\left(\frac{2}{r+1}\right)^{(r+1)/(2r-2)} \qquad (8.8)$$

From a plot of experimental x *vs.* t data, both x_m and $(\mathrm{d}x/\mathrm{d}t)_{\mathrm{max.}}$ can be determined. The value of r may be obtained by substituting x_m in (10), or by the use of Curve 2 in Fig. 2. Equation (8.8) can then be used to evaluate K from r and $(\mathrm{d}x/\mathrm{d}t)_{\mathrm{max.}}$. Exact location of the inflection

---

(16) The term $-k_1n^2$, which represents the rate of consumption of monomers by reaction (1), has been omitted in (6). Except when the chain length is very short, this term is negligible compared with $-k_2Nn$.

(17) Equation (8.1) could have been derived directly from (5) and (6) by placing $k_4 = 0$ in the former.

(18) Equation (8.2) is the solution of (5) and (6) for the "steady state" condition $(\mathrm{d}N/\mathrm{d}t) = 0$.

point will, in general, be subject to a large uncertainty, although $(\mathrm{d}x/\mathrm{d}t)_{\mathrm{max.}}$ may be determined quite accurately. When x_m is sufficiently near unity, *i. e.*, when r is large, the following approximate equation can be used satisfactorily.

$$\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)_{\mathrm{max.}} = -\frac{K}{r^{1/2}} = -n_0k_1^{1/2}\,k_2/k_4^{1/2} \qquad (8.9)$$

Although determination of r $(=k_4/k_2)$ and K $(=n_0(k_1k_2)^{1/2})$ is feasible, evaluation of the individual velocity constants from experimental determination of the course of the polymerization is impossible.

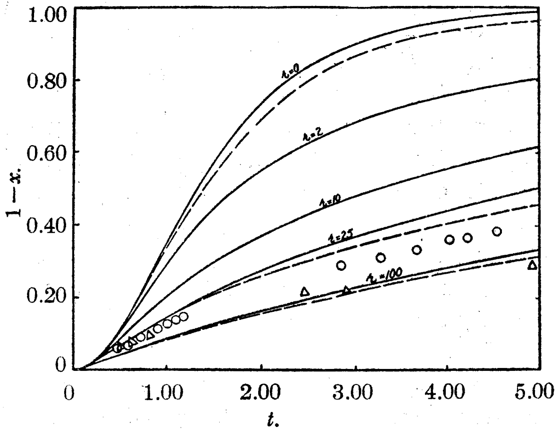

Fig. 1A.—Extent of polymerization *vs.* time for various values of r. Solid curves represent polymerization when chain initiation is second order with time expressed in units of $1/K$; dashed curves represent polymerization when chain initiation is third order, with t in units of $1/K'$. ○, experimental points for the polymerization of 60% vinyl acetate in toluene at 100.9°[19] △, experimental points for 22.5% styrene in toluene at 98.2°.[8]

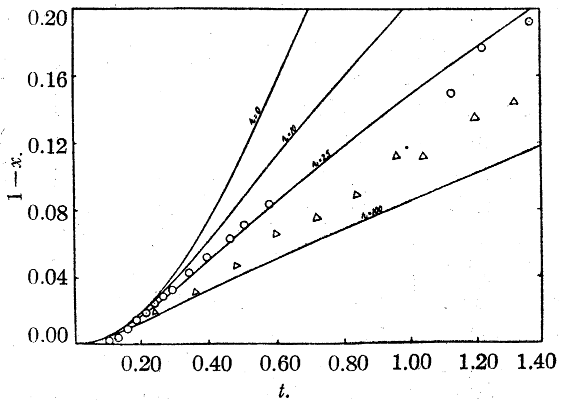

Fig. 1B.—Initial portions of curves shown in Fig. 1A. These are equally applicable to polymerization with second order chain initiation (t in $1/K$ units) or with third order chain initiation (t in $1/K'$ units). ○, 60% vinyl acetate in toluene at 81.8° [19]; △, undiluted styrene at 98.2°.[8]

Polymerization Kinetics Assuming Third Order Chain Initiation.—If reaction (1) is third order, equation (5) must be replaced by

$$\mathrm{d}N/\mathrm{d}t = k_1n^3 - k_4N^2 \qquad (11)$$

Solving (11) and (6) simultaneously gives

$$\mathrm{d}x/\mathrm{d}t = -K'x^{5/2}\left(\frac{1-x^{2r-3}}{r-3/2}\right)^{1/2} \qquad (12)$$

where $r = k_4/k_2$ as before, and $K' = n_0^{3/2}(k_1k_2)^{1/2}$. This equation closely resembles (8); x^2 in (8) has been replaced by $x^{5/2}$, the quantities in parentheses in the two equations differ only slightly, and n_0 in the K in (8) has been replaced by $n_0^{3/2}$ in K'. When r assumes large values (8) approaches a simple second order equation, whereas (12) approaches a five-halves order equation.

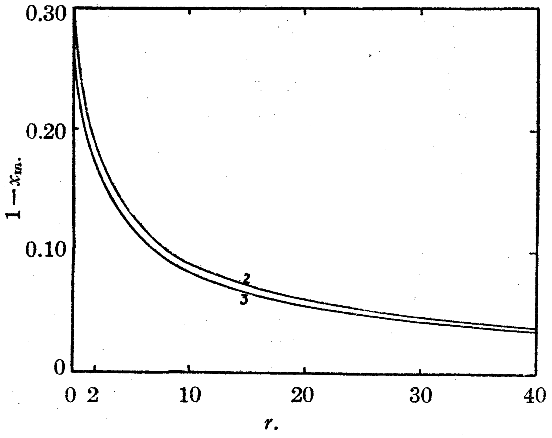

Fig. 2.—Relation of x_m, the value of x at $(\mathrm{d}x/\mathrm{d}t)_{\mathrm{max.}}$, to r for second order initiation (curve 2) and for third order initiation (curve 3).

Several integrals of (12) are shown by the dashed curves in Fig. 1A. Each of these for values of x sufficiently near unity merges with the solid curve for the same r value; in the region shown in Fig. 1B the two sets of curves are substantially identical.

The $r = 0$ curve has been obtained from an integral solution of (12). The other curves have been obtained by the graphical evalution of the integrals in the equation

$$K't = 1/2\,(r-3/2)^{-1/2}\int_1^x x^{-3/2}\,\mathrm{d}\ln\left[\frac{1+(1-x^{2r-3})^{1/2}}{1-(1-x^{2r-3})^{1/2}}\right]$$
$$= 2/3\,(r-3/2)^{1/2}\int_1^x (1-x^{2r-3})^{-1/2}\,\mathrm{d}(x^{-3/2})$$

the first integral being used for x values very close to unity, and the second for all smaller x values.

The relation of x_m to r, obtained by differentiating (12) and equating to zero, is

$$x_m = [2/5\,(r+1)]^{1/(3-2r)} \qquad (14)$$

A comparison of the graph of (14), curve 3 of Fig. 2, with the graph of (10), curve 2 of the same figure, emphasizes the similarity of the two equations. The equation analogous to (8.8) for the maximum rate, obtained by substituting (14) in (12), is

$$(\mathrm{d}x/\mathrm{d}t)_{\text{max.}} = -K'x_m^{5/2}(r+1)^{-1/2} \qquad (12.8)$$

When r is large, $x_m \cong 1$, and

$$(\mathrm{d}x/\mathrm{d}t)_{\text{max.}} = -K'/r^{1/2} = n_0^{3/2}k_1^{1/2}k_2/k_4^{1/2} \qquad (12.9)$$

which is the same as (8.9) except for a factor $n_0^{1/2}$. Using (12.8) or (12.9) K' can be determined from a graph of x *vs.* t in the same manner as was discussed in connection with the corresponding equations in the preceding section. In view of the similarity of the two sets of equations, this method can be used for satisfactory evaluations of r and of K or K' without distinguishing the order of (1), unless r is of the order of unity or less.

Equations have been worked out according to the above methods assuming first order chain initiation, in which case the mechanism becomes the same as assumed by Gee.[12] They too are similar to the equations for second order initiation. Thus, the character of the conversion of monomer to polymer is only slightly dependent upon the order of reaction (1). The kinetic orders of (2) and (4) are highly important, however, in determining the character of the conversion kinetics.

As mentioned before, the above treatment is intended for application to strictly non-catalytic polymerizations only. In general, catalysts may either accelerate reaction (1), ("positive" catalysts) or reaction (4) ("negative" catalysts or inhibitors), or both. If the action of the catalyst is limited to acceleration of (1), the above treatment can be expected to apply, although the order of (1) may be altered. If the catalyst causes chain termination, a term should be added to equation (5), or (11), and the polymerization kinetics will be materially affected. Nearly all catalysts (O_2, Na, $SnCl_4$, etc.) which are known to accelerate the polymerization are also effective chain terminators; the converse is not true.

Application to Experimental Data

Most of the experimental data pertaining to vinyl polymerization kinetics quoted in the following pages has been taken from one of the three following sources: the results of Starkweather and Taylor[19] on vinyl acetate, Mark and Raff's[8] results on styrene, and the work of Starkweather, Flory and Carothers[20] on methyl methacrylate. Starkweather and Taylor using a specially refined technique to prevent contamination (and using Pyrex glass) obtained consistently reproducible results on vinyl acetate. Mark and Raff's results on styrene were also quite reproducible, but the results referred to above on methyl methacrylate were erratic. In a study of catalysis of vinyl polymerizations, Breitenbach and Raff[21] found that, under their experimental conditions (using Jena or soft glass), the polymerization of acrylic ester definitely was catalyzed by the walls of the container, vinyl acetate was subject to the catalysis to a lesser extent, and styrene was free from catalysis. Irreproducibility seemed to accompany catalysis. Considering the reproducibility of the results referred to above on vinyl acetate, the polymerization results for this substance, as well as the results for styrene, must have been substantially free from the effects of catalysis. The polymerization of methyl methacrylate was probably catalytic.

In Figs. 1A and 1B representative experimental data on styrene and vinyl acetate have been included for comparison with the family of theoretical curves. Time units have been adjusted by a factor arbitrarily chosen to bring about the best possible fit with the curves. Considering the likelihood of accompanying secondary effects not taken into account by the simple theory given here, exact agreement with the theoretical curves is not to be expected. It is particularly significant that the theory describes satisfactorily the course of the polymerization during the acceleration period (Fig. 1B), which is so characteristic of most vinyl polymerizations. Although the points are more nearly in agreement with a third order chain initiation (dashed curves in Fig. 1A), a choice between the two mechanisms is scarcely justified by these results alone.

When, as in the case of the polymerization of indene,[22] the acceleration period is apparently absent, the theory leads to the conclusion that r is very large.

Apparent Energies of Activation.—Regardless of whether reaction (1) is second or third order, $(\mathrm{d}x/\mathrm{d}t)_{\text{max.}}$ is proportional, according to (8.9) and (12.9), to $k_1^{1/2}k_2/k_4^{1/2}$ to a satisfactory approximation when r is sufficiently greater than unity. Upon

substituting an Arrhenius expression, $k = Ae^{-E/RT}$, for each velocity constant

$$\log_{10}(\mathrm{d}x/\mathrm{d}t)_{\max.} = B - E_a/2.303RT \qquad (15)$$

where B is a constant containing the A's and E_a is the "apparent energy of activation" defined by

$$E_a = 1/2\,E_1 + E_2 - 1/2\,E_4 \qquad (16)$$

E_1, E_2 and E_4 denoting the activation energies of (1), (2) and (4), respectively.

The $(\mathrm{d}x/\mathrm{d}t)_{\max.}$ values in Table I for styrene, vinyl acetate and methyl methacrylate at various temperatures have been evaluated graphically from plots of experimental data. The data in Figs. 1A and 1B show that at least for styrene and vinyl acetate r is large enough (between 25 and 100) to permit assumption of the proportionality relation upon which (15) is based. In Fig. 3, $\log_{10}(\mathrm{d}x/\mathrm{d}t)_{\max.}$ is shown to be a linear function of $1/T$ in agreement with (15). E_a values given in Table I have been calculated from the slopes of the lines in the figure. For styrene and vinyl acetate they are nearly the same, but E_a for methyl methacrylate is much lower.

[a] The rates for styrene are based on the data of Mark and Raff. [b] The rates for vinyl acetate have been evaluated from the unpublished detailed measurements of Starkweather and G. B. Taylor.[19] [c] Unpublished work carried out by Starkweather, Flory and Carothers.[20]

Chain Lengths and Degree of Polymerization.—According to the proposed mechanism of polymerization two chain lengths must be differentiated: (ν, the average number of monomers caused to polymerize by one active center from its creation in reaction (1) to its annihilation by (4), and λ, the average number of monomers added to a particular chain free-radical from its formation by either (1) or (3) until its growth is arrested by chain transfer (3). According to the present theory many polymer molecules are formed for each active center created and so $\nu >> \lambda$.

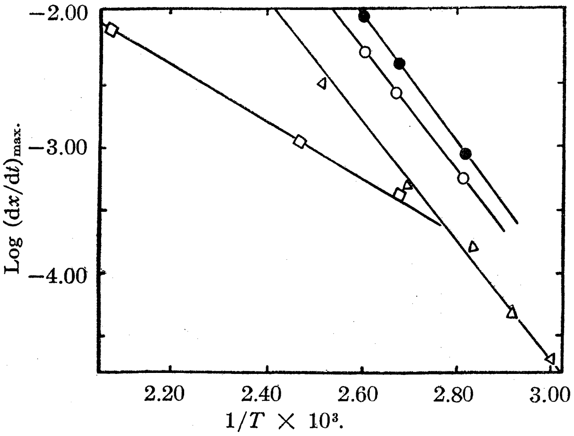

Fig. 3.—Decadic logarithm of maximum rate *vs.* the reciprocal of the absolute temperature: ○, 60% vinyl acetate in toluene; ●, undiluted vinyl acetate; △, styrene; □, methyl methacrylate (see Table I).

The average kinetic chain length, or "ν chain length," is equal to the ratio of the rate of (2) to the rate of (4), *i. e.*

$$\nu = k_2n/k_4N \qquad (17)$$

Since according to (6) the rate of polymerization is proportional to N, ν is inversely proportional to the rate. Although $k_2/k_4(=1/r)$ can be estimated from the course of the polymerization, the absolute value of N cannot be determined from such data, and so ν also evades evaluation.

The average "λ chain length" is equal to the ratio of the rate of (2) to the rate of (3). It follows that

$$\lambda = (k_2/k_3)f \qquad (18)$$

where f is a function of n (and perhaps of the amount of solvent also; *cf. seq.*) depending on the kinetic orders of (2) and (3). Reaction (2) is obviously second order, but the kinetic order of (3), which will be discussed in a later section, is uncertain. Whatever is the exact mechanism of (3), at the same concentration of monomer λ should be proportional to k_2/k_3 according to (18). If no chain branching (*cf. seq.*) occurs, λ is equal to the average degree of polymerization $D.\ P.$ Upon introducing the Arrhenius equation into the above proportionality relation

$$\log_{10}\lambda = \log_{10}(D.\ P.) = C + (E_3 - E_2)/2.303RT \quad (19)$$

where C is a constant.

In Table II the available data on the *D. P.*'s of polymers prepared at two or more temperatures are given. These are all based on estimates of molecular weights obtained by the Staudinger viscosity method.[23] In Fig. 4 the log (*D. P.*) values (Table II) for styrene, vinyl acetate and methyl methacrylate are shown to be linear functions of $1/T$ in agreement with (19). This simple quantitative relation of observed molecular weights to temperature stands in excellent confirmation of the theory developed above. The $E_3 - E_2$ values in the last column of the table have been calculated from the slopes of the lines in the figure; in the case of ethyl acrylate, where data are available at two temperatures only, $E_3 - E_2$ values have been calculated directly from equation (19).

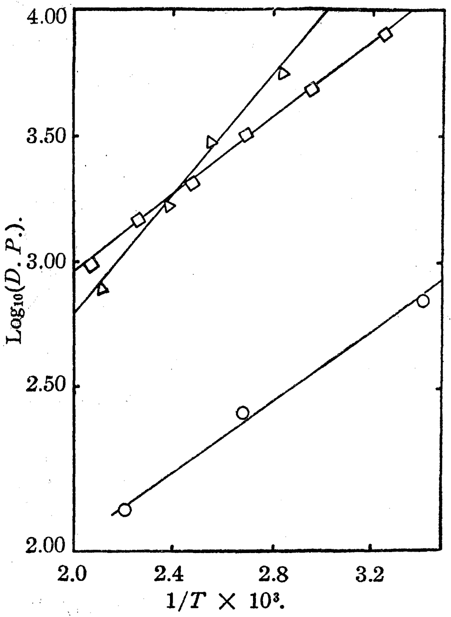

Fig. 4.—Log_{10} (*D. P.*) *vs.* $1/T$: ○, vinyl acetate; △, styrene; □, methyl methacrylate (see Table II).

[a] These are relative values of *D. P.*, which may only roughly approximate the correct absolute values. [b] Staudinger and Husemann, *Ber.*, **68**, 1618 (1935). [c] Staudinger and Schwalbach.[15] [d] Starkweather, Flory and Carothers.[20] [e] Staudinger and Trommsdorff.[34] [f] The 20° vinyl acetate polymer and 35° methyl methacrylate polymer were obtained by photopolymerizations.

Photochemical Polymerization.—The experiments of Taylor and Vernon[24] on the photopolymerizations of styrene and vinyl acetate are of particular interest because of their bearing on activation energies. Radiation in the near ultraviolet region (3000 to 4000 Å.), such as Taylor and Vernon used, is absorbed by the double bond and not by other parts of the molecule. Consequently, the initial step consists of activation of the monomer at the double bond, and not formation of free radicals through the dissociation of C–C or C–H bonds. Although many of the optically excited monomers must lose their energy in collisions with other molecules, some of them evidently react with other unexcited monomers yielding active centers and thereby initiating polymerization chains. Since the initiation of chains must therefore be second (or third) order[25] and since it may be assumed that other processes occurring in the polymerization are unaffected by the light, the theory given above for thermal poly-

---

(23) Staudinger and Schulz, *Ber.*, **68**, 2320 (1935) have shown that for polystyrene the constant, K_m, in the Staudinger equation, $(\eta_r - 1)/C = K_m$ (M. W.), (η_r = relative viscosity of a dilute solution of polymer of concentration C) varies slightly with the temperature of polymerization, *e. g.*, from 0.61×10^{-4} at 80° to 0.41×10^{-4} at 200°. This behavior of polystyrene they attribute to chain branching (*cf. seq.*). Since it is the length of the chain (λ), rather than *D. P.*, which is primarily important in the evaluation of $E_3 - E_2$, and since according to Staudinger the viscosity molecular weight is fundamentally a measure of chain length, a constant value of K_m ($= 0.50 \times 10^{-4}$) has been preferred in calculating the *D. P.*'s for polystyrene in Table II from the $(\eta_r - 1)/C$ values given by Staudinger and Husemann. For the evaluation of $E_3 - E_2$, only relative values of M. W. at the various temperatures are required; hence, the absolute value of K_m is unimportant.

(24) H. S. Taylor and Vernon, THIS JOURNAL, **53**, 2527 (1931).

(25) In cases where all, or nearly all, of the incident light is absorbed, (1) may be first order because the amount of light absorbed is no longer dependent upon concentration.

merizations is equally applicable to photopolymerizations. Only the kinetic mechanism of reaction (1) differs in the two cases; E_a in equation (15) should be replaced by

$$E'_a = 1/2\, E'_1 + E_2 - 1/2\, E_4 \qquad (16.1)$$

where E'_1 is the activation energy which is required in addition to the photochemical excitation energy for the initiation of chains. E'_1 must be very small and within the limits of accuracy of the other E's, $1/2\, E'_1$ can be omitted in (16.1), *i. e.*

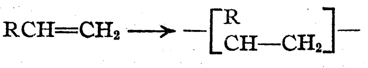
$$E'_a = E_2 - 1/2\, E_4 \qquad (16.2)$$

Taylor and Vernon found average 10° temperature coefficients of 1.30 for styrene in the range 30 to 100°, and 1.26 for vinyl acetate in the range 40 to 70°. For both substances the amount of light absorbed was independent of the temperature. The corresponding activation energies, E'_a, are 5.9 kcal. for styrene and 4.9 kcal. for vinyl acetate.

Activation Energies of Individual Reactions.—Combining the E'_a with the E_a values (equation 16) for these two compounds one obtains values for E_1, namely, 32 kcal. for styrene, and 35 kcal. for vinyl acetate. Assuming any reasonable value of $E_2 - 1/2\, E_4$ for methyl methacrylate, E_1 must be less than about 20 kcal., *i. e.*, appreciably less than for styrene or vinyl acetate. If, as mentioned before, the polymerization of methyl methacrylate was catalytic, a low value for E_1 is in accord with expectation. E_4, the energy requirement for the inter-reaction of two free radicals (whether it be by combination or disproportionation, *cf. seq.*) must be very low, certainly less than 5 kcal. Hence, from the values of $E'_a = E_2 - 1/2\, E_4$, E_2 must be about 6 kcal. for styrene and about 5 kcal. for vinyl acetate.[26,27] Recalling the values of $E_3 - E_2$ in Table II, E_3 for styrene must be about 12 kcal. and for vinyl acetate about 9 kcal.

Heats of Polymerization

In a vinyl polymerization an unsaturated monomer is converted to a saturated (or less unsaturated) structural unit of a polymer molecule; that is



$$\mathrm{RCH{=}CH_2} \longrightarrow -\left[\begin{matrix}\mathrm{R} & \\ \mathrm{CH} & -\mathrm{CH_2}\end{matrix}\right]- \qquad (20)$$

Rossini[28] has shown that the heat of formation in kcal. of a straight chain paraffin hydrocarbon in the gaseous state is given by the linear function of n

$$\Delta H^\circ_{298} = -7.91 - 5.55n$$

when n, the number of carbon atoms, is greater than four. When $n < 5$, the following corrections must be applied to this equation: −1.59 kcal. for $n = 2$, −0.83 kcal. for $n = 3$, and −0.46 kcal. for $n = 4$. Rossini's[29] comparisons of heats of combustion of isobutane and tetramethylmethane with the heats of combustion of their respective straight chain isomers suggest that the above formula may be used for branched chain hydrocarbons by applying the corrections, −1.63 kcal. for each  $\overset{\mathrm{C}}{\underset{}{|}}$—C—C—C— structure and −4.9 (±1) kcal. for each  —C—$\underset{\mathrm{C}}{\overset{\mathrm{C}}{\mathrm{C}}}$—C— structure. With the aid of these corrections the heat of formation of any paraffin hydrocarbon can be calculated. The heat of formation of a structural unit of the polymer is

$$\Delta H_u = -5.55n + \Delta_u$$

where Δ_u is the sum of the corrections for each unit.

The very accurate determinations of heats of hydrogenation carried out by Kistiakowsky and co-workers[30] enable one to calculate the heats of formation of unsaturated hydrocarbons (monomer in (20)) using the formula

$$\Delta H_m = -7.91 - 5.55n - \Delta H_{hyd} + \Delta_m$$

where ΔH_m is the heat of formation of the gaseous unsaturated monomer, ΔH_{hyd} is the heat of hydrogenation to the corresponding saturated hydrocarbon, and Δ_m is the sum of the corrections for this saturated hydrocarbon. The heat of polymerization is then

$$\Delta H_p = \Delta H_u - \Delta H_m = 7.91 + \Delta H_{hyd} + \Delta_u - \Delta_m \quad (21)$$

The very small correction necessary for conversion of ΔH_p to the liquid state will be overlooked. If the monomer is a diolefin (*e. g.*, if R in (20) is unsaturated), ΔH_{hyd} is the heat of hydrogenation of both double bonds and allowance must be made in Δ_u for the heat of hydrogenation of the single unsaturated group in the polymer unit (29.95 kcal. for $-\mathrm{CH{=}CH_2}$ and 27.80 kcal. for $-\mathrm{CH{=}CH}-$).

---

[26] Melville, *Trans. Faraday Soc.*, **32**, 258 (1936), has estimated that E_2 in the polymerization of gaseous acetylene is about 4 kcal.

[27] F. O. Rice and K. K. Rice, "The Aliphatic Free Radicals," The Johns Hopkins Press, Baltimore, Md., 1935, p. 190, state that the addition of ethylene to an alkyl free radical probably requires less than 10 kcal. of activation energy.

[a] Kistiakowsky and co-workers give heats of hydrogenation at 355°K. These have been corrected to 298°K. by assuming that the correction for all olefins is the same as for ethylene, namely, +0.25 kcal. For diolefins 0.50 kcal. has been used.

It is significant that for all of the mono-olefins the heat of polymerization approximates −23.0 kcal. in spite of the wide variations in structure. For conjugated diolefins ΔH_p is about 20 kcal. For styrene there are no direct thermochemical data upon which to base a value of ΔH_p. However, Kharasch[31] in his calculations of heats of combustion from the principle of bond additivity uses a correction of −3.5 kcal. for an aryl-alkyl linkage and −6.5 kcal. for an aryl-vinyl linkage. It follows that the heat of polymerization of styrene should be about 3 kcal. less than the "normal" value of 23 kcal., which leads to a value the same as for conjugated diolefins.

Reaction Mechanisms

Chain Initiation.—The only conceivable unimolecular processes by which (1) might occur are the formation of free radicals through the spontaneous dissociation of a C–C or a C–H bond, or the opening of the double bond to yield a divalent free radical. The value for D_{C-C}, the heat of dissociation of a carbon-carbon bond, is about 75 kcal.[32] and D_{C-H} is about 95 kcal., although these values may be somewhat affected by substituent groups.[33] The opening of a double bond should require about 60 kcal. The much smaller experimental values for E_1 definitely rule out these unimolecular mechanisms of chain initiation.

A second order mechanism such as

$$2CH_2=CHR \longrightarrow CH_3—CHR— + CH_2=CR— \quad (1.1)$$

in which two free radicals are formed by the exchange of a hydrogen atom, also requires too much energy.

For the process in which two monomers are coupled to form a di-free radical, *viz.*

$$2CH_2=CHR \longrightarrow —CHR—CH_2—CH_2—CHR— \quad (1.2)$$

$\Delta H_{1\cdot 2} = D_{C-C} + 2\Delta H_p$; $\Delta H_{1\cdot 2} = 29$ kcal., when $R = H$. When the monomer is a substituted ethylene (*e. g.*, when $R = H$), $\Delta H_{1\cdot 2}$ will be lowered due to the effect of substituents in stabilizing free radical groups; *i. e.*, as Conant[33] has pointed out, D_{C-C} is lowered by the substituents on the carbon atoms separated on dissociation. Consequently, for styrene and vinyl acetate the estimate for $\Delta H_{1\cdot 2}$ should be less than the above value of 29 kcal., and compliance of this mechanism with the necessary condition, $\Delta H_1 < E_1$ (see above experimental values for E_1), is thus assured.

Although the above mechanism (1.2) appears quite plausible, it is open to the objection that reversal of (1.2) might occur with such ease that it should be written as an equilibrium. If this be the case the initiation of chains becomes third order, *viz.*

$$2CH_2=CHR \rightleftarrows —CHR—CH_2—CH_2—CHR— + CH_2=CHR \longrightarrow —CHR—CH_2—CHR—CH_2—CH_2—CHR— \quad (1.3)$$

E_1 according to this mechanism will be the sum of the heat of the first reaction and the activation of the second step. Since this second step is equivalent to (2), $E_{1\cdot 3} = \Delta H_{1\cdot 2} + E_2$. If $R = H$, $E_{1\cdot 3} \cong 35$ kcal.; if $R \neq H$, $E_{1\cdot 3}$ should be some-

---

(31) Kharasch, *Bur. Standards J. Research*, **2**, 359 (1929).

(32) As yet no reliable value has been obtained for the strength of a C–C or a C–H bond in an ordinary hydrocarbon. Rossini's[28] heats of formation of hydrocarbons and Schmid's [*Z. Physik*, **99**, 274, 281 (1936)] recent work on the heat of dissociation of CO can be combined to yield the heats of *complete* dissociation of hydrocarbons, but not to yield the heat of dissociation of a single bond without rupture of the other bonds in the molecule. The above values of D_{C-C} have been chosen largely on the basis of the activation energies for dissociation of ethane and propane into free radicals, given by Rice and Rice[27] (book, p. 78).

(33) Conant, *J. Chem. Phys.*, **1**, 427 (1933), has suggested that the reduction of D_{C-C} by substituents on the carbons joined by the bond dissociated is approximately an additive effect, D_{C-C} being lowered 6 kcal. by each alkyl group and 11 kcal. by each aryl group.

what less than this. These values are also in agreement with the experimental values of E_1, and choice between these similar mechanisms, (1.2) and (1.3), is impossible at present. For this reason two theoretical treatments, one for second order and one for third order chain initiation, have been presented above.

In either mechanism (1.2) or (1.3) the dimeric free radical having the substituted groups at its ends is the most likely to form since, according to Conant's conclusions, this is the most stable structure. The presence of substituents, especially negative substituents such as C_6H_5— and CH_3-OCO— on one of the carbons adjoining the double bond of the monomer should render the dimeric intermediate more stable[33] and consequently lower E_1 and facilitate the polymerization. This conclusion is in agreement with fact as shown by the tabulations of Staudinger (Tables I and II of reference 5); *e. g.*, $CH_2{=}C(CH_3)_2$ polymerizes more readily than either $CH_2{=}CH_2$ or $CH_2{=}CH{-}CH_3$, and $CH_2{=}CH{-}C_6H_5$ more readily than $CH_2{=}CH{-}CH_3$. By the same argument the coupling reaction (2) should nearly always take place between the free radical and the unsubstituted (or less substituted) carbon of the vinyl group, so that the "new" free radical will appear at the substituted end of the vinyl group. This leads to the formation of a chain having a preponderance of the substituents *R* on alternate carbon atoms.

Chain Transfer.—In order to explain the approximate constancy of molecular weight during polymerization, Schulz[13] has concluded that the process which causes cessation of polymer growth is of the same kinetic order as polymer growth. In the light of the present concepts, this means that reaction (3) is of the same kinetic order as (2), *i. e.*, second order. On the other hand, there is an abundance of evidence to show that the molecular weight of the polymer decreases on dilution of the monomer with an inert solvent. For example, Staudinger and Schwalbach[15] by polymerizing a 50% solution of vinyl acetate in benzene obtained a polymer of roughly half the molecular weight of a polymer prepared from undiluted vinyl acetate at the same temperature. The molecular weights of the polyethyl acrylates prepared by Staudinger and Trommsdorff[34] from undiluted monomer and solutions of various concentrations of monomer in butyl acetate are approximately proportional to the concentration. These results indicate that (3) is of lower kinetic order than (2), *i. e.*, that (3) is first order, in disagreement with Schulz's conclusion and equation (18). Any unimolecular mechanism for the process of chain transfer would of necessity consist of the expulsion of a free radical, or a hydrogen atom, from the chain bearing the free bond with simultaneous formation of a double bond in the chain molecule; for example

$$\mathrm{M}_n{-}\mathrm{CH_2}{-}\mathrm{CHR}{-} \longrightarrow \mathrm{M}_n{-}\mathrm{CH}{=}\mathrm{CHR} + \mathrm{H} \qquad (3.1)$$

where M_n denotes a sequence of *n* structural units preceding the terminal structural unit of the polymer. ΔH for this process is about 35 or 40 kcal., and for the expulsion of an alkyl group ΔH $(= -\Delta H_p)$ is about 20 kcal. Both values are so much greater than E_3 estimated from experimental data (13 and 9 kcal., see above) that it is necessary to reject unimolecular mechanisms.

Taylor and Jones[6] have proposed the bimolecular chain transfer reaction

$$\mathrm{M}_n{-}\mathrm{CH_2}{-}\mathrm{CHR}{-} + \mathrm{CH_2}{=}\mathrm{CHR} \longrightarrow \mathrm{M}_n - \mathrm{CH_2}{=}\mathrm{CHR} + \mathrm{CH_3}{-}\mathrm{CHR}{-} \qquad (3.2)$$

in order to explain their results on the polymerization of gaseous ethylene. Another possible mechanism for (3) consists of saturation of the free radical with an atom from another molecule, for example

$$\mathrm{M}_n{-}\mathrm{CH_2}{-}\mathrm{CHR}{-} + \mathrm{R'}{-}\mathrm{CH_2}{-}\mathrm{R''} \longrightarrow \mathrm{M}_n{-}\mathrm{CH_2}{-}\mathrm{CH_2R} + \mathrm{R'}{-}\overset{|}{\mathrm{C}}\mathrm{H}{-}\mathrm{R''} \qquad (3.3)$$

The molecule R′—CH$_2$—R″ might be a monomer, a polymer or a solvent molecule. Rice and Rice[27] estimate that the activation energy for such a reaction is about 20 kcal. when the R's are alkyl groups and appreciably lower than this when either R′ or R″ is a negative group. Both of these bimolecular reactions (3.2) and (3.3) lead to constancy of molecular weight during polymerization. Participation of the solvent in (3.3) would provide an explanation of the decrease in molecular weight upon dilution with solvent. Choice of a definite mechanism for (3) is not possible at present, however.

Chain Termination.—The destruction of active centers by the inter-reaction of two of them may involve the coupling of the two radicals

$$\mathrm{M}_m{-}\mathrm{CH_2}{-}\mathrm{CHR}{-} + \mathrm{M}_n{-}\mathrm{CH_2}{-}\mathrm{CHR}{-} \longrightarrow \mathrm{M}_m{-}\mathrm{CH_2}{-}\mathrm{CHR}{-}\mathrm{CHR}{-}\mathrm{CH_2}{-}\mathrm{M}_n \qquad (4.1)$$

or the disproportionation reaction

$$\mathrm{M}_m{-}\mathrm{CH_2}{-}\mathrm{CHR}{-} + \mathrm{M}_n{-}\mathrm{CH_2}{-}\mathrm{CHR}{-} \longrightarrow \mathrm{M}_m{-}\mathrm{CH_2}{-}\mathrm{CH_2R} + \mathrm{M}_n{-}\mathrm{CH}{=}\mathrm{CHR} \qquad (4.2)$$

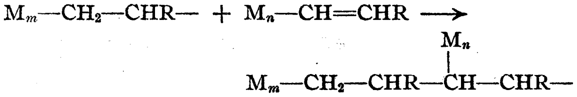
---

(34) Staudinger and Trommsdorff, *Ann.*, **502**, 201 (1933).

Neither of these reactions should require a preactivation energy. Cramer[35] has concluded that in the recombination of ethyl radicals in benzene solution disproportionation (4.2) predominates over coupling (4.1).

Chain Branching and Molecular Weights.—That each polymer molecule has on the average one double bond has been shown by Staudinger and Steinhofer[36] for catalytically polymerized polystyrene, and by Whitby,[37] for polyindene. In both instances this observation has been advanced in an effort to prove particular mechanisms for the polymerization processes. Regardless of the mechanism of the polymerization, if extraneous substances (including solvents) are either completely absent or do not participate in the polymerization, and if no cyclic structures or triple bonds are formed, the polymerization of a monovinyl compound must yield a mixture of molecules having an average of one double bond each. Consequently, the formation of unsaturated polymer molecules in vinyl polymerizations is inevitable and not an indication of the mechanism involved.

Theoretically, a polymer molecule bearing a double bond is susceptible to reaction with a free radical according to (2), and thus a polymer molecule may be included as one member of a polymerization chain; thus, for example



$$\mathrm{M}_m\text{—CH}_2\text{—CHR— } + \mathrm{M}_n\text{—CH=CHR} \longrightarrow \mathrm{M}_m\text{—CH}_2\text{—CHR—}\overset{\mathrm{M}_n}{\overset{|}{\text{CH}}}\text{—CHR—}$$

The frequency of the formation of branched chain molecules in this way must depend upon the relative reactivities with respect to (2) of the double bonds in polymers and those in monomers, and upon the relative numbers of polymers and monomers. If chain transfer proceeds according to (3.3), occasionally a free radical active center may be transferred to some point along the chain of a previously formed polymer molecule; subsequent growth from this center would also yield a branched chain. The possibility that inactive polymer molecules may participate in the subsequent polymerization is implied by both chain branching mechanisms. Houtz and Adkins[38] have presented experimental evidence to show that polystyrene added to polymerizing monomer actually does undergo further polymerization. The results of Staudinger and Frost[4] on the relative viscosities of solutions of polystyrene obtained at various stages of the polymerization show a slight increase as the reaction progresses, which may be an indication of an increase in molecular weight due to participation of "inactive" polymer in the subsequent polymerization. Staudinger and Schulz[23] have observed that a series of polystyrenes prepared at different temperatures deviate from strict adherence to the Staudinger viscosity law. They attribute this deviation to a particular type of chain branching reaction involving the disruption of the hexatriene bond structure of the phenyl group. Such a reaction would require a great deal of energy, and in the absence of definite evidence it seems preferable to avoid a specific mechanism in favor of the general explanation of chain branching given above.[39]

During the early stages of the polymerization when the quantity of monomer exceeds the quantity of polymer, branched chain molecules must be few. The average degree of polymerization should not differ appreciably from λ and the distribution of molecular sizes derived by Schulz[13,40] should prevail. At later stages of the polymerization the occurrence of chain branching may become appreciable. If so, *D. P.* will exceed λ and the distribution of molecular sizes will deviate from Schulz's distribution theory. If, as Staudinger claims, the viscosity of a dilute solution of polymer depends upon the length of the molecule and is independent of its lateral dimensions, the apparent viscosity molecular weight should no longer be proportional to *D. P.*

Since this article was submitted Schulz and Husemann[41] have published a comprehensive paper on the kinetics of styrene polymerization. Their basic concepts of the polymerization mechanism, the same as previously published by Staudinger and Frost[4] and by Schulz,[13] differ principally from those presented in this paper in that they do not include reaction (3). The kinetics of the conversion of monomer to polymer, which depends only upon (1), (2) and (4), should be essentially the same regardless of which interpretation is adopted. However, the equations given above

(38) Houtz and Adkins, This Journal, **55**, 1609 (1933).

(39) From measurements of streaming double refraction, Signer [*Helv. Chim. Acta*, **19**, 897 (1936)] has shown recently that Staudinger and Schulz's polystyrenes prepared at higher temperatures consist of molecules less nearly linear in shape than those prepared at lower temperatures.

(40) This distribution is identical with that obtained by the author [*ibid.*, **58**, 1877 (1936)] for linear condensation polymers, although the equations differ slightly in their form.

(41) Schulz and Husemann, *Z. physik. Chem.*, **B34**, 187–213 (1936).

differ a great deal from those given by Schulz and Husemann. The source of the dissimilarity lies in the different expressions obtained for the concentration of active centers, namely, equation (7) in this paper and their equation (12). The latter is incorrect for chain reactions in which the active centers are simultaneously created and destroyed.

From their experimental measurements they have derived 23.2 kcal. for the quantity herein designated as E_a. From the same data as quoted here, they obtain 5.7 kcal. for "Q," which according to the method of evaluation is equivalent to $E_3 - E_2$. These values are in good agreement with the ones given above. The present interpretation of these quantities is much different, however; *e. g.*, Schulz and Husemann regard E_a as equal to the activation energy of (1). Consistent interpretation according to the mechanism which they assume leads to $Q = 5.7$ kcal. $= E_4 - E_2$. That the activation energy E_4 for the reaction of two free radicals with one another should exceed the activation energy E_2 for the reaction of a free radical with a monomer molecule seems exceedingly unlikely.

The author is particularly indebted to Drs. Wallace H. Carothers and Elmer O. Kraemer for their valuable criticisms of this work.

Summary

A mechanism consisting of the four processes, (1) chain initiation, (2) chain propagation, (3) chain transfer and (4) destruction of active centers, has been proposed to account for the known characteristics of typical vinyl polymerizations. The free radical active centers must of necessity be both created (1) and destroyed (4) in pairs. The previously proposed process of coupling of monomers to the free radical through the opening of the double bond has been adopted for chain propagation (2). A chain transfer process (3), whereby the active center is transferred from one polymer molecule to another molecule, leaving the former "inactive" and endowing the latter with the ability to add on monomers successively (2), has been introduced in order to account for the independence of molecular weight on number of active centers.

Upon the basis of this mechanism, the kinetics of the conversion of monomer to polymer has been subjected to a theoretical analysis and equations have been derived to represent the course of the conversion. These are in satisfactory agreement with the limited available experimental data. The variation of relative molecular weight with temperature is in excellent agreement with the proposed mechanism for vinyl polymerizations.

Activation energies of the individual processes have been estimated from experimental data; the approximate values are: for styrene $E_1 = 32$ kcal., $E_2 = 6$ kcal., and $E_3 = 12$ kcal.; for vinyl acetate, $E_1 = 35$ kcal., $E_2 = 5$ kcal. and $E_3 = 9$ kcal.; for methyl methacrylate $E_1 < 20$ kcal. It has been assumed that $E_4 < 5$ kcal. in consideration of the ease with which two free radicals should inter-react. Heats of polymerization, ΔH_p, have been calculated for a number of unsaturated compounds from the recent thermochemical data of Rossini and Kistiakowsky and co-workers. For all types of mono-olefins $\Delta H_p = -23\ (\pm 1)$ kcal.; for conjugated diolefins (styrene included) $\Delta H_p = 20$ kcal.

In the light of their activation energies probable mechanisms for the individual reactions have been presented. The occasional formation of branched chain molecules is theoretically probable.

Ammonia. The Heat Capacity and Vapor Pressure of Solid and Liquid. Heat of Vaporization. The Entropy Values from Thermal and Spectroscopic Data

BY ROY OVERSTREET AND W. F. GIAUQUE

In a former communication, Giauque, Blue and Overstreet[1] showed that the existing low temperature calorimetric data on ammonia lead to an entropy value about one cal./deg. per mole greater than the value obtained from band spectrum observations. The purpose of this research has been to obtain accurate calorimetric data in the hope of eliminating the discrepancy. As was expected, the inconsistency was found to be due chiefly to the inaccuracy of the existing calorimetric data.

Preparation of Ammonia.—The ammonia used in this investigation was prepared by the action of a saturated solution of potassium hydroxide on C. P. ammonium chloride. The gas was subjected to a preliminary drying by conducting it slowly through a vertical glass column, approximately one meter in length, containing broken sticks of potassium hydroxide. The ammonia issuing from the column was condensed over sodium in one of a series of glass distillation bulbs by means of solid carbon dioxide in ether. Approximately 250 cc. of liquid was prepared in this manner. After standing over sodium for twelve hours, the substance was then distilled five times. In each case the first 10 cc. of distillate and the final 10 cc. portion was discarded. Following each distillation, the gas was cooled to the temperature of liquid air and the line was evacuated to 10^{-5} mm.

The amount of liquid-soluble solid-insoluble impurity was estimated to be not more than one mole in one hundred thousand. This estimate was made on the assumption that the slight rise in heat capacity below the melting point was due to premelting. The single high observation given later in Table IV was confirmed by several measurements, not included, over smaller temperature intervals just below the melting point.

Apparatus.—The measurements were carried out in Gold Calorimeter II[2] which was rebuilt and described by Blue and Giauque.[3] A full description of a calorimeter of this type has been given by Giauque and Egan.[4]

The temperature scale was obtained from the copper-constantan thermocouple of laboratory designation "W."[5] The thermocouple, which was originally compared with a hydrogen gas thermometer, has been compared frequently with the oxygen and hydrogen vapor pressure thermometers. The latest comparison, made after the completion of this work, gave the following corrections to be added to the original calibration made nine years before: 0.01° at the boiling point of oxygen, 90.13° K., 0.11° at the melting point of oxygen, 54.39° K., 0.13° at the 43.76° K. transition of oxygen, 0.15° at the boiling point of hydrogen 20.37° K. and 0.17° at the triple point of hydrogen, 13.95° K. These corrections were employed in the temperature scale used in this research. The gold resistance thermometer-heater, used for greater calorimetric precision and accuracy, was calibrated continuously during the measurements by comparison with the thermocouple.

The Vapor Pressure of Ammonia.—The vapor pressure was determined by means of a manometer which could be connected directly with the calorimeter. A cathetometer was used as a comparison instrument with a standard meter mounted in the manometer case. The vapor pressure observations on solid ammonia from 176.92°K. to the melting point, 195.36°K., have been represented by the equation

$$\log_{10} P \text{ (int. cm. Hg)} = -1630.700/T + 9.00593 \quad (1)$$

For liquid ammonia from 199.26 to 241.59°K.

$$\log_{10} P \text{ (int. cm. Hg)} = -1612.500/T - 0.012311\ T + 0.0000125217T^2 + 10.83997 \quad (2)$$

In Table I the observed values are compared with those given by equations 1 and 2. The pressure observations are corrected to international centimeters of mercury by means of data given in the "I.C.T."[6] The standard acceleration of gravity was taken as 980.665 cm./sec.². The gravitational acceleration, 979.973 cm./sec.² has been determined for this location by Sternewarte.[7] Because of the high relative accuracy, which could be obtained with the resistance thermometer, the temperatures for the liquid are given to 0.001°. The absolute error may be as high as several hundredths of a degree.

From equation 2 the boiling point was calculated to be 239.68°K.

The deviations given in the third column of Table I were calculated by assuming that the temperature observations were correct. The deviations given in the fourth column of the table were calculated assuming that the pressures were correct.

TABLE III

MELTING AND BOILING POINT TEMPERATURES OF AMMONIA

M. p., °K.	B. p., °K.	Observer
....	239.90	Keyes and Brownlee[8] (1918)
195.40	239.75	Cragoe, Meyers and Taylor[9] (1920)
....	239.74	Henning and Stock[10] (1921)
195.5	....	Eucken and Karwat[11] (1924)
195.36	239.68	This research

As may be seen from Table III the melting and boiling point temperatures agree fairly well with those obtained by Cragoe, Meyers and Taylor[9] and by Henning and Stock.[10] The latter authors did not make observations at the melting point but by substituting the observed triple point pressure in their vapor pressure equation the value 195.39°K. is found as compared to the present observation of 195.36°K.

The present value obtained for the boiling point is 0.07° below that of Cragoe, Meyers and Taylor and 0.06° below that of Henning and Stock.

The agreement is perhaps all that can be expected when one considers the possible errors of the several experimenters. The gas thermometer scale calibration by Giauque, Buffington and Schulze,[5a] of the thermocouple used in the present work, was estimated by those authors to be accurate to ±0.05°. However, high relative accuracy was obtained by means of the resistance thermometer which was read with a scale giving about 10^4 mm. per degree. The resistance thermometer was calibrated by comparison with the thermocouple at frequent intervals over a wide temperature range.

The value, 4.558 cm., given for the triple point pressure is in good agreement with an observation of Bergstrom[11a] who obtained 4.55 cm. Also by putting the melting point observation of the present research in the vapor pressure equation of Henning and Stock one obtains the value 4.55 cm. The observation, 4.49 cm., of Cragoe, Meyers and Taylor is evidently in error. Putting their value for the melting point, 195.40°K., into their vapor pressure equation one obtains 4.53 cm.

The Heat Capacity of Ammonia.—The heat capacity results are given in Table IV. For the calculation of energy, 1.0004 absolute joules were taken equal to 1 international joule and 4.185 absolute joules were taken equal to 1 calorie. The data are shown in Fig. 1. The heat capacity of ammonia has been measured by Eucken and Karwat[11] and by Clusius, Hiller and Vaughen.[12] In Table V are recorded heat capacity values picked from a smooth curve through the observations. Since Eucken and Karwat have prepared a similar table, deviations from their data are included. Deviations from the data of Clusius, Hiller and Vaughen are not included, since their investigations were carried out, for the most part, at temperatures below 20°K. However, their data at higher temperatures are too high by

Heat of Fusion.—Determinations of the heat of fusion of ammonia are given in Table VI. With the temperature slightly below the melting point, heat was added until all of the substance was melted and the liquid heated slightly above the melting point. Correction was made for the $\int C_p dT$ and the premelting effect. It is interesting to compare the value for the heat of fusion obtained in this research with that calculated by Eucken and Donath[13] from measurements of the heat of sublimation and heat of vaporization near the melting point. By a small extrapolation of their heat of condensation measurements, they have calculated the difference between the heat of sublimation and the heat of vaporization at the melting point to be 1380 ± 8 cal. Considering the large quantities of heat dealt with, the agreement between their value and the value of this research is good.

TABLE VI

HEAT OF FUSION OF AMMONIA

Eucken and Donath,[13] from heats of sublimation and heat of vaporization			1380 ± 8
From vapor pressure equations of this research, assuming a Berthelot gas			1376

Heat of Vaporization.—The heat of vaporization was measured by adding energy and determining the amount of gas evolved. The ammonia was vaporized against a constant pressure, which was slightly above atmospheric pressure. A small correction was applied to obtain the value corresponding to 760 mm. A summary of the data is given in Table VII. Osborne and Van Dusen[14] have measured the heat of vaporization of ammonia through the range −42 to +52°. The value 5573 interpolated from their data is in excellent agreement with the value obtained in this research.

It has been of interest to calculate the heat of fusion and the heat of vaporization from the vapor pressure data. This has been done by assuming that Berthelot's equation of state can be used to correct for gas imperfection. The values are included in Tables VI and VII. The agreement with the experimental values is sufficiently close to justify the use of Berthelot's equation for the calculation of the entropy correction for the actual to the ideal gas states.

.38839	110	5589
.37590	100	5575
	Mean	5581
Osborne and Van Dusen		5573
From vapor pressure equation 2, assuming a Berthelot gas		5614

Measurement of Amount of Ammonia.—All amounts were measured gravimetrically. The gas vaporized during the heat of vaporization runs was absorbed in 6 N sulfuric acid and weighed. The absorption bulbs were of 110-cc. capacity. All necessary precautions were taken to avoid loss of moisture from the bulb to the outside or the gain of moisture in the bulb from the outside. Following the heat of vaporization runs, the remainder was absorbed in a large absorption bulb (800 cc.) containing 6 N sulfuric acid and weighed. The small amount of gas remaining in the apparatus was calculated from the pressure and volume.

The Entropy from Calorimetric Data.—The entropy was calculated by graphical integration of $\int_0^T C_p \, d \ln T$ plus the entropies of fusion and vaporization. The entropy correction for gas imperfection was made using Berthelot's equation of state and the thermodynamic equation

$$\left(\frac{\partial S}{\partial P}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_P \quad \text{from which}$$

$$\Delta S = S_{\text{ideal}} - S_{\text{actual}} = 27RT_c^3P/32T^3P_c$$

$T_c = 406.0$°K.[15] and $P_c = 112.3$ atmospheres[15]

Then $\Delta S = 0.07$ e. u. at the boiling point of ammonia. The entropy calculation is summarized in Table VIII.

The Entropy of Ammonia from Spectroscopic Data.—The translational entropy of ammonia was obtained from the Sackur–Tetrode equation

$$S_T = 3/2R \ln M + 5/2\, R \ln T - R \ln P + 5/2\, R + R \ln (2\pi k)^{3/2}/h^3N^{5/2} + R \ln R \quad (3)$$

$$= 3/2R \ln M + 5/2\, R \ln T - R \ln P + 4.967 - 16.024 + 8.757 \quad (4)$$

TABLE VIII

CALCULATION OF THE ENTROPY OF AMMONIA

0–15°K., Debye function $h c \nu / k$ = 210	0.056
15–195.36°K., Graphical	10.16
Fusion 1351.6/195.36	6.919
195.36–239.68°K., Graphical	3.646
Vaporization 5581/239.68	23.29
Entropy of actual gas at boiling point	44.06 ± 0.10 cal./deg. per mole
Correction for gas imperfection	0.07
Entropy of ideal gas at boiling point	44.13

R = 1.9869 cal./deg. per mole. The values of all natural constants are those given in the "I. C. T."[6] The remaining entropy was evaluated by means of the equation

$$S = R \ln Q + RT \, \mathrm{d} \ln Q/\mathrm{d}T \qquad (5)$$

where $Q = pe^{-\epsilon/kT}$ summed over all states. p is the *a priori* probability and ϵ the energy of the state. For the rotational entropy the approximation

$$Q_R = \frac{1}{\sigma} \times \frac{8\pi^2}{h^3} \times (2\pi kT)^{3/2} \, (I_1 I_2 I_3)^{1/2} \qquad (6)$$

was used, where σ is the symmetry number and I_1, I_2 and I_3 are the principal moments of inertia. Therefore

$$S_R = R/2 \ln I_1 I_2 I_3 + 3/2 \, R \ln T + R \ln \frac{8\pi^2}{h^3} \cdot (2\pi k)^{3/2} + 3/2R - R \ln \sigma \qquad (7)$$

$$= R/2 \ln I_1 I_2 I_3 + 3/2 \, R \ln T - R \ln \sigma + 267.65 \qquad (8)$$

The moments of inertia have been taken from the observations of Wright and Randall[16] on the pure rotation spectrum of ammonia. Since the molecule is a symmetrical top

$$I_1 = I_2 = 2.782 \times 10^{-40} \text{ g. cm.}^2$$
$$I_3 = 4.33 \times 10^{-40} \text{ g. cm.}$$

The vibrational entropy was calculated by means of equation 5. Ammonia has four normal vibrational frequencies. ν_2 and ν_4 have double *a priori* weights. ν_1 and ν_3 are single. ν_1 = 3335 cm.$^{-1}$ [17] ν_3 = 948 cm.$^{-1}$ [18] ν_4 = 1631 cm.$^{-1}$ [17] ν_2 has never been observed spectroscopically. However, since it is known to be the largest frequency and does not contribute to the entropy below 298.1°K., an estimate of Howard[19] ν_2 = 3450 cm.$^{-1}$ was assumed.

From the above equations and data the entropy of the ideal gas at the boiling point was calculated to be 44.10 cal./deg. per mole. The contribution due to vibration was only 0.05 cal./deg. per mole. The value at 298.1°K. was found to be 45.91 cal./deg. per mole. These values are compared with the experimental results in Table IX.

In making the above calculations the nuclear spin entropy has been ignored. Since the hydrogen atom has a spin of $^1/_2$ and nitrogen a spin of 1 unit, the amount $R \ln 24$ = 6.31 cal./deg. per mole must be added to obtain the absolute entropy which has been included in Table IX for the sake of completeness. The values which do not include the nuclear spin contribution are the ones which should be used in ordinary thermodynamic calculations or compared with experimental values obtained from the ordinary application of the third law of thermodynamics.

TABLE IX

COMPARISON OF EXPERIMENTAL AND SPECTROSCOPIC ENTROPY VALUES OF AMMONIA

	Cal./mole/deg.			
	Spectroscopic		Experimental	
T, °K.	Absolute	Less nuclear spin entropy	Actual	Corrected to ideal state
239.68	50.41	44.10	44.06	44.13
298.1	52.22	45.91	...	45.94

As may be seen from Table IX the value obtained from the third law of thermodynamics is in excellent agreement with that obtained with the assistance of spectroscopic data.

Lewis and Randall[20] have given an equation for the free energy change in the reaction

$$1/2 \, N_2 + 3/2 \, H_2 = NH_3(g)$$

By means of this equation and the known entropies of nitrogen, N_2, $S_{298.1}$ = 45.79[21] and hydrogen, H_2, $S_{298.1}$ = 31.23[22] a value of 46.0 cal./deg. per mole is obtained for the entropy of ammonia at 298.1°K. This value is in excellent agreement with the experimental value 45.94 cal./deg. per mole.

We thank Dr. C. C. Stephenson for assisting with the measurements and many of the calculations.

Summary

The heat capacity of solid and liquid ammonia has been determined over their respective ranges from 15°K. to the boiling point. The melting and boiling points were found to be 195.36 and 239.68°K., respectively.

---

(21) Giauque and Clayton, THIS JOURNAL, **55**, 4875 (1933).

(22) Giauque, *ibid.*, **52**, 4816 (1930).

The heat of fusion is 1351.6 cal./mole. The heat of vaporization at the boiling point is 5581 cal./mole.

The vapor pressure of solid and liquid ammonia has been measured and the data have been represented by the equations: solid ammonia 176.92 to 195.36°K. $\log_{10} P$ (int. cm. Hg) $= 1630.700/T + 9.00593$; liquid ammonia 199.26 to 241.59°K. $\log_{10} P$ (int. cm. Hg) $= -1612.500/T - 0.012311\, T + 0.000012521 T^2 + 10.83997$.

The molal entropy of the gas at the boiling point has been calculated by means of the third law of thermodynamics and the experimental data. The value found, 44.13 ± 10 e. u., is in excellent agreement with the value 44.10 e. u. calculated from spectroscopic data.

From band spectrum data the entropy of ammonia at 298.1°K. and 1 atmosphere was calculated to be 45.91 cal./deg. per mole.

The above entropy value, which should be used in ordinary thermodynamic calculations, does not include the nuclear spin entropy. The absolute entropy is 52.22 cal./deg. per mole.

The Relative Atomic Weight of Oxygen from Air and Water Determined by an Interchange Reaction

BY THOMAS O. JONES AND NORRIS F. HALL

An important difference in the composition of oxygen from the air and from water has been brought to light recently both in America and in Japan,[1] and this has been confirmed subsequently[2] by others. Various somewhat questionable assumptions and methods incident to the earlier papers have been discussed by Smith and Matheson,[2] but there seems little doubt of the reality of the difference, which readily accounts for certain otherwise unexplained results of workers other than the discoverers.[3] All of the results referred to above were obtained by burning elementary hydrogen with different sorts of oxygen, and electrolytic methods were generally employed to produce one or both of the gases.

We have now demonstrated this important effect by a method which involves neither electrolysis nor combustion, and which may prove practical for the preparation of large quantities of water abnormal as to its O^{18} content. The equilibrium between water and oxygen

$$2H_2O^{16} + O_2^{18} = 2H_2O^{18} + O_2^{16}$$

if established at low temperatures would, according to Dole,[1a] account for the observed difference. On the other hand, it is found, using the methods outlined by Urey and Greiff,[4] that at *high* temperatures the constant of this reaction closely approaches unity (at 1000°A., K is 1.0038, at 1500°A., K is 1.0002, at 2500°A., K is 1.0004), and that the departure of oxygen from a perfectly random atomic distribution in the three molecular forms is negligible in this temperature range.

Consequently, at 1500°A., for example, the O^{18}/O^{16} ratio of a sample of water in equilibrium with a large excess of air should be *the same* as in the air within 0.1 γ (water density at 25°) and within 0.09 γ at 2000°A. These differences are less than the probable error of the density determination. If then a sample of ordinary water were vaporized, heated with excess air and recondensed, its density should measurably increase, provided (a) air oxygen is really heavier and (b) there is an approach to equilibrium. The D/H ratio should remain unaffected.

Assuming that 7 γ is the correct value of the Dole effect for surface water, the equilibrium density increases to be expected are roughly

Experimental

In a first series of runs a large excess of cleaned air was passed through samples of ordinary water at room temperature with entirely negative results. (Average change of density in five runs lasting three to six days each $+0.3\ \gamma \pm 0.5\ \gamma$.)

In series 2 (4 runs at 100°) the results were also negative. Here air was bubbled through boiling water which was condensed and frozen out of the air stream and continuously returned to the flask. The average density change was $+0.15\ \gamma \pm 0.35\ \gamma$.

Since it seemed possible that the exchange might be promoted by catalysts of the type on which the reaction of oxygen and hydrogen is known to occur, steam and air were passed in series 3 over finely divided palladium, platinum, and platinum and silver oxide mixtures on asbestos. The results were again entirely negative. No significant changes in density were observed in nine days of treatment at temperatures up to 300°.

After this work was finished, we learned that W. Heinlen Hall and Johnston[2b] (p. 1922) had already reached the conclusion that "an exchange reaction between steam and molecular oxygen does not appear to be significantly catalyzed by platinum at 300°."

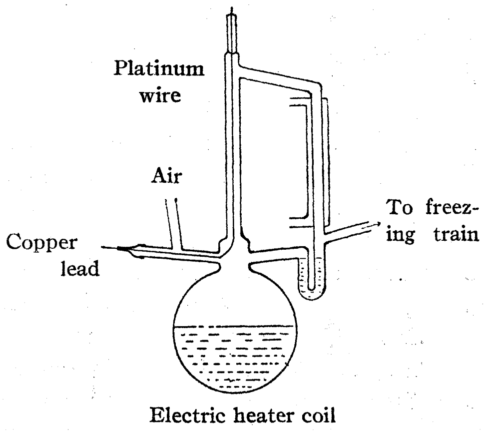

Fig. 1.—Equilibrator.

It now seemed quite likely that a much higher temperature would be required for activation. An apparatus was accordingly constructed which facilitated passing clean (dried) air together with steam over a platinum wire heated by an electric current to temperatures ranging from 1500°A. to 1800°A. (Fig. 1). A single strand of no. 30 wire about 25 cm. long was hung vertically under slight tension between bare copper leads in the center of an 8-mm. glass tube connected to a flask of water heated to 90–95°. The volume of the water samples was 100–110 cc. Air was admitted through a side-arm above the water surface. After passing the hot wire the bulk of the water vapor was condensed immediately from the air stream and returned to the original sample. That water which remained in the air stream was caught by means of a freezing train and also returned to the flask. The air flow was constant and limited to a rate such that nearly all the vapor could be removed in the freezing train. The loss of water in six days of treatment was less than 1%, a loss so small that it could not account for the changes in density observed. The quantity of air which passed over the wire with the water and the rate of reaction at 1800°A. were such that equilibrium was apparently established within three days. In each determination the time allotted was from two to three times this period. The rate of air flow was approximately 15 liters per hour. The temperature of the wire was determined by means of an optical pyrometer. In this series four samples of ordinary water were run under the regular conditions as described above with the wire heated to approximately 1800°A. Two other samples were run under exactly the same conditions as the first four except that the temperature of the wire was set at 1500 and 1600°A., respectively. Each sample was purified carefully and its density determined by means of a magnetic swimmer as described in a previous paper.[3a] The results are given in Table II.

5	1600	6	3.2
6	1500	6	3.3

[a] Sample 4a was replaced in the apparatus and equilibrated again for three days (becoming sample 4b). The slight increase in density was within the experimental error in the determination, indicating that equilibrium had been reached in the previous trial.

The results at lower temperatures (samples 5 and 6) were obtained with all other conditions unchanged and indicated that at 1600°A. about twenty-five days instead of three would be required for complete equilibrium and about sixty days at 1500°A. These data do not permit the calculation of the activation energy, because the limiting factor in attaining equilibrium at 1800°A. was that at any one instant the quantity of air in contact with the steam was limited. The great increase in the time required indicated, however, that the velocity of the reaction is greatly reduced by this reduction in temperature. From the fact that high temperature appears to be the necessary condition for the reaction, it may be presumed to depend on thermal dissociation rather than on activated adsorption.

This technique appears to make possible the easy preparation in a few days of considerable quantities of water whose slightly high density is due to oxygen alone. This aspect of the problem is now being studied further. An unknown sample of water may be normalized by this method (with respect to air oxygen rather than to a standard water) as an alternative to treatment with equilibrated carbon dioxide, sulfur dioxide, etc.[5]

We are indebted to the Research Committee of the University and to the Wisconsin Alumni Research Foundation for grants in aid of this work.

Summary

It has been found that the exchange equilibrium between water vapor and oxygen is rapidly established on a hot wire at 1800°A. and above, but much more slowly at lower temperatures. Water thus equilibrated with excess air increases in density by about 7 p. p. m., and the Dole effect is confirmed. Oxygen-abnormal water may be prepared conveniently by this method, and the oxygen isotope ratio of an unknown sample may be studied with its aid.

MADISON, WIS. RECEIVED DECEMBER 2, 1936

---

[5] Dr. Charles H. Greene kindly writes as follows (December 22, 1936): "There is a small error in your result. The hot platinum in your apparatus brings the water vapor to the same isotopic composition as atmospheric oxygen. Water vapor, however, is slightly richer in O^{16} than the liquid water with which it is in equilibrium. Thus the liquid water in your apparatus, after equilibrium is attained, will be somewhat richer in O^{18} than atmospheric oxygen. From the results of Wahl and Urey, *J. Chem. Phys.* **3**, 411 (1935), I estimate the effect as 0.9 ± 0.3 p. p. m. This correction would bring your results into very good accord with our own."

If Dr. Greene's correction is accepted, our value of the Dole effect for liquid fresh water becomes 6.1 γ, assuming that complete equilibrium was reached.

The Oxybromides of Silicon

BY WALTER C. SCHUMB AND CAROLYN H. KLEIN

Although considerable information has been gathered concerning the oxychlorides of silicon,[1] little was known of the oxybromides of that element at the outset of this research. An investigation of the oxybromides of silicon was begun in 1934, with the object of isolating an homologous series of these compounds.

Of the various methods previously employed in the preparation of the oxychlorides, the ones which appeared most promising for adaptation to oxybromide preparation were the oxidation of the silicon tetrahalide, and the reaction of a mixture of oxygen and the halogen on silicon. In addition to these two successful methods, we have made studies of the oxidation of hexabromodisilane Si_2Br_6, silicobromoform $SiHBr_3$, and of Si_2OBr_6, as well as the effect of ozone and of silver oxide on silicon tetrabromide.

I. The Reaction of a Mixture of Oxygen and Bromine with Silicon and with Calcium Silicide.—The apparatus used in a study of the simultaneous effect of oxygen and bromine on silicon was similar to that used by Gattermann[2] for the preparation of silicon tetrabromide. A stream of oxygen, dried with calcium chloride, was bubbled through a trap of bromine (at 55°) at a rate of about 3 liters per hour (a velocity such that some oxygen bubbled through at the exit of the apparatus). The mixture of oxygen and bromine resulting was then passed over commercial silicon (averaging 97.5% Si) heated by a gas furnace to the desired temperature, about 700°. The product of the reaction was collected in a trap cooled in ice water.

The crude product was distilled fractionally, the excess bromine and silicon tetrabromide passing off first, followed by higher boiling material, which was collected up to 225° under a high vacuum. After repeated fractionation with an efficient column a separation of the compounds present in the mixture was effected. The combined results of two experiments, together with the formulas of the compounds isolated and identified by methods described below, are collected in Table I.

These substances all hydrolyze in the presence of moisture of the air, the speed being directly proportional to the volatility of the compound. They are miscible in all proportions with carbon tetrachloride, carbon disulfide, chloroform, and silicon tetrabromide. With the exception of the first and third, they have not been reported previously in the literature, and the two which were reported were prepared independently and by a different process.[3]

In order to determine the effect of a lower reaction temperature on the products formed, calcium silicide was used in another experiment in place of silicon, it being known that certain silicides react more readily with halogens at a lower temperature than does silicon itself. The reaction was carried out at a temperature of 180 to 200°, but in this case the product consisted almost wholly of hexabromodisilane, oxybromides being formed only in minute amounts. Evidently, in spite of an excess of oxygen, a Si–Si bond formed in preference to a Si–O–Si linkage.

Incidentally, the procedure just mentioned constitutes a far more satisfactory method of preparation of Si_2Br_6 than any hitherto described, as the yield is almost quantitative.

TABLE I

Fraction	Appearance	Approx. no. g.	Approx. %	B. p., °C.	B. p., Mm.	F. p., °C.	Formula
I	Colorless liquid readily freezing to colorless tabular crystals	100	20.6	118	15	27.9 ± 0.1	Si_2OBr_6
II	Colorless liquid freezing in ice water to colorless solid	240	49.4	159	12	17.5 ± 0.2	$Si_3O_2Br_8$
III	Heavy white solid melting to colorless liquid	5	1.0	155	7	123–123.5	$Si_4O_4Br_8$
IV	Colorless liquid becoming very viscous on cooling and freezing to a glassy solid	60	12.4	122	<0.5	−91 ± 2°	$Si_4O_3Br_{10}$
V	Same	50	10.3	150	<0.5	−82 ± 2°	$Si_5O_4Br_{12}$
VI	Heavy colorless oil freezing in liquid air to glassy solid	30	6.2	160–180	<0.5	< −78°	Higher residue

II. The Reaction of Silicon Tetrabromide with Oxygen.—The silicon tetrabromide employed for the oxidation was prepared according to the method of Gattermann[2] by entraining bromine in a stream of carbon dioxide, and passing the resulting mixture over heated silicon. The oxidation of the tetrabromide was studied, early in the course of this research, between the temperatures 800 and 900°. It was found that, although the rate of oxidation was slow, the reaction proceeded all of the way to the formation of silica.

That further study of this reaction would be desirable was realized, but before this was accomplished a paper by Rheinboldt and Wisfeld[3] appeared, in which the results of their study of the same reaction are given. These workers found that the optimum temperature range for the formation of oxybromides is 670 to 695°; above this the reaction progresses to silica. Two oxybromides only were isolated by them, Si_2OBr_6 (m. p. began at 26.5°, but mostly at 28.5°, b. p. approx. 120° at 15 mm.) formed in small quantities, and $Si_4O_4Br_8$ (m. p. began at 121.5° but mostly at 123.5°, b. p. 170° at 15 mm.), formed in large quantities. The work of these authors was repeated and the results obtained are summarized in Table II.

TABLE II

Fraction	Product G.	Product %	Formula
I	18	14.4	Si_2OBr_6
II	37	29.6	$Si_3O_2Br_8$
III	38	30.4	$(SiOBr_2)_4$
IV	13	10.4	$Si_4O_3Br_{10}$
V	12	9.6	$Si_5O_4Br_{12}$
VI	7	5.6	Higher residue

From this table it can be seen that $(SiOBr_2)_4$, formed only as a trace by the simultaneous action of oxygen and bromine on silicon, is obtained in large amounts by the oxidation of silicon tetrabromide, a fact which is in agreement with the results reported by Rheinboldt and Wisfeld. It is apparent, however, that appreciable quantities of several other compounds, not reported by them, are also formed in the reaction. The purification and analysis of these compounds is described below.

III. Other Methods Studied

a. Oxidation of Hexabromodisilane, Si_2Br_6.—Since oxybromides may be prepared by the oxidation of silicon tetrabromide, it was thought that the oxidation of such substances as hexabromodisilane and silicobromoform might be of interest. The Si–Si bond present in Si_2Br_6 would be expected to break to admit oxygen more readily than the Si–Br linkage of the tetrabromide. When, however, oxygen was bubbled through the hexabromodisilane (prepared as described in Section I), which was heated to 230 to 250°, and the resulting mixture was passed back and forth through a tube heated electrically to the desired temperature, it was found that below 250° oxidation is negligible, and above this temperature silicon tetrabromide and silica are formed. In a typical experiment, with the Si_2Br_6 kept at 250°, the oxygen stream at a rate of 3 liters per hour, and the furnace temperature 300°, in the course of seven hours, 10 g. of Si_2Br_6 was decomposed to form silicon tetrabromide and silica. The reaction is evidently $2Si_2Br_6 + O_2 = 3SiBr_4 + SiO_2$.

b. Oxidation of Silicobromoform, $SiHBr_3$.—In 1868 A. J. Besson reported that in the preparation of silicobromoform from silicon and hydrogen bromide he noted the formation of a trace of material crystallizing in yellow platelets, and, since some air got into his apparatus during the reaction, he thought this substance probably was an oxybromide of silicon. Consequently it was decided to study the oxidation of silicobromoform in some detail in the hope of isolating this yellow material. The silicobromoform was prepared by passing a stream of hydrogen bromide over heated silicon.[4]

Dry air was bubbled at a rate of about two liters an hour through a solution containing 10 g. of silicobromoform, diluted with an equal volume of silicon tetrabromide to retard the reaction, and the exit tube for the gas was protected by a drying tube. The mixture in the trap was warmed gradually to 90°, at which temperature a deposit of the appearance of silica gradually precipitated, but no yellow color appeared. The reaction was accompanied by a slow evolution of hydrogen bromide, and distillation of the material in the trap showed the other products to be silicon tetrabromide, silicon dioxide, and a white solid (probably silicoformic anhydride), which exploded on impact. The formation of this could be explained as due to the hydrolysis of silicobromoform by the water formed as a product of the oxidation of silicobromoform.

c. The Reaction between Silver Oxide and Silicon Tetrabromide.—About 80 g. of silicon tetrabromide was refluxed slowly with 20 g. of silver oxide (dried for twenty-four hours at 75°, two hours at 120°, and one hour at 140°). The dark brown color of the silver oxide slowly disappeared, being replaced by the yellow color characteristic of silver bromide, and at the end of thirty hours the process was completed. Distillation of the product showed that the reaction had gone quantitatively according to the equation

$$2Ag_2O + SiBr_4 \longrightarrow 4AgBr + SiO_2$$

---

[4] See W. C. Schumb and R. C. Young, THIS JOURNAL, **52**, 1464 (1930).

With the hope of stopping the action intermediately, the experiment was repeated with the tetrabromide diluted with an equal volume of carbon tetrachloride, and the temperature was kept at 80°. After forty hours of refluxing the reaction was completed, but in this case, too, the oxidation had progressed to silica.

d. The Ozonization of Silicon Tetrabromide.—The effect of ozone on silicon halides apparently has not been investigated previously. It was thought that such a reaction might prove interesting, since ozone forms an oxygen linkage between two carbons in certain organic compounds.

A stream of ozonized oxygen (8% ozone) was bubbled at a rate of about 3 liters an hour through a trap containing 30 g. of silicon tetrabromide. Since little or no effect was observed at room temperature, the trap was warmed gradually. After a period of two hours at 45°, the solution became pale orange in color, but, since the reaction was so slight, the temperature was gradually raised to 75°, whereupon the color deepened at a noticeable rate. Since this color is necessarily due to bromine set free, dilution with silicon tetrabromide must prevent the reaction of the bromine with the ozone from becoming violent at this temperature.

At the end of twenty hours a few cc. of bromine had collected, and a deposit of a gelatinous-looking solid appeared on the walls of the traps. Distillation showed the products of the reaction to be bromine, silica, and a trace of a high boiling oil. In the hope of increasing the amount of the latter, ozonization of silicon tetrabromide was repeated with the addition of a diluent. For this purpose carbon tetrachloride was chosen, since it is unreactive with ozone. After thirty hours, with a mixture of equal volumes of silicon tetrabromide and carbon tetrachloride kept at 40°, sufficient oxidation had occurred to warrant a distillation of the product. The results obtained, however, did not differ materially from those found in the first trial.

e. Thermal Decomposition of Si_2OBr_6.—Several articles relating to the formation of higher oxychlorides from Si_2OCl_6 appeared in 1876.[5] Since large quantities of Si_2OBr_6 were already available, the effect of oxygen on this compound was tried, the method employed being identical with that used for the oxidation of hexabromodisilane. It was found that there was no reaction below 200°, at which temperature an exceedingly slow action occurs, resulting in the formation of silicon tetrabromide and silica, together with a trace of a high boiling oil. The rate of decomposition gradually increases as the temperature is raised, but even at 260°, close to the boilingpoint of the oxybromide, the reaction is very slow.

Any reaction occurring obviously is not an oxidation process, since no bromine is set free; it evidently proceeds for the most part according to the equation $2Si_2OBr_6 = 3SiBr_4 + SiO_2$, and to a very small extent in this manner: $4Si_2OBr_6 = 3SiBr_4 + Si_5O_4Br_{12}$. In either case the oxygen used plays no part in the process and any inert gas should serve as well; as was shown experimentally to be the case.

Purification of Products and Freezing Point Determinations.—The purification of fractions II, IV and V (Table I) was effected entirely by repeated fractional distillations. The type of column which proved most satisfactory was a two-foot (60 cm.) vapor-jacketed column of the Podbielniak type, with a solid glass spiral fitted into a Pyrex tube (outside diameter 8 mm.). For the purification of fraction I partial crystallization from its own liquor was used, as well as distillation. In the case of number III, fractional distillation was followed by two crystallizations from carbon disulfide, the crystals being separated from the solution in the absence of moisture by means of a sintered glass plate, and washed with fresh solvent.

Of the physical constants of the compounds obtained tabulated in Table I, the freezing points were quite sharp with the first three compounds, but some difficulty was experienced in obtaining accurate values in the case of the last two compounds. These liquids became increasingly viscous on cooling to the temperature of solid carbon dioxide, and upon immersion in liquid air froze to a colorless solid with a glassy appearance. Whether this was due to polymerization of the molecules on cooling is not known, but seems probable. Approximate freezing point determinations of these two compounds were made by immersion in alcohol cooled with liquid air.

Methods of Analysis and Molecular Weight Determinations.—In the analytical work required to establish the composition of the oxybromides prepared in this work, both the bromine and the silicon content were determined, gravimetrically, the former as silver bromide and the latter as silica. The percentage of oxygen was calculated by difference.

Molecular weight values were determined by the Beck-

TABLE III

ANALYTICAL DATA AND MOLECULAR WEIGHTS

Fraction	Si, %	Br, %	Mean ratio Si:O:Br	Mol. wt. (by f. p. method)
I		87.21		
	10.20	86.85	2:0.99:5.98	597
	10.17	86.77		573
Si_2OBr_6	10.14	86.96	2:1:6	552

$Si_4O_3Br_{10}$	11.67	83.33	4:3:10	959
V	12.03	82.33	5:4.05:12.00	1299
	12.02	82.46		1232
				1223
$Si_5O_4Br_{12}$	12.03	82.47	5:4:12	1163
VI	12.14	82.15		
	12.18	82.10	6:5.0:14.4	[a]
$Si_6O_5Br_{14}$	12.28	81.85	6:5:14	1367

[a] The results on this fraction, while less complete and less accurate than the preceding five, strongly indicate the presence of the oxybromide $Si_6O_5Br_{14}$.

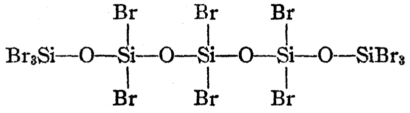
---

[5] L. Troost and P. Hautefeuille, *Ann. chim. phys.*, [5] **7**, 453 1876).

mann freezing point lowering method. Ethylene bromide (Eastman Reagent) which was used as the solvent in the molecular weight work, was dried by allowing it to stand over phosphorus pentoxide for twenty-four hours, after which it was fractionally distilled from fresh drying agent, giving a sample with a boiling point of 129.5 to 130°. The cryoscopic constant of ethylene bromide was taken as 12.50° per mole per 1000 g. of solvent.[6]

The fractions given in the following tabulation refer to those of Table I. The same weight of solvent, 54.73 g. (the contents delivered by a calibrated pipet), was used in each molecular weight determination.

The simplest conceivable oxybromide, $SiOBr_2$, like the corresponding chloride, is probably incapable of existence outside the vapor state, and in the liquid state polymerizes to $(SiOBr_2)_4$, or $Si_4O_4Br_8$. With the exception of $(SiOBr_2)_4$, the compounds are all members of the series of general formula $Si_nO_{n-1}Br_{2n+2}$, of which series $SiBr_4$ itself might be considered as the first member. Although there is evidence of a ring structure for $(SiOBr_2)_4$, the other substances are most probably straight-chain compounds, with an oxygen atom linked between each Si atom, such as



$$Br_3Si{-}O{-}\underset{Br}{\overset{Br}{Si}}{-}O{-}\underset{Br}{\overset{Br}{Si}}{-}O{-}\underset{Br}{\overset{Br}{Si}}{-}O{-}SiBr_3$$

Compounds containing the terminal linkage $-\underset{\displaystyle Br}{\underset{|}{Si}}{=}O$, although logically to be expected, apparently are not realized.

Summary

1. The following series of silicon oxybromides was prepared: $(SiOBr_2)_4$, Si_2OBr_6, $Si_3O_2Br_8$, $Si_4O_3Br_{10}$ and $Si_5O_4Br_{12}$, definite indication of the existence of $Si_6O_5Br_{14}$ (and perhaps of higher oxybromides) also being shown. All but the first compound belong to the homologous series $Si_nO_{n-1}Br_{2n+2}$. The compounds all hydrolyze readily in the presence of moisture, the rate of hydrolysis decreasing with a decrease in volatility. They are miscible in all proportions with CS_2, CCl_4, $CHCl_3$ and $SiBr_4$.

With the exception of the first two compounds (which were prepared independently in the present work, and by independent methods) these substances have not been reported previously, nor has as complete a series of any other silicon oxyhalides been prepared.

2. With the hope of obtaining oxybromides of silicon, the following reactions were studied: A, the simultaneous reaction of oxygen and bromine, both with silicon and with calcium silicide; B, the reaction of silicon tetrabromide with oxygen; C, the oxidation of hexabromodisilane; D, the oxidation and the thermal decomposition of Si_2OBr_6; E, the reaction of silicobromoform with oxygen; F, the effect of silver oxide on silicon tetrabromide; G, the ozonization of silicon tetrabromide. The first two methods resulted in the formation of large quantities of oxybromides. In no other case were appreciable quantities of oxybromides formed, the reaction progressing all of the way to silicon dioxide.

The Electrode Potential of the Iodine–Iodate Electrode at 25°[1]

BY WALTER O. LUNDBERG,[2] CARL S. VESTLING[3] AND J. ELSTON AHLBERG

The purpose of the present investigation has been to gather additional data necessary to determine more closely the standard potential at 25° for the electrode reaction

$$^1/_2I_2(s) + 3H_2O(l) = IO_3^- + 6H^+ + 5E^-$$

The value of the standard potential available until now is based upon the work of Sammet,[4] but several experimental factors contribute to considerable uncertainty in his results. The most important of these is that he measured the potential of the iodine–iodate electrode at 25° against a normal calomel potassium chloride electrode maintained at 18°. Furthermore, the liquid potentials with which he had to deal were relatively high, ranging up to 0.034 volt. The results of Sammet have been recalculated employing the activity coefficients of hydrogen ion as given by Lewis and Randall[5] and those of iodic

acid as measured by Abel, Redlich and Hersch.[6] The thermocouple effect existent in the cell (+0.005 volt) was calculated from the data of Coggeshall[7] and the proper correction applied. The liquid potentials as calculated by Sammet were employed. The voltage of the normal calomel electrode at 25° was taken to be −0.2822 volt as given by Lewis and Randall.[5] The recalculated results of Sammet are summarized in Table I. Other reviewers[5,8] of the work of Sammet have neglected to take into account the thermocouple effect.

TABLE I

EXPERIMENTAL RESULTS OF RESEARCH BY V. SAMMET[4]: ELECTRODE POTENTIAL OF THE IODINE–IODATE ELECTRODE AT 25°

Reaction: $^1/_2I_2(s) + 3H_2O(l) = IO_3^- + 6H^+ + 5E^-$
Cell employed: Pt, $I_2(s)$, HIO_3 (*xm*), KCl(*xm*), KCl(*N*), HgCl, Hg. Pt, $I_2(s)$, HIO_3(*xm*) at 25°. KCl(*N*), HgCl, Hg at 18°

Concn., mole per liter	0.1	0.01	0.001	0.001[a]
Voltage **E**, observed	−0.784	−0.710	−0.630	−0.666
Mean deviation of **E**	0.001	0.001	0.001	0.001
Liquid junction potential	−0.034	−0.034	−0.034	0.000
Standard potential **E**°	−1.187	−1.190	−1.191	−1.193

[a] For this single measurement the liquid junction was between 0.001 *m* iodic acid and 1 *N* potassium chloride.

In the present investigation the standard potential was determined using inert electrodes of platinized platinum in contact with saturated solutions of iodine in iodic acid at 0.1 and 0.01 *M* concentrations. The potential of this electrode was measured against a hydrogen electrode (both at 25°) in which the concentration of the hydrochloric acid was the same as that of the iodic acid at the other electrode. The liquid junction is of the most simple type and its potentials should be only a few millivolts.

The data presented here when combined with those available in the literature do not at present allow an ultimate evaluation of the standard electrode potential. The principal reason for being unable to do this lies in the fact that the simple expression of Lewis and Sargent[9] (later derived by MacInnes and Yeh[10]) for the potential of the liquid junction existent in the cell employed for these measurements is apparently not strictly applicable. When this expression is employed a discrepany of 0.004 volt exists between the standard potentials calculated from the measurements at 0.1 and 0.01 *M*. The activity coefficients available[6] are strictly only applicable at the freezing points of the corresponding solutions. It is of course possible that the activity coefficients are sufficiently different at 25° to account for the discrepancy. The employment of Planck's equation[11] for the liquid junction potential gives standard potentials which agree very well. However, it is not safe to assume that the expression of Planck is applicable since its derivation restricts its use to extremely dilute solutions. It is also important to note that in the calculation of the standard potential (exclusive of the liquid potentials) it is necessary to assume that the activity of the hydrogen ions at the hydrogen electrode and at the iodine–iodate electrode are the same. Fuoss and Kraus[12] have shown that the electrical conductivities of dilute solutions of iodic acid can be explained upon the basis of the interionic attraction theory (Debye–Hückel) provided one assumes that iodic acid is not completely ionized. They find that its dissociation constant (expressed in terms of activity) must be chosen to be 0.17 to give agreement with experiment. MacInnes and Yeh[10] show that the formula of Lewis and Sargent requires that the electrolytes be ionized completely and that the activities of hydrogen ion be the same in the solutions of iodic and hydrochloric acids. Calculations based upon the above equilibrium constant indicate that at 0.1 *M* the hydrogen ion activities differ to such an extent that the liquid potential cannot be calculated with exactness. However, at 0.01 *M* the equilibrium constant indicates that iodic acid may be considered almost completely ionized (hence the hydrogen ion activities almost equal) and to such an extent that the liquid potential is probably given by the equation of Lewis and Sargent with an accuracy of 0.001 volt.

On several occasions the question has been raised whether the several possible reactions of iodine and its derivatives with water might make for a number of electrode reactions which would interfere with the measurement of the potential of the main reaction in which one is interested. For that reason it is well to emphasize that as long

as all of the substances reacting at *any* electrode are in chemical equilibrium, the measured potentials for the main reaction and all other secondary reactions are the same. Furthermore, if the concentrations of the reactants and products of the secondary reactions are known, their respective standard potentials may be calculated. The above statement may be proved readily from a thermodynamic standpoint by employment of the free energy function or by the use of activities. It is important to note that the free energy changes involved when iodine is added to the iodic acid solutions used in the present measurements are such that the iodic acid concentrations are not appreciably changed. From a practical standpoint they are unchanged.

Experimental

The measurements were carried out in an air thermostat. The temperature within the thermostat, as read from an accurately calibrated mercury thermometer, could be maintained constant at 25° to within 0.02° over periods of several hours. When the thermostat was unattended in the intervals between the periods of observation, temperature deviations of 0.1° were noted. All potential measurements were made with a Leeds and Northrup type K potentiometer. The sensitivity of the galvanometer was such that with the solutions at concentrations of 0.01 *M* or greater, the potential could be easily read with an accuracy of 0.0001 volt.

The hydrogen electrode vessel was essentially the same as that described by Lewis, Brighton and Sebastian.[13] It was constructed of Pyrex glass and contained two electrodes of platinized platinum. In preparing the electrodes the platinum was thoroughly cleaned with strong chromic acid solution and hot concentrated nitric acid, and then was heated almost to white heat in the flame of a blast lamp. A thin coating of platinum black was then applied according to the procedure recommended by Clark.[14] The platinum leads were sealed into the glass, and at no time was mercury used as a seal for either the hydrogen or the iodine–iodate electrodes.

The iodine–iodate electrode vessel was so constructed that it could be filled completely with solution thus completely excluding air. It contained two electrodes of platinized platinum; the platinum coating was of such thickness that the glint of the underlying metal could be seen. In setting up the cell for a set of measurements, a saturated solution of iodine in iodic acid solution was introduced into the cell. None of the stopcocks in the iodine–iodate electrode vessel was greased.

The two electrode vessels were connected by means of an all-glass bridge containing a three-way stopcock. The third arm of the stopcock was used as a drain and also as a point of connection for the calomel cell which was used to check the hydrogen electrode.

Electrolytic tank hydrogen was used for all measurements. The hydrogen was purified by bubbling through a concentrated solution of potassium hydroxide, passed over a copper gauze heated to 450° by an electric furnace, and then through a soda lime tower.

Conductivity water was used in the preparation of all solutions. C. P. iodine was purified by treatment with potassium iodide to remove other halogens, and subsequently by several sublimations.

The iodic acid solutions used for the first set of measurements (series A-1, and A-2) were prepared from Kahlbaum best grade of iodic acid. The most concentrated (0.0950 *M*) solution (used in series A-1) was standardized with standard sodium hydroxide for its hydrogen ion concentration and with standard sodium thiosulfate for its iodate ion concentration. The values for duplicate determinations of the concentration of each ion did not differ by more than 0.1%. The average value of the concentration of each of the ions agreed exactly to the fourth decimal. The solution used for series A-2 (0.01 *M*) was made up by accurate dilution of the 0.0950 *M* solution.

The iodic acid used for the second set of measurements (series B-2) was prepared by oxidation of highly purified iodine with fuming nitric acid and hydrogen peroxide. The iodic acid was purified by several crystallizations from aqueous solutions by the addition of concentrated nitric acid. The crystals obtained were dried (for twelve hours) by vacuum desiccation at room temperature. From this white crystalline material a 0.1060 *M* solution was prepared. Triplicate analyses for hydrogen ion had a mean deviation of 0.2%. Duplicate analyses for iodate ion differed by 1.0%. The discrepancies are largely due to the fact that inadequate volumes were available for the titrations. The average value of the hydrogen ion concentration was 0.1063 *M* and that of iodate ion 0.1057 *M*. The solution used for series B-2 (0.01000 *M*) was made up by accurate dilution of the 0.1060 *M* solution.

The solid iodic acid prepared for series B-2 was further purified by recrystallization from aqueous solution by concentrated nitric acid. The crystals were dried for forty-eight hours by vacuum desiccation at room temperature. This solid (perfectly white) iodic acid was used for the third set of measurements series C-1, and C-2. A 0.0954 *M* solution was prepared. Triplicate analyses for hydrogen ion had a mean deviation of less than 0.07%. Triplicate analyses for iodate ion had a mean deviation of less than 0.02%. The average value of the hydrogen ion concentration was 0.0956 *M* and that of the iodate ion 0.0953 *M*. While this discrepancy may be due to the presence of a trace of nitric acid it has been attributed to differences in the standard reagents. The value 0.0954 *M* is a weighted average of the last two figures.

The solutions of hydrochloric acid were made up from Baker's Analyzed C. P. concentrated hydrochloric acid. These stock solutions were standardized against pure sodium carbonate and against silver chloride (gravimetrically). The concentrations given by the two methods agreed to within 0.1%.

All other chemicals used either directly or indirectly were of the highest quality.

Comparison of the hydrogen electrodes with freshly prepared calomel electrodes indicated that the hydro-

gen electrodes functioned properly during the measurements.

It was necessary to allow the iodine–iodate cells to stand for some time before equilibrium was established. For the 0.1 *M* solutions equilibrium was established fairly rapidly (less than two hours). For the 0.01 *M* solutions the rate of attainment of equilibrium was less rapid (less than ten hours). The periods of time that the potentials of the cells were observed and their fluctuations are given in Table I. At 0.001 *M* the cells would not give reproducible results and are consequently not reported. An attempt was made to make similar measurements on the bromine–bromate electrode but due to lack of reproducibility of potentials the investigation was discontinued.

The conditions under which the liquid junction was established were varied considerably in order to study its reproducibility. In most of the measurements the liquid junction was formed at the ungreased three-way stopcock which connected the electrode vessels. Readings were taken with the stopcock open and closed. When this stopcock was left open another stopcock in the bridge to the hydrogen electrode vessel was kept closed to prevent motion of the liquid in the bridge and to preclude the possibility of diffusion of iodine into the hydrogen electrode vessel. Readings taken with the three-way stopcock open remained constant for relatively long periods of time and were readily reproduced when the bridge was flushed and refilled with fresh solutions. Readings taken with the three-way stopcock closed changed after a few minutes, probably because of composition changes of the solutions forming a thin film in the closed stopcock. When the stopcock was again flushed the original readings were obtained.

The cell employed to measure the electromotive force of the iodine–iodate couple may be represented as

$$\text{Pt}, I_2(s), HIO_3(xm), HCl(xm), H_2(g), \text{Pt}$$

The total cell reaction is

$$\text{(A)} \quad ^1/_2I_2(s) + 3H_2O = 5/2H_2(g) + H^+ + IO_3^-$$

The measured potential[15] at 25° is given by

$$\mathbf{E} = \mathbf{E}^\circ + \mathbf{E}_L - (0.05913/5) \log (H_2)^{5/2} (H^+)(IO_3^-)$$

As discussed before it is difficult to evaluate the liquid potential term. The liquid potential for such a junction is usually given by

$$\mathbf{E}_L = +0.05913 \log \frac{\Lambda_{H^+} + \Lambda_{Cl^-}}{\Lambda_{H^+} + \Lambda_{IO_3^-}}$$

Planck[11] was the first to give the theory of such a liquid junction, but his equation must be regarded as only strictly applicable at infinite dilution. Planck's expression is the same as that above, with the conductivity terms being those at infinite dilution. The liquid potential given by Planck's expression is the same (+0.0025 volt) for the 0.1 and 0.01 *M* solutions. Consequently the standard potentials calculated by Planck's equation are in excellent agreement. The Lewis and Sargent[9] equation derived by MacInnes and Yeh[10] is applicable at all concentrations provided both electrolytes are completely ionized and the activities of the common ion are the same in both solutions. The Lewis and Sargent equation is that given above with the conductivity terms being those at the concentrations employed. The equivalent conductivities employed are those given in the "International Critical Tables," 1929. When employed in the Lewis and Sargent equation these values give +0.0034 and +0.0083 volt at 0.01 and 0.1 *M* concentrations, respectively.

The products of the activities of the hydrogen ions and iodate ions were calculated from the activity coefficients of iodic acid.[6]

The experimental results are tabulated in Table II.

It is estimated that the averages of the directly measured potentials at each concentration are accurate to about 0.0005 volt. The incomplete dissociation of iodic acid at 0.1 *M* is consistent with the discrepancies noted in the standard potentials calculated from the measurements at

---

[15] The conventions employed are those given by Lewis and Randall, ref. 5.

0.01 and 0.1 *M* concentrations. Since iodic acid may be considered almost completely dissociated at 0.01 *M*, it is believed that −1.195 volts should be accepted for the present as the standard potential for the iodine–iodate reaction (A). It is estimated that the probable error of this last value is about 0.002 volt.

Free Energy and Heat of Formation of Iodate Ion.—From the standard electrode potential given by this research one may calculate the standard free energy change at 298.1°K. for the reaction

$$^1/_2I_2(s) + 3H_2O(l) = 5/2H_2(g) + H^+ + IO_3^-$$
$$\Delta F^\circ_{298\cdot1} = -5 \times 23066 \times (-1.195) = 137{,}819 \text{ calories}$$

Gordon[16] has computed the entropy of water from spectroscopic data and with the heat of formation of water[17] and the entropies of hydrogen[18] and oxygen,[19] he calculates the free energy of formation of water

$$3H_2 + 3/2\,O_2 = 3H_2O(l) \quad \Delta F^\circ_{298\cdot1} = -170.070 \text{ calories}$$

By subtraction of the last reaction from the preceding reaction one may calculate the free energy of formation of iodate ion.

$$^1/_2I_2(s) + 3/2\,O_2 + {}^1/_2H_2 = H^+ + IO_3^- \quad \Delta F^\circ_{298\cdot1} = -32{,}251$$

The entropies of iodine[20] and of iodate ion[21] are known in addition to those of hydrogen and oxygen. The entropy change in this reaction is 76.20 cal./deg. and combination with the value for the free energy change gives for the heat of formation of iodate ion $\Delta H^\circ_{298\cdot1} = -54{,}966$ calories. It is well to note that this value at 298.1°K. is in good accord with the value at 291°K. given in the summary by Bichowsky and Rossini.[22]

The authors wish to thank Professor W. M. Clark and Dr. E. G. Ball of the Physiological Chemistry Department of The Johns Hopkins University for helpful advice.

Summary

The electrode potentials of the iodine–iodate electrode reaction have been measured at several concentrations and its standard electrode potential evaluated

$$^1/_2I_2 + 3H_2O = IO_3^- + 6H^+ + 5E^- \quad E^\circ_{298\cdot1} = -1.195 \text{ volts}$$

The free energy, entropy and heat of formation of iodate ion have been evaluated.

The Catalytic Decomposition of Hydrogen Peroxide by Aluminum Oxyiodide Hydrosols

BY ARTHUR W. THOMAS AND BENJAMIN COHEN

The catalytic decomposition of hydrogen peroxide by aluminum oxyiodide hydrosols[1] has been investigated for the first time for the purpose of studying the changes of the iodide ion concentration in these colloidal systems under various conditions.

This particular reaction was chosen for the following reasons: (1) It has been shown by several investigators that over a large range of iodide concentration, the decomposition of hydrogen peroxide in neutral solution is strictly proportional to the iodide ion concentration. (2) Hydrous aluminum oxide itself, and also in the presence of several potassium salts used in this study, had no appreciable catalytic effect upon hydrogen peroxide. (3) The decomposition of hydrogen peroxide by the sols was homogeneous and first order.

The *p*H values of the hydrosols were about 5.6 and increased to a maximum of *p*H = 8 upon the addition of certain potassium salts. In this range of *p*H, the steady state function for the iodide–iodine couple as investigated by Abel[2] and Liebhafsky[3] indicates that less than 1% of the total iodide present in our hydrosol systems will be removed to form iodine or tri-iodide ion. In

[a] In milliequivalents per liter. [b] P. F. = "Promotion Factor," defined as the ratio of the observed velocity constant to the velocity constant calculated for a system where all the iodide is free or unbound. [c] Sol 5 was rather unstable and began to precipitate after standing three weeks. [d] Sol 7 was used for e. m. f. measurements only. Iodide ion activities of sols 6, 7 and 8 were 7.9, 54 and 3.6 × 10^{-4}, respectively.

this sense, the reaction was independent of the pH changes encountered in the present investigation.

Preparation of Hydrosols.—The hydrosols used in this investigation were prepared by the action of dilute hydriodic acid solutions upon aluminum amalgam in all details as previously described.[4] The description of these sols is given in Table I.

Other Materials Used.—Merck "Superoxol" was distilled under reduced pressure in a previously steamed "Pyrex" glass apparatus and stored in paraffined containers. The 0.1 *N* potassium salt solutions were prepared from suitable purified materials and they had the following pH values: iodide 7.01, nitrate 6.48, acetate 6.42, sulfate 6.12 and tartrate 6.66; the pH values of the acetate and tartrate are lower than those found in solutions of these "neutral" salts owing to deliberate addition of some acetic and tartaric acids, respectively.

Measurement of H^+ and I^- Activities.—Electrode measurements were made at 25 ± 0.05°. The hydrogen ion activity of the sols was measured by means of the quinhydrone electrode using a saturated potassium chloride calomel half cell as the additional element. The platinized platinum hydrogen gas electrode was used when the pH value was near 8.

Iodide ion activity measurements were made with silver–silver iodide electrodes made up according to Owen.[5] Electrodes made in this way are reported to be reproducible to ±0.05 mv.[5,6] and have been found reliable in very dilute solutions.[6] In this work, silver–silver iodide electrodes were indistinguishable in 0.1 *N* potassium iodide, the precision of the potentiometer system being ±0.1 mv. In undialyzed sols, duplicate electrodes agreed within ±0.2 mv., whereas in dialyzed sols they performed less satisfactorily with variations frequently as large as one millivolt. The technique of measurement was as follows: a constant volume of salt solution (2 cc.) was added to 20 cc. of sol, the mixture shaken and two silver–silver iodide electrodes, fitted in a rubber stopper, were immersed in the solution. The cell was allowed to equilibrate overnight at 25°; using a saturated potassium chloride calomel cell as the additional element, the e. m. f. of the cells was then measured at three-hour intervals until constant readings were obtained.

The normal electrode potential of the silver–silver iodide electrode was taken as $E^0 = 0.151$ volt, the average of three values reported in the literature.[5,7,8]

Method of Measurement of the Velocity of Decomposition of Hydrogen Peroxide.—Since in the present work, the greatest iodide content of the reaction system was two milliequivalents per liter, it was found possible to employ the titration method, determining the concentration of hydrogen peroxide during the course of the reaction by titration with potassium permanganate solution.

The procedure was usually as follows: a 100-cc. portion of hydrosol was pipetted into a previously steamed 200-cc. "Non-Sol" glass bottle. A measured volume of salt solution (usually 10 cc.) was added. The mixture was shaken and then kept overnight in a water thermostat at 25 ± 0.005° to ensure equilibrium. To start the reaction a measured volume of hydrogen peroxide solution was added to the mixture. At various time intervals, a 25-cc. portion of the reaction mixture was withdrawn and permitted to flow into a 250-cc. Erlenmeyer flask containing 125 cc. of an ice and sulfuric acid mixture.[9] The oxygen was expelled from the reaction system before withdrawing aliquots by gently shaking the bottle in the thermostat, then removing the bottle from the thermostat and shaking the mixture violently for about ten seconds. Except when the reaction was relatively slow, the time of sampling was recorded as the time when the pipet was half emptied. Titration with potassium permanganate followed immediately.[10]

In some of the measurements (sols 1, 2, 3 and 6) the procedure was slightly changed. After the reaction had been started, 25-cc. portions of the reaction mixture were transferred into separate 250-cc. wide-mouthed glass-stoppered "Pyrex" flasks which had been well steamed previously.

(5) Owen, *ibid.*, **57**, 1526 (1935).

(6) Keston, *ibid.*, **57**, 1671 (1935).

(7) Pearce and Fortsch, *ibid.*, **45**, 2852 (1923).

(8) Gerke, *ibid.*, **44**, 1684 (1922).

(9) "Stopping" the reaction by the ice–sulfuric acid mixture was effective due to dilution and cooling. Considering the fact that in acid solution, hydrogen peroxide will oxidize I^- to I_2, the titer of hydrogen peroxide would decrease 1% in the most unfavorable cases were this reaction to go to completion.

(10) No correction was made for the iodine formed during the titration of hydrogen peroxide by potassium permanganate since the error involved was within the precision of the experiment.

At various time intervals an ice and sulfuric acid mixture was poured into the vessels and titrated immediately with permanganate.[10] Although the second method obviated the necessity of withdrawing the entire reaction mixture from the thermostat to expel the oxygen, the precision was practically unaltered.

The concentration of hydrogen peroxide at the beginning of the reaction was adjusted to 0.5 N in the case of systems having 1.5 or more milliequivalents per liter of iodide. In other cases an initial concentration of 0.3 N hydrogen peroxide was used.

Measurements upon a given hydrosol were completed as soon as possible in order to avoid errors arising from the changes which these hydrosols undergo upon aging even at room temperature. During a series of measurements the reaction mixture was kept in the dark.

The reaction followed the first order equation

$$K = \frac{2.303}{t} \log \frac{a}{(a - x)}$$

where a was taken as the number of cc. of potassium permanganate solution used in the first titration and $(a-x)$ the number of cc. of potassium permanganate used after the reaction had progressed t minutes.

The precision of this method may be seen from some representative experiments which follow:

Experimental Results

Neutral Salt Effect upon Decomposition of Hydrogen Peroxide by Potassium Iodide.—Since aluminum oxyiodide sols in the presence of added electrolyte have velocity constants approaching a value for which the total iodide of the system is unbound, it was thought advisable to investigate the salt effect on H_2O_2–KI systems under conditions comparable with those existing in the work on sols.

Table II shows a list of values for unimolecular velocity constants of a 1.544×10^{-3} N potassium iodide solution in the presence of various salt concentrations.

TABLE II

THE DECOMPOSITION OF HYDROGEN PEROXIDE BY 1.544×10^{-3} N KI IN THE PRESENCE OF POTASSIUM SALTS

Salt concn. equiv./liter	$K \times 10^3$ in presence of			
	Nitrate	Acetate	Sulfate	Tartrate
0	2.15	2.15	2.15	2.15
6.0×10^{-4}	2.16	2.18	2.15	2.14
6.0×10^{-3}	2.15	2.23	2.15	2.19
6.0×10^{-2}	2.17	2.21	2.13	2.19

It can be seen from Table II that the salt effect is less than 4% over the concentration range investigated. Walton[11] observed similar behavior for the cases of potassium nitrate and sulfate. The specific constant of 0.001544 N potassium iodide calculated from the data in Table II is 1.39 $min.^{-1}$ which is in good agreement with Walton's[11] value of 1.35 and with Liebhafsky's[2,12] value of 1.38.

The specific constant increased with dilution; however, when corrections were made for the decomposition of hydrogen peroxide by water, the specific constant remained practically unaltered.

Effect of Salts upon the Decomposition of Hydrogen Peroxide by Sols

Neither pure hydrous aluminum oxide nor an aluminum oxychloride hydrosol (0.254 equivalent of aluminum and 0.006 equivalent of chloride per liter) alone or in the presence of the potassium salts (used in this study) had any effect upon hydrogen peroxide.

Typical results for the effect of the added salts are furnished by sol 4 (Table III) and by sols 6 and 8 (Table IV, Figs. 1 and 2). Ten cc. of salt solution was added to 100 cc. of the sol. Then 5 cc. of hydrogen peroxide solution was added to start the reaction. In the case of sol 6, precipitates were produced upon the addition of 0.05 and 0.1 N sulfate and tartrate. Sol 8 showed precipitation upon the addition of 0.1 N acetate, and 0.01 (and higher) sulfate and tartrate. In all

(12) Liebhafsky and Mohammad, THIS JOURNAL, **55**, 3977 (1933).

instances reported in this paper, however, these precipitates remained uniformly suspended during the measurements. In a few experiments, not cited herein, where the precipitates settled out, analogous results were obtained also. In a separate experiment, dry potassium sulfate was added to sol 6 to render it 0.1 N with respect to the sulfate which completely precipitated the micelles.

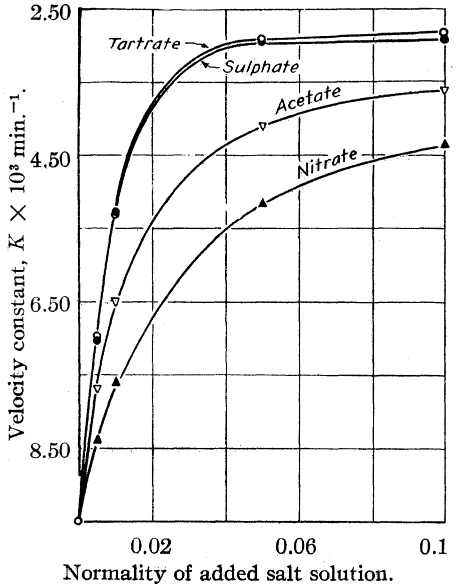

Fig. 1.—Effect of potassium salts on the velocity constant of sol 6. The velocity constant in the case of all iodide unbound is $K = 2.71 \times 10^{-3}$. The normality of salt in the system is found in this and in the remaining figures by dividing "Normality of Added Salt Solutions" by eleven.

After thirty minutes of shaking, the system was centrifuged and the clear supernatant liquid analyzed for iodide. The value of 2.208 milliequivalents per liter was found as compared to 2.234 in the original hydrosol. By a similar procedure the clear supernatant liquid obtained from sol 8 (rendered 8.7×10^{-3} normal with respect to sulfate) showed an iodide content of 1.011 milliequivalents per liter compared to 1.025 in the original sol.

TABLE III

EFFECT OF POTASSIUM SALTS ON VELOCITY CONSTANT[a] OF SOL 4

The velocity constant for the system with all the iodide unbound is 1.91×10^{-3} min.$^{-1}$.

Normality of added salt soln.	Nitrate	Acetate	Sulfate
0.0	7.74	7.74	7.74

.01	5.50	4.89	3.19
.1	4.03	3.13	2.25

[a] Numbers represent $10^3 K$ min.$^{-1}$.

TABLE IV

EFFECT OF POTASSIUM SALTS ON VELOCITY CONSTANT[a] OF SOL 8

The velocity constant for the system in which the total iodide is unbound is 1.24×10^{-3} min.$^{-1}$.

Normality of added salt soln.	Nitrate	Acetate	Sulfate	Tartrate
0.0	3.59	3.59	3.59	3.59
.005	2.95	2.59	2.05	2.13
.01	2.66	2.23	1.38↓	1.40↓
.05	1.81[b]	1.56[b]	1.26↓	1.25↓
.1	1.60[b]	1.41↓	1.27↓	1.25↓

[a] Numbers represent $10^3 K$ min.$^{-1}$. [b] These sols became turbid upon addition of the electrolyte. ↓ Signifies precipitation.

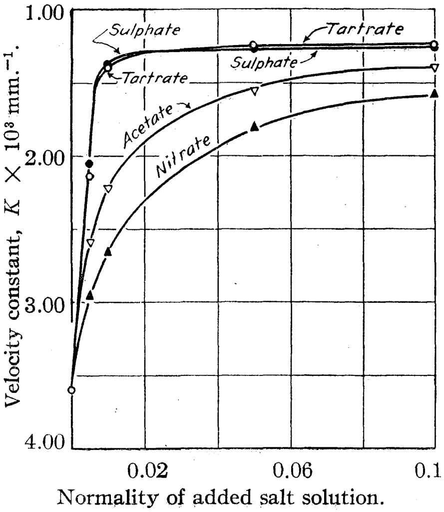

Fig. 2.—Effect of potassium salts on the velocity constant of sol 8.

Since added salts should displace bound iodide from the colloidal particles, it would appear from

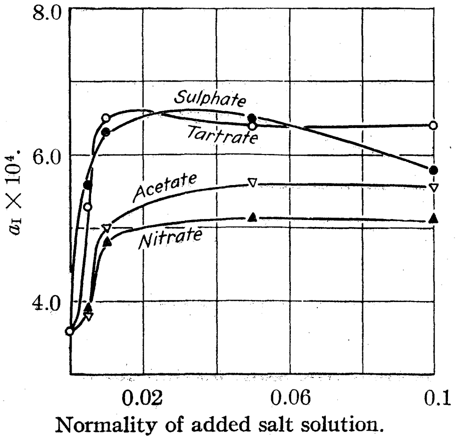

Fig. 3.—Effect of potassium salts on the iodide ion activity of sol 8.

the results of these experiments that the velocity constant for aluminum oxyiodide sols is a measure of the bound iodide of the system. To determine whether the iodide ion activity of the sol increased with addition of salts, silver–silver iodide electrodes were used upon sol 8 with salt concentrations similar to those used in the kinetic experiments. To 20 cc. of sol, 2 cc. of salt solution was added. *p*H measurements were also performed on identical systems. The results are plotted in Figs. 2 and 3.

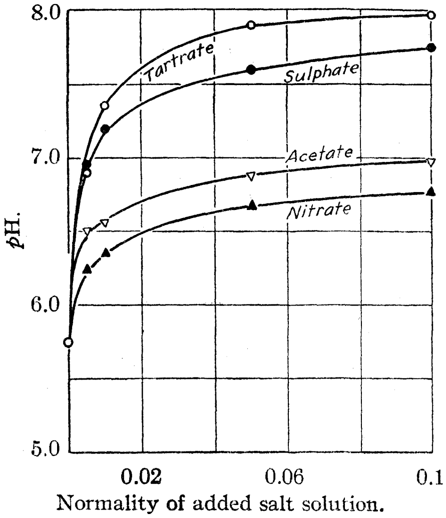

Fig. 4.—Effect of potassium salts on the *p*H of sol 8.

The iodide ion activity measurements were repeated upon sol 7 which was much richer in iodide than sol 8 and not dialyzed. The data obtained are plotted in Fig. 5.

The results obtained with the silver–silver iodide electrode indicate that iodide is being displaced from the colloidal micelles upon the addition of salts. However, it is not possible to estimate the iodide ion concentration in these systems, since the activity coefficients are unknown. The decrease in iodide ion activity at relatively high concentrations for some salts may be due to the decrease in the activity coefficient being larger than the amount of iodide that is displaced. Qualitatively the electrode measurements indicate that the order of effectiveness for potassium salts in increasing the iodide ion activity is about the same as that for decreasing the catalytic activity of these sols. The order of effectiveness of anions in increasing the *p*H of the sols is also the same.

According to the literature concerning the few iodide complexes[13] investigated, the catalytic effect on hydrogen peroxide for these complexes has been less than that for the iodide ion. This research suggests the further investigation of the catalytic effect of iodide complexes.

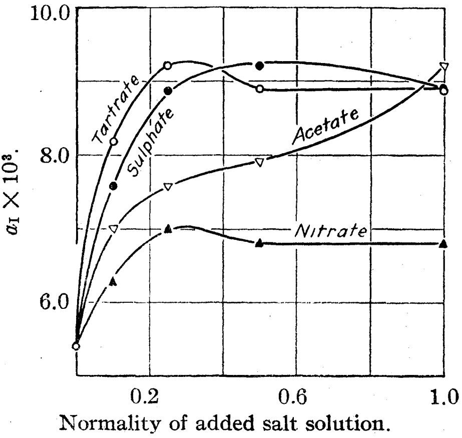

Fig. 5.—Effect of potassium salts on the iodide ion activity of sol 7.

Summary

The catalytic effect of aluminum oxyiodide hydrosols upon the decomposition of hydrogen peroxide is several times greater than that of aqueous solutions of iodide ions of the same concentration: this catalytic activity of these hydrosols is lowered by the addition of certain potassium salts, the order of effectiveness being tartrate > sulfate > acetate > nitrate, this being also the order for their effectiveness in increasing the iodide ion activity of the hydrosols.

It is apparent that basic aluminum micelles containing bound iodide (iodo groups) are more reactive toward hydrogen peroxide than iodide ion and it is postulated that the added anions displace iodo groups from the micelle, converting them to free iodide ions. Iodide ion activity measurements support this postulate and the order of effectiveness is identical to the effectiveness of these anions in replacing hydroxo groups from the micelle, converting them to hydroxyl ions.

The Heat Capacity of Ethane from 15°K. to the Boiling Point. The Heat of Fusion and the Heat of Vaporization

BY R. K. WITT[1] AND J. D. KEMP

Calorimetric measurements on ethane extending to low temperatures are of interest in the general program of obtaining entropies with the aid of the third law of thermodynamics. The value of the entropy of ethane obtained in this research is also important in demonstrating the correctness of the entropies of other simple hydrocarbons obtained by the application of the third law. This has been discussed briefly by Kemp and Pitzer.[2] A fuller discussion appears concurrently with this paper.

Preparation.—Ethane was prepared by the electrolysis of a potassium acetate solution as suggested by Moser.[3] For purification, the gas was passed successively through a 30% solution of sodium hydroxide, fuming sulfuric acid, concentrated sulfuric acid, an alkaline solution of sodium hydrosulfite, sodium hydroxide sticks and phosphorus pentoxide. Previous to the purification, the line was evacuated with a mercury diffusion pump. About 160 cc. of liquid ethane was prepared and then, for a final purification, fractionated. The middle fraction of 80 cc. was used in the measurements.

The purified ethane contained about 5 parts in a thousand of liquid-soluble, solid-insoluble impurity. This was calculated from the premelting heat effect evident in the heat capacity measurements preceding the melting point.

Apparatus and Measurement of Amount.—The measurements were made with a vacuum calorimeter assembly similar to that described by Giauque and Wiebe.[4] The copper calorimeter used in this research had a volume of 70 cc. A copper–constantan thermocouple, of laboratory designation W-23, was soldered in a well on the bottom of the calorimeter with Wood's metal. W-23 had previously been compared with thermocouple W-22, the present laboratory standard, which had been calibrated directly against a helium thermometer.

The amount of ethane was measured volumetrically in the calibrated bulb described in detail by Giauque and Johnston.[5] The following data from the "I. C. T." were

used in the calculation: gas density at 0° and 760 mm. = 1.3566 g./l., molecular weight = 30.0462, coefficient of thermal expansion = 0.0036777 and the coefficient of deviation from Boyle's law = −0.00120. The pressure observations were converted to international atmospheres.

The Heat Capacity of Ethane.—The heat capacity measurements were calculated using the method described by Giauque and Johnston.[5] Corrections were made for the heat effects due to the evaporation into the dead space above the liquid in the calorimeter. The constants used for the energy calculation were: 1.0004 absolute joules = 1 international joule, 4.185 absolute joules = 1 calorie.

The heat capacity data are collected in Table I. Fig. 1 gives a graphical representation of the heat capacity measurements.

The heat capacity measurements in Table I which are marked with an asterisk are high due to the premelting effect caused by the presence of impurities in the ethane.

Values of the heat capacity of ethane taken from the smooth curve are given in Table II. Correction has been made in this table for the effect of premelting on the measured heat capacities. The percentage deviations of the results of other observers from those of this research are also given in Table II.

The measurements of Wiebe, Hubbard and Brevoort[6] on liquid ethane are in excellent agreement with our results. The work of Eucken and Hauk,[7] however, shows extremely large deviations. Wiebe, Hubbard and Brevoort[6] have discussed these deviations adequately.

The accuracy of our measurements is estimated to be about 0.4% from 35°K. to the boiling point of ethane. At 25°K., the accuracy may be about 1% decreasing to about 2 or 3% at 20°K. and to about 5% at 15°K.

The Melting Point and Boiling Point of Ethane.—The melting point was observed for various percentages of the ethane melted. 89.87 ± 0.1° K. was obtained as the melting point of ethane, after appropriate correction was made for the amount of impurity present.

Only a rough measurement was made of the boiling point. The value obtained was 184.1 ± 0.1°K. Table III summarizes measurements of the melting and boiling points of ethane.

TABLE III

MELTING POINT AND BOILING POINT TEMPERATURES OF ETHANE

(0°C. = 273.10°K.)

The Heat of Fusion.—The heat of fusion was measured by starting the energy input at a temperature somewhat below the melting point and continuing until a temperature a few degrees above the melting point was reached. Correction was made for the $\int C_p dT$ and the premelting effect. Table IV summarizes the data on the heat of fusion.

TABLE IV

THE HEAT OF FUSION OF ETHANE

Temperature interval	Corrected total heat input per mole	$\int C_p dT$ and premelting effect	ΔH, cal./mole
86.729–91.038	739.6	57.0	682.6
86.776–90.447	727.1	44.1	683.0
86.395–91.696	756.7	73.6	683.1
		Accepted value	682.9 ± 0.7

Wiebe, Hubbard and Brevoort[6] have obtained 667.5 cal./mole for the heat of fusion of ethane. This value is probably low due to their inability to apply an accurate premelting correction. They had a larger amount of impurity and could not extend their measurements to a low enough temperature in order to obtain a reasonably good idea of the course of the true heat capacity of ethane near the melting point.

The Heat of Vaporization.—The heat of vaporization of ethane was measured directly using the five-liter measuring bulb and a constant pressure regulating device described by Giauque and Johnston.[5] Table V gives a summary of the heat of vaporization measurements.

TABLE V

THE HEAT OF VAPORIZATION OF ETHANE

of the melting point was used, as the heat of fusion has been corrected for the effect of premelting. Thus very little uncertainty is introduced in the calculation of the entropy by the premelting effect.

The expression, $\Delta S = R(27T_c^3P/32T^3P_c)$, obtained by using Berthelot's equation in connection with the thermodynamic equation $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$, was used to correct the entropy for gas imperfection at the boiling point. The critical pressure and temperature were taken as $P_c = 48.8$ atm and $T_c = 305.2$°K.[14]

The discussion of Kemp and Pitzer in the following paper shows that it is correct to use the third law value of the entropy of ethane in thermodynamic calculations.

Summary

The heat capacity of solid and liquid ethane has been measured from 15°K. to the boiling point.

The melting point of ethane has been determined to be 89.87 ± 0.1°K. The heat of fusion of ethane has been found to be 682.9 cal./mole.

The heat of vaporization of ethane at the boiling point has been found to be 3514 cal./mole.

The entropy of ethane gas at the boiling point calculated from the above data is 49.54 e.u. The entropy at 298.1°K. is 54.85 e.u.

The Entropy of Ethane and the Third Law of Thermodynamics. Hindered Rotation of Methyl Groups

By J. D. Kemp and Kenneth S. Pitzer[1]

Since the development of methods of calculating entropy from spectroscopic and molecular structure data, it has become possible to investigate the practical applicability of the third law of thermodynamics in a larger number of cases than previously. For many molecules, there is no question about the correctness of directly applying the third law to low temperature heat capacity measurements in obtaining entropies to be used in thermodynamic calculations. However, in certain cases, false equilibrium, encountered in obtaining low temperature calorimetric measurements, has complicated the use of the third law. The reasons for the complications in the several known cases are understood, and the immediate problem is to gather more information as to which molecules will be affected in order to increase the general usefulness of the third law.

The discrepancy found in hydrogen was first explained correctly by Giauque and Johnston,[2] who suggested the possibility of similar discrepancies in other molecules containing symmetrically placed hydrogens. Later investigations of the entropies of ammonia,[3] hydrogen sulfide[4] and methane[5] have shown that there is no persistence of rotation in the crystal lattices of these molecules which contain symmetrically placed hydrogens. A discrepancy has been found to exist in the case of water, but it has been explained by Pauling[6] as due to the formation of hydrogen bonds in the crystal. In all of these cases, there is no reason to doubt that the calculation of the entropies from molecular structure data is correct.

As attempts are made to deal with larger and more complicated molecules, it becomes more difficult to obtain sufficient molecular data to make even approximately correct calculations of thermodynamic quantities. An increased knowledge as to which molecules the third law may be applied unambiguously will thus be very valuable.

It is of interest therefore to consider the correlation between the third law value of the entropy of ethane obtained by Witt and Kemp[7] and the various possible values of the entropy which may be calculated assuming different molecular models.

In this paper, a comparison of the third law value for the entropy of ethane with one derived

from reliable data on the heat and free energy of hydrogenation of ethylene will be found to prove definitely that no false equilibrium exists in ethane. This, of course, means that it is correct to use the third law value in thermodynamic calculations.

In order to make a statistical mechanical calculation of the entropy of ethane, it will be necessary to consider the energy levels of the restricted rotator.

The Energy Levels of Ethane.—Since the spectroscopic interpretation of ethane is uncertain, it was necessary to make certain assumptions with regard to the potential barrier hindering the internal rotation of the methyl groups. A potential function, $^1/_2\, V_0\,(1 - \cos 3\phi)$, which gives three humps of height V_0, was assumed to modify the relative rotation of the methyl groups. Although this form of the potential function is entirely arbitrary, it is a reasonable one and is the only form for which solutions of the wave equation are available.

The quantum mechanical problem as set up in the preceding paragraph has been solved by Nielsen[8] and by Teller and Weigert,[9] who found that the wave equation separates into two parts. One of these is the usual equation for the rotation of a symmetric top with energies

$$W_{J,K} = \left(\frac{h^2}{8\pi^2}\right)\left[\frac{J(J+1)}{I_z} + K^2\left(\frac{1}{I_z} - \frac{1}{I_x}\right)\right]$$

while the second may be transformed easily into Mathieu's differential equation. Of the acceptable solutions for the latter, some are the ordinary Mathieu functions for which the characteristic values and thereby the energies are given by Ince.[10] The energies for the remaining solutions were obtained easily with sufficient accuracy for the present purpose by approximate means.

Nuclear spin was neglected in all calculations, and the molecules were assumed to be equally divided between states with odd and even values of the quantum number K. A symmetry number of 18 was used.

For vibrational frequencies we have used the assignment of Teller and Topley[11] except for one frequency $^2\nu_\alpha^M$ which they fixed only from specific heat data assuming free internal rotation. We have fixed $^2\nu_\alpha^M$ by the same method, obtaining different values depending on the restricting potential, V_0. The order of magnitude has been restricted to about 1000 cm.$^{-1}$ as indicated by the analogous frequencies in ethylene.

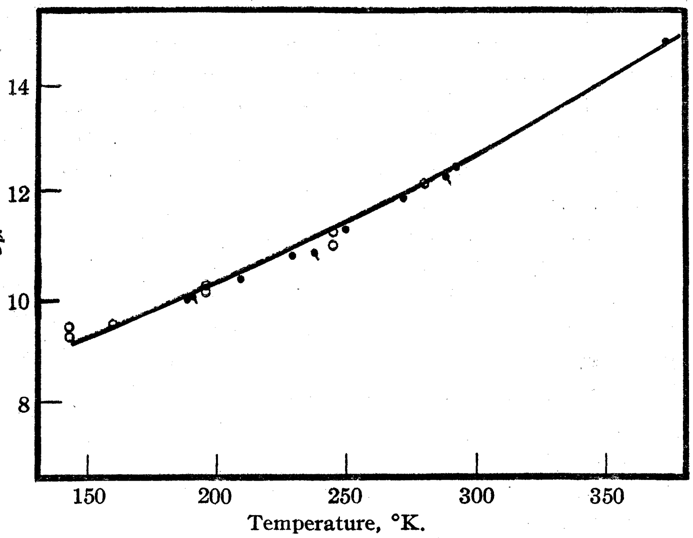

Fig. 1.—Heat capacity of ethane gas in calories per mole per degree: ● Eucken and Parts; ● Heuse; ○ Eucken and Weigert; the smooth curve represents the theoretical calculation.

It has been assumed that each methyl group has the same configuration as in methane and that the carbon–carbon distance is 1.52Å. One thus obtains $I_z = 40.1 \times 10^{-40}$ g. cm.^{2} and $I_{CH_3} = I_x/2 = 5.4 \times 10^{-40}$ g. cm.^{2}.

The Heat Capacity of Ethane Gas.—The heat capacity of ethane gas has been measured recently by Eucken and Parts[12] and by Eucken and Weigert.[13] Their results agree very well with the earlier measurements of Heuse.[14] Eucken and Parts, whose measurements extend down to the boiling point, find that their data may be fitted either by the assumption of free rotation with the unknown frequency $^2\nu_\alpha^M = 712$ cm.$^{-1}$ or with a torsional vibration of frequency 298 cm.$^{-1}$ and $^2\nu_\alpha^M = 920$ cm.$^{-1}$. Eucken and Weigert compared the thermal conductivity of ethane and ethylene and, assuming the same accommodation coefficient for both, calculated the heat capacity for ethane down to 140°K. Using the calculations of Teller and Weigert,[9] they found

that the best fit is obtained with a potential barrier of 315 cal.

We have also calculated the heat capacity of ethane in the range 140 to 400°K. and find that in addition to the combination $V_0 = 315$ cal., ${}^2\nu_\alpha{}^M = 750\ \text{cm.}^{-1}$,[15] a fit may also be obtained for V_0 near 3150 cal. and ${}^2\nu_\alpha{}^M = 1160\ \text{cm.}^{-1}$ as is seen in Fig. 1. The latter is, of course, essentially the second alternative of Eucken and Parts, but is based on a restricted rotator model rather than an oscillator. Since no other reasonable combinations of V_0 and ${}^2\nu_\alpha{}^M$ even approximate the specific heat curve, we need consider only these two in later calculations.

The Entropy of Ethane.—We have calculated the entropy of ethane from molecular structure data using the familiar expression for the rotational entropy of a rigid symmetric top and adding to it the entropy due to the hindered internal rotation of the methyl groups and the ordinary vibrational and translational contributions. A symmetry number of 18 was used.

It has been shown that in order to explain the observed heat capacity of ethane gas, a potential barrier of about 3150 cal. or one near 315 cal. must be assumed. Table I gives a comparison of the entropy of ethane, calculated from molecular structure data, assuming various potential barriers, with the calorimetric entropy obtained by Witt and Kemp.[7]

TABLE I

THE ENTROPY OF ETHANE CALCULATED FROM MOLECULAR STRUCTURE DATA COMPARED WITH THE ENTROPY OBTAINED CALORIMETRICALLY FROM THE THIRD LAW[16]

T, °K.	Potential barrier V_0, cal./mole	Statistical mechanical entropy, cal./deg./mole	Third law entropy, (exptl.) cal./deg./mole
184.1	0	51.09	
184.1	315	50.98	
184.1	3150	49.30	49.54 ± 0.15
298.1	0	56.36	
298.1	315	56.26	
298.1	3150	54.62	54.85 ± 0.2

It may be seen from Table I that there is agreement between the calorimetric and calculated entropies, within the limits of uncertainty, when a potential barrier of 3150 cal. is assumed.

A further comparison may be obtained between the third law entropy and entropies calculated from the heat and free energy of hydrogenation of ethylene. The heat of hydrogenation of ethylene has been measured accurately by Kistiakowsky and co-workers.[17] A preliminary value calculated from heats of combustion by Rossini[18] is in very good agreement with the direct determination of Kistiakowsky. The equilibrium data have been summarized by Teller and Topley[11] and the value they select as the most reliable ($\log K_p = 1.613$ at 863°K.) was used in our calculations. The entropy change in the reaction $C_2H_4 + H_2 = C_2H_6$ may then be obtained at 355°K., provided that the heat capacities of the various gases are known from 355 to 863°K. It is given by the expression

$$\Delta S^\circ_{355} = \frac{\Delta H^\circ_{355} - \Delta F^\circ_{863}}{863} - \int_{355}^{863} \Delta C_p \left(\frac{1}{T} - \frac{1}{863}\right) \mathrm{d}T$$

Since no experimental data are available on the heat capacity of ethane above 400°K., it was necessary to calculate that quantity, using the various molecular models found to give satisfactory heat capacities below 400°K. Fortunately, as can be seen in the expression above, the effect of the heat capacity is small, particularly at the higher temperatures. In calculating the entropy of ethane from the heat and free energy of the hydrogenation of ethylene, the assignment of frequencies of ethylene given by Bonner[19] and the moments of inertia given by Badger[20] were used. The entropy of ethylene at 355°K. obtained by using these values is 54.43 e.u. The thermodynamic constants for hydrogen were taken from the tables given by Davis and Johnston.[21] The values of the entropy of ethane so obtained depend chiefly upon the ΔF and ΔH of hydrogenation of ethylene and only to a small extent upon the assumption made regarding the potential barrier.

Table II gives a comparison between the third law value of the entropy of ethane and the value obtained from the ΔH and ΔF of hydrogenation of ethylene. For further comparison, values of the entropy obtained from a statistical mechanical calculation are also included.

The comparison of the entropies obtained from ΔF and ΔH with the entropy obtained from the third law shows that, regardless of the

---

[15] The difference between Teller and Topley's assignment of the remaining vibration frequencies and that of Eucken and co-workers leads to the difference in ${}^2\nu_\alpha{}^M$.

[16] The values in this table differ slightly from the preliminary survey by Kemp and Pitzer, *J. Chem. Phys.*, **4**, 749 (1936).

TABLE II

A SUMMARY OF THE ENTROPY OF ETHANE AT 355°K.

Potential barrier, V_0, cal./mole	0	315	3150
S_{355} from molecular structure data, cal./deg./mole	58.74	58.64	57.06
S_{355} from ΔH°_{355} and ΔF°_{863}, cal./deg./mole (exptl.)	56.61	56.61	57.34
S_{355} from the third law, cal./deg./mole (exptl.)		57.20 ± 0.2	

height of the potential barrier assumed, no residual entropy, such as would be left if there were false equilibrium in the crystal at very low temperatures, remains after the ordinary extrapolation of the heat capacity data to absolute zero. Indeed, for barriers lower than 3150 cal., the impossible situation of obtaining too much entropy from the third law arises. As the correctness of the third law value for the entropy of ethane is now established, the values calculated assuming potential barriers of 315 cal. or less must be in error. It is strong evidence for the existence of a potential barrier of the order of 3000 cal. per mole, which has heretofore been considered improbable.[10,22]

Unfortunately, numerous statistical mechanical calculations have been published with respect to molecules allowing similar rotations for which no potential barrier was assumed. The results for ethane suggest that the entropies so calculated may be in error by as much as 1.5 cal./deg./mole for each internal rotation.[23] Several authors have obtained such disagreements. Kassel[18] was unable to correlate the ΔF and ΔH for the hydrogenation of some higher olefins, finding entropy differences of from 2 to 3 cal./mole/deg. Since one single bond has been formed and the restricting potentials for others probably have been changed by the reaction, the apparent disagreement may well be due to the assumption of completely free rotation in the calculations. Aston and Messerly[24] in the case of tetramethylmethane obtained a disagreement of about 8 cal./deg./mole between the third law entropy and a calculated value of the entropy, while Kassel[25] obtained a similar difference of 3.76 cal./deg./mole for *n*-butane. They suggested that the calorimetric rather than the calculated entropies (assuming free rotation) are in error and ascribe the disagreement to a lack of equilibrium in the crystal at very low temperatures. The work on ethane indicates that this view is probably erroneous and that the entropies of simple hydrocarbons obtained from the application of the third law of thermodynamics to calorimetric data extending to hydrogen temperatures are the correct entropies to use in thermodynamic calculations. As we now know that the calorimetric entropies of ammonia, hydrogen sulfide, methane and ethane are the correct ones to use in thermodynamic calculations, an even more general statement may be made. That is: very probably no molecules other than hydrogen and deuterium retain any entropy due to the persistence of rotation in the crystal below 10°K.

Summary

The entropy of ethane has been calculated from the heat and free energy of hydrogenation of ethylene considering ethane as a restricted internal rotator. A comparison of the values so obtained, with the entropy obtained from calorimetric measurements extending to low temperatures by use of the third law of thermodynamics, proves the correctness of the third law value.

Very strong evidence has been presented for the existence of a potential barrier of about 3150 cal./mole restricting the internal rotation of the methyl groups in ethane by the comparison of the experimental values of the entropy of ethane with values obtained from statistical mechanical calculations. It is believed that the discrepancies noted by some authors in the cases of other hydrocarbons are due to the assumption of incorrect molecular models involving free internal rotation of the methyl groups. From a knowledge of the correctness of the third law entropies in the cases of ammonia, hydrogen sulfide, methane and ethane, it may be stated that very probably no molecules other than deuterium and hydrogen will have any residual entropy due to the persistence of rotation in the crystal at temperatures below 10°K.

Chloro and Fluoro Compounds Related to Adrenalone

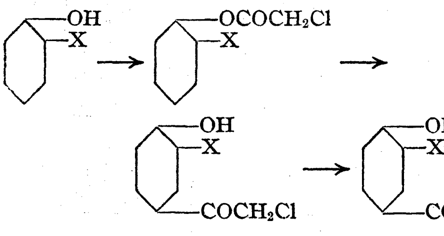
BY HAROLD L. HANSEN

The influence of nuclear chlorine and bromine on the chemical and pharmacological properties of amines of the pressor type has engaged the attention of several investigators. Zeynek[1] prepared both 3,5-dichloro- and 3,5-dibromotyramine. Glynn and Linnell[2] prepared ω-amino-3,4-dichloroacetophenone as well as 3,4-dichlorophenyl-β-aminoethanol and reported for the latter substance a pressor effect much smaller than that of epinephrine but also a correspondingly lower toxicity. While the present investigation was in progress Edkins and Linnell[3] published a report on the preparation of 3-chloro-4-hydroxy-ω-aminoacetophenone and several derivatives of ω-aminoacetophenone bearing nuclear chlorine or bromine.

Aside from the work of Schiemann and Winkelmüller[4] on 3-fluoro-4-hydroxyphenylethylamine and 3-fluorophenylethylamine no reference was found in the literature to pressor compounds containing nuclear fluorine.

The purpose of this investigation was to prepare and to make a preliminary pharmacological study of 3-chloro-4-hydroxy-ω-methylaminoacetophenone and of the corresponding fluorine compound, 3-fluoro-4-hydroxy-ω-methylaminoacetophenone. Both of these are closely related chemically to adrenalone and it was hoped they might be of some value in a study of the comparative influence of chlorine and fluorine on substances of the vaso pressor type.

The synthetic methods employed in this investigation are well known and may be summarized as follows



Various attempts to reduce the amino ketones to the secondary alcohols, including the use of hydrogen with a platinum catalyst, sodium amalgam in acid solution and aluminum amalgam, either failed to give the desired products or produced small amounts of compounds which it has not yet been possible to identify. Apparently both removal of halogen and splitting of the carbon–nitrogen bond were involved in these reduction reactions. Edkins and Linnell[3] were unable to obtain the secondary alcohol from 3-chloro-4-hydroxy-ω-aminoacetophenone by reduction.

The structures of both derivatives of adrenalone reported here were established by conversion of these compounds to the corresponding halogenated methoxybenzoic acids, the constitution and physical properties of which have been previously reported.

Preliminary pharmacological work shows that both 3-fluoro-4-hydroxy-ω-methylaminoacetophenone and the corresponding chloro compound possess vaso pressor properties weaker than that of adrenalone. Intravenous injections into anesthetized dogs produced a blood pressure rise of 2 to 4 mm. of mercury with doses of 1.3 mg./kg. The work also indicates that the fluoro compound is somewhat less active than the chloro.

Experimental Part

***o*-Chlorophenyl Chloroacetate.**—This was prepared from 119 g. of thionyl chloride, 94.5 g. of chloroacetic acid and 128.5 g. of *o*-chlorophenol according to the procedure used by Hartung, Munch, Miller and Crossley[5] in the synthesis of phenyl propionate. The yield of oily product, b. p. 123–125° at 6 mm., was 154 g. or 75%. After two distillations under reduced pressure the product had the following properties: d^{25}_4 1.3589, n^{25}_D 1.5335; *MR*D found 46.86; calcd. 46.33.

Anal. Calcd. for $C_8H_6OCl_2$: Cl, 34.60. Found: Cl, 34.44.

3-Chloro-4-hydroxy-ω-chloroacetophenone.—*o*-Chlorophenyl chloroacetate, 102 g. was dissolved in about 100 cc. of carbon disulfide and treated with 53 g. of anhydrous aluminum chloride according to the directions of Hartung, *et al.*[5] At the end of the reaction the hard black mass was pulverized and added in small portions with brisk stirring to a mixture of concentrated hydrochloric acid and ice. The black precipitate was removed by suction filtration, dissolved in ether and the ether solution dried over sodium sulfate. The solid remaining after removal of the

TABLE I

ANALYTICAL AND OTHER DATA FOR THE FLUORO COMPOUNDS

Compound	Yield, %	B. p., °C. (4 mm.)	M. p., °C.	Solvent	Formula	Analyses, % Calcd.	Analyses, % Found
o-Fluorophenyl chloroacetate	73	90–94	36–38		$C_8H_6O_2FCl$	Cl, 18.81	18.88
3-Fluoro-4-hydroxy-ω-chloroacetophenone[a]	27–40		101–102	Tol-hept.	$C_8H_6O_2FCl$	Cl, 18.81	18.59
3-Fluoro-4-hydroxy-ω-methylaminoacetophenone[b]	21–31						
3-Fluoro-4-hydroxy-ω-methylaminoacetophenone·HCl	Soft, dark 228°		235–236 dec.	Abs. EtOH	$C_9H_{11}O_2ClFN$	N, 6.38	6.46

[a] Strong irritant and lachrymator. [b] Gray powder, fairly soluble in water.

ether was twice crystallized from dry toluene. The yield varied from 40 to 60 g., or 39 to 59%. Evaporation of the toluene mother liquor gave a few grams of very impure, low melting product which was not studied further. The chloro ketone was further purified by crystallization from dry, crude heptane from which it was obtained as yellow crystals, m. p. 141–142°. This substance is extremely irritating to mucous membrane and is a powerful lachrymator.

Anal. Calcd. for $C_8H_6OCl_2$: Cl, 34.60. Found: Cl, 34.80.

An attempt to prepare this compound by action of phosphorus oxychloride on *o*-chlorophenyl chloroacetate in benzene solution according to the method used by Ott[6] in preparation of adrenalone resulted in failure. The starting material was recovered unchanged.

3-Chloro-4-hydroxy-ω-methylaminoacetophenone.—This compound was prepared according to the directions of Stolz[7] for adrenalone. Fifty grams of finely powdered 3-chloro-4-hydroxy-ω-chloroacetophenone and 25 cc. of absolute ethanol were cooled in an ice–salt bath. To the chloro ketone was added with stirring 100 cc. of a 40% methylamine solution. The reaction mixture was then allowed to stand at room temperature for two days. At the end of this time it was reduced to about one-half its original volume under diminished pressure, thoroughly chilled and filtered by suction. The precipitate was washed with cold water, dissolved in dilute hydrochloric acid and reprecipitated with ammonium hydroxide. The yield of pale yellow crystalline product was about 20 g. or 41%. The hydrochloride of this substance was isolated by evaporation of its aqueous solution on the steam-bath. Crystallization from absolute alcohol gave a faint yellow, water soluble, crystalline material. The substance shrivels at 180°, starts to melt at 210–211° and decomposes at 217°.

Anal. Calcd. for $C_9H_{11}O_2Cl_2N$: N, 5.93. Found: N, 5.99.

Proof of Structure for 3-Chloro-4-hydroxy-ω-methylaminoacetophenone.—The compound obtained above was converted to the methyl ether with methyl sulfate and the resulting ether was oxidized with potassium permanganate. The acid thus obtained was crystallized once from dilute acetic acid, from which it was obtained as small white crystals, m. p. 211–212°. This is in good agreement with the properties listed for 3-chloro-4-methoxybenzoic acid.[8] The benzoic acid derivative obtained above was further converted to the methyl ester which, after one crystallization from dilute ethanol, melted at 94–95°. This corresponds with the properties of methyl 3-chloro-4-methoxybenzoate.[8]

***o*-Fluorophenol.**—This was prepared from *o*-anisidine according to the directions of Schiemann.[9]

Since the procedures employed in the preparation of the fluoro compounds are identical with those previously mentioned, the analytical and other data have been summarized in Table I.

Proof of Structure of 3-Fluoro-4-hydroxy-ω-methylaminoacetophenone.—The phenol was methylated with methyl sulfate and the resulting ether oxidized with potassium permanganate. The acid thus obtained after crystallizing from dilute ethanol melted at 208–210°. 3-Fluoro-4-methoxybenzoic acid[10] has been found to melt at 204°. The 3-fluoro-4-methoxybenzoic acid was further prepared as follows: *p*-cresol was nitrated to produce 3-nitro-4-hydroxytoluene according to the directions of Lucas and Liu.[11] The phenolic compound was converted to the methyl ether with methyl sulfate and the nitro group was reduced to the amine with hydrogen in the presence of a platinum catalyst. The 3-amino-4-methoxytoluene was converted to the fluoro compound which was found to be identical with the 3-fluoro-4-methoxytoluene described by Schiemann.[12] Oxidation with potassium permanganate gave a product with m. p. 208–210°. A mixed melting point determination showed that this substance is identical with the 3-fluoro-4-methoxybenzoic acid obtained from 3-fluoro-4-hydroxy-ω-methylaminoacetophenone.

The pharmacological data presented here were furnished by Professor Carl A. Dragstedt. The author is also grateful for the helpful suggestions of Professor C. M. Suter and Mr. Elmer J. Lawson.

Summary

1. The 3-chloro and the 3-fluoro derivatives of adrenalone have been prepared.

2. Both substances possess weak vaso pressor properties.

A Study of Cellulose Hydrolysis by Means of Ethyl Mercaptan[1]

By M. L. Wolfrom and Louis W. Georges[2]

It is difficult to obtain exact information concerning the structure of the cellulose molecule. The classical methods of organic structural determination involve the study of the breakdown of the organic molecule by degradative methods. The cellulose molecule may be degraded by acid hydrolysis and any new information obtained by a study of this hydrolytic process should be of service eventually in interpreting the true structure of the cellulose molecule. The recent studies of Freudenberg and of Freudenberg and Kuhn[3] on the hydrolytic breakdown of cellulose by sulfuric acid and by acetolysis constitute some of the more important recent contributions to the problem of the constitution of cellulose.

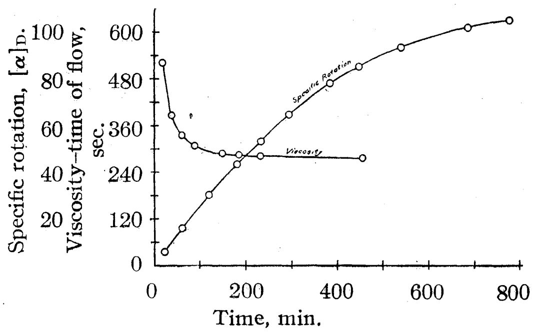

Fig. 1.—Specific rotation and viscosity of 3% solution of cellulose in fuming HCl (d_4^{15} 1.203) at 23°.

In 1913, Willstätter and Zechmeister[4] prepared solutions of cellulose in fuming hydrochloric acid and followed the hydrolysis at 16° by polarimetric and copper reduction methods. With a cellulose preparation that was apparently only solvent-extracted, they obtained an initial induction period and an inflection point at a specific rotation of +14°. In 1923, Sherrard and Froehlke[5] in identifying some purified wood celluloses, demonstrated their similarity to cotton cellulose by applying the polarimetric method of Willstätter and Zechmeister. They also made a run on cotton cellulose as a control. They found the first break in the curve of all celluloses examined at a specific rotation of +43° instead of +14° and found in addition a second break at a specific rotation of +73°. Their temperature of hydrolysis was 20°. It is probable that variations in the type of this polarimetric curve can be ascribed to different methods of cellulose purification.

We have followed polarimetrically the hydrolysis curve at 23° of a sample of chemically purified, high viscosity cotton linters, employing solution concentrations and tube lengths to ensure adequate observed rotations. In agreement with previous work, we find that the initial rotation is zero. With the β-glucose chain conception of the cellulose structure, it is rather difficult to understand why this initial rotation should be zero rather than levo. We did not find any initial induction period, nor did we find any breaks in the curve (Fig. 1). Many intermediate readings other than those shown were obtained. Data were obtained for two concentrations of cellulose and are tabulated in Table I. An analysis of the data (Table I) shows that the calculated monomolecular velocity constants show a slight but definite upward drift. The average value of the velocity constant for the greater part of the reaction is practically independent of the initial cellulose concentration. The polarimetric data so obtained verify the results of Hibbert and Percival,[6] who followed polarimetrically the hydrolysis of cellulose (alkali-purified) in a hydrochloric acid–zinc chloride medium. These workers likewise obtained no breaks in the polarimetric curve and found that the calculated monomolecular velocity constant exhibited a definite upward drift. Their average velocity constant value is in excellent agreement with the one determined in this Laboratory, employing a fuming hydrochloric acid medium at the same temperature.

In agreement with previous workers, we find that the final rotation ($[\alpha]_D$ + 100°) is approximately that of an equivalent amount of d-glucose. The equilibrium rotation of d-glucose is profoundly affected by the hydrogen chloride concen-

tration. This variation is plotted in Fig. 2 and is in fair agreement with previous data. In agreement with Willstätter and Zechmeister,[4] we find that this rotation change is reversible under the conditions of time and temperature employed and accordingly it must represent a true tautomeric shift.

[a] The initial time was determined here by the backward extrapolation of the curve to zero rotation. [b] $k = \frac{1}{t} \ln_e \frac{\alpha_0 - \alpha_\infty}{\alpha_t - \alpha_\infty}$ (t in minutes; $\alpha_0 = 0$).

We were also interested in following the viscosity changes in the cellulose solutions. We found that at 25° the first measurable viscosity value was quite low and that the solutions attained the viscosity of an apparent equivalent amount of *d*-glucose when the specific rotation was approximately +25°. These data are shown in Figs. 1 and 3.

The main object of our investigation was to insert a carbonyl reagent into the hydrolytic mixture in order to follow the breakdown of the cellulose molecule by means of the intermediate reaction products. Ethyl mercaptan is a suitable reagent for this purpose. This substance will react with the free reducing groups of sugars in concentrated hydrochloric acid to form the sugar mercaptals or thioacetals.[7] At the present stage of our investigations, the mercaptalated cellulose hydrolytic products, other than glucose ethyl mercaptal, were isolated as amorphous mixtures and no attempt was made to separate them into their pure components. They were characterized by means of their sulfur content.

The reaction between a reducing sugar and ethyl mercaptan takes place with extreme rapidity and at low temperatures. Under the Willstätter–Zechmeister hydrolytic conditions, the effective sugar concentration is relatively low and we found it necessary to study the mercaptalation of *d*-glucose under such conditions. A 5% solution of *d*-glucose in fuming hydrochloric acid can be mercaptalated by vigorous mechanical shaking with an excess of ethyl mercaptan for fifteen minutes at 0°. At the end of this period the solution has lost its Fehling reduction capacity and the glucose diethyl mercaptal may be isolated in approximately eighty per cent yield.

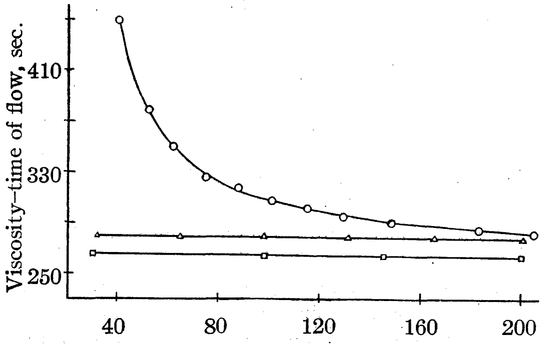

Fig. 3.—Comparison of viscosity at 25°: ○, 3% solution of cellulose in fuming HCl; △, 3% solution of glucose in fuming HCl; □, fuming HCl.

The glucose mercaptal that separates, after sodium bicarbonate neutralization, is contaminated with appreciable amounts of sodium chloride. For quantitative purposes, it was found desirable to leave this salt in the product and correct for its presence by an ash determination. We are probably dealing here with an addition compound

---

(7) E. Fischer, *Ber.*, **27**, 673 (1894).

similar in nature to the well-known *d*-glucose–sodium chloride compound. The mother liquor could then be investigated by concentration to dryness and acetylation, the acetylated product being purified by pouring into a large volume of water. Difficulties were here encountered in acetylating quantitatively, a small amount of material adhering to a relatively large amount of crystalline salt that was insoluble in the acetylating mixture.

The optimum mercaptalation procedure thus established for *d*-glucose was then applied to the cellulose hydrolytic solutions and the course of hydrolysis of cellulose (5%) in fuming hydrochloric acid solutions at 16° was studied by means of the mercaptalated products obtained from the reaction of ethyl mercaptan with the cellulose solutions at various stages of hydrolysis. Simultaneous polarimetric data were obtained. Sulfur analyses served to determine the average molecular size of the mixtures of mercaptalated products isolated from the cellulose hydrolysis. The pertinent data are tabulated in Table II. An analysis of these data is given in Table III and shows that the cellulose molecule fragments with extreme rapidity under these conditions. Glucose ethyl mercaptal first appears when the hydrolysis is approximately two-thirds completed. Its amount gradually increases. When the hydrolysis was approximately at the half-period, the

(*a*) The addition of 5 cc. of water preceding the mercaptan addition was omitted.

(*d* to *n*) The acid solution was poured into a suspension of 68 g. of sodium bicarbonate in 100 cc. of water.

(*d*, *e*) No product precipitated.

(*f*) After standing for one day, 0.4 g. of a crystalline product separated. This material was characterized as *d*-glucose diethyl mercaptal. On recrystallization the substance melted at 127° (unchanged on admixture with an authentic specimen of *d*-glucose diethyl mercaptal).

(*g to n*) Crystalline products were obtained which were mixtures of glucose diethyl mercaptal and sodium chloride. They were removed by filtration and were not washed. The sodium chloride content was determined by conversion to sodium sulfate in a platinum crucible with concentrated sulfuric acid. Calcd. for *d*-glucose ethyl mercaptal: S, 22.4. The glucose ethyl mercaptal was isolated and identified as its pentaacetate for one typical run. A portion (1.5 g.) of the crude water-insoluble product from (*k*) was acetylated overnight with acetic anhydride (10 cc.) and pyridine (5 cc.) and poured into ice and water (400 cc.); yield, 1.6 g. On recrystallization from methanol–water the substance was identified as *d*-glucose diethyl mercaptal pentaacetate; m. p. 45–47° (mixed m. p. unchanged); $[\alpha]^{24}_D$ +13.3° (*c*, 3.6; $CHCl_3$).

(*j* to *n*) A second solution of cellulose (30 g.) was prepared as previously described and used after it had been allowed to hydrolyze at 16° for twenty-seven and one-half hours.

(*a′*) A trace of amorphous material was obtained.

(*b′*) A solid, amorphous product was obtained.

(*c′*, *d′*) These products separated as gummy masses contaminated with salt. They were taken up in chloroform and the extract washed with sulfuric acid (1 molar), aqueous sodium bicarbonate and water. On solvent removal and trituration with ether the products were obtained as granular solids.

(*e′* to *h′*) The products separated as viscous sirups which hardened to a solid mass on standing.

(*i′* to *n′*) These sirupy products were treated as described for (*c′*) and (*d′*) and were obtained as glassy solids after drying in a vacuum desiccator.

isolated mixtures of products corresponded to the trisaccharide stage. The amount of this type of material gradually decreased but appreciable quantities were still present at the last point determined.

n	55	..	2.4	1	1.3	2.5

[a] D. p. = degree of polymerization or number of glucose units in the chain. For (a), (b) and (c), this was calculated by the following close approximation: d. p. = $\frac{100 \times 2S}{\%S \times C_6H_{10}O_5} = \frac{40}{\%S}$.

Further work is in progress in this Laboratory.

Experimental

Cellulose Characterization.—The cellulose used throughout this research was a sample of purified cotton linters[8] of high viscosity which had been subjected to the customary alkali kier and mild bleaching process. The material showed the following characterization: alpha cellulose, 99.2%; ash, 0.04%; iron, 10 p. p. m.; moisture, 4.0%. The material was analyzed for pectin by the Link[9] modification of the Lefèvre–Tollens[10] procedure and was found to be pectin-free by this method. The cuprammonium viscosity of the cellulose was determined in 0.1% concentration at 25 ± 0.02°: $n = 2.732$ centipoises; $[\eta]$ (intrinsic

$$\text{viscosity}) = \frac{\ln_e \eta_r}{C} = \frac{\ln_e \frac{409.5}{192.3}}{0.1} = 7.559.^{11}$$

Preparation and Measurement of Cellulose Solutions.—Fuming hydrochloric acid (98.74 cc.; $d^{15}{}_4$ 1.203) was added to the cotton linters (1.000 g.; moisture content, 4.0%) in a glass-stoppered flask and the mixture shaken until the cellulose was completely dissolved (eight minutes) with occasional cooling in an ice-bath. The density of the solution after three hours of standing was found to be 1.2003; 25°/4°. This made a 1% solution of cellulose (moisture-free basis) in fuming hydrochloric acid. A portion of the solution was used for the polarimetric observations and another portion was used for the direct determination of viscosity in an Ostwald type viscometer. A similar procedure was used in obtaining data for a 3% cellulose concentration. The results obtained for one typical cellulose concentration are shown in Fig. 1. The data shown in Fig. 3 were obtained for comparative purposes. The calculated velocity constant data are tabulated in Table I. The optical rotations of *d*-glucose in various concentrations of hydrochloric acid are shown in Fig. 2.

Reversibility of the Optical Rotation of *d*-Glucose in Concentrated Hydrochloric Acid.—The experiment to be described was performed to determine whether the rotation of *d*-glucose in fuming hydrochloric acid was due to a permanent change in structure or to a reversible tautomeric equilibrium. *d*-Glucose (1.0623 g.) was dissolved in fuming hydrochloric acid ($d^{15}{}_4$ 1.202) to make 50.00 cc. of solution; $[\alpha]_D$ +100.3°. This solution was then diluted to 99.90 cc. with water. This lowered the hydrogen chloride percentage to approximately 20.1% and the concentration of *d*-glucose from *c*, 2.125 to *c*, 1.063; $[\alpha]_D$ +57°. The specific rotation for *d*-glucose in acid of the same concentration was found to be +56°. This indicates that the equilibrium is essentially reversible and that the rotation changes are measures of true tautomeric shifts.

Mercaptalation of a 5% *d*-Glucose Solution.—*d*-Glucose (3.3 g.) was dissolved in 60 cc. of hydrochloric acid ($d^{20}{}_4$ 1.184) and the solution cooled to 0°. Purified ethyl mercaptan (8 cc.; cooled to 0°) was added and the mixture vigorously shaken by mechanical means for fifteen minutes at 0°. The faint yellow solution was poured with stirring into a suspension of 60 g. of sodium bicarbonate in 100 cc. of water. The heat change was negative and the neutralization could thus be effected at low temperatures. The mixture was cooled in an ice–salt bath and the crystalline product removed by filtration, washing being omitted; yield, 4.9 g. or 4.0 g. on a salt-free basis (77%).

Anal. Ash as Na_2SO_4: 21.0. Calcd. as NaCl, 17.3. S (NaCl-free basis): 21.6. Calcd. for $C_6H_{12}O_5(SC_2H_5)_2$, 22.4.

A portion (1.5 g.) of the above salt-containing product was acetylated overnight with acetic anhydride (10 cc.) and pyridine (5 cc.) and poured into 400 cc. of ice and water. A crystalline product was obtained that was characterized as glucose diethyl mercaptal pentaacetate by its melting point of 45–47° (mixed m. p. unchanged); $[\alpha]^{24}D$ +12.8° (*c*, 3.6; $CHCl_3$); yield, 2.1 g. (calcd., 2.17 g.). Wolfrom[12] recorded for this substance the constants: m. p. 45–47°; $[\alpha]^{29}D$ +11° ($CHCl_3$).

Mercaptalation of Cellulose Hydrolytic Products.—An amount of 30 g. of cellulose was dissolved in 600 cc. of fuming hydrochloric acid ($d^{15}{}_4$ 1.203) by shaking in a 1-liter glass-stoppered bottle. After seventeen minutes a clear solution ($d^{15}{}_4$ 1.219) was obtained that contained 4.669 g. of cellulose per 100 cc. of solution. This solution was kept in a thermostated constant temperature bath held at 16 ± 0.1°. The water in the bath was cooled by means of an immersed coil which was connected with a

refrigeration unit. Samples of the solution under investigation were removed at stated intervals for mercaptalation. Polarimetric readings at 16° were taken simultaneously and when plotted showed again a continuous curve. The mercaptalation products were isolated and analyzed. In the experiments herein reported, no attempts were made to isolate the various mercaptalated oligosaccharides in pure form. The data are tabulated in Table II. The various mercaptalations are denoted by letter in this table and will be referred to by these designations. The mercaptalation procedure employed was that described for *d*-glucose, unless otherwise specified. An amount of 60 cc. (equivalent to 2.80 g. of cellulose) of the solution was transferred to a glass-stoppered pressure bottle, 5 cc. of water and 8 cc. of purified ethyl mercaptan were added and the whole shaken mechanically for fifteen minutes at 0°. The addition of a small amount of water at this point lowered the acid concentration to that of ordinary concentrated hydrochloric acid. The product was precipitated by pouring the solution gradually into a suspension of 68 g. of sodium bicarbonate in 200 cc. of water. The excess bicarbonate was neutralized with acetic acid. The material was centrifuged and the residue washed successively with water, ethanol, acetone and petroleum ether. The washed product was dried in a vacuum oven at 50°.

The mother liquors from the precipitates were tested with Fehling's solution and negative results were obtained in each case. They were then concentrated at 55°, under reduced pressure to a moist salt and this transferred to a Büchner funnel, washed with acetone and dried at 40°. The salt residue was then acetylated for two days at room temperature (occasional shaking) with acetic anhydride (36 cc.), and pyridine (18 cc.) and the acetylation product isolated by pouring into ice and water (800 cc.). The data obtained are tabulated in Table II.

The data tabulated in Table II were calculated to their average degrees of polymerization by means of the sulfur analyses and these calculated results are shown in Table III.

The authors are indebted to E. I. du Pont de Nemours and Co., Inc., for the fellowship grant which has made this research possible, and to Dr. Robert W. Rothrock for practical assistance in the experimental work.

Summary

1. Ethyl mercaptan has been used as a reagent to follow the course of hydrolysis of the cellulose molecule in fuming hydrochloric acid.

2. The hydrolysis of cellulose (chemically purified linters of high viscosity) in fuming hydrochloric acid at 23° was followed polarimetrically and by viscosity measurements. The rate of increase of the optical rotation from 0° to that of *d*-glucose ($[\alpha]_D + 100°$) was found to be a continuous function. The calculated monomolecular velocity constants showed a slight but definite upward drift. At an early stage ($[\alpha]_D + 25°$, approx.) of the hydrolysis the viscosity of the solution approached that of a solution containing an equivalent amount of apparent *d*-glucose.

3. The course of hydrolysis of cellulose in fuming hydrochloric acid solutions (5%) at 16° was studied by means of the mercaptalated products obtained from the reaction of ethyl mercaptan with the cellulose solutions at various stages of hydrolysis. Simultaneous polarimetric data were obtained. Control experiments were made to determine the optimum procedure for the mercaptalation of *d*-glucose and this procedure was used in the cellulose reactions. Sulfur analyses served to determine the average molecular size of the mixtures of mercaptalated products isolated from the cellulose hydrolysis.

4. The data indicate a rapid hydrolysis to surprisingly small units. When the hydrolysis was approximately at the half-period, the isolated products corresponded to the trisaccharide stage. Glucose diethyl mercaptal first appeared when the hydrolysis was approximately two-thirds completed and gradually increased in amount.

Some New Sulfonic Acid Esters

BY STEWART E. HAZLET[1]

In the course of some other work in progress in this Laboratory it was necessary to prepare some benzene- and *p*-toluenesulfonic acid esters which had not been reported previously. In each case the three isomers have been characterized and the results are summarized in Table I and Table II.

TABLE I

ESTERS OF BENZENESULFONIC ACID

Starting material	Solvent	Crystal form	Yield, %	M. p., °C.	Formula	Analyses, % Halogen Calcd.	Halogen Found	Sulfur Calcd.	Sulfur Found
o-Bromophenol	Methanol	Colorless platelets	90	54–56	$C_{12}H_9O_3BrS$	25.55	25.53[a]		
m-Bromophenol	(B. p. 217–218° at 10.5 mm.)		61		$C_{12}H_9O_3BrS$	25.55	25.78[a]		
p-Bromophenol	Petroleum ether[c]	Colorless needles	67	50–55[d]	$C_{12}H_9O_3BrS$	25.55	25.43[a]		
o-Phenylphenol	Dilute alcohol	Colorless needles	93	66–68	$C_{18}H_{14}O_3S$			10.32	10.34[a]
m-Phenylphenol	(B. p. 273° at 16 mm.)	Colorless solid	94	.....	$C_{18}H_{14}O_3S$			10.32	10.63[b]
p-Phenylphenol	Methanol[e]	Colorless needles	66	104–105	$C_{18}H_{14}O_3S$			10.32	10.63[a]

[a] Determinations made by the Carius method. [b] Determination made by the Parr bomb method. [c] Separated at about −82°. [d] The crude product boiled at 197–206° at a pressure of 2.5 mm [e] Final recrystallizations were from dilute ethyl alcohol.

TABLE II

ESTERS OF *p*-TOLUENESULFONIC ACID

Starting material	Solvent	Crystal form	Yield, %	M. p., °C.	Formula	Analyses, %[a] Halogen Calcd.	Halogen Found	Sulfur Calcd.	Sulfur Found
o-Bromophenol	Dil. alcohol	Colorless plates	98	77–79	$C_{13}H_{11}O_3BrS$	24.46	23.96		
m-Bromophenol	Methanol	Colorless rods	86	52–54	$C_{13}H_{11}O_3BrS$	24.46	24.46		
p-Bromophenol	Dil. alcohol	Colorless rectangular prisms	Quant.	93–95	$C_{13}H_{11}O_3BrS$	24.46	24.35		
o-Phenylphenol	Dil. alcohol; ligroin (68–70°)	Colorless needles	Quant.	64–66	$C_{19}H_{16}O_3S$			9.88	9.94
m-Phenylphenol	Methanol	Colorless cubes	90	52–54	$C_{19}H_{16}O_3S$			9.88	9.88
p-Phenylphenol	Alcohol:acetone = 1:1; benzene–ligroin (68–70°)	Colorless plates	75	178.5–179.5	$C_{19}H_{16}O_3S$			9.88	[b]

[a] These analyses were made by the Parr bomb method. [b] This compound was reported by Bell and Kenyon [*J. Chem. Soc.*, 3049 (1926)]. No yield was recorded; the reported m. p. was 177° for lustrous plates obtained from acetic acid.

To obtain these products the required acid chloride (1.1 mols) was added slowly with agitation to a pyridine solution of the phenol that was held at about 10°. Next the mixture was heated for half an hour at 60°, then gently refluxed for an equal period, cooled and treated with water and dilute hydrochloric acid. Products which separated as solids were collected by filtration; others were extracted with ether. The extracts were shaken successively with a 5% solution of potassium hydroxide, water, 5% hydrochloric acid and water. The ethereal solutions were dried with anhydrous sodium sulfate in the presence of norite. The mixtures were filtered, the ether distilled off, and the products allowed to solidify. The products obtained by either method were purified by crystallization from suitable solvents.

Summary

Some new esters of benzene- and *p*-toluenesulfonic acid have been prepared and their properties reported.

Organic Oxidation Equivalent Analysis. I. Theory and Applications

BY ROGER J. WILLIAMS

In connection with the problem of analysis of very small samples of biological materials, the possible importance of being able to determine the amount of oxygen required for their complete combustion was noted. Further study revealed the fact that in the case of the vast majority of pure compounds this determination offers an alternative to the familiar "combustions" for carbon and hydrogen.

A search of the literature shows that apparently no one has approached the subject from exactly this angle. Strebinger,[1] using potassium iodate as the oxidizing agent, determined the oxygen required for the complete combustion of organic compounds and from this and the known carbon and hydrogen contents he calculated the oxygen contents of the compounds. Simon and Guillaumin[2] oxidized certain (non-nitrogenous) organic compounds with sulfuric acid and silver dichromate and from the carbon dioxide formed and the oxidizing agent used up calculated the hydrogen content of the compounds. Stanek and Nemes[3] developed a complicated micro method (using iodate) for the quantitative determination not only of the "oxygen consumed" but also carbon, nitrogen and halogens. The determination of oxygen consumed along with the other values made possible with rather complicated equations the calculation of hydrogen content. They pointed out that the amount of oxygen required for complete oxidation of an organic compound is itself a very characteristic quantity, but did not deal experimentally with this determination except as a part of their general set-up for complete micro analysis.

Sample Calculation.—The way in which the oxidation equivalent value may be used as a substitute for "combustion" data in determining the formula for a compound may best be illustrated by a specific case in which we will use the following designations

$C_xH_yO_z$ = formula of unknown
M = its molecular weight
E = its oxidation equivalent (grams oxidized by one gram atom of oxygen; 17.90 in the case cited below)
$M/E = N$ = the number of atoms of oxygen required to oxidize one molecule of the compound.

Suppose that one gram of an "unknown" containing only carbon, hydrogen and oxygen (gluconic acid) is found experimentally to require 0.894 g. of oxygen (calcd. 0.898) for complete combustion. From this it can be calculated that one gram atom of oxygen will completely oxidize 17.90 g. (17.82 calcd.) of the unknown.

The molecular weight M must be an even integer (except in the case of odd molecules) and a multiple of E. Which multiple of E it is, can be determined cryoscopically or better yet, in this case, by titration. If $N = 10$, $M = 178$; if $N = 11$, $M = 196$; if $N = 12$, $M = 214$. Experimentally it is easily ascertained that N is 11.

Of the above values x, y, z, M and N are all integers (of these y and M are *even* numbers) and it is possible to set up the simple Diophantine equations (1) and (2) from which may be derived (3), (3a) and (4).

$$12x + y + 16z = M \qquad (1)$$
$$2x + 0.5y - z = N \qquad (2)$$
$$y = (6N - M + 22z)/2 \qquad (3)$$
$$z = (M - 6N + 2y)/22 \qquad (3a)$$
$$x = (M - 2N - 18z)/8 \qquad (4)$$

Substituting 196 and 11 for M and N, respectively, in equations (3) and (4) we obtain (5) and (6)

$$y = (-130 + 22z)/2 \qquad (5)$$
$$x = (174 - 18z)/8 \qquad (6)$$

Below are given the values of y and x derived from equations (5) and (6) by substituting various integral values of z. From these it is evident that the formula of the unknown can be nothing other than $C_6H_{12}O_7$.

Integral values of z	Corresponding values of y	Corresponding values of x
5	−10	10.5
6	1	8.25
7	12	6
8	23	3.75
9	34	1.5

Calculations for N and S Compounds.—In order to calculate in a similar way the formula for a compound containing reduced nitrogen, $C_xH_yO_zN_b$, M is used to represent the weight of the residue after b equivalents of NH_3 have been subtracted. For calculating in case of a compound contain-

---

(1) Strebinger, *Z. anal. Chem.*, **58**, 97–114 (1919).
(2) Simon and Guillaumin, *Compt. rend.*, **176**, 1065 (1923).
(3) Stanek and Nemes, *Z. anal. Chem.*, **95**, 244 (1933).

ing nitrogen and sulfur (both in reduced condition), $C_xH_yO_zN_bS_c$, M is used to represent the residue after $3c$ moles of water have been *added* and b molecules of NH_3 and c molecules of SO_3 subtracted. This is on the assumption that ammonium and sulfate ions are the end products of the oxidation, respectively. Separate analyses for nitrogen and sulfur must, of course, be made.

Applicability to Different Types.—The question naturally arises as to whether the value of the molecular weight of an unknown can be determined with sufficient accuracy so as to make the calculation valid. This problem has been given careful study and there appears to be no difficulty except in the case of certain compounds of carbon, hydrogen and oxygen which have a high molecular weight and/or low value of E, and the molecular weights of which it is impossible to determine by titration or otherwise, with reasonable accuracy. These, however, can be handled as indicated below. In the case of many simpler compounds such as glycerol or oxalic, tartaric and succinic acids the molecular weight determinations as well as those of the oxidation equivalents can be very inexact and yet lead inevitably to the correct results. Nitrogen compounds in general offer no difficulty provided the nitrogen can be determined accurately since the value obtained along with the oxidation equivalent data, is basis for a sufficiently accurate value for the molecular weight. If, in the case of carbon–hydrogen–oxygen compounds which offer difficulty because of uncertainty regarding the molecular weight, one additional fact is known, namely, the degree of unsaturation, then the difficulty disappears. These are illustrated by the type $C_8H_{10}O_4$ and $C_9H_8O_4$, which, in this case, have exactly the same oxidation equivalent value, and molecular weights which differ from each other by less than 6%. They differ markedly in the number of double bonds and/or rings present, however, and could in general be easily differentiated, without a carbon and hydrogen analysis.

With regard to compounds of high molecular weight, calculation of the molecular formula has limitations in accuracy similar to those which hold for traditional combustion analyses. In either case unless the analyses are very accurate, the data may fit several formulas equally well.

Notes on Calculations.—There are several points regarding the calculations which need to be clarified. It is not infrequent that more than one *mathematical* solution to the equations can be found, but that only one falls within the limits possible for a chemical formula. Thus, the same data fit approximately the formulas $C_8H_2O_6$, $C_6H_{12}O_7$ and $C_4H_{22}O_8$, but this should not cause any uncertainty, because the two extremes are either impossible as compounds or else would have very unusual properties. In the case of higher molecular weight compounds two solutions may arise as above, both of which represent *possible* compounds. In such cases the two are so far apart in their hydrogen content that they could be distinguished easily without analysis because of differences in chemical behavior.

It should be emphasized that in order to have a valid calculation, the value of N (which is an integer) *must be correctly assigned.* If this is done, then the value of M is obtained with considerable accuracy ($N \times E$) and by substituting reasonable values[4] of y in equation (3a), z can be established with certainty. These values of z, if substituted in (3) and (4) then lead to integral values of x and y unless the molecular weight value is slightly in error. If it is high or low by two integers the value of x will differ from an integer by $^1/_4$, and y will be an odd number. If M is high or low by 4 integers (but this should not happen if the oxidation equivalent value is obtained with satisfactory accuracy) then the value of x will differ from an integer by $^1/_2$ and y will be even.

Use in Checking Composition.—In practical experience there is seldom an occasion to analyze an organic compound which is entirely unknown. Usually the analysis serves as a check to avoid false assumptions.

Here the usefulness of the oxidation equivalent analysis is apparent when the data in the case are studied. In order to study this problem a table was prepared giving the calculated oxidation equivalent values for all of the C_8 and C_9 compounds (containing C, H, O and reduced N) which are listed in Richter's "Handlexicon." The total number of molecular formulas in the sample was 547 and should be representative.

The oxidation equivalent values in the sample ranged from 4.56 to 99, and it is a striking fact that the formulas represented are very evenly spread through a wide range. The distribution

---

(4) The possible values must lie at 11 unit intervals. Various relationships exist which may be helpful in determining reasonable values of y, *e. g.*, for any compound containing carbon, hydrogen, oxygen and reduced nitrogen $y = 2x + 2 - 2\alpha + b$, where α is the number of rings and/or double bonds and the other terms have the meanings previously assigned.

is approximately even from the values 6 to 16 inclusive and about 27% of the formulas lie outside this range. In all cases observed throughout the whole table where the oxidation equivalent values lie close together the formulas represented differ materially in molecular weight, nitrogen content or in some cases in degree of unsaturation as previously explained.

Use in Determining Hydrogen Content.—Whether a sample constitutes a pure compound or not, if it contains only carbon, hydrogen and oxygen (plus other elements that may be determined and corrected for), its hydrogen content can be determined accurately by analysis for carbon and for its oxidation equivalent. Strebinger,[1] from the oxidation requirements of the elements, calculated (using slightly different notation and uncorrected values) that $8/3 \cdot \%\ \mathrm{C} + 7.93 \cdot \%\ \mathrm{H} - \%\mathrm{O} = \%\mathrm{O_R}$ where $\%\mathrm{O_R}$ is the oxygen requirement in grams per hundred grams of sample. Combining this with the relationship that for a compound or residue under consideration the sum of the carbon, hydrogen and oxygen percentages is equal to 100, we obtain

$$\%\mathrm{H} = (\%\mathrm{O_R} + 100 - 11/3 \cdot \%\mathrm{C})/8.93$$

The molecular formulas of certain compounds (particularly sterols) have been in doubt because the hydrogen percentage could not be determined with sufficient certainty so as to make possible a definite choice between two values which lie 4–5 parts per hundred apart. Fisher[5] indicates the "allowed" error for a hydrogen analysis in macro combustions to be 2 parts and never over 3 parts per hundred.

Carbon can be determined much more accurately than this[5] without undue complication in apparatus. It should be possible by careful work to determine both the carbon percentage and the oxidation equivalent value with an error of one part per thousand. This would allow a calculation of the hydrogen content (*e. g.*, of cholesterol) with an error of not more than 5 parts per thousand even if the errors in analysis were in opposite directions thus producing the maximum error in the value for hydrogen percentage.

Other Applications.—Very small samples of tissue, bacteria, etc., can be subjected to a proximate analysis for "protein," carbohydrate and fat by combining an oxidation equivalent analysis with a determination of nitrogen on a micro scale. For carbohydrate (starch or glycogen) the oxidation equivalent value is 13.5; for a protein (egg albumin) it is 10.47; for a fat (triolein) it is 5.53. The proportions in a mixture can be calculated readily from the data mentioned above. The method of oxidation equivalents also has a possible application in the determination and characterization of organic matter in soils and in water.

The writer wishes to express his thanks to Professor W. E. Milne, who has been kind enough to consult with him freely regarding the mathematical aspects of the problem, and to Professor Bert E. Christensen, who was early convinced of the value of the method and agreed to collaborate on experimental methods.

Summary

Equations are given by which the molecular formula of a compound can be calculated from its molecular weight and the amount of oxygen required for its complete combustion. The use of oxidation equivalent data as a substitute for that obtained from carbon and hydrogen combustions is discussed.

Organic Oxidation Equivalent Analysis. II. By the Use of Iodate. (Micro and "Sub-micro" Methods)

BY ROGER J. WILLIAMS, EWALD ROHRMAN AND BERT E. CHRISTENSEN

The use of potassium iodate in slightly diluted sulfuric acid recommended itself to Strebinger[1] as a suitable process for determining the amount of oxygen used up in the oxidation of a compound because its use avoids the production of carbon monoxide, and allows for a simple back titration of the unused oxidizing agent. Stanek and Nemes[2] without cognizance of Strebinger's work used potassium iodate in concentrated sulfuric acid under similar conditions in a complicated system of micro organic analysis in which "oxygen consumed," carbon, nitrogen and halogens were determined.

We have investigated the quantitative oxidation of organic compounds by potassium iodate in concentrated sulfuric acid and have found the method to be applicable under suitable conditions to most carbon–hydrogen–oxygen compounds and to certain nitrogen compounds, but that it has definite restrictions other than those indicated by the work of the authors mentioned above. We shall, for economy of space, leave out data which fall in line with the observations of Strebinger and Stanek and Nemes and give in more detail the results which supplement or are contradictory to theirs.

Danger of Oxidizing Nitrogen.—While under the conditions used by Stanek and Nemes there is probably not a serious danger of oxidizing nitrogen, Strebinger's conditions are more unfavorable in this regard. On the basis of numerous duplicate analyses we find that when nitrogenous compounds are analyzed and the sample is increased up to the concentration used by Strebinger there is an extra "oxygen consumption" which must be due to the oxidation of ammonia.

That the danger lies in the accumulation of liberated iodine was shown by several experiments. For example three samples of acetanilide 4.02 mg. (pipetted in solution in test-tubes and evaporated in vacuum) were treated alike except that to the second and third were added 10 and 100 mg., respectively, of iodine. Oxidation was for thirty minutes at 185°. The oxygen consumptions in the three cases were, respectively, 0.15% low, 0.45% high and 8.0% high, indicating that iodine brings about additional oxygen consumption. In order to avoid this possibility we have used 3–4 mg. samples and 5 ml. of concentrated sulfuric acid, which reduces the concentration to about one-half that used by Stanek and Nemes and to about one-fifth that used by Strebinger.

Failure to Oxidize Nicotinic Acid.—Stanek and Nemes[2] pointed out that quantitative oxidation of nitrogen compounds with iodate is accomplished only when the nitrogen can be determined by the Kjeldahl method. Nitro compounds, hydrazones and heterocyclic nitrogen compounds fail to yield satisfactory results. When we applied the method to nicotinic acid (185° for twenty minutes) 3.8 and 4.1% oxidation resulted in duplicate analyses. Raising the temperature sufficiently to oxidize the ring without oxidizing nitrogen and introducing other complications does not seem feasible.

Acetates.—As a result of a rather extensive study we conclude that *generally speaking* acetic acid is the most difficultly oxidized organic compound with which we have been concerned. However, acetic acid is oxidized with iodate more easily than nicotinic acid, though when permanganate is the oxidizing agent the situation is distinctly reversed. Succinic acid is likewise difficult to oxidize (with iodate or dichromate) but not as difficult as acetic acid.

Many organic substances liberate iodine in the cold when the sulfuric acid–iodate reagent is used. Succinic acid required four minutes in a bath at 185° before appreciable iodine color appeared. Acetic acid required eight minutes at this temperature to bring about visible iodine liberation. The difficulty of oxidizing acetic acid is further shown by the fact that acetanilide cannot be oxidized completely with iodate at 185° in twenty minutes (Tables I and II). The aniline portion of the molecule is easily oxidized, however, and liberates iodine from iodate in the cold.

Phthalate Oxidations.—A further limitation of the method appeared when we attempted to apply it to potassium acid phthalate and phthalic anhydride. Strebinger reported one satisfactory analysis of phthalic acid and one of a naphthol. Stanek and Nemes reported no analyses of phthalates. Two determinations on potassium acid phthalate yielded results indicating an 80% and a 75% oxidation, respectively. In the second one of these analyses the sample was dissolved carefully before heating or introduction of iodate took place, but the result was even farther in error than the first. Oxidation of phthalic anhydride at the same temperature (185°) for thirty minutes instead of twenty minutes as used above, resulted in only 74% oxidation. Potassium acid phthalate appears, however, to be oxidized completely at higher temperatures. Thirty minutes at 200° brought the oxygen consumption to about 88% of the theoretical, while at 210° the oxidation appeared 99.3% complete in the same time. At 220° for thirty minutes nearly 2% too much iodate was used. This excess may have been due to thermal decomposition of iodic acid[2] or to oxygen consumption by the sulfuric acid used.

Use on a Micro Scale.—The data given in Table I were obtained as a result of a series of analyses none of which was

discarded. It is given in some detail to show how closely duplicates may be expected to check and also to show that the method of analysis must be modified slightly for different types of compounds. A twenty-minute heating period gives remarkably accurate results with sucrose but with acetanilide (which is admittedly an extreme case due to acetic acid formation) large errors result using this length of time. A forty-minute period gives acceptable results with acetanilide but with sucrose this extra period throws the results off somewhat. Probably for general use thirty minutes gives the best results but it seems clear that modifications, dependent upon the character of the material analyzed, must be made to obtain the most accurate results. It seems likely from our experience that at least in the case of easily oxidized compounds (carbohydrates, for example) the iodate method may yield precise results. As a rapid micro method for obtaining results of moderate accuracy it should be useful and with materials of biological origin (with the exception of certain alkaloids) it should be applicable and useful.

Use on a "Sub-micro" Scale.—One of the reasons for being interested in the application of this method was the possibility that it might be used for analyzing samples weighing not more than a fraction of a milligram—or the order of one-tenth that used for ordinary micro combustions. That this is possible with certain types of compounds is indicated by the data presented in Table II. These constitute a consecutive series of determinations with no analysis excluded. The samples to be analyzed were each weighed into test-tubes in the form of a water solution, the weighed amount of iodate was added and the solution was evaporated overnight in a vacuum desiccator. For weighing the solutions (on an ordinary balance) bottles of the solution containing a ground glass medicine dropper were weighed before and after the samples were removed. The titrations were carried out with an ordinary buret using 0.025 *N* thiosulfate. The iodate can be weighed conveniently in solution with saving of time and as a result ten analyses can be completed within about one working day, with an overnight period allowed for evaporation.

Procedure.—The procedure which we recommend for "micro" work is exceedingly simple. The sample which weighs 3 or 4 mg. is introduced into a test-tube along with 5 ml. of sulfuric acid, 0.2 ml. of water, and sufficient potassium iodate to constitute at least 100% excess. Both the sample and iodate can be weighed in the form of water solution if desired and then evaporated. It is necessary that the sample and the iodate be well distributed throughout the medium before heating is begun. Whether or not the acid is diluted with a small percentage of water seems to make no material difference in the results. The samples are heated in a sulfuric acid bath to 185° for twenty to forty minutes (see above) after which the mixture is transferred to an Erlenmeyer flask, diluted with 60 ml. of water and steamed for five minutes using a suitable source of clean steam. The inlet tube for the steam is then rinsed with 40 ml. of water and after cooling 0.75 g. of sodium bicarbonate is added to the flask to reduce acidity and give an atmosphere of carbon dioxide; 1.5 g. of powdered potassium iodide is added and the iodine which is freed is titrated with 0.1 *N* sodium thiosulfate. Most of the precautions which have to be observed are those involved in iodometric titrations in general and are not properly presented or discussed here. The purest available chemicals including "Kahlbaum" potassium iodate and sulfuric acid were used. When the samples were very small and 0.025 *N* thiosulfate was used, suitable corrections were applied for the "titration error."

Summary

Oxidation with iodate in concentrated sulfuric acid and back titration of the unused iodate constitutes a method (which, however, is not perfectly general) for determining the amount of oxygen necessary for the complete oxidation of organic compounds (see first article in this series). There is danger of oxidizing nitrogen, however, if the concentration of the sample is too high. Phthalates are oxidized with difficulty and nicotinic acid, for example, is oxidized very little. It can, however, be applied rather widely to compounds of various types and accurate analyses are possible with samples weighing a fraction of a milligram.

Organic Oxidation Equivalent Analysis. III. General Method Using Dichromate

BY BERT E. CHRISTENSEN, ROGER J. WILLIAMS AND ANNE E. KING

Dry combustion methods have been devised for determining the amount of oxygen consumed in the oxidation of organic compounds,[1-3] but either they are inaccurate or else involve a complicated apparatus and exacting technique in operation. Wet combustion, if applicable, should involve simpler apparatus and easy experimental methods.

Of the available agents for wet combustion which are obtainable in pure form, potassium iodate and potassium dichromate are outstanding. The use of iodate has been studied[4] and found to be of somewhat restricted value. Potassium dichromate has been used for the determination of oxygen consumed during combustion but if employed at relatively low temperatures[5] (100° or thereabout) is applicable to the oxidation of only a few types of compounds. If used at a sufficiently high temperature to bring about the complete oxidation of compounds generally, free oxygen is invariably produced in considerable quantity accompanied by the formation of carbon monoxide[6] in many cases (oftentimes even at low temperatures). This eliminates the possibility of determining the unused oxidizing agent directly by back titration.

This study was directed toward the perfection of a method using dichromate under conditions which would oxidize organic compounds generally, yet allow for an evaluation of the whole of the unused oxidizing agent (including oxygen gas) and eliminate or correct for the carbon monoxide produced.

It is obvious that many different media and conditions could be employed for the oxidation with dichromate. We have investigated the use of phosphoric acid, sulfuric acid and mixtures of the two. Phosphoric acid (85%) has certain advantages, particularly in that it prevents the formation of insoluble chromous oxide, but its use in connection with nitrogenous compounds is not feasible due to oxidation of ammonia. In this Laboratory it was found that ammonia is almost quantitatively converted to the nitrate in a phosphoric acid medium (a fact which as far as we know has not been previously recorded). Slightly diluted sulfuric acid seems to be most favorable[7]

and was used in the work here reported. If five volumes of sulfuric acid are diluted with one volume of water, chromous oxide is not precipitated enough to cause serious inconvenience.

Preliminary experiments indicated that for practically all compounds satisfactory oxidation takes place if the temperature is brought to the point where oxidation is vigorous for a few minutes and then raised and held at 165° for twenty minutes. In the case of a few compounds, when the vigorous oxidation (which is easily noted) fails to take place below 165°, it is necessary to modify the heating so that the ultimate temperature is perhaps 10° above the point where the reaction appears to be vigorous. Temperatures up to 200° were not sufficient to cause appreciable oxidation of ammonia.

Considering the danger of escape of volatile, difficultly oxidized compounds (particularly acetic acid) on the one hand and the size of the correction due to dissolved gases on the other, it was deemed advisable to use 12 ml. of medium per 1.5-g. charge of dichromate.

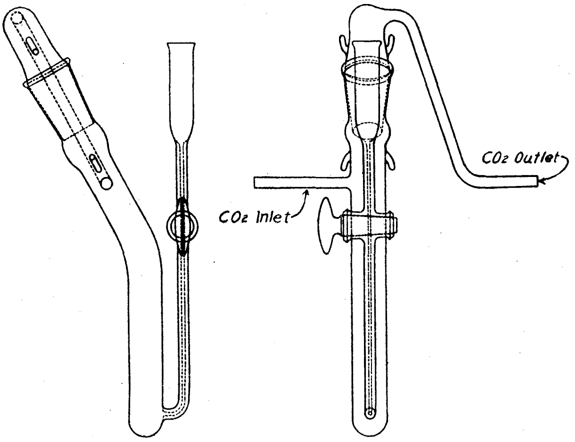

Fig. 1.

Two methods were available for the determination of the unreduced dichromate. The simplest procedure involves the thermal decomposition of the excess dichromate and the measurement of all the unused oxidizing agent as oxygen gas. However, in order to carry out the process in a reasonable length of time such high temperatures are required that ammonia if present, is oxidized. This makes the method inapplicable to nitrogenous compounds, and we were forced to determine the unreduced oxidizing agent by back titration. This was done iodometrically.

A cause of difficulty at this point is the fact that during the oxidation and partial decomposition of the dichromate small amounts of an intermediate product (perhaps perchromic acid or $Cr_2(SO_4)_5$[8]) are invariably formed which causes low results on titration. This was obviated by diluting the medium after oxidation with 12 ml. of 6 N sulfuric acid and boiling gently for five minutes. By this means complete recovery was consistently obtained when the oxygen gas collected and the unchanged dichromate were both taken into account.

We have found it impossible to prevent the formation of carbon monoxide while certain compounds (notably carbohydrates) are being oxidized. To avoid error due to this cause, the carbon monoxide may be oxidized to carbon dioxide with the oxygen which is evolved. This has been accomplished in this work by introducing a chamber containing a platinum spiral heated to dull red heat, into the train between the bubble counter and the oxygen buret, or by running the whole sample of gas after collection in the buret into a slow combustion pipet until all carbon monoxide has been oxidized.

Apparatus.—As some carbon monoxide is liable to be formed and large amounts of oxygen are always evolved during oxidation, it is necessary to utilize a closed system whereby these products can be retained. The apparatus used is simple and consists of (1) a Kipp generator for carbon dioxide production, (2) a reaction vessel of special design, (3) a bubble counter, (4) a gas buret (nitrometer), and (5) a slow combustion pipet.

The reaction vessel[9] is pictured in Fig. 1 and is made using a Pyrex No. 20 standard taper joint. The Kipp generator is charged with marble and air-free concentrated hydrochloric acid containing about 20% dissolved calcium chloride, in order that the carbon dioxide shall be as pure as possible; the bubble counter is one of the usual type but constructed so that there is no inverted pocket where gas may be retained; the gas buret is an ordinary Schiff nitrometer and the slow combustion pipet is of the type described by Engelder.[10]

The reaction vessel is heated by means of a special bath, which has been found very convenient, composed of 1 part of metaphosphoric acid and 4 parts of sirupy phosphoric acid.[11]

Procedure.—The reaction vessel is charged with a weighed quantity (about 1.5 g.) of potassium dichromate of known purity. The stopcock on the vessel is lubricated with phosphoric acid. Twelve ml. of a 5–1 (by volume) mixture of sulfuric acid and water is then introduced into

the reaction vessel through the capillary. The vessel is connected to the Kipp generator in such a position as to permit a porcelain boat to rest near the mouth of the vessel.

The porcelain boat containing a weighed sample to be analyzed (about 100 mg.[12]) is placed at the upper end of the reaction vessel. The seal is lubricated with sirupy phosphoric acid, closed and held together with small steel springs. The bubble counter is connected on the one hand to the outlet tube of the vessel and on the other to the gas buret. For connections sound heavy-walled rubber tubing (2 mm. internal diameter), well lubricated with water, is used.

In order to simplify the assembling of the apparatus the gas buret should be suspended from the top so that the position of the lower end can be adjusted easily.

The system is flushed with a moderate stream of carbon dioxide for about ten minutes; in the meantime the gas buret is charged with 30% potassium hydroxide solution which has been saturated previously with oxygen at room temperature. The flushing is complete when, as in the ordinary Dumas method for nitrogen, the bubbles are negligibly small (about 0.2 mm. in diameter).

The reaction vessel is now rotated to a position about 15° from vertical; this allows the boat and contents to slide into the reaction mixture, and the heating may be started. The bath is adjusted to surround the lower 5-cm. portion of the vessel and its temperature raised slowly (principally to avoid breaking the bath container since the bath mixture is viscous at first) until the oxidation proceeds vigorously. As indicated above, the bath mixture is in most cases held at approximately even temperature for two to five minutes and is then heated to about 165° for twenty minutes. The whole heating process as contrasted with that of carbon and hydrogen combustions is completed with a minimum of care since the bath temperature is regulated easily and, as a result of continuous evolution of gas, the reacting solution boils vigorously without any tendency to superheat or bump.

After the heating time has elapsed the bath is removed and 12 ml. of 6 *N* sulfuric acid is added through the capillary. The reaction mixture is boiled gently for five minutes using a free flame. The residual oxygen is flushed from the system for about four minutes or until the bubbles are negligibly small.

The gas buret is detached and connected to the slow combustion pipet where the carbon monoxide which may have been formed is oxidized by oxygen evolved during the oxidation. The gas is then transferred back to the nitrometer and allowed to stand in a room of even temperature until the volume remains constant.

In the meantime the contents of the reaction vessel are washed into a 500-ml. volumetric flask with boiled water. A 100-ml. aliquot is removed; to it are added 2 g. of sodium bicarbonate and 4 g. of potassium iodide. This is allowed to stand for a half hour in a stoppered bottle, diluted to about 300 ml. with boiled water, and titrated with 0.1 *N* sodium thiosulfate.[13]

The analysis is thus completed in less than two hours. A considerable part of this time (during the heating and waiting for the final titration) can be utilized for the preparation of samples for the next analysis, or completion of other analyses if more than one apparatus is available. It only remains to calculate the amount of oxygen (in milliequivalents) in the buret and the milliequivalents of residual oxidizing agent and subtract these from the milliequivalents of dichromate originally used. This gives the milliequivalents used by the sample. In calculating the milliequivalents of oxygen gas it is of course necessary to make the usual corrections for temperature, barometric pressure, vapor pressure of the potassium hydroxide solution[14] and calibration of the buret. In addition there is a small correction for the air which originates in the sulfuric acid solution or from the Kipp generator. This amounts to 0.3 to 0.4 ml. and as it is practically constant needs to be determined only occasionally. This is done by passing the gas into a Hempel pipet charged with alkaline sodium hydrosulfite, and measuring the unabsorbed gas. The air correction is calculated as five-fourths of the residual nitrogen.

Discussion and Results.—The results given in Table I are representative of those obtained under ordinary laboratory conditions. Partly through

TABLE I

RESULTS OF ANALYSES

The first nine analyses recorded were run with the platinum spiral combustion chamber in the combustion train behind the gas buret. This took the place of the slow combustion pipet.

Substance analyzed[a]	Percentage errors in milliequivalents of oxygen used. (Successive analyses)				
Succinic acid	+0.06[b]	+0.09	+0.30	+0.97	−0.11
Sucrose	.00	− .56[c]			
Potassium acid phthalate	− .17	− .31			
Sucrose	+ .10	+ .02			
Potassium acid phthalate	+ .47	+ .14			
Acetanilide	+ .45	− .51	−0.11	+0.22	
Benzoic acid	+ .22	+ .54	−2.06[d]		
	+ .03	−2.05[d]	+0.21	+0.19	
Leucine	+ .15	+0.06			
Quinoline	− .58[e]	− .92[e]			
Benzidine	+ .17	+ .68	+0.96		

[a] The samples used varied from about 0.15 g. for succinic acid down to 0.05 g. for benzidine. [b] The temperature of this combustion was 200° instead of 165°. [c] In this analysis, carbon monoxide was found to have escaped oxidation. The amount was determined and the value corrected accordingly. [d] The difficulty in these two benzoic acid determinations was found to be due to too rapid flushing and a consequent entrainment of some finely powdered benzoic acid which escaped oxidation. This defect was carefully guarded against in the last two analyses. [e] This compound was difficult to oxidize and the temperature was raised to 185° and held there for over thirty minutes. The indications are that even this may not have been entirely sufficient.

---

(12) If the material is of a waxy or oily consistency or is known to be a compound of high oxygen requirement, the sample should be reduced somewhat (even to about half this size); whereas, if it is known to be a highly oxygenated compound such as a carbohydrate, the size of the sample may be increased by 50% or more.

intention and partly through necessity most of the analyses were run under conditions far from ideal. After the proper conditions had been established, the method, in the hands of a relatively inexperienced student using ordinary balances, weights, volumetric apparatus, and chemicals, gave results which are far from unsatisfactory.

All analyses made after the method was established in its present form are included in Table I except exploratory tests on materials known to be impure, such as paraffin, and tests on certain compounds (particularly asparagine) which were found later to be impure and variable in composition. It seems to be a significant fact that we have experienced no difficulty in obtaining *highly satisfactory results with every compound the standard of purity of which was unusually high* (succinic acid, potassium acid phthalate, sucrose, acetanilide, benzoic acid).

Duplicate analyses of nicotinic acid (which is almost untouched by the iodate method[7]) gave consistent results which were only slightly low. This sample upon further investigation was found to be impure. Subsequent work with quinoline indicates that the method apparently is applicable to compounds containing the pyridine nucleus.

Analyses of paraffin showed it to be difficult to oxidize, apparently not because of its stability toward the oxidizing agent but because of its insolubility. Using the ordinary procedure it is over 90% oxidized, but after the reaction mixture cools small flakes of unchanged paraffin are visible on the surface. The indications are that by modifying the procedure accurate analyses could be obtained even on paraffin.

On the basis of the above facts we are of the opinion that by using extra precautions and precision equipment it should be possible to obtain highly precise results in the analysis of organic compounds generally. Under ordinary conditions one can obtain results which are in error less than 5 parts per thousand, which is satisfactory for the purposes outlined in the first paper of this series.

Preliminary experiments indicate that compounds containing sulfur may require some special treatment to obtain accurate results, though values which are at least approximately correct are obtained using the method as here outlined. The adaptation of the method as outlined to a micro scale has led to irregularities presumably associated with the formation of intermediate reduction products of dichromate, which as yet we have been unable to eliminate.

Summary

A method for the accurate determination of the oxidizing agent required for the complete combustion of organic compounds, using potassium dichromate as the oxidizing agent, is described.

In accordance with equations developed in the first paper in this series, this determination can be substituted in the majority of cases for a combustion analysis.

Its advantages over combustion analyses are: (1) considering all preliminary preparations, it is quicker; (2) it uses a minimum of special equipment and none which cannot readily be made in the laboratory; (3) it requires no special catalysts or materials which are likely to introduce complications; (4) it involves the simplest technique and no careful control of heating or gas evolution; (5) it, when taken in conjunction with an accurate carbon determination, makes possible a more accurate determination of hydrogen than has hitherto been possible under ordinary analytical conditions.

Quaternary Derivation of Pyridyl Ethers. Onium Compounds. XVI

BY R. R. RENSHAW AND R. C. CONN[1]

In previous publications the synthesis[2] and the pharmacological effects, determined by Reid Hunt,[3] of certain onium derivatives of pyridine, piperidine and pyrrolidine have been described. From these data and other work it was found that many of these quaternary derivatives without substitution on the cyclic carbon atoms acted on the autonomic nervous system producing the acetylcholine effect or the nicotine actions or both. Thus the carbethoxypyridinium ion was 75 times as active as choline in producing the acetylcholine effect and the beta - phenoxyethyl - methylpyrrolidinium ion half as active as nicotine in causing a rise of blood pressure.[3b]

A limited number of quaternary compounds having substituents on the cyclic carbon have been synthesized and studied. With the exception of quaternary derivatives of nicotine acid ester[3a,4] and its hydrogenated product[3a,4a] most of these showed little or no effect on the autonomic system even though the groups present[3b] (amide and acetamino) would produce these effects when introduced in the choline structure. Since the number of compounds of this latter type which have been investigated was so small we began in this Laboratory the preparation of a series of ethers, of choline type esters and of carbaminoyl derivatives of these heterocycles. The latter two fields will be the subject of papers to follow.

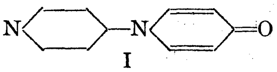
2-Pyridyl Ethers.—A number of 2-pyridyl ethers were prepared by heating 2-bromopyridine with the alkali salts of alcohols and phenols. Yields of 90% and better of 2-aryloxypyridines were obtained with no indication of any N-arylpyridines being formed. This is a more satisfactory method than that reported by Chichibabin[5] for the preparation of 2-phenoxypyridine, the only alpha-substituted pyridine reported in the literature. He obtained a mixture of ortho- and para-pyridyl phenols together with some 2-phenoxypyridine by warming 2-pyridyl diazotate with phenol.

The reaction was extended to include the use of alkylated phenols, resorcinol as a typical dihydric phenol and benzyl alcohol. With resorcinol, although the quantities of reactants were such as to give the mono-ether, only the dipyridoxy ether and an unidentified, very difficultly soluble, red crystalline product were obtained.

These 2-pyridyl ethers are very weak bases. This is probably due to the proximity of the aryloxy grouping to the ring nitrogen. They fail to deposit picrates from either ether or benzene solution and may be steam distilled from solutions of mineral acids. This behavior is in contrast to that of the corresponding 3- and 4-substituted ethers of pyridine which form stable picrates and salts of mineral acids. Alkyl halides add much more slowly to the 2-substituted ethers than to the corresponding 3- and 4-substituted derivatives although the final yields of pyridinium halides are essentially the same. 2-Pyridyl-benzyl ether did not yield a methiodide.

4-Pyridyl Ethers.—4-Pyridyl ethers were prepared by the interesting method of Koenigs and Greiner[6] whereby 4-pyridylpyridinium dichloride is heated with an alcohol or phenol in the optional presence of an acid binding agent. A number of previously reported ethers were prepared in this way and, in addition, one new alkoxy ether, 4-*n*-butoxypyridine, was prepared.

Methyl and ethyl iodide were also added to N-4′-pyridyl-4-pyridone (I) first prepared by Arndt



I

and Kalischek[7] by warming 4-hydroxypyridine with acetic anhydride. Although first considered by them to be 4,4′-dipyridyl ether, Arndt[8] later showed it to have the N-pyridyl-pyridone structure (I). We have found that, whereas I forms dibasic salts with hydrochloric, chloroplatinic and chloroauric acids, it will only add one mole of alkyl halide. This may be due to a steric effect or to the decreased basicity of the pyridone nitrogen.[9] Further confirmation for the pyridone structure

(9) Weitz, Werner and Schwechter, *ibid.*, **59**, 2307 (1926).

lies in the fact that both methiodide and ethiodide are colored.

3-Pyridyl Ethers.—No 3-substituted aryl ethers are reported in the literature and only two (3-methoxy[10,11] and 3-ethoxy[12,13]) alkyl ethers have been prepared.

We have prepared 3-phenoxypyridine in the two following ways:

(1) Pyridine ⟶ 3-pyridyl sulfonic acid ⟶ 3-hydroxypyridine ⟶ 3-phenoxypyridine

(2) 2-Chloro-5-nitropyridine ⟶ 3-aminopyridine ⟶ 3-iodopyridine ⟶ 3-phenoxypyridine

The final step (phenylation) in both these syntheses was carried out according to the method of Ullmann.[14] Method 2 proved to be the more satisfactory because of the better yields and fewer experimental difficulties in the intermediate steps and because of the considerably greater yield in the final phenylation.

Reduction of Ethers.—The catalytic reduction of the methiodides of the three isomeric phenoxypyridines prepared in this investigation was attempted with the hope of obtaining the corresponding phenoxypiperidines for the purpose of physiological study. It was found that both 2- and 4-phenoxymethylpyridinium iodide were reduced with cleavage of the phenoxy grouping, phenol and N-methylpiperidine being formed. This behavior is consistent with results obtained by other investigators. Graves[15] found that 2-methoxypyridine underwent a similar reductive cleavage with the formation of methyl alcohol and piperidine. Koenigs and Neumann[16] reduced 4-pyridyl ethers with sodium–alcohol and obtained 90% yields of piperidine.

In contrast to the behavior of the 2- and 4-phenoxypyridines, the catalytic reduction of 3-phenoxymethylpyridinium iodide proceeded rapidly and in good yields without loss of the 3-phenoxy group. In one experiment, however, where a comparatively large amount of catalyst was used, a cleavage did take place to an extent of almost 50%. In all cases the reduction product was converted directly into the dimethylpiperidinium compound by warming in alcohol solution with methyl iodide and excess barium hydroxide.

The stability of substituents in the 3-position as contrasted to the lability of 2- and 4-substituted groups is well illustrated by the behavior of these three phenoxy ethers on reduction. Similarly, the reactivity of 2-bromopyridine, which is essentially that of an aliphatic bromide, as contrasted to the inactivity of 3-iodopyridine is to be noted. This behavior is general, the stability and aromatic nature of 3-substituted pyridines being quite marked whereas 2- and 4-pyridyl derivatives are characterized by the lability and often by the anomalous behavior of the substituted groups.

Experimental Part

2-Pyridyl Ethers.—The method of preparation employed for the aryl ethers of this series was as follows: 0.05 mole of 2-bromopyridine,[17] 0.1 mole of phenol and 0.05 mole of anhydrous potassium carbonate were placed in a flask fitted with a long, upright air condenser and heated in a Wood's metal bath at 200–210° for three hours. The contents of the flask were then diluted with water, made strongly alkaline and steam distilled. The distillate was extracted with ether and the extract dried. After removing the ether, the residual oil was vacuum distilled. The yields and boiling points under reduced pressures obtained for these ethers are recorded in Table I.

The reaction with resorcinol was carried out in the same way except that only 0.025 mole of potassium carbonate was used. The reaction initially was quite vigorous, a deep red color developing in the melt. Resorcinol was removed from the reaction mixture by repeatedly washing with hot water until the aqueous extract no longer gave a color test with ferric chloride. The remaining tar was extracted with ether and the ethereal extract dried. A red, solid product remained which could only be dissolved in hot glacial acetic and concentrated sulfuric acids. No identification of this material has as yet been made. On working up the ether extract a solid residue was obtained which was purified by vacuum distillation and recrystallized from a benzene–ligroin mixture from which it separated as pale yellow plates, m. p. 154–156° (corr.). Analysis showed it to be resorcinol di-2-pyridyl ether.

2-Pyridylbenzyl Ether.—A solution of 1.15 g. (0.05 mole) of sodium in 22 g. (0.2 mole) of benzyl alcohol was heated with 7.9 g. (0.05 mole) of 2-bromopyridine for three hours at 210°. Since it was found that ether extraction of a hydrochloric acid solution of the product removed not only benzyl alcohol but 2-pyridylbenzyl ether as well, the two were separated by fractional vacuum distillation.

4-Pyridyl Ethers.—Yields and boiling points of the 4-pyridyl ethers prepared are listed in Table I. The four previously prepared aryl ethers were prepared from 4-pyridylpyridinium dichloride by the method of Koenigs and Greiner.[6] In each case 15 g. of recrystallized 4-pyridylpyridinium dichloride, 40 g. (excess) of phenol and 1.1 equivalents of the sodium salt of the phenol were used. The 70% yield obtained for 4-phenoxypyridine is somewhat better than that (53%) reported by the authors for the same compound. The sodium phenolates used here were

[a] All halogen analyses were carried out by the Fajans method of titration using 0.01 *N* silver nitrate. [b] Obtained as the pyridinium bromide. Calcd. for $C_{20}H_{20}O_2NBr$: Br, 20.70. Found: Br, 20.63, 20.61.

prepared by adding sodium wire to the phenol in benzene, filtering and washing with ether.

4-*n*-Butoxypyridine was prepared by refluxing a suspension of 22 g. of purified 4-pyridylpyridinium dichloride in 400 cc. of *n*-butyl alcohol containing 6.8 g. of sodium. 4-*n*-Butoxypyridine is insoluble in water and possesses an ethereal odor.

Preparation of Onium Derivatives.—The onium derivatives listed in Table II were prepared by allowing a solution of the pyridyl ether in 10 cc. of dry ether and an excess of alkyl iodide to stand at room or slightly elevated temperatures for periods varying from one to six days. Addition of methyl iodide to the 3- and 4-pyridyl ethers proceeded rapidly at room temperature but ethyl iodide added more slowly and the reaction was carried out at 40–50°. Addition to the 2-pyridyl ethers was still less rapid but by heating to 70° satisfactory yields were obtained.

The methiodides of the 4-pyridyl ethers were recrystallized from a hot mixture of Cellosolve and ethyl acetate and the other onium derivatives were recrystallized from hot amyl alcohol–amyl acetate. All were well-defined, crystalline products and were not generally hygroscopic. The low melting point of 3-phenoxymethylpyridinium iodide is interesting and the higher melting point of the corresponding ethiodide (3-phenoxyethylpyridinium iodide) is particularly surprising. Whereas the methiodide tended to form an oil on recrystallization and was appreciably hygroscopic, the ethiodide showed no tendency to form oils, crystallized without seeding and was not appreciably hygroscopic.

4-*p*-Cresoxy-β-phenoxyethylpyridinium bromide was prepared by heating 2 g. (0.001 mole) of 4-cresoxypyridine and 2.2 g. (0.001 mole) of β-phenoxyethyl bromide in dry toluene for three days at 70–80°. The toluene was decanted and the separated oil dissolved in water, the aqueous solution extracted with ether and evaporated to dryness on the water-bath. The residue was dried thoroughly and washed several times with dry benzene. Crystallization was effected by dissolving in absolute alcohol and slowly removing the solvent under reduced pressure. The product was recrystallized from hot Cellosolve–ethyl acetate.

N-4′-Pyridyl-4-pyridone.—This product was prepared by heating 4-hydroxypyridine with acetic anhydride following the directions of Arndt and Kalischek.[7] Considerable difficulty was encountered in obtaining a product melting above 168°, although a sample melting in the range (m. p. 177–178°) given by these authors was obtained. The lower melting product gave a chloroplatinate and chloroaurate which analysis without recrystallization showed to be quite pure. It was therefore used directly for the preparation of onium compounds.

The chloroaurate of the pyridone was obtained as a yellow crystalline powder, m. p. 218–219° (corr.).

Anal. Calcd. for $C_{10}H_9ON_2Cl_4Au{\cdot}2H_2O$: Au, 44.39. Found: Au, 44.36.

The chloroplatinate was obtained as a buff powder melting above 300°.

Anal. Calcd. for $C_{20}H_{18}O_2N_4Cl_6Pt{\cdot}2H_2O$: Pt, 31.59. Found: Pt, 31.55.

This pyridyl-pyridone forms a dihydrochloride which was obtained both by passing dry hydrogen chloride into an alcoholic solution of the base and by evaporating its solution in dilute hydrochloric acid. It was recrystallized from alcohol in which it was only sparingly soluble; m. p. 238° (dec.).

Anal. Calcd. for $C_{10}H_{10}ON_2Cl_2$: Cl, 28.95. Found: Cl, 28.90.

N-(4′-Methylpyridinium Iodide)-4-pyridone.—Methyl iodide was added to N-4′-pyridyl-4-pyridone, both in alcohol and benzene solution. The product obtained by adding ether to the alcoholic solution after twelve hours of heating at 70° was quite impure and it was found that better results could be obtained by carrying out the reaction in dry benzene. A suspension in benzene, in which it is only moderately soluble, was heated with an excess of methyl iodide at 80° for twelve hours. The crystalline methiodide was filtered and the precipitate extracted with hot benzene to remove the non-alkylated product. The yield was 95% based on the quantity of the pyridone used. The methiodide was recrystallized from hot absolute alcohol from which it separated as yellowish-brown, rectangular plates, m. p. 238–238.5° (corr.). Repeated recrystallization and treatment with mercury and Norite failed to change the color. Analysis showed both the product obtained from alcohol and that obtained from benzene to be the monomethiodide.

Anal. Calcd. for $C_{11}H_{11}ON_2I$: I, 40.41. Found: I, 40.25, 40.20.

N - (4′ - Ethylpyridinium Iodide) - 4 - pyridone.—Ethyl iodide was added to N-4′-pyridyl-4-pyridone in benzene solution in the same manner as methyl iodide. The yield of ethiodide was 91% based on the quantity of pyridone used. Recrystallization from hot absolute alcohol gave buff colored rectangular plates, m. p. 134–135° (corr.), which analyzed as the monohydrate. Repeating the preparation and recrystallizing from hot Cellosolve–ethyl acetate gave a product with the same melting point and analysis. Arndt and Kalischek[7] noted the curious tendency of the original pyridyl-pyridone to deposit a crystalline dihydrate from benzene solution when exposed to air.

Anal. Calcd. for $C_{12}H_{13}ON_2I{\cdot}H_2O$: I, 36.68. Found: I, 36.68, 36.73.

3-Phenoxypyridine. Method 1.—Nine and five-tenths grams (0.1 mole) of 3-hydroxypyridine and 5.6 g. (0.1 mole) of potassium hydroxide were heated at 150° to drive off water and a 6-g. excess of 3-hydroxypyridine was then added together with 15.7 g. (0.1 mole) of bromobenzene and 0.2 g. of copper bronze. The mixture was heated at 200° in a flask fitted with a long, upright air condenser. After six hours heating was discontinued and the reaction mixture worked up in the manner given for the 2-pyridyl ethers. The 3-phenoxypyridine obtained was purified by vacuum distillation, b. p. 147–149 at 17 mm. The yield was 4.7 g. or 27%. 3-Phenoxypyridine has the same pleasant ethereal odor possessed by 2- and 4-phenoxypyridine. It, unlike them, is a liquid at room temperature. No appreciable reaction was obtained when anhydrous potassium carbonate was substituted for potassium hydroxide.

Anal. Calcd. for $C_{11}H_9ON$: N, 8.18. Found: N, 8.01.

Method 2.—Ten and two-tenths grams (0.05 mole) of 3-iodopyridine[18] and 6.1 g. (0.05 mole) of potassium phenolate in an excess of phenol were heated with 0.2 g. of copper bronze as before. A yield of 59% of 3-phenoxypyridine was obtained. Using anhydrous potassium carbonate, the yield was 46%.

Reduction of Ethers.—2-(II), 3-(III) and 4-(IV) phenoxymethylpyridinium iodides were reduced catalytically using Adams platinum oxide catalyst and an initial hydrogen pressure of 3 atm. II and III were reduced in alcohol solution but IV, which was quite difficultly soluble in alcohol, was dissolved in water and reduced in this solvent.

---

[18] C. Räth, *Ann.*, **486**, 101 (1931).

The reduction products were not isolated directly but converted first into the corresponding dimethylpiperidinium iodides by the addition of methyl iodide and excess barium hydroxide to the alcoholic solution. In the case of IV, the aqueous solution was first evaporated to dryness and the solid residue taken up in alcohol. The alcoholic solution was dried and methyl iodide added as above.

After warming for twelve hours, the solution was filtered and dry hydrogen chloride passed in to precipitate barium chloride. This was filtered and, after shaking the filtrate with anhydrous sodium carbonate, the alcohol was removed and the last bits of solid product precipitated by the addition of ethyl acetate and ether. The products obtained from the reduction of II and IV were recrystallized from ethyl alcohol-ethyl acetate. They melted at 333–335° with decomposition. Analysis and comparison with an authentic sample showed them to be dimethylpiperidinium iodide, m. p. 334° (dec.).[19]

---

(19) Wedekind and Oechslen, *Ber.*, **35**, 1076 (1902).

3-Phenoxydimethylpiperidinium Iodide.—The reduction product of III gave a derivative melting, after recrystallization from ethyl alcohol-ethyl acetate, at 177–178° (corr.). It was obtained in the form of small blunt needles which were only moderately soluble in alcohol. Analysis showed it to be the 3-phenoxy derivative. The yield was 87%.

Anal. Calcd. for $C_{13}H_{20}ONI$: I, 38.10. Found: I, 37.97, 38.05.

Summary

1. The preparation of a number of new pyridyl ethers is described.

2. These ethers along with several previously known have been converted into their methyl and ethyl pyridinium salts for pharmacological examination.

NEW YORK, N. Y. RECEIVED OCTOBER 6, 1936

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, IOWA STATE COLLEGE]

The Production of Dihydroxyacetone by the Action of Acetobacter Suboxydans upon Glycerol*

BY L. A. UNDERKOFLER AND ELLIS I. FULMER

Since the discovery by Bertrand[1–3] that his "sorbose" bacterium (*Acetobacter xylinum*) transformed many polyhydric alcohols into the corresponding ketose sugars, several other species of the genus *Acetobacter* have been found to behave similarly. This type of conversion has been studied particularly with reference to the production of *l*-sorbose by the action of the appropriate organism upon sorbitol; the sorbose then serves as the starting point for the synthesis of ascorbic acid. The influence of the concentration of sorbitol upon the production of sorbose by the action of *Acetobacter suboxydans* has been studied quantitatively by Fulmer, Dunning, Guymon and Underkofler.[4] The authors give a brief literature survey and state the reasons for the use of *Acetobacter suboxydans* in the fermentation. The present communication deals with the optimum conditions for the production and isolation of dihydroxyacetone produced by the action of *Acetobacter suboxydans* upon glycerol.

Bertrand[1–3] was the first to report this conversion by *Acetobacter xylinum;* he isolated and identified the material. This reaction by the above organism was also studied by Fischer and Mildbrand[5] and by Bernhauer and Schoen.[6] Other organisms employed for this purpose include *Acetobacter dioxyacetonicum* by Virtanen and Bärlund[7] and *Acetobacter suboxydans* by visser't Hooft,[8] Virtanen and Nordlund,[9] and by Neuberg and Hofmann.[10] The latter authors considerably improved the methods of crystallization of the dihydroxyacetone and recovered 77% of the theoretical yield.

Experimental

Methods.—The culture of *Acetobacter suboxydans* was obtained from the American Type Culture Collection and is listed as No. 621. The stock cultures were carried on malt-extract agar slants. The cultures used for inoculation in these studies were kept active by transfer each forty-eight hours into a medium containing per 100 cc. 0.5 g. of yeast extract (Difco powdered product) and 6 g. of glycerol. Preliminary experiments showed temperatures of 28–30° to be optimum and all subsequent incubations

were at 28°. It was also found that concentrations of glycerol above 6% gave decreased yields of dihydroxyacetone. There was no appreciable difference between the action on C. P. glycerol and on glycerol which had been distilled in a vacuum. In each case the inoculum consisted of 3 cc. of active (twenty-four to seventy-two hour) culture per 100 cc. of fresh medium; 100 cc. of medium was used in 300-cc. Erlenmeyer flasks.

It has been noted[4] in studies on the production of sorbose by the action of *Acetobacter suboxydans* that disturbing the culture materially reduced the yield. A similar phenomenon was observed with reference to the production of dihydroxyacetone. Hence, each datum presented represents an analysis on a separate flask.

The course of the conversion of the glycerol into dihydroxyacetone was followed by use of the Shaffer–Hartmann[11] method. The dextrose value was multiplied by 1.5 to obtain the value for dihydroxyacetone. This factor was verified on the pure compound and is accurate only if the amount of the dihydroxyacetone in the sample is in the neighborhood of 75 mg. This finding agrees with that of Bernhauer and Schoen.[6]

The Development of the Medium.—In Table I are given the data for the effect of varying concentrations of yeast extract and of potassium dihydrogen phosphate and of various *p*H values upon the yields of dihydroyxacetone. Although analyses were obtained for periods of two to fourteen days, only the results for the seven-day period are given. In all cases incubation beyond the seven-day period did not give increased yields.

TABLE I

THE INFLUENCE OF THE CONCENTRATION OF YEAST EXTRACT AND OF POTASSIUM DIHYDROGEN PHOSPHATE AND OF *p*H VALUE UPON THE PRODUCTION OF DIHYDROXYACETONE BY THE ACTION OF *Acetobacter suboxydans* ON GLYCEROL

I Yeast extract		II KH_2PO_4		III *p*H	
G. per 100 cc.	Yield, %	G. per 100 cc.	Yield, %	*p*H	Yield, %
0.05	57	0.00	87	9.0	0
.10	67	.30	91	8.0	49
.20	72	.60	90	7.0	91
.30	75	.80	89	6.0	91
.40	76	1.00	87	5.5	89
.50	80	1.50	86	5.0	87
1.00	80	2.00	82	4.0	87
				3.0	87
				2.0	0

I. Medium contained per 100 cc.: 6.0 g. glycerol, yeast extract vary. II. Medium contained per 100 cc.: 6.0 g. glycerol, 0.50 g. yeast extract, KH_2PO_4 vary. III. Medium contained per 100 cc.: 6.0 g. glycerol, 0.50 g. yeast extract, 0.30 g. KH_2PO_4, *p*H vary.

The following conclusions may be drawn from the data presented. The medium must contain at least 0.5% of yeast extract. Optimum yields are obtained with concentrations of potassium dihydrogen phosphate of 0.10–0.30%; further addition of the phosphate decreases the yields. The optimum *p*H range is from 5.5 to 7.0.

The Recovery of Crystalline Dihydroxyacetone.—The method of Bertrand[3] did not give significant yields of crystals. The procedure of Fischer and Mildbrand[5] gave beautiful white crystals but the yield was small. The method finally adopted is a modification of that developed by Neuberg and Hofmann.[10] This modified procedure is illustrated by the example given below.

To 1000 cc. of the fermented medium are added 10 g. each of Norite, calcium carbonate and diatomaceous earth, the medium shaken and filtered. The clear filtrate is evaporated below 35°, *in vacuo*, to about 150 cc., 3–4 volumes of absolute alcohol are added, with stirring, and the mixture filtered. Most of the alcohol is evaporated from the filtrate at 30°, *in vacuo*, and the sirup poured into 10 volumes of acetone, stirring vigorously. The turbid solution is allowed to stand overnight, shaken with Norite and filtered. The clear filtrate is evaporated at 30°, *in vacuo*, to a very thick sirup. The remaining water and acetone are removed in a vacuum desiccator over sulfuric acid. The sirup crystallizes spontaneously into an almost solid mass. Seeding the sirup with a few crystals of dihydroxyacetone accelerates the crystallization somewhat but is not required. The crystalline mass is triturated with *cold* absolute alcohol, filtered with suction, and washed with *cold* absolute alcohol until the pure white crystals are obtained. The crystals are dried in a vacuum desiccator. A further yield may be obtained by combining mother liquors and wash liquids from several batches and proceeding as before by evaporating *in vacuo*, pouring into acetone, etc. The first crop is practically pure but it is readily purified further by recrystallization from acetone. By the above procedure over 80% of the dihydroxyacetone, as determined by the Shaffer–Hartmann method, is readily recovered as crystalline dihydroxyacetone.

Summary

A simple procedure has been given for the production of dihydroxyacetone by the action of *Acetobacter suboxydans* upon glycerol and for the preparation of the crystalline product from the fermented medium.

Remarks on the Spectra of Methyl Cyanide and Methyl Isocyanide[1]

BY RICHARD M. BADGER AND SIMON H. BAUER

The infra-red spectrum of liquid methyl cyanide was investigated several years ago by Coblentz,[2] using rather low dispersion, and more recently Raman studies[3] have been made on this substance and on methyl isocyanide. The data obtained appear never to have been interpreted completely but attention was called by Dadieu[4] to the presence of a frequency shift of around 2200 cm.$^{-1}$ in the Raman spectra of both substances. This he took as evidence for the presence of a triple bond between carbon and nitrogen in both cyanide and isocyanide. Lechner[5] made a simplified coördinate treatment of the molecules in which he assumed that in two of the vibrations the methyl group would behave as a rigid unit, and by the use of two observed frequencies calculated two of the force constants in each. The values of the larger constants so obtained are probably quite reliable and their magnitude is conclusive evidence for a carbon–nitrogen linkage which at least approaches very closely to triple bond in character. The calculation gave less reliable values for the single bond constants of the C–C and C–N linkages, respectively, since there are two vibrations in which both single bond and methyl group participate to a considerable extent, causing Lechner's values to be somewhat too small.

However, at the present time it is not possible to make a much more satisfactory calculation. The authors have attempted a complete normal coördinate treatment of all parallel vibrations, but when using the so-called "valence force" potential function there appear to be no real and probable values of the force constants which yield the observed frequencies. From this it is evident that additional interaction terms must be added to the potential function, but at present there is no very reliable method of estimating their magnitude.

It is the purpose of this paper to discuss in further detail the analysis of the spectra of methyl cyanide and methyl isocyanide, pointing out some facts of special interest, and to present some new data on harmonic bands in the photographic infrared.

In the Raman spectrum of methyl isocyanide all fundamental frequencies appear and no overtones or combinations have been observed. In the cyanide one frequency (1040 cm.$^{-1}$) is absent in the Raman spectrum but may be supplied from the infra-red where it occurs strongly. By comparison with other molecules, particularly the methyl halides, it is possible to make what appears to be a unique assignment of the fundamentals. This is done in Table I in which the vibration types are given an approximate description, and in which a classification is made as to parallel or perpendicular type. This classification of course only has an exact significance in case the molecules in question have an axis of symmetry.

TABLE I

IDENTIFICATION OF THE FUNDAMENTALS IN THE SPECTRA OF METHYL CYANIDE AND METHYL ISOCYANIDE

ν(cm.$^{-1}$)			
Cyanide	Isocyanide	Type	Approximate description
2996	3003	$\perp$	Vibrations principally confined to methyl group
2942	2951	$\parallel$	
1417	1456	$\perp$	
1370	1414	$\parallel$	
2250	2161	$\parallel$	$\mathrm{C{\equiv}N}$ vibration
917	928	$\parallel$	C—C vibration in cyanide, C—N vibration in the isocyanide
1040	1041	$\perp$	Swinging of methyl group with respect to remainder of molecule
376	290	$\perp$	Bending of $\mathrm{C{-}C{\equiv}N}$ group in cyanide and $\mathrm{C{-}N{\equiv}C}$ group in isocyanide

The possession of a threefold axis of symmetry will depend presumably only on whether the $\mathrm{C{-}C{\equiv}N}$ and $\mathrm{C{-}N{\equiv}C}$ groups are linear or not. In the case of the cyanide there seems no reason to doubt that the group is linear since it has been shown that hydrogen cyanide is definitely a linear

---

molecule,[6] but in the isocyanide there might possibly be some doubt on this point. Lechner's values for the "triple bond" force constants are 1.733 and 1.630 megadynes per cm. for the cyanide and isocyanide, respectively. These may be slightly in error, and their significance is not quite simple since they include certain interaction constants, but they are at least useful in comparing the two molecules which are so similar in many respects. It is evident that the carbon–nitrogen bond is appreciably weaker in the isocyanide than in the cyanide, suggesting that in the former the linkage may not be completely triple bond in character.

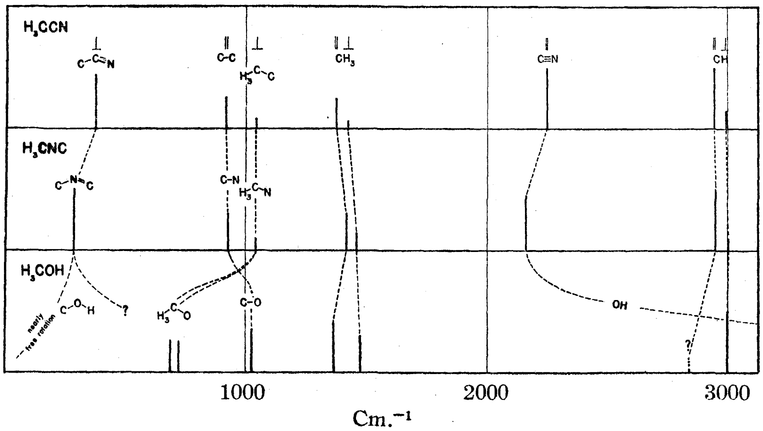

Fig. 1.—Comparison of the Raman spectrum of liquid methyl cyanide and isocyanide (data of Dadieu, etc.) with the infra-red spectrum of methyl alcohol vapor (data of Bartholomé and Sachsse). Missing fundamentals are supplied from the corresponding infrared or Raman spectrum, as the case may be.

It is interesting to compare the vibrations of lowest frequency in the two molecules. The motion in this case is pretty largely a bending of the C—C≡N or C—N≡C groups, and since the mass distribution is so nearly the same in the two cases we can get a rough estimate of the ratio of the force constants involved from the ratio of the squares of the frequencies. We find that the isocyanide bending constant is about 0.6 (or a little less than $^2/_3$) that of the cyanide. At present it is not possible to make any very general statement regarding the bending constants of molecules, but from a recent compilation of data by Penny and Sutherland[7] it appears that they are more or less proportional to the product of the stretching constants of the two bonds involved in the bending. Thus in this deformation oscillation the nitrogen–carbon bond in the isocyanide appears to behave as a double bond. This is probably to be expected since if a double bond structure contributes anything to the ground state of the isocyanide it would be likely to predominate more and more as the molecule is forcibly bent. The question now is whether this trace of double bond character which the bond appears to possess may cause any deviation from linearity in the C—N≡C group in the vibrationless state of the molecule.

Now if we have a bent structure in either the cyanide or isocyanide we should expect a splitting of those frequencies designated as perpendicular in Table I which correspond to degenerate vibrations in a molecule possessing a threefold axis of symmetry. The splitting would undoubtedly be too small to observe in the fundamentals of the internal vibrations of the methyl group, since these are little affected by the remainder of the molecule, but in the two others the separation should be appreciable. The extreme effect would of course be found in the splitting of the low frequency vibration corresponding to the deformation of the cyanide or isocyanide group, since in this case one of the components would take on the character of a torsional motion which would either be of very low frequency or would go over into a more or less free rotation. In order to show what effect may be expected in the absence of a symmetry axis we reproduce in Fig. 1 the infrared spectrum of methyl alcohol vapor, from the data of Bartholomé and Sachsse,[8] together with the Raman spectra of methyl cyanide and isocyanide for the sake of comparison.

By the investigation of both methanol and methanol-*d*, Bartholomé and Sachsse were able to identify a number of fundamental frequencies without uncertainty. They found a separation of 35 cm.$^{-1}$ between the two components of the vibration corresponding to the 1040 frequency in the cyanide and isocyanide, but in the case of the oscillations resulting from the splitting of the vibration analogous to that of lowest frequency in the other substances, neither component could

[6] Badger and Binder, *Phys. Rev.*, **37**, 800 (1931).

[7] Penny and Sutherland, *Proc. Roy. Soc.* (London), **A156**, 654 (1936).

[8] Bartholomé and Sachsse, *Z. physik. Chem.*, **B30**, 40 (1935).

be identified. From an investigation which the authors have recently made on certain harmonic bands of methyl alcohol[9] it appears probable that one of them has indeed gone over into a nearly free rotation which introduces a new complexity in the rotational structure of the bands.

The great similarity between the spectra of the cyanide and the isocyanide will be noted. From this and the absence of any indication of splitting in the degenerate vibrations it seems reasonable to conclude that the C—N≡C group in methyl isocyanide is linear.

Investigations in the Photographic Infra-red

The authors had hoped that it might be possible to photograph the rotational structure of some of the higher harmonic bands of methyl cyanide and isocyanide and to obtain further information about the structure, but this turned out to be impossible at present. The absorption was very weak except beyond 1 μ and in this region it was not possible to get sufficiently clean plates when using high dispersion, to attempt an analysis. The spectra of the liquid substances and also that of methyl cyanide vapor were, however, photographed under low dispersion (about 70 Å. per mm. at λ 9000) using a path length of 7.6 cm. for the liquids, and 3 meters for the vapor under about one atmosphere pressure. The results are presented in Fig. 2 and Table II. The diagrams were drawn with the use of several microphotometer curves as well as the original plates. The intensities of the bands beyond 1μ may be in considerable error since it is difficult to make estimates in a region in which the sensitivity of the photographic plate is dropping off rapidly with increasing wave length. For the same reason the maxima in this region may be slightly in error.

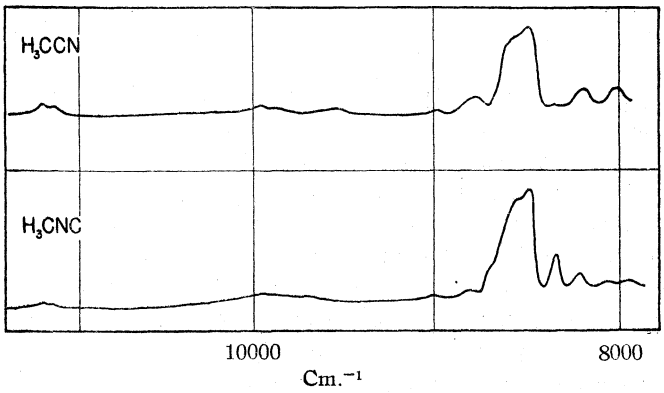

Fig. 2.—Representation of the absorption spectra of liquid methyl cyanide and isocyanide in the photographic infra-red.

TABLE II

WAVE LENGTHS AND FREQUENCIES OF ABSORPTION MAXIMA OF METHYL CYANIDE AND METHYL ISOCYANIDE IN THE PHOTOGRAPHIC INFRA-RED

Methyl cyanide Vapor λ, Å.	Methyl cyanide Vapor ν, cm.$^{-1}$	Methyl cyanide Liquid λ, Å.	Methyl cyanide Liquid ν, cm.$^{-1}$	Methyl isocyanide Liquid λ, Å.	Methyl isocyanide Liquid ν, cm.$^{-1}$	Approximate description of band
		12373	8080	12560	7960	2ν(C—H) + ν(C≡N)
		12182	8206	12380	8075	
				12138	8236	3ν(C—H)
		12007	8326	11968	8353	
11727	8525	11767	8496	11800	8472	
11602	8617	11626	8598	11628	8597	
				11473	8714	
11360	8801	11405	8765	11327	8826	Possibly H_2O
(11238)	(8896)	11140	8974	11093	9012	
		10490	9530	10310	9697	?
		10145	9854	10157	9843	
		10037	9960	10008	9989	
		8973	11141	8937	11187	4ν (C—H)
		8922	11205	8898	11235	

It does not seem possible to identify all the maxima at present except in a very general way as done in the table. The complexity of the spectrum in the 8500 cm.$^{-1}$ region is presumably due to the partial removal of the degeneracy in the C–H vibrations in the higher levels.

Summary

A vibrational analysis is made of the spectra of methyl cyanide and methyl isocyanide. Evidence is given which indicates that although the carbon–nitrogen linkage in the isocyanide approaches rather closely to a triple bond it does possess an appreciable amount of double bond character. This, however, does not produce any deviation from linearity in the C—N≡C group and methyl isocyanide appears to possess a threefold axis of symmetry.

The absorption spectra of methyl isocyanide in the liquid state, and of methyl cyanide in the liquid and vapor states have been photographed in the photographic infra-red.

The Densities of Fine Powders

BY J. L. CULBERTSON AND ALVER DUNBAR

No little work has been done in recent years on the problem of the densities of fine powders and especially those powders having a porous structure. Cude and Hulett[1] found in determining the density of charcoal in carbon disulfide, water, benzene and carbon tetrachloride that the apparent density, as determined in the different liquids, decreased in the order named. From a study of their results the conclusion was reached that the density values varied due to different degrees of penetration of the porous microstructure of the powder by the different liquids, the degree of penetration being governed by the surface tension and the fluidity of the liquids. Harkins and Ewing[2] also working with active charcoal made density determinations in a number of liquids. A similar variability was obtained though not in entire agreement with Cude and Hulett. They concluded that a compression of the liquid film at the solid–liquid interface caused the apparent density of the powder to be abnormally high and that the liquids with the greatest compressibility gave to the powder the greatest density. Later Howard and Hulett[3] with new data opposed the theory of film compression. Lamb and Coolidge[4] studying the heats of adsorption of vapors on charcoal found that the data gave support to the theory of a compressed layer at the solid–liquid interface and M. W. Tschapek[5] indicated that his density measurements of several solids in water and benzene lead to the same conclusion.

It appeared to the writers that a reconsideration of the apparent densities of two solids of quite different character as measured in each of a group of liquids should give a better concept of the causes of their variations in value. To this end the densities of silica gel and an active charcoal were determined in each of four different liquids.

Materials

All materials were carefully prepared or purified. The solids used were silica gel and an active (practically ash free) charcoal. The liquids were water, benzene, carbon tetrachloride and petroleum ether. The best laboratory reagent quality of the organic liquids was selected and each of these was specially purified. The purification in each case was concluded with thorough treatment with dehydrating agents in order to ensure completely anhydrous liquids, phosphorus pentoxide being used with carbon tetrachloride and sodium with benzene and petroleum ether.

Silica gel was prepared by precipitation from sodium silicate solution with ferric chloride by the method of Holmes, Sullivan and Metcalf.[6] After drying, the gel was pulverized in a pebble mill and screened through a 200-mesh screen.

Carbon was prepared from a commercial active charcoal, the mineral content being removed by the method of E. J. Miller.[7] The final treatment was to heat to approximately 900° in a closed crucible for a period of two hours. Analysis of this product showed it to have an ash content of 0.02 ± 0.005%.

Procedure

The density determinations were made by enclosing 2 to 3 g. samples of the solid in Pyrex bulbs and evacuating the bulbs while their temperature was maintained at 475 ± 20°. After evacuation the bulbs were sealed off while still hot, cooled, weighed in air, and then the tip, at the point of sealing, broken off under the surface of a portion of the freshly degassed liquid. The bulb was then suspended in the liquid by means of a loop of fine platinum wire and weighed while immersed. After emptying the bulb, it was reweighed in the liquid and in air, the tip broken off when the bulb was opened being accounted for in the latter weighing. Calculation of the density may be summarized in the following formula, after Lowry[8]

$$S = \frac{A - B}{[(A - B) - (C - D)]/d}$$

where A = weight glass and sample in vacuum
B = weight glass in vacuum
C = weight glass and sample in the liquid

D = weight glass in liquid
d = density of the liquid

The bulbs were evacuated by means of an oil pump. For the charcoal a period of eight to ten hours of evacuation was required and for the silica gel thirty-six to forty hours. Not having available a McLeod gage, the exact air pressure in the bulbs was not known, yet these periods were found to be of sufficient length that longer evacuation yielded no appreciable change in the density values. The final weighings of the sample suspended in the liquid were made approximately two hours after the sample was wetted. This procedure does not eliminate all the effect of the drift discussed by Cude and Hulett,[1] but from an inspection of the curves presented by these authors and from the reproducibility of the results found in the present investigation when weighings were made from one and one-half to two and one-half hours after wetting, it was concluded that the method adopted yielded values that might be confidently used for purposes of comparison.

Results and Discussion

The values of the densities of the active charcoal and silica gel in each of the four liquids are presented in Table I.

TABLE I

APPARENT DENSITIES OF CHARCOAL AND SILICA GEL AT 25°

	Charcoal, g./cc.	Silica gel, g./cc.
Water	1.821	2.246
Benzene	1.994	2.149
Carbon tetrachloride	1.860	2.132
Petroleum ether	2.083	2.125

It is interesting to note that in this restricted group, water, the liquid which yields the highest density for silica, yields the lowest density for charcoal, while the petroleum ether which yields the highest density for charcoal yields the lowest density for silica. It is the special purpose of this paper to point out this fact and to consider its consequences. The same sort of inverted relationship is seen between water and benzene, benzene and petroleum ether, water and carbon tetrachloride, carbon tetrachloride and petroleum ether but not between benzene and carbon tetrachloride. It should be stated immediately, however, that this inverted relationship is not as general as is indicated by the data from this group of liquids. Further work in this Laboratory[9] with other liquids develops such a point but the argument presented below is proposed with this fact in mind and is in no sense invalidated by it. In this series it is quite possible that the benzene–carbon tetrachloride relationship is affected by an abnormal condition of the charcoal–carbon tetrachloride system. This is suggested by the work of Pearce[10] who concluded that some decomposition of the carbon tetrachloride occurred at the charcoal surface and also, for the reasons discussed below, by his observation that the heats of adsorption of the chlorine substituted methanes increased with increased chlorine content up to the tri-substituted compound, then dropped off for the tetrachloride.

It is obvious that an adequate theory of the differences in the apparent density of a solid as indicated by different liquids must harmonize with the situation presented by the above data. This point is strengthened by the fact that the results are in good agreement with the values obtained for charcoal in most of the investigations noted above and for silica in the work of Tschapek.[5]

A consideration of the theories presented by the other workers, however, in the light of the values for the two solids, reveals certain elements of inconsistency. If the liquids penetrated the microstructure of the solids to different degrees as a result of differences in molecular size, fluidity or surface tension of the liquids themselves, it would be impossible for the situation indicated by these data to obtain: *e. g.*, high density of silica in water and low density of carbon in the same liquid. It is equally true that if the compressibility of the liquids were the sole factor involved then the observed data would hardly be explicable.

It appears to the writers that the mutual relation between liquid and solid at the interface must be of vital importance. Of all the highly porous insoluble powders readily obtained, charcoal seems to be more organophilic in nature than any other. This statement very probably will have a surer foundation if we limit it to the organic compounds of non-polar type. On the other hand, the silica gel is distinctly hydrophilic. The tentative hypothesis would be offered then that the observed variations in density are due to one or the other of the following factors: first, differences in the degree of penetration of the porous solid by the liquids as a result of differences

---

(9) Culbertson and Weber, unpublished data.

(10) Pearce, *J. Phys. Chem.*, **34**, 1260–1279 (1930).

in the surface energy decrease on wetting; or second, differences in the degree of compression of the liquids at the solid–liquid interface as determined, primarily, by the different forces of attraction at the interfaces and, secondarily, by the different compressibilities of the liquids. The results obtained as yet are such that either or both of these factors may be of significance. In case the liquid compression is dominant it is clear that the interfacial force or energy relations are of greater importance than the actual compressibilities of the liquids, for the reason mentioned above in connection with the compression theory. Either of the above postulates requires an intimate relation between density values and the decreases in surface energy when the solid is wetted by the liquids. The complexity of the situation, however, involving the unknown specific areas of the solids used and the possible subordinate role of the compressibilities of the liquids, renders the quantitative treatment of this relation yet impossible. A comparison of the order in which the density values fall, however, with some data on other interfacial phenomena such as adhesion tensions[11] and heats of wetting,[12] shows a rather striking similarity which seems to offer strong support for the postulates advanced.

Summary

Measurements of the apparent densities of charcoal and silica gel in water, carbon tetrachloride, benzene and petroleum ether have been made. The liquids, water and petroleum ether, which, respectively, show the highest and lowest apparent densities for silica yield values of the opposite order for charcoal. Some existing theories are examined in the light of the data found and a new postulate advanced.

Heats of Wetting of Activated Charcoal and Silica

By J. L. Culbertson and L. L. Winter

The results of a recent investigation in this Laboratory[1] on the apparent densities of active charcoal and silica gel, when various liquids were used as the buoying fluids, led to the suggestion that a significant relation existed between the density values and the interfacial energy changes when the solids were wetted by the liquids. In particular it was pointed out that when the apparent density values as found by immersion in the different liquids were arranged in increasing or decreasing order, then the corresponding values of the heats of wetting of similar solids by the liquids, as recorded by a number of investigators, were found in most cases to be in the same order. Since, in the investigation referred to, a considerable quantity of both the active charcoal and silica gel had been prepared, it was considered an excellent opportunity to study the heat of wetting characteristics of the solids when samples were available which were identical in all respects with the material used in the density determinations. In making these latter determinations the samples had been enclosed in glass bulbs and evacuated at elevated temperatures before immersion. It was decided therefore that, though in most of the studies of heats of wetting found in the literature non-evacuated samples were used, a technique must be adopted which would put the solid in approximately the same condition as it had been in the density measurements.

To accomplish this end the samples were enclosed in specially designed glass bulbs and evacuated at 220° for thirty-six hours by means of an oil pump. After sealing off the bulbs while still hot, the latter were cooled and weighed. Wetting of the sample in the calorimeter was accomplished by crushing the bulb, a mechanism being employed which permitted this to be accomplished without opening the calorimeter. This mechanism consisted of a steel holder so arranged that a screw, projecting through the calorimeter closure and operated by hand, compressed the bulb supports. A one-liter Dewar cylindrical flask closed with a thick tightly fitting cork served as the calorimeter. This was set in a water-bath main-

---

[1] Culbertson and Dunbar, This Journal, **59**, 306 (1937).

tained at 25 ± 0.1°. A motor-driven stirrer operated in the calorimeter throughout a determination and the heat capacity of the entire assembly was determined immediately after each run. This was accomplished by means of a measured amount of electrical energy introduced through a resistance wire. Temperature differences were read from a Beckmann thermometer.

Materials.—In the previous investigation referred to, four liquids had been used in determining the densities of the solids. These were water, benzene, carbon tetrachloride and petroleum ether. For the present work these were used and were prepared in the same way as in the previous study. In addition, two other liquids were prepared and used, nitrobenzene and carbon disulfide. The nitrobenzene was treated with sodium hydroxide, washed with water, and dried with calcium chloride. It was then distilled three times, a constant boiling middle portion being secured. The carbon disulfide was treated with mercury and with mercuric chloride, washed with water and dried with phosphorus pentoxide. It was then distilled three times as was the nitrobenzene. The solids, charcoal and silica gel, were portions of the same materials as were used in the density determinations and their preparation has been described in the report of that work.

Results and Discussion.—The values obtained for the heats of wetting of the two solids by the various liquids are indicated in Table I. Three values for each case show the order of agreement in duplicate determinations.

TABLE I

HEATS OF WETTING OF SILICA AND CHARCOAL

Liquid	$-\Delta H$ on silica, cal./g.	$-\Delta H$ on charcoal, cal./g.
Water	16.0	8.5
	16.2	8.5
	15.9	8.3
Average	16.0	8.4
Nitrobenzene	14.3	27.1
	14.5	27.2
	14.2	27.0
Average	14.3	27.1
Benzene	10.9	20.8
	11.4	21.2
	11.2	21.2
Average	11.2	21.0
Carbon disulfide	6.5	29.2
	6.7	29.6
	6.8	29.6
Average	6.7	29.5
Carbon tetrachloride	6.1	19.7
	6.3	20.1
	6.5	20.2
Average	6.3	20.0
Petroleum ether	4.1	23.7
	4.3	23.9
	4.5	23.8
Average	4.3	23.8

In general it may be said that the heats of wetting of silica gel agree well with those found by Berthon,[2] Patrick and Grimm,[3] and Bartell and Fu,[4] though somewhat greater differences between the values for the organic liquids are observed. With the charcoal the agreement with other workers is not so close due no doubt to the wide variations in charcoal used by different investigators. It is believed by the writers that these data represent very reliable values for the systems named because of the care used in evacuating the samples and also because of the fact that in the case of the charcoal, virtually ash free samples were used. The latter point seems especially significant for in view of the relationship between the heats of wetting of the water and the organic liquids on silica it appears that even a moderate percentage of mineral content in the charcoal would alter entirely the heat of wetting relationship. This is well substantiated by a glance at the tables of the "I. C. T."

Of especial interest is the fact that water with the highest heat of wetting on silica yields the lowest value on charcoal. It is also noteworthy that the petroleum ether, exhibiting the lowest heat change with silica, shows a high, though not the highest in the group, heat of wetting on charcoal. Qualitatively these relationships show clearly that the two fundamentally different types of solids, silica and charcoal, possess quite different energy change characteristics when wetted by liquids. In broad terms this is summed up in the statement that the charcoal undergoes a high energy change at the solid–liquid interface when wetted by organic liquids and relatively low change when wetted by water. The exactly opposite situation is obtained in the case of the silica gel. In more detail, however, it is to be noted that nitrobenzene appears in second place in each column. This probably may be interpreted to mean that on silica the polar nitro group is oriented to the solid surface while on the

carbon the orientation is in the opposite direction, though why the latter should show such an increased heat of wetting over that of benzene is not obvious.

In the previous work on the densities of these solids a correlation with existing data on heats of wetting is mentioned. How well this is borne out in the present work is indicated in Table II.

TABLE II

DENSITIES AND HEATS OF WETTING OF SILICA GEL AND CHARCOAL

Liquid	Silica: Heat of wetting, cal./g.	Silica: Density, g./cc.	Charcoal: Heat of wetting, cal./g.	Charcoal: Density, g./cc.
Water	16	2.25[a]	8.4	1.82
Nitrobenzene	14.3	2.23	27.1	2.00[a]
Benzene	11.2	2.15	21.0	1.99
Carbon disulfide	6.7	2.21[a]	29.5	2.02[a]
Carbon tetrachloride	6.3	2.13	20.0	1.86
Petroleum ether	4.3	2.12	23.8	2.08

[a] The values so indicated are due to Culbertson and Weber (unpublished data). Identical silica gel and charcoal were used but the method of Tschapek [*Kolloid. Z.*, **63**, 34–36 (1933)] was employed in making the determinations. This method was compared with that used by Culbertson and Dunbar and satisfactory checks were obtained.

For the most part high heats of wetting accompany high densities though carbon disulfide on silica appears to provide an exception to such a generalization. It is the contention of the writers, however, that such evidence as these data afford tends to confirm the ideas expressed in the paper by Culbertson and Dunbar,[1] *e. g.*, that differences in the apparent density of a porous solid as indicated by measurements made with different liquids as filling fluids are due either to differences of penetration of the pores of the solid by the liquids or to differences in the amount of compression of the liquid film at the interface, in either case the determining factor being the decrease in surface energy when the liquid wets the solid. Quantitative correlation is of course lacking in Table II, but in consideration of the fact that if the above view of these phenomena is correct, then the specific areas of the solids, the compressibilities and the heats of compression of the different liquids, satisfactory data for most of which are unavailable, would have to be taken into consideration in developing such quantitative ideas and therefore the irregularities found are quite within the expected magnitude.

Summary

The heats of wetting of charcoal and silica gel by water, nitrobenzene, benzene, carbon tetrachloride, carbon disulfide and petroleum ether have been determined. A correlation is noted between the order in which these values fall and that of the apparent densities of the solids as determined in the same liquids.

Accumulation of Alkali Promoters on Surfaces of Iron Synthetic Ammonia Catalysts

BY P. H. EMMETT AND S. BRUNAUER

It has been pointed out repeatedly that the high pressure activity of iron synthetic ammonia catalysts containing a per cent. or so of potassium oxide in addition to an approximately similar amount of aluminum oxide is considerably greater than that of a catalyst promoted with aluminum oxide alone.[1] So far as we are aware, however, no evidence has ever been published concerning the fraction of the catalyst surface actually covered by the few per cent. of the alkali oxide promoters contained in typical iron synthetic ammonia catalysts. It is the purpose of the present paper to show that some recently determined low temperature adsorption isotherms of nitrogen, carbon monoxide and carbon dioxide on five different synthetic ammonia catalysts, enable us to conclude that 1% or so of potassium oxide in a catalyst actually covers a large fraction of the catalyst surface.

Experimental

The adsorption apparatus used was similar to that already described[2] except that parts F, E, C′, C, M, A, N, L, K, J and trap H of the apparatus shown in Fig. 1 of that paper were eliminated, and a manometer made of 10-mm. tubing was attached at the top of buret B. Stopcocks 1 and 2 were replaced by mercury sealed vacuum cocks, and catalyst bulb A was replaced by one of 25-cc. capacity.

[2] Emmett and Brunauer, THIS JOURNAL, **56**, 35 (1934).

The Toepler pump used in some of the experiments was attached essentially as shown in Fig. 1 of the above paper.

The iron synthetic ammonia catalysts were samples that had been prepared as oxides about ten years previously by the fusion method of Larson and Richardson[3] and kept in stoppered bottles since that time. According to their procedure, the promoters (pure potassium nitrate and Norton R. R. Alundum) were incorporated into the fused oxides at about 1540°. The catalyst composition, weight, reduction schedule and activity toward the high pressure synthesis of ammonia are presented in Table I for each of the five different types of synthetic ammonia catalysts used.

TABLE I

Mesh size, 8 to 14. Apparent volume of catalysts, 25 cc. Hydrogen flow during reduction, 500 cc. per min.

Catalyst	Sample as oxide, g.	Promoter content, %	Reduction schedule Time, hrs. Temp., °C.	Activity[a] toward ammonia synthesis (% NH_3 at 450°, 100 atm. and 5000 space velocity)
930	64.5	1.07 K_2O	48 between 350 and 450	5.3
931	61.0	1.59 K_2O 1.3 Al_2O_3	18 at 300 to 350 65 more 350–450 18 more 450–530	12.3
954	66.8	10.2 Al_2O_3	48 at 350 to 450 48 more at 450–500	8.2
958	71.9	0.35 Al_2O_3 .08 K_2O	36 at 350 to 450 36 more at 450–500	10.4
973–I	63.4	.15 Al_2O_3	124 at 300 to 350 54 more at 375–500	3.3
973–II	67.0	.15 Al_2O_3	96 at 300 to 400	

[a] The high pressure activities given here were determined about ten years ago on other samples of these same catalysts. They are included in this table merely as illustrations of the approximate relative activities of the various catalysts.

Hydrogen from large electrolytic cells in operation at this Laboratory was used after being passed over hot copper and dried by phosphorus pentoxide. All copper purifiers were first heated in hydrogen for several hours at 750° to remove traces of sulfur that might be present. Tank nitrogen was passed slowly over hot copper and dried by passage over phosphorus pentoxide. Carbon monoxide prepared according to the method of Thompson[4] was taken from tanks and passed through liquid air traps to remove iron carbonyl and any traces of carbon dioxide. Tank carbon dioxide was dried by passage through a trap immersed in an alcohol–dry ice bath at −78° and was used without further purification after it had been shown to contain only a negligible amount of non-condensable gases.

The liquid oxygen used as a constant temperature bath was prepared immediately before use by passing tank oxygen into a condenser cooled in liquid air. The only two tanks of the oxygen analyzed contained 2.0 and 3.4% nitrogen; oxygen liquefied from the latter of these two tanks was found to retain 0.9% nitrogen. The Dewar flask used as a container for the liquid oxygen during the adsorption experiments was not silvered and permitted rapid evaporation of oxygen. Apparently quite a constant temperature was obtained during a given run, the temperature change during the day being less than 0.05° as judged by a ten-junction copper–constantan thermocouple used in conjunction with a type K potentiometer. The temperature of the cold bath was obtained by noting the barometric pressure and using the tables of Dodge and Davis[5] for the vapor pressures of liquid oxygen. The temperature of −78.5° was obtained by using an alcohol–dry ice bath stirred only by the bubbling caused by the gradual evaporation of carbon dioxide. It is realized that such a bath might have been a degree or so warmer at the top than at the bottom, though the temperature at the bottom of the bath opposite the catalyst bulb was close to −78.5° as indicated by a calibrated thermocouple and a pentane thermometer. The adsorption measurements were carried out in the usual fashion, helium[6] calibrations of the dead space in the catalyst bulb being made before each series of runs. The catalyst was always first cooled in helium to the desired low temperature before admitting either carbon monoxide or carbon dioxide. After sufficient time had been permitted for temperature equilibration between the catalyst and the surrounding bath the helium was removed and the catalyst evacuated to about 10^{-4} mm. immediately before each run. To avoid the possibility of traces of oxygen contaminating the catalyst overnight, a uniform reduction period of one hour, in a stream of about 500 cc. of hydrogen per minute, was carried out every morning at 450°.

The gas contained in the "dead space" around the catalyst was corrected in each case for deviations from the perfect gas laws with the help of data from the "International Critical Tables." The corrections used were 3.2% for carbon monoxide at −183°, 2.97% for nitrogen at −183°, 2.0% for carbon dioxide at −78.5° and 0.58% for carbon dioxide at room temperature. Values for the first three of these corrections were also obtained through the kindness of Dr. A. F. Benton from some measurements that he and his collaborators have made recently. His results are in substantial agreement with the above corrections.

Results and Discussion

The carbon dioxide adsorption on the various iron catalysts at −78.5° was found to have many of the characteristics to be expected for a purely physical type of adsorption. For example, the rate of adsorption is rapid at all pressures; furthermore, it is no slower for catalysts promoted with alkalies than for those promoted with aluminum oxide alone. However, even a cursory comparison of the adsorption isotherms for carbon dioxide and for nitrogen shows that the ratio of the volume of carbon dioxide capable of being adsorbed at −78.5° to the volume of nitrogen that can be adsorbed at −183° on the same catalyst is

much higher on a catalyst promoted with alkali than on one to which no alkali has been added.

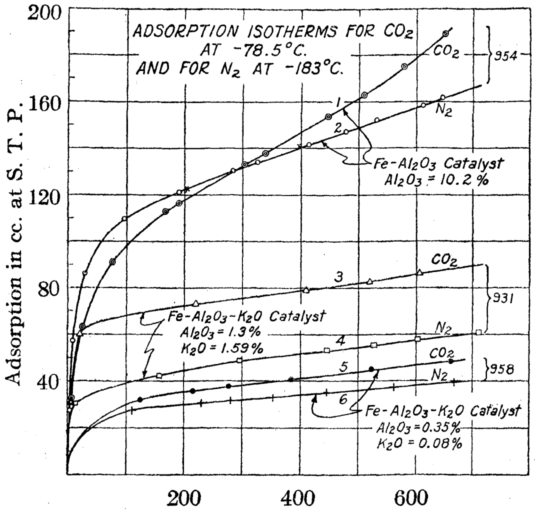

Fig. 1.—Comparison of the adsorption isotherm for carbon dioxide at −78.5° on a given iron synthetic ammonia catalyst with that for nitrogen at −183° on the same catalyst.

Figures 1 and 2 afford such a comparison between the isotherms of carbon dioxide at −78° and nitrogen at −183°, for the various catalysts. It is evident that at 300 mm. pressure[7] the volume of carbon dioxide adsorbed by catalyst 954 (10.2% Al_2O_3) at −78.5° is exactly the same as the volume of nitrogen adsorbed at −183°. On the other hand, at this same pressure in the case of catalysts 930, 931 and 958, which as pointed out above contain 1.07, 1.59 and 0.08% K_2O, respectively, the carbon dioxide isotherms at −78.5° exceed those for nitrogen at −183° by 78, 55 and 20%. For catalyst 973, to which no promoter had been added, the carbon dioxide adsorption for sample II is 10% larger at 300 mm. than the nitrogen adsorption at −183° and for sample I, 8% larger. In view of the marked influence of 0.08% K_2O in catalyst 958 on the total carbon dioxide adsorption it seems probable that the results on "pure iron" catalyst 973 may actually indicate the presence of a few hundredths of a per cent. of alkali even though none was intentionally added. Presumably, then, something other than the physical adsorption of carbon dioxide was occurring on the alkali-promoted catalysts at −78.5°.

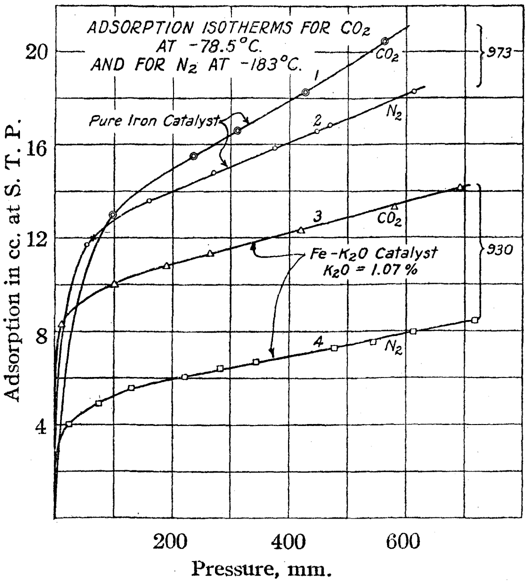

Fig. 2.—Comparison of the adsorption isotherm for carbon dioxide at −78.5° on a given iron synthetic ammonia catalyst with that for nitrogen at −183° on the same catalyst.

A reasonable interpretation of the large excess of carbon dioxide taken up by the catalysts containing potassium oxide appeared to be that the surface alkali was causing a very rapid[8] chemisorption of carbon dioxide to occur in addition to about the usual amount of physical adsorption. To obtain further evidence regarding the existence of such chemisorption and to ascertain the approximate amount of it that might be occurring, the catalysts were degassed by a diffusion pump for thirty minutes at 0° at the end of an isotherm determination, in order to remove the physically adsorbed carbon dioxide, after which the −78.5° isotherms were repeated. The slopes of the straight line portion of these second isotherms were in all cases practically the same as the slopes of the carbon dioxide isotherms shown in Figs. 1 and 2. However, the actual amount of adsorption occurring at −78.5° following the evacuation at 0° was smaller than the original carbon dioxide adsorption by 5 cc. for catalyst 954, 30 cc. for catalyst 931, 8 cc. for catalyst 958, 4.2 cc. for catalyst 930 and 2 cc. for catalyst 973. (For the

---

(7) 300 mm. was arbitrarily chosen as the pressure at which to make this comparison between catalysts promoted with alkali and those to which no alkali had been added. Any pressure in the range in which sufficient observations had been made to fix the shapes of the isotherms (roughly 100 to 700 mm.) would have served equally well.

(8) Only a few desorption points were taken on the runs with carbon dioxide at −78.5°. They showed, however, that on catalyst 931 at least 93% and possibly all of the chemisorption of carbon dioxide occurring during an entire isotherm determination had completed itself in the first fifteen minutes of the run and at a pressure of 25 mm. or less.

original carbon dioxide adsorption values see the curves in Figs. 1 and 2.) These values for the decreases in adsorption following the evacuation at 0° correspond to 67, 62 and 25% of the −183° nitrogen isotherm adsorption values at 300 mm. for the alkali-containing catalysts 930, 931 and 958, but only 4.7 and 13.5% in the case of catalysts 954 and 973 to which no alkali had been added. A comparison of these percentages with those given in the previous paragraph shows clearly that the volume of carbon dioxide that is rapidly adsorbed at −78.5° but not removed from the catalysts upon half an hour of evacuation at 0° is about sufficient to account for the amounts by which the total carbon dioxide adsorptions at −78.5° on the alkali-containing catalysts exceed the nitrogen adsorption at −183° and 300 mm. pressure. There seems to be little doubt, accordingly, that a considerable portion of the carbon dioxide adsorbed by the catalysts containing alkali is actually held to the catalyst by a process of chemisorption rather than physical adsorption.

An exact determination of the amount of chemisorption of carbon dioxide occurring on the various catalysts could be made only in case some temperature could be found at which all of the van der Waals adsorption would be removed by evacuation without any of the chemisorption being removed. If it could be shown, for example, that evacuation at 100° for a half hour removed none of the carbon dioxide that could not be removed by a similar period of evacuation at 0°, then the numerical values previously found for the differences between the initial total carbon dioxide adsorptions and the adsorptions following an evacuation at 0° would be considered correct values for the chemisorption of carbon dioxide at −78.5° on the various catalysts. This indeed proved accurately to be the case for most of the catalysts studied. Thus, three and one-half hours of evacuation of catalyst 931 at 0° removed no more carbon dioxide than had been removed in half an hour. Furthermore, pumping at 100° for half an hour removed no greater amounts of carbon dioxide from this catalyst or from catalysts 954 or 930 and only 0.2 cc. more from catalyst 973 than had been removed at 0°. Only from catalyst 958 did it appear possible by pumping at 100° to remove considerable carbon dioxide that could not be removed by pumping for a similar period at 0°. In this instance evacuation at 0° left 8 cc. of carbon dioxide on the surface whereas two 100° evacuations in separate runs left 7.1 and 5.0 cc. of carbon dioxide on the catalyst. Accordingly, one can merely say that out of the total carbon dioxide adsorption shown by curve 5, Fig. 1 (catalyst 958), between 5 cc. and 8 cc. is chemisorption. It may be of interest to point out that evacuation of catalyst 931 with a diffusion pump for thirty minutes at as high a temperature as 450° removed only about one-half the carbon dioxide that could not be removed at 0°. Analysis of the first 2 or 3 cc. of gas coming off the catalyst at 450° indicated the presence of both carbon monoxide and carbon dioxide, the latter predominating. The carbon monoxide probably came from the reaction of carbon dioxide with the iron atoms of the catalyst surface. It appears, therefore, that the chemisorbed carbon dioxide is very tightly bound to the catalyst surfaces containing alkali.

No definite evidence exists in the present work as to the number of carbon dioxide molecules that are chemisorbed on the catalysts by each alkali molecule on the catalyst surface. Neither is there any information concerning the nature of the surface alkali though presumably it cannot be present as potassium atoms since Brewer[9] has shown by photoelectric experiments that the concentration of free potassium atoms on the surface of promoted iron synthetic ammonia catalysts is very small. It seems probable that the alkali concerned in the chemisorption of carbon dioxide in the present experiments is in the form of an oxide or a complex with iron or iron oxide. By making the plausible assumption that each alkali molecule present on the surface of the catalyst is capable of holding one molecule of chemisorbed carbon dioxide, and by taking into account the amount of carbon dioxide needed to form a monolayer of physical adsorption on the catalyst as a whole, one is led inevitably to the conclusion that during the preparation or reduction of the catalyst alkali has accumulated to a marked extent on the catalyst surface. In fact, on the basis of our best estimates of the surface area[10] the alkali covers about 71 and 75% of the surface of catalysts 930 and 931, respectively, although the

---

[9] Brewer, THIS JOURNAL, **53**, 74 (1931).

[10] The principle of the method used in measuring the surface areas has already been presented [see Brunauer and Emmett, *ibid.*, **57**, 1754 (1935)]. A detailed discussion of the method with its application to a number of synthetic ammonia catalysts and other catalytic substances will soon be submitted for publication. The estimates of the surface areas used in the present paper are based on the final revised estimates of the surface areas resulting from this more comprehensive work.

alkali contents of these two catalysts as a whole are only 1.07[11] and 1.59%.

A fortunate characteristic of the adsorption of carbon monoxide on iron catalysts at −183° enabled us to obtain evidence regarding the fraction of the total surface that consists of iron atoms rather than alkali molecules and to confirm thereby the above conclusions in regard to the accumulation of alkali on the catalyst surface. Early in the work upon the determination of catalyst surface areas by the use of low temperature isotherms it was noted that on pure iron catalyst 973 (Sample I) the carbon monoxide adsorptions were roughly twice as large as the nitrogen adsorptions at the same temperature and pressure, although the carbon monoxide adsorption equilibrated as rapidly as that of nitrogen. To ascertain whether chemisorption of carbon monoxide was occurring the catalyst was evacuated by a diffusion pump at temperatures up to −78° immediately following a run at −183°. Carbon monoxide adsorption isotherms made at −183° immediately following this evacuation at −78° showed an amount of physical adsorption of carbon monoxide comparable to that of nitrogen at −183°. It was therefore concluded that on the iron catalyst at −183° a practically instantaneous chemisorption of carbon monoxide was occurring which could not be removed by pumping for half an hour with a diffusion pump at −78°. Furthermore, the fact that this chemisorption reached a saturation value instantaneously at pressures of only a few mm. of carbon monoxide and did not continue during the subsequent determination of the superimposed physical adsorption up to 760 mm. led us to believe that at −183° a complete monolayer of chemisorbed carbon monoxide was formed on the catalyst surface.

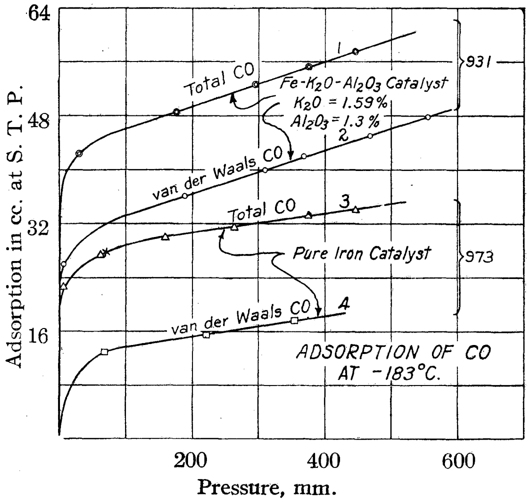

Fig. 3.—Comparison of the total carbon monoxide adsorption at −183° with the van der Waals adsorption for doubly promoted catalyst 931 and for pure iron catalyst 973. The X on curve 3 represents a desorption point.

If the chemisorption of carbon monoxide takes place on the iron atoms on the surface, then it should follow that the same catalysts that are capable of large chemisorptions of carbon dioxide should have low chemisorptions of carbon monoxide and *vice versa*. In Fig. 3 are presented curves showing the total adsorption and the van der Waals adsorption of carbon monoxide on a doubly promoted catalyst compared with an unpromoted catalyst. The isotherms designated as "van der Waals CO" were obtained at −183° immediately after determining the "total CO" isotherms at −183° and then evacuating the catalyst with a diffusion pump for a half hour at −78°. The difference between the two curves may be taken as the amount of chemisorbed carbon monoxide in each case because, as mentioned above, it was found that the chemisorbed carbon monoxide could not be removed by pumping at −78°. It is apparent that the doubly promoted catalyst, which had a large carbon dioxide chemisorption, has a small carbon monoxide chemisorption, whereas the pure iron catalyst with little or no chemisorption of carbon dioxide has large carbon monoxide chemisorption. The carbon dioxide and carbon monoxide chemisorptions therefore each leads independently to the conclusion that the 1 or 2% K_2O present in promoted iron synthetic ammonia catalysts covers a large fraction of the surface of the catalyst.

Throughout the present paper we have generally referred to the irreversible carbon monoxide and carbon dioxide adsorptions as chemisorptions. At present we do not wish to enter into an extended discussion in regard to the most appropriate nomenclature for sorptions of a chemi-

---

(11) In the course of the reduction of catalyst 930 the glass adsorption bulb became heavily frosted, presumably due to the volatilization of alkali from the catalyst. Analysis of the alkali on two of these frosted catalyst bulbs showed that 65 and 54%, respectively, of the 1.07% alkali had volatilized onto the glass. Hence, the alkali remaining in the catalyst was only 0.4 to 0.5% in all the runs on catalyst 930 rather than the 1.07% reported in the present paper. It was also shown by a blank run on a third such catalyst bulb from which the catalyst had been removed immediately after reduction that no carbon dioxide (less than 0.1 cc.) was taken up at −78° by the alkali on the glass. Any chemisorbed carbon dioxide reported in the present paper was therefore adsorbed by the catalyst or by the alkali on the catalyst and not by the alkali on the glass reaction vessel.

cal type. In those instances in which a surface adsorption can be shown to be a slow surface process whose rate is very sensitive to temperature, the name "activated adsorption" suggested by Taylor[12] is certainly descriptive and therefore appears to serve a useful purpose. However, in the present instances, the irreversible adsorptions of carbon monoxide on the iron catalysts and of carbon dioxide on the alkali promoted iron catalysts were not slow processes; they appear to be about as rapid as the accompanying van der Waals adsorption. The name "chemical adsorption" or "chemisorption" which has been used frequently in the past therefore appears to be a more descriptive one to apply to the present examples in order to emphasize their rather unique adsorption characteristics.

An accurate assessing of the present work as a contribution to a better understanding of the action of promoters in iron synthetic ammonia catalysts seems desirable at this point. Almquist[13] summarized the ways in which promoters may affect the activity of a catalyst by pointing out that they may serve either (1) to maintain a large surface area by retarding the growth of crystals in the catalysts, or (2) to change the qualitative nature of the surface by furnishing a promoter-catalyst interface that is more active as a catalyst than the same surface area of the pure catalyst. Furthermore, from the results of Almquist and Black,[14] as well as from previous work by Wyckoff and Crittenden,[15] it may be concluded that in the case of iron synthetic ammonia catalysts aluminum oxide alone, or aluminum oxide together with potassium oxide function in part at least in the first of these two ways. Recently determined[2] adsorption isotherms for nitrogen at −183° confirm this view by showing that catalysts promoted with either aluminum oxide or a combination of potassium oxide and aluminum oxide have much larger surfaces than have pure iron catalysts; however, they also show that a typical doubly promoted catalyst containing both potassium oxide and aluminum oxide has only about one-third as much surface as a catalyst promoted with aluminum oxide alone, even though the former is much more active at high pressures than the latter. It therefore seems very probable that an alkali such as potassium oxide, when added as a promoter to an iron catalyst together with a per cent. or so of aluminum oxide functions predominantly in the second of the two ways mentioned above, namely, by changing the qualitative nature of the catalyst surface. The present work, by indicating that about 70% of the surface of a doubly promoted catalyst is covered with alkali, brings to light the fact that only about one-third as much iron but about forty times as much alkali goes to make up the surface of a doubly promoted catalyst as one would have had reason to suspect heretofore. The precise mechanism through which the alkali when present with aluminum oxide so radically increases the activity of the surface per unit area is still a matter of conjecture and is not revealed by the present work.

Adsorption isotherms at −183° previously reported by Benton and White[16] for a sample of the same pure iron catalyst (973) as used in some of the present experiments agree qualitatively with our results in indicating that the total adsorption of carbon monoxide at −183° is much larger than that of nitrogen at −183°. However, their adsorption of carbon monoxide at −183° is only about 40% larger than that of nitrogen, whereas our results yield a total carbon monoxide adsorption that is consistently at least 100% larger than that of nitrogen. No explanation of this discrepancy between their results and ours is evident at this time.

Summary

With the help of adsorption isotherms for carbon monoxide and nitrogen at −183° and for carbon dioxide at −78.5° evidence has been obtained to show that a per cent. or so of potassium oxide in an iron synthetic ammonia catalyst actually covers more than 50% of the total surface of the catalyst. Apparently at −183° carbon monoxide rapidly forms a monolayer of chemisorbed carbon monoxide on the iron atoms of the catalyst, whereas at −78.5° carbon dioxide rapidly forms a layer of chemisorbed carbon dioxide on that portion of the surface that is covered by alkali.

The Equilibrium between Nitric Oxide, Nitrogen Peroxide and Aqueous Solutions of Nitric Acid

BY F. S. CHAMBERS, JR., AND T. K. SHERWOOD

The absorption of nitrogen oxides by water to produce nitric acid involves the principal reactions

$$2NO + O_2 = 2NO_2 \rightleftarrows N_2O_4 \qquad (1)$$

$$3NO_2 + H_2O = 2HNO_3 + NO \qquad (2)$$

The first proceeds slowly and probably determines the rate of nitric acid formation in dilute solution. The importance of the readily displaceable equilibrium (2) was first pointed out by Burdick and Freed,[1] who were able to give a rational explanation of the relatively low nitric acid strengths obtainable on the absorption by water of gases produced by the oxidation of ammonia.

Burdick and Freed also reported data on the equilibrium for the second reaction, expressing their results in the form of the equilibrium constant

$$K = \frac{(P_{NO})\,(P_{HNO_3})^2}{(P_{NO_2})^3\,(P_{H_2O})}$$

which they considered to be the product of the two parts

$$K_1 = \frac{(P_{NO})}{(P_{NO_2})^3} \qquad K_2 = \frac{(P_{HNO_3})^2}{(P_{H_2O})}$$

Determinations of the gas compositions in equilibrium with aqueous solutions of nitric acid led to values of K_1 for various acid strengths for temperatures from 10 to 75°. Separate determinations of the vapor pressures of water and of nitric acid over similar solutions led to values of K_2 covering a similar range. Since the publication of their results Taylor[2] has presented a summary of the available vapor pressure data, from which values of K_2 may be calculated.

More recently Abel, Schmid and Stein[3] have studied the equilibrium of reaction (2) and report values of K differing by roughly 10-fold from those of Burdick and Freed. From 35 to 60% nitric acid the discrepancy is relatively constant, the values of K reported by Abel, Schmid and Stein being about five times those of Burdick and Freed. At lower acid strengths the discrepancy is in the same direction but much greater. At low acid strengths, however, the accuracy is poor because of the difficulty of measuring the corresponding low pressures of nitrogen peroxide. Since this pressure enters as the third power in K_1 any errors in its measurement become greatly magnified.

The discrepancies between the results of Burdick and Freed and of Abel, Schmid and Stein suggested the present attempt to measure the equilibrium by a new method. Since the solution activities used[4] by Abel, Schmid and Stein in evaluating K_2 were consistent with the vapor pressure determinations of Burdick and Freed and with the correlation of vapor pressure data given by Taylor, it seemed clear that the discrepancy lay in the determination of K_1. Consequently, the present investigation was restricted to a measurement of gas compositions in equilibrium with acids of various strengths.

Burdick and Freed passed nitrogen dioxide diluted with nitrogen through an absorption train containing nitric acid solution. The nitrogen oxides in the gas leaving were absorbed in alkali, the resulting solution analyzed for nitrate and nitrite, and the amounts of absorbed nitric oxide and nitrogen dioxide then calculated. The equilibrium was approached only from the nitrogen peroxide side. Abel, Schmid and Stein employed a static method wherein they measured the total pressure of the undiluted nitrous gases over a solution of nitric acid, and determined the partial pressure of nitrogen peroxide and tetroxide by comparing the spectrum of the equilibrium gas with that of a standard gas system. The present investigation also employed a static method but involved a chemical rather than spectrographic analysis of the equilibrium gas mixture. The measurements covered the range of acid strengths from 37 to 59% nitric acid, and temperatures from 15 to 35°. In this range the equilibrium partial pressures of nitric oxide and nitrogen peroxide are of the same order of magnitude and the analytical procedure employed is believed to be reliable. Data were obtained by approaching the equilibrium from both directions.

Experimental Procedure

The nitric acid used was C. P. grade (sp. gr. 1.42). This was diluted to the strengths used in the experiments with distilled water and analyzed by titration with standard alkali. Nitrogen dioxide was prepared by thermally decomposing lead nitrate. The nitrogen dioxide evolved was condensed and further purified by oxygen distillation. Nitric oxide was made by allowing sulfuric acid to react with sodium nitrite.[5] The nitrogen used as diluent was from cylinders and was of purity of 99.85% or better.

Figure 1 is a diagrammatic sketch of the reaction vessel and sampling apparatus. The reaction vessel (A) consisted of a 2-liter round-bottomed flask into which were sealed two capillary gas sampling tubes (B,B), a tap for measuring pressure (C), and a tube for introduction and removal of the liquid (D). The stopcocks on these taps were lubricated with vaseline, which withstood the actions of nitric acid and nitrogen dioxide very well. Air was removed by filling the flask with acid to be used in the experiment. About a liter of this acid was displaced with nitrogen and 400 to 500 cc. more with either nitric oxide or nitrogen dioxide. About 500 cc. of acid was left in the flask, this quantity being sufficient to ensure no appreciable change in the composition of the solution during the experiment. The reaction vessel was then immersed and shaken in a constant temperature bath controlled to ±0.02°. As a result of check runs it was found that equilibrium was attained within a period of four hours at all temperatures reported.

Samples were taken by means of the two modified Gaillard bulbs[6] (E,E). Prior to sampling, the first bulb containing 25 to 50 cc. of distilled water was evacuated and weighed. A measured amount of standard potassium permanganate solution made slightly acidic with sulfuric acid was added to the second. This bulb was evacuated and swept out with nitrogen several times to ensure complete removal of oxygen before weighing.

A mercury manometer (F) was connected to (C) to determine the pressure in the reaction vessel. The Gaillard bulbs were then connected to (B,B) and the tube from the bottle (H) to (D). Acid of the same strength as that in the reaction vessel was allowed to flow from (H) at such a rate that the samples would be obtained at constant pressure. The pressure was maintained constant by regulating cock (G). After sampling the Gaillard bulbs were again weighed, the increase in weight being a direct measure of the amount of sample obtained.

In the analysis of the gas phase, one is confronted with the problem of determining six constituents: water vapor, nitric acid vapor, nitric oxide, nitrogen dioxide, nitrogen tetroxide and nitrogen. Water was neglected, and the inert gas assumed to be only nitrogen. The error from this simplifying assumption affected the calculated value of K less than 1% in the worst case. From the analysis of the first bulb, the total nitrous oxides plus the nitric acid were determined. In this analysis the oxides were converted to nitric acid and determined as such. This method is a modification of that advanced by Gaillard[6] for determination of conversion efficiencies in the commercial oxidation of ammonia to nitric acid. The second or permanganate bulb gave a measure of the ratio of nitrogen dioxide plus tetroxide to nitric oxide. That permanganate will convert nitrous oxides to nitrate has been demonstrated by several investigators.[7] This procedure was checked experimentally by analyzing a mixture consisting of nitrogen and nitric oxide only. In accordance with theory, the equivalents of nitric acid per gram of sample formed in the first bulb were a third of the equivalents of permanganate per gram of sample reduced in the second.

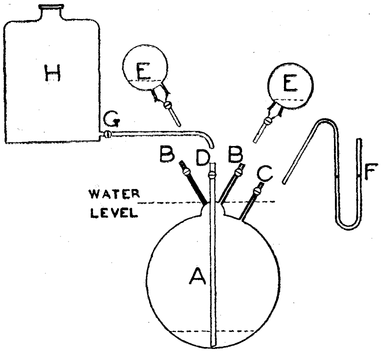

Fig. 1.

Oxygen was admitted to the first bulb with shaking until no further gas was taken up. This was taken as an indication that all the nitrous oxides had been converted to nitric acid. The solution in this bulb was then titrated with standard sodium hydroxide using methyl red as an indicator.

The bulb containing the permanganate was shaken for several hours to ensure completion of the reaction with nitric oxide. An excess of standard ferrous sulfate was added and the solution titrated to pink with permanganate. In this determination it was found that a large excess of potassium permanganate was necessary, as nitric oxide seemed to reduce it only as far as manganese oxide.

Taylor's data on the vapor pressure of nitric acid were used to calculate the amount of nitric acid taken in with the first sample, which value was applied as a correction to the titration of this sample. The ratio of dioxide to tetroxide was computed from Bodenstein's later values for the equilibrium constant.[8]

Results

The results are summarized in Table I and the calculated values of K_1 at 25° are plotted *vs.* acid strength in Fig. 2. In each case the pressures employed are in atmospheres and the logarithms are base 10. It is evident from the table that the results obtained starting with nitrogen peroxide check within the experimental error those obtained when starting with nitric oxide. Figure 2 also shows the results of Burdick and Freed and of Abel, Schmid and Stein. The vertical arrows indicate the extreme deviations of the results at a constant acid strength. It is evident that the

present data support the results of Abel, Schmid and Stein rather than those of Burdick and Freed.

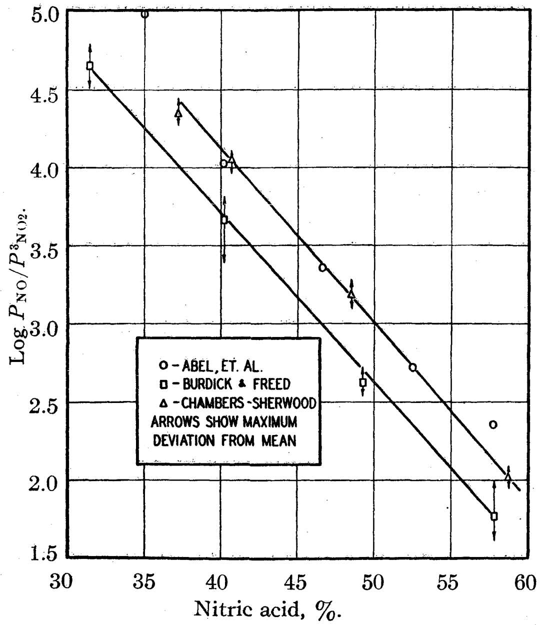

Fig. 2.

The mean value of K at 25° over the range of acid strengths studied is 0.017, which may be compared with 0.0046 from the results of Burdick and Freed and 0.019 obtained from the data of Abel, Schmid and Stein over the same range. The value of K reported by Abel, Schmid and Stein is 0.046, but this value was based only on two determinations at low acid strengths, where the partial pressures of nitrogen peroxide were very low.

It may be concluded that the results of Burdick and Freed are inaccurate, and that the data of Abel, Schmid and Stein, and those of the present investigation, serve as a more reliable basis for calculation of the equilibrium of this important reaction. It is difficult to suggest the source of error in the procedure used by Burdick and Freed, although it may be pointed out that they approached the equilibrium only from the peroxide side, and that failure to attain equilibrium would result in low values of K_1, as found.

It may be noted from Table I that K decreases with increased temperature, being 0.018 at 15° and 0.010 at 35°. The temperature range covered and the accuracy of the determinations are probably not great enough to justify a quantitative analysis of the trend of K with temperature, but it may be noted that the apparent temperature effect is considerably greater than that reported by Burdick and Freed, who found a 12% decrease in K on increasing the temperature from 25 to 75°.

Summary

The equilibrium of the reaction $3NO_2 + H_2O = 2HNO_3 + NO$ has been studied at 25° over the range of acid strengths from 37 to 59% nitric acid, and over the temperature range from 15 to

35° for an acid strength of 54–55% nitric acid. The results expressed in the form of the constant $K_1 = (P_{NO})/(P_{NO_2})^3$ agree well with the data of Abel, Schmid and Stein, deviating considerably from those of Burdick and Freed.

The Infra-red Absorption of Heavy Acid Solutions

BY DUDLEY WILLIAMS AND E. K. PLYLER

A previous study[1] has revealed the presence of intense absorption bands at 2.4 μ and near 5.5 μ in the spectra of aqueous solutions of a number of acids. These bands were attributed to the effects of hydration. As the position of the band near 5.5 μ varied slightly with the solute, this absorption was identified with a characteristic frequency of an associational group containing undissociated acid molecules, while the 2.40 μ band was attributed to a hydrate in which the H^+ ion is involved. An investigation of the spectra of solutions of hydrolyzing salts gave additional support to this conclusion.[2]

The present work was undertaken in order to determine the changes in the positions of these bands caused by the substitution of deuterium for the hydrogen in the aqueous solutions. The deuterium oxide used as a solvent was a Norwegian product containing only a trace of ordinary water. The DCl solution was obtained from the California Isotope Company of Berkeley and contained about 0.5% H_2O. The D_2SO_4 and D_3PO_4 solutions were prepared by dissolving known amounts of the anhydrides in deuterium oxide. The sulfur trioxide used in this process was obtained by heating fuming sulfuric acid and the gas was allowed to pass through two drying tubes containing phosphorus pentoxide before entering the solvent. From specific gravity determinations it is estimated that the D_2SO_4 solution was approximately four normal and a D_3PO_4 solution of equal concentration was prepared. The spectroscopic methods have been described in a previous paper.[3] A rock-salt prism was used in the region from 2.5 to 12.0 μ, additional measurements being made in the 2.0–3.8 μ region with a fluorite prism. The absorbing layers used in the region of longer wave lengths were 0.02 mm. in thickness, while the layers in the 2.0–3.8 μ region were 0.05 mm. thick.

The infra-red absorption of deuterium oxide has been studied previously by Ellis and Sorge,[4] by Casselman,[5] and by the authors.[3] Intense bands have been observed at 2.85, 4.00, 6.80 and 8.20 μ. Although the broad band at 4.00 μ has three maxima, it was impossible to resolve this band into its components with the rock-salt prism used in the present work. The results obtained with deuterium oxide in the present study are given by the upper curve of Fig. 1. In addition to the bands shown in the figure, another band appeared at 10.4 μ. This band probably corresponds to the band recently observed at 8.6 μ in the spectrum of ordinary water.[6]

The transmission of the DCl solution is shown in the lower curves of Fig. 1. It will be noted that there is a marked increase in absorption near 5.5 μ. The dotted curve shows the transmission of a more concentrated solution of DCl in this region. There is also a slight increase in absorption near 3.4 μ, and this absorption may be seen more clearly when thicker absorbing layers are used. The results obtained in the 3 μ region with thicker cells are shown in another figure. With the exception of the increased absorption in the 3.4 and 5.5 μ regions of the solution spectrum, the transmission curve for the DCl solution bears a close resemblance to the D_2O curve. The curves are practically identical from 9 to 12 μ, and for this reason the transmission curves obtained in this region are omitted from the figure. The results obtained with the D_2SO_4 and D_3PO_4 solutions are the same as those obtained with the DCl except for the appearance of bands near 9 and 4.8 μ which are characteristic of the sulfate and phosphate

groups. The spectra of compounds containing these groups have been studied extensively by reflection,[7] and regions of intense absorption appear at 9.0 μ in the sulfates and at 9.5 μ in the phosphates. These bands maintain their normal spectral positions even when the compounds are in solution.

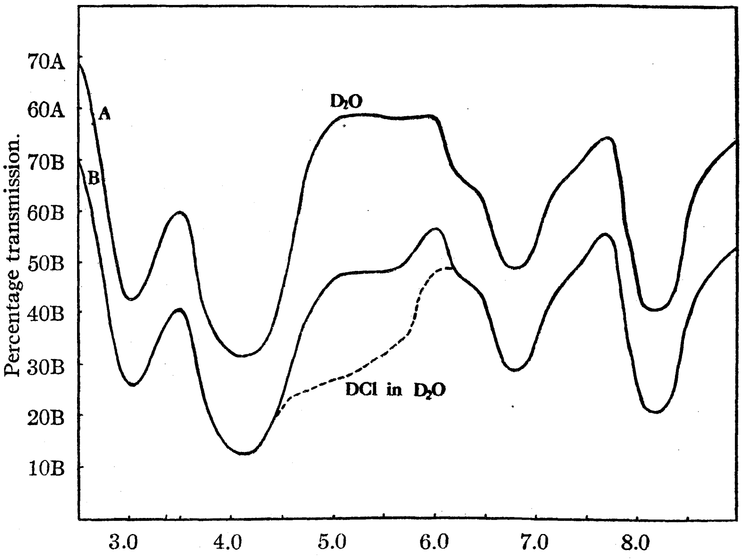

Fig. 1.—The percentage transmission of deuterium oxide and solutions of DCl: region, 2.5 to 9.0 μ.

In order to determine the positions of maximum absorption of the various solutions, curves were plotted showing the ratio of the solution transmission to the solvent transmission. The ratio curves for the 4.5–6.5 μ regions are shown in Fig. 2. As may be seen readily, all the solutions are strongly absorbing near 5.5 μ, the position of maximum absorption varying with the solution. The first two curves are plotted to the same scale and show the results obtained with two concentrations of DCl. It will be noted that increasing the DCl concentration causes additional absorption in the 4.9 μ region, where the absorption maximum of gaseous DCl appears, and it is possible that the absorption observed at this position may be caused by undissociated DCl molecules. However, the corresponding HCl band at 3.46 μ has never been observed in aqueous solution, and it would be surprising to find DCl molecules giving rise to a band of this type. The absorption of D_2SO_4 at 4.6 μ is the first harmonic of the SO_4 band at 9 μ mentioned above, and the D_3PO_4 band at 4.8 μ has a similar relation to the PO_4 maximum at 9.5 μ.

In Fig. 3 are given the results obtained between 2.0 μ and 3.8 μ with 0.05 mm. absorbing layers. The transmission determinations used in plotting the curves shown in this figure were made with a fluorite prism. The DCl curve given here was obtained with a sample of the less concentrated solution. The transmission curve shows intense absorption in the region of 3.4 μ. Increasing the concentration of DCl caused an increase in the intensity of this band, but a shift in position was not observed as in the case of the 5.5 μ region of absorption. The D_2SO_4 and D_3PO_4 solutions are also strongly absorbing in the 3.4 μ region, and additional absorption appears in the 2.2 μ region in the spectra of these latter solutions. The absorption in the 3.4 μ region is so intense that the plotting of ratio curves to aid in locat-

ing the absorption bands is not deemed necessary.

It is interesting to note that the spectra of deuterium oxide solutions of the hydrolyzing salts potassium carbonate and sodium carbonate studied in a previous investigation[3] contain bands near 5.5 μ. Since similar bands appear in the spectra of the heavy acid solutions used in the present work, it is probable that the bands at 5.5 μ in the spectra of the salt solutions are caused by heavy carbonic acid formed on hydrolysis of the salts. In solutions of hydrolyzing salts of this type one would expect D_2CO_3 molecules to be much more numerous than D^+ ions, and hence it is possible that the 5.5 μ bands arise from the hydration of undissociated acid molecules. Other evidence in favor of this hypothesis lies in the slight variations in position of these bands in the different solutions, an effect to be expected if different negative radicals are present in the complex. The exact numbers and natures of the units entering into these associational groups cannot be determined from the data obtained in this study. It will be noted, however, that the position of the associational band produced by heavy acid molecules in deuterium oxide solutions is the same as that of the corresponding band produced by ordinary acids in aqueous solution. This seems to indicate that large groups are involved, since the replacement of hydrogen by deuterium does not produce an appreciable shift. Since the bands observed at 3.4 μ do not change their positions in the different acid solutions, it is probable that they are caused by the hydration of the D^+ ions. The corresponding bands in aqueous solutions of ordinary acids appear at 2.40 μ. Thus, the shift in the position of this absorption is what would be expected if the H in a simple R-H oscillator were replaced by deuterium to form R-D, where the mass of the accompanying group R is large as compared with H and D. The exact nature of the group R is at present unknown.

The experimental results obtained in this study indicate that the 2.4 μ band appearing in aqueous solutions of acids is shifted to 3.4 μ when the hydrogen is replaced by deuterium, while the bands in the 5.5 μ region are common to both types of solution.

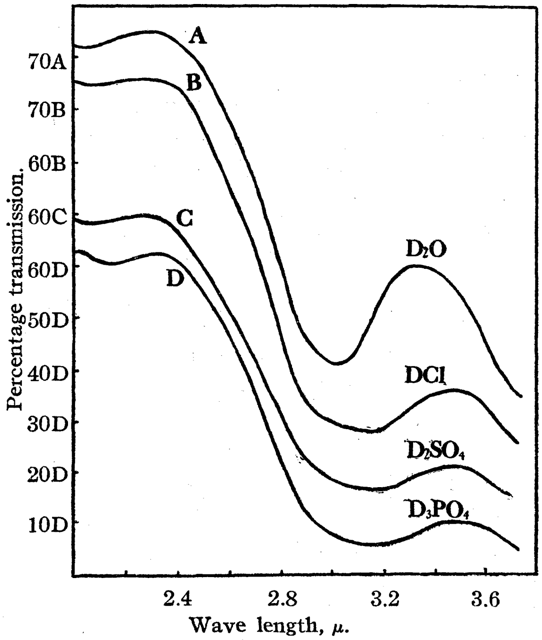

Fig. 3.—The transmission of deuterium oxide and three heavy acid solutions: region, 2.0 to 3.5 μ.

Abstract

The infra-red absorption of deuterium oxide and of DCl, D_2SO_4 and D_3PO_4 solutions has been measured in the region between 2 μ and 12 μ. In addition to the bands at 2.9, 4.0, 6.8 and 8.2 μ, a band at 10.4 μ has been found in the spectrum of deuterium oxide. In the spectra of all the heavy acid solutions studied intense absorption bands appear at 3.4 μ and near 5.5 μ in addition to the bands characteristic of the solvent. The solutions of D_2SO_4 and D_3PO_4 also give rise to characteristic SO_4 and PO_4 absorption, respectively. The intense bands at 3.4 and 5.5 μ are attributed to hydration effects.

Conditions Affecting the Formation of Malonates and Barbiturates. Halogenalkyl Derivatives

BY GLENN S. SKINNER

In a previous paper[1] it was reported that better yields of a 5-β-hydroxyethyl-5-alkyl barbiturate are obtained by refluxing the reaction mixture for relatively short periods of time followed by the distillation of the alcohol. It has now been shown to be unnecessary to heat the reaction mixture according to the generally followed procedure of Fischer and von Mering. In fact, the observance of the more vigorous treatment causes a decrease in the yield. According to the procedure herein described yields of more than 90% are obtainable.

Experience also has been gained in the preparation of the necessary malonates. Using benzene as the medium it was found that ethylene bromide did not react with sodiophenylmalonic ester at temperatures below approximately 60°. This may explain why a previous attempt to carry out this condensation in ether was unsuccessful. While the reaction above this temperature is comparatively slow, it is possible to obtain yields of the corresponding lactone in excess of 50%.

In using an inert solvent as a medium it has been found possible to increase the yield of the *n*-butyl β-bromoethyl derivative from approximatively 52% (based on sodium) to 80% simply by using one equivalent of sodium to two of the other reactants. The finely divided sodium not only dissolves much more readily but the reaction with the halide takes place more rapidly. Trimethylene bromide has been reported to condense with sodioisoamylmalonic ester to give a 44% yield of the γ-bromopropyl derivative.[2] The yield may be increased to 68% by using the sodium, ester and bromide in the ratio 1:3:4. No solvent was used in this experiment and this yield could doubtless be further improved by a more extensive study. Here the reaction is more rapid and a very considerable amount of high boiling material is formed, hence the greater importance of having the bromide in excess of the other reagents. With ethylene bromide the amount of high boiling material is small and is only slightly increased by using the other reactants in excess of the sodium. The omission of a solvent and the use of a sodium:ester:bromide ratio as high as 1:6:2 instead of a 1:2:2 ratio in benzene shows no appreciable change in the yield of β-bromoethyl ester or high boiling residue based on sodium but a slight increase based upon the ester consumed in the process. Potassium is not as satisfactory as sodium since the potassium derivative shows a greater tendency to precipitate and the yields are lower. The reaction of both halides with ethyl phenylmalonate gives a sharp increase in the amount of high boiling material.

Before a recently described improvement[3] of the method for the preparation of phenylmalonic ester was published, we had made some study of the conditions during the preparation of a quantity of it for our work. It had been reported that ethyl carbonate[4] could be condensed with ethyl phenylacetate to give phenylmalonic ester in yields not greater than 20%. Accordingly the effect of potassium was studied with the result that 10% potassium–sodium alloy, 50% potassium–sodium alloy and potassium showed maximum yields of 45, 49 and 41%, respectively. The condensation of ethyl oxalate with ethyl phenylacetate by potassium is too vigorous to be controlled properly. With 10 and 50% alloys in benzene the yields of phenylmalonic ester were 77 and 71%, respectively, using a ratio of 1:2:1 for the metal, oxalate and phenylacetate. Under the same conditions using sodium the yield was 66%. Using ether as the medium and a 10% potassium–sodium alloy the comparative yield based on metal was 80 or 87% based on ethyl phenylacetate.

The tendency of ethyl phenylacetate to react with itself rather than ethyl carbonate is diminished by potassium judging from the amount of ethyl phenylacetate recovered and the weight of the high boiling residue. An increase of the carbonate/acetate ratio increases the yield of phenylmalonic ester and decreases the loss of ethyl phenylacetate. Increasing the acetate/metal ratio decreases the yield of phenylmalonic ester and increases the loss of ethyl phenylacetate.

[3] "Organic Syntheses," **16**, 33 (1936).

[4] Nelson and Cretcher, THIS JOURNAL, **50**, 2759 (1928).

Markedly better results are obtained by the use of the metal, oxalate and phenylacetate in 1:2:1 ratio rather than the customary equivalent ratio.

5-β-Halogenethyl-5-alkyl barbiturates are formed in excellent yields by the action of the fuming halogen acids on the corresponding hydroxy compounds. The reaction proceeds smoothly for the bromides and iodides while the chlorides are formed with difficulty.

The γ-bromopropyl alkyl malonates are not converted to the lactones by distillation under similar conditions while, for example, β-bromoethyl phenylmalonate could not be distilled without decomposition to the lactone. This indicates a greater tendency for the formation of a five than a six-atom ring. Being an intramolecular temperature reaction this sharp difference is interesting especially as being in line with the older classical theory of ring formation. However, the experience that barbiturate formation takes place at ordinary temperatures encouraged the attempt to condense the halogen ester directly. The reaction mixture from γ-bromopropyl isoamylmalonic ester was successfully converted to γ-bromopropyl isoamylbarbiturate.

From the results of tests made through the courtesy of Dr. E. H. Volwiler of the Abbott Laboratories, β-iodoethyl and γ-bromopropyl isoamylbarbiturates appear to be the best tolerated and produce the most uniform depression. The latter employed intravenously in rabbits produced ataxia lasting one-half hour (300 mg./kg.) and Stage II anesthesia for one-half hour (500 mg./kg.).

Experimental Part

Halogenalkyl Malonates.—For the introduction of the β-bromoethyl group it is preferable to use the reagents in the following molal ratios: finely divided Na, 1.0; $RCH(CO_2C_2H_5)_2$, 2.0; $C_2H_4Br_2$, 2.0. The stirrer is run and the mixture is cooled during the addition of the alkylmalonic ester. If two mols of the ester is employed the complete solution of the sodium is fairly rapid. When the reaction slackens it is allowed to go to completion at room temperature. The ethylene bromide is added at once with stirring and cooling. The temperature of the bath is allowed to rise slowly to 70–75° where it is maintained for eight to ten hours. It is of no advantage to heat for longer periods to the disappearance of the last trace of alkali as the reaction is then substantially complete. The precipitation of sodium bromide begins near room temperature. However, if R is phenyl it is necessary to heat for seventy to seventy-five hours to secure substantial completion of the reaction, which does not begin until the temperature is near 60°. The phenyl bromoethyl compound could not be distilled without decomposition to the lactone which was obtained in only 52% yield.

Trimethylene bromide reacts more rapidly and the reaction flask must be surrounded with iced water at first. The mixture is then allowed to stand in a bath of water at room temperature for an hour and heated for about five hours at 70–75°. If R is phenyl the reaction begins near 45°. The phenyl derivative showed slight evidence of decomposition during distillation under diminished pressure with the bath at 220°, which is also indicated by the analysis. An attempt to convert the isoamyl derivative to the lactone by distilling it slowly at 196° (24 mm.) was unsuccessful.

n-Butyl γ-bromopropylmalonic ester: calcd. for $C_{14}H_{25}O_4Br$, Br 23.76%; found, Br 23.88%, b. p. 138 (2 mm.), n^{20}_D 1.4602; n^{25}_D 1.4580; d^{20}_4 1.188, d^{25}_4 1.182.

Phenyl γ-bromopropylmalonic ester: calcd. for $C_{16}H_{21}O_4Br$, Br 22.38%; found, Br 21.03%; b. p. 172° (1 mm.); n^{20}_D 1.5167, n^{25}_D 1.5143; d^{20}_4 1.274, d^{25}_4 1.269.

Ethyl Phenylmalonate.—From the results of ten runs in which both ether and benzene were used as solvents and the mass relationships were varied widely, the following procedure was selected as giving the best yield. Sodium (0.275 at.) and potassium (0.275 at.) are converted to a powdered alloy in the usual way except that overheating is avoided and the xylene is not removed. The alloy is covered with 250 cc. of dry benzene, cooled in finely crushed ice and at the incipient crystallization of the benzene a mixture of 0.50 mol. of ethyl phenylacetate and 2.00 mole of ethyl carbonate is added rapidly with mechanical stirring and readiness for additional cooling if necessary. The metal reacts completely within an hour. After standing for twenty-four hours and decomposing with a freezing mixture of ice and hydrochloric acid, there is obtained 1.20 mol. of ethyl carbonate, 0.116 mol of ethyl phenylacetate, 0.267 mol of ethyl phenylmalonate and 14 g. of residue. The malonate yield is thus 49% based on metal, 53% on ethyl phenylacetate used and 69% on ethyl phenylacetate consumed in the process. Similarly a 10% alloy gives a yield of 42% (metal) and a residue of 20 g. With 10% alloy, carbonate and phenylacetate in a 1:2:2 ratio the yield drops to 31% (metal) and the weight of the residue rises to 71 g. If the ratio is 1:4:2 the yield is 45% (metal) and the residue weighs 43.5 g. Pure potassium, carbonate and phenylacetate in a 1:2:1 ratio gives a yield of 41% (metal) and a residue of 20 g.

Similarly from an alloy of 0.055 at. potassium, 0.495 at. sodium, 250 cc. of dry ether, 1.00 mol of ethyl oxalate and 0.50 mol of ethyl phenylacetate there is obtained 0.418 mol of ethyl oxalate, 0.001 mol of ethyl phenylacetate, 0.437 mol of ethyl phenylmalonate and a residue of 10 g., corresponding to a yield of 80% (metal) and 87% (ethyl phenylacetate). With sodium alone under these conditions the yield dropped to 64 and 72%, respectively. Benzene, 50% alloy, and especially a lower oxalate–phenylacetate ratio decrease the yield.

Lactones.—The following new lactones are made by the distillation of the β-bromoethyl alkyl malonates under reduced pressure such that the material will not distil until the decomposition is complete. α-Carbethoxy-α-*n*-butyl-γ-butyric Lactone. Calcd. for $C_{11}H_{18}O_4$: C, 61.64; H, 8.47. Found: C, 61.1; H, 8.4; n^{20}_D 1.4487, n^{25}_D 1.4467;

d^{20}_4 1.063, d^{25}_4 1.059; b. p. 119 (3 mm.). α-Carbethoxy-α-phenyl-γ-butyric Lactone. Calcd. for $C_{13}H_{14}O_4$: C, 66.64; H, 6.03. Found: C, 66.6; H, 6.5, n^{20}_D 1.5211, n^{25}_D 1.5187; d^{20}_4 1.191, d^{25}_4 1.188; b. p. 145° (1 mm.).

β-Hydroxyethyl Barbiturates.—According to the following procedure the yield of β-hydroxyethyl-isoamylbarbituric acid has been increased from 75 to 89%. To a solution of sodium ethoxide prepared from 0.60 at. of sodium and 300 cc. of absolute alcohol is added 0.120 mol of lactone ester and then 0.40 mol of finely powdered urea. The flask is surrounded by a bath of water at room temperature and the stirrer is run until the urea dissolves. After standing until the next day a considerable amount of solid will have separated. A glassy residue remains after removal of the alcohol through a column under diminished pressure from a bath not heated above 50°. The aqueous solution is extracted with chloroform and the acid is precipitated with cooling by hydrochloric acid. An additional amount is obtained by extracting the filtrate with chloroform.

The yield of the *n*-butyl compound at the reflux temperature in six runs was 61–78% where the time of refluxing was one to five hours and the alcohol was distilled under diminished or ordinary pressure, the best yield being for a one-hour reflux. In one experiment where the alcohol was distilled at once and then under reduced pressure the yield was 75%. The yield was increased to 93% by mechanical stirring at a water-bath temperature of 45° to solution of the urea followed by distillation of the alcohol under reduced pressure. The acid melted at 147–148° which agrees with the value for the acid obtained by a different method.[5]

β-Halogenethyl Barbiturates.—β-Hydroxyethyl-isoamylbarbituric acid (0.20 mol) is heated with 200 cc. of fuming hydrobromic acid (55–60%) in 6 oz. (120 cc.) soda water bottles at a water-bath temperature of 55–60° for two hours with occasional shaking. The bottles are capped with crowns in which the cork has been replaced by disks of thin red gasket rubber. Bottles with wired well-ground glass stoppers also may be used. After standing at room temperature until the next day, 59 g. of crude product is obtained by suction filtration through sintered glass. One gram more is obtained by distillation of the filtrate under diminished pressure. The material is purified by dissolving in about three times its weight of warm alcohol, allowing to cool somewhat and stirring in an equal volume of ice water.

The preparation of the chlorides is more tedious, especially for the isoamyl derivative on account of its lesser solubility in the fuming acid. Here refluxing with four mols of thionyl chloride followed by the fuming acid treatment and repeated crystallization gives a pure product. The *n*-butyl derivative (0.050 mol) largely dissolves in 60 cc. of hydrochloric acid (1.19) at 60° with a current of hydrogen chloride passing through the mixture. The passage of the gas is continued while cooling in ice. After standing for two days at room temperature the material is filtered on sintered glass and washed with fuming acid. The crude material weighs 11.4 g. and melts at 138–139°. It must be crystallized repeatedly in the above manner in order to secure a sample melting sharply at 140°.

To prepare the iodide it is better to dissolve the hydroxy acid (0.19 mol) in 1.4 mol of ice-cold fuming 70% hydriodic acid. The solution is then allowed to stand for one day in a brown glass-stoppered bottle in the ice box, two days in a dark place at room temperature and finally one day in the ice box. The crude β-iodoethylisoamylbarbituric acid so obtained weighs 61 g. The filtrate heated to 50–60° for two hours and allowed to stand in the ice box gives 3 g. more. The material is crystallized from hot alcohol for the analysis. Two more crops melting at the same temperature (167°) are obtained by dilution, bringing the total yield of purified product to 58.5 g.

TABLE I

RR'C(CONH)$_2$CO

R	R'	M. p., °C.	Halogen, % Found	Halogen, % Calcd.	Yield, %
n-Butyl	β-Chloroethyl	140	14.28	14.38	92
n-Butyl	β-Bromoethyl	153.5	27.46	27.46	92
n-Butyl	β-Iodoethyl	192	37.53	37.55	92
Isoamyl	β-Chloroethyl	138.5	13.83	13.61	
Isoamyl	β-Bromoethyl	159.5	26.34	26.20	96
Isoamyl	β-Iodoethyl	167	36.18	36.05	91
Isoamyl	γ-Bromopropyl	150.5	24.73	25.05	40

γ-Bromopropyl-isoamylbarbituric Acid.—γ-Bromopropyl-isoamylmalonic ester (0.138 mol) when condensed with urea in the above manner gives 35.5 g. of a very viscous material which could not be induced to crystallize satisfactorily. This material when heated repeatedly with 100-cc. portions of 60% hydrobromic acid followed by the removal of the crystalline portion gives 25 g. of material melting at 143–147°. Repeated crystallization from chloroform did not give a pure product until after heating in an oven at its melting point (Table I). Further work is in progress.

Summary

1. The formation of 5-β-hydroxyethyl barbiturates is favored by lower temperatures than those heretofore employed for this reaction.

2. β-Bromoethyl and β-iodoethyl barbiturates are formed smoothly in excellent yields by the action of the fuming acids on the hydroxy compounds. The chloro compounds are also obtained but with more difficulty. γ-Bromopropyl-isoamylbarbituric acid was made although the desired intermediate lactone ester was not formed in the usual manner.

3. The use of two equivalents of malonate to one of sodium in making the desired halogenalkyl malonate is highly advantageous.

4. By the use of potassium and the adjustment of the mass relationships the yield of phenylmalonic ester is decidedly increased when either ethyl carbonate or ethyl oxalate is used.

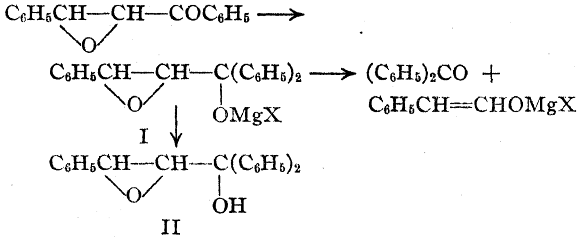
The Action of Organometallic Compounds on Alpha Oxido Ketones

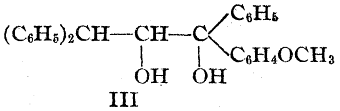
BY C. L. BICKEL

Alpha oxido ketones differing only slightly in structure behave quite differently when treated with phenylmagnesium bromide. Benzalacetophenone oxide reacts with one equivalent of phenylmagnesium bromide at −15°, giving the addition product I. Hydrolysis of this magnesium compound with acid gives the corresponding oxanol II. But at room temperature the magnesium compound I decomposes to give benzophenone and the magnesium derivative of the enolic form of phenyl acetaldehyde, a reaction represented below.

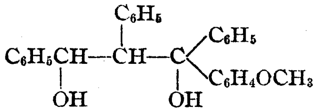


The oxide ring is not opened by phenylmagnesium bromide except through cleavage.[1] *o*-Chlorobenzalacetophenone oxide behaves in an analogous manner, opening of the oxide ring taking place only by cleavage of the magnesium derivative of the carbinol at higher temperatures.[2] Both of the above oxido compounds give a similar reaction with lithium phenyl, except that the lithium derivative of the carbinol decomposes more slowly.[2]

Conversely, Bergmann[3] found that benzal-*p*-methoxyacetophenone oxide behaves quite differently with phenylmagnesium bromide. His results indicated that two equivalents of reagent add to the oxide at room temperature with no resultant cleavage. Bergmann did not determine the structure of this product, but offered two possible structures, III and IV.



III

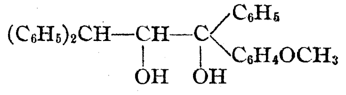


IV

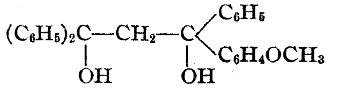
Either of these compounds would be formed by fission of the oxide ring and attendant addition. The point at which the ring opens would determine the nature of the product.

The present paper is concerned with the reaction of benzal-*p*-methoxyacetophenone oxide with lithium phenyl, a more detailed study of the reaction with phenylmagnesium bromide and the determination of the structure of the product first obtained by Bergmann.

Chromic acid oxidation of the compound obtained by Bergmann gave benzophenone and *p*-methoxybenzophenone as products. Only two compounds, III and VI, which could have been formed in the Grignard reaction would give these two oxidation products.



III



VI

Compound VI would be formed by rearrangement of the oxide to give a ketone which would add phenylmagnesium bromide. Compound III would be formed by the opening of the oxide ring by phenylmagnesium bromide with attendant addition.

The tertiary carbinol VI was synthesized from the beta diketone VII, the first reaction with phenylmagnesium bromide giving the two isomeric compounds VIIA and VIIB. The treatment of each of these isomers with lithium phenyl gave the carbinol VI, whose structure was confirmed by oxidation to benzophenone and *p*-methoxybenzophenone. The synthesis is represented by the accompanying formulas.

The carbinol VI was not identical with the product obtained from the *p*-methoxy oxide. Therefore, by elimination, the structure of the product obtained by Bergmann is represented by formula III.

A most interesting result was obtained when benzal-*p*-methoxyacetophenone oxide was treated with lithium phenyl in ether solution. None of

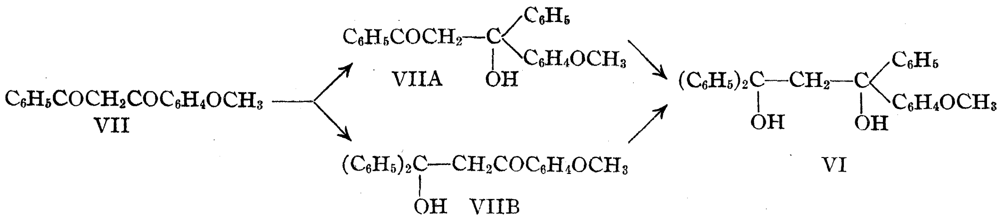
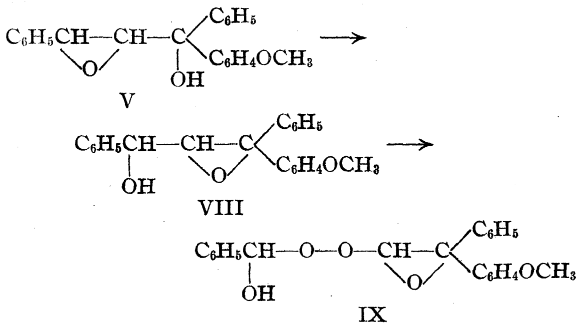
(3) Bergmann and Wolff, *ibid.*, **54**, 1644 (1932).



the compound III could be obtained. Instead, the oxide gave results analogous to those obtained with benzalacetophenone oxide or the corresponding *o*-chloro compound. In cold solution the oxanol V was the only product; at room temperature the expected cleavage of the oxanol V took place. The glycol III was produced in good yield when the oxanol V was treated with excess phenylmagnesium bromide.

The oxanol V behaves like the corresponding unsubstituted oxanol II when treated with a dilute alcoholic solution of sodium hydroxide. An isomeric oxanol VIII is produced. This oxanol is apparently much more unstable than the other known compounds of similar structure, cleavage and autoxidation proceeding very rapidly in the laboratory air. Indeed it is difficult to obtain a pure sample and it is more difficult to keep a pure sample long enough to determine its percentage composition, crystal form and melting point with any great degree of accuracy. Cleavage and autoxidation of this oxanol give a peroxide IX which forms benzoic acid and *p*-methoxybenzophenone by chromic acid oxidation.



Bergmann treated the oxide with excess of phenylmagnesium bromide at room temperature. One equivalent of phenylmagnesium bromide added inversely to a cold solution of the oxide should provide the best conditions for the production of the oxanol V. Yet when these conditions were fulfilled, 50% of the oxide was recovered unchanged and the remaining 50% was converted into the product obtained by Bergmann.

The inactivity of the oxide ring of the *p*-methoxy compound toward lithium phenyl suggests the possibility that oxide rings in general are unattacked by lithium phenyl under conditions which would give a reaction with phenylmagnesium bromide. Experiments now in progress will attempt to settle this question.

An explanation of the difference in the reaction of benzalacetophenone oxide and benzal-*p*-methoxyacetophenone oxide with phenylmagnesium bromide is as yet not evident. At least two explanations can be offered from the facts at hand. The anisyl group may activate the oxide ring so that fission of the oxide ring is made much easier. This would permit simultaneous addition to the carbonyl group and to the oxide ring, producing a magnesium derivative having no tendency to break up. The alternative is that the anisyl group strengthens the C–C bond between the carbonyl group and the oxide ring, thus preventing the cleavage of the primary magnesium derivative.

The fact that the anisyl compound shows addition to the oxide ring at low temperatures—while the unsubstituted oxide does not—indicates that the first explanation is more probably correct. Research now in progress may provide a more adequate explanation for this difference in behavior.

Experimental Part

2-Hydroxy-1,3,3-triphenyl-1-anisyl Propanol, III

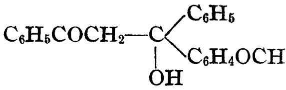
Inverse Grignard.—One equivalent of phenylmagnesium bromide in ether was added slowly to a stirred solution of 15 g. of benzal-*p*-methoxyacetophenone oxide in 300 cc. of ether maintained at −15°. The cold solution was stirred for thirty minutes after complete addition of the reagent and was then decomposed immediately with iced acid. The ether yielded 12 g. of the 132° compound III described by Bergmann, in addition to 4 g. of unchanged oxide. About 3.5 g. of unchanged oxide was also reclaimed from the solid clinging to the walls of the reaction flask.

Excess Grignard.—To a stirred solution of four equivalents of phenylmagnesium bromide in ether was added 15 g. of solid benzal-*p*-methoxyacetophenone oxide. After boiling the stirred solution for one hour the product was isolated in the usual way. The yield was 23.5 g. of the 132° compound III, compared with a calculated yield of 24.2 g.

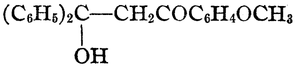
Oxidation.—Chromic acid oxidation of the carbinol III in glacial acetic acid solution gave benzophenone and *p*-methoxybenzophenone, identified by means of known samples. No benzoic acid could be detected.

3-Hydroxy-1,3,3-triphenyl-1-anisyl Propanol, VI.—To a stirred solution of four equivalents of phenylmagnesium bromide in ether was added in the course of two hours 25 g. of *p*-methoxydibenzoylmethane suspended in ether. After the mixture had been stirred and refluxed for four hours, hydrolysis with iced acid was accomplished as usual. The product was fractionally crystallized from methyl alcohol (kept slightly acid with glacial acetic acid to prevent cleavage), giving about 7 g. each of two isomeric compounds.

The 132° isomer VIIA is much more insoluble in methyl alcohol and crystallizes in small needles. Oxidation by chromic acid in glacial acetic acid solution gave benzoic acid and *p*-methoxybenzophenone. The 132° isomer is therefore



The 118° isomer VIIB is quite soluble in methyl alcohol and crystallizes in small needles. Oxidation by chromic acid gave anisic acid and benzophenone. The 118° isomer is therefore



$$(C_6H_5)_2\underset{\displaystyle OH}{\underset{|}{C}}—CH_2COC_6H_4OCH_3$$

Anal. Calcd. for $C_{22}H_{20}O_3$: C, 79.48; H, 6.07. Found: (132°) C, 79.36; H, 6.17; (118°) C, 79.31; H, 6.20.

Lithium Phenyl and the (118°, 132°) Isomer.—To a stirred solution of four equivalents of lithium phenyl in ether cooled to 0° was added 3 g. of the 132° isomer suspended in a small volume of ether. After two hours of stirring at 0° the solution was hydrolyzed in the usual way with iced acid. The dried ethereal solution, diluted with petroleum ether, deposited clusters of stout needles melting at 150°. The yield was about 3 g. The carbinol is fairly soluble in ether, quite soluble in methyl alcohol and insoluble in petroleum ether. The 118° isomer gave the same 150° carbinol in a similar reaction.

Anal. Calcd. for $C_{28}H_{26}O_3$: C, 81.91; H, 6.39. Found: C, 81.86; H, 6.37.

Oxidation.—Chromic acid oxidation of the carbinol VI gave benzophenone and *p*-methoxybenzophenone, identified by means of known samples.

2-Oxido-1,3-diphenyl-1-anisyl Propanol, V.—To a stirred solution of one equivalent of lithium phenyl in 200 cc. of ether maintained at −15° was added 10 g. of solid benzal-*p*-methoxyacetophenone oxide over a period of thirty minutes. Forty-five minutes of additional stirring at −15° produced a precipitate. Decomposition of this reaction mixture with iced acid gave an ether solution which deposited large plates melting at 136°. The yield was 12 g. None of the carbinol III could be detected. The oxanol V is quite soluble in acetone, moderately soluble in ether, insoluble in petroleum ether and forms beautiful plates from an acetone–petroleum ether mixture.

Anal. Calcd. for $C_{22}H_{20}O_3$: C, 79.48; H, 6.07. Found: C, 79.36; H, 6.12.

Oxidation.—Chromic acid oxidation of the oxanol V gave benzoic acid and *p*-methoxybenzophenone, identified by means of known samples.

Addition of Phenylmagnesium Bromide.—Two grams of solid V was added to a stirred solution of three equivalents of phenylmagnesium bromide in ether. After being boiled for one and one-half hours the solution was treated with iced acid and the product isolated in the usual way. The ether gave 2.5 g. of the 132° compound III, identified by a mixed melting point with known material.

Cleavage with Lithium Phenyl.—A stirred ether solution of three equivalents of lithium phenyl to which 5 g. of the solid V had been added was boiled for three hours. After decomposition with iced acid, the only solid product which could be isolated was *p*-methoxytriphenylcarbinol, identified by means of a known sample. The remaining material was the usual resinous aldehyde.

Rearrangement with Bases: 2-Oxido-1,3-diphenyl-3-anisyl Propanol, VIII.—To a solution of 0.2 g. of potassium hydroxide in 100 cc. of methyl alcohol was added 5 g. of the sparingly soluble oxanol V. The mixture was allowed to stand for three days during which time the solid gradually dissolved, then poured into ice water. The product crystallized from ether–petroleum ether in stout plates melting at about 120°. The melting point of the pure substance was not determined exactly because of very rapid deterioration in laboratory air. The rearrangement product is very soluble in methyl alcohol, acetone and ether and is but sparingly soluble in petroleum ether. No other product was isolated except the peroxide formed by autoxidation of VIII. The rapid decomposition of the compound made an accurate analysis most difficult.

Anal. Calcd. for $C_{22}H_{20}O_3$: C, 79.48; H, 6.07. Found: C, 79.1; H, 5.9.

Oxidation.—Chromic acid oxidation of the oxanol VIII gave only benzoic acid and *p*-methoxybenzophenone as products.

Autoxidation: The Peroxide, IX.—The oxanol VIII is autoxidized very rapidly in the air of the laboratory. A freshly prepared sample oiled and developed the odor of benzaldehyde after a few minutes of exposure. Complete autoxidation gave a white powder which was recrystallized from ether–petroleum ether. It separates as fine white needles and melts with brisk bubbling at 150°. It is sparingly soluble in acetone, methyl alcohol and ether and insoluble in petroleum ether.

Anal. Calcd. for $C_{22}H_{20}O_5$: C, 72.48; H, 5.54. Found: C, 72.4; H, 5.7.

Oxidation.—Chromic acid oxidation of the peroxide IX gave benzoic acid and *p*-methoxybenzophenone as products.

2-Oxido-1,1,3-triphenyl Propanol.[4]—Ten grams of solid benzalacetophenone oxide was added to a stirred solution of two equivalents of lithium phenyl in ether maintained at −15°. After forty-five minutes of stirring at −15° the solution was decomposed with iced acid. The ether gave a good yield of the 130° oxanol previously obtained by the use of phenylmagnesium bromide. The identity of the compound was verified by a mixed melting point with known material.

---

[4] Kohler, Richtmyer and Hester, THIS JOURNAL, **53**, 214 (1931).

2-Oxido-1,1-diphenyl-3-(*o*-chlorophenyl) Propanol.[5]—Ten grams of solid *o*-chlorobenzalacetophenone oxide was added to a stirred ethereal solution of two equivalents of lithium phenyl maintained at −15°. After forty-five minutes of stirring at −15°, the solution was decomposed with iced acid. The ether gave a good yield of the 107–108° oxanol previously obtained by the use of phenylmagnesium bromide. The oxanol was identified by comparison with a known sample.

The author gratefully acknowledges a gift from the Milton Fund of Harvard University, with which the starting materials used in this problem were purchased.

Summary

The action of lithium phenyl and of phenylmagnesium bromide on alpha oxido ketones is compared. The structure of the compound formed by the reaction of phenylmagnesium bromide and benzal-*p*-methoxyacetophenone oxide has been determined.

Stereochemistry of Deuterium Compounds. I. Optical Rotation of Methylhexyldeuterocarbinol

BY LEONA YOUNG AND C. W. PORTER

Many unsuccessful attempts have been made to obtain optically active compounds in which asymmetry is dependent upon differences between hydrogen and deuterium. It was our aim, a year ago, to prepare stereoisomeric compounds of the type RR'CHD and to isolate the *d* and *l* forms of these compounds. Attempts to prepare such compounds from optically active halides, through the Grignard reaction, led to complete racemization.[1] Attempts to isolate an optically active hydrocinnamic acid from the products formed when cinnamic acid was reduced by deuterium failed, presumably, on account of slight differences in the solubilities of the alkaloid salts. Failure to resolve racemic phenyldeuteroacetic acid, C_6H_5-CHD-COOH, into active components through fractional crystallization of alkaloid salts was attributed to the same cause.[2]

Biilman, Jensen and Knuth claim to have produced a measurable optical rotation in camphane through the substitution of deuterium for hydrogen in a methylene group[3] but their findings have not been confirmed and their technique has been the subject of adverse criticism.[4]

Recently we turned our attention to a comparison of the rotations of compounds in which the hydrogen and deuterium are not attached directly to the asymmetric carbon atom. One example of this type has been reported.[5] Methyl hexylcarbinol was resolved into active components and the dextrorotatory fraction was used in the experiments reported here. The active alcohol was esterified by treatment with acetyl chloride and the ester was, in turn, hydrolyzed with deuterium oxide. The rotation of the recovered alcohol was lower than that of the original sample. This alcohol was then reconverted into the original form through esterification and subsequent hydrolysis with ordinary water. The recovered compound had the same rotation as that of the original sample. The experiment was repeated several times and, within the limits of experimental error, the results were the same.

The measured rotations were as follows:[6]

	I	II	III
Original carbinol	17.45	19.00	17.90
Deuterium derivative	17.20	18.70	17.60

The average difference in rotations of the two compounds was 0.28 scale divisions or 0.11°. We feel justified, therefore, in reporting a real difference between the optical properties of ordinary methylphenylcarbinol and the compound formed

[6] The measurements were made with a Fric polarimeter. The scale divisions on this instrument are equivalent to 0.404 degrees. The reading +19.00 corresponds to 7.68°. The specific rotation of the pure dextro compound with green light (5461 Å.) is +11.80°. Our resolution of the racemic mixture was not quantitative but for the purpose of this study it was not necessary to have complete separation. It was necessary only to have a preparation of known rotatory power and to be sure that no racemization occurred in the treatment to which the compound was subjected.

by substituting deuterium for hydrogen in the hydroxyl group. The specific rotation of the deuterium compound, $[\alpha]^{17}_{5461}$, is +11.62°.[7]

In earlier attempts to replace the carbonyl hydrogen by deuterium the alcohol was converted into the sodium derivative and the sodium alcoholate was hydrolyzed by deuterium oxide. This treatment caused partial racemization. On the other hand, acetyl chloride acts upon the optically active alcohol without racemization and the acetyl derivative when hydrolyzed by dilute sodium hydroxide or by a solution of sodium ethylate yields the original alcohol without change in rotation.

The acetyl derivative of 2-octanol is very slightly soluble in water and the hydrolysis is necessarily accomplished in alcoholic solution. To guard against an exchange between the hydrogen of the hydroxyl group in the ethyl alcohol (used as a solvent) and deuterium in the hydroxyl group of the octyl alcohol, we hydrolyzed the ester in a mixture of NaOD, C_2H_5OD and D_2O when the heavy derivative was wanted and we used a mixture of NaOH, C_2H_5OH and H_2O when the light alcohol was wanted.

Experimental

The Resolution of Methylhexylcarbinol.—The standard method for the resolution of a racemic mixture of methylhexylcarbinol into its optical isomers was employed.[8]

Preparation of the Acetyl Derivative.—Thoroughly dried dextrorotatory methylhexylcarbinol was converted into the acetyl derivative by means of acetyl chloride. Slightly more than the equivalent weight of acetyl chloride was added to the alcohol, drop by drop and with constant stirring, at a temperature of from 10 to 15°. The mixture was allowed to stand overnight at room temperature. The excess of acetyl chloride was then distilled off on a water-bath. The remaining acetyl derivative of the alcohol was obtained by distillation under reduced pressure.

Preparation of the Deuterium Derivative.—One half of the acetyl derivative of the dextrorotatory methylhexylcarbinol (17.68 g.) was dissolved in 120 cc. of C_2H_5OD and 40 cc. of D_2O. To this was added 10 g. of NaOD. The solution was heated for one hour under a reflux condenser on a water-bath. The ethyl alcohol was then distilled off by immersing the flask in boiling water. When nearly all the ethyl alcohol had been removed the remaining mixture separated into two layers. The upper layer (methylhexylcarbinol) was removed and dried with anhydrous potassium carbonate. It was then fractionated to remove traces of ethyl alcohol and treated again with potassium carbonate. The process of alternate distillation and treatment with potassium carbonate was continued until there was no further change in rotatory power, *i. e.*, until all water and ethyl alcohol had been removed. The rotation was lower than that of the original alcohol as indicated in the table above.

The remaining half of the acetyl derivative of the methylhexylcarbinol was treated in the same way with NaOH, C_2H_5OH and H_2O. The final product showed no difference in optical rotation from that of the original substance. The result indicates that this method of esterification and hydrolysis does not cause racemization of the alcohol.

Conversion of the Deuterium Derivative of Methylhexylcarbinol to the Hydrogen Derivative.—The deuterium derivative of methylhexylcarbinol was converted into the acetyl derivative as described above. The ester was hydrolyzed in a solution of NaOH, C_2H_5OH and H_2O. The product was dried and distilled as previously described and its rotation returned to the original value.

Summary

Substitution of deuterium for hydrogen in the hydroxyl group of methylhexylcarbinol lowers the optical rotation of the compound.

BERKELEY, CALIF.

RECEIVED NOVEMBER 23, 1936

---

(7) Calculated from the measured rotation and known composition of the sample used. The specific rotation of ordinary 2-octanol is 11.80°. Our mixture consisting of *d*- and *l*-octanol had a rotation of +7.68°. This value is equal to $11.80\ M_1 - 11.80 M_2$ with M_1 and M_2 representing the mole fractions of the dextro and levo rotatory forms, respectively. The mole fraction of the *d*-form in the mixture is, therefore, 0.825 and of the *l*-form 0.175. The mole fractions are the same after conversion to the deuterium derivatives and this mixture in a 10-cm. tube has a rotation of 7.55°. From the equation $7.55 = 0.825\alpha - 0.175\alpha$ we obtain $\alpha = 11.62°$.

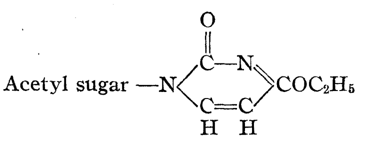
Synthetic Nucleosides—Some 1-Glycosidouracils

BY GUIDO E. HILBERT

Of the two known methods for synthesizing pyrimidine nucleosides, the one most recently introduced,[1] involving the interaction of 2,4-dialkoxypyrimidines and acetobromosugars, has the distinct advantage of actually introducing the sugar into the pyrimidine ring at the 1-position, which is that occupied by ribose in uridine and cytidine. Unfortunately the method seemed not to be as general as first expected. For example, two other types of pyrimidines, namely, 2-methoxy-4-amino-[2] and 2,4-dimethoxy-5-methyl-pyrimidine[3] formed in the presence of acetobromoglucose only methylated derivatives. These results suggest that the success of the method is dependent to a marked extent upon the nature of the substituents attached to the pyrimidine cycle. The following investigation was initiated (a) to test the generality of the reaction between various acetobromosugars and 2,4-diethoxypyrimidine and (b) with the hope of obtaining compounds similar in constitution to the anomalous 4-ethoxy-2-triacetyl-*d*-ribosidopyrimidine (I) obtained as a by-product in the interaction of acetobromo-*d*-ribose and 2,4-diethoxypyrimidine.[4] If such a product could be formed from an easily accessible sugar, there would be no difficulty in the way of obtaining sufficient material for a proof of structure.

Four different sugar derivatives, namely, acetobromo-*d*-galactose, acetobromo-*d*-xylose, acetobromo-*l*-arabinose and acetobromo-*d*-mannose, were used in this work. Each of the first three gave with 2,4-diethoxypyrimidine compounds of the type (II); in none of these reactions could crystalline analogs of the labile 4-ethoxy-2-triacetyl-*d*-ribosidopyrimidine (I)[4] be isolated. Considering the number of side reactions that are possible (see below), the yields of the 1,2-dihydro-2-keto-4-ethoxy-1-acetylglycosidopyrimidines (II) are quite satisfactory. The products (II) were converted by simultaneous deacetylation and deëthylation with alcoholic hydrogen chloride into the corresponding 1-glycosodouracils, which, like uridine, neither respond to the Wheeler-Johnson color test nor reduce Fehling's solution after acid treatment. It is interesting that the pentose-pyranosidouracils melt considerably higher, are thermally more stable and are much less soluble in water than uridine and the hexose–pyranosidouracils. Evidently the presence of a carbinol side group on a sugar ring affects significantly the properties of the nucleosides.

(II)



Of the acetobromosugars investigated, acetobromo-*d*-mannose, because of the similarity of its chemical reactions with those of acetobromo-*d*-ribose ("orthoacetate" formation[5]), was considered to offer the most promise of producing an analog of (I). Unfortunately, the interaction of acetobromo-*d*-mannose and 2,4-diethoxypyrimidine gave a sirup and the lability of the desired product precluded fractionation of the sirup to remove by-products. In view of the sluggishness with which most mannose derivatives crystallize and the complexity of the reaction product, this result was not altogether unexpected. However, presumptive evidence in favor of the formation of an analog of (I) in this reaction was obtained in the following manner. When the sirup was allowed to stand for a considerable length of time, a crystalline material gradually deposited. After separation and purification it proved to be 1,2-dihydro-2-keto-4-ethoxypyrimidine,[6] which had been obtained previously from the mild alkaline hydrolysis of (I). Presumably this was formed by the slow hydrolysis of 4-ethoxy-2-tetraacetyl-*d*-mannosidopyrimidine. Since the formation of a pyrimidine substituted in the 1-position by mannose was of less immediate interest, no effort was made to prepare 1-*d*-mannosidouracil by using a procedure similar to that employed for the isolation of 1-*d*-ribosidouracil.[4]

The 1,2-dihydro-2-keto-4-ethoxy-1-acetylglycosidopyrimidines (II) represented only a minor fraction of the product formed by the interaction

[6] This was also a secondary product of the interaction between acetobromo-*d*-galactose and 2,4-diethoxypyrimidine.

of 2,4-diethoxypyrimidine and acetobromosugars. Considerable ethyl bromide was formed, presumably by the degradation of the intermediate pyrimidinium bromide, and interacted competitively with 2,4-diethoxypyrimidine to give 1,2-dihydro-2-keto-1-ethyl-4-ethoxypyrimidine. This was separated readily from the other products of the reaction and on treatment with hydrogen chloride gave 1-ethyluracil quantitatively. A previous attempt to carry out the graded ethylation of 2,4-diethoxypyrimidine with ethyl iodide[7] was unsuccessful and gave only the end-product, 1,3-diethyluracil. In a few reactions, the by-products, 1,2-dihydro-2-keto-4-ethoxypyrimidine, mentioned above, and uracil, in traces, were also formed. Little is known regarding the other and major side product or products. In one instance, a mixture resulting from the interaction of acetobromo-*d*-glucose with 2,4-diethoxypyrimidine was fractionated and the material that did not crystallize distilled in a high vacuum (0.0001 mm.). Analysis of the distillate which could not be made to crystallize indicates that it is a tetraacetylglucosidoethoxypyrimidine.

From the preceding results and those previously published on 2,4-diethoxypyrimidine, it may be concluded that, although the reaction with acetobromoglycosides is quite complex, a certain amount of the sugar will enter the 1-position of this particular type of pyrimidine. This is of interest because, of the various pyrimidines that could be studied in the above type of reaction, the 2,4-diethoxy derivative is probably the most important, since its use can be directed not only to the preparation of analogs of uridine but also indirectly to those of cytidine.[8] As the synthesis of this type of compound seems to be independent of the kind of acetobromoglycoside used, it is believed that the synthesis of the naturally occurring pyrimidine nucleosides now resolves itself primarily into a sugar problem.

I wish to express my appreciation to Dr. R. T. Milner and Mrs. M. S. Sherman for performing the microanalyses recorded.

Experimental

Acetobromo-*d*-xylose,[9] acetobromo-*d*-mannose and acetobromo-*d*-galactose were prepared from the acetates by the method of Levene and Raymond.[10] Acetobromo-*l*-arabinose[11] was prepared directly from *l*-arabinose according to Hudson's[12] modification of the method of Chavanne.[13] All the acetobromoglycosides used in this work were recrystallized several times, generally from dry ether–petroleum ether. Acetobromo-*d*-galactose, which has rarely been obtained crystalline, melted at 87–88°[14,15]; $[\alpha]^{21}_{D}$ +216° (c = 7.44 in U. S. P. chloroform).

The reaction between 2,4-diethoxypyrimidine and the acetobromoglycosides was carried out in an oven (temperature control). Since considerable ethyl bromide is evolved in the reaction it is desirable to connect the flask containing the reactants with a glass tube leading to the outside atmosphere; the portion projecting from the furnace was fitted with a tube containing a drying agent.

1,2-Dihydro-2-keto-4-ethoxy-1-triacetyl-*d*-xylosidopyrimidine.—A mixture of acetobromo-*d*-xylose (38 g.) and 2,4-diethoxypyrimidine (38 g.) was heated at 65° for eighteen hours. After thirty minutes there was complete solution and in two hours large colorless plates started to separate. The final reaction mixture consisted of a mush of crystals in a pale yellow sirup. It was treated with 15 cc. of dry ether, filtered and the solid washed with ether; yield, 14 g. (31% of the theoretical yield based on the acetobromo-*d*-xylose or 16% based on 2,4-diethoxypyrimidine). The product was recrystallized from 150 cc. of 95% ethyl alcohol and deposited as needles on rapid cooling; m. p. 218° resolidifying at 200°; $[\alpha]^{22}_{D}$ 58.4° (c = 5.14 in U. S. P. chloroform). This xyloside was very soluble in cold chloroform, soluble in hot alcohol, slightly soluble in ether and sparingly soluble in water.

Anal. Calcd. for $C_{17}H_{22}O_9N_2$: C, 51.23; H, 5.57; N, 7.04; OC_2H_5, 11.31. Found: C, 51.35; H, 5.51; N, 6.96; OC_2H_5, 11.24.

The original sirup from which the nucleoside had been filtered, after standing for several hours, deposited an additional small quantity of the nucleoside, which was contaminated with a finely divided material. The latter was separated mechanically; it did not melt at 300° and was probably uracil.

1,2-Dihydro-2-keto-4-ethoxy-1-*d*-xylosidopyrimidine.—A solution of 3 g. of 1,2-dihydro-2-keto-4-ethoxy-1-triacetyl-*d*-xylosidopyrimidine in 50 cc. of warm absolute ethyl alcohol was treated with 20 cc. of alcohol containing 2 cc. of liquid ammonia. On cooling the solution to room temperature, the acetyl compound separated but redissolved gradually within several hours. After two days, the solution was concentrated under diminished pressure; the resulting colorless residue rapidly crystallized when agitated. It was recrystallized from 50 cc. of absolute ethyl alcohol and separated as large stout rods; the yield was practically quantitative. The product sintered at 206° and melted at 208°; it resolidified on

cooling and then melted again at 208°; $[\alpha]^{23}\text{D}$ +47.9° (c = 4.64 in distilled water). This xylosido derivative is very soluble in cold water, slightly soluble in hot alcohol and insoluble in non-polar solvents.

Anal. Calcd. for $C_{11}H_{16}O_6N_2$: C, 48.50; H, 5.93; N, 10.29; OC_2H_5, 16.55. Found: C, 48.58; H, 5.83; N, 10.39; OC_2H_5, 16.17.

1-*d*-Xylosidouracil.—To a solution of 4 g. of 1,2-dihydro-2-keto-4-ethoxy-1-triacetyl-*d*-xylosidopyrimidine in 65 cc. of hot absolute methanol was added 10 cc. of methanol containing 26% by weight of hydrogen chloride. After standing for three days, the clear solution was concentrated under diminished pressure and the residual sirup rapidly crystallized. The solid cake was broken up, triturated with alcohol and filtered; yield 2.35 g. It was recrystallized from 60 cc. of 90% ethyl alcohol, separating as distorted octahedra, which were anhydrous; sintered 243°, m. p. 245°; $[\alpha]^{24}\text{D}$ +21.8° (c = 1.46 in distilled water). On another occasion it separated as long silky needles containing 8.5% solvent of crystallization (slowly removed at the boiling point of xylene *in vacuo*). 1-*d*-Xylosidouracil is much less soluble in water than other pyrimidine nucleosides; about 30 cc. of water was required to dissolve 1 g. at room temperature.

Anal. Calcd. for $C_9H_{12}O_6N_2$: C, 44.24; H, 4.95; N, 11.48. Found: C, 44.42; H, 4.74; N, 11.39.

1,2 - Dihydro - 2 - keto - 4 - ethoxy - 1 - tetraacetyl - *d* - galactosidopyrimidine.—A solution of 40 g. of acetobromo-*d*-galactose and 40 g. of 2,4-diethoxypyrimidine was heated at 65° for twenty-one hours. The reaction mixture consisted of a pale brown sirup and a small amount (0.1 g.) of uracil. After adding an equal volume of dry ether, it was filtered and the filtrate placed in the ice-chest overnight. A crystalline cake separated, which was broken up, filtered and washed with ether; yield 16.7 g. (the yield based on acetobromo-*d*-galactose was 37%, or based on 2,4-diethoxypyrimidine 15% of the theoretical). It was recrystallized from 95% ethyl alcohol and separated as plates which when desolvated sintered at 156° and melted at 159°; $[\alpha]^{21}\text{D}$ +59.2° (c = 5.53 in U. S. P. chloroform). The amount of solvent of crystallization present in the crystals varied with the conditions of crystallization; for example, the loss in weight of air-dried specimens obtained from three different crystallizations was 5.0, 5.6 and 6.3%. The ethoxyl content of the air-dried specimen, which lost 5.6% by weight when heated *in vacuo*, was determined by analysis; found, 12.0, thus indicating that a portion of the solvent of crystallization is ethyl alcohol. After drying at 61° to constant weight it was analyzed.

Anal. Calcd. for $C_{20}H_{26}O_{11}N_2$: C, 51.04; H, 5.57; N, 5.96; OC_2H_5, 9.53. Found: C, 51.26; H, 5.90; N, 6.14; OC_2H_5, 9.47.

1 - *d* - Galactosidouracil.—1,2 - Dihydro - 2 - keto - 4 - ethoxy-1-tetraacetyl-*d*-galactosidopyrimidine was simultaneously deacetylated and deëthylated in the same manner as that described for the preparation of 1-*d*-xylosidouracil. The galactoside was recrystallized from 80% ethyl alcohol and deposited on cooling as thick rhombs; s. p. 235°; m. p. 250–251°; $[\alpha]^{25}\text{D}$ +59.9° (c = 5.01 in distilled water). It was soluble in an equal weight of boiling water and crystallized on cooling.

Anal. Calcd. for $C_{10}H_{14}O_7N_2$: C, 43.80; H, 5.11; N 10.22. Found: C, 43.47; H, 5.33; N, 10.21.

1,2 - Dihydro - 2 - keto - 4 - ethoxy - 1 - triacetyl - *l* - arabinosidopyrimidine.—Two grams of finely divided acetobromo-*l*-arabinose and 2 cc. of 2,4-diethoxypyrimidine were heated at 70° for nineteen hours. Acetobromo-*l*-arabinose was not very soluble in warm 2,4-diethoxypyrimidine and the mixture was frequently shaken to facilitate solution. The end-product of the reaction was a clear light brown sirup. It was dissolved in an equal volume of ether and placed in the ice-chest for one week as crystallization took place very slowly. The crystalline material was separated and washed well with ether; yield 0.90 g. (38% of the theoretical yield based on the acetobromo-*l*-arabinose). It was dissolved in hot ethyl alcohol, ether added and the solution cooled; the crystals separated without solvent of crystallization; $[\alpha]^{21}\text{D}$ +108.8° (c = 4.11 in U. S. P. chloroform).

Anal. Calcd. for $C_{17}H_{22}O_9N_2$: C, 51.23; H, 5.57; N, 7.04. Found: C, 51.35; H, 5.56; N, 7.12.

This arabinose derivative was dimorphous; when its alcoholic solution was chilled rapidly it had a tendency to separate as needles; m. p. 157°. When the solution was cooled very slowly it generally crystallized as huge monoclinic prisms; m. p. 167.5°. Apparently the latter was the stable form as the mixed melting point of the two was 167.5°. The melt sometimes crystallized in the unstable form and at other times in the stable form.

1-*l*-Arabinosidouracil was prepared in an analogous manner to that described for the preparation of 1-*d*-xylosidouracil. The sirup obtained after concentrating the alcoholic hydrochloric acid solution crystallized when treated with alcohol (frequent vigorous stirring); yield, practically quantitative. After crystallization from 90% ethyl alcohol from which it separated as diamond-shaped hexahedra it melted at 251–252°; $[\alpha]^{23}\text{D}$ +88.2° (c = 1.21 in distilled water).

Anal. Calcd. for $C_9H_{12}N_2O_6$: C, 44.24; H, 4.95; N, 11.48. Found: C, 44.40; H, 5.00; N, 11.51.

Some By-products Formed in the Interaction of Acetobromoglycosides with 2,4-Diethoxypyrimidine

1,2 - Dihydro - 2 - keto - 1 - ethyl - 4 - ethoxypyrimidine was isolated from the reaction mixtures in which the reactants with 2,4-diethoxypyrimidine were acetobromo-*d*-glucose, acetobromo-*d*-xylose and acetobromo-*d*-mannose. The manner in which it was obtained was the following one. After filtering the nucleoside that crystallized from the solution of the reaction sirup in ether, the filtrate was set in a refrigerator. The separation of 1,2-dihydro-2-keto-1-ethyl-4-ethoxypyrimidine was very slow, generally requiring several days. The solid product, after filtering and washing with ether, was quite sticky and was purified by sublimation (long plates); yield 4 g.[16] from 50 g. of acetobromo-*d*-glucose and 50 g. of 2,4-diethoxypyrimidine. It was recrystallized from ether as stout needles of m. p.

---

[16] This represents only a fraction of the product present in the reaction mixture. 1,2-Dihydro-2-keto-1-ethyl-4-ethoxypyrimidine can be removed quantitatively by extracting the ether solution of the original filtered sirup with water. This procedure was not adopted since it was desired to avoid the hydrolysis of and to isolate if possible "orthoacetates" or products in which the sugar was attached to the 2-position of the pyrimidine ring.

88°. This 1-ethyl derivative is very soluble in cold water, alcohol, and chloroform and slightly soluble in ether; it does not give a Wheeler–Johnson color test.

Anal. Calcd. for $C_8H_{12}O_2N_2$: C, 57.10; H, 7.20; N, 16.67. Found: C, 57.21; H, 7.13; N, 16.58.

1-Ethyluracil.—This was obtained by dissolving the above compound (1.00 g.) in concentrated hydrochloric acid (10 cc.) and concentrating to dryness on a steam-bath. The residue was crystallized from a solution of alcohol and ether and separated as clusters of prisms; m. p. 147.5°; yield 0.53 g. 1-Ethyluracil is very soluble in cold water, alcohol and acetone, slightly soluble in ether and sparingly soluble in hot carbon tetrachloride; it did not give a Wheeler–Johnson color test.

Anal. Calcd. for $C_6H_8O_2N_2$: C, 51.40; H, 5.76; N, 20.00. Found: C, 51.61; H, 5.75; N, 20.14.

1,2 - Dihydro - 2 - keto - 4 - ethoxypyrimidine was isolated from the products formed in the interaction of either acetobromo-*d*-mannose or acetobromo-*d*-galactose with 2,4-diethoxypyrimidine. As the methods of isolating the material in the two cases was quite similar only the details of the procedure, in which the former sugar was used, will be described. A solution of 7 g. of acetobromo-*d*-mannose and 7 g. of 2,4-diethoxypyrimidine was heated at 65° for seventy hours; after cooling a small amount of uracil deposited and this was removed. From the filtrate, 1,2-dihydro-2-keto-1-ethyl-4-ethoxypyrimidine (2 g.) slowly crystallized and after a week it was collected. The sirupy filtrate over a period of a year slowly deposited a crystalline product. The solid was removed by filtration and washed with a small amount of ether. Trituration with chloroform separated the ethoxy derivative from uracil. The chloroformic extract was concentrated and the residue recrystallized from a solution containing 90% benzene and 10% absolute ethyl alcohol; massive aggregates of colorless plates were thus obtained; yield 0.36 g.; m. p. 168°; a mixed melting point with 1,2-dihydro-2-keto-4-ethoxypyrimidine[17] was unchanged. The properties as well as the response to the Wheeler–Johnson color test are identical with those described previously for this compound.

Anal. Calcd. for $C_6H_8O_2N_2$: C, 51.40; H, 5.76; N, 20.00. Found: C, 51.75; H, 5.76; N, 19.95.

Uracil was isolated in traces in all experiments except when acetobromo-*d*-glucose was used. This pyrimidine was easily obtained in the pure state by triturating the crude material with chloroform and then recrystallizing from water; it was identified by its properties, Wheeler–Johnson color test and analysis.

Summary

Acetobromoglycosides, in general, interact with 2,4-diethoxypyrimidine to give 1,2-dihydro-2-keto-1-acetylglycosido-4-ethoxypyrimidines. Appreciable amounts of the secondary product, 1,2-dihydro-2-keto-1-ethyl-4-ethoxypyrimidine are also formed. Presumptive evidence indicates that by-products, structurally related to the 4-ethoxy-2-triacetyl-*d*-ribosidopyrimidine which is formed in the interaction of acetobromo-*d*-ribose and 2,4-diethoxypyrimidine, are present in the products of the reaction of 2,4-diethoxypyrimidine with acetobromo-*d*-mannose and with acetobromo-*d*-galactose; however, attempts to isolate these analogs in the crystalline condition have thus far been unsuccessful. Hydrolysis of 1-acetylglycosidopyrimidine derivatives with alcoholic hydrochloric acid produces the 1-glycosidouracils. 1-*d*-Xylosido-, 1-*l*-arabinosido- and 1-*d*-galactosidouracil were prepared in this manner and their chemical properties found to be similar to those of uridine.

Conductivities of One-Molal Mixtures of Alkali Halides and Nitrates

BY PIERRE VAN RYSSELBERGHE AND LEE NUTTING

Introduction

As pointed out by Smith and Gortner,[1] few systematic studies of the conductivity of mixed electrolytes are available for theoretical investigation. Moreover, the available data have not as yet received an entirely satisfactory interpretation. The small but definite departures from the mixture rule observed by Stearn and by Ruby and Kawai[2] in the case of mixed alkali halides have recently been discussed by Van Rysselberghe and Nutting.[3] They showed that these departures could be reduced appreciably if the mixture rule is corrected by means of simple but plausible assumptions concerning the adjustment of mobilities which takes place upon mixing. The modified form of the mixture rule obtained by them involves the transport numbers of the ions in solutions of the pure salts. As these transport numbers are not always known with great accuracy calculations of real significance cannot be carried

out in all cases. In this paper we present a series of data obtained with mixtures of alkali halides and alkali nitrates of total molality one. These data are compared with the values derived from the simple, uncorrected mixture rule.

Experimental

A complete description of the circuit used in this work has been given elsewhere by Nutting.[4] One feature of the method is the use of a vacuum tube oscillator as a source of alternating current. A frequency of 1000 ± 5 cycles was obtained by calibrating the oscillator against a 1000 cycle tuning fork. To facilitate the determination of the point at which the bridge was in balance, a two-stage audiofrequency amplifier was used. Comparative tests with a Grinnell Jones bridge used in this Laboratory for other purposes gave satisfactory results. The accuracy of the resistance measurements was estimated at ±0.05%.

The conductivity cell was similar in design to that proposed by McBain, Laing and Titley.[5] A detailed study of the variation of cell constant was made in connection with the present measurements and others to be reported later. Observations in general agreement with those of Jones and Bollinger[6] were made and the true value of the cell constant was obtained for each resistance through an extensive series of measurements involving the various Kohlrausch solutions (prepared according to "I. C. T.," Vol. VI, p. 230) and a number of solutions of single salts for which reliable data are available in the literature. A water thermostat (later replaced by an oil one without any noticeable change in the slight temperature fluctuations nor in the measured resistances) kept the temperature within 25 ± 0.02°.

Salts of the highest purity were used (Kahlbaum, für Analyse; Merck, Reagent, analyzed; Baker, C. P. analyzed). Water of specific conductance consistently lower than 2×10^{-6} was used throughout, but no correction was necessary as all our specific conductances were of the order of 10^{-1} and the accuracy was estimated at ±0.15%. Our results with pure salts compare quite well with those of Stearn and of Ruby and Kawai (for 1 molal KCl, S. finds 111.50; R. and K. find 112.29; we find 112.06; for 1 molal NaCl, S. finds 86.36; R. and K. find 86.07; we find 86.21).

The results are reported in Table I. The densities, specific and equivalent conductivities are given in columns 2 to 4. In column 5 we give the values computed by the ordinary mixture rule and in column 6 the differences ΔΛ between the experimental and theoretical values.

Discussion

The differences between measured and calculated values are in all cases quite definite but regularities are difficult to detect. It can be seen that in most cases the departure from the mixture rule is the larger, the larger the difference between the conductivities of the pure salts. There are, however, conspicuous exceptions (mixtures of sodium chloride and potassium nitrate and mixtures of potassium chloride and sodium nitrate). In Table II we have arranged the various mixtures studied by us and the 1-molal mixtures of NaCl + KCl, NaBr + KBr, NaI + KI studied by Stearn in the order corresponding to decreasing differences between the conductivities of the pure salts. For each pair of salts we give this difference (λ) and the maximum deviation between measured and calculated conductivities (ΔΛ) for the intermediate mixtures. There is a rough parallelism between these two quantities (if the KCl + $NaNO_3$ and the NaCl + KNO_3 mixtures are left out of consideration). A similar parallelism holds at the other total concentrations for which data are available. The mixture rule is thus more nearly correct when the mobilities of the component ions are only slightly different from one another in solutions of the pure salts. The mobilities in the mixtures will then differ but little from their values in solutions of the pure salts. When mobilities are quite different, the adjustment which has to take place upon mixing is less likely

TABLE II

Mixtures	λ	ΔΛ
LiCl + KI	45.02	−0.92
KCl + $NaNO_3$	35.70	−2.91
NaCl + KI	32.35	−0.74
NaBr + KBr	26.60	− .60
NaI + KI	26.05	− .65
NaCl + KCl	25.24	− .63
KCl + NaI	20.35	− .26
KCl + KNO_3	19.23	− .30
KNO_3 + $NaNO_3$	16.47	− .38
NaCl + $NaNO_3$	9.85	− .24
NaCl + KNO_3	6.62	+1.79
KCl + KI	6.50	−0.13

to lead to satisfactory agreement with the mixture rule. When large departures are observed, as in the case of solutions containing simultaneously the ions Na^+, K^+, Cl^-, NO_3^-, some specific effect is probably present and its cause may be due to slightly incomplete dissociation of one of the salts present. Outside of these exceptional cases, the regularities which we have just discussed hold whether the salts have a common ion or not.

The application of the mixture rule to solutions of a given molality rather than to solutions of a given molar concentration has been quite customary. We have found that the departures between measured and calculated conductivities are of the same order of magnitude in both scales of concentration.

Summary

1. The densities and the conductivities of nine pairs of alkali halides and nitrates have been measured at a total concentration of one-molal.

2. The mixture rule has been found to be more nearly correct when the component salts have conductivities which differ but slightly.

3. Attention has been called to the wide discrepancies between measured and calculated conductivities in the case of solutions containing simultaneously the ions Na^+, K^+, Cl^- and NO_3^-.

Conductivities of Concentrated Binary Mixtures of Electrolytes with a Common Anion and at Least One Ion of Charge Two

BY PIERRE VAN RYSSELBERGHE, S. W. GRINNELL AND J. M. CARLSON

Introduction

In the foregoing paper, Van Rysselberghe and Nutting[1] have shown, in general agreement with previous results of Stearn and of Ruby and Kawai,[2] that mixtures of 1-1 salts exhibit but small departures from the mixture rule, with the exception of mixtures containing simultaneously the Na^+, K^+, Cl^- and NO_3^- ions for which the departure is sometimes larger than 2 conductivity units. The results seem to show that there is a rough parallelism between the maximum departure from the mixture rule observed for a series of mixtures of a given total concentration and the difference between the conductivities of the pure salts at this same concentration.

In the case of mixtures containing ions of higher valence Smith and Gortner[3] observed departures as large as 7 conductivity units on a Λ of about 120 at concentrations as low as 0.01 N. In the present investigation we have studied mixtures for which extreme departures from the mixture rule were observed (cadmium halides + potassium halides) and others for which large departures were expected but were actually found to be small (magnesium chloride + alkali halides). Other cases are of an intermediate type. Some of these mixtures have been studied previously in a less systematic manner from the point of view of complex ion formation. This older literature is reviewed in various monographs such as that of Walden.[4] The interpretation given by the various authors is based upon the Arrhenius theory and should be carefully revised.

Experimental

The method followed in the present work is essentially the same as that used by Van Rysselberghe and Nutting.[1] Solutions were prepared on a volume concentration basis by means of calibrated glassware. The salts used were of the highest possible purity (Baker C. P. Analyzed, Merck reagent analyzed, Kahlbaum für Analyse). Several of these salts, however, are very hygroscopic, others decompose upon drying at temperatures above 120° and, although all the usual precautions were taken, the accuracy is in several cases less than ±0.5% on the absolute value of the conductivity. Mixtures were prepared by mixing solutions of the pure salts. Conductivities of the pure salts were measured several times, each time with a freshly prepared solution, and were found to be at least as accurate as the data available in "I. C. T." or in the Landolt-Börnstein-Roth Tables. The temperature was in all cases 25 ± 0.02°. In Table I we give the measured specific conductivity, the measured equivalent conductivity, the equivalent conductivity as deduced from the mixture

rule and the difference ΔΛ between measured and calculated conductivities for a series of mixtures of cadmium iodide and potassium iodide. Several of these mixtures correspond to the composition $CdI_2 \cdot KI$ for which data were so far not available. Conductivities of mixtures corresponding to the composition $CdI_2 \cdot 2KI$ are given in the literature.

TABLE I

CONDUCTIVITIES OF MIXTURES OF CdI_2 AND KI AT 25°

2.0	1.0	.09001	30.00	43.8	−13.8

In order to follow the trend of ΔΛ in each series, the data for three mixtures (1 CdI_2 + 0.5 KI, 1 + 1, 2 + 1) are given twice in the table. The conductivities of the pure salts, used in the calculated Λ's, were taken from smooth curves obtained by plotting all the data available in the literature.

In Table II we give the conductivities of eight groups of mixtures arranged in series corresponding to the same total equivalent concentration. We represent by x and $1 - x$ the fractions of the total equivalent concentration corresponding to salts 1 and 2, salt 1 being the first in the title of the series. Some of the data given for the CdI_2 + KI mixtures were obtained from curves drawn by means of the data of Table I.

Discussion

If we classify the various groups of mixtures studied in the present paper according to the difference between the conductivities of the pure salts, we obtain Table III in which are given, for each type of mixture, this difference, λ, and the maximum departure from the mixture rule for the series, $\Delta\Lambda$.

If we except a few irregularities and make allowances for the experimental error, we notice a marked parallelism between λ and $\Delta\Lambda$. We consider this very simple observation as particularly significant and illuminating in view of the fact that several of the mixtures certainly contain large amounts of complex ions (CdI_3^-, $CdI_4^=$, etc.). A survey of the other data in the literature has convinced us that this parallelism is quite general, provided one excludes mixtures containing an acid and mixtures for which the sign of $\Delta\Lambda$ changes as concentration increases. Cases of this type of behavior have been reported by Smith and Gortner.[3] It seems worth mentioning that,

TABLE III

	Mixtures	λ	−ΔΛ
0.5 *N*	$CdI_2 + KI$	100.26	14.7
1 *N*	$CdI_2 + KI$	99.65	16.0
2 *N*	$CdI_2 + KI$	99.52	16.8
2 *N*	$CdBr_2 + KBr$	96.21	12.07
1 *N*	$CdBr_2 + KBr$	95.92	9.75
2 *N*	$CdCl_2 + KCl$	91.43	8.17
1 *N*	$CdCl_2 + KCl$	89.26	5.66
4 *N*	$ZnI_2 + KI$	70.92	6.84
6 *N*	$ZnI_2 + KI$	67.80	8.33
1 *N*	$CdSO_4 + K_2SO_4$	53.26	3.30
2 *N*	$ZnI_2 + KI$	50.87	2.86
1 *N*	$ZnI_2 + KI$	39.23	1.47
4 *N*	$MgCl_2 + NaCl$	17.85	0.73
5 *N*	$MgCl_2 + NaCl$	17.44	.65
2 *N*	$MgCl_2 + NaCl$	16.36	.27
1 *N*	$MgCl_2 + NaCl$	14.51	.51
9 *N*	$MgCl_2 + LiCl$	5.39	.30
5 *N*	$MgCl_2 + LiCl$	5.28	.11
2 *N*	$CdSO_4 + MgSO_4$	3.34	.03
4 *N*	$CdSO_4 + MgSO_4$	0.57	.14

for several mixtures of cadmium and zinc halides with the corresponding potassium salt, the equivalent conductivity is smaller than the contribution deduced from the mixture rule for the potassium salt alone.

Summary

1. Specific and equivalent conductivities of eight groups of binary mixtures of 2-1, 2-2 and 1-1 electrolytes with a common anion have been measured at total equivalent concentrations ranging from 0.5 to 9 *N*.

2. It is pointed out that there is a marked parallelism between the difference of the conductivities of the pure salts and the maximum departure from the mixture rule observed with the mixtures of the same total concentration.

Solubility. XV. The Solubility of Liquid and Solid Stannic Iodide in Silicon Tetrachloride

BY J. H. HILDEBRAND AND G. R. NEGISHI

Stannic iodide and silicon tetrachloride differ considerably in molecular size and very greatly in internal pressure or molecular field strength, so much so, indeed, that not only is the solubility of solid stannic iodide at 25° only 3% of the ideal solubility, but also in the liquid state they form two liquid phases below 140°. This system is particularly adapted to an investigation of the critical mixing phenomenon in its simplest aspects, because it is free from the complications introduced by the presence of electric dipoles or hydrogen bonds such as are present in most known cases of incomplete liquid miscibility. We have turned to it, therefore, in an effort to throw light upon the question of the extent to which the randomness of thermal mixing is affected by the tendency toward molecular clustering due to differences in the strength of intermolecular forces.[1]

The substances were prepared and purified by methods previously described.[2] The solubility of solid stannic iodide from 0 to 40° was determined by analysis of a solution saturated by shaking in a thermostat, as in earlier investigations in this Laboratory. The bulb containing a sample of saturated solution was placed, for analysis, in a thick-walled glass-stoppered 750-cc. flask containing 100 to 150 cc. of water. The air was displaced by carbon dioxide to prevent oxidation of iodide ion. The bulb was then broken and the flask shaken till the reaction was complete. The contents were transferred to a 500-cc. separatory funnel, about 25 cc. of carbon tetrachloride and a little concentrated tartaric acid solution added and the iodide ion oxidized to iodine by permanganate.[3] The iodine was extracted, separated and titrated with thiosulfate. The method proved rapid, simple and accurate. Three determinations of solubility were made at each temperature, 0.2, 25 and 40°, and the largest deviation from the mean was 0.5%.

The determinations at higher temperatures were made by the "synthetic method." The stannic iodide was introduced into each tube in a dry box, the air in the tube displaced by strongly dried and purified nitrogen and the stannic iodide melted into a single mass. The tube was then evacuated and a capillary seal broken, permitting the distillation of silicon chloride into it, after which it was sealed. The tube was weighed, both empty and after each substance had been added.

The solution temperature for each tube was determined in an oil-bath contained in a one-gallon (4-liter) unsilvered Dewar flask and heated electrically. Near the solution temperature the rate of heating was slow, 0.01° or less per

minute. The solution temperature of solid stannic iodide could be determined only with rising temperature, since supercooling occurred with falling temperature. When the stannic iodide was liquid, however, the consolute temperature was determined going in both directions, the observations agreeing within 0.05°.

The results are given in Table I.

The figures for the liquid–liquid portion are plotted in Fig. 1. We read the critical solution temperature and composition from this curve as 139.9° and 39 mole per cent. of stannic iodide. The results for both solid and liquid are plotted in Fig. 2 in the form of the logarithm of the mole fraction of stannic iodide against the reciprocal of the absolute temperature, as has been customary in reporting the data obtained in this Laboratory on the solubility of solids.

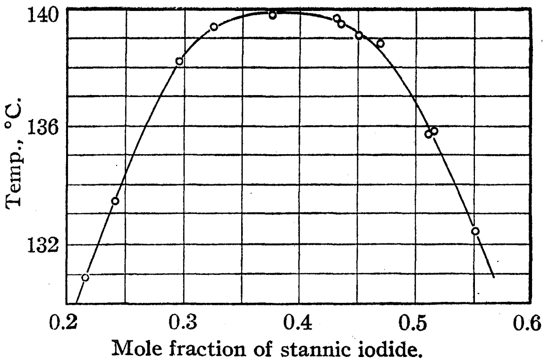

Fig. 1.—Solubility in the liquid–liquid system.

We will now examine the correlation between the curves for solid and liquid stannic iodide by applying the approximate equation[4]

$$RT \ln \frac{a_2}{N_2} = V_2\, \vartheta_1^2\, D_1^2 \qquad (1)$$

where a denotes activity in terms of the pure liquid; N, mole fraction; V, molal volume of the pure liquid; ϑ, the volume fraction of one component; and D the difference between square roots of the energy of vaporization per cc. of the pure components. The subscript 2 we shall take as referring to stannic iodide and the subscript 1 to silicon chloride. When the solution is in equilibrium with solid stannic iodide we can write $a_2 = N_2^i$, the ideal solubility, calculated from its melting point and heat of fusion by the equation

$$\log \frac{1}{N_2^i} = \frac{\Delta H}{2.303R}\,\frac{T_m - T}{T_m T} - \frac{\Delta C_p}{2.303R}\,\frac{T_m - T}{T} + \frac{\Delta C_p}{R} \log \frac{T_m}{T} \qquad (2)$$

where ΔH is the heat of fusion at the melting point, T_m, and ΔC_p is the excess of the molal heat capacity of the liquid over that of the solid. We shall use the recent values obtained in this Laboratory by the junior author,[2] *i. e.*, ΔH = 4600 cal. and ΔC_p = 5.7 cal. per degree. The melting point is 144.5°. The curve in Fig. 2 marked "ideal" has been obtained in this way.

To apply equation 1 we must know also the molal volumes of both components in the liquid form; the equation neglects any change of volume that may occur on mixing. The values for stannic iodide are extrapolated from the observations of Dorfman[5] obtained in the range, 144.5 to 275°.

For silicon chloride we use the equation of Pierre,[6] $v/v_0 = 1 + 0.001294t + 0.0_5 2184t^2 + 0.0_7 4086t^3$, obtained over the range −32 to +59°. This gives values differing appreciably from those of Thorpe, but agrees excellently with a single value reported by Mendelejeff[7] at 99.9°. Our

higher temperatures involve, unfortunately, an extrapolation of this formula, but since other errors involved in the use of equation 1 cannot be avoided until a great deal more is known about the system we must be content with the following approximate analysis which, nevertheless, permits significant conclusions to be drawn.

Table II contains the values of N_2, N_2^i, V_1, V_2 and ϑ_1 used in calculating D^2, given in the last column, from equation 1.

The values for the liquid–liquid system are calculated by putting $a_2 = a_2'$ and $a_1 = a_1'$, where the unprimed letters denote the activity in one saturated liquid phase and the primed letters in the other. Writing equation 1 for both liquid phases and for both components (interchanging subscripts) yields the equation

$$RT \ln (N_2'/N_2) = V_2(\vartheta_1^2 - \vartheta_1'^2)D^2 \qquad (3)$$

and its symmetrical counterpart. This equation becomes indeterminate at the critical solution temperature, where we must use the equation[4] (p. 144)

$$RT_c(N_1V_1 + N_2V_2) = 2V_1V_2\vartheta_1\vartheta_2D^2$$

The values of D^2 so calculated are plotted against temperature in Fig. 3. It is evident that the gradual drop in D^2 becomes suddenly accentuated in the immediate neighborhood of the critical point, so that this accentuation may be regarded as a measure of the failure of equation 1 to take into account the clustering which, according to all theoretical and experimental criteria that we possess,[8] appears rather sharply in the neighborhood of the critical point, and falls off rapidly on departing therefrom either in temperature or composition. If the rate of drop of D^2 found for the solid curve were continued right up to the critical point, we would get about 11.9 instead of 10.6, and if we reversed the calculation, using 11.9 to calculate the critical temperature, we would miss it by the amount shown by the dotted curve in Fig. 2.

Although it will be desirable to make a study of the effect of volume changes and structure in the critical region before attempting a more rigid analysis, the above figures serve to show fairly well the inaccuracy caused by neglect of clustering in this region. We hope to carry out an X-ray determination of the structure of these solutions; meanwhile the attention of students of the problem by the methods of statistical mechanics is invited to this system.

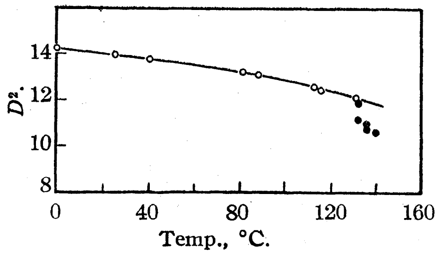

Fig. 3.—Effect of temperature on deviations for stannic iodide solutions in silicon chloride: ○, solid, ●, liquid.

Summary

Solubilities in the system silicon chloride–stannic iodide have been determined from 0 to 140°, including the range of both solid and liquid stannic iodide up to the critical solution temperatures.

This system is "regular" and free from effects of unsymmetrical molecular fields, hence is exceptionally well suited to estimate the effect of clustering in the critical region in causing deviations from the equations for regular solutions which have been derived with neglect of this effect. The error involved is about 10% in the absolute critical temperature.

The Effect of Departure from Spherical Shape on the Viscosity Caused by Colloidal Particles and Large Molecules[1]

BY JAMES W. MCBAIN AND M. E. LAING MCBAIN

The object of the following note is to point out that accepted hydrodynamic theory applicable to colloidal particles and macromolecules does not predict a very great increase in viscosity caused by extreme departure from spherical shape. Einstein[2] is responsible for the formulas commonly employed for Brownian motion, viscosity, and diffusion of colloidal particles. He obtained these by applying the ordinary formulas for hydrodynamics, assuming that the particles were spherical and large as compared with a molecule of water, that they were uncharged, that there was no slip between them and the water with which they were actually in contact (that is, the water adhered to their surface), and, finally, that turbulence was avoided. He did not hesitate to apply his calculations to molecules of sucrose in water, relating the viscosity and diffusion with the Avogadro number which he thus deduced as being equal to 6.56×10^{23}. By this procedure he obtained the well-known formula for relative viscosity $\eta_r = 1 + 2.5v$, where the viscosity, η_r, is referred to that of the solvent, $\eta_0 = 1$, and where v is the fraction of the total volume occupied by the dispersed phase.

Notoriously, the viscosity of many dilute colloidal sols is enormously greater than that so predicted by Einstein; for example, a 0.1% solution of nitrocotton may have[3] a relative viscosity equal to 1.500, that is, an increase above the solvent equal to 0.500. This increase is many hundred times greater than the value between 0.001 and 0.002 predicted from the Einstein theory for spheres (nitrocotton being much denser than acetone).

Four explanations have from time to time been put forward. First, hydration has been postulated to raise the volume to the required value. At the present time few would care to suggest solvation (additional to, or differing from, Einstein's adherent water, but not including enclosed or enmeshed solvent) to an amount greater than one weight of solvent to one of particle. Hence this explanation can account for only one or two per cent. of the observed excess. Second, the electro-viscous effect of Smoluchowski[4] is here negligible. Third, the structural viscosity advocated by many authors[5] as the method of producing the highest apparent viscosity with the least amount of material is universally accepted for many colloids such as soap. The reasoning and data to be presented indicate that here also it is the chief operative factor.

It will be noted that according to the Einstein formula mere aggregation of molecules or colloidal particles to form larger compact massive particles or micelles has no effect upon the viscosity. To produce an effect it is necessary that the aggregation should be loose and ramifying, the molecules or particles tending to stick at points where they touch, forming an incipient "brush-heap" structure such as is now ascribed to jellies, enclosing and enmeshing tracts of free solvent.

Finally, as a result of his extensive and important work upon long chain polymers or macromolecules, Staudinger has suggested that in certain cases, such as cellulose and its derivatives, as in the case here cited, enhanced viscosity may be ascribed to the extreme elongation of the molecule. In a 0.1% solution the molecules are regarded as completely independent, although of course structural viscosity is recognized in much more concentrated solutions.

Since this hypothesis did not appear to be accessible to direct experiment, the coefficient relating viscosity to molecular elongation was obtained by empirical extrapolation from substances of lower measurable molecular weight. It has been overlooked that this calculation and extrapolation must include any tendency toward association or agglomeration, a tendency which, as is most strikingly shown in the homologous series of the soaps and the sulfonates, rapidly increases with increase in molecular weight.

This note points out the maximum possible effect that can be ascribed to elongation in increas-

ing frictional resistance to movement even when the molecule remains rigidly straight. The most extreme case so far suggested has been a long chain of glucose residues of "molecular weight" about 500,000 and with length about 5000 times the mean radius. For all other cases the effect must be less. The effect must be exhibited equally in all kinds of movement of the particles where turbulence is avoided.

The hydrodynamic formulas have been discussed by Overbeck, Lamb and Allen,[6] and are developed by Gans[7] in approximate form as follows.

The resistance to movement of a sphere is $W = 6\pi\eta\, av$. A very elongated ellipsoid is a fair model of a macromolecule or rod. For an ellipsoid of revolution, where the long semi-axis is a, the same as that of the sphere, and the other two very much smaller semi-axes, b and c, are equal, the resistance to movement is then δ times less. For the rod moving lengthwise, as when it falls in a vertical position, $\delta_a = \frac{3}{4}\left(2 \log_e \frac{2a}{c} - 1\right)$. For the rod moving broadside on, as when a horizontal fiber falls

$$\delta_c = \frac{3}{8}\left(2 \log_e \frac{2a}{c} + 1\right)$$

The terminal velocity of a falling sphere (Lamb[6]) is $\frac{2}{9} \times \frac{a^2g(s - s')}{\eta_0}$, and that of the ellipsoid $\frac{2}{9} + \frac{c^2g(s - s')}{\eta_0} \cdot \delta$, where g is the gravitational constant, $s - s'$ the difference in the density of the falling particle and the liquid, and η_0 is the viscosity of the latter. It is now easy to show that for a sphere and an ellipsoid of the same volume the ratio of their velocities is $\left(\frac{a}{c}\right)^{2/3} \times \frac{1}{\delta}$ where δ however still refers to the sphere whose diameter is equal to the length of the ellipsoid. The ratio of the two resistances to movement has this same value.

Therefore for the extreme example where $c/a = 1/2500$, and δ_a equals 12.03 and $\delta_c = 6.76$, a sphere of given weight will fall 15.3 times faster than the ellipsoid falling end on, and 27.2 times faster than the ellipsoid falling sidewise, with the intermediate positions having intermediate values. There will be no rotation of the ellipsoid as it falls,[6,7] and its deflection from the vertical fall cannot exceed 19°28′ as a maximum.[8]

Taking an average effect, for this extreme case, the frictional resistance will be only about 21-fold that of the sphere, whereas for 0.1% nitrocotton we have to explain an increase in specific viscosity of between 250- and 500-fold.

For $a/c = 100$, $\delta_a = 7.197$ and $\delta_c = 4.349$, and the sphere falls only 2.99 and 4.95 times faster than the elongated ellipsoid. For $a/c = 10$, $\delta_a = 3.744$, and $\delta_c = 2.622$, and the sphere falls 1.24 and 1.77 times faster than the elongated ellipsoid.

Hence Staudinger is correct in pointing out an influence of extreme elongation, but it is a very minor effect in comparison with viscosity increments observed. We therefore conclude that 94% or more of the total observed excess viscosity has a structural basis, whose influence is of a higher order of magnitude than that of any of the other three suggested factors.[9]

Since Lamb[6] pointed out that for purely viscous movement to be maintained, the quantity vas/η must be small compared to unity, he stated that for a silica sphere falling in water the diameter has to be small compared to 0.114 mm. Hence Stokes' law and these relations apply only to much smaller particles, which are not readily subjected to experimental study. We have attempted to overcome this difficulty by employing instead of water 60% sucrose solution, whose viscosity is 56.2-fold greater at 20°.

Our procedure was to let thin silica fibers fall through water and the sucrose solution in a vertical and in a horizontal position and also in intermediate positions. Afterward the same fibers were fused into spherical form and then time of fall was again observed. The fibers fell in water always without change in orientation, but usually failed to do so in the sucrose solution. Likewise the difference in rate between fiber and sphere was less than that calculated. Part of this was found to be due to volatilization of the silica during fusion. Also each "sphere" had a thickened tail which could not be completely removed. Hence the spheres were compared with fibers of the same

(8) For recent discussions of the hydrodynamic equations where rotation is involved and experiments in which orientation and interference between rod-like particles (structural viscosity) occur, see for example Guth, *Kolloid-Z.*, **75**, 15 (1936); Eirich, Margaretha and Bunzl, *ibid.*, 20 (1936). See also Gans, *Ann. Phys.*, [4] **86**, 652 (1928); and Jeffrey, *Proc. Roy. Soc.* (London), **A102**, 176 (1923).

(9) In a private communication Dr. S. S. Kistler adds the information, confirmatory of the present conclusion, that owing to the difference in behavior of a sphere and of a cylinder (Lamb, *Phil. Mag.*, **21**, 112 (1911)) with regard to very low Reynolds numbers, the force acting upon a cylinder of the same volume as a sphere will not be much larger than that on the sphere.

weight, 59.7 mm. long where the ratio of length to diameter was only 1933 instead of 2500. The diameter of the fibers was 0.040 mm., that of the spheres 0.485 mm.; probably they were all still too coarse for the requirements of the formula, but the results are of interest as approximately illustrative of the general formulas.

Vertical fibers fell 17.7 cm. through sucrose solution in 901 and 949 seconds, respectively, whereas the spheres required a minimum of 84 sec. The value calculated for the sphere from Stokes' formula was 68.9 sec. The ratio between the fibers and the theoretical value for the sphere was 13.07 and 13.77, mean 13.4, whereas the theoretical ratio predicted was 13.3, and the actual ratio found was not larger than 11. In water, typical experiments gave a ratio between that observed for a vertical fiber and that calculated for a sphere the same weight equal to 14.3 as compared with the predicted value 15.3.

The effect of elongation is even less under conditions where turbulence is prominent in the observation of rate of fall. For the silica fibers and spheres falling through water the observed effect was only between 4-fold for vertical and 8-fold for horizontal fall. In dropping $^3/_8''$ (9.5 mm.) steel balls through still water and comparing them with the same weight of steel wire (0.0243″ (0.61 mm.) in diameter) whose length was again 5000 times its radius, the relative rates varied only between 1.6 for vertical and 4.5 for horizontal. Hence, in viscosity measurements the effect of elongation is even less when turbulence is not eliminated.

Summary

From observations on the actual effect on resistance to movement when a sphere is elongated to a fiber 2500 longer than its diameter, it is concluded in accordance with the hydrodynamic theory employed by Einstein for colloidal particles and large molecules that although the effect of extreme departure from sphericity is measurable it is of too low a magnitude to explain the high viscosity which 0.1% of certain colloids, such as nitrocotton, impart to solvents in which they are dissolved. It is therefore concluded that the chief factor is structural viscosity due to entanglement and local adherence of molecules and particles, effectively immobilizing a disproportionate amount of the solvent in comparison with the amount of the colloid itself.

An X-Ray Study of Some Linear Polyesters

BY C. S. FULLER AND C. L. ERICKSON

By means of intermolecular polycondensation reactions Carothers and his co-workers[1] have been able to synthesize linear polyesters of high molecular weight from dihydric alcohols and dibasic aliphatic acids. Carothers and Hill[2] have pointed out the surprising fiber-like characteristics which can be obtained in certain of these polyesters when the molecular weights are sufficiently high (superpolyesters). They have also demonstrated that the polyesters in massive form are microcrystalline, furnishing sharp X-ray powder diagrams, while in the oriented state (cold-drawn fibers) they are capable of giving fiber patterns. Up to this time, however, no attempt apparently has been made to verify the chemical structures which have been proposed for these compounds by means of a study of their X-ray fiber patterns.[3] The X-ray structure of synthetic fibers of known chemical constitution is also of considerable interest since it offers a means of confirming present conceptions in regard to high polymeric substances.

In the present investigation a series of polyesters has been prepared and examined by means of X-rays. Six of these have been carried to the superpolyester state so that highly oriented fiber patterns could be obtained from them. It is the purpose of this investigation to present and discuss the results of the measurement of these fiber patterns.

Materials and Method

Since many polyesters do not crystallize, or do so very slowly, the number which is suitable for X-ray study is somewhat limited. Table I lists the materials which have been investigated together with the approximate molecular

(3) A. W. Kenney (ref. 2) has found that the fiber period of some polyesters approximates the length of the chemical repeating unit.

weights,[4] the melting[5] or softening points, densities and drawing properties of each. The preparation and other properties of these materials are described in the experimental part of this paper.

For the purpose of obtaining the X-ray diagrams the substances were examined in the form of bars (for the Debye–Scherrer photographs) 0.4 mm. thick, 1.0 mm. wide and about 15 mm. long or in the form of cylindrical fiber bundles (for the fiber diagrams) 0.5 to 1.0 mm. in diameter. The fibers were prepared by cooling the molten polyesters into solid rods of suitable sizes and cold drawing these so as to form well oriented fibers. These were then wound under tension on U-shaped holders so as to form bundles of parallel fibers. The fiber bundles were fixed in a perpendicular position to the X-ray beam which was collimated to a diameter approximately equal to that of the sample.

The X-ray cameras employed were similar in construction to those described by J. R. Katz.[6] Except in the case of very weak or diffuse reflections the precision of measurement of the X-ray reflections was approximately 1% on check photographs of the same material.

The source of X-rays was a Philips Metalix X-ray tube which was operated at 13 ma. and approximately 25 kv. A copper target was employed and the resulting K-alpha radiation (1.539 Å.) separated from the K-beta by means of a nickel filter 0.015 mm. thick. The maximum due to the white radiation, which occurred at approximately 0.8 Å., was observed near the primary beam in nearly all cases but it is not believed that the effects due to it have been confused with the monochromatic reflections from the samples. Exposure times varied between four and six hours.

Results

Debye–Scherrer photographs of samples of polyethylene sebacate representing bands of progressively increasing average molecular weight (1–4, Table I) showed the same interplanar spacings within the precision of measurement in all cases. The relative intensity (visual) of corresponding rings was also found to be the same on all photographs. The interplanar distances determined from these photographs agreed with those determined from the fiber pattern of polysebacate.

Highly oriented fiber diagrams were obtained from polyethylene succinate, polyethylene adipate, polyethylene azelate and polyethylene sebacate. The fibers drawn from polytrimethylene sebacate and polydiethyleneoxide sebacate yielded less well defined photographs. In all cases an uniaxial type of crystallite orientation is present. Several attempts to produce a higher degree of orientation[7] (folienstruktur) by rolling the polyethylene sebacate ester into thin films showed that no further orientation of the crystallites occurred, since the same fiber diagram was obtained when the film was exposed parallel and perpendicular to the film plane. Further efforts to secure such samples of higher orientation are being made. In Fig. 1, (a) to (f) are schematic drawings of the fiber patterns obtained from the six polyesters.

TABLE I

PROPERTIES OF THE POLYESTERS

		Average mol. wt.	Softening point, °C.	Density (25°C.)	Cold-drawing properties
		Debye–Scherrer photographs			
1	P-ethylene sebacate	4,000	69	. . .	Does not draw
2	P-ethylene sebacate	13,000	69–70	. . .	Does not draw
3	P-ethylene sebacate	15,000	68–71	. . .	Draws well
4	P-ethylene sebacate	18,000	70–74	1.148	Draws well
		Fiber patterns			
5	P-ethylene succinate	13,000	104–106	1.358	Draws well
6	P-ethylene adipate	12,000	52–54	1.250	Draws well
7	P-ethylene azelate	10,000	44–46	1.172	Draws well
8	P-ethylene sebacate (same as 4)	18,000	70–74	1.148	Draws well
9	P-trimethylene sebacate	13,000	54–55	1.090	Draws well (cold)
10	P-diethylene oxide sebacate	18,000	36.5–39	1.128	Draws well (cold)

In the case of each of the polyesters the identity periods along the fiber axis have been calculated from averaged measurements of the reflections obtained from at least two and generally three independent exposures. The interplanar distances, identity periods along the fiber axes and relative intensities of the reflections for the six polyesters listed in Table I, 5–10 are recorded in Table II. The average values of the fiber periods are collected in the second column of Table IV. In the case of polyethylene azelate, polytrimethylene sebacate and polydiethyleneoxide sebacate several values for the fiber periods are possible because of

---

(4) No great significance can be attached to the molecular weight values in Table I since in every case mixtures of polymers are present. The values here given were obtained by the use of Staudinger's viscosity method ("Die hochmolekulären organischen Verbindungen"). The constant ($y = 1.5 \times 10^{-3}$) given by Staudinger and Schwalenstöcker (ref. 20) for aliphatic glycol esters in chloroform solution has been employed.

(5) As W. H. Carothers and J. A. Arvin, THIS JOURNAL, **51**, 2560 (1929), have pointed out the melting points are not sharp.

missing spectra. A consideration of the chemical structures, however, together with the probable lengths of the radicals involved, leads in each case to a choice of the value given as the true one.

For polyethylene azelate it appears from these considerations that only every third layer-line is present up to the sixth layer-line. In the case of polytrimethylene sebacate the first six layer-lines prove to be missing and in the case of polydiethyleneoxide sebacate the layer-lines 1, 2, 3, 5, 6, 7 are absent or very weak.

Strong diatropic planes occur in the normal fiber diagram for polyethylene azelate (Fig. 1 (c)), indicating the presence of a two-fold screw axis of symmetry parallel to the fiber axis. Polytrimethylene sebacate and polydiethyleneoxide se-

bacate also show strong reflections on the meridian line which appear to arise from planes parallel to (001). Diatropic planes for the other esters were sought by exposures in which the primary beam formed various acute angles with the fiber axes (Schiefeaufnahme). In this way a definite diatropic plane was found on the second layer-line of the polyethylene succinate diagram indicating the presence of a two-fold screw axis. No strong diatropic planes were observed for polyethylene sebacate or polyethylene adipate. However, weak reflections appear to exist on the seventh and fifth layer-lines of these esters, respectively. Calculations of the fiber periods from the diatropic planes agree well with those made in the usual manner by the application of the Polanyi equation.[8]

The limitations of the fiber diagram in furnishing further crystallographic information other than the identity period along the fiber axis have often been pointed out.[9] There are, however, certain observations which can be made on these diagrams which are of value, especially when chemically related substances of known constitution are under consideration. In addition, in cases where the diagrams are rich in reflections and in which the reflections are sharp enough to allow accurate measurements of the spacings to be obtained, the method, based on the use of the reciprocal lattice, described by Sauter,[10] offers a means of indexing the reflections and arriving at a plausible determination of the unit cell. These solutions are, of course, not necessarily unique[11] but they serve the purpose of furnishing a basis for further crystallographic study.

This method has been applied to each of the fiber diagrams represented in Fig. 1 (a) – (f) with the results summarized in Table III.

A comparison of the fiber diagrams of the six polyesters (Fig. 1) shows immediately that the crystal structure of polyethylene adipate, azelate and sebacate are very similar to one another and different from the other esters. For example, the equatorial spacings prove to be almost identical within the limit of experimental error and the arrangement and intensity of the layer-line reflections is analogous in all three cases.[12] There can be little doubt therefore that these esters possess

(11) For example the reflections of the ethylene adipate, azelate and sebacate esters in Table II agree almost as well, with orthorhombic units cells of cross-section: a = 21.8 Å., b = 33.3 Å., and c-axes equal to the corresponding fiber periods as with the monoclinic cells proposed in Table III.

(12) Two additional weak equatorial reflections occur in the case of the azelate. These, however, may be due to errors in observation or to planes too weakly reflecting to be observed in the other esters.

unit cells of the same dimensions in the plane at right angles to the fiber axis and belong to the same crystal system. That this is the case is confirmed by a calculation of the number of chain molecules (number of X-ray repeating units) passing through the unit cell in each case from the formula

$$Z = Vd/1.65\,M \qquad (1)$$

where V, d and M are the volume of the unit cell, the density (Table I) and the molecular weight of the repeating unit, respectively. The values of Z

[1] Fiber period.

are given in Table III and for the esters in question are identical within the limit of error.

There is likewise a close similarity between the fiber diagrams obtained for polytrimethylene sebacate and polydiethyleneoxide sebacate. In these cases, although the equatorial spacings are not identical, the fact that one side spacing, different in each case, occurs in several orders makes a tetragonal form of unit cell probable.

Discussion

Crystal Lattice of the Polyesters.—Carothers[13] has suggested that the linear polyesters may have a macromolecular type of crystal lattice[14] in which molecules of various lengths crystallize together. Since the reflections corresponding to the lengths of even the smallest polymers of these compounds would fall very close to the central beam, the identity of the Debye–Scherrer photographs (1–4, Table I) does not constitute proof that such a lattice does or does not exist.[15] In whatever manner in which the individual molecules are grouped in the crystal lattice, however, the existence of well-defined fiber diagrams shows that the microcrystals are arranged with an important crystallographic axis parallel to the direction of the fiber axis and that all degrees of rotation around this axis exist. Furthermore, the observation of meridian reflections (from planes perpendicular to the fiber axis) requires the presence of crystal systems of symmetry higher than the triclinic and also that the orthogonal monoclinic axis is parallel to the fiber axis. The molecules in the polyesters therefore should be arranged in the crystals with their long axes parallel to the fiber direction.

The determination of the exact arrangement of the long chain molecules in the unit cells with regard to axial orientation and displacement lengthwise relative to one another is much too complex a problem to be solved on the basis of the existing data. The relatively large number of chains involved in the unit cells suggests that the positions with respect to one another are determined by the interaction of the polar carbonyl groups along the chains in such a way that identity is established only after the association of a considerable number of chains. It should be emphasized again that the unit cells which have been given above as a result of the application of the reciprocal lattice method are not necessarily the true ones since they are based on the data provided by fiber patterns alone. It is believed, however, that the lengths of the axes found for these cells as given in Table III at least set a lower limit to the size since it is not possible to secure satisfactory agreement with the observed reflections if smaller values are assumed.

Chain Configurations of the Polyesters.—Lycan and Adams[16] and Carothers and Arvin[5] have postulated a long chain structure for the polyesters. As in the case of most reactions leading to high polymers, chain molecules of various lengths are formed.[17] The X-ray studies of Müller[18] and others on the paraffins and aliphatic acids have established the fact that planar zig-zag chains of carbon atoms joined at the tetrahedral angle are present. The recent work of Sutton and Brockway[19] has shown that the tetrahedral angle is observed (within a few degrees) for oxygen in ethereal linkage. These authors have also determined accurately the length of the C–O bond as 1.43 Å. These data, together with the known C–C bond distance of 1.54 Å., enable the calculation of the lengths of the chemical repeating units of the polyesters on the assumption that planar zig-zag chains are present.

The results of these calculations are given in the third column of Table IV. The fourth column of this table records the difference between the observed and calculated periods referred to the chemical repeating unit. It is noted immediately that in the case of the esters having an odd number of chain atoms (3, 5 and 6, Table IV) the length of the chemical repeating unit is approximately one-half the observed fiber period. Since this occurs for the polyethylene azelate in which the acid is odd and in the polytrimethylene sebacate and polydiethyleneoxide sebacate in which the glycols are odd and does not occur for the even esters, the presence of a zig-zag chain is indicated. However, the difference between the observed and calculated lengths of the chemical repeating units (column 4, Table IV) is in all cases too large to be accounted for by experimental error. We must conclude, therefore, that the chains are

either planar but not zig-zag or that they are non-planar. Since it has not been possible to obtain satisfactory agreement with the observed fiber periods on the basis of any planar arrangement of atoms, it is believed that the polyesters have non-planar chain configurations.

TABLE IV

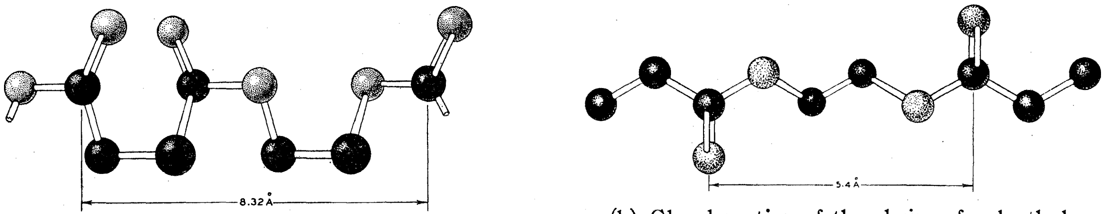
COMPARISON OF OBSERVED AND CALCULATED FIBER PERIODS (ÅNGSTRÖM UNITS)

	Polyester	Obsd. fiber period	Calcd. chem. rep. unit	Difference based on chem. rep. unit
1	P-ethylene succinate	8.32 ± 0.06	9.70	1.4
2	P-ethylene adipate	11.71 ± .07	12.21	0.5
3	P-ethylene azelate	31.2 ± .2	16.0	.4
4	P-ethylene sebacate	16.67 ± .06	17.24	.5
5	P-trimethylene sebacate	33.5 ± .3	18.5	1.7
6	P-diethyleneoxide sebacate	38.0 ± .3	20.8	1.8

This is particularly the case with polyethylene succinate, in which the observed fiber period of 8.32 Å. can be produced only by a helical arrangement of the chain atoms. The close analogy to the polymethyleneoxides and polyethyleneoxides described by Sauter[16] is particularly striking, and suggests that the spiral structure is derived from the cis or "tub" form of chain rather than from the zig-zag form. Figure 2 (a) illustrates this type of chain.

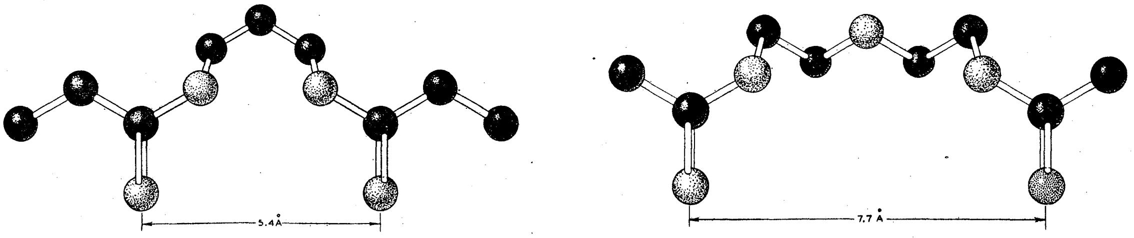
The equality of the differences observed in Table IV for the ethylene glycol esters of adipic, azelaic and sebacic acids is again in agreement with the identities in the dimensions of the unit cells mentioned above, and suggests that these esters have the same chain configuration and depart only slightly from the plane zig-zag arrangement of chain atoms. The constancy of the deviation (*ca.* 0.5 Å.) indicates that any shortening of the chains occurs in the ethylene glycol portion since the acid portions of the chains are of varying lengths. Figure 2 (b) shows how a shortening of the planar zig-zag chain may arise through a displacement of the chain oxygen atoms toward one another. This motion of the oxygen atoms results in forcing the carbon atoms between them out of the plane of the chain.

The last two esters, polytrimethylene sebacate and polydiethyleneoxide sebacate, in Table IV likewise show deviations from the planar zig-zag form. A number of configurations which agree with the observations is possible in these cases. It might be assumed that since the sebacic acid radical in polyethylene sebacate appears planar, this structure would be retained in its other esters. If this assumption is made the shortening can be accounted for in the glycol radical. Figure 2 (c) and (d) indicate (schematically) glycol configurations for these esters which produce the desired agreement.



(a) Chain atoms of polyethylene succinate.

(b) Glycol portion of the chains of polyethylene adipate, polyethylene azelate and polyethylene sebacate.



(c) Glycol portion of the chain of polytrimethylene sebacate.

(d) Glycol portion of the chain of polydiethyleneoxide sebacate.

Fig. 2.—Chain configurations of the polyesters which reproduce the observed spacings. Dark balls represent carbon and light balls represent oxygen atoms.

Staudinger and Schwalenstöcker[20] on the basis of viscosity studies report that ethylene glycol esters in solution have an extended form of chain which is shortened because of the attraction of the "secondary valences" of the oxygen atoms. Since these authors believe their conclusions apply equally well to the solid state, it might be expected that the polyesters would behave in a similar manner with regard to the glycol configuration. The chain forms given above are in qualitative agreement with the conclusions of Staudinger and Schwalenstöcker. It therefore seems reasonable to conclude that the chain configurations assumed by the polyesters can be regarded as resulting from the attractions of atoms or dipoles attached at intervals to the chains.

Experimental Part

The polyesters were prepared by heating together dibasic acids and glycols according to a modification of the method employed by Carothers and Arvin.[5] The acid and the glycol (in the ratio of 1 to 1.05 moles) corresponding to the ester desired were placed in a distilling flask deeply immersed in a sand-bath. A slow stream of pure, dry nitrogen was bubbled through the heated mixture during the reaction. The nitrogen served the purpose of providing an inert atmosphere and of removing the water formed in the reaction. For the first few hours of reaction a condenser and receiver were attached to the flask. During this time the temperature rose from about 160 to 180° and about 75 to 90% of the theoretical amount of water distilled over. The temperature was then raised to 200 ± 10° and maintained at this point until the molecular weight required for cold drawing was obtained (forty-eight to one hundred and twenty hours). The samples of polyethylene sebacate of lower average molecular weight than that required for cold drawing were obtained by taking out samples periodically during the reaction.

The succinic (m. p. 184–186°), adipic (m. p. 151–153°) and sebacic (m. p. 129–129.5°) acids were obtained from the Eastman Kodak Company. The azelaic acid (m. p. 106°) was prepared from castor oil by oxidation of the ricinoleic acid by means of potassium permanganate.[21] The glycols employed for the preparation of the esters were obtained by distilling the purest compounds that could be obtained commercially. In each case the middle portion was selected. The ethylene glycol was distilled at atmospheric pressure (b. p. 195–195.5°), the trimethylene glycol and diethyleneoxide glycol were distilled under reduced pressure.

The polyesters prepared as above showed the following values of carbon and hydrogen on ultimate analysis as compared with theoretical. Polyethylene succinate—found, 50.03% C, 5.93% H; calcd., 49.98% C, 5.59% H. Polyethylene adipate—found, 55.85% C, 6.67% H; calcd., 55.78% C, 7.03% H. Polyethylene azelate—found, 61.75% C, 8.41% H; calcd., 61.64% C, 8.47% H. Polyethylene sebacate—found, 63.71% C, 8.41% H; calcd., 63.11% C, 8.84% H. Polytrimethylene sebacate—found, 64.97% C, 8.93% H; calcd., 64.41% C, 9.16% H. Polydiethyleneoxide sebacate—found, 62.31% C, 8.83% H; calcd., 61.72% C, 8.89% H. These were considered sufficiently pure for the X-ray work. Small portions of the polyesters were purified by solution in chloroform and precipitation with petroleum ether for the determination of the densities and the softening points.

Summary

1. Debye–Scherrer photographs of polyethylene sebacates of increasing average molecular weight are identical and show the same interplanar spacings as the fiber diagrams of the oriented materials.

2. Fiber diagrams of six highly oriented polyesters show that in the oriented state the chain molecules are parallel to the axes of the fibers. A comparison of the observed fiber periods with the lengths of the chemical repeating units calculated on the basis of a planar zig-zag chain shows that polyethylene succinate possesses a helical arrangement of the chain atoms whereas polyethylene adipate, polyethylene azelate and polyethylene sebacate have similar configurations which deviate only slightly from the planar zig-zag form. The sebacate polyesters of trimethylene glycol and diethyleneoxide glycol also conform best to a configuration in which the chain atoms are nonplanar. The deviations of the configurations from the planar zig-zag type of chain are attributed to attractive forces residing in the ester groups.

3. The data obtained from the fiber patterns have been treated graphically and solutions for the unit cells found which agree in all cases with the observed interplanar spacings.

Studies in Proteins. VI. The Solubility of the Nitrogenous Constituents of Certain Seeds in Sodium Chloride Solutions

BY L. P. O'HARA AND FELIX SAUNDERS

Introduction

These studies were undertaken principally in the hope that a more precise and explicit definition of globulins might be proposed. At present no two writers of textbooks on biochemistry define globulins in the same way. For example: Globulins are "soluble in dilute solutions of neutral salts, not soluble, however, in concentrated solutions; precipitated by half-saturated ammonium sulfate" (Williams)[1]; "simple proteins insoluble in pure water but soluble in neutral solutions of salts of strong bases with strong acids" (Bodansky)[2]; "insoluble in water, but soluble in neutral dilute solutions of salts of strong bases and acids, such as sodium chloride" (Mathews).[3] According to the "Joint Recommendation of the Physiological and Biological Committees on Protein Nomenclature"[4] globulins should be defined as "simple proteins insoluble in pure water but soluble in neutral solutions of salts of strong bases with strong acids." Gortner[5] has questioned the validity of these definitions. He says, "a definition which is based upon solubility, *i.e.*, peptization in a dilute salt solution, is so ambiguous as to be absolutely meaningless."

In the preceding papers of this series the following facts have been brought out. (1) As would be expected from the usual definitions of globulins, normal alkali halide salts extract from orange-seed meal the same amount of protein (pomelin) and nitrogenous material.[6] (2) Normal solutions of various sodium salts, some neutral and some alkaline, extract the same amount of nitrogenous material, presumably protein, from orange-seed meal.[7] The present work was undertaken in order to determine how much nitrogenous material is extracted by different concentrations of sodium chloride from various seed meals so that we may test our definition of globulins on another point, that of solubility in concentrated salt solutions.

Experimental

The seeds were ground, defatted and sifted in the manner already described.[7] The orange-seed meal was 60–80 mesh, the peanut meal and the flaxseed meal were 80–100 mesh. Total nitrogen was determined for the air-dried seed meal. A weighed amount[8] of the seed meal was placed in a 250-cc. centrifuge bottle and 50 cc. of solution added. The bottles were shaken for thirty minutes in a mechanical shaker, centrifuged for twenty minutes and the supernatant liquid decanted directly into a Kjeldahl flask. The extraction was repeated two more times and the total nitrogen determined in the combined solutions by the Kjeldahl macro method.

As long as the scope of the investigation had to be limited it seemed best to select seeds representing as many different types as possible. Consequently, the following seeds were chosen: orange and flax, which yield crystalline globulins; peanut, which gives a well-defined but non-crystalline globulin; and rye, which probably does not contain any globulin. Sodium chloride was chosen because it is the salt most commonly used in protein-extraction studies.

In order to study the effect of time a series of extractions was run on flaxseed meal with 0.37 *N* sodium chloride. The time intervals for extraction were one-half, two, and four times the usual interval. The results as shown in Table I indicate that time is a negligible factor within the limits chosen for this experiment.

TABLE I

THE EFFECT OF TIME UPON THE AMOUNT OF NITROGENOUS MATERIAL EXTRACTED FROM FLAXSEED MEAL BY 0.37 *N* SODIUM CHLORIDE

Time (x = usual time interval)	Total N extracted, %
0.5x	60.77
1.0x	60.46
2.0x	59.82
4.0x	60.68

Several times, especially during the summer months, discordant results were obtained. It was finally concluded that the deviations might be due to temperature changes which are often very marked and sudden in Chicago. In order to check this hypothesis, several extractions of seed meal with 4 *N* sodium chloride were run at various temperatures. The results (Table II) clearly show a temperature coefficient. Temperature changes are probably negligible during the winter when buildings are steam heated, but during the summer temperature must be con-

trolled. After the importance of temperature variations was demonstrated, extractions were run at constant temperature.

TABLE II

EFFECT OF TEMPERATURE UPON THE AMOUNT OF NITROGENOUS SUBSTANCE EXTRACTED FROM ORANGE-SEED MEAL BY 4.0 *N* SODIUM CHLORIDE

Temperature, °C.	Total N extracted, %
39.7	48.65
26.0	41.43
−2.5	35.92

The two findings reported above were only incidental to the main problem, namely, to determine how the amount of nitrogen extracted from seed meals would vary with changes in the concentration of the extracting sodium chloride solution which ranged from 0 to saturation. The data (Table III) demonstrate clearly that (1) the most efficient extraction of nitrogenous material occurs when the concentration of the sodium chloride is between 0.25 and 3.0 *N* and (2) even a saturated sodium chloride solution will extract almost as much as a normal solution. Because of this fact, extraction with saturated sodium chloride has been made our standard procedure for the isolation of crystalline globulins, since the extracted material is less likely to be contaminated with gummy substances which interfere with further purification.[9]

TABLE III

EFFECT OF CONCENTRATION UPON THE AMOUNT OF NITROGENOUS SUBSTANCE EXTRACTED FROM VARIOUS SEED MEALS BY SODIUM CHLORIDE

Normality of NaCl soln.	Total N extracted from seed meals, %			
	Flax 3-g. sample	Orange 3-g. sample	Peanut 1.5-g. sample	Rye 5-g. sample
Distilled water	24.27	32.24	52.86	14.81
0.125	41.73	35.59	71.15	20.32
.25	58.63	51.10	91.76	32.45
.375	64.59	58.12	94.85	34.75
.50	64.50	65.54	94.55	34.13
.75	64.48	70.22	93.88	26.69
1.0	64.59	73.34	94.42	25.00
2.0	65.19	72.38	95.37	17.03
3.0	63.75	71.59	94.14	18.57
4.0	61.71	67.62	95.89	14.49
5.0	56.29	67.82	92.26	11.23
6.0	50.12	65.84	87.68	7.65
Saturated	45.53	64.92	81.23	7.65

Discussion

If we make the assumption that most of the nitrogen extracted represents protein, then the data of Table III show that in solutions of sodium chloride greater than 0.5 *N* the concentration of the sodium chloride has little effect upon the solubility of the protein. This assumption is probably justified (except in the case of rye flour) since it can be shown that as much as 90% of the total nitrogen extracted by *N* sodium chloride can be recovered as crystalline globulin (unpublished results) and, as mentioned above, crystalline globulin can be extracted from some seed meals by saturated sodium chloride solutions. The crystalline globulins obtained by extraction with either *N* or saturated sodium chloride solutions have the same crystalline form and give the same analytical figures for total sulfur, total nitrogen and nitrogen distribution.

It has also been shown[7] that *N* solutions of strong bases and weak acids such as sodium benzoate and sodium acetate will extract just as much nitrogen from orange-seed meal as will solutions of salts of strong bases and strong acids.

The data in Table III show that the proteins of rye flour, in which gliadin predominates, show a type of solubility curve entirely different from those of the other three seeds in which globulin predominates. In the case of the rye flour, which contains little or no globulin, the curve rises to a definite peak and then falls off rapidly. In the case of the globulin-containing seeds the curve rises steeply and then remains almost horizontal.

The findings reported above show that the ordinary definitions of globulins are false and misleading, at least by implication. Certainly some globulins are soluble in saturated salt solutions and they are also soluble in solutions of salts of strong bases and weak acids. A satisfactory definition of globulins must take these facts into consideration explicitly.

Several workers have questioned the advisability of basing definitions and classification of proteins on solubility. Staker and Gortner,[10] referring to an earlier paper, state, "Gortner, Hoffman and Sinclair[11] were the first to object to a system of protein classification based upon 'solubility'." These authors[11] also state, "It may be that only 'crystalline' globulins are chemical entities and that the amorphous globulin preparations recorded in the literature are non-homogeneous fractions whose chemical and physical properties depend upon the technic employed in their isolation."

It is interesting to note that McCalla and Rose,[12] working with the gliadin–glutenin system of wheat flour, have also come to the conclusion

that, "definitions of flour proteins based on solubility in a solution such as 70% alcohol are purely arbitrary." Their work has no bearing on the specific problem of the definition of globulins but is of importance in the general problem of protein classification.

Undoubtedly the solubilities of different proteins are a reflection of the kind and arrangement of their constituent amino acids. Any definition must necessarily be inadequate and empirical until more is known about the composition of proteins.

Conclusions

1. The amount of nitrogenous material extracted from certain seed meals by saturated sodium chloride solutions is almost as large as that extracted by N solutions. In those seed meals where this conclusion is true, the material which is extracted appears to consist almost wholly of a crystalline or hemi-crystalline protein having the characteristics of a globulin.

2. When a solution of given concentration is used for the extraction of nitrogenous material, a marked temperature coefficient is found.

3. The ordinary textbook definitions of globulins do not adequately consider the solubility properties of globulins.

The Mechanism of Coprecipitation of Anions by Barium Sulfate[1]

BY FRANK SCHNEIDER[2] AND WILLIAM RIEMAN, III

Five theories[3] have been advanced to account for the contamination of precipitates, *viz.*, formation of mixed crystals, occlusion, surface adsorption after the formation of the precipitate, compound formation and postprecipitation. If coprecipitation is defined as the retention of soluble substances by a precipitate, compound formation and postprecipitation cannot be regarded as true coprecipitation. Surface adsorption is important only in the cases of amorphous and flocculent precipitates. Therefore, coprecipitation by barium sulfate is due either to the formation of mixed crystals or to occlusion. By occlusion is meant the adsorption of foreign ions during the growth of the crystals of the precipitate and subsequent entrapping of these foreign ions by the growing crystals.[3]

All conditions of precipitation such as temperature, concentration, time of addition of reagents, time of digestion, etc., being the same, the amount of coprecipitated ion in a precipitate should depend upon some specific property of this ion. As stated by Paneth[4] and Fajans,[5] the occlusion theory maintains that this determining factor is the solubility of the compound formed by the coprecipitated ion and the ion of opposite charge of the precipitate. On the other hand, the mixed-crystal theory of Grimm[6] and coworkers holds that this property is the similarity in crystal structure of the precipitated and coprecipitated substances. Otto Hahn[7] was among the first to recognize that both explanations might be correct. He also stated that mixed crystals may be formed even when Grimm's[8] conditions are not fulfilled. His rules, however, are not very clear and are apparently contradictory in certain respects.

A study of the coprecipitation of various anions by barium sulfate throws considerable light upon this subject. Weiser and Sherrick[9] determined the quantity of coprecipitated anions under identical conditions of precipitation. They did not use the Paneth–Fajans rule to interpret their results and hence were somewhat at a loss to explain them. Sofin[10] repeated their work under more carefully controlled conditions. Using iodide, chloride, bromide, nitrite, nitrate and chlorate, he found that, in accord with the Paneth–Fajans rule, the lower the solubility of the barium

salt of the anion, the greater was the amount coprecipitated. The nitrite, however, was an exception. He attempted to show, without success, that the abnormally high amount of coprecipitated nitrite was due to the formation of mixed crystals of sodium nitrite and barium sulfate.

Differences between Occlusion and Mixed-Crystal Formation.—Contamination by occlusion differs from contamination by mixed-crystal formation in the following respects.

(1) As Hahn[7] has pointed out, the extent of occlusion is dependent upon the ion of the precipitate which is present in excess in the solution at the time of precipitation. If barium sulfate is precipitated by adding a sulfate to an excess of barium ion, the growing crystals are charged positively; hence they adsorb and occlude foreign anions to a greater extent than when the precipitate is formed by pouring a barium salt into an excess of sulfate ion. On the other hand, the excess of lattice ion is unimportant in the case of mixed-crystal formation; in this case the contamination is proportional to the concentration of the ion which is coprecipitated.

(2) The adsorptive forces which attract foreign ions to a growing crystal depend primarily on the solubility of the compound which these ions form with the oppositely charged lattice ions. Therefore, contamination by occlusion follows the Paneth–Fajans rule. If the adsorbed ions fit well into the crystal lattice of the precipitate, a larger portion of them is retained by the growing crystals than would otherwise be the case. Therefore, contamination by mixed-crystal formation is greater than the Paneth–Fajans rule indicates. The simple relationship between adsorption and solubility is subject to some exceptions, however. Therefore, deviations from the Paneth–Fajans rule for coprecipitation should not be interpreted as mixed-crystal formation unless the effect of excess lattice ion, the crystal size and the effect of digestion (paragraphs 1, 3 and 4, respectively) also indicate the formation of mixed crystals.

(3) It is well known that the growth of a crystal is retarded by the presence of an adsorbed layer on its surface. If the adsorbed layer can fit into the crystal lattice, however, the retardation is much less than it would be otherwise. Therefore, extensive occlusion causes a fine grained precipitate, whereas contamination by mixed-crystal formation has little effect on crystal size.

(4) Digestion is more effective in removing occluded contamination than in removing mixed-crystal contamination, because the crystals are smaller in the former case, and because their impurities are less uniformly distributed than in the case of mixed crystals.

(5) X-Ray examination may be helpful. It must be emphasized, however, that a small displacement of the lattice dimensions does not indicate that mixed-crystal formation is the sole or even the major cause of the contamination. A given precipitate may be contaminated by both occlusion and mixed-crystal formation.

Application to Coprecipitation of Anions by Barium Sulfate.—As pointed out previously, the amount of nitrite ion coprecipitated by barium sulfate is greater than would be expected from the Paneth–Fajans rule. On the basis of the theory just outlined, it is postulated that (1) iodide, bromide, chloride, chlorate and nitrate ions are coprecipitated by occlusion and (2) that nitrite ion is coprecipitated by the formation of mixed crystals of barium nitrite with barium sulfate. If these postulates are true, it follows that:

(1) The quantity of iodide, bromide, chloride, chlorate and nitrate coprecipitated when the respective barium salt is added to excess sodium sulfate will be much less than when sodium sulfate is added to an excess of the barium salt. In the case of the nitrite, the excess of the precipitating ion will be much less important. The amounts of nitrite coprecipitated will be proportional to the total concentrations of nitrite ion present.

(2) Digestion should be comparatively effective in removing the ions which are occluded but relatively ineffective with the precipitate containing the nitrite.

(3) Extensive coprecipitation of iodide, chloride, bromide, nitrate and chlorate should result in a very fine grained precipitate.

Experimental Work

In order to test this hypothesis, two sets of experiments were carried out. First, barium sulfate was precipitated (a) in the presence of an excess of the barium salt and (b) in the presence of an excess of sodium sulfate. Second, the barium sulfate was precipitated as in the first set of experiments (both a and b) but allowed to digest for a period of twenty-two days before filtering and determining the amount of coprecipitated anion.

Procedure.—Solutions (0.1000 *M*) of barium iodide, bromide, chloride, nitrite, nitrate and chlorate were prepared. A sodium sulfate solution was also made up to

0.1000 *M*. The actual precipitations were carried out as follows: 90 ml. of the barium solution was added to 120 ml. of water; then 40 ml. of the sodium sulfate solution was run in in thirty seconds with vigorous stirring. All solutions were at 30°. Precipitate and solution were allowed to stand for ten minutes after the beginning of precipitation. Separation of solution and precipitate was effected by centrifuging and decanting. The precipitate was washed with 120 ml. of water, and the coprecipitated anion was then determined in the precipitates. The time of centrifuging and washing was carefully controlled to take exactly fifty-five minutes. The experiment was then repeated exactly as before except that 40 ml. of barium salt solution was added to 9 mmol. of sodium sulfate dissolved in 210 ml. of solution.

The precipitates containing iodide, chloride, bromide and chlorate were fused with a carbonate mixture, and the anion was determined in the extract from the melt. The iodide was determined iodometrically, the bromide, chloride and chlorate gravimetrically as the silver salt. The nitrate and nitrite were determined by the method described by Walden and Cohen.[11] In this method the precipitate is digested with a sodium hydroxide–carbonate solution; Devarda's alloy is added; the ammonia is distilled off and countertitrated. In the case of the precipitates formed from barium chloride, the coprecipitated sodium was also determined by the method of Allen and Johnston.[12] The results of this set of experiments are shown in Table I.

TABLE I

Ion	Micromoles of anion per 4 mmol. $BaSO_4$[a] Excess Ba salt	 Excess Na_2SO_4	Ratio	Soly. of barium salt at 30° in moles per 1000 g. water
Iodide	1.3	0.20	6.5	5.64
Bromide	66	14	4.7	3.55
Chloride	107	18	5.9	1.83
Chlorate	390	107	3.6	1.37
Nitrite	408	177	2.3	3.49
Nitrate	783	217	3.6	0.455
Sodium	163	355	1/2.2	

[a] Averages of duplicate determinations. The relative mean deviation was 5% or less except for the iodide, where the relative mean deviation was 20%.

It can be seen that the amount of contaminant increases as the solubility of the barium salt decreases, with the notable exception of the nitrite. The latter is present in an amount far in excess of what would be expected if the solubility of the barium salt were the only determining factor. This indicates that the nitrite is probably coprecipitated by the formation of mixed crystals of barium sulfate and anhydrous barium nitrite and that the other ions are coprecipitated by occlusion. In support of this hypothesis we observed that the precipitate containing 177 micromoles of nitrite ion was much coarser than the precipitates containing 217 micromoles of nitrate ion or 107 micromoles of chlorate ion. Furthermore, the influence of the excess precipitant (barium ion or sulfate ion) was much less in the case of the nitrite ion. Indeed, the observed ratio of 2.3 corresponds surprisingly well to the theoretical value of 9/4 or 2.25 (the ratio of the quantities of nitrite ion used).

Effect of Digestion.—The barium sulfate was precipitated in the same way but was allowed to digest in contact with the mother liquor for a period of twenty-two days at 30° before being centrifuged and analyzed. The results of these experiments compared with the results of the first set are shown in Table II.

TABLE II

Ion		Micromoles of ion per 4 mmol. $BaSO_4$ Before digestion	 After digestion	% Loss
Nitrite				
(A)	Excess of Ba salt	408	160	61
(B)	Excess of Na_2SO_4	177	111	37
Nitrate				
(A)	Excess of Ba salt	783	172	78
(B)	Excess of Na_2SO_4	217	0	100
Chloride				
(A)	Excess of Ba salt	107	42	61
(B)	Excess of Na_2SO_4	18	0	100
Sodium				
(A)	Excess of Na_2SO_4	355	207	42
(B)	Excess of $BaCl_2$	163	110	32

Discussion

The precipitates containing the nitrate and chloride ions lost the impurities more rapidly than the precipitates containing nitrite ion.

Thus it is seen that the nitrite ion behaves differently from the other anions in regard to (1) the Paneth–Fajans rule, (2) the effect of excess lattice ion, (3) the influence on crystal size and (4) the effect of digestion. All these differences support the hypothesis that the nitrite is coprecipitated by mixed-crystal formation, whereas the others are occluded. It is of interest to note that the loss of sodium on digestion indicates that it is held by the barium sulfate in the form of mixed crystals, probably as sodium sulfate.

In connection with the experiments on barium nitrate which showed that the nitrate was present as occluded material, it is of interest to note the recent work of Walden and Cohen.[11] These two authors studied the lattice parameters of precipitates containing coprecipitated nitrate. They have related the lattice parameters to the nitrate content, showing that the parameters increased with increased nitrate content. They concluded, therefore, that the nitrate was present in the form of solid solution or mixed crystals. This conclusion is not supported by our investigation.

Their data unquestionably indicate that mixed crystals were formed to a certain extent, not

---

[11] Walden and Cohen, THIS JOURNAL, **57**, 2591 (1935).

[12] Allen and Johnston, *ibid.*, **32**, 588 (1910).

necessarily to a large extent. Walden and Cohen, themselves, realized the possibility that other mechanisms may have played a role in the contamination of their precipitates, for they stated, "That such mechanisms (occlusion or adsorption) may account for a part of the contamination is of course not ruled out by the present investigation, but even this may be questioned because of the remarkably homogeneous and strain-free character of the precipitates." The following considerations indicate that occlusion was probably the major cause of the coprecipitation.

(1) The coprecipitation of 4.53% of nitrate ion increases the volume of the unit cell by only 0.4%. Unless the second component of the mixed crystals (barium nitrate or nitric acid) is unusually similar crystallographically to barium sulfate, a much greater change in the volume of the unit cell is to be expected.

(2) The relationship between the lattice dimensions and the composition differed from linearity more than is to be expected in the case of mixed-crystal formation between salts.

(3) When mixed crystals are in equilibrium with the mother liquor, the partition law is valid.

$$\frac{\text{component A in crystals}}{\text{component B in crystals}} = K\frac{\text{component A in solution}}{\text{component B in solution}}$$

Unless the crystallization is performed extremely slowly, equilibrium may not be established, and the partition law may not be strictly valid. Nevertheless, there is abundant evidence[13] to prove that the mole percentage of the minor constituent in the mixed crystals is dependent primarily on the concentration of this substance in the aqueous solution. On the other hand, Walden and Cohen remark in discussing their results, "A very striking feature of these results, and one hardly to be anticipated, is that the nitrate content of the precipitates is practically independent of the nitrate content of the precipitating solutions. . . . To be noted, however, is the fact that the nitrate content of the precipitates varies with barium ion concentration." These observations are at odds with the hypothesis that mixed-crystal formation is the major cause of the contamination of their precipitates and entirely in harmony with our belief that occlusion was the major phenomenon.

(4) Walden and Cohen remark that extending the range of concentration for further study will have to lead to the use of more dilute solutions since "in the more concentrated range the precipitates settle as muds which are difficult to wash and filter and which give poor X-ray photograms." Since contamination by mixed-crystal formation has only a slight effect on the particle size of the precipitate, the formation of these muds is another indication that the coprecipitation was due chiefly to occlusion.

We conclude, therefore, that occlusion is a more important factor than the formation of mixed crystals in accounting for the contamination of their precipitates.

Summary

(1) Precipitates that are contaminated by occlusion differ from those that are contaminated by mixed-crystal formation in respect to (a) the effect of excess of the lattice ion during precipitation, (b) application of the Paneth–Fajans rule, (c) the size of the crystals and (d) the effect of digestion.

(2) Iodide, bromide, chloride, nitrate and chlorate anions are occluded by barium sulfate, whereas nitrite ion is coprecipitated by mixed-crystal formation. These conclusions are based on the following observations: (a) The excess of lattice ion influences the coprecipitation of nitrite ion much less than it influences the coprecipitation of the other anions. (b) All these anions except the nitrite follow the Paneth–Fajans rule. (c) The size of the crystals of the precipitate is decreased much less by the coprecipitation of nitrite ion than by the coprecipitation of the other anions. (d) The nitrite ion is removed on digestion more slowly than the other anions.

(3) The conclusions of Walden and Cohen are discussed.

[Contribution from the Nutrition Laboratory of the Carnegie Institution of Washington]

The Constancy of the Atmosphere with Respect to Carbon Dioxide and Oxygen Content[1]

By Thorne M. Carpenter

The constancy of the percentages of carbon dioxide and oxygen in uncontaminated atmospheric air was established by Benedict[2] in 1912 by the use of the Sondén[2,3] gas analysis apparatus. As a control upon the correct functioning of the apparatus, analyses of air compressed in a cylinder were made daily along with the analyses of atmospheric air. Only when it was established that the apparatus would give constant results with the compressed air was it found that the composition of the outdoor air was constant. Since that time there has been developed in this Laboratory an apparatus[4] especially for the determination of the changes in the composition of atmospheric air that may be produced by the respiration of animals or of man in a confined space. The apparatus is constructed with a compensating pipet that takes care of the changes in the volume of a gas due to variations in temperature and in atmospheric pressure. The absorption of carbon dioxide is by the use of 10 to 20% potassium hydroxide and the absorption of oxygen takes place by means of potassium pyrogallate solution. The buret is so constructed that readings may be estimated to 0.001% of the volume.

This apparatus has been employed regularly for metabolism experiments which require the use of respiration apparatus and analysis of air samples. Based upon previous work of Benedict,[2] the standardization of the apparatus was made by frequent analysis of atmospheric air. During the course of several investigations, three series have been accumulated in which a control analysis was made on each day that the apparatus was used for experimental purposes.

The first series consists of 75 analyses between August, 1934, and June, 1935, at the Laboratory for Animal Nutrition in the University of New Hampshire. Another series consists of 790 analyses on nearly as many days from January, 1933, to May, 1936, that were made at Baltimore in the Department of Embryology of the Carnegie Institution of Washington, located in the building of the Johns Hopkins Medical School. The third series consists of 291 analyses on the same number of days from June, 1930, to December, 1932, in this Laboratory.

In Table I are given the averages of the analyses in the three series including the standard deviations and ranges for carbon dioxide and oxygen. For carbon dioxide the averages are identical in all three series and the standard deviations have a narrow range of from 0.0015 to 0.0017%. The ranges for the series at Durham and at Boston are practically identical. The range for the carbon dioxide in the series at Baltimore is wide, due to the inclusion of one analysis of 0.060%. Excluding this value, the range for the remaining 789 was 0.028 to 0.033%. The average per cent. of oxygen in the three series is nearly identical with a range of only 0.002% in the three series. The standard deviations for the groups at Durham and at Boston are practically identical. The standard deviation for the group at Baltimore is somewhat larger due to the inclusion of results on twenty-one days that were outside of the range of 20.930 to 20.950%. Of these, 17 were repeated immediately following the aberrant analysis and an average of 20.937% was found with a standard deviation of 0.0027%. The value of 20.926 for the minimum at Durham was exceptional as the range of the other 74 was from 20.933 to 20.948%.

Table I

Averages of Analyses of Atmospheric Air at Durham, N. H., Baltimore, Md., and Boston, Mass.

	No.	Average	S. D.[a]	Range
		Per cent. Carbon Dioxide		
Durham	75	0.031	0.0016	0.027–0.035
Baltimore	790	.031	.0015	.028–0.060
Boston	291	.031	.0017	.026–0.035
		Per cent. Oxygen		
Durham	75	20.939	.0032	20.926–20.948
Baltimore	790	20.938	.0046	20.909–20.957
Boston	291	20.940	.0033	20.931–20.947

[a] S. D. = Standard deviation.

(1) Presented at the Pittsburgh meeting of the American Chemical Society, September, 1936.

(2) F. G. Benedict, "The Composition of the Atmosphere with Special Reference to its Oxygen Content." Pub. No. 166, Carnegie Institution of Washington, 1912.

(3) Sondén, *Z. Instrumentenk.*, **9**, 472 (1889).

(4) Carpenter, *J. Metabolic Research*, **4**, 1 (1923); Carpenter, Fox and Sereque, *J. Biol. Chem.*, **83**, 211 (1929); Carpenter, Lee and Finnerty, *Wiss. Arch. Landw.*, Abt. B., **4**, 1 (1930); Carpenter, Abderhalden's "Handbuch der biolog. Arbeitsmethoden," Abt. IV, T. **13**, 593 (1933).

The division of the series at Baltimore into yearly results is shown in Table II. The averages of the carbon dioxide for the four years are identical and the standard deviations for three years for carbon dioxide are low, whereas the standard deviation for 1936 is somewhat higher due to the inclusion of one aberrant result of 0.060%. The averages for the percentages of oxygen for the four different years have a range of only 0.003%. The standard deviations are under 0.005% for each of the four years.

Table II

Yearly Averages of Analyses of Atmospheric Air at Baltimore

Year	No.	% CO_2	S. D.[a]	% O_2	S.D.[a]
1933	229	0.031	0.0010	20.938	0.0049
1934	230	.031	.0010	20.936	.0044
1935	230	.031	.0012	20.939	.0038
1936	101	.031	.0032	20.938	.0044

[a] S.D. = Standard deviation.

An example of the monthly averages for a single year is given in Table III. The average carbon dioxide ranges from 0.030 to 0.031; thus there was constancy in the percentage of carbon dioxide throughout the year. The monthly standard deviations of carbon dioxide ranged from 0.0010 to 0.0015%. The average of oxygen percentages by months ranged from 20.938 to 20.940%. The range of the standard deviations for the oxygen percentages by months is slightly larger than in the series by years and is due to the occasional finding of an erroneous result which has been included. Thus at Baltimore it was found that the percentages of both carbon dioxide and oxygen were practically constant over a period of nearly four years. A subdivision into months shows that practically the same constancy remains throughout the year.

Table III

Monthly Averages of Analyses of Atmospheric Air at Baltimore, 1935

Month	No.	% CO_2	S. D.[a]	% O_2	S. D.[a]
Jan.	23	0.031	0.0010	20.938	0.0045
Feb.	19	.031	.0011	20.939	.0041
Mar.	23	.030	.0010	20.940	.0038

Dec.	18	.031	.0012	20.939	.0070

[a] S. D. = Standard deviation.

The yearly averages of the analyses at Boston are shown in Table IV. The carbon dioxide percentages are identical for the three years with a value of 0.031%. Similarly the oxygen percentages are practically constant and the standard deviations by years for the oxygen percentages in the series in Boston are under 0.004% for each year. An example of the monthly averages is given in Table V for the year 1931 at Boston.

Table IV

Yearly Averages of Analyses of Atmospheric Air at Boston

Year	No.	% CO_2	S. D.[a]	% O_2	S. D.[a]
1930	79	0.031	0.0016	20.940	0.0032
1931	135	.031	.0017	20.939	.0032
1932	77	.031	.0017	20.940	.0034

[a] S. D. = Standard deviation.

Table V

Monthly Averages of Analyses of Atmospheric Air at Boston for Year 1931

Month	No.	% CO_2	S. D.[a]	% O_2	S. D.[a]
Jan.	5	0.031	0.0011	20.941	0.0022
Feb.	17	.031	.0011	20.939	.0023
Mar.	8	.032	.0014	20.939	.0024
April	12	.032	.0017	20.940	.0033
May	7	.031	.0016	20.938	.0033
June	16	.030	.0017	20.940	.0037
July	14	.031	.0016	20.940	.0025
Sept.	5	.032	.0013	20.939	.0012
Oct.	14	.031	.0015	20.939	.0026
Nov.	18	.032	.0021	20.940	.0037
Dec.	19	.031	.0020	20.938	.0038

[a] S. D. = Standard deviation.

No analyses were made in August. The carbon dioxide percentages average from 0.030 to 0.032%, the standard deviation ranging from 0.0011 to 0.0021%. The averages of the oxygen percentages range from 20.938 to 20.941%, the standard deviation ranging from 0.0012 to 0.0038%. Thus the composition of the atmospheric air at Boston with respect to its carbon dioxide and oxygen content was practically constant for the period of time covering nearly three years and a subdivision into monthly groups does not increase the range of the averages.

The laboratory in New Hampshire is located on the college campus and is not far from a heavily wooded section. The laboratory at Boston is situated about 200 feet (61 meters) from a heat, light and power plant. There are two stacks of 180 feet (55 meters) and 190 feet (58 meters) each and the total fuel consumption varies from 35 to 95 tons of coal per day. In spite of the widely different local conditions of the three laboratories there is no evidence that variations in season or proximity of large consumers of fuel cause any measurable differences in carbon dioxide and oxygen content of the atmospheric air. As pointed out by Benedict,[2] many of the atomic weights are not known beyond the fourth significant figure, but here is a physical mixture of gases, with the percentage content of one of its constituents, namely oxygen, having a constancy beyond the accuracy of many atomic weight determinations.

The analyses were made at Durham by Mrs. H. H. Latimer and Mr. N. F. Colovos, at Baltimore by Mr. K. Koudelka, and at Boston by Mr. E. L. Fox.[5]

[5] Died Dec. 19, 1934.

Summary

Three series of samples of outdoor air consisting of 75 at Durham, New Hampshire, 790 at Baltimore and 291 at Boston were analyzed for carbon dioxide and oxygen content by means of an apparatus on which readings are estimated to 0.001%. Each series was scattered over nearly the same number of days as there were analyses. The grand average of all three series gave 0.031% for carbon dioxide and 20.939% for oxygen. In spite of widely different local conditions of the three laboratories there was no evidence that variations in season or proximity of large consumers of fuel caused any measurable differences in carbon dioxide and oxygen content of atmospheric air.

Note on the Relative Partial Molal Heat Content of Zinc Sulfate in Aqueous Solution

BY HERBERT S. HARNED

Cowperthwaite and La Mer[1] have measured the electromotive forces of the cells

Zn(2-phase amalgam) | $ZnSO_4(m)$ | $PbSO_4$-Pb(2-phase amalgam)

at concentrations from 0.0005 to 0.01 *M*, and from 0 to 50° at 12.5° intervals. They showed that these results were in conformity with the Gronwall, La Mer and Sandved[2] extension of the Debye and Hückel theory, provided that 3.64 Å. was used for the mean distance of approach of the ions, *a*. With this equation, they obtained the standard potentials of the cell at the temperatures at which they were measured.

From these data, La Mer and Cowperthwaite[3] have computed the relative partial molal heat content, $\overline{L}_2$. This quantity has also been obtained from calorimetric data by Lange, Monheim, and Robinson,[4] who derived values which differed considerably from those computed from the electromotive forces. Such a discrepancy detracts from the value of Cowperthwaite and La Mer's proof of the validity of the extended theory unless it can be shown that this disagreement disappears upon further consideration of the results.

Following Cowperthwaite and La Mer, we shall employ the quantity E_0', defined by the equation of the cell by

$$E_0' = E + \frac{\gamma RT}{NF} \ln m = E_0 - \frac{\gamma RT}{NF} \ln \gamma \quad (1)$$

where E is the measured electromotive force corrected for lead sulfate solubility, E_0 the standard potential of the cell, and the other symbols have their usual connotation. The calculation of $\overline{L}_2$ by La Mer and Cowperthwaite is open to two criticisms. In the first place, they employed a five constant power series equation ending in a term containing T^4 to express five results. If one or more of the results are in error, this procedure will not yield an accurate temperature coefficient at a given temperature. Secondly, their results at 50° were obtained with difficulty and in fact seem to be inconsistent with the results at the lower temperatures. Electromotive force measurements as a function of temperature usually may be expressed with high accuracy by a quadratic equation. To test this in the present instance, the first order differences of Cowperthwaite and La Mer's results[1] were plotted against T. These plots are straight lines with the exception of the one which involves the 50° reading, a fact which indicates that a quadratic equation may

[3] La Mer and Cowperthwaite, THIS JOURNAL, **55**, 1004 (1933).

[4] Lange, Monheim and Robinson, *ibid.*, **55**, 4733 (1933).

be used to compute E'_0 from 0 to 37.5°. In Table I are given the constants of the equations

$$E' = E'_{25} + a'(t - 25) + b'(t - 25)^2 \qquad (2)$$

and

$$E_0 = E_{0(25)} + a'(t - 25) + b'(t - 25)^2 \qquad (3)$$

where E_0 is the standard potential. These equations will express the results with an average deviation of 0.07 mv. in regions of concentration from 0.001 to 0.01 M, inclusive. The 0.0005 M result is not so good, but the values of E_0 from the extrapolation of Cowperthwaite and La Mer agree with those computed by equation (3) to within 0.05 mv. On the absolute temperature scale these equations become

$$E'_0 = a + bT + cT^2 \qquad (4)$$

$$E_0 = a_0 + b_0T + c_0T^2 \qquad (5)$$

from which $\overline{L}_2$ in calories may be computed as shown by Harned and Thomas[5] by

$$\overline{L}_2 = -46{,}118\ [(a - a_0) - (c - c_0)T^2] \qquad (6)$$

The values of a were smoothed by plotting against m. In Table I, values of $(a - a_0)$, $(c - c_0)$ and $\overline{L}_2$ computed by this method are collected. In the eighth column are given the values of this quantity calculated by Lange, Monheim and Robinson from their heat of dilution data. The agreement between the values derived from these two types of measurement is good, particularly since an error of 0.001 mv. per degree in the temperature coefficient of electromotive force causes an error of 14 cal. in $\overline{L}_2$. Further, since an error of 0.1 in the estimation of $(c - c_0) \times 10^7$ produces an error of 41 cal., the discrepancy at 0.0005 M is not serious. Indeed, it is hardly likely under the most favorable circumstances that $\overline{L}_2$ can be estimated from these results with an accuracy greater than 30 cal. In the last column of the table the results of La Mer and Cowperthwaite's calculation are given. As the concentration increases, there is an increasing deviation between their results and those derived from heat of dilution data which amounts to 200 cal. at 0.01 M. At 0.0005 M, La Mer and Cowperthwaite's value checks the calorimetric, but as previously mentioned this may not be significant since the whole computation is so sensitive and since the electromotive force data are less consistent at this concentration.

TABLE I

$\overline{L}_2$ OF ZINC SULFATE. CONSTANTS OF EQUATIONS (2), (3) AND (6)

m	$E_{0(25)}$	$(-a'_0 \times 10^3)$	$(-b'_0 \times 10^6)$					
0.0	0.41087	1.106	4.00	....		...	...	...
	E'_{25}	$(-a' \times 10^3)$	$(-b' \times 10^6)$	$(a - a_0)$	$(c - c_0) \times 10^7$	$\overline{L}_2$, e. m. f.	$\overline{L}_2$, cal.	$\overline{L}_2$ La M.
0.0005	0.41725	1.085	3.93	0.0019	0.7	(198)	255	266
.001	.42002	1.052	3.87	.0032	1.3	385	355	395
.002	.42365	1.025	3.82	.0055	1.8	480	492	563
.005	.42989	1.005	3.76	.01024	2.4	674	676	812
.01	.43524	0.980	3.68	.01525	3.2	772	790	978

Summary

By employing a quadratic equation to express the electromotive force data of the cell[1] Zn (2-phase amalgam) | $ZnSO_4(m)$ | $PbSO_4$-Pb (2-phase amalgam) from 0 to 37.5° with the omission of an uncertain result at 50°, values of the relative partial molal heat content of zinc sulfate were computed. These values are in agreement with those obtained by measurements of heats of dilution,[4] a fact which seems to justify our method of procedure. We may conclude that from 0 to 37.5° the electromotive force data possess a high accuracy which we judge to be of the order of ±0.05 mv. If the method here employed is correct, the previous discrepancy between the values of $\overline{L}_2$ obtained from heat data[4] and electromotive force measurements[3] disappears. This agreement is excellent evidence for Cowperthwaite and La Mer's extrapolation of the electromotive forces, and lends confirmation to their proof of the effect of the extended terms of the Debye and Hückel theory.

Systems of Sulfur Dioxide and the Isomeric Xylenes

BY W. F. SEYER, K. MARTIN AND L. HODNETT

A number of systems of sulfur dioxide and aromatic compounds have been studied. Thus Znozzetti and De Carli measured the freezing points of sulfur dioxide and benzene solutions and claimed to have obtained evidence showing the existence of three compounds.[1] In later publications F. De Carli states he had obtained compounds of sulfur dioxide with toluene, ethylbenzene and certain other derivatives of benzene. He made no mention of having investigated the three xylenes and, as it was of interest to know whether the three xylenes behaved in a similar manner with the solvent sulfur dioxide, a series of freezing point measurements were made on the three systems.

Materials.—The organic compounds used were obtained from Kahlbaum. As the ortho, meta and para xylenes were the purest available, no further purification beyond distilling over sodium was attempted. The sulfur dioxide was the usual C. P. variety supplied by Baker and Co. in little iron tanks. Before condensation, the gas was bubbled through dilute sulfuric acid to remove any sulfur trioxide, then through several wash bottles of concentrated acid and over phosphorus pentoxide to remove any traces of water.

Procedure.—The bulb method was used throughout as it was the most convenient and was considered to be sufficiently accurate for the results desired. Various amounts of the hydrocarbons were introduced into a series of bulbs by means of a thin-stemmed thistle tube. The bulbs, whose volumes averaged about 2.5 cc. and whose stems were about 20 cm. in length, were then capped and weighed to obtain the amount of xylene. Definite quantities of sulfur dioxide were next condensed in these tubes which were then sealed and weighed. The amounts of xylene and sulfur dioxide could thus be obtained directly, and as a check, the sulfur dioxide content was always determined after the freezing point had been found, by titration with sodium hydroxide.

Sulfur dioxide was introduced into the bulbs in two ways. In the case of *p*-xylene, the apparatus described in Vol. 23, p. 327, of the *J. Ind. Eng. Chem.* was used. Bulbs, containing weighed amounts of *p*-xylene, were cooled until the contents froze and they were then sealed onto the filling line. The air was removed by a mercury vapor pump (the xylene being kept frozen in the meantime) after which the desired amounts of sulfur dioxide were condensed in each bulb. It was found that if the air were not sufficiently removed, the contents of the bulbs became red and finally dark in color when allowed to attain room temperature. In the absence of air, however, solutions of any one of the xylenes and sulfur dioxide remained clear and colorless even after standing for some months at room temperatures.

In the case of ortho and meta xylene, whose freezing points are much lower than that of the para compound, a simpler method of filling the bulbs was found to be equally successful. All that was required was to cool the bulb containing the xylene, first sweep out the air with sulfur dioxide and then by further cooling cause the gas to condense. It was found that the amount of xylene vapor lost during the removal of the air was negligible.

The next step was to determine the freezing point of the solution in each bulb. A bath, containing 95% alcohol and a little ether, was set up in a Dewar tube and connected to a container from which liquid air was blown to cool the bath. A pentane thermometer, a platinum resistance thermometer, standardized by the Bureau of Standards, and one of the bulbs were placed in the bath. The temperature was slowly lowered by the liquid air until crystals appeared in the solution in the bulb. The temperatures on the thermometers were noted and the bath was allowed to warm slowly until only one or two crystals remained. The temperature was kept at this level for several minutes, or as long as there was no apparent increase or decrease in the size or number of crystals. The bath was then allowed to warm slightly and the point at which the crystals disappeared was taken as the freezing point. Because of the viscosity of the solutions it was difficult to stir the contents of the bulbs thoroughly; this of course affected the freezing point of the solution, hence reported freezing points would vary as much as one degree. The results recorded in Table I are the averages of three determinations. The freezing point of sulfur dioxide was taken as 75.43°.

.1356	9.8676	99.18	−76.2
.1063	11.9383	99.46	−75.7

Freezing point of *m*-xylene −53.6°.

The data when plotted as curves in Fig. 1 show each system to have only one entectic. Thus there is no indication of compound formation. To further test this point crystals of the hydrocarbons which formed from solutions containing varying amounts of sulfur dioxide were analyzed but with unsatisfactory results.

By utilizing the well-known equation

$$\ln N = \frac{-L}{R}\left(\frac{1}{T} - \frac{1}{T_m}\right)$$

the values of the latent heat of fusion were calculated. These are given in Table IV and compared with those measured directly.

TABLE IV

LATENT HEAT OF FUSION OF THE XYLENES

	Calculated	Temperature range, °C.	Found
p-Xylene	3560 cal.	13.2– 0.8	4168[a] cal.
o-Xylene	3550	−27.1−−42	3333[b]
m-Xylene	6317	−53.6−−57.4	2760[b]

[a] "International Critical Tables." [b] Rossini, *Bur. Standards J. Research,* **11**, 553–559 (1933).

It thus appears that the *o*-xylene and sulfur dioxide behave very nearly as ideal solutions but this is not so in the case of the two others, the *p*-xylene deviating positively and the *m*-xylene negatively from the ideal solution.

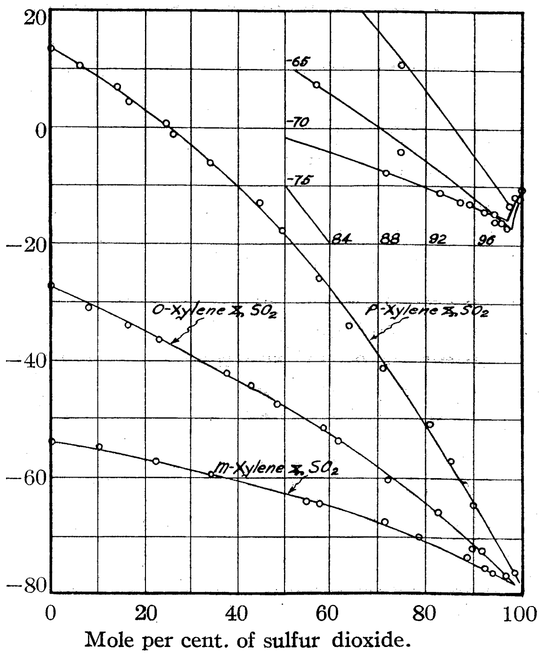

Fig. 1.

Summary

1. The freezing point curves of para, ortho and meta xylenes with sulfur dioxide have been constructed from freezing point data. There appears to be no compound formation, as there is only one eutectic in each case.

2. The calculated latent heats of fusion when compared with the experimental values show the para and meta solutions to deviate considerably from the ideal.

The Beta to Alpha Conversion of Fully Acetylated Sugars by Alkali

By M. L. Wolfrom and Donald R. Husted

In some work carried out in this Laboratory on a reaction involving *β-d*-glucose pentaacetate, it was found that this *β*-form had been isomerized unexpectedly to *α-d*-glucose pentaacetate. This change was obtained under conditions entirely different from those recorded in the literature for effecting the conversion of a fully acetylated *β*-form of a sugar to the corresponding *α*-isomer. Such a conversion had been produced previously by treating the *β*-pentaacetate in acetic anhydride solution with either zinc chloride[1] or sulfuric acid;[2] or by treatment with stannic chloride in chloroform.[3] The experimental conditions which we found effective for producing this conversion were studied in considerable detail in order to determine the agent producing the change. We believe that the effective agent was a very mild alkalinity. This is in contrast to the acidic conditions previously used to cause the shift. This result can be harmonized with modern theories of sugar mutarotation, since both acidic and basic catalysts are effective in the transformation of a non-substituted reducing sugar into its *alpha* and *beta* forms.[4]

The procedure used by us was to shake a solution or suspension of the completely acetylated *β*-form of the sugar in a suitable non-aqueous solvent with solid sodium hydroxide and a suitable drying agent. Anhydrous and alcohol-free ether as well as dioxane were found to be suitable solvents but were most effective when used in an equal mixture. No difference was found in the action of commercial or highly purified dioxane. Either sodium or anhydrous calcium sulfate (Drierite) was suitable as drying agent, such an agent apparently being required to protect the reaction mixture from becoming too alkaline. The sodium hydroxide was essential. These conditions are those of incipient alkaline deacetylation and some deacetylation always occurred. Consequently, this reaction is not the equal of the previously established methods for preparative purposes, but we believe that it is of theoretical interest, particularly in its relation to the study of the interconversion of isomeric sugar structures.

The reaction was extended successfully to *β-d*-mannose pentaacetate, *β-d*-galactose pentaacetate and *β*-lactose octaacetate.

Experimental

***α-d*-Glucose Pentaacetate.**—An amount of 25 cc. of dry dioxane (a high grade commercial product dried with sodium or anhydrous calcium sulfate (Drierite)) and 25 cc. of diethyl ether (anhydrous and alcohol-free) were placed in a citrate pressure bottle and approximately 3 g. of sodium and 3 g. of crushed, solid sodium hydroxide were added. This mixture was shaken mechanically for approximately fifteen minutes and then 3 g. of pure *β-d*-glucose pentaacetate was added quickly and the mixture shaken for a period of four to six hours. Some dark brown sludge formed and the solution was colored brown. After a little experience the completeness of the reaction could be judged by this color. At the end of the shaking, some Carboraffin was added and the mixture rapidly filtered with suction into a flask containing a few cc. of acetic acid. The acidified filtrate was light yellow in color and showed a specific rotation varying from +70 to +90°. The residue obtained after solvent removal under reduced pressure was crystallized from 95% ethanol (Carboraffin), the first crop of crystals being *α-d*-glucose pentaacetate of good purity; m. p. 110–111° (unchanged on admixture with known material of the same purity); $[\alpha]$ +96°[5] ($CHCl_3$); average yield approximately 1.2 g., maximum 1.5 g.; acetyl, 13.0 cc. 0.1 *N* NaOH per 100 mg. (calcd., 12.8 cc.). After several recrystallizations the following constants were obtained: m. p. 112–113°; $[\alpha]^{22}$ +98.5° (*c*, 3; $CHCl_3$). Hudson and Dale[6] record for *α-d*-glucose pentaacetate the constants: m. p. 113°; $[\alpha]^{20}$ +101.5° ($CHCl_3$).

When the conditions described above were adhered to rigidly, no *β*-form was isolated from the reaction. If the reaction was stopped short of completion, some *β*-form could be isolated. After a little experience, the results described above could be obtained in about 90% of the trials, the limitations being that if the reaction was stopped short of the optimum point some *β*-form was obtained, while if the reaction was allowed to proceed too far or if too much moisture was accidentally introduced, deacetylation resulted.

It was thought at first that the rearrangement might have been effected by impurities contained in the dioxane but no difference was noted when dioxane was used that had been purified by the method of Kraus and Vingee.[7]

[5] All of the recorded rotations were measured to the D-line of sodium.

[6] C. S. Hudson and J. K. Dale, This Journal, **37**, 1264 (1915).

[7] C. A. Kraus and R. A. Vingee, *ibid.*, **56**, 511 (1934).

This point was settled satisfactorily when it was found that ether alone could be used as a solvent if the time of shaking was prolonged to from eighteen to twenty-four hours. Purified dioxane could also be used alone but then the reaction likewise proceeded at a very slow rate. The sodium used in the procedure served merely as a drying agent, since anhydrous calcium sulfate (Drierite) could be substituted for it without affecting the yield. When sodium was used and the solid sodium hydroxide omitted, a very low yield of α-glucose pentaacetate was obtained. This small amount of conversion was undoubtedly due to the slight quantity of sodium hydroxide produced by unavoidable contamination with moisture. All of these experiments pointed to the conclusion that the active interconverting agent was the sodium hydroxide. When α-*d*-glucose pentaacetate was used initially, it was recovered unchanged in approximately 50% yield but no β-form was isolated. This would indicate either that the equilibrium was displaced to favor the α-form or that the β-isomer was more readily deacetylated.

α-*d*-Galactose Pentaacetate.—Pure β-*d*-galactose pentaacetate (3.0 g.) was treated exactly as described for β-*d*-glucose pentaacetate except that the time of shaking was from five to seven hours. The acidified filtrate showed a specific rotation of from +60 to +80°. The sirup obtained after solvent removal under reduced pressure was dissolved in ethanol, treated with Carboraffin, filtered and the ethanol removed under reduced pressure. The residual sirup was dissolved in chloroform and the solution washed successively with 5% hydrochloric acid, 5% aqueous sodium bicarbonate and then with water, dried, the solvent removed under reduced pressure and the residual sirup crystallized from a small amount of hot ethanol; yield 0.8 to 1.0 g.; m. p. 94–95° (mixed m. p. unchanged); $[\alpha]^{27}$ +104° (*c*, 3.7; $CHCl_3$). Hudson and Parker[8] record for α-*d*-galactose pentaacetate the constants: m. p. 96°; $[\alpha]^{20}$ +107° ($CHCl_3$).

α-*d*-Mannose Pentaacetate.—Pure β-*d*-mannose pentaacetate (3.0 g.) was treated exactly as described for β-*d*-glucose pentaacetate except that the time of shaking was from four to four and one-half hours. The acidified filtrate showed a specific rotation of approximately +45°. The sirup obtained after solvent removal was crystallized from hot water; yield 1.2 g.; m. p. 73–74°; $[\alpha]^{33}$ +59° (*c*, 2.6; $CHCl_3$; 2-dm. semimicro tube). After one further recrystallization the substance showed the constants: m. p. 74–75° (mixed m. p. unchanged); $[\alpha]^{28}$ +60° (*c*, 3.3; $CHCl_3$; 2-dm. semimicro tube). Levene and Bencowitz[9] record for α-*d*-mannose pentaacetate the constants: m. p. 75°; $[\alpha]^{22}$ +55° ($CHCl_3$).

α-Lactose Octaacetate.—Pure β-lactose octaacetate (3.0 g.; m. p. 90°; $[\alpha]$ −4.2°, $CHCl_3$) was treated exactly as described for β-*d*-glucose pentaacetate and the sirup obtained after solvent removal was dissolved in ethanol (Carboraffin) and the ethanol removed under reduced pressure. The residual sirup was triturated with several portions of cold water and obtained crystalline from either ethanol or ether by slow evaporation of the solvent. α-Lactose octaacetate is difficult to crystallize and the yield was very low; m. p. 149–150°; $[\alpha]^{21}$ +51° (*c*, 2.9; $CHCl_3$; 2-dm. semimicro tube). On one further recrystallization the melting point was 152° (mixed m. p. unchanged). Hudson and Johnson[1b] record for α-lactose octaacetate the constants: m. p. 152°; $[\alpha]^{20}$ +54° ($CHCl_3$).

Summary

1. A method was found for converting β-*d*-glucose pentaacetate to the α-form, using sodium hydroxide as the reagent.

2. The method was extended to the corresponding fully acetylated derivatives of *d*-galactose, *d*-mannose and lactose. It is probably of general application.

The Configurations of α- and β-*p*-Bromobenzophenone Oximes

BY RAYMOND WRIGHT JOHNSON AND JOE GOLENTERNEK

An earlier contribution by Johnson and Stieglitz[1] from this Laboratory reported the details of an empirical method for the determination of the velocity of hydrolysis of oximes. Data were reported which showed that the individual members of the pair of stereoisomeric oximes of *p*-methylbenzophenone hydrolyzed at considerably different rates.

The purpose of this study was, first, to test the generality of this difference in rates by the investigation of another pair of stereoisomeric oximes and, second, to extend the study to include a comparison of the rates of hydrolysis of the stereoisomeric forms with those of the corresponding symmetrical oximes. It was hoped that this might throw some light on the configurations of the stereoisomeric compounds. The compounds selected were the α and β forms of *p*-bromobenzophenone oxime and the related oximes of benzophenone and *p,p'*-dibromobenzophenone.

Preparation of Materials

Benzophenone Oxime.—This compound was prepared by the method of Fischer.[2]

---

[1] Johnson and Stieglitz, THIS JOURNAL, **56**, 1904 (1934).

[2] Fischer, "Anleitung zur Darstellung organ. Prepärate," Braunschweig, 1908, p. 68.

***p,p′*-Dibromobenzophenone Oxime.**—A mixture of the ketone (10 g.) and hydroxylamine hydrochloride (6.5 g.) dissolved in ethyl alcohol (700 cc. of 95%) to which a solution of sodium carbonate (10 g. in 30 cc. of water) had been added was refluxed on a steam-bath for ten hours and then allowed to cool. The unreacted ketone (about 25% of the original amount) and sodium carbonate was removed by filtration. The filtrate was diluted with water (2500 cc.) and chilled. Crystals of the crude oxime (7.5 g., m. p. 140–145°) were obtained. Two recrystallizations from ligroin (b. p. 90–100°) produced the pure oxime (m. p. 150–152°).

Anal. (Micro) Calcd. for $C_{13}H_9ONBr_2$: N, 3.94. Found: N, 3.94, 4.02.

α- and β-*p*-Bromobenzophenone Oximes.—Anhydrous sodium acetate (100 g.) was added to a solution of the ketone (50 g.) and hydroxylamine hydrochloride (60 g.) in ethyl alcohol (400 cc. of 95%). The mixture was refluxed for six hours on a steam-bath. The alcohol was removed by distillation and the residue was washed several times with warm water. The crude mixture of the two oximes (51 g.) when dry had a melting point of 102–160°. The method used for the separation of the two forms was based on the difference in their solubility in solutions of sodium hydroxide. The crude mixture of oximes was extracted with successive portions (700, 150, 85 and 50 cc.) of a hot (90°) solution of sodium hydroxide (2 *N*). The undissolved oxime (m. p. 160–165°) on recrystallization from ethyl alcohol produced the pure α-oxime. The melting point of this pure α-form (m. p. 168–170°) was higher than that reported (165–166°) previously by Schäfer.[3] The combined alkaline extract was saturated with carbon dioxide gas to precipitate the oxime in solution. This material was washed with water until free from alkali. The dried material was dissolved in hot ethyl alcohol (absolute). Fractional crystallization was obtained by means of the addition of small quantities of water from time to time. Relatively small amounts of the pure β-form (m. p. 109–111°) were obtained.

Anal. (Micro) Calcd. for $C_{13}H_{10}ONBr$: N, 5.07. Found: (α-form), N, 5.01, 4.93; (β-form), 5.03, 4.88.

Method

The method used for the determination of the velocity of hydrolysis of the oximes was essentially that of Johnson and Stieglitz.[1] The limited solubility of these bromo compounds in an acetic–hydrochloric acid mixture such as was used by them required the use of a mixture richer in acetic acid. This necessitated a slight change in the extraction procedure. The procedure followed in each of the determinations listed below was identical. A weighed quantity of the oxime was dissolved in glacial acetic acid (140 cc. of reagent quality) at 25° in a 200-cc. graduated flask. At a definite noted time exactly 50 cc. of hydrochloric acid (1.899 *N*) at 25° was run in. The volume of the solution was quickly made up to 200 cc. by the addition of glacial acetic acid. After it was thoroughly mixed, the solution was placed in a thermostat at 25 ± 0.02°. From time to time a sample (25 cc.) of the solution was pipetted into a Squibb separatory funnel. At a definite noted time 35 cc. of water was added and the procedure from that point on was the same as that described by Johnson and Stieglitz.[1] The concentration of the oxime in the various determinations ranged from 0.03 to 0.045 *N*.

Tests with known solutions showed that this procedure yields quantitative results with acetic–hydrochloric acid solutions of hydroxylamine such as were obtained in this investigation.

The fact that the reactions in each case were normal and yielded only the respective ketone and hydroxylamine was proved when examinations of the content of completely hydrolyzed solutions yielded only these two substances.

Results

The average of at least two determinations of the velocity of hydrolysis of each of the oximes studied is given in Table I.

TABLE I

VELOCITY OF HYDROLYSIS OF OXIMES (25°)

Compound, oxime	Concn. of HCl in hydrolyzing solution, *N*	$K \times 10^5$
Benzophenone	0.4747	60.21
α-*p*-Bromobenzophenone	.4747	67.49
β-*p*-Bromobenzophenone	.4747	55.85
p,p′-Dibromobenzophenone	.4747	46.83

Discussion

In the article by Johnson and Stieglitz[1] the hydrolysis of oximes tentatively was assumed to consist of at least two consecutive reactions, the first reaction consisting of the addition of a molecule of water to the double bond between carbon and nitrogen in the oxime or its salt, followed by the decomposition of this intermediate hydrated form to produce the normal end products. Furthermore, it was pointed out that, if such is the true mechanism for the reaction, the experimentally determined rate of hydrolysis of the stereoisomeric oximes must be that of the addition of water to form the intermediate hydrated compound. The data reported in this paper are most logically explained by this theory. The fact that the rate of hydrolysis of chloral oxime[4] is very much less than the rate of hydrolysis of the hydrate of chloral oxime supports this general theory.

If this simple mechanism is valid, and, if *cis* addition of the molecule of water takes place, one might expect that that one of the two stereoisomeric oximes investigated which has the *syn*-phenyl configuration would hydrolyze at a rate more nearly approximating the rate of hydrolysis of benzophenone oxime than the rate for *p,p′*-dibromobenzophenone oxime. Similarly of the two the rate of hydrolysis of the form with the *syn-p*-bromophenyl configuration might be ex-

---

[3] Schäfer, *Ann.*, **264**, 152 (1891).

[4] Unpublished data.

pected to approximate more nearly the rate of hydrolysis of *p,p'*-dibromobenzophenone oxime. An examination of the data in Table I shows that the rate of hydrolysis of α-*p*-bromobenzophenone oxime more nearly approximates the rate for benzophenone oxime than it does that for *p,p'*-dibromobenzophenone oxime. Thus this criterion of configuration would assign the *syn*-phenyl configuration to the α-*p*-bromobenzophenone oxime. Similarly, the closer relationship between the rates of hydrolysis of the β-*p*-bromobenzophenone oxime and *p,p'*-dibromobenzophenone oxime would assign the *syn-p*-bromophenyl configuration to the β-*p*-bromobenzophenone oxime. These configurations agree with those assigned to the α- and β-forms of this oxime by the method of Hantzsch, based on the products of the Beckmann rearrangement of the individual oximes. However, if *trans* addition of water occurs, the interpretation of the above data would reverse the assigned configurations. Thus no claim can be made for the validity of this method until further investigations have been made on other pairs of oximes. In particular data on the rates of hydrolysis of oximes whose configurations have been determined by other means are needed. This work will be done in this Laboratory.

Summary

1. The velocities of hydrolysis of benzophenone oxime, *p,p'*-dibromobenzophenone oxime and the stereoisomeric α- and β-*p*-bromobenzophenone oximes were determined under identical conditions.

2. A possible tentative method for the assignment of configurations to stereoisomeric oximes, based on a comparison of velocity of hydrolysis constants, is discussed.

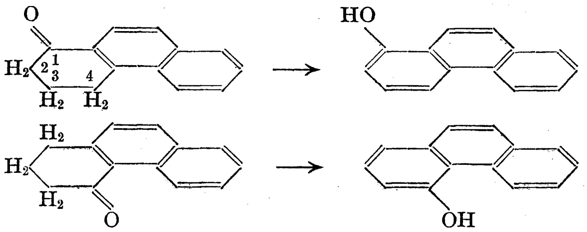
Studies in the Phenanthrene Series. XIV. The Preparation of 1- and 4-Phenanthrol

BY ERICH MOSETTIG AND HARRY M. DUVALL[1]

As starting material for the synthesis of new compounds which might possess oestrogenic activity, we were in need of several of the phenanthrols. While all five of the possible monohydroxyphenanthrenes are known, heretofore there has been no satisfactory method of preparing the 1- and 4-isomers. The total synthesis of 1- and 4-methoxyphenanthrene by Pschorr's method[2] can hardly be considered for large scale preparation. The synthesis of the 1-hydroxy- and in particular of the 4-hydroxyphenanthrene by the pyrolysis of α- and β-naphthylparaconic acid,[3] respectively, appears quite impracticable. The more recent preparations of 1-phenanthrol by potassium hydroxide fusion of the rare 1-sulfonic acid[4] and by diazotization of 1-aminophenanthrene[5] do not appear feasible.

In a previous communication of this series[6] we stated that 1-phenanthrol can be obtained from 1-keto-2-bromo-1,2,3,4-tetrahydrophenanthrene in a yield of about 50% by elimination of hydrogen bromide, while 4-phenanthrol is obtained only in small amounts by an analogous reaction. A more direct way, however, appeared to be dehydrogenation of the 1- and 4-ketotetrahydrophenanthrenes themselves, according to the scheme



The principle of this method is not new and has been applied successfully by Darzens and Levy[6,7] in the preparation of phenols from the corresponding hydroaromatic ketones, using sulfur and selenium as dehydrogenating agents. Since we found the application of these agents to the ketotetrahydrophenanthrenes not very successful,

a systematic investigation on catalytic dehydrogenation was carried out with respect to solvent, time of reaction, catalyst and amount of catalyst, which finally enabled us to prepare 1- and 4-phenanthrol in yields of 68–86% and 56–63%, respectively. As the ketotetrahydrophenanthrenes are relatively accessible,[8] this method appears to be a convenient approach to the hitherto rare 1- and 4-phenanthrol. Furthermore, we found that, with the exception of the few cases noted in Table I, the ketotetrahydrophenanthrene which was not converted to phenanthrol can be recovered nearly quantitatively.

[e] Shriner and Adams, THIS JOURNAL, **46**, 1683 (1924). [f] In the proportion 0.14 g. palladium on 0.86 g. charcoal. Ott and Schröter, *Ber.*, **60**, 633 (1927). [g] Compare Akabori and Suzuki, and Akabori and Saito, *Proc. Imp. Acad.* (Japan), **5**, 255 (1929); **6**, 236 (1930); *C. A.*, **23**, 4671 (1929); **24**, 5037 (1930). [h] See experiment without solvent, Mosettig and Burger, ref. 6. [i] All solvents were dried and purified by refluxing and distilling over sodium. [j] This solvent was chosen in view of the dehydrogenation experiments of Kindler and Peschke, *Arch. Pharm.*, **272**, 236 (1934). It is noteworthy that when platinum oxide catalyst was used, all of the ketotetrahydrophenanthrene which had not been dehydrogenated to phenanthrol could be recovered, but when palladium black catalyst was used, only about half of the expected ketotetrahydrophenanthrene could be recovered, indicating that with the latter catalyst side reactions had taken place (possibly hydrogenation by means of the fixed hydrogen of the tetralin). [k] An unidentified by-product (0.4 g.), insoluble in ether and in alkali, and sparingly soluble in benzene, melting with decomposition at about 340°, was obtained. [l] No attempt was made to work up the non-phenolic part of the reaction products. [m] No ketotetrahydrophenanthrene could be recovered. The formation of water was observed in both cases. It is very likely that phenanthrene was formed; see Cook and Hewett, *J. Chem. Soc.*, 403 (1933), who obtained phenanthrene on selenium dehydrogenation of 4-ketotetrahydrophenanthrene. [n] A by-product (1.5 g.) insoluble in ether and in alkali, but moderately soluble in benzene, melting without decomposition at 306–309°, was obtained. It is probably identical with the compound, m. p. 312°, which Cook and Hewett[m] obtained as a by-product from the selenium dehydrogenation of 4-ketotetrahydrophenanthrene. [o] The figures in this column represent the yield of about 90–95% pure phenanthrol. [p] These conditions were adopted as most satisfactory for the preparation of the phenanthrols in larger quantities. Thus, in two runs on 10.0-g. batches of 1-ketotetrahydrophenanthrene, using 0.33 g. of palladium black catalyst, we obtained yields of 82 and 84%. These yields were obtained using portions of the same catalyst. With another catalyst, prepared from the same stock of palladium chloride, the yield dropped to 68%, apparently because of uncontrollable factors in the preparation of the catalyst. 4-ketotetrahydrophenanthrene was dehydrogenated in two 25.0-g. batches, using 3.30 g. of palladium black catalyst, whereby yields of 56 and 63% were obtained.

We plan to subject the phenanthrols, in part continuing previous work,[9] to the Friedel and Crafts reaction, using various acid chlorides and anhydrides, which should give us a variety of hydroxy carbonyl compounds, including those containing a fourth ring.

Experimental Part

Dehydrogenation Experiments.—The ketotetrahydrophenanthrene was refluxed with the catalyst in ten parts

by weight of solvent. The catalyst was recovered from the reaction mixture, either by filtration of the latter, if liquid at room temperature, or by filtration of an ethereal solution of the reaction mixture. The reaction solvent was removed either by distillation under reduced pressure or by steam distillation, after removal of the ether. The residue from these distillations was then warmed for about fifteen minutes with an excess of 5% potassium hydroxide solution, and the undissolved material taken up in ether. Four or five extractions of the ethereal solution with alkali removed practically all of the phenanthrol. The alkaline extracts were combined with the first alkaline solution and acidified with concentrated hydrochloric acid, whereupon the phenanthrol separated in a crystalline state. From the residue of the ethereal solution the unreacted ketotetrahydrophenanthrene may be recovered as its semicarbazone. The results of some of the experiments are summarized in Table I.

1-Phenanthrol.—Pure 1-phenanthrol was obtained from the dehydrogenation product by one distillation at 1 mm., followed by sublimation; m. p. 153–154°.

Anal. Calcd. for $C_{14}H_{10}O$: C, 86.56; H, 5.19. Found: C, 86.21; H, 5.16.

The acetate and the methyl ether melted at 134–135° and 103–104°, respectively. The melting points agree with the corresponding values given in the literature.[2a,3a,4,6]

4-Phenanthrol.—4-Phenanthrol was purified in the same manner as the 1-isomer, and melted at 113–115°, in agreement with the value given by Mosettig and Burger.[6]

Anal. Calcd. for $C_{14}H_{10}O$: C, 86.56; H, 5.19. Found: C, 86.44; H, 5.55.

The acetate and methyl ether melted at 58–59.5° and 67–68°, respectively, in agreement with the values given in the literature.[2b,3b]

Summary

1- and 4-phenanthrol have been prepared in yields of 68–86% and 56–63%, respectively, by the catalytic dehydrogenation of 1- and 4-keto-1,2,3,4-tetrahydrophenanthrene.

The Chemical Constitution of a Bituminous Coal as Revealed by its Hydrogenation Products

BY BURNARD S. BIGGS[1] AND J. F. WEILER

In earlier contributions from this Laboratory[2] it was shown that both the extract and the residue from the extraction of a Pittsburgh seam coal with benzene at 260°, yielded, upon high pressure hydrogenation at 350° with a copper–calcium chromite catalyst, 80% of their carbon as petroleum ether soluble oils essentially hydrocarbon in nature. Boiling points, refractive indices and hydrogen–carbon ratios indicated that these hydrocarbons were partially hydrogenated polycyclic aromatic compounds. Because of (1) the nature of the catalyst employed, which is particularly effective in breaking cyclic and linear ether oxygen linkages, (2) the moderate temperatures used, which preclude appreciable degradation of hydrocarbon structures and (3) the large fraction of the carbon of the original coal converted, it appears that these oils properly may be regarded as fundamental units of the coal in the sense that the coal structure may be considered as built of such units combined through peripheral functional groups.

In this paper are presented the results so far obtained in the characterization of these oils. The oils recovered from the preliminary hydrogenation with copper–calcium chromite were completely saturated by hydrogenation over Raney nickel catalyst, then fractionally distilled and the fractions characterized through their boiling points, refractive indices, molecular weights and hydrogen–carbon ratios.

Experimental.—Both the residue and the extract from the extraction of Edenborn[3] coal with benzene at 260° were hydrogenated over Adkins catalyst by the stepwise procedure described by Biggs[2b] in which hydrogenation, followed by removal of petroleum ether soluble oils, was repeated until there was practically complete conversion to oils. From 200 g. of residue there was obtained in seven steps 24.5, 21.7, 18.6, 20.4, 26.5, 12.6 and 9.2 g., or a total of 133.5 g. of petroleum ether soluble oils containing 79.7% of the carbon of the starting materials. From 100 g. of extract there was obtained in five steps 21.5, 26.7, 19.5, 12.8 and 4.7 g., or a total of 85.2 g. of petroleum ether soluble oils representing 87% of the carbon of the original extract. The accumulated products in each case were then dissolved in benzene and subjected to a final hydrogenation over Adkins catalyst at 280° for twenty-four hours. After removal of benzene the product was dissolved in cyclohexane and subjected to hydrogenation over 10% of Raney nickel catalyst at 220° and 1800 pounds (120 atm.) initial hydrogen pressure until the absorption of hydrogen had ceased. This necessitated cooling the bomb

[a] Nos. R_1–R_5 are from the refractionation of a fraction taken off at atmospheric pressure. No. R_9 is the residue remaining in the still. No. E_6, non-distillable in the conventional apparatus, was further distilled in a molecular still, but with partial decomposition so that analytical data for this fraction are not available. [b] Reproducible to 1 part in 10. [c] Atmospheric boiling points given in brackets are estimated from values given for lower pressures.

after five hours in order to replenish the hydrogen. The total time at 220° was approximately ten hours. The oils from both the extract and the residue absorbed from 2–3 g. of hydrogen per 100 g. of oil. That hydrogen absorption had not ceased due to poisoning of the catalyst was established by the activity of the catalyst in a subsequent hydrogenation of benzene at 180°. The resulting products were freed of cyclohexane on a water-bath and then fractionally distilled at 1 mm. pressure up to a temperature of 350°.

Microanalyses for carbon and hydrogen were made on all fractions; molecular weights were determined cryoscopically in both catechol and diphenyl according to the method of Smith and Howard,[4] and the initial atmospheric boiling points and refractive indices were noted. The presence of some oxygen in the lower boiling fractions led to the estimation of hydroxyl contents by acetylation with acetic anhydride in pyridine solution.[5]

Results and Conclusions

The properties of the various fractions of the oils obtained by hydrogenation of residue and extract are given in Table I. For the purpose of comparison the properties of some known hydroaromatic compounds are given at the bottom of the table. That these fractions represent a true range of building units and not various degrees of polymerization or association of some unit or units is indicated by the close agreement of the values for the molecular weights determined in catechol and in diphenyl. In the undistilled fraction, R_9, there was some divergence which would indicate that this fraction had not been depolymerized completely. However, a further hydrogenation of this fraction at 280° for forty-eight hours produced only traces of material distilling below 400°.

An interesting point is the hydroxyl content of these supposedly hydrocarbon substances. Hydroxyl oxygen accounts for from 70–90% of the "oxygen by difference." The constant molar hydroxyl content for the various fractions from both the residue and extract suggests that oxygen-containing groups have entered into the coalification process in some systematic manner. Although the replacement of hydrogen by hydroxyl in a hydrocarbon raises the refractive index

---

[4] Smith and Howard, THIS JOURNAL, **57**, 512 (1935).

[5] Freed and Wynne, *Ind. Eng. Chem., Anal. Ed.*, **8**, 278 (1936).

slightly, the hydroxyl content of this material is sufficiently small to permit the drawing of valid conclusions concerning the nature of the hydrocarbons present from a comparison with known hydrocarbons.

If properties of known hydroaromatic compounds are compared with those of the various fractions, we find that of the residue fractions, R_1 and R_2, limpid water white liquids, correspond rather closely to decalin; R_3 and R_4, light yellow slightly viscous liquids, correspond to dodeca- and tetradecahydrophenanthrene; and R_5 and R_6, golden yellow very viscous liquids of marked tackiness, correspond to hexadeca- and octadecahydrochrysene. The inclusion of dodecahydrophenanthrene and hexadecahydrochrysene, compounds lacking two hydrogen atoms of complete saturation, in the list of completely saturated compounds for comparative purposes is justified because of the great difficulty of introducing these last two hydrogen atoms. Due to lack of data on known compounds of more than four condensed rings, we can only surmise from the regular increase in boiling points and refractive indices and from molecular weight and composition that fractions R_7, R_8 and R_9 were composed of larger members of the type assigned to the lower fractions. Thus, in molecular weight and hydrogen–carbon ratio fraction R_7 and a hypothetical seven-ring compound were nearly identical.

The fractionation of the product from the extract was not so close as that of the product from the residue and consequently we find fraction E_1, a yellow oily liquid, corresponds roughly to a mixture of decalin and the hydrophenanthrenes; fraction E_2, a yellow very viscous tacky oil, corresponds to the hydrochrysenes; and fraction E_3, a yellow resinous substance, corresponds to a hypothetical seven-ring compound.

Despite evident overlapping, it is concluded that the respective fractions are composed chiefly of the polycyclic hydrocarbons, and their isomers and homologs, to which they are found to correspond in the above comparison. Although chiefly hydrocarbon in nature, each fraction has a hydroxyl content equivalent on the average to one hydroxyl group per three hydrocarbon molecules. That coals of lower rank contain fundamental structural elements of a cyclic nature has been indicated by the fact that low temperature (290–400°) serial hydrogenation of a brown coal in presence of MoS_3 was found[6] to yield benzine and kerosene fractions consisting predominantly of aromatic and naphthenic hydrocarbons.

An approximate distribution of the various sized building units in the residue and in the extract is summarized in Table II. Although there is present in both materials upward of 50% by weight of building units of molecular weight of approximately 700, the calculated average molecular weight in both cases is about 300. This compares with the results of Smith and Howard,[4] who found molecular weights ranging from 200–300 for humic acids prepared by the oxidation of Edenborn coal.

TABLE II

APPROXIMATE DISTRIBUTION OF BUILDING UNITS IN THE EXTRACT AND RESIDUE ACCORDING TO THE NUMBER OF CONDENSED RINGS PRESENT IN THE UNITS

No. of rings	Residue		Extract	
	Mol. %	Wt.[a] %	Mol. %	Wt. %
2	18	7	27	13
3	12	7		
4	22	15	15	9
5–7	16	15	27	23
?>7	32	56	32	55

[a] Corrected for loss.

The agreement found for the distribution of units in residue and extract is further evidence in support of the viewpoint that the benzene insoluble and soluble parts of this coal differ more in the size of the polymeric aggregate than in essential chemical structure.[2b]

While in this study the general constitution and distribution of the building units in this coal have been shown, further evidence as to the exact nature of these substances is extremely desirable. The catalytic dehydrogenation of these hydroaromatic oils to the corresponding aromatic compounds to permit isolation and identification through addition compounds such as picrates is being studied in this Laboratory.

Summary

By catalytic hydrogenation, first over Adkins catalyst at 350°, and then over Raney nickel catalyst at 220°, approximately 80% of the carbon of the extract and of the residue from the benzene extraction of a Pittsburgh seam coal at 260° has been converted to hydroaromatic oils which may be regarded as the hydrocarbon skeletons of the building units in the respective materials.

Fractionation of these oils followed by charac-

[Contribution from the Chemistry Laboratory of the University of Michigan]

The Reaction between Triarylmethyl Halides and Phenylmagnesium Bromide. III. 9-Phenylxanthyl Chloride[1]

By C. S. Schoepfle and J. H. Truesdail

In 1901, Werner[2] found that xanthenol gave a colored solution with hydrochloric acid and concluded that a colored xanthyl chloride was formed. Since the benzenoid structure (I) would not account for the color of this salt, he accepted the oxonium structure (II) which had been assigned to such compounds the year before by Hewitt.[3] Bünzly and Decker[4] later prepared phenylxanthenol which likewise formed colored salts with mineral acids to which they assigned oxonium structures. Neither Werner nor Bünzly and Decker obtained the pure chlorides but they were able to isolate colored addition products with metallic salts such as ferric chloride and mercuric chloride. Xanthyl chloride and phenylxanthyl chloride were first prepared in pure form by Gomberg and Cone[5] and found to be colorless. With dry hydrochloric acid gas, however, phenylxanthyl chloride gave a red addition product containing one molecule of hydrogen chloride. The color observed by Werner and by Bünzly and Decker when xanthenols were treated with hydrochloric acid was, therefore, not due to the chlorides but to the chloride–hydrochlorides which were formed.

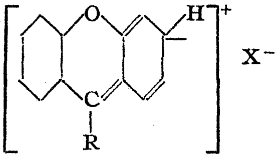
III

or



IV

X = $Cl \cdot HCl$, $Cl \cdot FeCl_3$, etc.

Gomberg and Cone assigned a quinonoid structure (III) to the colored addition products of xanthyl chlorides because of the close agreement in the properties of these compounds with the corresponding addition products of the triarylmethyl halides. One of the many arguments cited in favor of the quinonoid structure of the latter compounds was the fact that a bromine atom in the para position in bromotriphenylmethyl chloride is labile and is readily replaced when shaken with silver chloride in a sulfur dioxide solution,[6] while a bromine atom in the ortho or meta position is not replaced under any conditions. The same situation was found to exist with the xanthyl halides.[5] If the bromine atom in bromophenylxanthyl halides was in the 3-position, it was readily replaced by chlorine either by shaking with silver chloride in a benzene solution containing a small amount of hydrogen chloride, or merely by treating with excess of dry hydrochloric acid gas at room temperature. However, the bromine atom could not be replaced if it was in the phenyl group which is not a part of the xanthene ring, which showed that the phenyl group does not become quinonoid.

Further evidence that triarylmethyl halides can exist in two modifications was obtained from the reaction of triphenylchloromethane with phenylmagnesium bromide,[7] where the chloride reacts partly in the benzenoid form to give tetraphenylmethane (usually 5–8% yield), and partly in the quinonoid form to give biphenyldiphenylmethane (50–80% yield).[8] In the present paper it is shown that 9-phenylxanthyl chloride likewise reacts in two forms with phenylmagnesium bromide.

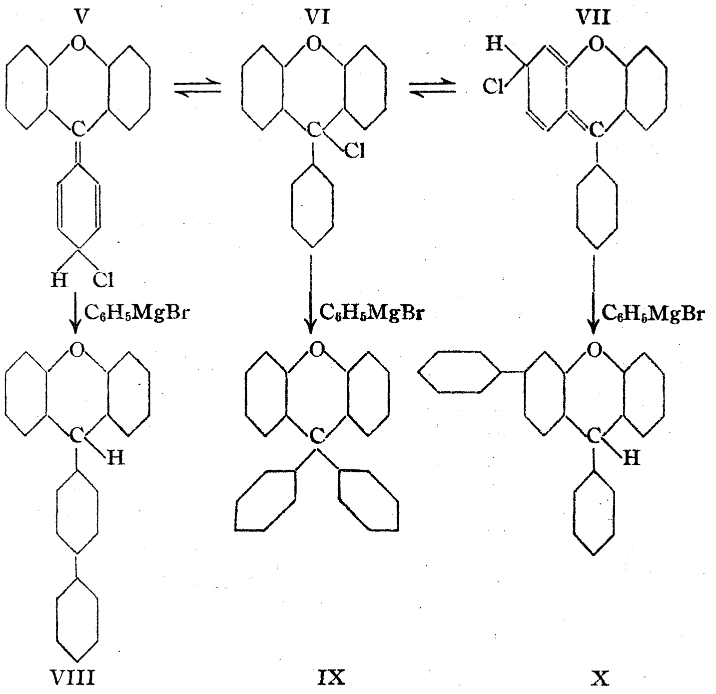
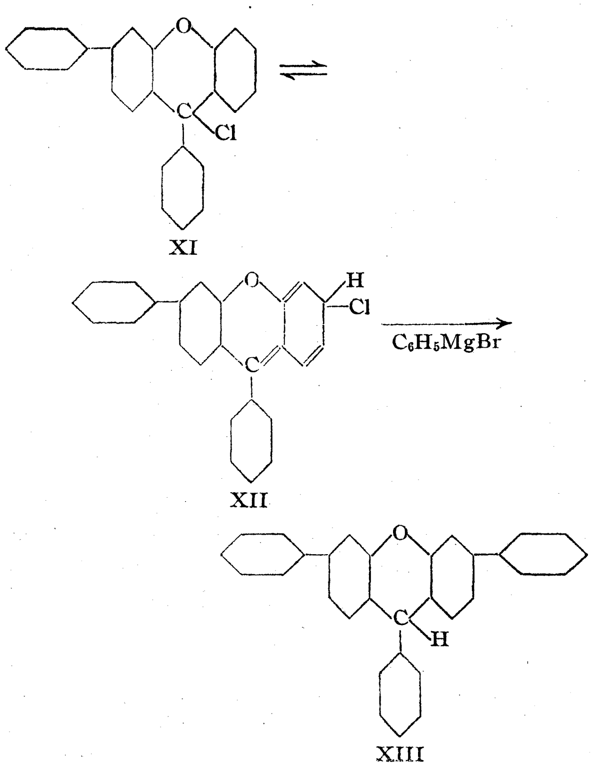
Theoretically, it is possible for 9-phenylxanthyl chloride to exist in a benzenoid modification (VI), and in two quinonoid modifications, one in which the 9-phenyl group assumes a quinonoid structure (V), and the other in which part of the xanthene ring assumes a quinonoid structure (VII). If the benzenoid form (VI) reacts with phenylmagnesium bromide, 9,9-diphenylxanthene (IX) will be obtained. However, if the quinonoid form (V) reacts, the replacement of the chlorine atom by the phenyl group gives an intermediate unstable molecule which will rearrange to 9-biphenylxanthene (VIII). Finally, if the quinonoid form (VII) reacts, then the intermediate compound obtained will rearrange to give 3,9-diphenylxanthene (X).



Only two of these three compounds were actually isolated from the reaction between 9-phenylxanthyl chloride and phenylmagnesium bromide, namely, 9,9-diphenylxanthene (IX) in traces, and 3,9-diphenylxanthene (X) in 34–51% yield. In addition, however, there were obtained 3,6,9-triphenylxanthene (XIII) in 3–14% yield and 9-phenylxanthene in 13–21% yield. (The variations in yields are due no doubt to experimental difficulty in isolating the crystalline compounds rather than to variations inherent in the reaction itself.)

3,6,9-Triphenylxanthene and 9-phenylxanthene evidently are secondary rather than primary products of the reaction. Corresponding compounds were obtained in small amounts in the reaction of triphenylchloromethane and phenylmagnesium bromide, and their formation was explained by assuming an intermolecular oxidation–reduction reaction between unreacted triphenylchloromethane and the primary reaction product, biphenyldiphenylmethane.[8b] In the present case, a similar explanation is offered. During the course of the reaction, a part of the 3,9-diphenylxanthene at the moment of formation (or the intermediate compound from which the xanthene is obtained) reacts with unchanged 9-phenylxanthyl chloride to give 9-phenylxanthene and 3,9-diphenylxanthyl chloride (XI). The latter compound will now react further with phenylmagnesium bromide and, by analogy with 9-phenylxanthyl chloride, it should react mainly in the quinonoid form (XII) to give 3,6,9-triphenylxanthene (XIII).

It has been found that in the reaction of triphenylchloromethane with phenylmagnesium bromide,[8b] the magnesium bromide present in solution favors the formation of the



quinonoid modification. This effect is shown clearly by the fact that a much higher yield of tetraphenylmethane may be obtained if triphenylchloromethane is allowed to react with diphenylmagnesium[9] in place of phenylmagnesium bromide. Magnesium bromide should induce an even higher concentration of the quinonoid modification of 9-phenylxanthyl chloride than of triphenylchloromethane, since the former becomes quinonoid more readily than the latter. However, because only a small amount of 9,9-diphenylxanthene and a large amount of 3,9-diphenylxanthene are obtained in the reaction of phenylmagnesium bromide with 9-phenylxanthyl chloride, it must not be inferred that the chloride exists principally in the quinonoid form. Instead, the probable explanation is that the rate of reaction of the benzenoid form of 9-phenylxanthyl chloride with phenylmagnesium bromide is exceedingly slow in comparison to the rate of reaction of the quinonoid form. At present, the relative rates of reaction cannot be determined because of the disturbing effect of the magnesium bromide on the equilibrium between the two forms. It is of interest to note that no 9-biphenylxanthene was isolated in the reaction, indicating that the phenyl group does not become quinonoid, which is in agreement with the results of Gomberg and Cone who found that halogens in the phenyl group were not labile.

In order to identify the products of the reaction between 9-phenylxanthyl chloride and phenylmagnesium bromide, it became necessary to synthesize 3,9-diphenylxanthene and 3,6,9-triphenylxanthene. Acetyl-4-aminobiphenyl was chlorinated in acetic acid solution and the product hydrolyzed to give 3-chloro-4-aminobiphenyl.[10] The position of the chlorine atom in this compound was established definitely by a synthesis in which diazotized 3-chloro-4-nitroaniline was coupled with benzene to give 3-chloro-4-nitrobiphenyl which was reduced to 3-chloro-4-aminobiphenyl. The products from the two procedures were identical. The Sandmeyer reaction was used to prepare 3-chloro-4-cyanobiphenyl from 3-chloro-4-aminobiphenyl and the cyanide hydrolyzed to 2-chloro-4-phenylbenzoic acid. The remaining steps in the synthesis of 3,9-diphenylxanthene were the preparation of 2-phenoxy-4-phenylbenzoic acid from 2-chloro-4-phenylbenzoic acid by the Ullmann reaction, ring closure to give 3-phenylxanthone, treatment with phenylmagnesium bromide to give 3,9-diphenylxanthenol, and finally reduction to the xanthene.

3,6,9-Triphenylxanthene was synthesized in a similar manner. 2-(3′-Phenylphenoxy)-4-phenylbenzoic acid (XIV) was obtained by the Ullmann reaction from potassium 2-chloro-4-phenylbenzoate and sodium-3-phenylphenolate. Ring closure gave two compounds, 3,6-diphenylxanthone (XV) and 1,6(or 3,8)-diphenylxanthone (XVI), of which only the one occurring in the larger amount was isolated in pure form. This compound was assigned the first structure (XV), inasmuch as ring closure of the acid should take place largely in the 6′-position since this position is para to the phenyl group and since the activity of the 2′-position should be decreased due to the blocking effect of the adjacent phenyl group. Moreover, the properties of the compound isolated were in agreement with the expectation that 3,6-diphenylxanthone would have a higher melting point and a lower solubility than the less symmetrical 1,6-diphenylxanthone. The final steps in the synthesis were the preparation of 3,6,9-triphenylxanthenol by treating 3,6-diphenylxanthone with phenylmagnesium bromide, and the reduction of the xanthenol to 3,6,9-triphenylxanthene (XIII).

pending 15 g. of the corresponding carbinol in 150 cc. of petroleum ether, adding 20 cc. of freshly distilled acetyl chloride and refluxing the mixture until all of the carbinol had dissolved. The solution was concentrated to about 75 cc. and the chloride allowed to crystallize. Moisture was excluded rigorously at all times. One recrystallization from petroleum ether gave pure colorless crystals of the chloride.

An ether solution of from 10 to 15 g. of 9-phenylxanthyl chloride was poured with swirling into an ether solution of twice the theoretical amount of phenylmagnesium bromide which was cooled in ice. Several minutes were required for the addition. At first, the Grignard solution in the vicinity of each entering drop of the chloride solution acquired an orange color which immediately disappeared, but as the reaction proceeded the solution became dark green. The mixture was refluxed for an hour, cooled and decomposed with ice and ammonium chloride. The ether extract was washed, concentrated and the product steam distilled, after which the residue was dissolved in ether and the solution dried over calcium chloride.

When the ether solution of the reaction product was allowed to evaporate spontaneously and slowly, a mass of white solid material formed which was found to be a mixture of 3,9-diphenylxanthene and 3,6,9-triphenylxanthene. The solid was filtered and washed with small amounts of cold ether, and the filtrate allowed further to evaporate very slowly. A second lot of white material was thus formed which was again composed chiefly of the above-mentioned compounds but which in some cases also contained very small amounts of 9,9-diphenylxanthene. No other substances could be isolated following this particular procedure.

The solubilities of 3,9-diphenylxanthene and 3,6,9-triphenylxanthene are very similar, hence they are difficult to separate. If the mixture was dissolved in hot acetic acid, a mass of crystals formed on cooling. When these crystals were digested with hot alcohol, a beady precipitate remained in the bottom of the flask and a flocculent precipitate became suspended in the solution, the two being separated by decantation. The flocculent precipitate was impure 3,6,9-triphenylxanthene, which could be obtained pure by repeated crystallization from ether, benzene or butanol. The beady precipitate and the material which dissolved in the alcohol was impure 3,9-diphenylxanthene, which could be obtained pure by crystallization from benzene.

Experiments indicated that no other compounds were present in appreciable amounts. Therefore, a melting point curve of known mixtures of these two compounds was prepared and the melting point of the unknown mixture was taken as a guide in estimating the percentage composition. In four typical runs, the estimated yields of 3,9-diphenylxanthene and 3,6,9-triphenylxanthene, respectively, were as follows: 34%, 14%; 43%, 3%; 51%, 6%; 51%, 14%. As mentioned previously, the variations in yield are due to experimental difficulty in isolating the crystalline compounds.

Molecular distillation with a Hickman still[12] was used in an attempt to better the yields, and if possible to isolate other products from the reaction mixture. Molecular distillation at a temperature of about 125° gave a large amount of material, part of which sublimed to the top of the still and part of which distilled into the receiver. Crystallization of the sublimed material from alcohol gave well formed crystals melting at 140–141° which showed no lowering in melting point when mixed with authentic 9-phenylxanthene. The distillate in the receiver was found to be a mixture of 9-phenylxanthene and 3,9-diphenylxanthene, from which the latter could be obtained in pure state by repeated recrystallization from alcohol. 3,6,9-Triphenylxanthene could not be recovered in this manner since when the temperature of the still was raised to 150°, decomposition occurred as was evidenced by blackening of the residue and evolution of gas.

The amount of 9-phenylxanthene present in the reaction mixture was determined by removing it by sublimation at 0.001 mm. pressure and 100°. The molecular sublimation apparatus was patterned after the still described by Carothers.[13] The quantities obtained in three experiments were 21, 13 and 19%, respectively.

9-(*p*-Biphenyl)-xanthenol.—Xanthone was added to an ether solution of excess *p*-biphenylmagnesium bromide and the mixture refluxed overnight. After chilling in an ice–salt-bath, the precipitate was filtered and decomposed with ice and hydrochloric acid. The ether extract was filtered to remove a small amount of insoluble dibiphenyl, then concentrated and steam distilled, and the residue dissolved in benzene from which practically pure biphenylxanthenol crystallized. Recrystallized from ether, the compound melted at 178–179°; yield, 85%. The carbinol gives a deep red color with concentrated sulfuric acid.

Anal. Calcd. for $C_{25}H_{18}O_2$: C, 85.69; H, 5.18. Found: C, 85.38; H, 5.23.

9-(*p*-Biphenyl)-xanthene.—One gram of 9-(*p*-biphenyl)-xanthenol and 10 g. of dry sodium formate were added to 30 cc. of anhydrous formic acid and the mixture refluxed for one hour. At first, a deep red color was obtained but this soon disappeared and the xanthene crystallized. After dilution with water, the product was filtered and dried. Recrystallization from benzene gave colorless crystals which melted at 206–207°; yield, 95%.

Anal. Calcd. for $C_{25}H_{18}O$: C, 89.78; H, 5.43. Found C, 89.65; H, 5.49.

3-Bromo-4-methylbiphenyl.—Forty-four grams of 2-bromo-4-aminotoluene hydrochloride was treated with 25 cc. of concentrated hydrochloric acid, the mixture cooled in an ice–salt-bath and 18 cc. of water added. When cold a saturated solution of 16 g. of sodium nitrite was added dropwise to the mechanically stirred solution. Following the procedure of Gomberg and Bachmann,[14] the solution of the diazonium chloride was poured into 150 cc. of pure benzene at 5°, and 25 cc. of 40% sodium hydroxide solution added drop by drop over two hours, keeping the temperature below 9°; nitrogen was evolved. The stirring was continued for two to three hours. The resulting mixtures from two such runs were combined, the benzene layer concentrated and the product steam distilled at a temperature of 170–190°. About eight liters of distillate were caught, extracted with ether and the extract concentrated.

[14] Gomberg and Bachmann, *ibid.*, **46**, 2339 (1924); Gomberg and Pernert, *ibid.*, **48**, 1372 (1926).

Distillation at 2 mm. pressure gave a light yellow oil which boiled at 123–123.5° and melted at 9°; yield 30%.

Anal. Calcd. for $C_{13}H_{11}Br$: Br, 32.36. Found: Br, 32.18.

Various attempts to oxidize 3-bromo-4-methylbiphenyl to 2-bromo-4-phenylbenzoic acid gave unsatisfactory yields.

3-Chloro-4-nitrobiphenyl.—Nineteen grams of 3-chloro-4-nitroaniline was heated to 70° with 45 cc. of concentrated hydrochloric acid, cooled, and diazotized by introducing a concentrated solution of sodium nitrite below the surface of the acid. The diazonium chloride solution was poured into 75 cc. of benzene, and 45 cc. of 40% sodium hydroxide solution added dropwise to the vigorously stirred mixture. The benzene solution was concentrated and the product distilling at 160–180° at 2 mm. pressure was crystallized from alcohol. Yellowish needles were obtained, melting at 78.5–79.5°; yield, 20%.

Anal. Calcd. for $C_{12}H_8ClNO_2$: Cl, 15.15. Found: Cl, 14.97.

3-Chloro-4-aminobiphenyl.—A solution of 10 g. of hydrated stannous chloride in 10 cc. of concentrated hydrochloric acid was poured slowly into a solution of 2 g. of 3-chloro-4-nitrobiphenyl in 15 cc. of alcohol. Repeated crystallization of the amine from dilute alcohol gave a compound melting at 69–69.5°. A mixed melting point showed that this compound was identical with the compound which Scarborough and Waters[10] obtained by chlorinating acetyl-4-aminobiphenyl and hydrolyzing the product. The latter method was therefore used for the preparation of further amounts of this amine.

3-Chloro-4-cyanobiphenyl.—This compound was obtained from 3-chloro-4-aminobiphenyl by the Sandmeyer reaction. The cuprous cyanide solution (150 cc.) was prepared in the usual manner from 18 g. of sodium cyanide, and was covered with 100 cc. of benzene and cooled to 5°. Twenty-four grams of 3-chloro-4-aminobiphenyl hydrochloride was suspended in 15 cc. of concentrated hydrochloric acid plus a small amount of ice and diazotized with a concentrated solution of sodium nitrite. The excess acid was made neutral to congo red paper with sodium bicarbonate solution and then added slowly to the vigorously stirred cuprous cyanide solution. The products of several such runs were combined and the benzene layer separated and washed with sodium carbonate solution and with water. Distillation at 2 mm. pressure followed by crystallization from alcohol gave the pure cyanide melting at 101–101.5°; yield 30%.

Anal. Calcd. for $C_{13}H_8ClN$: Cl, 16.60. Found: Cl, 16.39.

2-Chloro-4-phenylbenzoic Acid.—Twenty grams of 3-chloro-4-cyanobiphenyl was dissolved in 240 cc. of alcohol and 75 g. of 40% sodium hydroxide solution, and refluxed about six hours. The solution was cooled, poured into a liter of water, filtered, and the acid precipitated with hydrochloric acid. Crystallization from alcohol after treatment with norite gave white needles melting at 166.5–167°; yield 90%.

Anal. Calcd. for $C_{13}H_9ClO_2$: Cl, 15.25. Found: Cl, 15.19.

2-Phenoxy-4-phenylbenzoic Acid.—The potassium salt of 2-chloro-4-phenylbenzoic acid was prepared by dissolving the equivalent weights of the acid and of potassium carbonate in water, filtering the solution and concentrating to dryness on the sand-bath. To 3.5 g. of the salt was added 3.0 g. of phenol and a solution of sodium methylate prepared from 0.4 g. of sodium and 40 cc. of methanol, and the mixture refluxed until all the salt had dissolved. About 0.1 g. of copper powder was added and the methanol removed by distillation, after which the flask was placed in an oil-bath and the temperature slowly raised to 150°. At this temperature the reaction takes place rapidly and the temperature of the melt may reach 165–170°. After a few minutes the melt was cooled and digested with about 20 cc. of cold 5% sodium hydroxide solution. The phenol and original acid are quite soluble while the sodium salt of 2-phenoxy-4-phenylbenzoic acid is practically insoluble even in 1% sodium hydroxide solution. If necessary, the sodium salt may be purified readily by recrystallization from water. The acid was obtained by adding hydrochloric acid to a water solution of the sodium salt. Crystallization from alcohol or benzene gave colorless leaflets or small plates which melted at 169.5–170°; yield 80%.

Anal. Calcd. for $C_{19}H_{14}O_3$: C, 78.59; H, 4.87. Found: C, 78.51; H, 4.99.

3-Phenylxanthone.—When ring closure of 2-phenoxy-4-phenylbenzoic acid was attempted using hot concentrated sulfuric acid as the agent, a very poor yield of the xanthone was obtained; most of the product was water soluble and had a high melting point, indicating that sulfonation had occurred. The following procedure proved to be more satisfactory. Three grams of 2-phenoxy-4-phenylbenzoic acid was dissolved in 35 cc. of dry benzene, 3 g. of phosphorus pentachloride was added and the mixture heated. The solution thus obtained was cooled, 4 g. of anhydrous aluminum chloride added, and the mixture refluxed until no more hydrogen chloride was evolved. After treatment with ice, the product was steam distilled and the residue crystallized from alcohol or petroleum ether. Colorless needles were obtained melting at 141–141.5°; yield 95%.

Anal. Calcd. for $C_{19}H_{12}O_2$: C, 83.80; H, 4.45. Found: C, 83.50; H, 4.55.

3,9-Diphenylxanthenol.—A benzene solution of 3-phenylxanthone was added to an ether solution of excess phenylmagnesium bromide, the mixture refluxed for one hour and then decomposed with ice and ammonium chloride. The benzene–ether layer was concentrated, steam distilled and the residue dissolved in hot petroleum ether. Colorless crystals were obtained which upon recrystallization from benzene–petroleum ether melted at 128.5–129°; yield 90%. With concentrated sulfuric acid, the carbinol gives a light red color with yellow-green fluorescence.

Anal. Calcd. for $C_{25}H_{18}O_2$: C, 85.69; H, 5.18. Found: C, 85.49; H, 5.24.

3,9-Diphenylxanthene.—This compound was obtained by the reduction of 3,9-diphenylxanthenol with formic acid following the procedure described for the preparation of 9-biphenylxanthene. Crystallization from alcohol or petroleum ether gave colorless needles which melted at 146.5–147°; yield 95%.

Anal. Calcd. for $C_{25}H_{18}O$: C, 89.78; H, 5.43. Found: C, 89.53; H, 5.43.

2-(3′-Phenylphenoxy)-4-phenylbenzoic Acid.—3-Nitrobiphenyl was prepared by coupling diazotized *m*-nitraniline with benzene in alkaline solution,[15] and was reduced to 3-aminobiphenyl which was diazotized and added to boiling 30% sulfuric acid[16] to give 3-hydroxybiphenyl.

Four grams of potassium 2-chloro-4-phenylbenzoate, 3 g. of 3-hydroxybiphenyl and a methanol solution of sodium methylate prepared from 0.35 g. of sodium were placed in a flask, sufficient methanol being used so that the contents dissolved on refluxing. About 0.1 g. of copper powder was then added and the methanol removed by distillation, after which the flask was placed in an oil-bath and the temperature gradually raised. The reaction takes place readily at 150° and when the temperature of the bath reached 180° the flask was removed and the contents dissolved in about two liters of water containing a few grams of potassium hydroxide, after which the solution was filtered and the 2-(3′-phenylphenoxy)-4-phenylbenzoic acid precipitated with hydrochloric acid. Recrystallization from benzene or alcohol gave small, colorless needles which melted at 186–187°; yield 50–60%.

Anal. Calcd. for $C_{25}H_{18}O_3$: C, 81.93; H, 4.95. Found: C, 81.52; H, 4.95.

3,6-Diphenylxanthone.—Ring closure of 2-(3′-phenylphenoxy)-4-phenylbenzoic acid was accomplished with phosphorus pentachloride and aluminum chloride following the procedure described for the preparation of 3-phenylxanthone. A quantitative yield of crude material was obtained which appeared to be a mixture of 3,6-diphenylxanthone and 1,6-diphenylxanthone. Crystallization of this mixture from 1:1 methanol–benzene gave about a 35% yield of colorless needles which melted at 193.5–194.5°. The reasons for believing this compound to be 3,6-diphenylxanthone have been stated previously. The isomeric 1,6-diphenylxanthone was not obtained in pure form.

Anal. Calcd. for $C_{25}H_{16}O_2$: C, 86.18; H, 4.63. Found: C, 85.56; H, 4.64.

3,6,9-Triphenylxanthenol.—3,6-Diphenylxanthone, dissolved in benzene, was added to an ether solution of excess phenylmagnesium bromide and the mixture refluxed for about an hour. The product was decomposed with ammonium chloride and ice, and the ether extract concentrated and steam distilled. Crystallization of the residue from benzene gave colorless crystals which decomposed at 238–239°; yield 90%. With concentrated sulfuric acid, the carbinol gives a light red color with yellow-green fluorescence.

Anal. Calcd. for $C_{31}H_{22}O_2$: C, 87.29; H, 5.20. Found: C, 86.90; H, 5.32.

3,6,9 - Triphenylxanthene.—3,6,9 - Triphenylxanthenol was reduced to 3,6,9-triphenylxanthene by formic acid using the procedure previously described. Crystallization from benzene–petroleum ether gave small colorless plates which decomposed at 220°; yield 95%.

Anal. Calcd. for $C_{31}H_{22}O$: C, 90.69; H, 5.41. Found: C, 90.24; H, 5.42.

Summary

The reaction between 9-phenylxanthyl chloride and phenylmagnesium bromide has been studied, and it has been found that the chloride reacts largely in a quinonoid form and only to a limited extent in the benzenoid form. A number of xanthene derivatives have been prepared and described.

The Structure of Metal Ketyls. V. The Conductance Function

BY CHARLES BUSHNELL WOOSTER

I. Introduction

Previous papers in this series[1] have reported some studies of the chemical reactions of monosodium benzophenone in liquid ammonia solution. It has become increasingly evident that such solutions comprise a system of rather complex equilibria and that further progress on the problem of the structure of metal ketyls would be facilitated greatly by more accurate information regarding the nature and interrelations of these equilibria. It is the purpose of the present paper to show that the conductance of sodium benzophenone in liquid ammonia as measured by Kraus and Bien[2] may be described quantitatively by assuming the presence of the following equilibria

$$[(C_6H_5)_2CO]Na \rightleftharpoons [(C_6H_5)_2CO]^- + Na^+ \tag{1}$$

$$2[(C_6H_5)_2CO]Na \rightleftharpoons (C_6H_5)_2C(ONa)\text{—}C(ONa)(C_6H_5)_2 \tag{2}$$

$$(C_6H_5)_2C(ONa)\text{—}C(ONa)(C_6H_5)_2 \rightleftharpoons Na^+ + Na[(C_6H_5)_2CO]_2^- \tag{3a}$$

$$[(C_6H_5)_2CO]Na + [(C_6H_5)_2CO]^- \rightleftharpoons Na[(C_6H_5)_2CO]_2^- \tag{3b}$$

that is, simple ionization of the metal ketyl (1), association of the metal ketyl molecules (ion pairs) to the un-ionized pinacolate (2), and formation of

triple ions by primary ionization of the pinacolate (3a) or by reaction between simple metal ketyl anions and metal ketyl ion pairs (3b). Only three of these four equilibria are independent and for the purpose of mathematical convenience equilibrium 3b has been chosen in preference to 3a as the basis of analysis; the reasons for omitting equilibria involving doubly charged pinacolate anions are discussed in the fourth section of this paper.

Kraus and Bien found that the conductance curve did not correspond to a simple binary equilibrium (as, for instance, that expressed in equation 1), and also noted that the equivalent conductance was much higher than that of the structurally similar salt, sodium benzohydrolate, at corresponding concentrations. They did not attempt further analysis of the conductance curve. According to the present interpretation the higher conductance may be attributed[3] in part to the presence of the third ionic species (triple ions) formed in accordance with equation 3b. This triple ion equilibrium bears a formal resemblance to that discussed by Fuoss and Kraus[4] but is distinctly different in two important respects. First, the triple ion formation is in the present instance due primarily to the quantum forces involved in the formation of a carbon–carbon bond. It is this fact which permits these triple ions to play an important part in the conduction process at concentrations between 0.01 and 0.0001 N in liquid ammonia where the formation of triple ions as the result of coulomb forces alone is excluded by the high dielectric constant of the medium. Second, these quantum forces operate only between the ion pair and an *anion;* there is no corresponding tendency toward triple ion formation by combination of an ion pair with a cation. As a result of this unilateral triple ion formation, the conductance function differs from that deduced by Fuoss and Kraus[4] for bilateral triple ion formation.

In Section II the conductance function for unilateral triple ion formation is derived and compared with the experimental results in the region 0.001–0.0001 N where the influence of the equilibrium expressed in equation 2 is negligible. In Section III the association of the ion pairs is considered and in Section IV the bearing of the results on the problem of the structure of the metal ketyls is discussed.

II. Unilateral Triple Ion Formation

For simplicity and for convenient comparison with the equations of Fuoss and Kraus we shall first consider the case of very low ion concentrations, where the activity coefficients and (square root) mobility corrections may be set equal to unity, and where the fraction of solute present as ions may be neglected in comparison with unity.

Abbreviating the simple ions as A^+ and B^- and representing the complex species in a corresponding manner, the mass action equation for the binary equilibrium

$$[A^+][B^-]/[AB] = K \qquad (4)$$

then reduces to

$$C\gamma(\gamma + \gamma_3) = K \qquad (5)$$

where C is the total concentration, K is the mass action constant, and γ and γ_3 are the ratios of the concentrations of the simple anions and the triple anions, respectively, to the stoichiometric concentration.[5]

The mass action equation for the triple ion formation

$$[AB][B^-]/[AB_2^-] = k \qquad (6)$$

reduces to

$$C\gamma/\gamma_3 = k, \ \gamma_3 = C\gamma/k \qquad (7)$$

and the observed conductance Λ is given by

$$\Lambda = \gamma\Lambda_0 + \gamma_3\lambda_0 \qquad (8)$$

where Λ_0 is the sum of the limiting conductances of the two simple ions, and λ_0 the sum of the limiting conductances of the triple ions and of the simple cations.

Solving equations 5 and 7 for γ and γ_3, substituting in equation 8 and simplifying gives

$$\Lambda(1 + C/k)^{1/2} = (\Lambda_0\sqrt{K})/\sqrt{C} + (\lambda_0\sqrt{K}/k)\sqrt{C} \qquad (9)$$

which differs from the corresponding equation of Fuoss and Kraus[6] by the coefficient of Λ. This coefficient prevents the equation from assuming a linear form on multiplication by $\sqrt{C}$, but a linear equation may be obtained from equation 9 in the following way. If we multiply equation 9 by $\sqrt{C}$, add and subtract $(C\Lambda_0\sqrt{K}/k)$ on the right-hand side of the equation, divide by $(1 + C/k)^{1/2}$, square both sides and simplify, we obtain

---

[3] This interpretation supersedes the suggestion made in the previous paper, ref. 1d. However, it is possible that a part of this higher conductance may be due to a resonance phenomenon (discussed in the latter part of this paper) and therefore to this extent it may be the result of a certain analogy between sodium benzophenone and sodium triphenylmethyl.

[4] Fuoss and Kraus, This Journal, **55**, 2387 (1933).

[5] If C represents the total concentration in equivalents (as AB) per liter and the quantities in brackets represent concentrations of the included species, then $[B^-] = C\gamma$, $[AB_2^-] = C\gamma_3$, $[A^+] = C(\gamma + \gamma_3)$ and $[AB] = C(1 - \gamma - 2\gamma_3)$. In the simplified expressions above $(1 - \gamma - 2\gamma_3)$ is set equal to unity.

[6] Ref. 4, equation 4.

$$C\Lambda^2 = \Lambda_0^2K + [2\lambda_0/\Lambda_0 - 1 + (1 - \lambda_0/\Lambda_0)^2/(1 + k/C)]\Lambda_0^2KC/k \qquad (10)$$

The term $(1 - \lambda_0/\Lambda_0)^2/(1 + k/C)$ becomes negligible at sufficiently low concentrations and at high concentrations approaches asymptotically the limit $(1 - \lambda_0/\Lambda_0)^2$. Accordingly, this entire term may be neglected when the value of λ_0/Λ_0 is sufficiently close to unity to render $(1 - \lambda_0/\Lambda_0)^2$ negligible with respect to $(2\lambda_0/\Lambda_0 - 1)$. Under these conditions equation 10 assumes the following form which is linear with respect to the variables $C\Lambda^2$ and C.

$$C\Lambda^2 = \Lambda_0^2K + C(2\Lambda_0\lambda_0 - \Lambda_0^2)K/k \qquad (11)$$

This equation is, of course, applicable only to instances of unilateral triple ion formation at low total ion concentrations as for instance in dilute solution in a solvent of low dielectric constant. In order to apply it to solutions in solvents of higher dielectric constant such as liquid ammonia it is necessary to include the interionic terms in $\sqrt{C}$ in activity and mobility as well as the fraction of un-ionized solute which may no longer be set equal to unity. These corrections may be approximated in the manner of Fuoss and Kraus[4] by substituting $2C\Lambda/\Lambda_0$ for the ion concentration $2C(\gamma + \gamma_3)$ in the usual formulas and applying the results as appropriate correction terms to (11).

If the various corrections are made to (5), (7) and (8), by introducing the activity coefficient f defined by the relation $-\log f = \beta\Lambda_0^{-1/2}\sqrt{C\Lambda}$, a mobility coefficient $m = 1 - \alpha\Lambda_0^{-3/2}\sqrt{C\Lambda}$ and the term $(1 - \Lambda/\Lambda_0)$ as an approximation for the un-ionized fraction of the solute, we obtain

$$\begin{aligned} &Cf^2\gamma(\gamma + \gamma_3)/(1 - \Lambda/\Lambda_0) = K \\ &C\gamma(1 - \Lambda/\Lambda_0)/\gamma_3 = k \\ &\gamma_3 = C\gamma(1 - \Lambda/\Lambda_0)/k, \text{ and} \\ &\Lambda = m(\gamma\Lambda_0 + \gamma_3\lambda_0) \end{aligned}$$

Combining these equations[7] yields the corrected form of equation 11

$$\left(\frac{f\Lambda}{m}\right)^2 \frac{C}{(1 - \Lambda/\Lambda_0)} = \Lambda_0^2K + \frac{(2\Lambda_0\lambda_0 - \Lambda_0^2)K}{k}\left(1 - \frac{\Lambda}{\Lambda_0}\right)C \qquad (12)$$

Comparison with Experiment.—In order to apply equation 12 to the conductance data on monosodium benzophenone, it is necessary to choose a value for Λ_0. As a matter of fact, the linearity of the equation is not very sensitive to the value of Λ_0 chosen, which therefore need only be approximate. In consequence, however, equation 12 is of little assistance in suggesting a choice of Λ_0. Fortunately this constant may be closely approximated from a knowledge of the conductance of similar salts in liquid ammonia. The limiting equivalent conductance of the sodium ion in liquid ammonia[8] is known to be 130 and the limiting equivalent conductances, Λ_0', of a number of anions in liquid ammonia[8] are collected in Table I.

TABLE I

CONSTANTS OF ELECTROLYTES IN AMMONIA

No.	Salt	Λ_0	Λ_0'	$K \times 10^4$	$a \times 10^8$
1	KNH_2	351	187	0.7	2.2
2	$NaNHC_6H_5$	316	(186)	8.2	3.1
3	$NaOC_6H_5$	279.4	149.3	3.82	2.7
4	$NaN(C_6H_5)_2$	235	105	58	6.7
5	$KN(C_6H_5)_2$	266	102	50.5	6.0
6	$NaSn(C_6H_5)_3$	226	96	130	(10.4)
7	$KNH_2 \cdot B(C_6H_5)_3$	257	93	130	10.4
8	$NaNH_2 \cdot B(C_6H_5)_3$	215	85	150	10.9

Since the values of Λ_0' in a given solvent at a fixed temperature are doubtless primarily determined by the size of the migrating ion, the value of Λ_0' for the ion $[(C_6H_5)_2CO]^-$ may be expected to lie between the limits 96 and 105 and to be closer to the upper than to the lower limit. For purposes of calculation the upper value has been chosen so that $\Lambda_0 = 235$. The value of λ_0' may be estimated from the assumed value of Λ_0 by means of Stokes's law to be approximately 77, corresponding to $\lambda_0 = 207$. On this basis, the maximum alteration in the slope of the plot due to the neglected term of equation 10 would be 1.87%, which is well within the limits of experimental error.

A plot of $f^2C\Lambda^2/m^2(1 - \Lambda/\Lambda_0)$ against $C(1 - \Lambda/\Lambda_0)$ appears in Fig. 1 and, in conformity with the requirements of equation 12, this plot is linear throughout the dilution range 10^3–10^4 liters. The values of the constants obtained from the intercept and slope are, respectively, $\Lambda_0^2K = 5.6$ and $(2\Lambda_0\lambda_0 - \Lambda_0^2)K/k = 2.4 \times 10^3$. Introducing the estimated values of Λ_0 and λ_0, the following values are obtained for the mass action constants: $K = 1.01 \times 10^{-4}$ and $k = 1.8 \times 10^{-3}$.

III. The Association of Ion Pairs

At concentrations above 0.001 N the equivalent conductance of monosodium benzophenone falls below that predicted by equation 12. This deviation may be due in part to the failure at higher ion concentrations of the approximations intro-

---

[7] The coefficients α and β have the same significance as in the paper of Fuoss and Kraus [THIS JOURNAL, **55**, 476 (1933)]. In liquid ammonia at its boiling point $\alpha = 2.133\Lambda_0 + 442$ and $\beta = 4.742$.

[8] Fuoss and Kraus, *ibid.*, **55**, 1027 (1933); Kraus and Hawes, *ibid.*, **55**, 2784 (1933); Kraus and Kahler, *ibid.*, **55**, 3541 (1933); Kraus and Johnson, *ibid.*, **55**, 3545 (1933).

duced in the estimate of the activity and mobility terms, etc. However, these deviations seem to be much larger than would be expected on this basis alone and it is likely that they are due primarily to a reduction in the concentration of the ion pairs as the result of association in accordance with equation 2.

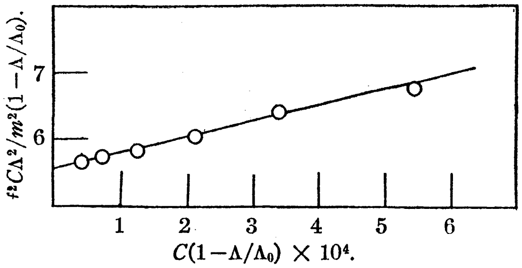

Fig. 1.—Unilateral triple ion formation.

Equation 12 may be corrected for this effect by introducing the term $C\gamma_2(1 - \Lambda/\Lambda_0)$ in place of $C(1 - \Lambda/\Lambda_0)$ for the concentration of the ion pairs, (γ_2 represents the fraction of non-conducting solute present as ion pairs) and assumes the form

$$\left(\frac{f\Lambda}{m}\right)^2 \frac{C}{(1-\Lambda/\Lambda_0)\gamma_2} = \Lambda_0^2K + \frac{(2\Lambda_0\lambda_0 - \Lambda_0^2)K}{k}\left(1-\frac{\Lambda}{\Lambda_0}\right)C\gamma_2 \qquad (13)$$

The mass action equation for ion pair association

$$[AB]^2/[A_2B_2] = k_4 \qquad (14)$$

reduces to

$$2C\gamma_2^2(1-\Lambda/\Lambda_0)/(1-\gamma_2) = k_4 \qquad (15)$$

and the required values of γ_2 could be obtained if k_4 were known. Conversely k_4 should be determined by the values of γ_2 required to satisfy equation 13. These may be obtained from the experimental results by substituting the constants as determined at lower concentrations in equation 13 and solving for γ_2. Since equation 15 may be transformed as follows

$$2C\gamma_2(1-\Lambda/_0) = k_4/\gamma_2 - k_4 \qquad (16)$$

the values of γ_2 may be tested for conformity with the mass action equation by plotting $2C\gamma_2(1 - \Lambda/\Lambda_0)$ against $1/\gamma_2$. The plot should yield a straight line crossing the $1/\gamma_2$ axis at unity and k_4 may be obtained from either the slope or the other intercept. Such a plot appears in Fig. 2 from which it is evident that the values of γ_2 comply satisfactorily with the stated requirements over the dilution range 50–800 liters, yielding the value $k_4 = 1.56 \times 10^{-2}$.

Calculation of the Conductance Curve.—The conductance curve may be calculated from the final conductance equation (13) in the following way. Abbreviating $C(1 - \Lambda/\Lambda_0)$ to x and substituting the values of the constants, equation 13 may be solved readily for $f C\Lambda/m$

$$fC\Lambda/m = \sqrt{5.6x\gamma_2 + 2400(x\gamma_2)^2} \qquad (17)$$

and, similarly, equation 15 may be solved for γ_2

$$10^2\gamma_2 = -0.39/x + \sqrt{(0.39/x)^2 + 78/x} \qquad (18)$$

Thus by substituting arbitrary values of x, the corresponding values of $fC\Lambda/m$ may be obtained from equations 18 and 17. Since $fC\Lambda/m$ is a function of $C\Lambda$ and known constants (Λ_0, β and α), the corresponding values of $C\Lambda$ may be read from a plot of $fC\Lambda/m$ against $C\Lambda$. The concentration corresponding to the chosen value of x is then given by $C = x + C\Lambda/\Lambda_0$ and Λ may be obtained from C and $C\Lambda$. Of course, for sufficiently low values of x it is possible to set $\gamma_2 = 1$ and dispense with the use of equation 18.

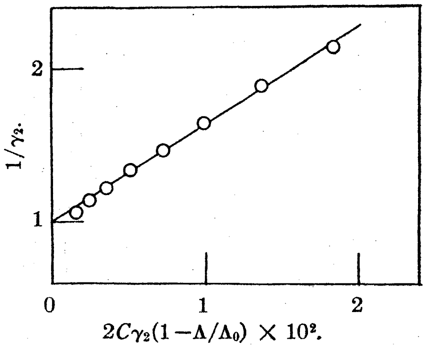

Fig. 2.—Ion pair association.

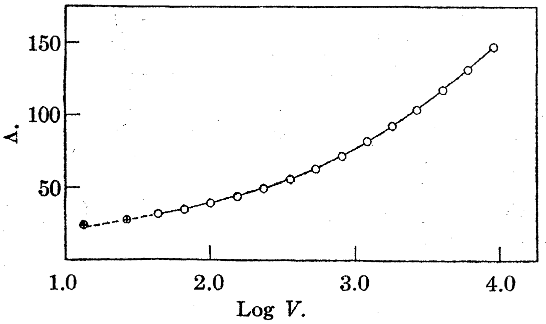

Fig. 3.—The conductance curve.

In Fig. 3 a plot of Λ against log V is shown in which the calculated values are represented by the continuous curve and the experimental values by the circles. In addition to the published values, Kraus and Bien obtained two series of lesser accuracy. These measurements show erratic deviations at high dilutions, but at higher concentrations, where they are more reliable, the two series agree with the calculated curve within the limits of experimental error. Two measurements from one of these series, which were made at higher concentrations than any of the published values, are indicated in Fig. 3 by the crossed circles and lie reasonably close to the calculated curve. The extrapolated portion of this curve is represented in the figure by a broken line.

IV. Discussion of Results

There can be no doubt that the final conductance equation adequately reproduces the experimental data and there is no reason to question the existence of the postulated equilibria involving the five solute species: AB, A_2B_2, A^+, AB_2^-, B^-. The existence of the simple ions and the corresponding ion pairs is indicated by all the well-known evidence in favor of the free radical nature of the metal ketyls, and association to the pinacolate (A_2B_2 or its ions) has been demonstrated both in ether[9] and in liquid ammonia solution.[1b] The omission of the sixth solute species (B_2^{--}, the doubly charged pinacolate anion) in the formulation of the conductance equation was based on the assumption that this ion would be too highly dissociated (in virtue of the electrostatic repulsion of the two negative charges) to play a significant part in the conduction process. Although there is no entirely independent evidence in support of this assumption, it is interesting to note that the assumption may be shown to be consistent with the observed values of the mass action constants.

The primary ionization constant of the pinacolate, K_4, may be calculated from the other three constants

$$[A^+][AB_2^{--}]/[A_2B_2] = K_4 = Kk_4/k = 8.75 \times 10^{-4}$$

and from this value the corresponding secondary ionization constant, $K_3 = [A^+]\,[B_2^{--}]/[AB_2^-]$, may be estimated roughly to be 5.23×10^{-7} by suitable modifications of the method of Fuoss and Kraus.[10] Since the concentration of sodium ions cannot be less than that of the triple anions ($[A^+] > [AB_2^-]$), the concentration of pinacolate anions, $[B^{--}]$, cannot exceed 5.23×10^{-7}. The ratio of the concentration of the pinacolate anions to that of the simple anions is proportional to the square root of the former

$$[B_2^{--}]/[B^-] = (K_3[B_2^{--}]/kK)^{1/2} = 1.7[B_2^{--}]^{1/2}$$

and on substituting 5.23×10^{-7} as the maximum value of $[B_2^{--}]$, the maximum value of the ratio is found to be 1.23×10^{-3}, which implies that only a negligible fraction of the current is carried by the doubly charged pinacolate anions at any concentration.

For these reasons we may proceed to discuss the significance of the results with respect to the structural problems of the metal ketyls on the assumption that the observed mass action constants represent the true values within the limits of error imposed by the approximations introduced in the correction terms for mobility, activity and un-ionized fraction.

The Structure of the Ion Pair.—Previous studies of the reaction between the metal ketyl and alkyl halides[1] have furnished evidence that the observed carbon alkylation occurs in the first step of the reaction, presumably as the result of a simple substitution process. On this basis, the suggestion was made that the charge on the metal ketyl anion was not located exclusively on the oxygen atom, but was "shared" to some extent with the extra-nuclear carbon. The available chemical evidence does not permit a precise definition of the term "shared"; this evidence is equally compatible with a model involving a triple electron bond between carbon and oxygen and with a resonance model,[11] including in the complete wave equation the structures $(C_6H_5)_2\underset{\cdot}{C}:\underset{\cdot\cdot}{\ddot{O}}:$ and $(C_6H_5)_2\underset{\cdot\cdot}{C}:\underset{\cdot}{\ddot{O}}:$ together with many others which locate the charge on quinonoid rings. Furthermore, the extent to which a similar sharing is involved in the structure of the ion pair is not revealed by the chemical evidence, for it is even conceivable that the ion pairs undergo alkylation only after a preliminary separation into free ions.[12]

---

[9] Bachmann, THIS JOURNAL, **55**, 1179 (1933).

[10] Fuoss and Kraus, *ibid.*, **55**, 1021–1024 (1933). When one ion is doubly charged, equation 6 of Fuoss and Kraus assumes the form

$$K_3^{-1} = \frac{4\pi N}{1000}\left(\frac{2e^2}{DkT}\right)^3 Q(b)$$

where $Q(b)$ is the function tabulated by these authors and $b = 2e^2/aDkT$. In making the above estimate, the fact that the two charges in the pinacolate anion are not located at the same point was ignored. This corresponds very crudely to the assumption that the sodium ion is equidistant from the two negative charges in the triple ion. The value used for the parameter a was that corresponding to the primary ionization constant, K_4. Since K_4 is greater than K, it is possible that repulsion between the sodium ions in the pinacolate may play a part in determining K_4. Such repulsion is absent in the triple ion and *on this basis* it would be predicted that the parameter a corresponding to K_3 should be less than that assumed and, accordingly, the estimated value of K_3 might be regarded as a maximum.

[11] (a) Pauling and Wheland, *J. Chem. Phys.*, **1**, 362 (1933); (b) Bent and Keevil, *ibid.*, **58**, 1370 (1936).

[12] It is, perhaps, desirable to state here that the phrase "carbon–sodium bond in the metal ketyl" used in the previous paper of this series (ref. 1d) was not intended to refer specifically to the ion pair. In fact, it was immediately elaborated in terms of the free anion. It was used as a general term to designate a structural fea-

Fuoss and Kraus[10] have derived an expression relating the dissociation constant of an ion pair to a parameter *a* which may be considered as the minimum distance of separation of the positive and negative charges in an ion pair formed from spherical ions. Although the significance of *a* cannot be so simple when unsymmetrical ions are involved, it seems reasonable to suppose that even in such cases *a* is primarily determined by this minimum distance.[13] Accordingly it is interesting to compare the *a* value for the metal ketyl ion pair with the estimates of those corresponding to the ionization of sodium benzohydrolate, $(C_6H_5)_2CHONa$, and the primary ionization of disodium benzophenone, $(C_6H_5)_2CNaONa$, which appear in Table II.[14]

TABLE II

CONSTANTS OF SODIUM BENZOPHENONE AND RELATED SALTS IN LIQUID AMMONIA

No.	Salt	$K \times 10^4$	$a \times 10^8$
1	$[(C_6H_5)_2CHO]Na$	0.32	2.01
2	$[(C_6H_5)_2CO]Na$	1.01	2.28
3	$[(C_6H_5)_2CONa]Na$	3.2	2.70

In the sodium benzohydrolate ion pair the sodium ion is presumably located in the vicinity of the oxygen atom which carries the anionic charge. The *a* value for this salt, lower than any listed in Table I, is entirely compatible with this model, for it indicates the absence of the steric factors which, coming into play on closer approach of the sodium ion to the phenyl groups, result in the much larger *a* value of sodium diphenylamide. The very low *a* value is probably also due in part to specific influences resulting from the location of the charge on oxygen, as is suggested by comparison of the *a* values for the similarly constituted sodium phenolate and sodium anilide (nos. 3 and 2, Table I).

The primary ionization of disodium benzophenone is in some respects the closest available analog of the ionization of a metal ketyl ion pair in which the charge is effectively located on the extra-nuclear carbon, but it is probable that the *a* value is somewhat lower than that which would correspond to the ionization of such a metal ketyl ion pair.[15] Nevertheless, the fact that the observed *a* value for the actual metal ketyl ion pair lies between the other two listed in Table II is qualitatively significant and may be interpreted in two ways. First, the actual structure of the metal ketyl ion pair may not correspond to a model in which the sodium ion is definitely located in the vicinity of the oxygen (*i. e.*, analogous to sodium benzohydrolate) or to one in which the sodium ion is located in the vicinity of the extra-nuclear carbon, but it may, instead, possess an intermediate character. If the *a* values are assigned quantitative significance, the intermediate structure would appear to be approximated more closely by the first model. Second, the structure of the metal ketyl anion may correspond to the resonance model, previously mentioned, and the sodium ion may be definitely located in the vicinity of the oxygen in the ion pair. On this basis, the increase in the *a* value over that of sodium benzohydrolate can be ascribed to the coulomb interaction of the sodium ion and the electrons which may be considered to give rise to resonance in the

---

ture which might characterize either the ion pair, the free anion or both. From this point of view, it is evident that the conclusions of Bent (ref. 11b) regarding the structure of the ion pair are restrictive rather than contradictory. Further discussion regarding the relation between the chemical evidence and the structure of the ketyl anion will be reserved for a subsequent paper.

(13) As calculated from dissociation constants by Coulomb's law, the parameter *a* gives the diameter of a fictitious sphere which will duplicate the properties of the real physical system. Since a strictly accurate calculation should involve a form factor, the omission of this factor in the present theory is absorbed in the numerical value of *a*. Consequently, any space factor (steric hindrance) which would decrease the probability of formation of ion pairs will appear as a numerically larger *a* value than that corresponding to the actual atoms on which the charges are located.

(14) The data on the conductance of sodium benzohydrolate in liquid ammonia[2] are not sufficiently accurate to permit the precise determination of Λ_0 by extrapolation. By the use of the approximate formula

$$K = \left(\frac{f\Lambda}{m\Lambda_0}\right)^2 \frac{C}{(1 - \Lambda/m\Lambda_0)}$$

setting $\Lambda_0 = 235$, the value of $K \times 10^4$ for this salt was found to lie between 0.29 and 0.35 over the dilution range 616–6450 liters per mole. The average of ten determinations from two independent series of measurements was 0.32. The data on disodium benzophenone were treated in a similar way, attributing all of the conductance to the primary ionization (in order to obtain a maximum value of K for this process) and setting $\Lambda_0 = 221$ (estimated for $[Na^+][(C_6H_5)_2CONa]^-$ by means of Stokes' law). The resulting values of $K \times 10^4$ fell between the limits 2.8 and 3.7 over the dilution range 96–1700 liters per mole and the average of nine determinations from two independent series was 3.2.

(15) Two disturbing factors which are absent in such a metal ketyl ion pair may play a significant part in the determination of the *a* value found for disodium benzophenone. The fact that this primary dissociation may lead to the formation of two types of anions might be expected to result in greater ionization and accordingly to a somewhat larger *a* value than would otherwise be the case. On the other hand, it seems likely that in any reasonable models of un-ionized disodium benzophenone which locate one sodium ion in the vicinity of the extra-nuclear carbon and the other in the vicinity of the oxygen, the first sodium ion will be closer to the negatively charged oxygen than to the other sodium ion. Accordingly, the resultant influence of the sodium–oxygen dipole on the first sodium ion will be an attraction and will tend to reduce the ionization and the corresponding *a* value. Since this effect is fundamentally similar to that responsible for bilateral triple ion formation which does not occur extensively except in solvents of much lower dielectric constant, it would be expected to reduce the *a* value by only a moderate amount, yet it appears to counteract both the first disturbing influence mentioned above as well as at least a part of the steric hindrance of the phenyl groups.

metal ketyl anion as a result of their wandering around in the benzene rings.[11b] This coulomb interaction would tend to localize the charge electron in the vicinity of the sodium ion so that the ion pair would be formed at the expense of some of the resonance energy of the anion, and the resulting instability of the ion pair would be revealed by an increase in the values of K and a. The difference between the a values of the metal ketyl and of sodium benzohydrolate corresponds to an energy difference of 0.55 kcal., which could be considered as an approximate measure of the *minimum*[16] contribution of the charge electron to the resonance energy of the free anion. The conductance data furnish no basis for a decision between these two interpretations, but the evidence advanced by Bent[11b] establishes a presumption in favor of the second hypothesis. It should be noted, however, that these alternative hypotheses are merely limiting cases since the two factors suggested as possible causes of the increased a value are not, necessarily, mutually exclusive.

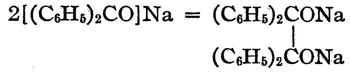
The Association of Ion Pairs.—The mass action constants k and k_4 are much more sensitive than K to errors[17] in the approximations introduced in applying the conductance equation and are, perhaps, reliable only as to order of magnitude. The independent evidence regarding association to the pinacolate in 0.3 normal solution, presented in the second paper of this series,[1b] indicated a much lower degree of association than is obtained by extrapolation to that concentration using these observed values of the mass action constants. Although such extrapolation is justified only as a crude approximation, it is unlikely that the discrepancy is due entirely to the uncertainties in the constants or in the extrapolation. It is probable that the actual proportion of pinacolate in such concentrated solutions is higher than was indicated by the application of a modification of Bachmann's method[9] to liquid ammonia solutions, and that a considerable fraction of the pinacolate dissociated during the decomposition with ammonium chloride.

Summary

1. It has been shown that the conductance of sodium benzophenone in liquid ammonia may be described quantitatively by assuming the presence of the following equilibria

$$[(C_6H_5)_2CO]Na = [(C_6H_5)_2CO]^- + Na^+$$

$$[(C_6H_5)_2CO]Na + [(C_6H_5)_2CO]^- = Na[(C_6H_5)_2CO]_2^-$$



$$2[(C_6H_5)_2CO]Na = \begin{array}{c}(C_6H_5)_2CONa \\ | \\ (C_6H_5)_2CONa\end{array}$$

2. The structure of the ion pair has been discussed. The available evidence is consistent with the hypothesis that the sodium ion is located in the vicinity of the oxygen in the ion pair, provided it is further assumed that this ion pair is formed at the expense of some of the resonance energy of the free anion and that the charge electron participates in the resonance phenomenon in this anion.

PROVIDENCE, R. I. RECEIVED DECEMBER 4, 1936

---

[16] The coulomb interaction may cancel only a fraction of the contribution of the charge electron to the resonance energy.

[17] It seems likely that such errors can be reduced by using a solvent of lower dielectric constant. Accordingly, an attempt will be made to measure the conductance of metal ketyls in pyridine.

The Dissociation Constants of Diaquotetrammine Cobaltic Cation as an Acid

BY ARTHUR B. LAMB AND EDWIN B. DAMON

Diaquotetrammine cobaltic ion may be regarded, in accordance with Brønsted's definition, as a cation acid which dissociates in two steps as follows

$$[Co(NH_3)_4(H_2O)_2]^{+++} \longrightarrow [Co(NH_3)_4(H_2O)(OH)]^{++} + H^+$$

and

$$[Co(NH_3)_4(H_2O)(OH)]^{++} \longrightarrow [Co(NH_3)_4(OH)_2]^+ + H^+$$

Brønsted and his collaborators[1] have measured the primary dissociation constants of this and of a number of similar aquo ion acids and have found interesting differences among them. Their measurements, in the case of the diaquotetrammine cation, were carried out by two independent methods. In the first method, the solubility of the slightly soluble diaquotetrammine salt of the oxalodinitrodiammine cobaltic anion was measured in solutions of varying known acidity; this was compared with the solubility of the luteo salt under similar conditions. In the

[1] J. N. Brønsted and C. V. King, *Z. physik. Chem.*, **130**, 699 (1927); J. N. Brønsted and K. Volqvartz, *ibid.*, **134**, 97 (1928).

second method, the concentration of hydrogen ion in a solution containing this cation was ascertained from the rate of aquation of added nitratoaquotetrammine cobaltic nitrate (as shown by measurements of the electrical conductance of the solution).

These methods are ingenious and elegant and have evidently been applied with skill. Nevertheless there appear to be difficulties inherent in them, since successive determinations by both methods under substantially identical conditions showed variations of 20% and more in the dissociation constants obtained.

In this situation it has seemed to us worth while to ascertain whether the glass electrode, thanks to its rapidity of response and its indifference to the presence of oxidizing substances, could not be used to measure these constants with greater precision and certainty. We have, therefore, applied this instrument to solutions of diaquotetrammine cobaltic chloride containing known, varying amounts of sodium hydroxide. In other words, we have carried out a non-cumulative electrometric titration of the cation acid.

This procedure has the advantage that minute impurities, which might seriously alter the hydrogen ion concentration if the salt were merely dissolved in pure water, have a decidedly smaller effect in the presence of the added alkali. Also, measurements in the more alkaline solutions permit the determination of the secondary as well as the primary disssociation constant.

From numerous points on the titration curve thus obtained, we have computed a series of values for the primary and also for the secondary dissociation constant of the diaquotetrammine ion.

In carrying out this titration it was important to recognize that this ammine is by no means a stable substance under these conditions. In the first place, it changes into the acido salt to at least a limited extent; Stevens[2] found in the case of the chloride that in a 0.005 M solution at 25° an equilibrium was reached in about 200 minutes, at which analyses indicated the presence of 12% of the chloroaquoammine. In the second place, this ammine suffers an irreversible decomposition in which ammonia is liberated and an oxide or hydroxide of cobalt ultimately is precipitated. While in acid solution this decomposition is relatively slow, the rate increases rapidly as the solution becomes more alkaline and this decomposition sets an upper limit to the pH value at which useful measurements can be made.

Apparatus

The glass electrode assembly used in these measurements was of the convenient, durable type described by MacInnes and Belcher.[3]

Measurements of e. m. f. were made with a Compton quadrant electrometer and a Leeds and Northrup type K potentiometer, standardized against an Eppley standard cadmium cell. With this arrangement it proved more rapid and convenient not to balance the potentiometer exactly, but rather to set the slide wire within one or two millivolts of the unknown e. m. f., and then determine the difference from the electrometer deflection. The total deflection on reversing the connections to the electrometer amounted to not less than 10 mm. per millivolt, so that the e. m. f. could be measured to 0.1 mv.

For this use with an electrometer the series of tapping keys provided in the potentiometer for use with a galvanometer were disconnected by detaching the movable part of the switch marked "STD. CELL–E.M.F.," leaving the center posts of the switch open. The end posts of the switch were then bridged across by U-shaped brass strips, which served to connect the "E.M.F.–" and the "STD CELL–" binding posts directly to the potentiometer circuit. An external switchboard could then be connected to the potentiometer through the "E.M.F." and "STD. CELL" binding posts, without making any internal changes.

The glass electrode assembly, potentiometer and auxiliary apparatus were surrounded by appropriate electrostatic shields of copper sheet or gauze, which were interconnected and earthed. The potentiometer and its accessories were kept dry by trays of calcium chloride, and were operated from outside the shield by means of suitably insulated, earthed metal rods.

The glass electrode and the solutions were contained in a large air thermostat which, undisturbed, maintained a temperature of 25.00 ± 0.02°. However, opening the door to operate the glass electrode caused fluctuations of temperature which were best corrected by a manual readjustment. Readings of the temperature made at the time of every measurement with the glass electrode showed, however, that the temperature of the cell could hardly have varied more than about 0.1° from 25.0° during these measurements.

Materials

Diaquotetrammine cobaltic chloride was prepared from pure carbonatotetrammine chloride (described below) by the method of Jörgensen.[4] The crystals thus obtained were washed 3–5 times with ice-cold concentrated hydrochloric acid, then 3–5 times with cold 95% alcohol, a motor-driven centrifuge being used to settle the wash liquors before decantation. They were then transferred to a platinum Gooch crucible, washed 5 times with absolute alcohol and drained in the centrifuge. After a final centrifuging

for twenty to fifty minutes, the apparently dry crystals were exposed in the open air for one to two hours before weighing. The product was in all cases used on the day it was prepared.

Analyses of the six different preparations used in these measurements gave the following percentages of cobalt: 21.93, 21.93, 21.96, 21.92, 21.94, 21.96; average, 21.94. Analysis of a seventh sample, prepared in the same way, gave the following additional data.

	I	II	Average	Calculated for $Co(NH_3)_4(H_2O)_2Cl_3$
Cobalt, %	21.93	21.92	21.93	21.87
Total chlorine, %	39.39	39.40	39.39	39.47_5
Complexly bound chlorine, %	0.236	0.230	0.233	0.000

The high value found for cobalt probably indicates the presence of a small amount of cobalt oxide, formed by decomposition of the complex. The 0.233 g. of complexly bound chlorine found in 100 g. of sample is equivalent to 1.650 g. of chloroaquotetrammine chloride, containing 0.699 g. of chlorine all told. This leaves 38.69 g. of chlorine, equivalent to 98.02 g. of diaquotetrammine chloride, in 100 g. of sample. The cobalt analyses show an excess of cobalt over that contained in these ammines equivalent to 0.19 g. of cobaltic hydroxide. The analysis of this sample thus corresponds to that of such a mixture as

Diaquotetrammine chloride	98.02%
Chloroaquotetrammine chloride	1.65%
Cobalt hydroxide, $Co(OH)_3$	0.19%
Moisture, etc., by difference	0.14%

Previous investigators who have analyzed this salt have obtained low values for chlorine and high values for cobalt. Thus for total chlorine Jörgensen[4] found 39.17 *versus* 39.475%, and for cobalt Birk[5] found 21.95 *versus* 21.87%.

Carbonatotetrammine Cobaltic Chloride.—This ammine prepared by following the directions of Jörgensen[6] proved on analysis to have a low and variable content of chlorine. This presumably was caused by the presence therein of carbonato bicarbonate and by the separation of a part of the product as an oil, rather than as crystals, on precipitation with alcohol.

We found that these difficulties could be remedied by a more careful regulation of the concentration of ammonium carbonate and ammonium chloride, and, after careful precipitation with alcohol, by recrystallizing the product first from a solution of ammonium chloride and finally from water. Our procedure with these supplementary details was as follows.

Twenty grams of cobalt carbonate was dissolved, with warming, in 56 ml. of 1:1 hydrochloric acid. The clear solution, diluted to 100 ml., was poured into 800 ml. of a solution containing 100 g. of ammonium carbonate and 250 ml. of concentrated ammonium hydroxide (sp. gr., 0.90). After oxidation by a vigorous current of air for three hours, the solution was transferred to a porcelain dish (diameter, 30 cm.) and evaporated on a steam-bath for two hours, with the addition of small (2.5 to 3 g.) lumps of ammonium carbonate at five-minute intervals. The solution, now concentrated to a volume not greater than 250 ml., was filtered while warm, cooled in an ice-bath and diluted to 300 ml. with a solution containing 18 g. of ammonium chloride in the required amount of distilled water. The solution, cooled in ice, was treated with 750 ml. of cold 95% alcohol, added in 50-ml. portions at ten-minute intervals. The product, which usually separated in good crystalline form, was collected on a suction filter, washed with cold 70% alcohol and dried in the open air; yield, about 24 g.

The crude material from ten such batches was combined for purification. To convert into chloride any carbonato bicarbonate that might be present, it was dissolved at room temperature in the required amount of a 15% solution of ammonium chloride, which had been made neutral to litmus with ammonium hydroxide; the resulting solution was cooled in ice and treated with cold 95% alcohol added in 150-ml. portions at ten-minute intervals. The crystals thus formed were collected and washed as before.

After two such recrystallizations, the product was crystallized once from water without the addition of alcohol. In this process, the salt was divided in several portions, and the mother liquor from the crystallization of the first portion used over and over again. (At the end, a small amount of less pure material was precipitated by adding alcohol to the mother liquor.) The crystals were collected in a platinum Gooch crucible, washed once with cold water and drained in the centrifuge; yield, 101 g. of good crystals, plus 18 g. of less pure material.

The crystals obtained in this way were clear, garnet-red 4- and 6-sided prisms, mostly small, but a few as long as 1 mm. On standing, the crystals became less transparent, while the color changed toward purple. After being ground and exposed over calcium chloride for forty-eight hours they were analyzed with the following results.

	I	II	Average	Calculated for $Co(NH_3)_4(CO_3)Cl$
Cobalt, %	26.56	26.54	26.55	26.49
Chlorine, %	15.94	15.91	15.92_5	15.93

Standard Solution of Sodium Hydroxide, 0.1 M.—A solution sufficiently free from carbonate for our purposes was prepared by the method of Sørensen[7] and Cowles.[8] After dilution with boiled distilled water, the solution was standardized first against potassium biphthalate and found to be 0.0999, 0.1001 and 0.1001 *M;* and second, against oxalic acid and found to be 0.1001, 0.1001 and 0.1000 *M;* average, 0.1000_5 *M;* temperature, 23–24°. The solution was kept in a Pyrex bottle, protected by soda-lime tubes.

Analytical Methods

Cobalt was determined as usual by conversion to cobaltous sulfate. A porcelain crucible was employed with the serrated, clear quartz lid described by J. D. Main Smith[9] for prevention of loss by spattering.

In determining the complexly bound chlorine in the diaquotetrammine chloride (presumably present as chloroaquo chloride) every precaution was taken to prevent loss

of complex chlorine by aquation. A 1-g. sample was dissolved rapidly in 175 ml. of 0.33 *M* nitric acid, containing 100 g. of clear cracked ice in a 500-ml. glass stoppered Erlenmeyer flask; and then 25 ml. of 0.5 *M* silver nitrate was run in from a pipet, with shaking. The flask was stoppered and shaken vigorously for two minutes; the solution was then filtered rapidly with suction through two sheets of Whatman No. 42 filter paper supported on the sintered Jena glass disk of a suction funnel, care being taken to avoid transferring ice, which might contain unprecipitated chloride, to the funnel. Filtration was completed ten minutes after starting to dissolve the sample. After 6 to 10 washings with 0.001 *M* silver nitrate, the first silver chloride precipitate was discarded. The filtrate and washings, which appeared perfectly clear, were treated with 3 ml. of 30% hydrogen peroxide, heated to boiling, and boiled gently for fifteen minutes. This brought about complete decomposition of the complex ion. After standing overnight in a dark place, the second precipitate of silver chloride was collected and weighed.

Measurements with the Glass Electrode

For standardizing the glass electrode assembly, 0.05 *M* potassium biphthalate was used as our standard buffer. We have assumed that the *p*H of this solution at 25.0° is 3.983, as determined by MacInnes and Belcher.[10] To detect possible changes in the asymmetry potential of the glass membrane, standardizations were carried out at the beginning and end of each day's series of measurements (and in some cases more frequently).

The above-mentioned instability of the tetrammine ion made it necessary not only to determine the hydrogen ion concentration on a series of independent solutions, each with its quota of sodium hydroxide, but also to follow in each solution the change in potential of the glass electrode with time and to extrapolate these potentials back to the moment at which the solid ammine was added to the solution. It was assumed that the salt dissolved instantaneously, and that the relative amounts of diaquo and chloroaquo salts in the solution at that moment were the same as in the solid sample. In performing the extrapolation, it was necessary to take into account that in the large Pyrex container the ammine might decompose at a rate different from the rate in the glass electrode vessel, where the solution is exposed to a relatively large surface of soft, alkaline glass.

Details of a typical experiment are given in the following. Four buffer solutions (*i. e.*, mixtures of the diaquo chloride and sodium hydroxide) were generally prepared and measured on the same day. Approximately 1-liter samples of distilled water, contained in 2-liter Pyrex Erlenmeyer flasks, were boiled to remove carbon dioxide, cooled to room temperature under the protection of soda-lime tubes, weighed, and brought to 25.0° by standing overnight in the air thermostat. Measured volumes of standard 0.1 *M* sodium hydroxide were added from a recalibrated buret. Samples of diaquotetrammine chloride, which had been prepared on the same day, were weighed on watch glasses small enough to enter the necks of the 2-liter flasks. At the same time, samples were weighed for the determination of the percentage of cobalt.

At a suitable moment a stop-watch was started and the sample of ammine was dropped into the dilute alkali solution. This was immediately shaken very vigorously for sixty to ninety seconds. The glass electrode vessel was then rinsed three times and filled with the buffer solution; the time when the solution entered the glass spiral was noted. The first measurement of e. m. f. was in most cases made at four minutes by the stop-watch, but with the least stable buffers this time was reduced to two and one-half minutes. Measurements of e. m. f. were repeated at one and one-half to two and one-half minute intervals. At about ten minutes, and again at about twenty minutes, the buffer solution in the glass spiral was replaced by a fresh sample.

The observed values of e. m. f. were then graphically extrapolated in two steps: first, the values observed with each sample of the buffer were extrapolated to find the e. m. f. at the moment when this sample was run into the glass electrode; then these corrected values were extrapolated to zero time.

The slope of the extrapolation curve at zero time, $(dE/dt)_0$, may be taken as a measure of the instability of the buffer solution. In Fig. 1, values of $(dE/dt)_0$ (as read from the extrapolation curves) are plotted as a function of *p*H. It will be seen that the more acid solutions changed

---

[10] Duncan A. MacInnes and Donald Belcher, THIS JOURNAL, **53**, 3326 (1931). This value conforms to the widely used, arbitrary *p*H scale defined by the specifications of W. Mansfield Clark, "The Determination of Hydrogen Ions," 3rd ed., Williams and Wilkins Co., Baltimore, 1928, p. 480. Dr. MacInnes has kindly pointed out (private communication, also *Cold Spring Harbor Symposia on Quantitative Biology*, **1**, 190 (1933)) that in accordance with his present point of view an agreement between *p*H measurement and thermodynamic ionization constants, etc., is best attained by shifting the scale by about 0.03 unit; the *p*H of the phthalate buffer is then 4.015. Adoption of this *p*H scale would result in raising the *p*H values reported in this paper by 0.032. When the individual dissociation constants in Table I are recalculated on this basis, the average values become $k_1 = 4.42 \times 10^{-6}$, $k_2 = 4.7 \times 10^{-8}$.

very slowly; with these, the change may have been due to a shift in the relative proportions of diaquo and chloroaquo ions. In solutions of higher *p*H, the more rapid changes were caused principally by decomposition of the complex ion; in such solutions a precipitate of cobalt hydroxide was formed on standing. The most alkaline buffer of this series, *p*H = 6.066, became perceptibly cloudy within thirteen minutes. This appeared to be the most alkaline buffer with which useful measurements could be made.

The *p*H values of the freshly prepared buffer solutions were finally calculated from the extrapolated values of e. m. f. In these calculations, the diffusion potential at the junction between buffer solution and saturated potassium chloride was neglected. The data which we have obtained are collected in Table I.

The first column of this table gives the volume of exactly tenth molar sodium hydroxide used in preparing a volume of buffer solution containing 0.004 mole of pure diaquo chloride; the second column gives the volume of this buffer solution; the third column gives the *p*H of the freshly prepared buffer solutions. (In correcting for the presence of chloroaquo chloride and other impurities, it is assumed that all samples of diaquo chloride crystals had the composition stated on page 385.)

TABLE I

BUFFER SOLUTIONS CONTAINING 0.004 MOLE OF $[Co(NH_3)_4(H_2O)_2]Cl_3$

Volume 0.1 *M* NaOH, ml.	Volume buffer soln., ml.	*p*H	*A*	$10^6 k_1$	$10^8 k_2$

.00	948	3.865	2.968	(4.5)	...
Average of accepted values				4.80	5.0

By plotting the *p*H values of these buffers as a function of the volume of tenth molar sodium hydroxide solution we obtain the titration curve shown in Fig. 2. This curve represents the titration of 0.004 mole of diaquotetrammine chloride in an average volume of solution of 1020 ml. (plus or minus about 2%).

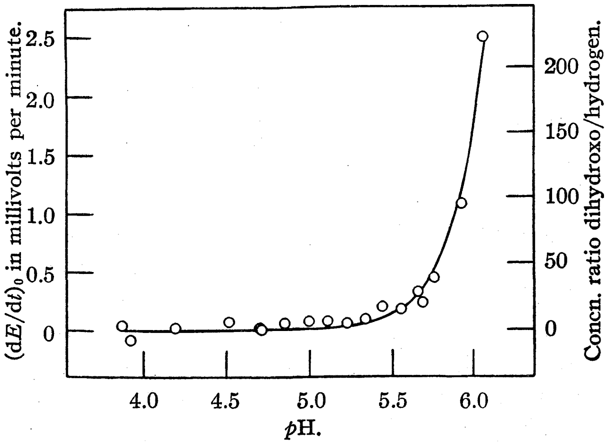

Fig. 1.

Calculation of Dissociation Constants

The primary and secondary dissociation constants of the cation acid, $Co(NH_3)_4(H_2O)_2^{+++}$, have been calculated from the data for titration with sodium hydroxide given in Table I. The method of calculation is similar to that outlined by Britton.[11] In these calculations, we have assumed the relation

$$pH = -\log h$$

(where *h* represents the concentration of hydrogen ions) as a sufficiently good approximation for our present purposes. As a result, the constants which we obtain are neither thermodynamic dissociation constants in terms of activities, nor classical dissociation constants in terms of true concentrations; they are approximately the same as the "acidity constants" defined by Brønsted.[12]

In the following discussion, brackets are used to denote concentrations; other symbols are tabulated below.

[+++]	concentration of $Co(NH_3)_4(H_2O)_2^{+++}$
[++]	concentration of $Co(NH_3)_4(H_2O)OH^{++}$
[+]	concentration of $Co(NH_3)_4(OH)_2^{+}$
b	concentration of added sodium hydroxide
c	total concentration of diaquotetrammine chloride
h	concentration of hydrogen ion

---

[11] H. T. S. Britton, "Hydrogen Ions," Chapman and Hall, Ltd., London, 1929, page 150.

[12] J. N. Brønsted and Cecil V. King, *Z. physik. Chem.*, **130**, 700 (1927).

The primary and secondary dissociation constants, k_1 and k_2, are defined by the equations

$$k_1 = [^{++}]h/[^{+++}] \qquad (1)$$

$$k_2 = [^{+}]h/[^{++}] \qquad (2)$$

Since the total concentration of diaquotetrammine chloride is known, we may write

$$[^{+++}] + [^{++}] + [^{+}] = c \qquad (3)$$

From the law of electroneutrality we obtain the relation

$$3[^{+++}] + 2[^{++}] + [^{+}] + [H^+] + [Na^+] = [Cl^-] + [OH^-]$$

In the buffers included in these measurements, the concentration of hydroxyl ion is very small and may be neglected. The concentrations of Cl^- and Na^+ are known from the concentrations of the ammine and of the added hydroxide; the concentration of H^+ from the measurements of pH

$$[H^+] = h \quad [Na^+] = b \quad [Cl^-] = 3c$$

Substitution of these values in the above equation gives

$$3[^{+++}] + 2[^{++}] + [^{+}] = 3c - b - h \qquad (4)$$

By eliminating the unknown concentrations $[^{+++}]$, $[^{++}]$ and $[^{+}]$ from equations 1, 2, 3 and 4 we obtain the expression

$$\frac{3h^2 + 2k_1h + k_1k_2}{h^2 + k_1h + k_1k_2} = \frac{3c - b - h}{c} = A \qquad (5)$$

which defines the convenient function, A. Values of A, calculated from known values of b, c and h for the various buffer solutions, are listed in Table I.

By substituting in equation 5 values of h and A for two different buffer solutions in which these values are h_1, A_1 and h_2, A_2, we obtain a pair of simultaneous equations, from which, by elimination of k_2 or k_1, we obtain finally

$$k_1 = \frac{(A_1 - 1)(3 - A_2)h_2^2 - (A_2 - 1)(3 - A_1)h_1^2}{(A_1 - 1)(A_2 - 2)h_2 - (A_2 - 1)(A_1 - 2)h_1} \qquad (6)$$

and

$$k_2 = \frac{(A_2 - 2)(3 - A_1)h_1^2h_2 - (A_1 - 2)(3 - A_2)h_1h_2^2}{(A_1 - 1)(3 - A_2)h_2^2 - (A_2 - 1)(3 - A_1)h_1^2} \qquad (7)$$

The dissociation constants k_1 and k_2 may now be calculated by substituting numerical values in equations 6 and 7. The results of such calculations are presented in the last two columns of Table I. In selecting the different pairs of buffers to be used in these calculations, we have combined, wherever possible, measurements made on the same day using the same sample of ammine.

Correction for Chloroaquotetrammine Chloride

In the preceding calculations, chloroaquotetrammine chloride has been treated as an inert impurity. The chloroaquotetrammine ion, however, is presumably an acid of about the same strength as the hydroxoaquotetrammine ion, that is, an acid with a dissociation constant of the same magnitude as k_2. It is accordingly worth while to investigate how large an error in the values of k_1 and k_2 might have been caused by the presence of 1.65% of chloroaquo chloride in the samples of diaquo chloride.

Calling c' the total concentration of chloroaquotetrammine chloride and k' the dissociation constant of the chloroaquotetrammine ion as an acid, and inserting them in equations 3–5 above, we obtain as a corrected value of A

$$A' = \frac{3c - b - h}{c} + \frac{k'c'}{(k' + h)c} \qquad (8)$$

In the buffers of Table I the value of c' is 7×10^{-5}. If it is assumed that k' has the same value as k_2, we find that the maximum value of the correction to be applied to A (*i. e.*, in the case of the most alkaline buffer) amounts to 0.001. It is evident that in the present measurements this correction may be neglected.

Calculation of the Theoretical Titration Curve

To test the agreement between the individual measurements and the average calculated values of k_1 and k_2, we have computed the volumes of 0.1 M alkali which must be added to 0.004 mole of diaquo chloride in 1020 ml. of solution in order to produce buffer solutions having predetermined pH values. These are shown as small shaded circles in Fig. 2 and through them we have drawn the theoretical titration curve shown as a solid line. It can be seen that the observed values, shown as open circles, lie within 0.015 of a pH unit from this curve except in the case of those for solutions in pure water where in one instance the discrepancy is three times this amount.

To test this concordance still further we have constructed similar curves based on $k_1 = 4.3 \times 10^{-6}$ and 5.3×10^{-6} and $k_2 = 10^{-7}$ and 10^{-8} instead of our calculated values of 4.80×10^{-6} and 5×10^{-8}, respectively. These curves are shown as broken lines in the inserts in Fig. 2. Their distance from the curve through the observed points is several times the experimental error and justifies an estimate of the precision of our calculated values of k_1 and k_2 as about 2 and 20%, respectively.

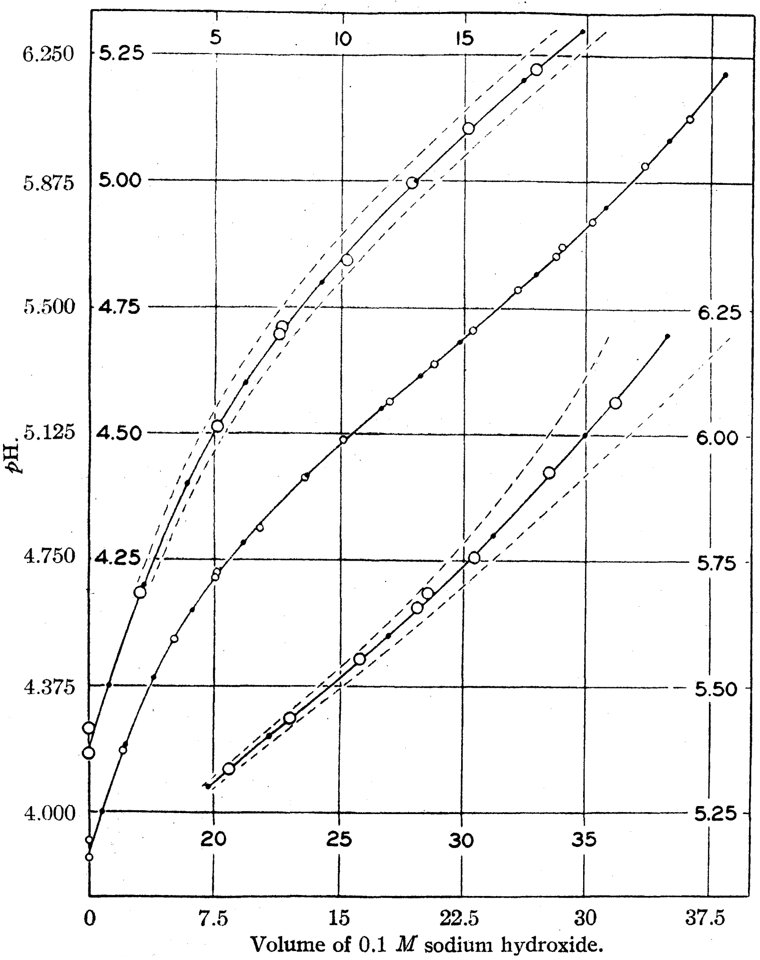

Fig. 2.—Titration curve of diaquotetrammine cobaltic ion: open circles, observed points; small shaded circles, points calculated for $k_1 = 4.8 \times 10^{-6}$, $k_2 = 5 \times 10^{-8}$. Inserts show same curve on 50% larger scale, with broken lines showing (upper insert) effect of varying k_1 between 4.3 and 5.3 $\times 10^{-6}$ and (lower insert) effect of varying k_2 between 10^{-7} and 10^{-8}.

Velocity of Decomposition

In conclusion, it should be pointed out that the data on the change in the potential of the glass electrode with time (used above in extrapolating to zero time) permit some interesting inferences regarding the decomposition of this ammine. The observed values of $(\mathrm{d}E/\mathrm{d}t)_0$ are a measure of the fraction of the hydrogen ions present in the solution which are neutralized in unit time;

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\frac{RT}{F}\frac{\mathrm{d}\ln h}{\mathrm{d}t} = -\frac{RT}{F}\frac{1}{h}\frac{\mathrm{d}h}{\mathrm{d}t} \qquad (9)$$

Except for small changes resulting from shifts in the relative proportions of aquo and acido ions, this decrease in acidity undoubtedly reflects the liberation of ammonia from the ammine. From a comparison of Figs. 1 and 2, it is evident that the rate of this reaction, starting from approximately zero, begins to increase very rapidly at the pH value where k_2 first becomes important in determining the shape of the titration curve. This suggests that it is the dihydroxo ion which undergoes decomposition, and hence that the rate at which hydrogen ions are used up is proportional to the concentration of the dihydroxo ion;

$$-\mathrm{d}h/\mathrm{d}t = K[^+] \qquad (10)$$

Combination of equations 9 and 10 leads to

$$\frac{\mathrm{d}E}{\mathrm{d}t} = \frac{RT}{F}K\frac{[^+]}{h} \qquad (11)$$

This relation is tested by the solid curve shown in Fig. 1, which represents the variation with pH of the concentration ratio $[^+]/h$, as calculated for the average concentration of diaquotetrammine chloride in our solutions, using our values of k_1 and k_2. It can be seen that this curve runs very exactly through the observed values of $(\mathrm{d}E/\mathrm{d}t)_0$.

As a more explicit test of equation 10, we have computed from $(\mathrm{d}E/\mathrm{d}t)_0$ the actual change in hydrogen ion concentration in the nine least acid solutions, namely, in those solutions where the arithmetical change is not swamped by the experi-

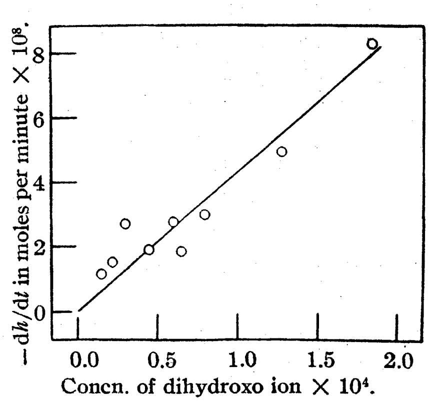

Fig. 3.

mental error. The resulting values are shown in Fig. 3, the straight line there drawn through the points being the best one as determined by the method of least squares. Its equation is

$$-dh/dt = 4.3 \times 10^{-4}\,[+] \qquad (12)$$

The concordance of these points with a straight line indicates that the reaction of decomposition is unimolecular with respect to the dihydroxotetrammine ion.

Summary

It has been shown:

1. That concordant values of the dissociation constants of diaquotetrammine cobaltic ion as an acid can be obtained by measuring with the glass electrode the concentration of hydrogen ion in solutions of this ammine ion to which various amounts of sodium hydroxide have been added.
2. That the velocity of decomposition of this ion in these solutions is proportional to the first power of the concentration of the dihydroxotetrammine ion in equilibrium with it, as computed from these values of the dissociation constants.

The Lead–Uranium–Thorium Ratio of a Single Crystal of Wilberforce Uraninite

BY CHESTER M. ALTER AND LAURA A. YUILL

It has been shown recently[1] that the composition of a single crystal of uraninite from near Wilberforce, Cardiff Township, Ontario, may not be uniform throughout the crystal. Ellsworth[2] has found the same phenomenon in the case of Villeneuve uraninite. It is interesting to note that in both cases the percentage of thorium is highest in the outer portion of the crystal, decreases toward the interior and then increases again in the core. The variation in thorium content was not great in the case of the Villeneuve crystal but was very noticeable in the Wilberforce crystal. The lead and thorium contents showed certain irregularities which were also difficult to explain, especially by any process of leaching.

Alter and Kipp removed succeeding layers of the crystal by dissolving in nitric acid. In spite of the fact that this dissolution was done very rapidly, it was thought possible that there may have been preferential leaching throughout the crystal while any one layer was being dissolved. In that case the results would be meaningless, as definite layers of the crystal would not have been removed for analysis. In order to preclude such a possibility it was decided to repeat the work by analyzing various layers which had been mechanically removed from a single crystal rather than by acid dissolution.

For this purpose a rather well-developed crystal, a part of a large collection of material from the Wilberforce locality,[3] weighing approximately 42 g., was obtained from Professor Alfred C. Lane. According to Dr. H. V. Ellsworth[4] this material was collected from Pit 4[5] where the uraninite occurs in a gangue of fluorite and calcite. He further reports that the uraninite from this pit is considerably altered. This specimen, however, apparently carried very little of the usual surface alteration products and exhibited very distinct crystal faces and angles. A spot of apparently foreign material appeared on one face, and this proved to penetrate well into the core of the crystal.

The crystal was divided into three parts—outer, middle, and core—by carefully removing successive parts by means of a steel file. Each face was filed down an equal amount, great effort being taken to maintain the original form of the crystal during the process of filing off the outer portions. The outside, middle, and core portions weighed, respectively, 12.7 g., 15.2 g., and 13.5 g.

The particles of steel introduced in the samples were removed by very thorough magnetic separation.

The analytical procedures for the determination of lead, thorium, and uranium were in general those described in detail by Alter and Kipp.[1] Approximately one-gram samples were dissolved

in nitric acid, evaporated to dryness, diluted, the insoluble material filtered off, ignited, and weighed. The lead was precipitated from acid solution as sulfide, converted to sulfate, and weighed. Uranium and thorium were twice precipitated as hydroxide. After the combined hydroxides were dissolved in nitric acid, the thorium was precipitated as oxalate, dissolved in nitric acid, and precipitated as thorium sebacate with sebacic acid. The thorium sebacate was dissolved and reprecipitated, washed free from sebacic acid, ignited, and weighed as ThO_2. Iron and aluminum were removed from the uranium solution by precipitation with ammonium carbonate. The uranium was precipitated as ammonium uranate, ignited, and weighed as U_3O_8.

Unusual precaution was taken to carry out precipitations under best conditions to ensure purity. Filtrates were all evaporated and tested for desired constituents.

TABLE OF RESULTS

Discussion

The ratio Pb/(U + 0.36Th) of the outer layer indicates that the crystal had not been subjected to surface alteration since it is commonly found that any leaching process tends to cause a rise in this ratio. The higher ratio in the core of the crystal is unusual.

The variation of the thorium content in various sections of the crystal is of great interest. It will be seen that this variation is of the same magnitude and direction as that noticed by Alter and Kipp.[1] Since this phenomenon exists in all three cases where methods have been used that would detect it, it would be of great interest to examine, in a like manner, crystals of uraninite from other localities.

The ratios obtained by Alter and Kipp and those reported here are slightly higher than those reported for Wilberforce material by Todd[7] and Ellsworth.[8,2] The latter[9] has pointed out that this is no doubt due to the fact that the Lane material from Pit No. 4 and analyzed in this Laboratory is of inferior quality compared with that analyzed earlier by Todd and by Ellsworth and which was obtained from Pit No. 1.[5] However, it has been observed that the two uraninite-bearing bodies of Pits 1 and 4 are not visibly connected although they are in line.

The results emphasize the necessity for careful selection of material in order to obtain reliable data for age calculations. Erroneous results may be obtained if even a single crystal in its entirety is ground and analyzed. Based on the age formula:

$$\text{Age} = \frac{\log(U + 0.36Th + 1.155Pb) - \log(U + 0.36Th)}{6.6 \times 10^{-5}} \text{ million years}$$

the discrepancy in age using the data for the whole crystal and those for the core amounts to approximately eighty million years, while the discrepancy between the ages calculated for the whole crystal and outside portion is about forty million years. These errors, although large, lose some of their impressiveness when they are compared with the age of this mineral, which is calculated by the above formula to be between 1100 and 1200 million years.

A part of this work was supported by a grant from the National Research Council, for which the authors wish to acknowledge gratitude.

Summary

1. Determinations of the lead–uranium–thorium ratio of sections of a single crystal of uraninite removed mechanically confirm earlier results in which the sections were removed by acid solution.

2. The composition of a single crystal of uraninite may vary exceedingly, especially in regard to thorium content.

3. The results may throw some light on the conditions in the pegmatite during crystallization.

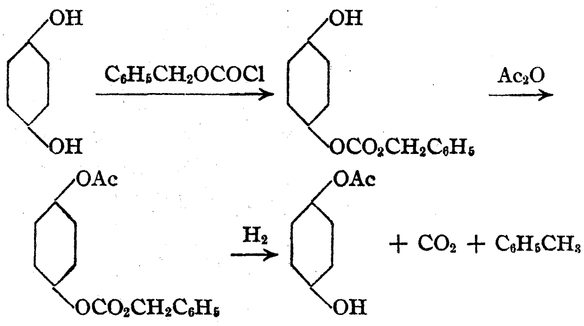
Monoacetates of Hydroquinone and Catechol

BY H. S. OLCOTT

In the course of studies on antioxidants in fats[1] we wished to investigate, among other phenolic compounds, hydroquinone and catechol monoacetates, and could find no references to their preparation or properties. Preliminary attempts at synthesis with limited quantities of an acetylating reagent yielded appreciable amounts of the diacetates. The successful use of benzyl chloroformate by Bergmann and Zervas[2] in the synthesis of peptides suggested that this reagent might also be useful in the preparation of the compounds mentioned above. Carbobenzoxy esters, prepared by means of benzyl chloroformate, can be split by hydrogen in the presence of a platinum or palladium catalyst, thus avoiding the hydrolyzing action of acids or bases.

The monoacetate of hydroquinone or catechol was prepared easily by a series of reactions involving the preparation of the monocarbobenzoxy derivative, acetylation of the remaining hydroxyl, and removal of the carbobenzoxy group by hydrogenation.



It was later found possible, and much more practicable, to obtain the monoacetates in fair yields by careful acetylation of the dihydroxy compounds in aqueous solution. However, the methods used in the first syntheses are described inasmuch as they may prove useful in more complicated synthetic procedures.

Experimental

The benzyl chloroformate[3] was prepared as directed by Bergmann and Zervas.

Monocarbobenzoxyhydroquinone.—A mixture of 2 g. of hydroquinone and 1 g. of sodium carbonate was dissolved in 30 cc. of water in a 200 cc. rubber-stoppered bottle kept filled with nitrogen. To this solution was added 3.5 g. of benzyl chloroformate in several portions. Between the additions the bottle was shaken in a mechanical shaker. When the reaction was complete, as indicated by the disappearance of the odor of benzyl chloroformate, the solid product was filtered, washed with water, dissolved in alcohol, boneblacked and crystallized from 50% alcohol. The white, irregular flat prisms melted at 120–120.5°[4]; yield, approximately 50%.

Anal. Calcd. for $C_{14}H_{12}O_4$: C, 68.8; H, 5.0. Found: C, 68.8; H, 5.5.

Dicarbobenzoxyhydroquinone.—This compound was prepared by a similar procedure except that double the quantities of sodium carbonate and benzyl chloroformate were used. The insoluble reaction product crystallized from hot alcohol in the form of fine white needles, m. p. 142–143°.

Anal. Calcd. for $C_{22}H_{18}O_6$: C, 69.8; H, 4.8. Found: C, 69.6; H, 5.2.

Dicarbobenzoxyhydroquinone in alcohol was hydrogenated in the presence of a platinum catalyst.[5] The catalyst was removed and the alcohol evaporated to dryness. The residue was identified as hydroquinone, by the m. p. of the impure product, 163°, and of the sublimed crystals, 169°.

Monocarbobenzoxyhydroquinone Monobenzoate.—Monocarbobenzoxyhydroquinone was dissolved in five parts of pyridine to which was added one part of benzoyl chloride. The mixture was allowed to stand overnight and then poured into an excess of water. The precipitate was filtered, washed and recrystallized from alcohol. The fine white platelets melted at 97–98°.

On hydrogenation, monocarbobenzoxyhydroquinone benzoate yielded hydroquinone monobenzoate which, after crystallization from 70% alcohol, melted at 160°. A mixture with a specimen synthesized by the method of Robertson and Waters[6] melted at 160–161°.

Monocarbobenzoxyhydroquinone Monoacetate.—Monocarbobenzoxyhydroquinone (1 part) was quantitatively acetylated with acetic anhydride (1 part) in pyridine (5 parts) by standing at room temperature for twelve hours. The precipitate which formed when the mixture was poured into water was filtered, washed and recrystallized from small amounts of alcohol in which it tended to form supersaturated solutions. The minute colorless crystals melted at 75–76°.

Anal. Calcd. for $C_{16}H_{14}O_5$: C, 67.1; H, 5.0. Found: C, 67.2; H, 5.2.

Hydroquinone Monoacetate. Method 1.—Monocarbobenzoxyhydroquinone monoacetate was hydrogenated in

alcohol with a platinum catalyst. Palladium[5] and Raney nickel[7] were also effective but hydrogen was absorbed more slowly. When absorption had ceased, the catalyst was filtered and washed with alcohol, and the filtrate was evaporated to dryness. The residue was crystallized from large amounts of petroleum ether (b. p. 60–70°).

Method 2.—Hydroquinone was acetylated with the equivalent of one mole of acetic anhydride following the directions of Chattaway[8] for the preparation of acetates except that sodium carbonate was substituted for sodium hydroxide. Stirring was continued for an hour after the addition of the last of the acetic anhydride and the mixture was then allowed to stand at room temperature overnight. The hydroquinone diacetate, amounting approximately to 30% of the original hydroquinone, was filtered off. The filtrate was extracted with ether, and the ether layer was washed, dried with anhydrous sodium sulfate and evaporated to dryness. The residue was extracted repeatedly with boiling petroleum ether, from which, on cooling, hydroquinone monoacetate crystallized in colorless irregular prisms, m. p. 62–63°.

Hydroquinone monoacetate is very soluble in water, alcohol and ether. The aqueous solution gives no color with ferric chloride.

Anal. Calcd. for $C_8H_8O_3$: C, 63.1; H, 5.3. Found: C, 63.1; H, 5.6.

On further acetylation, hydroquinone monoacetate yields the diacetate, m. p. 120.5–121°; mixed m. p. with a product obtained from hydroquinone and an excess of acetic anhydride, 121°.

Monocarbobenzoxycatechol.—This compound, prepared by procedures similar to those used for the analogous hydroquinone derivative, crystallized from petroleum ether (b. p. 60–70°) in rosets of colorless needles, m. p. 88.5–89°.

Anal. Calcd. for $C_{14}H_{12}O_4$: C, 68.8; H, 5.0. Found: C, 69.1; H, 5.1.

Monocarbobenzoxycatechol Monoacetate.—On pouring the mixture used to acetylate monocarbobenzoxycatechol into water, a colorless oil separated. This was extracted with ether. The ether layer was washed, dried and evaporated to dryness and the residue distilled in high vacuum (0.1 mm.). Only 2 cc. was distilled and a satisfactory distilling temperature was not recorded; most of the material distilled between 100–150°.

Anal. Calcd. for $C_{16}H_{14}O_5$: C, 67.1; H, 5.0. Found: C, 67.2; H, 5.0.

Catechol Monoacetate.—Prepared by both methods outlined under hydroquinone monoacetate, catechol monoacetate was obtained as a colorless oil which did not crystallize at low temperatures. Traces of catechol were removed by crystallization from petroleum ether in which the monoacetate is more soluble. The monoacetate distilled approximately at 130–140° (0.1 mm.).

Anal. Calcd. for $C_8H_8O_3$: C, 63.1; H, 5.3. Found: C, 62.9; H, 5.5.

Catechol monoacetate possesses a slight phenolic odor and is soluble in water, alcohol, ether and petroleum ether. Dilute aqueous solutions give a green color with ferric chloride. On acetylation, the diacetate of m. p. 60° is obtained.

Antioxidant Properties.—All of the compounds described were assayed for their antioxygenic properties by determining the effect of adding small amounts to lard. The method used for measuring the length of the induction period has been described previously.[1,9] Only the monoacetates showed any protective effect (Table I). The monoacetate of catechol was more effective than that of hydroquinone, in contrast to the results with the monomethyl esters of these two phenols.[1,10] Other monoesters of hydroquinone are ineffective.[1] Neither monoacetate approaches the effectiveness of the original dihydroxy compounds. In view of the fact that catechol monoacetate could not be purified by crystallization, its antioxygenic effect might have been due to traces of catechol.

TABLE I

ANTIOXIDANT PROPERTIES OF THE MONOACETATES OF HYDROQUINONE AND CATECHOL IN LARD

Amount of added substance, %		Induction period (75°), hrs. With inhibitor	Without inhibitor
0.02	Hydroquinone monoacetate	19	18
.02		25	22
.02		15	11
.10		52	11
.02	Catechol monoacetate	52	18
.02		62	22
.01	Hydroquinone[9]	410	14
.01	Catechol[11]	408	9

The author is indebted to Lever Brothers Company for a grant in support of this research.

Summary

Hydroquinone and catechol monoacetates have been prepared by careful acetylation of the diphenols and also with the use of carbobenzoxy derivatives. Catechol monoacetate is more effective as an antioxidant than hydroquinone monoacetate but much less effective than either catechol or hydroquinone.

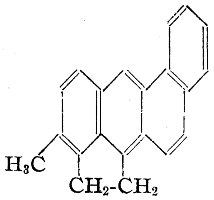
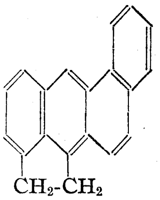
Aceanthrene Derivatives Related to Cholanthrene

BY LOUIS F. FIESER AND E. B. HERSHBERG[1]

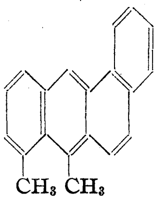
It was reported in a paper by one of us with Seligman[2] that the methyl group of methylcholanthrene (I) is not important in determining the high carcinogenic potency of this hydrocarbon, for cholanthrene (II) produces transplantable tumors only slightly less rapidly than methylcholanthrene.[2,3] Fieser and Newman[4] investigated further simplifications of the molecule, and it was found that 5,10-dimethyl-1,2-benzanthracene (III) retains the properties characteristic of methylcholanthrene and produces tumors regularly and with great rapidity. Dr. M. J. Shear has confirmed the preliminary report[4] and found that the hydrocarbon has about the same activity as methylcholanthrene, producing in mice transplantable tumors which appear, on the average, after about three months. The five-membered ring present in the cholanthrenes evidently is not important in determining the biological action of the compounds, and it is not even essential for high activity that both methyl groups be retained. Dr. Shear has found that 10-methyl-1,2-benzanthracene[4] (IV) is comparable in carcinogenic activity with the hydrocarbons I–III. Injected subcutaneously into mice in 5-mg. dosage, the hydrocarbon gave tumors which made their first appearance in two months. At the end of four months, tumors had been obtained in fifteen of twenty mice. Three of these tumors were transplanted successfully. In contrast to this powerful agent, 5-methyl-1,2-benzanthracene produces tumors only slowly[5] and is more nearly comparable with 1,2,5,6-dibenzanthracene than with the cholanthrenes.



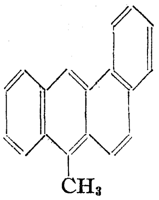
I



II



III



IV

From these results it is evident that the carcinogenic potency of methylcholanthrene cannot be attributed to a special pentacyclic structure, as was suggested by the early work of Cook and his associates,[3b] or to the fact that the hydrocarbon is a 1,2-benzanthracene derivative with alkyl substituents at the 5- and 6-positions. From the present results it appears that the structural feature of greatest importance is the presence of a simple carbon substituent at the meso position 10 in the 1,2-benzanthracene ring system. In comparison with the effect of such a group, the influence of alkyl substituents at the 5- and 6-positions[5] is of secondary significance. Evidently the size and structure of the substituent at the 10 position is of considerable importance, for the English investigators[5] found that 10-isopropyl- and 10-benzyl-1,2-benzanthracene are devoid of carcinogenic activity. The contrasting effects of methyl and isopropyl groups at position 10 are surprising in view of the observation[5] that 6-methyl-1,2-benzanthracene is somewhat inferior in carcinogenic properties to the 6-isopropyl compound. The 5-*n*-propyl compound, however, was found to give fewer tumors than the 5-methyl derivative.[3a] The relationship between the 10-methyl and 10-isopropyl compounds appears to be comparable also with that between the highly potent methylcholanthrene and the slowly acting 16,20-dimethylcholanthrene.[6] The latter hydrocarbon, which carries a larger and more branched substituent at the meso position, produces tumors which appear in about the same average time[7] as in the case of 1,2,5,6-dibenzanthracene (seven and one-half months). It is clearly important to explore further the relationship of structure and carcinogenic activity in the series of 10-alkyl-1,2-

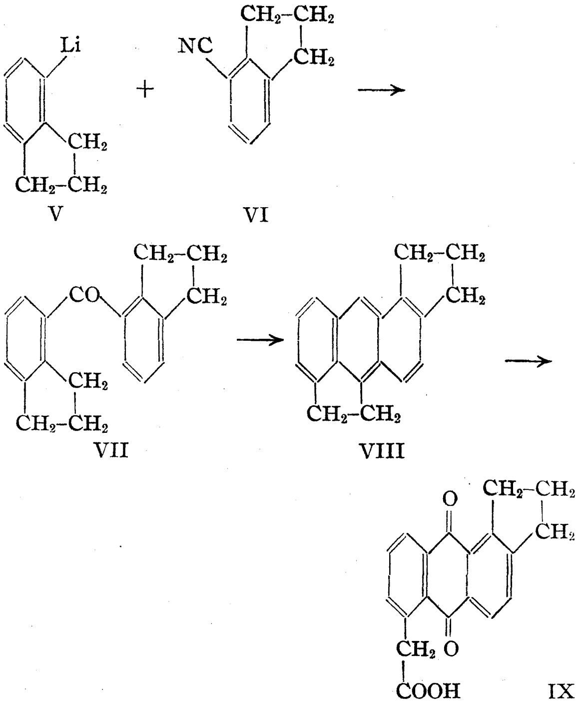
benzanthracenes, and such work is in progress.[8] It is interesting that the powerfully carcinogenic 3,4-benzpyrene may be regarded as a 1,2-benzanthracene with a carbon substituent at the alternate meso position 9, and that 8,9-dimethylene-1,2-benzanthracene[2] shows some activity, producing tumors in an average time of about seven months.[7] The influence of a methyl group at the 9-position is being investigated in independent work by Dr. M. S. Newman.

It is hoped that by defining the features of structure associated with high carcinogenic activity, some clue may be found which will help to reveal the nature of the action of cancer-producing hydrocarbons on cellular tissue. The recognition that the potency of methylcholanthrene is retained in compounds of much less complicated structure may serve at least to clarify the problem. In order to provide as sound a basis for speculation as possible, it seemed desirable to determine whether 10-methyl-1,2-benzanthracene represents a limiting structure beyond which the process of simplification cannot be carried without great loss in activity. The 10-methyl group clearly is important, for the parent hydrocarbon is almost completely inactive.[5] It is conceivable that the angular aromatic ring attached to the anthracene system in the 1,2-position may be subject to modification, for the 5,6-dimethyl- and 5,6-cyclopenteno derivatives of 1,2-benzanthracene are comparable with 1,2,5,6-dibenzanthracene in carcinogenic activity.[5] In order to test this point we have synthesized for comparison with cholanthrene one hydrocarbon differing from this substance in having two methyl groups in place of the angular benzenoid ring, and another one having a cyclopenteno ring in the 1,2-position.

For the synthesis of 1,2-cyclopenteno-5,10-aceanthrene (VIII), 4-chlorohydrindene was prepared from *o*-chlorobenzaldehyde through the known 4-chlorohydrindone-1[9] and a part of the material was converted into the lithium derivative V, while a part was transformed into 4-cyanohydrindene (VI) by interaction with cuprous cyanide in pyridine solution. By the condensation of V and VI and hydrolysis of the resulting ketimine, the ketone VII was obtained in a crystalline condition. Since the ketone is symmetrical, the Elbs reaction theoretically can proceed in only one direction, and the sole product found in the reaction mixture was the hydrocarbon VIII. The yield of nearly pure material was 21%, which is considerably better than is usually obtained in the Elbs condensation of *o*-methylated diphenyl ketones. On the other hand, the pyrolysis proceeds less smoothly than in the methylcholanthrene synthesis,[10] where the cyclopenteno ring involved in the cyclization interacts with a naphthoyl, rather than a benzoyl, group. The structure of the hydrocarbon was established by oxidation in glacial acetic acid solution to the anthraquinone acetic acid derivative IX.



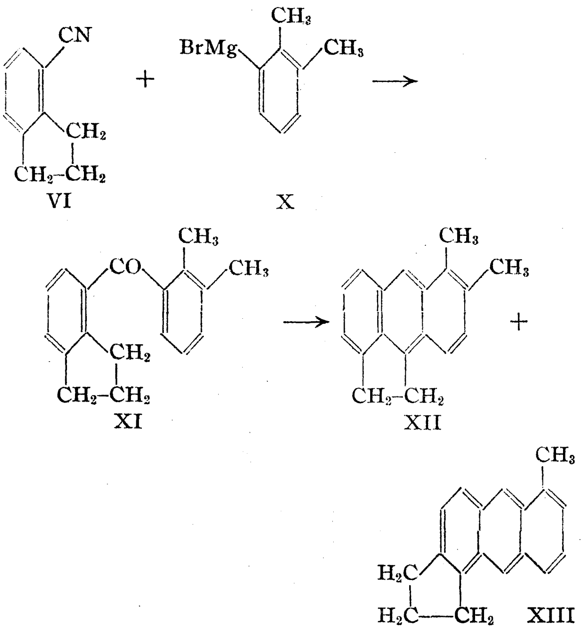
1,2-Dimethyl-5,10-aceanthrene (XII) was obtained along with the isomeric 1-methyl-5,6-cyclopentenoanthracene (XIII) by the pyrolysis of the ketone (XI) resulting from the condensation of 4-cyanohydrindene with the Grignard reagent (X) from *vic.*-bromo-*o*-xylene. The hydrocarbons were isolated in a satisfactory condition of purity only in very small amounts and oxidation experiments were completed only in the case of the lower melting isomer. This yielded a neutral anthraquinone having the full complement of carbon atoms, and therefore it must have come from 1-methyl-5,6-cyclopentenoanthracene (XIII). The other hydrocarbon probably has the alternate

---

[8] 10-Methyl-1,2-benzanthracene has been prepared from 1,2-benz-10-anthrone and methylmagnesium iodide, a method previously investigated without success by Cook, *J. Chem. Soc.*, 1089 (1930). The 10-ethyl compound, m. p. 113.5–114°, corr., has been prepared in a similar manner.

[9] Mayer, Philipps, Ruppert and Schmitt, *Ber.*, **61**, 1966 (1928).

[10] Fieser and Seligman, (a) THIS JOURNAL, **57**, 942 (1935); (b) **58**, 2482 (1936).



structure XII, but this was not established rigidly. An acidic substance giving a strong vat test was formed on oxidation, but it was not obtained in a pure condition.

In tests conducted by Dr. M. J. Shear 1,2-cyclopenteno-5,10-aceanthrene (VIII), injected subcutaneously into mice, has given no tumors in four months. Tests with the hydrocarbons XII and XIII have been negative after two months. No tumors have been obtained with aceanthrene[11] in one and one-half years.

Experimental Part[12]

4-Chlorohydrindene.—*o*-Chlorocinnamic acid was prepared from *o*-chlorobenzaldehyde, acetic anhydride, and potassium acetate according to the procedure of Lasch.[13] In experiments in which the heating was conducted for eight hours and for fourteen hours, the yields of recrystallized material, m. p. 207–209°, were 62 and 56%, respectively. The product was accompanied by a resinous substance insoluble in sodium carbonate solution. *o*-Chlorohydrocinnamic acid[14] was prepared by the catalytic hydrogenation of 77 g. of the unsaturated acid in 500 cc. of warm dioxane, using a total of 1 g. of Adams catalyst. The reaction proceeded to completion in about ten hours, the course of the reduction being followed most satisfactorily by precipitating the material with water from a test portion of the solution and determining the melting point. A small amount of unchanged acid raises the melting point and is detected easily. Continued hydrogenation beyond the desired point leads to an inferior product. The yield of satisfactory material, m. p. 93–95°, was 95%. A sample recrystallized from benzene–ligroin melted at 94.5–95.5°. For conversion to β-(*o*-chlorophenyl)-propionyl chloride[9] 70 g. of the acid was refluxed for three hours with 136 g. of purified thionyl chloride, the excess reagent was distilled, and the product was obtained as a colorless liquid, b. p. 147.5–149° (26 mm.); yield 73 g. (95%). A solution of this material (73 g.) in 1800 cc. of carbon bisulfide was cooled to 5° and 66 g. of aluminum chloride was added with vigorous mechanical stirring. The resulting light yellow solution was allowed to come to room temperature in one and one-half hours, during which time a white complex separated. After refluxing for fifteen minutes the product was collected in the usual way and taken into ether–benzene. The solution was washed in succession with dilute acid, dilute alkali, and saturated sodium chloride solution, and after removal of the solvent the product was distilled. The yield of colorless 4-chlorohydrindone-1,[9] b. p. 123–124° (5 mm.), m. p. 89–90.5° (recrystallized, 90–90.5°), was 55.5 g. (93%).

The Clemmensen reduction of the ketone (114 g.) was conducted exactly as described for the preparation of 4-methyl-7-chlorohydrindene.[10] The yield of 4-chlorohydrindene, b. p. 108–110° (24 mm.), was 93 g. (89%). Material for use in the formation of the lithium derivative was further purified by shaking it repeatedly with successive, equal, portions of concentrated sulfuric acid until an impurity which at first imparted to the acid a brilliant scarlet coloration was largely removed. Little material was lost in the process.

4-Cyanohydrindene.—Following the procedure described in an analogous case,[10b] 46 g. of the 4-chlorohydrindene heated with 27.8 g. of cuprous cyanide and 40 cc. of pyridine at 220° for seventeen hours, gave 34.5 g. (80%) of redistilled nitrile, b. p. 139–141° (22 mm.). The higher boiling material remaining after distillation of the nitrile boiled at about 120–180° (22 mm.) and proved to be largely the corresponding **amide.** Crystallized from alcohol, it formed long, flat, colorless needles, m. p. 173–173.5°, and it was identical with a sample prepared by the reaction of the acid chloride with aqueous ammonia solution.

Anal. Calcd. for $C_{10}H_{10}NO$: C, 74.49; H, 6.89. Found: C, 74.09; H, 6.60.

The nitrile proved very resistant to acid hydrolysis, refluxing with 6 *N* hydrochloric acid for two days giving only a small amount of the acid. When 1 g. of the nitrile was heated with 15 cc. of concentrated hydrochloric acid for ten hours at 180–200° there was some carbonization and 0.8 g. of **hydrindene-4-carboxylic acid** was obtained. Recrystallized from dilute alcohol, the acid formed flat needles, m. p. 152.5–153.5°.

Anal. Calcd. for $C_{10}H_{10}O_2$: C, 74.03; H, 6.24. Found: C, 73.69; H, 6.16.

Di-(4-hydrindyl) Ketone (VII).—For the manipulation of lithium metal it was found convenient to prepare wire of uniform diameter in a sodium press equipped with a 3-mm. die. The wire is collected under heavy paraffin oil and cut into uniform 12-cm. lengths, which are placed in a test-tube having a stopcock at the bottom and a nitrogen inlet near the stopper. The sticks of metal are washed with successive portions of benzene and ether under nitrogen pressure, draining the wash liquor through the stop-

[14] Gabriel and Herzberg, *Ber.*, **16**, 2037 (1883).

cock. The wire is calibrated by weighing one of the sections, or a part thereof. The lithium is introduced to the reaction flask after this has been flushed with nitrogen and with the gas streaming from the widest opening of the flask. While flushing the opened lithium container with nitrogen, the test-tube is held at right angles to the mouth of the flask, a length of lithium wire is withdrawn and short cylinders are cut with scissors and allowed to drop into the flask. Fresh, silvery surfaces are thus exposed and protected until the other reactants are added.

The reaction between 4-chlorohydrindene (12.1 g.) and lithium (1.1 g.) in ether (75 cc.) started at once without the use of catalysts but proceeded slowly owing to the formation of an adherent coating on the metal. After stirring the mixture under nitrogen for eighteen hours, titration of a 1-cc. portion indicated 71% conversion to the aryl lithium. There was little change at the end of forty hours (75% conversion), and the solution was cooled to −70° and 10 g. of 4-cyanohydrindene in 25 cc. of ether was added rapidly. The solution was allowed to come to room temperature and refluxed for one hour to complete the reaction. The mixture was decomposed with dilute hydrochloric acid, using in all about 100 cc. of 3 *N* acid, the ether was evaporated, 5 cc. of glacial acetic acid was added to facilitate the hydrolysis of the ketimine hydrochloride, and the mixture was refluxed for four hours. The ketone was taken into ether and the solution was filtered from a little suspended material and distilled, affording 10.5 g. (51%) of ketone, b. p. 206–209° (4 mm.). The distillate solidified completely and on crystallization from petroleum ether the compound formed large, colorless prisms, m. p. 77–78°.

Anal. Calcd. for $C_{19}H_{18}O$: C, 87.33; H, 6.93. Found: C, 86.88; H, 7.00.

1,2-Cyclopenteno-5,10-aceanthrene (VIII).—Two lots of the ketone VII, totaling 13.3 g., were pyrolyzed separately at 415–420° for thirty minutes and the product was distilled in vacuum and crystallized from ligroin. The crude, yellow hydrocarbon obtained melted at 160–170° and weighed 2.6 g. (21%). For purification a solution of the material in benzene–ligroin was passed through an adsorption tower of activated alumina, which removed some foreign material. The process was repeated and the material from the first portion of the filtrate after two crystallizations from ligroin formed pale yellow needles melting at 175.5–176° (0.3 g.). The bulk of the material, similarly crystallized, melted at 174–176° (1.7 g.). The hydrocarbon forms a light yellow, fluorescent solution in concentrated sulfuric acid.

Anal. Calcd. for $C_{19}H_{16}$: C, 93.40; H, 6.60. Found: C, 93.70; H, 6.99.

The picrate crystallized from ligroin in the form of purplish black needles, m. p. 140.5–141.5°. The regenerated hydrocarbon was unchanged in melting point.

Anal. Calcd. for $C_{19}H_{16}\cdot C_6H_3O_7N_3$: N, 8.88. Found: N, 8.69.

1,2 - Cyclopenteno - 9,10 - anthraquinone - 5 - acetic Acid (IX).—A solution of 0.65 g. of 1,2-cyclopenteno-5,10-aceanthrene and 3.5 g. of sodium dichromate in 35 cc. of glacial acetic acid was refluxed for two hours and the solution was diluted with a large volume of water. The precipitated material (0.35 g.) formed pale yellow microplates on crystallization from xylene. When heated rapidly, the substance melts with decomposition at 284–285°. It is soluble in hot, dilute soda solution and gives a red vat with alkaline hydrosulfite.

Anal. Calcd. for $C_{19}H_{14}O_4$: C, 74.54; H, 4.61. Found: C, 74.75; H, 4.38.

On attempting to decarboxylate the acid with copper carbonate in quinoline solution there was much decomposition and only a small amount of an impure neutral quinone, m. p. 121–123°, was isolated.

***vic.*-Bromo-*o*-xylene.**—The preparation of this halide by sulfonating *o*-xylene,[15] brominating the resulting 4-sulfonic acid, and hydrolyzing the bromo sulfonic acid is reported by Stallard,[16] but experimental details are lacking. After some investigation, the following procedure was developed.

A mixture of 106 g. of *o*-xylene and 107 cc. of concentrated sulfuric acid was heated on the steam-bath with mechanical stirring for one and one-half hours and the clear solution was dissolved in one and one-half liters of water. The solution was rendered neutral to litmus with 473 g. of hydrated barium hydroxide dissolved in about 750 cc. of water and the solution was filtered hot, cooled to 50–60°, and treated with a solution of 192 g. of bromine and 200 g. of barium bromide in 700 cc. of water. The temperature of the solution was maintained at 50–60° for fifteen hours, during which time barium 2-bromo-1,2-dimethylbenzene-4-sulfonate separated. The solid was collected after cooling, washed well with water, and air dried; yield, 225 g. This amount of pure salt (trihydrate) would correspond to a yield of 63%, but from the results of hydrolysis it is evident that the product contained some *o*-xylene sulfonate.

The hydrolysis with superheated steam was conducted in a distillation apparatus constructed with interchangeable ground-glass joints. The joint between the copper coil superheater and the glass inlet tube was made satisfactorily with a brass compression fitting, using alternate layers of asbestos and lead wool as packing. A total of 693 g. of barium salt was hydrolyzed in three lots, each of which was mixed with about 300 cc. of sulfuric acid, sp. gr. 1.67, in the distillation flask. The inlet steam was at 200–220° and the exit vapor was held at 150–160°. With the use of an automatic separatory take-off, the aqueous portion of the distillate was discarded and the heavy layer of oil was collected. The oil was washed with water, dried and fractionated twice through a 1-meter packed column. About 40 g. of *o*-xylene was recovered and the yield of *vic.*-bromo-*o*-xylene, b. p. 210.5–212.5°, was 149 g. (42%, calculated on the basis of pure barium salt).

4 - (2′,3′ - Dimethylbenzoyl) - hydrindene (XI).—An ethereal solution of the Grignard reagent from 48 g. of *vic.*-bromo-*o*-xylene was added to an ice-cold solution of 26.1 g. of 4-cyanohydrindene in ether. Considerable heat was liberated and the precipitate first formed largely dissolved. After refluxing the mixture overnight in an atmosphere of nitrogen a clear red solution resulted. This was treated with 3 *N* hydrochloric acid, the ether was distilled, and the mixture was refluxed for four hours to effect hydrolysis. An ethereal extract of the ketone was

washed with water, dried with saturated sodium chloride solution, and distilled, giving 38.3 g. of a yellow oil, b. p. 183–186° (4 mm.). which slowly solidified. On crystallization from petroleum ether (b. p. 20–40°), 25.6 g. (56%) of the ketone was obtained in a satisfactory condition, m. p. 74–75°. A sample recrystallized from the same solvent formed large, colorless cubes melting at 75–75.5°.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.49; H, 7.24. Found: C, 86.63; H, 7.32.

1,2 - Dimethyl - 5,10 - aceanthrene (XII) and 1-Methyl-5,6-cyclopentenoanthracene (XIII).—The ketone XI (20.5 g.) was pyrolyzed at 420–430° for two hours and the product was distilled in vacuum and taken up in petroleum ether (b. p. 20–40°). On standing at 0° a crystalline product (0.84 g.) consisting largely of the crude dimethylaceanthrene slowly separated. This was purified by passage of a solution in benzene through an adsorption tower of alumina, conversion to the picrate, regeneration with ammonia solution, and crystallization of the hydrocarbon from ligroin. **1,2-Dimethyl-5,10-aceanthrene** was obtained as pale yellow, glistening leaflets melting at 206–207°; yield 0.25 g. (1.3%).

Anal. Calcd. for $C_{18}H_{16}$: C, 93.06; H, 6.94. Found: C, 93.35; H, 6.45.

The picrate formed long, permanganate-colored needles from benzene–ligroin and melted at 169–170°.

Anal. Calcd. for $C_{18}H_{16}\cdot C_6H_3O_7N_3$: N, 9.11. Found: N, 8.96.

On refluxing a solution of 50 mg. of the hydrocarbon and 200 mg. of sodium dichromate in 5 cc. of glacial acetic acid for one hour and adding water, there was obtained a brown precipitate which partly dissolved in carbonate solution. This solution gave a strong vat test on adding sodium hydrosulfite, but the amount of product was insufficient for more definite characterization.

The second hydrocarbon, **1-methyl-5,6-cyclopentenoanthracene,** was isolated as the picrate from the initial petroleum ether mother liquors, after first removing extraneous material by purification in an adsorption tower. After repeated crystallization from benzene–ligroin, the **picrate** formed deep brownish red needles, m. p. 156–157°.

Anal. Calcd. for $C_{18}H_{16}\cdot C_6H_3O_7N_3$: N, 9.11. Found: N, 8.80.

The regenerated hydrocarbon, after crystallization from ligroin, formed pale-yellow blades melting at 131–132°; yield, 0.58 g. (3%).

Anal. Calcd. for $C_{18}H_{16}$: C, 93.06; H, 6.94. Found: C, 92.94; H, 6.87.

Oxidation to **1-methyl-5,6-cyclopentenoanthraquinone** was accomplished by refluxing a solution of 50 mg. of the hydrocarbon and 300 mg. of sodium dichromate in 5 cc. of glacial acetic acid for one hour and precipitating the product with water. The crude quinone was purified by crystallization from dilute alcohol, vacuum sublimation, and recrystallization from dilute alcohol. It formed long, slender, light yellow needles, m. p. 125–127°. Like other di-α-substituted anthraquinones, the compound does not give a vat test with hydrosulfite in aqueous alkali.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.49; H, 5.38. Found: C, 82.20, 82.18; H, 5.35, 5.56.

Summary

Tests with the previously described 5,10-dimethyl-1,2-benzanthracene and 10-methyl-1,2-benzanthracene indicate that these hydrocarbons are of the same order of carcinogenic potency as methylcholanthrene and cholanthrene, from which it appears that methylcholanthrene owes its high activity to the presence of the 1,2-benzanthracene ring system with a simple alkyl substituent at the 10-position. In order to determine if further simplifications of the structure can be made without loss in potency, 1,2-cyclopenteno-5,10-aceanthrene and 1,2-dimethyl-5,10-aceanthrene have been synthesized for comparison with cholanthrene (1,2-benz-5,10-aceanthrene), and biological tests are in progress.

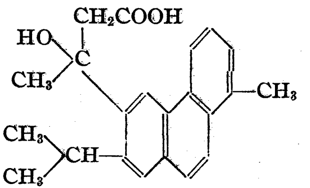
Investigations in the Retene Field. VIII. The Synthesis of 3′-Methyl-5,6-cyclopentenoretene

BY DAVID E. ADELSON[1] AND MARSTON TAYLOR BOGERT

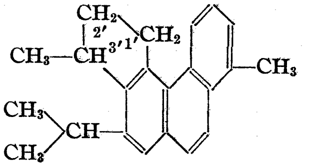
In a preliminary communication[2] announcement was made of the synthesis of 3′-methyl-5,6-cyclopentenoretene using 6-acetylretene[3] as the starting material. At that time attention was called to the fact that such a polycyclic hydrocarbon should be of interest because it arose as a synthetic product of retene, itself a natural product containing methyl and isopropyl groups which apparently have a very significant function in nature. Furthermore, 3′-methyl-5,6-cyclopentenoretene was shown to be of interest because it is a methyl isopropyl homolog of Diels' hydrocarbon[4] which has been the subject of much scientific investigation because of its isolation as a dehydrogenation product of a wide variety of naturally occurring materials.

It is of significance that retene was used for comparative purposes in preliminary work on the structure of Diels' hydrocarbon. Rosenheim and King[5] pointed out the striking similarity between the ultraviolet absorption spectra of Diels' hydrocarbon and retene and cited this fact as conclusive proof that this $C_{18}H_{16}$ was a phenanthrene derivative. Bernal and Crowfoot[6] suggested that Diels' hydrocarbon was a methylcyclopentenophenanthrene because of the striking similarity of the cell dimensions of this $C_{18}H_{16}$ to those of retene.

The Reformatsky reaction between 6-acetylretene, ethyl bromoacetate and zinc dust yielded a hydroxy ester which was hydrolyzed to β-hydroxy-β-6-retylbutanoic acid (I). The latter was further characterized by the preparation of its methyl ester. The hydroxy acid (I) was dehydrated by means of acetic anhydride to β-6-retylcrotonic acid which was then reduced to β-6-retylbutanoic acid. Cyclization of the acid chloride of the latter through the agency of aluminum chloride in benzene solution gave 1′-keto-3′-methyl-5,6-cyclopentenoretene which was characterized by the preparation of its oxime. This cyclic ketone was converted into 3′-methyl-5,6-cyclopentenoretene (II) by means of the Clemmensen reduction.



(I)



(II)

Inasmuch as 6-acetylretene was used as the starting material, the structure of 3′-methyl-5,6-cyclopentenoretene was defined at once. C_7 being occupied by the isopropyl group, only C_5 was available for ring closure. Solutions of 3′-methyl-5,6-cyclopentenoretene exhibited no fluorescence. Hillemann[7] has reported similar findings for three isomeric methylcyclopentenophenanthrenes.

The picrate of 3′-methyl-5,6-cyclopentenoretene was found to be unstable, being readily split into its components on repeated recrystallization. This is similar to the behavior of the picrate of 3′-methyl-1,2-cyclopentenophenanthrene.[8,9,10]

The physiological properties of 3′-methyl-5,6-cyclopentenoretene are being studied and will be reported at an early date.

Acknowledgment.—Our thanks are due to the Hooker Electrochemical Company, Niagara Falls, N. Y., for a generous supply of anhydrous aluminum chloride.

Experimental

β-Hydroxy-β-6-retylbutanoic Acid.—To a solution of 10 g. of 6-acetylretene and 17 g. of ethyl bromoacetate in 40 cc. of dry benzene, there was added 14 g. of zinc dust and a few crystals of iodine and the resulting mixture was carefully heated to the boiling point. After the initial vigorous reaction had subsided somewhat, the mixture was refluxed for three hours, cooled and poured onto a mixture of

cracked ice and 10% sulfuric acid. The benzene layer was separated, washed successively with 10% sulfuric acid, water, 5% sodium carbonate solution and water and the solvent was removed. The brown oil which remained could not be induced to crystallize. It was dissolved in 80 cc. of methanol containing 10 g. of potassium hydroxide and the resulting solution was refluxed for four hours. Most of the methanol was removed in a current of air, water added and the solution acidified. A brown precipitate (11.4 g.) formed. Recrystallized from a mixture of chloroform and petroleum ether (b. p. 40–60°), β-hydroxy-β-6-retylbutanoic acid appeared as fine, white crystals which melted with decomposition at 118–119° (corr.); yield, 8 g. Further recrystallization raised the melting point to 121–122° (corr.) where it remained constant.

Anal. Calcd. for $C_{22}H_{24}O_3$: C, 78.52; H, 7.20. Found: C, 78.24; H, 7.44.

Methyl Ester.—This was prepared and worked up as described above from 3.5 g. of 6-acetylretene, 6 g. of methyl bromoacetate and 5 g. of zinc dust in 30 cc. of dry benzene. After removal of the benzene, there remained an oil which solidified upon standing to a pale yellow solid; yield, 4 g. From 95% ethanol methyl β-hydroxy-β-6-retylbutanoate appeared as tiny, pale yellow crystals, m. p. 90–90.5° (corr.).

Anal. Calcd. for $C_{23}H_{26}O_3$: C, 78.81; H, 7.48. Found: C, 78.59; H, 7.32.

β-6-Retylcrotonic Acid.—A mixture of 10 g. of β-hydroxy-β-6-retylbutanoic acid, 20 g. of anhydrous sodium acetate and 75 cc. of freshly distilled acetic anhydride was refluxed for three hours, cooled and poured into 500 cc. of water. After the acetic anhydride had been destroyed and the aqueous solution removed by decantation, the crude solid was boiled with 400 cc. of 1% potassium hydroxide solution and filtered. Acidification precipitated 9 g. of a pale brown solid. Recrystallized from an ethanol–water mixture (norite), β-6-retylcrotonic acid appeared as short, white needles, m. p. 205–206° (corr.) with decomposition; yield, 7 g. An acetone solution of the unsaturated acid decolorized a solution of potassium permanganate in acetone.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.98; H, 6.97. Found: C, 83.25; H, 7.15.

β-6-Retylbutanoic Acid.—Eight grams of β-6-retylcrotonic acid was dissolved in 110 cc. of absolute methanol containing 2 g. of potassium hydroxide and 180 g. of 3% sodium amalgam was added. The resulting mixture was refluxed for six hours, allowed to stand overnight and filtered. Dilution of the filtrate followed by acidification yielded 8 g. of solid material. β-6-Retylbutanoic acid crystallized from a petroleum solvent[11] as small, glistening white plates, m. p. 152.5–153.5° (corr.); yield, 7 g.

Anal. Calcd. for $C_{22}H_{24}O_2$: C, 82.45; H, 7.56. Found: C, 82.60; H, 7.50.

1′-Keto-3′-methyl-5,6-cyclopentenoretene.—A mixture of 10 g. of β-6-retylbutanoic acid, 7 g. of powdered phosphorus pentachloride and 75 cc. of dry benzene was stirred and refluxed for one hour, cooled and 6.7 g. of anhydrous, powdered aluminum chloride was added in portions with stirring. The resulting mixture was stirred one-half hour at room temperature, then two and one-half hours at gentle reflux, cooled and poured onto cracked ice containing some concentrated hydrochloric acid. The benzene was removed by steam distillation and the viscous solid that remained behind was extracted with 350 cc. of 3% potassium carbonate solution. Acidification of the carbonate filtrate yielded 2 g. of unchanged β-6-retylbutanoic acid. The carbonate-insoluble residue was dissolved in 75 cc. of *n*-propanol, a hot solution of 7 g. of picric acid in 40 cc. of *n*-propanol was added and the mixture boiled for five minutes. The picrate that separated on cooling was recrystallized twice from 95% ethanol and the keto compound was regenerated by distribution between a 5% sodium carbonate solution and ether; yield, 3 g. Recrystallized from a petroleum solvent[11] and then from 95% ethanol, 1′-keto-3′-methyl-5,6-cyclopentenoretene appeared as short, pale yellow needles, m. p. 111.5–112.5° (corr.).

Anal. Calcd. for $C_{22}H_{22}O$: C, 87.37; H, 7.34. Found: C, 87.08; H, 7.57.

Oxime.—A suspension of 0.4 g. of the above ketene, 0.8 g. of hydroxylamine hydrochloride and 1.2 g. of anhydrous barium carbonate in 25 cc. of absolute methanol was refluxed for eight hours, filtered and the filtrate diluted with water. This precipitated the oxime in nearly theoretical yield. Recrystallized from dilute ethanol, it appeared as short, white needles which darkened somewhat at 192° (corr.) and melted with decomposition at 194–195° (corr.).

Anal. Calcd. for $C_{22}H_{23}ON$: C, 83.23; H, 7.31. Found: C, 82.96; H, 7.32.

3′-Methyl-5,6-cyclopentenoretene.—A mixture of 1.6 g. of 1′-keto-3′-methyl-5,6-cyclopentenoretene, 9 g. of amalgamated zinc and 20 cc. of concentrated hydrochloric acid was refluxed for twenty-four hours, an additional 5 cc. of acid being added after twelve hours. The pale yellow oil that resulted was taken up in ether, the ethereal solution washed with 10% hydrochloric acid, water and the solvent evaporated. The residue was dissolved in hot 95% ethanol, a hot solution of 1.9 g. of picric acid in 95% ethanol was added and the resulting picrate was twice recrystallized from absolute ethanol. The hydrocarbon (1 g.) was recovered by distribution of the picrate between a 5% sodium carbonate solution and ether. Recrystallized from an ethanol–water mixture, 3′-methyl-5,6-cyclopentenoretene appeared as short, white needles, m. p. 74.5–75.5° (corr.). The hydrocarbon was soluble in the common organic solvents and in vegetable oils.

Anal. Calcd. for $C_{22}H_{24}$: C, 91.61; H, 8.39. Found: C, 91.52, 91.95; H, 8.68, 8.73.

Picrate.—This was prepared by mixing hot solutions of 0.174 g. of the pure hydrocarbon and 0.146 g. of picric acid each in 4 cc. of absolute ethanol and boiling for five minutes. The picrate crystallized out in quantitative yield on cooling. Recrystallized from absolute ethanol, it appeared as bright orange needles, m. p. 154–155° (corr.). The picrate of 3′-methyl-5,6-cyclopentenoretene was readily split into its components on repeated recrystallization.

Anal. Calcd. for $C_{28}H_{27}O_7N_3$: C, 64.96; H, 5.26. Found: C, 64.36; H, 5.43.

[11] B. p. 77–115°. The solvent gave no coloration when shaken with concentrated sulfuric acid.

Summary

1. Hydrolysis of the product obtained in the Reformatsky reaction between 6-acetylretene and ethyl bromoacetate yields β-hydroxy-β-6-retylbutanoic acid.

2. Dehydration of this acid followed by reduction gives β-6-retylbutanoic acid whose acid chloride yields upon cyclization 1′-keto-3′-methyl-5,6-cyclopentenoretene.

3. The Clemmensen reduction of this cyclic ketone yields 3′-methyl-5,6-cyclopentenoretene.

A Series of Aliphatic Dimethyl Amides[1]

BY JOHN R. RUHOFF[2] AND E. EMMET REID

Dimethyl amides have been prepared by several investigators,[3] but the data on them are incomplete and not correlated. It seemed desirable to make a complete series of them so that comparisons can be made, not only between individual compounds, but also between this and other series. The eight dimethyl amides of the normal acids from formic to caprylic have been prepared and characterized. An unexpected discovery was that the acids except formic and their dimethyl amides give azeotropes boiling 4–5° *above* the amides. The data are in Table I and II. All of these dimethyl amides are mobile liquids which mix in all proportions with carbon disulfide, chloroform, carbon tetrachloride, benzene, ether, acetone and alcohol. The first two have limited solubility in petroleum ether, while the others mix with it. The lower members mix with water, but the higher homologs become increasingly insoluble; the solubility of VIII in water is less than 1%. In these respects dimethyl amides resemble esters, except that they are much more soluble in water and boil at substantially higher temperatures than esters of the same carbon content.

Another object was to investigate further the method of preparation of dimethyl amides recently proposed by Mitchell and Reid.[4] Repetition of their work showed that dimethyl amides are formed in liberal amounts by their procedure, but that the reactions are not complete, except with formic acid. Fractionation, taking very close cuts, gave what appeared to be pure compounds, but these proved to be azeotropic mixtures of the dimethyl amides and the acids. These azeotropes caused Mitchell and Reid to overestimate their yields and troubled van der Zande.[5] The data on these constant boiling mixtures are brought together in Table II.

Experimental

Two equivalents of gaseous dimethylamine was passed into an acid which was heated under a reflux condenser from the top of which the excess of amine passed to a water trap. The water in the condenser jacket was kept warm enough to permit water vapor to escape. When there seemed to be no further reaction, the product was fractionated through a six-foot (2 meter) precision still,[6] a narrow cut being taken at what appeared to be the boiling point. The products were found to contain free acid which was titrated with the results given in Table II. Several experiments were made with acetic acid, noting the temperature of the boiling mixture, and titrating samples of it after successive portions of amine had been added. No matter how much amine was passed in the liquid in the flask never became neutral.

Dimethyl acetamide was obtained in 78% yield by heating 360 g. of acetic acid, saturated with gaseous dimethylamine at 35°, for five hours at 200° in a steel bomb. Solid caustic potash was added to the product to take up water and acetic acid. The liquid thus purified was distilled at 162–165°; it was then dried and fractionated taking the cut 164.8–164.9° at 759 mm. Analysis showed this to be 99.25% pure. The dimethyl amides of butyric, heptoic and caprylic acids were made similarly. With the higher acids a new difficulty was encountered; the potassium salt of the acid is soluble in the dimethyl amide. In such cases the reaction product was taken up in a large volume of benzene and this solution shaken with potassium hydroxide solution, dried and distilled. Franchimont and Klobbie prepared heptoic dimethyl amide by this method.

Other dimethyl amides were obtained in good yields by adding the acid chloride dropwise during three hours to a

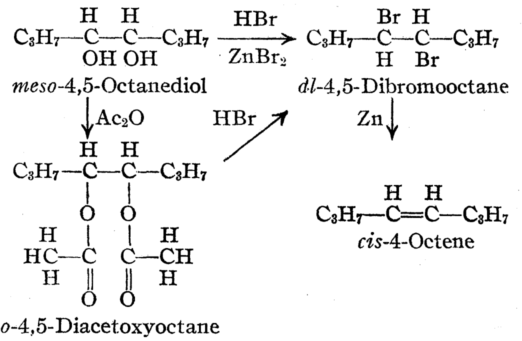
Investigations on the Stereoisomerism of Unsaturated Compounds. III. The Preparation of the *cis* and *trans* 4-Octenes[1]

BY WILLIAM G. YOUNG, ZENE JASAITIS AND LEO LEVANAS

The *cis* and *trans* 4-octenes were prepared from the *dl*- and *meso*-4,5-dibromooctanes by the method of Gladstone and Tribe as modified by Wilkinson.[2] The 4,5-dibromooctanes were obtained from the *meso*- and *dl*-4,5-octanediols in two ways: (a) by the direct action of a reagent made by saturating an aqueous solution of zinc bromide with hydrogen bromide at 20° and (b) by the action of hydrobromic acid (saturated at 0°) on the diacetates of the *dl*- and *meso*-4,5-octanediols. The reactions involved are as follows



$$\begin{tikzcd}
dl\text{-4,5-Octanediol} \arrow[r, "HBr", "ZnBr_2"'] \arrow[d, "Ac_2O"] & meso\text{-4,5-Dibromooctane} \arrow[d, "Zn"] \\
dl\text{-4,5-Diacetoxyoctane} \arrow[ru, "HBr"'] & trans\text{-4-Octene}
\end{tikzcd}$$

The dibromooctane derived from the meso glycol by the HBr–$ZnBr_2$ method was first throught to be a mixture of both *meso* and *dl* modifications since it boiled over a considerable range (83–98° at 4.5 mm.) and contained the correct quantity of bromine by Carius analysis. The fact that this bromide gave a mixture of octane and octene when treated with zinc and alcohol brought still more concern for it indicated that this reagent had caused a partial replacement of bromine by hydrogen. A reduction of this type had never been observed by the authors in dealing with similar dibromo compounds. However, when the dibromooctanes, prepared from the 4,5-diacetoxyoctanes, were treated with zinc in alcohol they produced only 4-octene. It was therefore considered unlikely that the octane mentioned above was formed by the reduction of the 4,5-dibromooctane in the previous sample. A discussion of these results with Professor H. J. Lucas of the California Institute of Technology brought out the fact that the HBr–$ZnBr_2$ treatment of the 2,3-butanediols gave very poor yields of dibromide. On the other hand, a ketone was formed as the result of a pinacolone rearrangement. In our case the rearrangement undoubtedly was followed by replacement of hydroxyl by bromine before ketone formation occurred, thus giving rise to 4,4-dibromooctane. In order to separate the mixture of 4,4- and 4,5-dibromooctanes the material was converted into a mixture of octene and octane which was then treated with bromine. The dibromide thus formed was separated from the octane by distillation. The product collected was identical with the *dl*-4,5-dibromooctane obtained from *meso*-4,5-octanediol by the diacetate method. The HBr–$ZnBr_2$ method proved to be the most satisfactory for the preparation of the dibromide from the *meso*-glycol and the HBr–diacetate method was best for the dibromide from the *dl*-glycol.[3]

The Configuration of Compounds Involved in the Synthesis of the *cis* and *trans*-4-Octenes.—Since previous work[4] on the reaction of stereoisomeric dibromides with potassium iodide in ethyl or methyl alcohols has shown that the meso isomer has the higher reaction rate, we have concluded from the specific second order reaction rate constants, k_2, for the 4,5-dibromooctanes,[5] that the value of $k_2 = 0.0996$ for the dibromide from the *meso*-4,5-octanediol shows that it is the *dl*-modification while the value of $k_2 = 0.1268$ for the dibromide from the *dl*-4,5-

[1] This paper was presented before the Organic Division at the ninety-second meeting of the American Chemical Society held in Pittsburgh, Pa., September 7–11, 1936. The work was accomplished with the aid of a grant from the Board of Research of the University of California.

[2] Wilkinson, *J. Chem. Soc.*, 3057–62 (1931).

[3] This procedure was tried at the suggestion of Professor H. J. Lucas who had found that the 2,3-dibromobutanes could not be prepared by the HBr–$ZnBr_2$ method, Wilson and Lucas, THIS JOURNAL, **58**, 2396 (1936).

[4] (a) Van Duin, *Rec. trav. chim.*, **45**, 345–62 (1926); (b) Dillon, Young and Lucas, THIS JOURNAL, **52**, 1953–64 (1930).

[5] The details of this work, together with that on other dibromides, will be published elsewhere.

octanediol shows that it is the *meso* isomer. Obviously, a change in configuration has taken place in going from the glycols to the dibromides. A similar change in configuration has been observed in the case of the 2,3-butanediols by Lucas and Wilson.[3] It should be noted that only one of the asymmetric carbon atoms is involved in the inversion. If both asymmetric carbons were involved, the configuration change would not be apparent.

Fortunately, it is possible to confirm the conclusion that the *dl*-glycol gives the *meso*-dibromide. The *meso*-4,5-dibromooctane having the higher reaction rate should give the higher melting *trans*-4-octene and the *dl*-4,5-dibromooctane should give the lower melting *cis*-4-octene. The melting points of the octenes were found to be in agreement with the prediction.

Since the formation of the *meso*-4,5-dibromooctane from the *dl*-glycol involves two steps the question naturally arises: At which step does the change of configuration take place? A comparison of physical properties such as density and refractive index of the 4,5-diacetoxyoctanes with those of other known *meso*- and *dl*-stereoisomers leads to the conclusion that the *meso*-glycol gives the *meso*-diacetate. Work is now in progress in this Laboratory in which the dextrorotatory 4,5-octanediol is being converted into the diacetate and thence into the dibromooctane. The optical rotation is being followed at each step.

The Synthesis of Normal cis-trans-Alkenes

Although the preparation of alkene hydrocarbons has received much attention in the literature, it has been recognized only in recent years that the usual methods of preparation of olefins give rise to mixtures of structural as well as geometrical isomers.[6] In spite of the fact that this problem of dealing with mixtures has been partially solved by the development of (a) high precision fractionating columns and (b) synthetic methods which give rise to pure products, nevertheless, only the pure *cis*- and *trans*-butenes and pentenes are known.[7] Although several *cis*-isomers of the higher molecular weight normal alkenes have been prepared,[8] no pure *trans*-isomers have been obtained. Both the bromo-ether method[9] and the unsaturated acid method[7] of preparing alkenes give rise to pure structural isomers, but, unfortunately, fractionation of the intermediate or final products into their geometrical isomers becomes more difficult as the molecular weight increases in the homologous series. Schmitt and Boord[6a] have pointed out the fact that the apparent nonexistence of *cis–trans* isomerism in the case of 2-hexene and 3-hexene is due to the similarity in boiling point of the isomers. In the present paper it may be noted that the isomeric 4-octenes also have identical boiling points. The work of Lucas and Prater[7d] indicates that the unsaturated acid method has another disadvantage. The α-ethylcrotonic acids were prone to form equilibrium mixtures readily, a difficulty which was not encountered with the α-methylcrotonic acids.[7b] If this tendency to undergo stereomutation increased with molecular weight, it would be very difficult to isolate and keep the *cis* and *trans* acids necessary in the preparation of the isomeric normal hexenes and heptenes.

Although the action of zinc on dibromoalkanes has been used frequently in the purification of alkenes,[10] this procedure ordinarily has not been used in the preparation of pure *cis* and *trans* isomers since the usual source of the pure isomeric dibromides has been the hydrocarbons themselves. However, the method has been used in the synthesis of the polyene hydrocarbons[11] and now that it is feasible to obtain the pure *meso*- and *dl*-glycols[3,12] required for the preparation of the pure isomeric dibromides, this method should prove invaluable in synthesizing the *cis*- and *trans*-hexenes, heptenes, etc.

Work is now under way in this Laboratory on the preparation of the 3-hexenes and 3-heptenes from the corresponding glycols.

Experimental Part

***meso*- and *dl*-4,5-Octanediols.**—The pure *meso*- and *dl*-4,5-octanediols used in this work were prepared according to the method recently described.[12] The isomers had the

following properties: *meso*-isomer, m. p. 123.5–124.5°; *dl*-isomer, m. p. 28°; b. p. (8 mm.) 109.8–110.0°; $n^{24.5}_D$ 1.4419.

The Reaction of Phosphorus Tribromide with the 4,5-Octanediols.—The most promising method of preparing the 4,5-dibromooctanes appeared to be the reaction of phosphorus tribromide on the dipropylglycols. However, when the general procedure described by Farmer and coworkers[11a] for the preparation of dibromohexadiene from divinylglycol was applied to the 4,5-octanediols, the yields were unsatisfactory.

Preparation of 4,5-Dibromooctanes, HBr–ZnBr$_2$ Method.—A mixture of 44 g. (0.3 mole) of *meso*-4,5-octanediol, 270 g. of 40% hydrobromic acid and 270 g. (1.2 moles) of zinc bromide contained in a 500-ml. round-bottomed flask was saturated with hydrogen bromide at 20°. The reaction mixture was allowed to stand overnight at this temperature. The flask was then attached to a reflux condenser and gradually warmed to 40° in a water-bath. This temperature was maintained during the day time over the next forty-eight to fifty-four hours but the flask was allowed to return to room temperature during the night. The dibromooctane, which gradually separated as an oil phase, amounted to 65–75% of the theoretical yield. At temperatures higher than 40° the reaction mixture had a tendency to become so dark that it was difficult to see the boundary between the dibromide and aqueous phases. The crude dibromide was then separated and washed several times with dilute sodium bicarbonate solution to neutralize the acid. The last washing was made with the bicarbonate solution since water occasionally formed a stable emulsion with the dibromide. The crude dibromide was then diluted with twice its volume of carbon tetrachloride and dried with anhydrous calcium chloride in the dark. Distillation of the dried solution through a 60-cm. Vigreux column gave 50 g. of dibromide, b. p. (4.5 mm.) 83–98°, n^{20}_D 1.4945. Per cent. bromine by Carius method, found: 58.24, 58.43; calcd.: for $C_8H_{16}Br_2$, 58.77. When the above method was used in preparing the dibromide from *dl*-4,5-octanediol, the reaction mixture became excessively colored and the yield of dibromooctane was less than half that obtained from the *meso*-glycol. Consequently, another procedure was adopted for preparing the dibromide from the *dl*-glycol (see HBr–diacetate method below).

Purification of *dl*-4,5-Dibromooctane from *meso*-4,5-Octanediol by the HBr–ZnBr$_2$ Method.—Since the dibromide obtained from the *meso*-4,5-octanediol described above had a boiling range of 15° and yet contained the required quantity of bromine for dibromooctane, it was at first thought to be a mixture of both the *dl*- and *meso*-dibromides. However, when it was treated with zinc in alcohol it gave a product which was approximately 50% unsaturated. (See discussion for explanation.) Consequently, several dibromide preparations were combined and purified as follows. The dibromide mixture was converted into a hydrocarbon mixture by the method of Gladstone and Tribe as modified by Wilkinson.[2] This hydrocarbon mixture was then placed in an all glass reaction flask kept at −15° and brominated by adding small amounts of bromine from time to time. At the end of the reaction, a slight excess of bromine was added to remove the last trace of unsaturated hydrocarbon. The product was washed immediately with dilute sodium bisulfite solution, sodium bicarbonate solution, and water, and then dried with anhydrous calcium chloride. Fractional distillation of the product at reduced pressures through a 70-cm. lagged, Vigreux column equipped with a Hopkins condenser in the Claisen-head gave crude octane, b. p. 123–125.5°, and *dl*-dibromooctane, b. p. (4.3 mm.) 84.3–85.8°. After further fractionation the *dl*-dibromooctane possessed the following properties: b. p. (4.3 mm.) 84.0–84.5°; d^{20}_4 1.4569; n^{20}_D 1.4981; MR found, 54.72; calcd. for $C_8H_{16}Br_2$, 54.38. Specific second order reaction rate constant with potassium iodide in methyl alcohol at 75°, $k_2 = 0.0996$. Per cent. bromine by Carius method, found, 58.46; calcd., 58.77.

Preparation of *meso*- and *dl*-Diacetoxyoctanes from *meso* and *dl*-4,5-Octanediols.—One-half mole quantities (73.0 g.) of either *meso*- or *dl*-4,5-octanediol, 2.5 moles (237 ml.) of acetic anhydride, and 1.5 moles (120 ml.) of pyridine were heated together under a reflux condenser at 85–95° for seven hours.[13] The mixture was then cooled, diluted with 600 ml. of water and saturated with sodium chloride. The upper layer which contained the diacetate was separated, diluted with an equal volume of ether and dried over anhydrous calcium chloride. After removal of the solvent the diacetate was fractionally distilled at reduced pressure through the column used in the distillation of the dibromooctanes. The yields of diacetates from both glycols averaged 75% of the theoretical. The products had the following properties: diacetate from *meso*-4,5-octanediol, b. p. (5.0 mm.) 100°; n^{20}_D 1.4252; d^{20}_4 0.9686; MR found, 60.89; calcd. for $C_{12}H_{22}O_4$, 60.84; equivalent weight, found: 114.5; calcd., 115.1; diacetate from *dl*-4,5-octanediol, b. p. (5.5 mm.) 110°; m. p. 26°; n^{20}_D 1.4283; d^{20}_4 0.9732; MR found, 60.88; calcd., 60.84; equivalent weight, found, 115.6; calcd., 115.1.

Preparation of 4,5-Dibromooctanes, HBr–Diacetate Method.—Three-tenths of a mole (69.0 g.) of the diacetate from either *meso*- or *dl*-4,5-octanediol and 210 g. of 48% hydrobromic acid were placed in a 500-ml. glass-stoppered bottle and the mixture was saturated with hydrogen bromide at 0°. After the glass stopper was wired on, the bottle was placed in an ice box. After ten days the oil phase which formed was separated, washed, dried, distilled and purified as described above for the dibromide from the HBr–ZnBr$_2$ method. The yields of dibromooctanes from both of the diacetates averaged 55% of the theoretical before the final purification, in which there was usually a 90–95% recovery. The properties of the *meso*-4,5-dibromooctane obtained from the diacetate from the *dl*-4,5-octanediol are as follows: b. p. (4.3 mm.) 79–80.0°; n^{24}_D 1.4967; d^{20}_4 1.4525; MR found, 54.94; calcd. for $C_8H_{16}Br_2$, 54.38. Specific second order reaction rate constant with potassium iodide in methyl alcohol at 75°, $k_2 = 0.127$. Bromine by Carius method, found, 58.64; calcd., 58.77%.

Preparation of the *cis*- and *trans*-4-Octenes

(a) The Reaction of Phosphorus Triiodide with *meso*-4,5-octanediol.—Since phosphorus triiodide was used ef-

---

[13] This procedure was adopted with the idea of obtaining good yields of a product free from the mono-acetate. Since the results were entirely satisfactory it was used throughout the work. It is possible that smaller quantities of acetic anhydride and a shorter period of heating would be just as acceptable.

fectively in the preparation of the diphenyl polyenes by Kuhn and Winterstein,[11b] this reagent, prepared from yellow phosphorus and iodine in carbon disulfide, was allowed to react with *meso*-4,5-octanediol (0.1 mole) according to their directions. The reaction mixture was then poured onto ice and the carbon disulfide layer was washed with dilute sodium thiosulfate solution, dilute sodium bicarbonate solution, and water, and dried over anhydrous calcium chloride. Distillation of the dried solution through a 60-cm. Vigreux column gave 6.3 g. of product, b. p. (47 mm.) 112–114°. This product did not react with bromine. It evolved iodine, however, when exposed to the light but not when heated at 75° for several hours. Molecular weight by Beckmann method in benzene, found, 240; calcd. for $C_8H_{17}I$, 240.1. It was therefore concluded that the product was probably 4-iodooctane formed by partial reduction. No further identification was made. There was no evidence for the formation of 4-octene by this method.

(b) **The Reaction of 4,5-Dibromooctane with Potassium Iodide in Aqueous Acetone at 75°.**—A mixture of 27.2 g. (0.1 mole) of dibromooctane from the HBr–$ZnBr_2$ method, and 40 ml. of saturated potassium iodide solution was made up to a volume of 250 ml. with acetone and sealed in a 500-ml. glass bulb. The bulb was placed in a thermostat at 75°. Every twelve hours the bulb was cooled rapidly to room temperature and opened. A 5-ml. portion of the reaction mixture was titrated against standard sodium thiosulfate solution and the bulb was resealed and placed in the thermostat again. After forty-eight hours the iodine concentration became constant. The yield of octene based on the iodine liberated was calculated to be 55.5%. It was concluded that this poor yield resulted from the establishment of an equilibrium between diiodooctane, iodine and octene and the method was discarded in favor of the zinc–copper couple method of preparing octene. However, since it was found later that the dibromooctane used in this work was actually a mixture of approximately equal quantities of 4,5-dibromooctane and of 4,4-dibromooctane which would not be expected to liberate iodine with potassium iodide, it is evident that the reaction to form octene actually went to completion and the method described above would be just as acceptable for the preparation of octene as the zinc–copper couple method.

(c) **The Reaction of *meso*- and *dl*-4,5-Dibromooctane with Zinc–Copper Couple in Alcohol.**—*cis* and *trans*-4-octenes were prepared from the pure *dl*- and *meso*-4,5-dibromooctanes by the method of Gladstone and Tribe as modified by Wilkinson.[2] After distillation at reduced pressure the octenes possessed the following properties:[14] *cis*-4-octene from *dl*-dibromooctane, m. p., approx. −115°; b. p. (97.4 mm.) 61.9°; b. p. (760 mm.) 20–20.5°; $n^{24.2}D$ 1.4111; d^{20}_4 0.7186; MR found, 38.92; calcd., 38.46. Analysis for unsaturation, 100.5% *trans*-4-octene from *meso*-dibromooctane, m. p. approx. −105°; b. p. (103 mm.) 62.9 mm.; b. p. (760 mm.) 20–20.5°; $n^{24.2}D$ 1.4110; d^{20}_4 0.7165; MR found, 39.03_4; calcd., 38.46. Analysis for unsaturation, 99.7%.

The authors are indebted to Dr. G. Ross Robertson of this Laboratory and Professor H. J. Lucas of the California Institute of Technology for their helpful suggestions.

Summary

1. *cis* and *trans*-4-octenes have been prepared from *dl*- and *meso*-4,5-dibromooctanes by the action of zinc–copper couple in alcohol. The direct action of phosphorus triiodide on *meso*-4,5-octanediol gives a monoiodooctane instead of the expected octene.

2. *meso*- and *dl*-4,5-dibromooctanes have been prepared: (a) from *meso*- and *dl*-4,5-octanediols by the action of a solution of zinc bromide, saturated with hydrogen bromide at 20°, on the glycols and (b) by the action of hydrobromic acid, saturated at 0°, on the 4,5-diacetoxyoctanes from the *meso*- and *dl*-4,5-octanediols.

3. A change of configuration occurs during the conversion of the glycols into the dibromooctanes. The *meso*-4,5-octanediol gives *dl*-4,5-dibromooctane and the *dl*-4,5-octanediol gives *meso*-4,5-dibromooctane.

4. 4,4-Dibromooctane is also formed from the *meso*-4,5-octanediol by the HBr–$ZnBr_2$ reagent, due to a pinacolone rearrangement.

5. The synthesis of the normal *cis–trans*-alkenes has been discussed.

LOS ANGELES, CALIF. RECEIVED DECEMBER 14, 1936

---

[14] The approximate melting points of the 4-octenes were obtained through the kindness of Mr. Saul Winstein, a graduate student at the California Institute of Technology. Due to the fact that the necessary equipment was not available, the exact melting points of the octenes have not yet been determined.

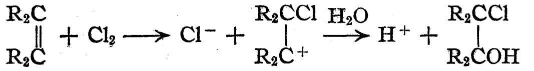
The Mechanism of Addition Reactions. Chloro- and Bromo-Beta-Lactones from Dimethylmaleic and Dimethylfumaric Acids

BY D. STANLEY TARBELL AND PAUL D. BARTLETT

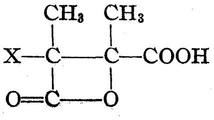
Recent kinetic evidence on the bromination of stilbene in methyl alcoholic solution[1] has by analogy strengthened the view that the following steps are involved in the formation of chlorohydrins in aqueous solution



$$\begin{matrix}R_2C\\ \| \\ R_2C\end{matrix} + Cl_2 \longrightarrow Cl^- + \begin{matrix}R_2CCl\\ | \\ R_2C^+\end{matrix} \xrightarrow{H_2O} H^+ + \begin{matrix}R_2CCl\\ | \\ R_2COH\end{matrix}$$

where the first and second steps may or may not occur synchronously. We have investigated the aqueous chlorination and bromination of dimethylmaleic and dimethylfumaric acids in the search for more detailed information about this process.

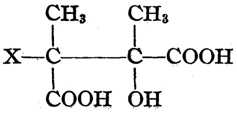
When the sodium salt of dimethylmaleic acid is treated with chlorine water or bromine water, there can be isolated in poor yield from the resulting oil a halogenated beta-lactone (I or II),



I X = Cl, m. p. 92–94°

II X = Br, m. p. 95–96°

whose structure is established by analysis, neutralization equivalent and molecular weight determinations. Several hours of standing in 5% sulfuric acid at room temperature opens the lactone ring irreversibly to the halohydrin acid (III or IV). This accounts for the small amounts of halohydrin acid which appear occasionally along with the lactones when these have been allowed to stand in solution before isolation.



$$\begin{array}{ccc} & CH_3 & CH_3 \\ & | & | \\ X- & C- & C-COOH \\ & | & | \\ & COOH & OH \end{array}$$

III X = Cl, m. p. 171–173°

IV X = Br, m. p. 168–170°

The reaction of sodium dimethylfumarate with chlorine water or bromine water takes an exactly similar course, leading to a pair of beta-lactones (V, m. p. 141–142°, and VI, m. p. 148–150°) which are stereoisomeric with I and II. Acid hydrolysis opens these lactones to the same chlorohydrin and bromohydrin, respectively, (III and IV) as are obtained from the lactones of the maleic series. Since these halohydrin acids melt with decomposition, a check on the stereochemical purity and identity of the chlorohydrins was obtained by measuring the rate of their reaction with aqueous sodium hydroxide, a type of process whose rate in the unmethylated series[2] is very dependent upon configuration. Both I and V yielded samples of III which reacted as a single substance with sodium hydroxide, and both at the same rate, within the experimental accuracy. This test was not applied to the bromohydrin acids.

The beta-lactones cannot be made from the halohydrins; therefore if any *one-step addition* (of chlorine or hypochlorous acid) preceded the formation of the chlorolactone in solution, it must have been the addition of chlorine to give a symmetrical sodium dichlorodimethylsuccinate (VII) which might then eliminate sodium chloride to form the lactone. Only one of the two possible acids of this structure is known,[3] but since both lactones have been prepared, the known acid should give one of them if a dichloro acid is intermediate at all in this process. It was found, as expected from previous work,[4] that when this acid was neutralized with sodium bicarbonate and allowed to stand at room temperature for two days, there was produced chlorotiglic acid (VIII), m. p. 66–68°, some of the starting material still remaining unchanged, and no beta-lactone appearing. A quantitative run on the elimination of sodium chloride from VII showed that this reaction requires about twenty-four hours at 25°, while both lactones have been isolated in less than half an hour from the reaction mixture. Therefore the dichloro acid is not intermediate in the formation of the lactone, which is instead the product of a two-step addition process.

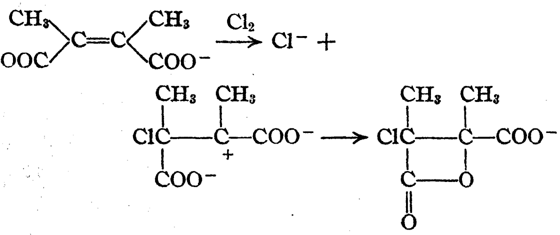
[4] Otto and Beckurts, *Ber.*, **18**, 847 (1885); Otto and Holst, *J. prakt. Chem.*, **149**, 467 (1890).

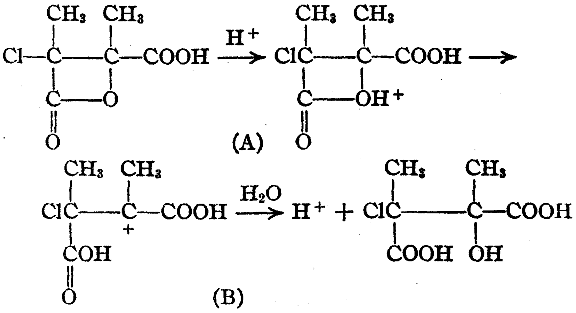
The most likely such process, in view of the evidence in the case of analogous reactions, is



These steps may be pictured as occurring in succession, or synchronously. Against the idea of successive reaction steps stands the unlikelihood that the intermediate zwitterion could long survive without a stereochemical equilibration which would lead to identical products from both dimethylmaleic and dimethylfumaric acids. On the other hand, the idea of a simultaneous attack of halogen and carboxylate oxygen upon the ends of the double bond places us immediately in stereochemical difficulties; for a model of the molecule in question shows that either a methyl or a carboxylate group directly confronts the attacking oxygen in the fumarate or maleate ion, and very large torsion of the rigid double bond structure would be necessary if this attack occurred *before* the complete opening of the double bond by the halogen. These difficulties are best avoided by the hypothesis that the reaction steps occur in the quickest possible succession.

Two other well-known puzzling facts of organic chemistry are reëmphasized in this series. One is the total inertness of the completely substituted ethylene, dimethylmaleic anhydride, toward bromine, described below. The other is the great effect of methyl substitution in favoring ring-closure. Free dimethylmaleic acid is completely unknown, the spontaneous formation of its anhydride being very rapid under all experimental conditions; the appearance of beta-lactones on halogenation of its salts is another manifestation of the enhancement of ring closure by methyl groups. Probably a satisfactory explanation of these effects of methyl substitution, and of the course of the halogenlactone formation, can be found only at the same source.

The formation of a common chlorohydrin acid from the two isomeric chlorolactones makes it clear that the ring-opening of these lactones by 5% sulfuric acid is not an ordinary ester hydrolysis, a process which occurs without stereochemical inversion at the alcoholic hydroxyl group. Models show so little difference in the apparent availability of the lactonic carbonyl groups of the two isomers to attack, that we propose that *neither* ring-opening is a normal ester hydrolysis, but that the opening occurs according to the mechanism



Here the exchange reaction between the positive ion (B) and water is assumed to be slow enough to permit the positive ion (B) to take up its preferred configuration before reaction. Thus in the lactone *formation* the presence of an active negative ion near the positive carbonium center makes reaction faster than steric equilibration; under the acid conditions of hydrolysis the intermediate must react with a neutral molecule (water), and the reverse is true.

The hydrolysis of the lactones under alkaline conditions would have been interesting from this point of view, but it was attended by replacement of the halogen and led to no isolable compounds. From treatment of the chlorohydrin with barium hydroxide at 0° a small amount of material was obtained, m. p. 158–160° with decomposition, which gave analytical figures for the oxidic acid, 2,3-epoxybutane-2,3-dicarboxylic acid. That no hydroxylactone was formed in this reaction was shown by a rate run in which the amount of chloride ion produced was always equal to that of hydroxyl ion consumed. When the sodium salt of the chlorolactone (I) was heated in aqueous solution on the steam-bath, chlorotiglic acid was produced; similar treatment of the isomeric chlorolactone salt yielded a solid mixture melting at 180–240°, which was not studied further.

In agreement with Michael,[3] we were unable to obtain a bromine addition product from dimethylmaleic anhydride in carbon tetrachloride solution. Illumination with a 400-watt projection lamp discharged the bromine color in a few minutes, but hydrogen bromide was evolved copiously, and the starting material was the only solid obtainable from the solution. Only the bromohydrin acid resulted from treatment of the bromolactone II with 40% hydrobromic acid. Equivalent quantities of dimethylmaleic anhydride and bromine stood for three weeks in glacial acetic acid 1 *N* in hydrogen bromide (catalytic conditions, in the experience of Williams and James[5]) without visible reaction.

Experimental

Preparation of Dimethylmaleic Anhydride.—Acetoacetic ester was methylated with methyl bromide, the bisulfite derivative of the methylated ester treated with sodium cyanide, the nitrile hydrolyzed and the resulting dimethylmaleic acid dehydrated, according to the procedure of Ott,[6] with an over-all yield of 19.5%.

Bromination of Dimethylmaleic Acid.—Twenty-five grams of dimethylmaleic anhydride was neutralized with 16 g. of sodium hydroxide in 200 cc. of water, and added to a solution of 32 g. of bromine in 2 liters of water. Reaction was complete in a few minutes. The solution was extracted three times with ether, then acidified with 0.2 equivalent of sulfuric acid and extracted three times more. The ether was evaporated, yielding 38.3 g. of mixed oil and crystals. After four crystallizations from benzene–petroleum ether, there resulted 5.3 g. (11%) of bromohydrin acid, m. p. 155–160°, and 14.8 g. of pure lactone (33%), m. p. 95–96°, crystallizing in clumps of thick needles. The presence of ether interferes with crystallization of the lactone. It is very soluble in the common solvents, except petroleum ether.

Anal.[7] Calcd. for $C_6H_7O_4Br$: C, 32.3; H, 3.2; Br, 35.83. Found: C, 32.3; H, 3.4; Br, 36.37, 35.10. Molecular weight calculated, 223; found in benzene, 422; in acetic acid, 197, 192. Equivalent weight by titration with alkali in the cold, 205; in hot water, 85.4, indicating that the ring has been opened and the bromine removed.

In the presence of much bromide ion no dibromo acid was isolated, but only the lactone. Five grams of anhydride, 3.2 g. of sodium hydroxide, and 6.4 g. of bromine reacted in 25 cc. of water containing 10 g. of sodium bromide; 2.7 g. (30%) of lactone, m. p. 80–90°, was obtained, and the only other product in evidence was a soluble lachrymator.

Action of Acids on the Bromolactone.—One gram of bromolactone was dissolved in 50 cc. of 10% sulfuric acid and let stand overnight at room temperature; a white solid, melting with decomposition at 168–170°, was obtained, which was recrystallized from chloroform. It is soluble in water, ether, acetone, ethyl acetate, slightly soluble in chloroform, and almost insoluble in benzene. It is best recrystallized from ethyl acetate–chloroform, or ethyl acetate–benzene.

Anal. Calcd. for $C_6H_9O_5Br$: C, 29.9; H, 4.1. Found: C, 29.8, 29.9; H, 4.2, 4.1.

To find out whether the bromohydrin acid isolated in the bromination of dimethylmaleic acid was formed from the lactone, a rough rate run was carried out by dissolving 1.0 g. of lactone in 50 cc. of 5% sulfuric acid, and determining the melting points of samples extracted at intervals.

Time	M. p., °C.
15 min.	60– 80
71 min.	80–100
220 min.	130–145
20 hrs.	166–169

It appears that the reaction is fairly complete at four hours, and hence the bromohydrin and chlorohydrin acids are considered secondary products.

Chlorination of Dimethylmaleic Acid.—Five grams of the anhydride was neutralized with 3.2 g. of sodium hydroxide in 100 cc. of water, and chlorine passed in until the presence of an excess was shown by a test with potassium iodide paper. Isolation and fractional crystallization of the product in the same manner as for the bromolactone gave 0.55 g. of chlorohydrin acid (7%), m. p. 150–168°, and 2.9 g. (41%) of chlorolactone, m. p. 80–90°. The best sample of this lactone obtained melted at 92–94°. The chlorolactone has the same solubility properties and general crystalline form as the bromolactone.

Anal. Calcd. for $C_6H_7O_4Cl$: C, 40.3; H, 4.0; mol. wt., 178.5. Found: C, 39.9, 40.0, 40.0; H, 4.7, 4.5, 4.8; mol. wt. in glacial acetic acid, 158.

Hydrolysis of the Chlorolactone I.—One gram of the chlorolactone was dissolved in 50 cc. of 10% sulfuric acid and let stand overnight at room temperature. Extraction and crystallization of the product from ethyl acetate–benzene gave a substance which decomposed at 173–174° when heated from 150° at 5° per minute. The solubility properties are similar to those of the bromohydrin.

Anal. Calcd. for $C_6H_9O_5Cl$: C, 36.6; H, 4.6. Found: C, 36.6; H, 4.9.

The chlorohydrin acid was also prepared in 62% yield from dimethylmaleic anhydride by conducting the hydrolysis without isolation of the chlorolactone.

Formation of the Oxidic Acid.—Two grams of the chlorohydrin acid was dissolved in 50 cc. of water, treated with 4.7 g. of barium hydroxide, and kept overnight at 0°. The solution was neutral in the morning. It was evaporated under diminished pressure over a period of several days and 1.4 g. of barium salt filtered off. This was suspended in water and acidified with 10 cc. of 1 *N* hydrochloric acid. From the ether extract a small amount of white compound crystallized, which gave no Beilstein test. Recrystallized from ethyl acetate–benzene, it melted at 158–160° with decomposition.

Anal. Calcd. for $C_6H_8O_5$: C, 45.0; H, 5.0. Found: C, 44.7; H, 5.3.

Reaction Rate of Chlorohydrin Acid with Sodium Hydroxide.—1.010 g. of chlorohydrin acid was dissolved in water and made up to 100 cc. Fifty cubic centimeters of this solution, cooled to 0°, was added to a solution of 300 cc. of water and 85.94 cc. of 0.0973 *N* sodium hydroxide at the same temperature. This was 25% excess alkali over that required to produce the sodium salt of the oxidic acid. Parallel 25-cc. samples were pipetted out at intervals and titrated for hydroxyl ion and chloride ion, respectively. The Cl^- ion produced was equal, within a few per cent., to the OH^- ion consumed, throughout the reaction. The relationship between time and log $(OH^-)/(\text{chlorohydrin})$ is linear, and from it we obtain the rate constant for the bi-

---

[7] These three analyses were carried out by Mrs. G. M. Wellwood.

molecular reaction 0.163 (time in minutes, concentration in moles per liter).

Time	OH^- consumed	Cl^- produced
250	0.00126	0.00134
885	.00299	.00310
1095	.00331	.00347
1480	.00392	.00398
2365	.00457	.00468
2725	.00466	.00489

Preparation of Dimethylfumaric Acid.—This was accomplished by the method of Ott;[8] a high pressure hydrogenation bomb served as the reaction vessel. Sodium dimethylmaleate is heated in aqueous solution for two days at 185–190°. Acidification and extraction yields a mixture of dimethylmaleic anhydride, dimethylfumaric acid and methylitaconic acid, which can be separated by crystallization from chloroform, in which only the dimethylfumaric acid is insoluble. This is recrystallized from water, and melts at 245°. It was obtained in 37% yield, 7.5% of methylitaconic acid being obtained and 41% of dimethylmaleic anhydride recovered from the same run.

The bromination and chlorination of dimethylfumaric acid were carried out in the same manner as for dimethylmaleic acid, but speed in isolation was especially necessary in order to forestall hydrolysis of the halogen lactones to halohydrin acids. These halogen lactones are higher melting than their isomers and are advantageously crystallized from chloroform.

The bromolactone from dimethylfumaric acid was obtained melting at 148–150°, crystallizing in white rods from chloroform. When titrated in the cold with sodium hydroxide to phenolphthalein, it showed an equivalent weight of 185, compared to 223 calculated. The end-point drifted rather rapidly.

Anal. Calcd. for $C_6H_7O_4Br$: C, 32.3; H, 3.2. Found: C, 32.0; H, 3.4.

The Chlorolactone from Dimethylfumaric Acid.—Twelve grams of dimethylfumaric acid yielded, after two fractional crystallizations of the product, 0.4 g. of starting material, 3.0 g. of chlorohydrin acid, m. p. 155–160° (18.3%), 4.1 g. of lactone, m. p. 138–140° (27.5%), and 1.6 g. of lower-melting fractions. The best sample obtained melted at 141–142° without decomposition. It is soluble in water and the common organic solvents, and crystallizes from benzene in typical rosets of needles.

Anal. Calcd. for $C_6H_7O_4Cl$: C, 40.3; H, 4.0; mol. wt., 179. Found: C, 40.0, 40.2; H, 4.3, 4.4; mol. wt. by titration in the cold, 160; in hot water, 65.5.

The identity of the chlorohydrin acid obtained from dimethylfumaric acid with that obtained from dimethylmaleic acid could not be established by mixed melting points, since this compound melts with decomposition. Therefore a pure sample obtained from dimethylfumaric acid was characterized by the rate of its reaction with sodium hydroxide at 0°, in the same manner as described for the sample from dimethylmaleic acid. The bimolecular rate constant obtained in the present instance was 0.152 compared with 0.163 in the other case. This difference is within the experimental error.

Experiments with *sym*-Dimethyldichlorosuccinic Acid.—The acid was prepared by the method of Michael[3] and after recrystallization from benzene–ether melted at 182–184° with decomposition. One gram was neutralized with sodium carbonate in 50 cc. of water and let stand for two days at room temperature. Acidification and extraction, followed by fractional crystallization from benzene, yielded starting material and chlorotiglic acid, m. p. 66–68°.

The rate of elimination of sodium chloride from sodium dimethyldichlorosuccinate was determined by making 100 cc. of an aqueous stock solution containing 0.4805 g. of the free acid. Fifty cubic centimeters of this solution was neutralized by 22.66 cc. of 0.0973 *N* alkali and kept at 25° in a thermostat. Ten cubic centimeter samples were titrated for chloride ion at intervals with silver nitrate.

Time, min.	30	105	1065	2505
Titer	0.48	0.88	4.96	7.91
% reaction	6	12	66	105

Both chlorolactones have been isolated in less than thirty minutes, so the salt of the dichloro acid does not decompose fast enough to account for the formation of either lactone.

Summary

1. The chlorination or bromination of sodium dimethylmaleate and dimethylfumarate in aqueous solution yields stereoisomeric chloro- or bromo-beta-lactones as the primary products of reaction.

2. The isomeric chlorolactones are readily hydrolyzed irreversibly to a single chlorohydrin acid, and the isomeric bromolactones to a single bromohydrin acid.

3. It is shown that these facts are inconsistent with a mechanism of addition of halogen in a single step, and the probable mechanisms of these reactions are briefly discussed.

4. Conclusions previously reached on the basis of kinetic results are now confirmed by preparative evidence.

Studies in the Oxidation of Alpha Ray Cuprene[1]

BY S. C. LIND[2] AND C. H. SCHIFLETT[3]

Acetylene under alpha-radiation from radon yields a yellow solid polymer of acetylene, cuprene. The yield per ion pair is approximately twenty molecules.[4] The product is unusually inert to ordinary reagents, and no satisfactory solvent has been found by means of which a molecular weight determination can be made.

Analysis by combustion of the freshly prepared product and of the gas phase indicates the product to be almost an exact polymer. The following is a typical analysis of the solid: C, 90.5%; H, 7.52%; diff., 1.98%; C:H ratio 12.03. The theoretical C:H ratio is 11.80. This 1.98% difference is very probably due to reaction with oxygen of the air, as some ten minutes were required for obtaining and weighing the sample for analysis, during which time the product was open to the air. (It will be shown later that oxidation proceeds rapidly when the product is first exposed to oxygen.) The discrepancy between the experimental and theoretical C:H ratio (for a true polymer) is no doubt due to loss of hydrogen which previously has been shown to accompany the reaction.[5]

In view of the fact that in most instances at any rate the substance under investigation was not the original condensation product but an oxidized product, it was considered worth while to determine whether the freshly prepared unoxidized substance possessed the same indifference toward solvents as had been found for the oxidized substance. Accordingly a sample of the freshly polymerized cuprene was opened in an atmosphere of acetylene and portions treated with the following in the hope of effecting solution for a molecular weight determination: water, ethyl alcohol, ether, acetone, carbon disulfide, carbon tetrachloride, benzene. After a period of twenty-four hours with frequent shaking none had dissolved in any of these liquids.

Many previous attempts[6] have been made to determine the constitution of cuprene (prepared by electrical discharge, or by the catalytic effect of copper), and although it was known that oxygen was absorbed rapidly from the air, apparently many of these investigations were made not only in the presence of air but after the substance had been exposed to air for some time. Losanitsch[7] reported much difficulty in analysis of the polymer due to rapid absorption of oxygen from the air. Jovitschitsch[8] found a 22% deficiency on analysis by combustion and claims to have excluded the possibility of oxidation from the air by working rapidly. He also found no difference in two samples, one analyzed immediately, the other after long standing in the air. However, this is entirely out of agreement with other workers.

From the C:H ratio in the above analysis one calculates that hydrogen is liberated to the extent of approximately 1% of the total acetylene polymerized. By manometric measurements during the course of reaction it was found (*loc. cit.*) that this per cent. ranges from about 0.7% at the beginning to several per cent. at the end, averaging about 2% over the entire course of the polymerization.

It was found that this product oxidizes spontaneously at room temperature, and the present study was undertaken with a view to determine the rate and extent of the oxidation. The oxidation has been followed both manometrically and gravimetrically. The products were analyzed with the results given elsewhere in this paper.

Experiment No. 1.—Cuprene was prepared in a 524-cc. flask from acetylene at a pressure maintained at approximately one atmosphere, by admission of the gas at various intervals. Radon was mixed with the acetylene. After eleven days, when the radon had decayed to approximately 14% of its original amount, the vessel was evacuated thoroughly. Oxygen at 682.3 mm. pressure (S. T.) was then admitted and the pressure was read at intervals. The manometric data are plotted in Fig. 1.

The oxidized product from the above reaction was then

removed from the reaction vessel, a sample was taken for combustion analysis and the remainder weighed and kept in a desiccator, open to the air. Over a period of eighteen months the product showed no further gain in weight. The analysis of the product was: C, 68.8%; H, 5.90%; diff., 25.3%; C:H ratio 11.69.

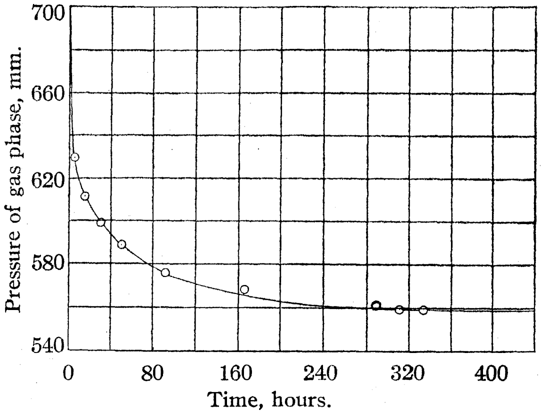

Fig. 1.—Oxidation of cuprene followed manometrically.

In another experiment cuprene was prepared in the same manner as given above and opened to desiccated air for a period of three and one-half months, when it was analyzed with the following results: C, 69.3%; H, 5.91%; diff., 24.75%; C:H ratio 11.65.

Experiment No. 2.—In another experiment, the freshly prepared cuprene was removed from the reaction vessel and weighed as quickly as possible. It was then kept exposed to desiccated air and weighed at intervals. The results are shown in Fig. 2. After six and one-half months this product was analyzed as follows: C, 67.51%; H, 5.59%; diff., 26.9%; C:H ratio 12.08.

Experiment No. 3.—In a 215.15-cc. vessel, 0.1609 g. (0.00619 mole) of acetylene was polymerized in the usual manner and the remainder of the gas was pumped off. Oxygen was then introduced. After eleven days and five and one-half hours, a decrease in pressure, corrected to S. T., of 85.8 mm. was observed. The remaining gas, 273.0 mm. (S. T.), was then pumped out by means of a Toepler pump through two traps, the first surrounded by solid carbon dioxide–acetone and the second by liquid air and then into a receiver for analysis of the gas. Upon removal of the liquid air a pressure rise of 2.3 mm. at 24.8 was observed, less than 1% of the total. Upon removal of the solid carbon dioxide–acetone bath a pressure rise of 2.1 mm. at 24.8 was observed. The average of a series of semi-micro analyses shows the gas remaining after oxidation is complete to consist of traces of carbon dioxide, water vapor, 7.13% carbon monoxide and 92.85% oxygen. Reduced to standard conditions this amounts to 5.4 cc. of carbon monoxide and 71.7 cc. of oxygen. From the total amount of oxygen originally introduced, 101.6 cc., and the amount remaining, 71.7 cc., the amount of oxygen reacting is seen to be 29.9 cc. This is approximately five and one-half times the volume of carbon monoxide formed. The following chemical equation accounts for these results: $(C_2H_2)_{20} + 5^1/_2O_2 \longrightarrow C_{39}H_{40}O_{10} + CO$. The percentage composition of the above formula is: C, 70.1; H, 6.0; O, 23.9; C:H ratio, 11.67. This is in fair agreement with the data obtained by combustion analysis of the oxidized product.

Before the production of carbon monoxide was established definitely it was proposed that this process might consist simply of adsorption, and to clear up this point the oxidized product was heated in an evacuated vessel to 200°, at which temperature charring and decomposition with the distillation of a brown, oily liquid began to occur. Up to approximately 200° no pressure of gas was developed and no obvious change occurred.

Heats of combustion of the unoxidized and the oxidized cuprene, respectively, were determined and found to be as follows:

	Cal./gram	Cal./mole
Unoxidized cuprene	10,203.7	265,296.2
Oxidized cuprene	7,113.5	184,951.0

These values are 85.6 and 59.4%, respectively, of 312,000 cal./mole, which is the value given for the heat of combustion of acetylene in the literature.[10] It was found necessary to pellet these materials with about ten times their weight of sugar for these determinations in order to secure complete combustion. The ignition in the oxygen bomb of cuprene itself and even too rich mixtures of cuprene with sugar resulted in explosion and consequent scattering of the material in the bomb. The value of the heat of combustion of the unoxidized cuprene given above when compared with that of acetylene indicates clearly that the polymerization process is an exothermic one, and is consistent with the conclusions of Heisig.[11] The difference in the heats of combustion of acetylene and of the polymer gives at once the heat of polymerization, *viz.*, ap-

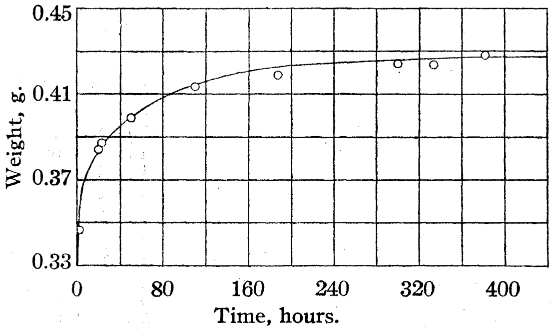

Fig. 2.—Oxidation of cuprene followed gravimetrically.

---

(9) It should be pointed out in connection with the above chemical equation proposed to account for the analysis of solid and gaseous products and the manometric data that other equations will account for the facts almost equally well. For example

$$(C_2H_2)_{24} + 6^1/_2O_2 \longrightarrow C_{47}H_{48}O_{12} + CO$$

would give a net pressure drop only 2 mm. greater than the equation proposed above. The solid would analyze: C, 70.2; N, 6.02; O, 23.78; C:H ratio 11.67, which is nearly as satisfactory as the other. The difference in the gas analysis would also be well within the limits of error. However, it seems quite certain that these equations tell in general the nature of the reaction, *viz.*, that some polymer of acetylene of the order of 20 molecules reacts with oxygen to a definite compound and that in this oxidation carbon is eliminated with the formation of a small amount of carbon monoxide.

proximately 47 kcal. per molecule of acetylene condensed. Calculating the theoretical heat of polymerization from the values of atomic linkages given by Fajans,[12] on the assumption that in the polymerization one C≡C (161.6 kcal.) is broken and one C=C (122.9 kcal.) and one C—C (73.5 kcal.) are formed per molecule of acetylene, one obtains the value 35 kcal. This is not in too good agreement with the experimental value to be sure, but perhaps as satisfactory as one could expect when it is remembered that the atomic linkages are admittedly only average values.

Acknowledgments.—We wish to thank Dr. F. H. Stodola, to whom we are indebted for the analyses of the solid products, and to acknowledge the kindness of Professor A. E. Stoppel who collaborated with us in determining the heats of combustion.

Summary

Cuprene was prepared by polymerization of acetylene by means of radon mixed with the gas. The solid polymer was then exposed to oxygen and the spontaneous reaction with oxygen at room temperature was followed manometrically. Both the solid and gaseous products were analyzed. The solid product after oxidation (which is nearly complete in twelve or fifteen days) contains approximately 25% oxygen. A little carbon monoxide is formed. The complete analysis shows the following reaction equation to be approximately correct

$$(C_2H_2)_{20} + 5^1/_2O_2 \longrightarrow C_{39}H_{40}O_{10} + CO$$

The spontaneous oxidation was also followed gravimetrically by exposing the freshly prepared cuprene to dry air and weighing at intervals. The results agree with the manometric method and analysis both as to extent and rate of oxidation. The heat of combustion of the oxidized cuprene is approximately 30% less than that of the unoxidized cuprene.

A Catalytic Method for Determination of Iodine

BY HAROLD P. LUNDGREN[1]

Among the methods used for determination of iodine there are: those determining iodine colorimetrically in a solvent, those titrating iodine using the blue starch–iodine complex as an indicator, those employing a color or precipitation reaction of iodine and those employing the catalytic power of iodine.

It is often necessary to analyze for iodine in concentrations too low to be detected by ordinary colorimetric, volumetric or gravimetric technique. The concentration of iodine may be increased by the Winkler technique until it is within the analytical range. The success of the Winkler method depends on how far the reactions concerned go toward completion. Furthermore, any trace of oxidizing agent left in the solution will cause serious error.

The catalytic methods for determination of iodine are in many cases sensitive to microgram quantities of iodine and are relatively simple and accurate procedures. Bredig and Walton[2] utilized the catalytic activity of iodine in the decomposition of hydrogen peroxide; Bobtelsky and Kaplan[3] utilized the rate of decoloration of permanganate by oxalic acid as catalyzed by iodine. Baines[4] employed the catalytic effect of iodine on the oxidation of thiosulfate by nitrite. Sandell and Kolthoff[5] made use of iodine catalysis in the oxidation of arsenous acid by ceric sulfate in sulfuric acid solution.

It is often necessary to analyze iodine in sulfite solutions since such are commonly used to absorb iodine, especially after combustion technique. In such a solution it would be impossible to apply the previously mentioned catalytic methods since all involve oxidation–reduction reactions and sulfite would interfere.

In a sulfite solution whose hydrogen ion concentration is less than 2 *N*, methylene blue was found to be decolorized more or less rapidly. At an acid concentration of 2 *N*, the reduction of the dye is immeasurably slow; iodide catalyzes the

---

[1] The author wishes to acknowledge with thanks the helpful criticism and suggestions of Professor J. F. McClendon, who has interested him in the field of iodine from the biochemical point of view. Abstracted from part of a thesis included among the requirements for the degree of Doctor of Philosophy in the Graduate School of the University of Minnesota.

[2] Bredig and Walton, *Z. Electrochem.*, **9**, 114 (1903).

[5] Sandell and Kolthoff, THIS JOURNAL, **56**, 1426 (1934).

reaction, and the rate was found to be proportional to the iodide concentration. Free diffusion of oxygen into the solution must be prevented, although the presence of the small amount of dissolved oxygen at the beginning does no harm, as indicated by the uniformly smooth curves of color depth *versus* time (Fig. 3). Any oxygen present apparently is destroyed before the first reading of color depth can be made. The sealed narrow neck of the reaction vessel (Fig. 1) prevented the introduction of oxygen, and diffusion of the gas above into the liquid was too slow to influence the reaction rate. Bush,[6] through her studies on the reaction of sulfuric acid and potassium iodide, gave an explanation of the reaction mechanism

$$2SO_2 + 4H_2O + 2I_2 = 2H_2SO_4 + 4HI$$
$$4HI + O_2 = 2H_2O + 2I_2$$

Methylene blue may replace oxygen as oxidizing agent in the second equation. It is quite likely that the mechanism is more complicated than indicated, especially in strong acid solution, since sulfurous acid has two oxidation–reduction levels—one in which dithionous acid is formed. Although sulfurous acid does not reduce methylene blue in strongly acid solution, dithionous acid does. Furthermore, the reaction may be complicated by formation of iodine–sulfur complexes which have been shown by Foerster and Gruner[7] to have catalytic properties.

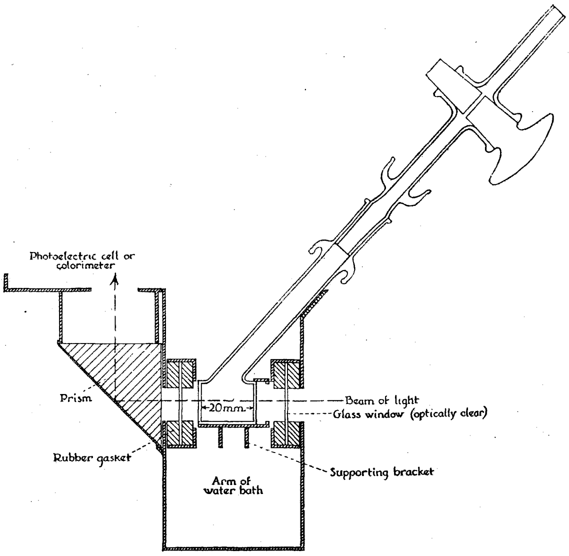

Fig. 1.

Although the mechanism is not understood, as low as 0.3 microgram of iodide may be detected, and chloride or bromide does not interfere. The closed system described below is employed to prevent free circulation of air above the liquid during the determination. Evacuation of the apparatus gave rise to erratic results when less than 5 micrograms of iodide was used. An increase in temperature increases the rate of fading of the indicator. When small quantities (0.3–5γ) of iodide are involved, the acid concentration is so great that it causes a slow decomposition of methylene blue, yielding colored products interfering with the measurement of fading time. By using the correct color filter together with the apparatus shown in Fig. 1, the color fading due to the main reaction may be successfully followed.

Apparatus.—The solution is placed in a cylindrical reaction container[8] made of optically clear glass which holds about 4 cc. of fluid. The container rests in the arm of a waterbath between two windows of optically clear glass as shown in Fig. 1. A beam of light from a constant source after passing through the fading solution is reflected upward by a prism. Its intensity can be measured either by means of a colorimeter or by a photoelectric cell.[9] The plunger of the stationary side of the colorimeter is set directly in line with the beam of light from the fading solution and the color intensity of this is compared with that of a standard solution of methylene blue in the movable cup. The amperage obtained from the photoelectric cell is directly proportional to the intensity of light falling upon it. For convenience, since it is not necessary to know the absolute value of the intensity, the reading of the microammeter may be taken as the intensity.

The light from a 400-watt lamp was monochromatized by passing through color filter H. R. Signal Red No. 243 (Corning). This filter has only 5% transmission at 608 mμ and 40% at 622 mμ; it permits the passage of the excess of red which has not been absorbed by the methylene blue and holds back the yellow color present in the fading solution.

Analytical

A. Reagents and Technique. Potassium Iodide.—Mallinckrodt Anal. Reag. (recryst.). A standard solution was prepared so that 0.1 cc. = 1 microgram of iodine (as KI).

Methylene Blue.—National Aniline Co. 88% (recryst. twice). The solution used in the reaction contained 1 g./100 cc. of water. The solution used as a standard for colorimetric comparison contained 1 mg./100 cc. of water.

Sodium Sulfite.—Merck C. P. (recryst.). A saturated aqueous solution was used.

Hydrochloric Acid.—Grasselli concentrated.

The reagents are placed in the reaction container as follows. To 0.4 cc. of a standard solution of iodide and 0.5 cc. of satd. aq. sodium sulfite are added 3.5 cc. of concentrated hydrochloric acid and 0.1 cc. of methylene blue solution (1 g./100 cc.). Calibrated Bausch and Lomb micro-

[9] The Duboscq type colorimeter and Weston photronic cell were used.

pipets were used for transferring the liquids. The stopcock is then closed and the reaction container is placed in a water-bath at 80°.

Measurement

A. With Colorimeter.—As the solution fades the color intensity of the standard solution of methylene blue (1 mg./100 cc.) in the movable cup is matched at intervals with the fading solution.

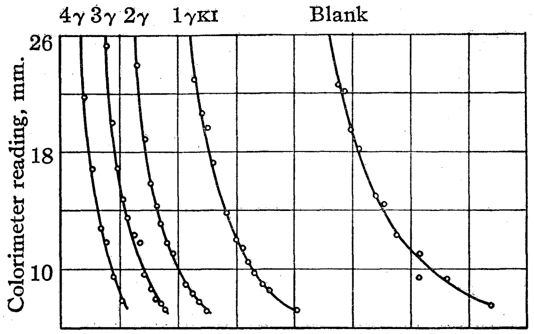

Fig. 2.

When the readings of the standard l_s are plotted against the corresponding times, t, the set of curves in Fig. 2 is obtained for the lowest range of iodine detected by the catalytic system. When the logarithm of the readings is plotted against the reciprocal of the respective times, the straight lines shown in Fig. 3 are obtained. Accordingly, the decoloration of methylene blue can be represented by the equation

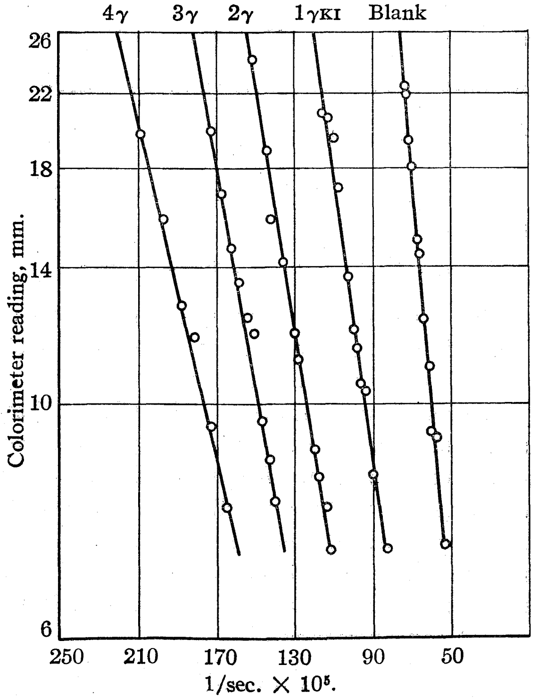

Fig. 3.

$$l/t = k \log l_s + K \qquad (1)$$

but according to Beer's law when the intensities of the two beams are equal the reading of the standard l_s is proportional to the concentration of the methylene blue in the fading solution or

$$l/t = k' \log c + K \qquad (2)$$

B. With the Photoelectric Cell.—According to Beer's law

$$C = \frac{\log I_0/I_e}{K'} \qquad (3)$$

where I_0 is the intensity of light before passing through the solution and I_e the intensity of the light which has escaped absorption at depth e and C is the concentration of the solution. On substitution of 3 in 2, the following equation is obtained

$$l/t = k' \log \frac{\log I_0/I_e}{K'} + K \qquad (4)$$

$$= k' \log \log \frac{I_0}{I_e} + K'' \qquad (5)$$

This equation expresses the relation between time and intensity of light of the fading solution as measured by the photoelectric cell. The curves obtained by plotting log log microamperage against the reciprocal of time are straight lines within limits of experimental error. Figure 4 is the curve obtained using the photoelectric cell

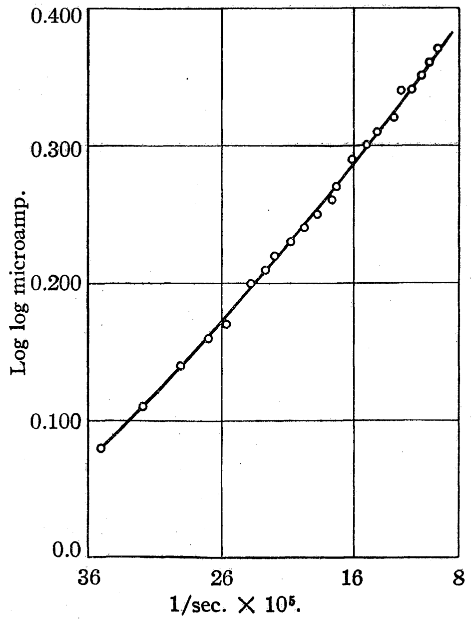

Fig. 4.

when 4 micrograms of iodine was present in the reaction solution.

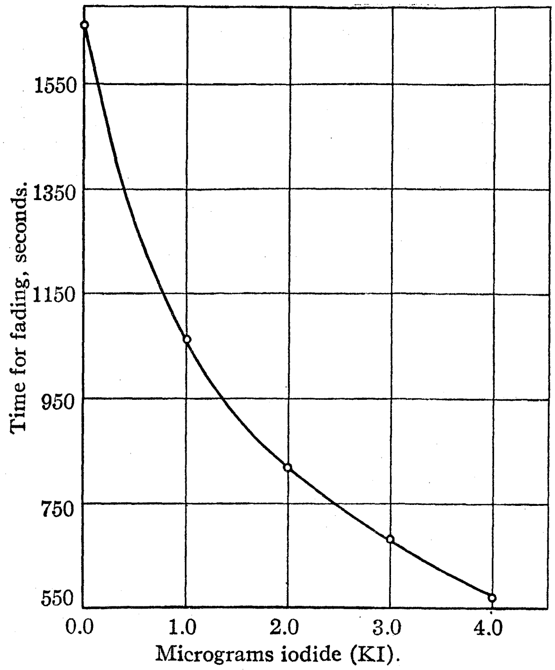

Fig. 5.

The light transmission errors, and errors due to deviation from Beer's law, for practical purposes are therefore negligible and either the colorimeter or the photoelectric cell can be used to measure the fading of methylene blue by the system.

For comparison of times for fading of methylene blue catalyzed by different concentrations of iodine a color intensity equal to 10 mm. of the standard solution of methylene blue (1 mg./100 cc.) in the movable cup of the colorimeter was chosen. When the times to reach this intensity are plotted against the corresponding concentrations of iodine, curve Fig. 5 is obtained. The method of plotting the fading curves as straight lines serves as a method of averaging the colorimetric readings.

A series of analyses carried out using this technique check within 5%.

Summary

A method for determination of iodine in sulfite solutions in concentrations up to 4 micrograms (as potassium iodide) has been devised from considerations of a system of reactions in which iodine acts as a catalyst and sulfite enters into the reaction mechanism. The method is carried out by adding hydrochloric acid and methylene blue to the sulfite solution and measuring the fading as the reaction proceeds in a specially designed apparatus.

Electric Potentials at Crystal Surfaces, and at Silver Halide Surfaces in Particular

BY I. M. KOLTHOFF AND H. L. SANDERS[1]

With the exception of the glass electrode, very few investigators have studied the thermodynamically reversible potentials which exist at non-metallic surfaces.[2]

For various reasons a study of the potential at the interface of slightly soluble salts in equilibrium with their saturated solutions is of interest. It has been claimed by Haber[3] that this potential, π, is determined by the concentration (or, better, the activity) of the lattice ions in the solution according to the equation

$$\pi = K_c + \frac{RT}{nF} \ln a_c = K_a - \frac{RT}{nF} \ln a_a$$

in which a_c denotes the activity of the cations, and a_a that of the anions in solution. Actually Haber used ion concentrations instead of activities.

Some rough measurements[3] with silver chloride and calomel membranes were in agreement with the above equation. Recently Tendeloo[4] has made measurements with slices of minerals like heavyspar ($BaSO_4$) and fluorite (CaF_2), finding under specified conditions an approximate agreement with the foregoing equations over a limited range of concentrations.

In the present paper are given the results of a more detailed study of cells involving pure silver halide membranes.

Introduction

The following cells were measured in this study

Cell I: $\mathrm{Ag/AgX(s),\ X^-(a_1)/\underset{\text{membrane}}{AgX}/X^-(a_2)/KNO_3(satd.)/}$ $\mathrm{KCl(satd.)\ Hg_2Cl_2/Hg}$

Cell II: $\mathrm{Ag/AgX(s),\ X^-(a_1)/\underset{\text{membrane}}{AgX}/X^-(a_2),\ AgX(s)/Ag}$

Cell III: $\mathrm{Ag/AgX(s),\ X^-(a_2)/KNO_3(s)/KCl(satd.),\ Hg_2Cl_2/Hg}$

in which X^- represents the chloride, bromide or iodide ion, and AgX the corresponding silver halide.

The expression for the e. m. f. of cells of types I and II can be derived by considering the reactions at each phase boundary. Suppose one faraday of electricity passes through cell I from left to right. The following reactions then take place at each phase boundary in the case of a silver chloride cell

$$\begin{aligned} \mathrm{Ag} + \mathrm{Cl^-}(a_1) &= \mathrm{AgCl(s)} + \mathrm{e} \\ \mathrm{AgCl_{memb.}} &= \mathrm{Ag^+_{memb.}} + \mathrm{Cl^-}(a_1) \\ \mathrm{Ag^+_{memb.}} + \mathrm{Cl^-}(a_2) &= \mathrm{AgCl(s)} \\ \mathrm{Hg_2Cl_2(s)} + 2\mathrm{e} &= 2\mathrm{Hg} + 2\mathrm{Cl^-(satd.\ KCl)} \end{aligned}$$

The total cell reaction is therefore the sum of these partial reactions, and is

$$\mathrm{2Ag(s) + Hg_2Cl_2(s) + 2Cl^-}(a_2) = \mathrm{2Hg + 2AgCl(s) + 2Cl^-(satd.\ KCl)}$$

The equilibrium constant of this reaction is

$$K' = (a\mathrm{Cl^-})^2_{\mathrm{satd.\ KCl}}/(a\mathrm{Cl^-})^2_2$$

Since the activity of the chloride ion in the saturated potassium chloride is constant, the equilibrium constant becomes

$$K = 1/(a\mathrm{Cl^-})^2_2$$

and the equation for the e. m. f. of cell I is then

$$\begin{aligned} E &= RT/2F \ln K + RT/2F \ln (a\mathrm{Cl^-})^2_2 \\ &= E^0 + RT/F \ln (a\mathrm{Cl^-})_2 \end{aligned}$$

It is readily shown that $E^0 = E_{\mathrm{S.C.E.}} - E^0_{\mathrm{AgCl}} = 0.246 - 0.222 = 0.024$ v.

whence $$\begin{aligned} E &= 0.024 + RT/F \ln (a\mathrm{Cl^-})_2 \\ &= 0.024 - 0.0591\ p(\mathrm{Cl^-})_2\ (25°) \end{aligned}$$

For cells of type I, then, if we neglect the small liquid junction potential between the saturated calomel reference electrode and the halide solution, the relation between the e. m. f. and $p(\mathrm{X^-})_2$ should be a straight line with slope equal to RT/F and intercept equal to the difference in e. m. f. between the saturated calomel electrode and the corresponding silver–silver halide electrode, provided there is no asymmetry potential.

It is derived from the same considerations that the e. m. f. of cells of type II should be zero at all concentrations of the halide solutions on each side of the membrane, if there is no asymmetry potential across the membrane.

Cells of type III serve to measure the actual pX value of the solutions in contact with the membrane.

The derivation of the above equation involves chloride going into solution on the left side of the membrane and deposition of chloride from the solution on the right side of the membrane in the form of silver chloride. Apparently, then, in order for cells of this type to function reversibly, one or both of the lattice ions must be able to migrate in the solid. If this condition is not fulfilled, cells of the above type cannot function.

It should be emphasized that the foregoing derivation does not involve any assumption with regard to the individual potential differences (π) at the interface on each side of the membrane, which of course are impossible to measure.

Experimental

Apparatus.—In order to overcome the high resistances in some of the systems investigated, and to eliminate possible polarizing currents from the potentiometer, an electron tube voltmeter was constructed. The design of the instrument was similar to those described by Greville and Maclagan,[5] Dubois[6] and others. An FP54 General Electric pliotron tube was used, together with a sensitive galvanometer, rated at 27,000 megohms. The method of floating grids was not employed. Tests showed that e. m. f.'s could be read to 0.1 mv. through resistances of several hundred megohms.

All measurements were made in an air-bath, held at 25.0 ± 0.1°. The bath also served to shield the silver salts from excessive exposure to light.

Materials.—Most of the work was carried on with the silver halides. For their preparation Mallinckrodt analytical grade silver nitrate proved sufficiently pure, melting without any trace of darkening—a delicate test. For preparing silver chloride, redistilled hydrochloric acid was used.

The preparation of the silver halides was carried out by slowly adding tenth molar silver nitrate solution to tenth molar halide solution in a dim red light. Conductivity water was used throughout. Occlusion of traces of silver nitrate by the silver halide results in discoloration of the latter upon fusion, but this is prevented by the use of dilute solutions. The precipitated halide was washed repeatedly by decantation.

(5) G. D. Greville and N. F. Maclagan, *Trans. Faraday Soc.*, **27**, 210 (1931).

(6) D. Dubois, *J. Biol. Chem.*, **88**, 729 (1930).

The standard silver–silver halide electrodes used were made by silver plating platinum electrodes, then making these anodes in the appropriate tenth molar halide solution.

Silver Halide Diaphragms.—Several methods for making impermeable silver halide "electrodes" were tried. They could not be blown into bulbs like glass, nor could they be coated over glass bulbs. The Haber[3] method of melting some of the salt in the bend of a U-tube gave leaky plugs. Finally the problem was solved by melting the salt in a clean porcelain crucible in a small electric oven. The solidified melt, in disk form, about five millimeters thick, could be removed after soaking in water. These disks were then fastened over one end of a 10-mm. glass tube with sealing wax. Some 0.01 M halide solution (a_1) was poured in, and a standard silver–silver halide electrode inserted. This arrangement is termed the "crystal electrode" and is reminiscent of a MacInnes and Dole membrane glass electrode. Disk resistances were of the order of ten megohms.

In practice, our procedure was to immerse a standard silver–silver halide as well as several crystal electrodes in a solution, then measure each of these against a saturated calomel half-cell, using a saturated potassium nitrate salt bridge. The value of a_2 in cell I was varied by adding silver nitrate or sodium halide to the outer solution. In each case the value of a_2 (plotted as pX) was determined by measuring the e. m. f. between the ordinary silver halide electrode in the solution and the saturated calomel electrode, using cell III.

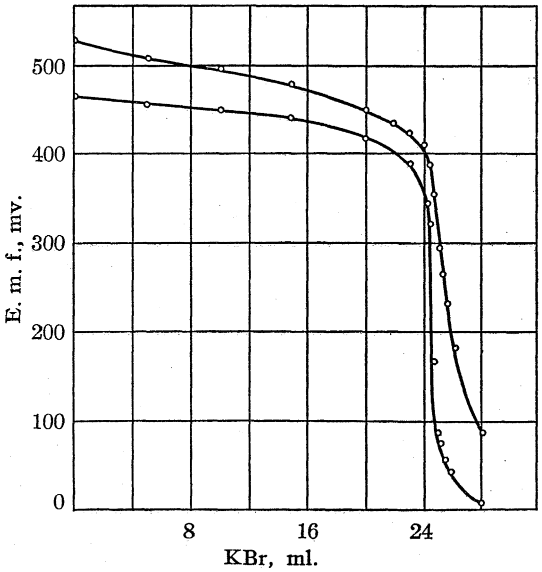

Fig. 1.—Titration of silver nitrate with bromide in the presence of potassium permanganate: upper curve, Ag–AgBr; lower curve, crystal AgBr.

Since the total e. m. f. of cell II is zero, it follows that cells I and III should have identical e. m. f. values provided that a_2 is the same in each, and there is no asymmetry potential across the membrane. Stated in other words the standard silver–silver halide electrode should give the same reading as a composite crystal electrode.

Experimental Results

Table I gives the results found on the first trial of the crystal silver chloride electrodes. The disk used had a very low asymmetry potential. Later readings were made to four decimal places.

TABLE I

COMPARISON OF SILVER CHLORIDE STANDARD AND CRYSTAL ELECTRODES

$AgNO_3$ soln. (approx.), M	E. m. f. Standard AgCl No. 6 (Cell III)	E. m. f. Crystal AgCl No. 2 (Cell I)
10^{-5}	0.279	0.280
10^{-4}	.339	.337
10^{-3}	.384	.381
10^{-2}	.453	.453
10^{-1}	.500	.500

Although, as we have pointed out, this agreement was to be expected, the objection might be raised that it was found only because a film of metallic silver had formed on the supposedly pure salt disk by accidental reduction. That this was not the case is shown by the following considerations. (1) The silver chloride disks were perfectly clear and transparent with no discoloration whatever visible. (2) On adding potassium permanganate to the solution the potential of the disk remained constant, but that of a standard silver chloride electrode changed by over 100 mv. due to an oxidation potential being set up at the metallic silver. When a disk was purposely reduced superficially with tin and hydrochloric acid, it then became sensitive to permanganate. (3) On soaking a standard and a crystal electrode in platinic chloride solution overnight, the former was spoiled, due to separation of platinum onto the silver, but the latter was unaltered. (4) A silver nitrate solution was titrated with potassium bromide in the presence of permanganate, using both standard and crystal silver bromide electrodes. As Fig. 1 shows, the former gave higher e. m. f. readings than the latter, and the break in potential at the equivalence point was less pronounced with the standard electrode, due to secondary effects.

These permanganate tests were not so conclusive in the case of crystal silver iodide electrodes, perhaps due to oxidation of the salt itself.

In Fig. 2 are shown graphically the main results of this investigation. In it the e. m. f. of cell I is plotted against the pX value of the solution. These curves are not averaged values, but are typical runs. At least six electrodes of each kind were prepared, and several runs made with each. Though the asymmetry potentials changed several millivolts between runs, all satisfactory electrodes showed a constant linear relation on consecutive runs. About four out of five of the crystal electrodes prepared were considered satisfactory.

Equilibrium potentials were established very quickly whether or not the solution around the electrode was pre-saturated with the appropriate silver halide; in most of the runs it was saturated, however.

The silver chloride line had a slope of 0.0579, the silver bromide of 0.0574—both slightly less than the theoretical value of 0.0591 at 25°. With silver iodide, the precision was not as great as with the other two electrodes, as seen by Fig. 2. In this case the slope of the line was 0.052.

If these lines are extrapolated to $pX = 0$, the following values for the cell E^0 are found: E^0(AgCl) = +0.020 v.; E^0(AgBr) = +0.160 v.; E^0(AgI) = +0.380 v. Taking the potential of the saturated calomel electrode as 0.246 v., the following are the calculated values: E^0(AgCl) = +0.024 v.; E^0(AgBr) = +0.175 v.; E^0(AgI) = +0.398 v.

The agreement between the experimental and calculated values is very good in the case of silver chloride membranes, indicating that the asymmetry potential is very small (4 mv.); in the case of silver bromide, the asymmetry potential was usually found to be of the order of 15 mv., and with silver iodide of 18 mv. The asymmetry potentials depend upon the method of preparation and the age of the membranes, their magnitude decreasing with age.

Certain writers seem to have thought that pure silver halide electrodes may be obtained by coating a platinum wire with the salt. Thus Hiltner[7] melted silver chloride round a platinum wire using a blast lamp flame, and found satisfactory behavior. We carefully melted silver bromide about a silver wire in the electric oven. The cooled mass was clear, the imbedded length of the wire being plainly visible through the transparent salt. Such a "rod" type of electrode showed a fluctuating and indefinite potential, which changed greatly on mere agitation of the solution. Similar results were found with silver chloride. Since the silver halides are not electronic conductors they naturally cannot behave as metallic electrodes because no reversible electron reaction can occur at their surface.

Finally, the effects of various ions on the crystal electrode potentials were studied. In a solution saturated with potassium nitrate the silver bromide membrane electrode cells again gave linear e. m. f.–pX curves at all concentrations of bromide ion used, the slopes being about the same as those found in the absence of the nitrate. The silver chloride membrane cells showed no changes in potential upon addition of small amounts of hydrogen, lead or thallous ions. Ions which are supposedly potential-determining, like chloride and bromide, failed to affect the potentials of the silver iodide membranes under conditions at which no chemical precipitation could occur.

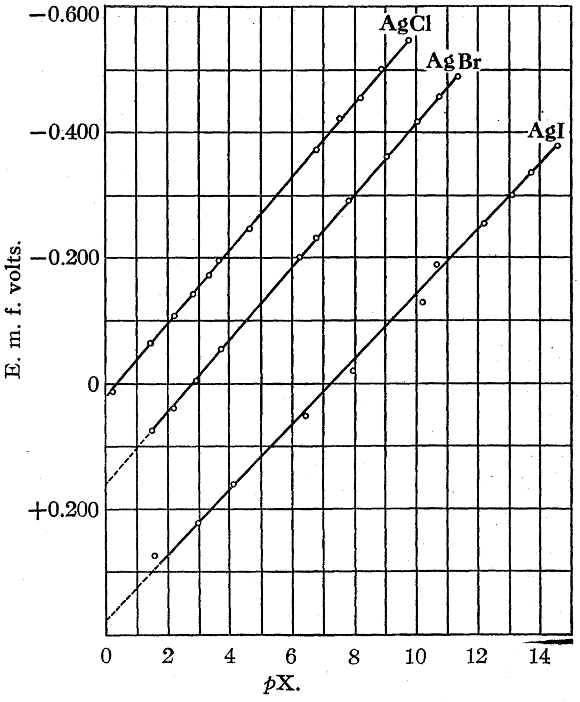

Fig. 2.—Change of potential of silver halide surfaces.

Following much the same technique as above, an attempt was made to duplicate the results of Haber with paraffined calomel tablets, and of Tendeloo with heavyspar and fluorite, but with no success, the observed potentials being unreproducible, and changing upon the addition of any ion. Our results with the fluorite electrode are in agreement with those reported recently by Anderson[8] who, contrary to Tendeloo, found that the calcium fluoride membrane did not function as a calcium electrode.

It is hoped to extend this work and discuss some of its theoretical implications in the near future.

Acknowledgment.—The junior author wishes

to express his gratitude to McGill University, Montreal, for its award of the Moyse Travelling Scholarship, which enabled him to do this work. We are particularly indebted to Professor F. H. MacDougall for his aid in the derivation of the equations presented in the first part of this paper.

Summary

An expression has been derived for the e. m. f. E of cells involving silver halide membranes, of the type

$$\mathrm{Ag/AgX(s),\ X^-(}a_1\mathrm{)/\underset{membrane}{AgX}/X^-(}a_2\mathrm{)/KNO_3(sat.)//KCl(sat.),\ Hg_2Cl_2/Hg}$$

It was found that

$$E = E^0 + RT/F \ln (a_2)$$

The experimental results obtained with fused silver halide membranes over a wide range of values of a_2 showed that $E = E^0 + A \ln(a_2)$ in which A was found to be slightly less than the theoretical value.

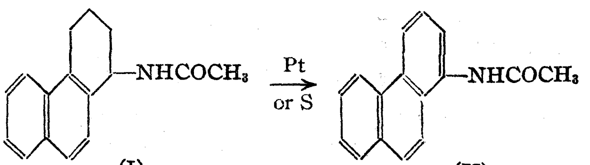
NOTES

A New Synthesis of 1-Aminophenanthrene

BY W. E. BACHMANN

Recently[1] we described the preparation of 1-aminophenanthrene, starting from phenanthrene. This new phenanthrylamine can also be obtained from naphthalene through the intermediate compound, 1-keto-1,2,3,4-tetrahydrophenanthrene. The oxime of this cyclic ketone is reduced by sodium amalgam and alcohol to 1-amino-1,2,3,4-tetrahydrophenanthrene[2] and the acetyl derivative (I) of the amine is dehydrogenated to 1-acetylaminophenanthrene (II). The free base, 1-aminophenanthrene, can be obtained by hydrolysis of the acetyl derivative.

Complete dehydrogenation of 1-acetylamino-1,2,3,4-tetrahydrophenanthrene takes place rapidly when the compound is heated with half its weight of platinum black at 320°; the 1-acetylaminophenanthrene is obtained pure by a single recrystallization from benzene. We have also employed sulfur for the dehydrogenation; with this reagent some oily by-products are formed in the reaction, but the 1-acetylaminophenanthrene can be isolated in pure form in yields of 50–60%.



(I) (II)

Experimental

1 - Acetylamino - 1,2,3,4 - tetrahydrophenanthrene.—A mixture of 13 g. of 1-keto-1,2,3,4-tetrahydrophenanthrene,[3] 6 g. of hydroxylamine hydrochloride and 8 cc. of pyridine in 80 cc. of absolute alcohol was heated on a steam-bath for three hours. The solution was evaporated to dryness and the residue was digested with water. The oxime, which was formed in quantitative yield, was filtered off and when dried was sufficiently pure for the next step.

A mixture of 13 g. of the oxime and 180 cc. of alcohol was warmed to 50–60° and treated with 150 g. of 2% sodium amalgam in portions in the course of half an hour. Throughout the reaction the temperature was kept below 60° by external cooling and the solution was kept acidic by addition of acetic acid. Any sodium acetate that precipitated was brought back into solution by addition of small amounts of water. When the reaction was complete, the solution was separated from the mercury and the alcohol was evaporated. The residue was taken up in water and a small amount of oily impurities was removed by extraction with carbon tetrachloride. The aqueous solution was made alkaline and the 1-amino-1,2,3,4-tetrahydrophenanthrene was extracted by benzene. Evaporation of the benzene left the amine as an oil which quickly solidified. A mixture of the crude amine and 15 cc. of acetic anhydride was refluxed for five minutes. The acetic acid and the excess of acetic anhydride were removed by directing a jet of air onto the warm solution. The crystalline residue of the acetyl derivative was digested with cold acetone and the colorless crystals were filtered off; yield, 10 g. 1-Acetylamino-1,2,3,4-tetrahydrophenanthrene crystallizes from acetone in colorless needles; m. p. 176°. The compound is not very soluble in cold acetone but dissolves in benzene and in acetic acid.

Anal. Calcd. for $C_{16}H_{17}ON$: N, 5.9. Found: N, 6.0.

Dehydrogenation of 1-Acetylamino-1,2,3,4-tetrahydrophenanthrene.—A mixture of 10 g. of 1-acetylamino 1,2,3,4-tetrahydrophenanthrene and 2.5 g. of sulfur was

[2] Our experiments on the preparation of this compound were already completed at the time Burger and Mosettig [*ibid.*, 58, 1570 (1936)] reported its preparation by the same method.

[3] Haworth, *J. Chem. Soc.*, 1128 (1932).

heated at 250–260° in a distilling flask having a wide side-arm sealed to a receiver. After half an hour, when evolution of hydrogen sulfide had ceased, the product was distilled at 0.5 mm. pressure. Recrystallization of the distillate from benzene yielded 5 g. of 1-acetylaminophenanthrene in the form of colorless needles; m. p. 219–220°. From the benzene filtrate there was obtained 1.5 g. of unchanged tetrahydro derivative which can be used in another dehydrogenation reaction. The 1-acetylaminophenanthrene was identical with the product obtained by acetylation of 1-aminophenanthrene prepared through the Beckmann rearrangement.[1] On hydrolysis by twenty-four hour boiling with an alcoholic solution of hydrochloric acid the acetyl derivative was converted completely to 1-aminophenanthrene; m. p. 146–147°.

The Action of Benzylamine on Aliphatic Esters

BY C. A. BUEHLER AND CHARLES A. MACKENZIE

In an attempt to develop an improved method for the identification of aliphatic esters, they were treated with benzylamine in aqueous solution. This scheme is similar to that already in use for certain halogenated aliphatic esters which, with ammonium hydroxide in the cold, form the corresponding amides. Both these reagents possess approximately the same dissociation constants, but it appeared that benzylamine, in contrast to ammonia, might be employed successfully at boiling temperatures with the esters of weaker acids because of its higher boiling point.

From Tables I and II it can be seen that benzylamine reacts with the esters studied either to form the N-benzylamide or the benzylamine hydrohalide. With the polyhalogenated esters investigated, the corresponding N-benzylamides form readily even in the cold. Of the monohalogenated esters studied, only one, ethyl chloroacetate, could be induced to undergo a similar reaction. This type, by the more vigorous treatment used for non-halogenated esters or, preferably, by heating with the amine in the absence of water, yields the benzylamine hydrohalide, a reaction[1] which has been represented as

$$XCH_2COOR + 2C_6H_5CH_2NH_2 \longrightarrow C_6H_5CH_2NHCH_2COOR + C_6H_5CH_2NH_2 \cdot HX$$

By refluxing from one to five hours, depending upon the strength of the acid present in the ester, the non-halogenated esters produced N-benzylamides. All the esters, save those of the higher fatty acids, gave satisfactory yields.

Experimental

Preparation of Ester Derivatives

(a) **Polyhalogenated Esters.**—A mixture of 0.5 cc. of ester, 2 cc. of benzylamine and 0.5 cc. of water was im-

---

[1] Mason and Winder, *J. Chem. Soc.*, **65**, 187 (1894).

mersed in an ice-bath and shaken vigorously at intervals of a few minutes until a solid formed. Purification of the solid was effected by recrystallization from ligroin.

(b) **Monohalogenated Esters.**—Although the derivatives of monohalogenated esters may be prepared as in (c), a better procedure is to heat 2 mols of the amine with 1 mol of the ester for a few minutes when the hydrohalide forms. To obtain the salt in pure form, it was dissolved in hot ethyl acetate containing sufficient ethyl alcohol to effect solution, after which the solid crystallized from the cooled solution upon the addition of a few cc. of ether.

(c) **Non-halogenated Esters.**—The ester, 2 cc., mixed with 4 cc. each of benzylamine and water and, when necessary, sufficient ethyl alcohol or dioxane to effect solution, was refluxed one hour (for formates), two hours (for acetates) or from four to five hours (for higher esters like caproates). The excess of reagents was removed by distilling up to 200°, after which the derivative[2] in the distillation flask was crystallized from hot ligroin by cooling to room temperature or lower.

---

(2) Before final crystallization, derivatives melting below 50° were distilled off over a range beginning at 290° and continuing until decomposition occurred in the distillation flask.

The Thermal Decomposition of Gaseous Hydrogen Peroxide

BY G. B. KISTIAKOWSKY AND S. L. ROSENBERG[1]

The thermal decomposition of gaseous hydrogen peroxide was investigated semi-quantitatively by a static method at 85 and 98°. A very pure, 70% peroxide was used. The reaction in a quartz flask is heterogeneous, with an almost negligible temperature coefficient. Times for 50% reaction varying from one to thirty minutes were obtained, the reaction rate increasing with time due to changes in the reaction vessel surface. No stopping of the reaction at about 15% completion as described by Elder and Rideal[2] could be detected. Furthermore, the pressure increase accompanying the reaction proved to be the theoretical value of 50% (based on hydrogen peroxide present), rather than the somewhat astonishing value of about 1000% found by these authors.

Some experiments were tried, where the reaction vessel was flushed with oxygen prior to the reaction. This had no effect, so that neither oxygen from the reaction nor other oxygen leads to a stoppage of the reaction before completion. In another experiment a thin coating of paraffin wax was applied to the interior of the quartz reaction bulb. This slowed down the reaction somewhat, demonstrating its heterogeneity.

We take this opportunity of thanking Mr. P. Giguere of McGill University for the gift of some very pure 70% hydrogen peroxide.

Syntheses from Ethanolamine. IV. A Synthesis of β-Chloroethyl Phthalimide

BY HENRY WENKER

This paper presents a convenient method of preparing β-chloroethyl phthalimide, an intermediate which can be used for most purposes in place of the less readily accessible β-bromo analog.[1] The reactions involved are: phthalic anhydride and ethanolamine react in molar proportions to form β-hydroxyethylphthalimide; this compound reacts with one mole of phosphorus pentachloride to yield β-chloroethyl phthalimide.

Experimental

Garelli and Racciu[2] obtained β-hydroxyethyl phthalimide from phthalic anhydride and ethanolamine, using absolute ethanol as a solvent. It has been found that by omitting the solvent and heating both components[3] for about thirty minutes to 210°, a quantitative yield is obtained. On cooling, the product solidifies in crystalline form, melting at 127–128° (lit. 127–128°). Through the action of phosphorus pentachloride, β-chloroethyl phthalimide was obtained from this product in the usual way. The yield was 94%, the melting point 81° (lit. 79–81°).

COMMUNICATIONS TO THE EDITOR

BENZANTHRONE AND 4-PHENYLBENZANTHRONE

Sir:

In a recent elaboration of their former work, Charrier and Ghigi [*Ber.*, **69**, 2211 (1936)] have suggested that in our study of Grignard addition to benzanthrone [This Journal, **57**, 740 (1935)] we failed to concede priority to them. We regret that our mode of presentation failed to make clear that the Italian workers first proved two instances of 1,4-addition of the Grignard reagent to benzanthrone and predicted the structure of 4-phenylbenzanthrone.

WALDEN INVERSION IN SUBSTITUTION REACTIONS ON INORGANIC COMPLEX COMPOUNDS

Sir:

Recently Bailar, Haslam and Jones [This Journal, **58**, 2226 (1936)] have published an interesting paper on the steric course of the substitution reaction between *l*-dichloro-diethylene-diamino-cobaltichloride and 2 moles of ammonia which leads to a *levo*-product at low, to a *dextro*-product at high, temperature. Since the theoretical considerations about Walden inversion on which the paper is based are likely to be misunderstood, I would like to draw attention to the following point. According to the authors, Bergmann, Polanyi and Szabo [*Z. physik. Chem.*, **20B**, 161 (1933); *Trans. Faraday Soc.*, **32**, 843 (1936)] in their theory of Walden inversion predict that each reaction involving a single step in substitution on the tetrahedral carbon atom will bring about inversion, an even number of substitutions therefore reproducing the original configuration. In the above case, this apparently is not always the fact. As a matter of fact, Bergmann, Polanyi and Szabo are concerned expressly with substitutions of polar bonds by ions;[1] they assert that substitution of such a polar bond by a negative ion is necessarily connected with configurational inversion, while substitution by a positive ion leads either to the initial configuration or to a racemic product. The reaction under discussion does not involve a substitution by ions, and especially not by negative ions; it reminds one of the well-known observation of Senter and co-workers [*J. Chem. Soc.*, **107**, 638 (1915); **109**, 1091 (1916); **117**, 140, 151 (1918)] that *l*-phenylchloroacetic acid by interaction with ammonia in water or alcohol gives *d*-, in acetonitrile or liquid ammonia *l*-phenylaminoacetic acid, or the experiments of Holmberg [*Ber.*, **60**, 2194, 2198 (1927)] on the relationship between the rotation of xanthogeno-succinic acid and the temperature at which it was prepared from active bromosuccinic acid. The theory of Bergmann, Polanyi and Szabo does not make any prediction for such cases.

It may be added that in the group of these octahedral complexes some substitutions by negative ions are already known to be accompanied by configurational inversion. Without discussing the whole existing material, reference may be made to the following two reactions: (*a*) *cis*-Chloro-isorhodanato-diethylenediamino-cobaltic ion is converted by means of rhodanide ions into *trans*-diisorhodanato-diethylenediamino-cobaltic ion [A. Werner, *Ann.*, **386**, 1 (1912)]. (*b*) *trans*-Chloro-isorhodanato-diethylenediamino-cobaltic salts are converted by hydroxide ions (aqueous ammonia solution) into *cis*-hydroxoisorhodanato-diethylenediamino-cobaltic salts. Likewise, the auto-racemization observed in some of the inorganic complex compounds may be due to the same mechanism as the racemization of  $\overset{a}{\underset{b}{>}}\mathrm{CH{-}Hal}$ by halogenide ions, *e. g.*, the autoracemization of dichloro-diethylenediamino-cobaltic chloride to the substitution of the inner chloro atoms by negative chloride ions. [Werner, *Ber.*, **44**, 3279 (1911); **45**, 3294 (1912), suggested that the racemization is caused by aquation, but this has never been proved by isolation of a chloroaquo-diethylene-diamino-cobaltic salt.] Of course, we cannot predict whether all the known cases fit into our simple scheme, but we hope to come to some definite conclusions in the course of our further investigations on Walden inversion.

---

[1] It may be added that the afore-mentioned inorganic complex salt has an octahedral, not a tetrahedral, structure, but the theory should really be extendable to this case.

THE EFFECTS OF SULFURIC ACID AND OF ZINC CHLORIDE ON THE MAIN RAMAN BAND OF WATER

Sir:

In the course of a systematic study of the effects of dissolved salts, acids, and bases on the Raman spectrum of water, we have found that sulfuric acid and zinc chloride produce unique changes in the shape and in the frequency of the maximum of the main band, which are illustrated in the accompanying figures. The shift in the maximum is related to the concentration as follows, at 40°.

H_2SO_4, % by wt.	$\Delta\Delta\nu$, cm.$^{-1}$	$ZnCl_2$, % by wt.	$\Delta\Delta\nu$, cm.$^{-1}$
0.0	0	0.0	0
15.3	+ 14	14.3	+ 9
25.6	+ 34	31.6	+58
65.0	+ 32	41.8	+78
80.0	+ 20	50.0	+91
95.0	−336	57.1	+82

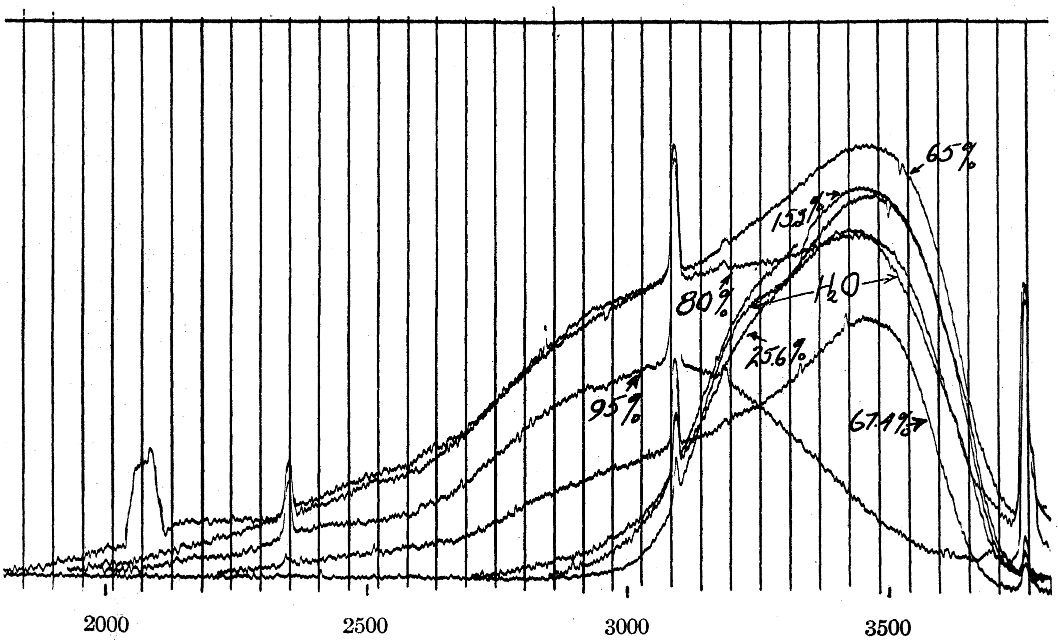

Fig. 1.—Showing the effect of various concentrations of sulfuric acid on the main Raman band of water.

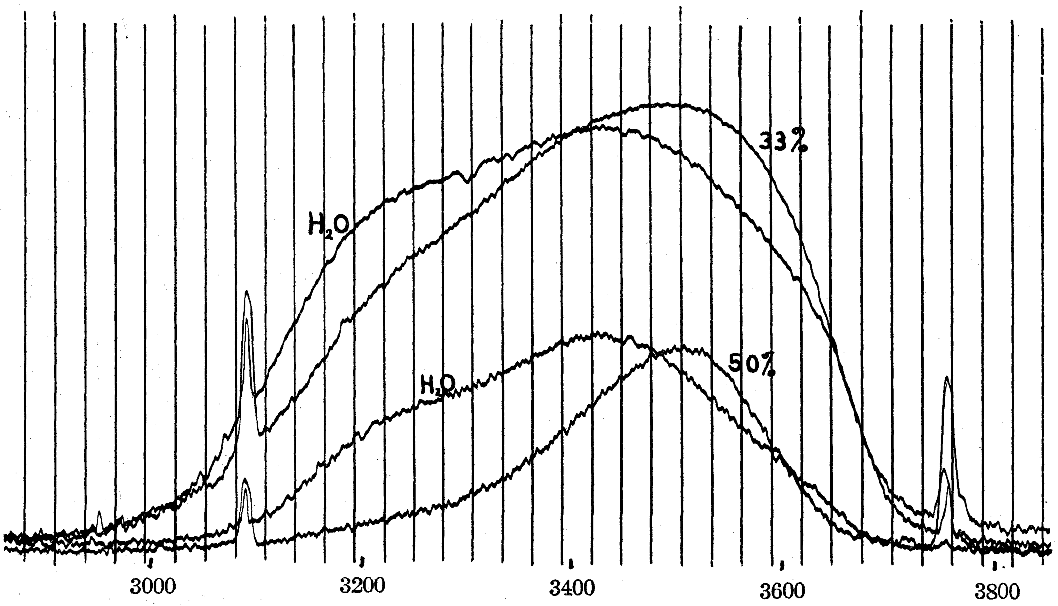

Fig. 2.—Showing the effect of 33% and 50% zinc chloride on the main Raman band of water.

The apparent broadening of the water band toward lower frequencies in sulfuric acid solutions of medium concentration (Fig. 1) is shown by the spectrum of 95% sulfuric acid to be due to the appearance of a new band, almost symmetrical in shape and with maximum at 3094 cm.$^{-1}$. A band at this frequency in pure sulfuric acid can only arise from a hydrogen or O–H vibration. Its width shows definitely that sulfuric acid is associated in the same manner as water and its change in intensity with dilution should be a function of the degree of ionization of sulfuric acid. In spite of the broadening toward lower frequencies, at concentrations below 65% the shift of the maximum toward higher frequencies in sulfuric acid is much larger than that in corresponding concentrations of sodium sulfate.

Like the alkaline earth chlorides, addition of zinc chloride to water causes the short frequency [ν(H)] component of the main band to disappear, indicating a dis-association of the solvent. While the net effect of this disappearance with the former compounds is to make the whole band more symmetrical, zinc chloride increases the asymmetry of the band and produces some three times as great a shift of the maximum as do alkaline earth chlorides in corresponding concentrations. The shift, which probably arises from and is an indication of the strong hydration of the zinc ion, increases up to a concentration corresponding approximately to one Zn^{++} to seven molecules of H_2O, it decreases with increasing concentration beyond that point.

INHIBITORY EFFECT OF PACKING ON THE METHYL ETHER DECOMPOSITION

Sir:

In their work on the kinetics of methyl ether decomposition, Hinshelwood and Askey [*Proc. Roy. Soc.* (London), **A115**, 215 (1927)] found that the rate in a silica bulb half-filled with powdered silica was appreciably lower than in a completely empty bulb. Thus at about 535° and 175 mm. initial pressure the values of t_{50} were 6.2 and 5.4 minutes for half-filled and empty bulbs, respectively. The packing thus decreased the rate by about 14%.

This effect, if real, is in harmony with the conclusion of Rice and Herzfeld [THIS JOURNAL, **56**, 284 (1934)] that the methyl ether decomposition involves long chains, the inference being that the chains may be broken at a silica surface by catalytic re-combination of the carriers. In order to obtain confirmation of the result, the following experiment was carried out.

Two Pyrex tubes, one empty and the other filled with 5 mm. Pyrex chips coated with potassium chloride, were bound together in a copper jacket and placed in an electric heater. Methyl ether vapor was introduced simultaneously into the two bulbs, and pressure differences and total pressures were determined.

The rate of pressure increase was definitely lower in the packed tube. In an experiment at 481°, the initial pressures were 458 and 440 mm. in packed and empty tubes, respectively. After twenty minutes, the corresponding pressures were 617 and 610 mm., giving increases of 159 and 170 mm. Correcting the latter for the lower initial pressure and for a small expansion (0.5%) gives 180 mm. for the corresponding pressure increase. The packing thus decreased the rate of pressure increase by 11.5%, as compared with the 14% reported by Hinshelwood and Askey.

It would seem to be clear that the reaction is not the simple homogeneous process originally postulated by Hinshelwood and Askey.

NEW BOOKS

Elementary Principles in Physical Chemistry. By T. J. Webb, Assistant Professor of Physical Chemistry, Princeton University. D. Appleton–Century Company, Inc., 35 West 32d Street, New York, N. Y., 1936. 344 pp. 15.5 × 23 cm. Price, $4.00.

As an introductory text in physical chemistry, this book is somewhat unconventional in choice of subject matter. This is doubtless in part due to the fact that it is written, according to the sub-title, "with special reference to the state of equilibrium in a chemical reaction and to the rate of attainment of equilibrium." As a result electrical conductance, for example, is treated with brevity and the phenomena of transference are largely omitted; similarly absent are the usual chapters on the liquid state, the solid state, the relation of physical properties to molecular constitution, and the colloidal state. Since rates of reaction are a primary object, the absence of a discussion of photochemical reactions is more difficult to understand. Subjects which are treated somewhat more fully than is usual in introductory texts are distribution laws (both Maxwell's and quantum theory), thermodynamics (making free use of entropy), the Debye–Hückel theory of electrolytes and its application to reaction rates, Eyring's theory of reaction rates, and Schrödinger's equation.

Numerous interesting tables of numerical results are included, but experimental methods receive scant attention. Consequently a student with no more than the usual experience of one beginning physical chemistry would often find himself studying theories of phenomena in advance of any appreciation of the facts; the extent to which this would create difficulty would depend upon the instructor. Since the treatment is largely analytical rather than descriptive, a student without a fair knowledge of calculus would lose much that is most useful in the book.

While it is possible to disagree with various details, on the whole the book gives evidence of having been thoughtfully written. The student who is interested primarily in the practical application of physical chemistry may perhaps not be attracted; but the student whose taste is for theoretical aspects of the subject, including those of fairly recent origin, will find much to interest him.

Roscoe G. Dickinson

Quantitative Analyse. (Quantitative Analysis.) By Dr. Otto Brunck, Professor em. an der Bergakademie Freiberg. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1936. 224 pp. 8 figs. Price, RM. 9.

"The Art of Gravimetric Analysis at Freiberg" would be a more exact title for this book. Professor Brunck presents the procedures of classical gravimetric analysis developed there by Clemens Winkler and enriched by his own life work. One sees on every page that the methods described have, as the author states in the preface, been tested with his own hands.

The first sixty-seven pages of the book are devoted to the general technique of quantitative analysis. Since Professor Brunck omits all chemical theory with which the student is presumably acquainted from previous study of qualitative analysis, a very thorough and helpful treatment of the practical operations such as fusions, filtrations, and ignitions is possible. A section on electroanalysis is included.

The remaining one hundred forty-seven pages are given to particular directions for the determination of water, the metals, and the non-metals. Besides the common metals of qualitative analysis, gold, platinum, palladium, molybdenum, tungsten, titanium, uranium, and beryllium are treated. At the end of each group of metals, directions for separation are added. In this part of the book repetition is avoided and cross reference is made easy by a very clear system of paragraph numbering.

It is easy to find flaws in a book written in the spirit of this one. Not all analysts will agree that calcium may be separated from magnesium by a single precipitation in alkaline solution and that the practice of weighing calcium as the oxide is to be abandoned. Many useful methods, such as the separation of iron, titanium, and other elements with cupferron, and the determination of sodium with uranyl acetate reagents, are not even mentioned. One regrets that Professor Brunck has limited the scope of his book through economic considerations. The lack of references is particularly unfortunate. Perhaps the most serious objection to the book as a text is that in many cases it would lead a student to employ gravimetric methods where volumetric methods are more suitable.

For these reasons the book is not to be recommended as a text for elementary quantitative analysis. It will be valuable, however, to more experienced workers, and teachers of quantitative analysis will find it most suggestive and stimulating.

Charles H. Greene

Die neuere Harnsäurechemie. Tatsachen und Erklärungen. (Modern Theories and Researches on the Chemistry of the Uric Acids.) By Prof. Dr. Heinrich Biltz, Breslau. Verlag Johann Ambrosius Barth, Salomonstrasse 18B, Leipzig C 1, Germany. 164 pp. 14.5 × 22.5 cm. Price, RM. 5.80.

Professor Biltz's investigations on glyoxalones led him to make a searching study of the complicated chemistry of uric acid. As a result, his newer investigations have contributed much important and valuable data leading to a better understanding of the chemistry and reactivity of uric acid, especially the nature of the 4,5 double bond in this oxypurine molecule. The conclusions and theoretical discussions of the author are reported under five subdivisions or chapters which may be expressed as follows: (1) purine constructions of the uric acid type in which the 4,5 double bond of the uric acid molecule is resistant to change; (2) derivatives of uric acid resulting from a rupture of the pyrimidine ring in the uric acid molecule; (3) derivatives of uric acid formed by rupture of the glyoxalone ring of this purine molecule; (4) chlorination products formed from uric acid and their characteristic reaction products and (5) characteristic caffolide and spirohydantoin ring compounds formed from uric acid. The author makes original applications of the electron conception of chemical action to explain many of the results obtained by experimentation, and uses this method of reasoning to explain the disagreement in chemical behavior between uric acid and xanthine. The author considers the 4,5 double bond in the uric acid molecule as a normal ethylene grouping, while in xanthine it functions in an entirely different manner as a result of its conjugation with a double bond in the 7,8 or 8,9 positions of the purine molecule.

Under these five subdivisions are discussed (1) uric acid and xanthine reactions, uric acid acidity, alkylation and acylation, hydrolytic degradation and oxidation, (2) uric acid glycols and their characteristic degradation changes, oxidation reactions with conversion to hydantoins and formation of allantoin, (3) the acetal derivatives of uric acid glycol, their behavior toward acids, reduction with hydriodic acid and interaction with diazomethane, (4) isouric acid derivatives, halogenated dihydrouric acids and pseudouric acids, and (5) the caffolides and formation of hydantoylamides, spirohydantoins and their conversion into hydantoins.

The books contain a large amount of most interesting data accumulated after years of research on uric acid. Abundant literature references are given which will be very helpful to the inexperienced worker in this field of chemistry. What is greatly needed, however, is a better organized system of classification of characteristic reactions to make the book more readable.

Treat B. Johnson

Physical Chemistry. By Frank H. MacDougall, M.A., Ph.D., Professor of Physical Chemistry, University of Minnesota. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1936. ix + 721 pp. 97 figs. 14.5 × 22.5 cm. Price, $4.00.

Another text-book of physical chemistry! Perhaps it might have been said, twenty-five years ago, that there were few good American text-books of physical chemistry, But certainly, today, we have six or eight such books, any one of which will afford plenty of good grist to a professor and his class throughout a full year's milling.

Dr. MacDougall's presentation follows, "in the main, the traditional order of presentation," as stated in the Preface. The chapter headings are: I, Introduction, Atomic Theory; II, Energy and the First Law of Thermodynamics; III, The Gaseous State; IV, The Liquid State; V, The Solid State; VI, The Structure of Atoms I; VII, The Structure of Atoms II; VIII, Physical Properties and Molecular Constitution; IX, The Second Law of Thermodynamics; X, Solutions; XI, Solutions of Electrolytes; XII, Thermochemistry; XIII, Equilibrium; XIV, Heterogeneous Equilibrium and Applications of the Phase Rule; XV, Chemical Kinetics; XVI, Electrical Conductance; XVII, Equilibrium Involving Ions; XVIII, Electromotive Force; XIX, Electrolysis; XX, Photochemistry; XXI, The Colloidal State; Index of Authors and Index of Subjects.

The book is written with an easy-flowing logic and with exceptional and gratifying clarity. Many intermediate steps in the derivations and expositions, often omitted in texts of this same class, are here included to help the student (and the professor) surmount some of the more troublesome hurdles. While several of the chapters seem very full and exhaustive for an introductory course, the topics are developed and arranged in such a way as to permit an adaptation of the subject matter to the needs of several different types of students. More than usual emphasis, but not unduly so, is given to thermodynamic approach, and the Author develops the treatment in fairly gentle stages.

This text deserves to rank with the best available. Many teachers will find it suited ideally to their requirements.

Edward Mack, Jr.

The Theory of the Properties of Metals and Alloys. By N. F. Mott, M.A., F.R.S., Professor of Theoretical Physics, and H. Jones, Ph.D., Lecturer in Theoretical Physics, The University of Bristol. Oxford University Press, 114 Fifth Avenue, New York, N. Y., 1936. x + 326 pp. 108 figs. 16 × 24.5 cm. Price, $8.00.

Elektronentheorie der Metalle. (Electron Theory of Metals.) By Dr. Herbert Fröhlich, Bristol. Verlag von Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1936. vii + 386 pp. 71 figs. 14.5 × 22 cm. Price, RM. 27; bound, RM. 28.80.

It is ten years since Fermi and Dirac suggested the principles of statistics which are now known by their names. This decade has seen those principles applied to the electrons in metals, with a success reminding one of the preceding years when Bohr's theory of hydrogen was being extended to explain the periodic table and the line spectra of the elements. The theory of metals is still far from the complete state which atomic theory has reached; the volumes under review are the first full sized books which have been devoted to it. But it is on the way and proceeding with great vigor.

The chemist should certainly be interested in this development. Most of the elements are metals, and they prefer to behave in ways quite different from the laws of valence which the chemists have worked out. Unlike the familiar chemical compounds, the laws of metals are not simple and qualitative ones, to be perceived without mathematical labors. The theory of metals is based on wave mechanics, and unfortunately on the more difficult and involved wave mechanics; and there seems to be no short cut to understanding it. But the theory is interpreting facts at such a rate that it can hardly be neglected, even by the most practical minded, for it is likely to be the foundation of the physical metallurgy of the future. There is no use pretending, however, that either of the volumes which have just appeared is easy reading, or even possible reading for one who is not already more or less familiar with the principles of wave mechanics. They are both well and clearly written, but the mathematics cannot be escaped. The day has passed when a chemist or metallurgist is educated to discuss the foundations of his science, if he does not know modern theoretical physics. It is just as fundamental to the chemical physics of the next generation as thermodynamics was to the physical chemistry of the last.

The two books under discussion are very similar, as is natural when one notes that both originate in Bristol, where Mott and Jones are members of the staff, and Fröhlich has been a visitor. England has been rather in the lead in the last few years in the theory of metals, partly with the help of expatriated German scientists, though this country, Russia, Germany and France have all contributed. It has been a development not only of many countries but of many people, and no collection of the leading workers in the field would be complete without fifteen or twenty names at the very least. The authors of these books have all made significant contributions, however, and naturally each emphasizes to some extent his own work. Thus Mott and Jones treat alloys in a good deal of detail; they discuss carefully the various types of lattices, and the methods of predicting the crystal structure and phase diagrams of alloys; they take up the properties of the transition metals; in general, they stay rather close to physics and chemistry, with a minimum of mathematics. Fröhlich, on the other hand, covers the mathematical part of the theory with more care, but considers principally the alkali and noble metals, the simplest group theoretically, with comparatively little treatment of the other groups of metals, and almost none of alloys. The chemist is likely to find Mott and Jones' book more to his liking. But both are in general excellent and authoritative, and both can be read with profit.

Since books on the theory of metals are a novelty, it is worth while saying what these contain. Mott and Jones begin with a discussion of the thermal properties of a crystal lattice—the equation of state, specific heat, phase diagrams of alloys, and superstructure. Then follows a treatment of the motion of electrons in a crystal lattice, first in the absence of an external field, then in a field, leading to electrical conduction, dispersion and absorption of light. The theory of cohesion and metallic binding, as applied both to pure metals and alloys, follows next, after which there is discussion of electronic specific heat, magnetic properties, and detailed calculation of electrical conductivity. Probably of most interest to chemists will be the part dealing with alloys and the conditions governing their formation and properties. Fröhlich, as has been stated, does not treat these problems, but does take up a few questions, such as thermionic emission, which Mott and Jones omit. Both books are more inclusive in some respects than the article in the "Handbuch der Physik" by Sommerfeld and Bethe, the best known previous treatment of the subject, and contain a good deal of new material, principally on cohesion and optical properties, which have developed since the time of that article. Both contain many references, those given by Fröhlich being in the form of a fairly extensive, though sometimes inaccurate, bibliography. While there are a few points on which one may take issue with the points of view of both books, these are minor affairs, and of small interest to the general reader. In general, it is safe to say that the electron theory of metals is now a branch of science in the most flourishing period of its growth, and that the books of Mott and Jones and of Fröhlich are excellent guides to its present development.
