Effect of *p*H and Temperature.—In order to choose the most advantageous reaction conditions rather than to adopt them arbitrarily, a set of experiments were run at different acidities and different temperatures.

For this study, sheeted, high-grade commercial cotton linters was used. The reaction was run at room temperature and 70°, both at *p*H 6. To adjust the *p*H, sufficient potassium dihydrogen phosphate was added to the water to give a 0.05*M* concentration; then, sufficient sodium hydroxide as a concentrated solution in water was added to achieve the desired *p*H. A Beckmann *p*H meter was used to determine acidity. For the 70° run, the cell was immersed in a thermostated bath and the water brought to temperature before adding the cellulose. The cell was not removed from the

bath until the run was completed. In this experiment, two triplicate samples were taken, the first set after one hour and the second after five and one-half hours. For the room temperature experiment, samples were taken singly but at more frequent intervals, and in addition a sample was taken after ten days of standing at room temperature. The results for both of these runs are plotted in Fig. 3; it can be seen that the influence of temperature is negligible over the range studied. The nature of the data obtained empirically in these two runs and its conversion into extent of exchange is illustrated by Tables I and II. In order to conserve space all other runs are summarized by the "characterization values" defined in the next section.

TABLE I

EXCHANGE OF COTTON LINTERS AT 70°

Weight of cellulose, x = 2.060 g.; moisture content on wet basis, m = 5.7%; weight of heavy water used, W = 9.653 g.; initial mole fraction of D_2O in heavy water, ξ_0 = 0.22; calculated values, A = 29.13 and B = 0.363.

[a] Average for three samples. [b] Average for two samples.

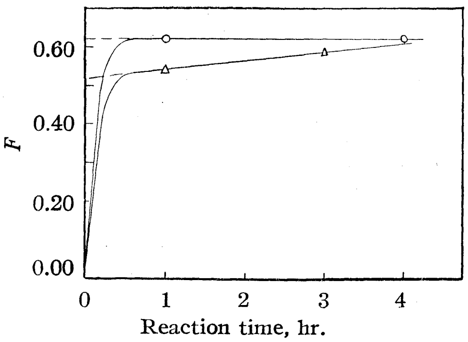

Fig. 4.—Effect of *p*H on rate of exchange: O, cotton linters, *p*H 3.9, 25°; Δ, cotton linters, *p*H 10.5, 25°.

Two additional runs were made at room temperature, one at *p*H 3.9, the other at *p*H 10.5. The results of these two experiments were plotted in Fig. 4; these curves together with the room temperature run of Fig. 3 indicate that the influence of *p*H also is negligible.

General Character of the Exchange Curve.—The shape of the exchange *vs.* time curve is simple and essentially similar for all the cellulose samples which were studied. Its characteristics are: (1) a very steep rise which is substantially terminated after a fraction of an hour, and (2) a horizontal part with such a small slope that the exchange value even after one week differs only slightly from the value observed at one hour.

Since the curves for different cellulose samples are so consistent in shape, a generalized notation to represent the data may be adopted which is more concise and lends itself to comparison better than the original curves. Specifically, let the intercept of the horizontal portion of the curve extrapolated to zero time be called the *a* value; the magnitude of *F* at four hours, the *b* value; and

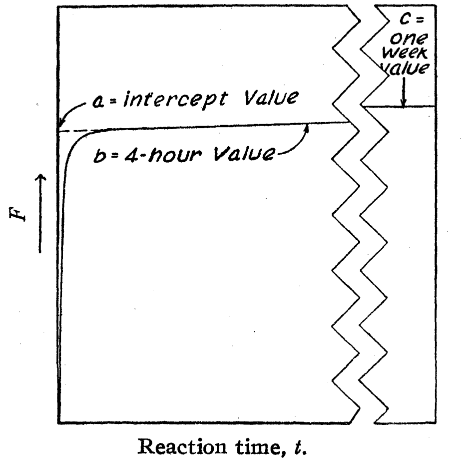

Fig. 5.—Generalized reaction curve and characterization values.

the magnitude of F at one week, the c value, all as indicated in Fig. 5. For convenience, these values collectively will be called the "characterization values" for the various samples.

Returning once again to the effect of temperature and *p*H on the exchange rate of a cotton linters sample, we may summarize the results by the characterization values as presented in Table III. It may be noted at this point that the four runs indicate an experimental precision that is about as good as that estimated in a previous section, especially if one considers the b value as the correct measure of accessibility. The average deviation of the a value is ±0.025, which is poorer than expected; but the average deviation of the b value is ±0.005, which agrees with the predicted value corrected for the multiplicity of the determinations.

TABLE III

EFFECT OF *p*H AND TEMPERATURE: COTTON LINETRS

Run	Reaction conditions *p*H	°C.	Characterization values *a*	*b*	*c*
1	6	70	0.61	0.62	..
2	6	25	.57	.61	0.64
3	3.9	25	.62	.62	..
4	10.5	25	.54	.61	..

It can be seen from the tables that many of the samples produce perfectly flat curves in the interval from the first to the fourth hour. Some of the samples, however, show a significant difference between the a and the b value. All samples appear to continue to exchange a small, but always a significant amount, in the interval from four hours to one week, and the extent of this exchange does not seem to be related to the magnitude of the difference between a and b. The reasons for the differences in magnitude of a, b, and c are under investigation at the present time; the results so far indicate that where b differs significantly from a, it may be attributed to a residual diffusion error. Accordingly, we shall tentatively assume the b value, *i. e.*, the value of F after four hours, to be the measure of accessibility.

Wood Pulp Samples.—Since the rate of exchange was not noticeably influenced by the variables studied, all of the experiments which follow were made at room temperature and *p*H 6.

Wood pulp samples previously studied by Drs. Conrad and Scroggie were used after the described one-week conditioning. The practice in this instance was to take frequent single samples rather than triplicate samples at widely spaced intervals. The data are summarized in Table IV.

TABLE IV

CHARACTERIZATION VALUES FOR WOOD PULPS

Run	Sample description	Characterization values *a*	*b*	*c*
5	Wood pulp from beech	0.53	0.54	0.68
6	Same, from southern pine	.48	.55	.57
7	Same, from western hemlock	.54	.55	.67
8	High alpha wood pulp from southern pine	.68	.68	.73
9	Wood pulp treated with caustic of approx. 10% concn.	.68	.74	.81

Regenerated Cellulose Samples.—Four different regenerated cellulose fibers were studied by the same methods as described above. The results are shown in Table V. In addition to these samples, two native cotton fibers were run; for one of these a b value of 0.41 was found, and for the other 0.46. These values are the lowest found for any of the samples studied and indicate that native cotton has a relatively small fraction of accessible chain segments.

TABLE V

CHARACTERIZATION VALUES FOR VISCOSE RAYON FIBERS

Run	Sample description	Characterization values *a*	*b*	*c*
10	"Cordura" high tenacity viscose rayon	0.86	0.86	0.89
11	Fiber G, high tenacity viscose rayon	.67	.67	.74
12	Textile viscose rayon	.66	.68	.75
13	Special viscose rayon spun without appreciable tension	.78	.81	.90

Discussion

If it is assumed that cellulose is composed of easily accessible (amorphous) and more difficultly accessible (crystalline) domains, it is probable that the rapid, limited exchange with D_2O involves all of the hydroxyls in the amorphous regions together with those in the surface of the crystalline arrays. One cannot ignore the contribution of the surface hydroxyls to the extent of the exchange reaction in estimations of crystallinity, for experimental evidence indicates that the areas of high lateral order are very small and, as a consequence, a large fraction of their hydroxyl groups are arranged in the surface. If this factor is taken into account, the relationship between the amount of crystalline material in a cellulose sample and the extent of the exchange reaction may be written

$$F' = \sigma\alpha + (100 - \alpha),$$

where

F' = $100F$, *i. e.*, the percentage of all of the hydroxyls which react rapidly with D_2O
σ = the fraction of the hydroxyls of the crystalline domains which are in the surface and accessible to D_2O
α = the per cent. of crystalline material in the sample

Solving for α

$$\alpha = \frac{100 - F'}{1 - \sigma}$$

In order to arrive at estimates of α for the samples which were studied, it is first necessary to assign a value to σ. To arrive at this value, it may be assumed that the effective surface development of the crystalline regions is represented by an infinitely long, square prism with a base of between

50 and 100 ångströms on edge.[11,12] A cross-section of such a prism would contain approximately twenty rows of cellulose chains, each row in turn consisting of ten chains. Now, if one takes a volume element of the idealized prism by passing through it two parallel planes which are perpendicular to the long edges of the prism, the surface development may be computed readily. In particular, if the transecting planes are spaced so that the element contains 200 anhydroglucose units, it is evident that 20 of these units will lie in the hydroxyl-rich surfaces, and 36 (edgewise) in the other two faces. Thus, for every 100 anhydroglucose residues in a crystalline domain, 28 lie in the surface. Assuming now that all hydroxyls attached to the latter are reactive, we arrive at $\sigma = 0.28$. This value was used to calculate the values for α shown in Table VI; values derived from a different method are shown for comparison.

TABLE VI

CRYSTALLINITY AS ESTIMATED FROM D_2O EXCHANGE AND NICKERSON DEGRADATION

		Accessibility		Crystallinity	
Run	Sample description	From D_2O exchange, F' (%)	Nickerson method[b] (%)	From D_2O exchange,[a] α (%)	Nickerson method,[c] %

12	Textile rayon	68	27	44	73
13	Special rayon	81	..	26	..

[a] Crystallinity estimated from D_2O exchange, $\alpha = (100 - F')/(1 - \sigma)$. [b] Values in this column determined by Nickerson method as modified by Drs. Conrad and Scroggie; these data were supplied through the courtesy of these investigators. [c] Crystallinity estimated from the Nickerson degradation by subtracting from 100 the per cent. accessibility to $FeCl_3$:HCl.

It might be well to mention at this point that while the accessibility, F, is an exact empirical value, the crystallinity, α, is only an approximation. How close α approaches the true value for crystallinity depends in part on the validity of σ and in part on the magnitude of the accessibility. For a sample in which all but 10% of the hydroxyls are accessible the magnitude of α would vary only from 14 to 23% if the value of σ were doubled; on the other hand, if one were to consider a much more crystalline sample, *e. g.*, cotton with 41% of the hydroxyls accessible, then the value for α would vary from 82% for $\sigma = 0.28$ to 100% for $\sigma = 0.41$, a much larger change in α for a much smaller change in σ. Since the computation of σ is based on two methods for estimating crystallite size,[11,12] it is not likely that it is in error by the magnitudes just discussed. In fact, if one compares the averaged values of Table VI with the estimates of crystallinity arrived at by Hermans[13] through a study of the density of various types of cellulose, it is noted that a fairly good agreement exists. The average values for crystalline content reported by Hermans are 60% for ramie and cotton, 50% for wood pulp and 25% for regenerated cellulose.

In contrast to the density method of Hermans, it is interesting to point out that the accessibility of cellulose to heavy water is in all cases distinctly greater than that observed with the Nickerson method, as is shown in Table VI. A possible explanation is that additional crystallization occurs in the early stages of the reaction. During hydrolysis, cellulose chains in the easily accessible areas are broken and new, free, chain ends are produced; this process removes constraints on these chains and makes their segments more easily mobile. They will now be able to arrange themselves in a higher degree of lateral order under the influence of the strong intermolecular forces between the chains, and part of the material which was disordered before will undergo crystallization. It has been pointed out previously by several observers[14] that, for the same polymer, low molecular weight fractions have a greater tendency to crystallize than those of higher molecular weight; also, Ingersol[15] has recently reported that treating cellulose fibers with hydrochloric acid sharpens their X-ray patterns. The increased density[16] and decreased moisture regain[17] of cellulose fibers upon prolonged treatment with the Nickerson reagent also points to the fact that additional crystallization occurs while glucosidic bonds are hydrolyzed in the easily accessible areas. It is therefore understandable that the D_2O exchange method indicates larger amounts of disordered material than the Nickerson method. Similar reasoning will also hold for the oxidation method[2] mentioned in the introduction, for it was carried out at a low *p*H and partial hydrolysis with subsequent crystallization was bound to occur in the easily accessible arrays.

The thallation method of Assaf, Haas and Purves[3] leads to lower accessibilities than any of the other procedures; this is probably due to the fact that it is carried out in an anhydrous system. It tests the texture of the sample in the bone-dry state and indicates only those domains as accessible that can be approached by an organic (hydrophobic) solvent. The ingenious extrapolation to zero molecular volume eliminates the volume re-

quirements of the solvent and probably leads to a true value of accessible hydroxyl groups for a non-swelling reagent. In an aqueous medium, swelling takes place and a number of weak (van der Waals) bonds between hydroxyl groups of adjacent chains are opened and hitherto inaccessible areas are made penetrable by the reagent. One should, therefore, expect that all methods using aqueous systems should indicate higher degrees of accessibility, which is in fact the case. The highest proportions of disordered areas should be given by X-rays, by density considerations,[13] and by the heavy water exchange method; the figures deduced from these three methods should also agree numerically. Table VII contains the accessibilities as reported by all methods and shows, indeed, that the thallation method gives the lowest values whereas the two "destructive methods" in aqueous media, involving hydrolysis and oxidation, give higher figures for the disordered areas and agree with each other to a first approximation. Finally, the non-destructive methods of X-ray diffraction, density evaluation and heavy water exchange lead to the highest figures for the accessible domains; these methods, too, agree with one another reasonably well.

TABLE VII

ORDER OF ACCESSIBILITY FOUND BY DIFFERENT METHODS

	% Accessible or amorphous			
Method	Cotton	Cotton linters	Wood pulp	Rayon

X-Ray densitometry[5]	..	...	..	81

[a] Data supplied through courtesy of Drs. Conrad and Scroggie. [b] Values averaged from Table IV. [c] Unswollen samples.

Summary

It has been found that cellulose reacts very rapidly with heavy water, provided sufficient agitation is used; the rapid reaction is of limited extent, and is succeeded by a much slower reaction which persists for days. In none of the cases studied were all of the hydroxyls exchanged, even at the end of one week. The techniques used and the calculations involved are outlined.

The extent of the rapid reaction is a measure of the accessibility of the cellulose sample, and from the accessibility an estimate is made of the amount of amorphous material present in each of the samples studied. The average amounts found for different types of cellulose were as follows: 21% for cotton, 46% for wood pulp and 66% for rayon.

The different accessibility values found for the same cellulose sample when different methods are used are discussed and compared. These methods fall into three classes. In the first class is the thallation method, where a non-swelling solvent is used, and with which the lowest values are found. In the second class are the two hydrolytic, aqueous methods, which give intermediate values for accessibility. In the last class are the physical, non-destructive methods which give the highest values.

n-Alkyl Diselenides

BY GEORGE G. STONER AND ROGER W. WILLIAMS

In connection with a program[1] of research on selenium and its compounds, it was of interest to examine a number of *n*-alkyl diselenides. Of this particular homologous series, methyl,[2,3] ethyl,[2,4] propyl,[2,3,5] butyl[3] and dodecyl[6] diselenides are known, having been prepared by a variety of methods.

A convenient method of synthesis, based on the following three reactions,[7] and not previously applied to this series, was used to prepare butyl, amyl, hexyl, heptyl, octyl, and nonyl diselenides.

$$\mathrm{Se} + \mathrm{K_2SO_3} = \mathrm{K_2SeSO_3}$$

$$\mathrm{RX} + \mathrm{K_2SeSO_3} = \mathrm{RSeSO_3K} + \mathrm{KX}$$

$$2\mathrm{RSeSO_3K} + \mathrm{I_2} + 2\mathrm{H_2O} = \mathrm{RSeSeR} + 2\mathrm{KHSO_4} + 2\mathrm{HI}$$

This sequence of reactions yields *n*-alkyl diselenides which are less likely to be contaminated than those prepared by the other methods,[2–6] and the yields are good (Table I). The offensive odors of the *n*-alkyl diselenides decrease considerably in intensity above hexyl in the homologous series.

[a] Temperature readings were not corrected for emergent stem. [b] The atomic refraction of each Se in the diselenide calculated from the experimental molecular refraction (formula of Lorenz and Lorentz), assuming the atomic refraction for C and H to be 2.418 and 1.100 ml., respectively (sodium D light). [c] Selenium was determined by a method developed by Justin S. McNulty (to be published). Samples were decomposed and selenium was determined gravimetrically as elemental selenium. [d] Backer and van Dam (ref. 3) reported that butyl diselenide distilled in the range of 129–130° at 13 mm.

At room temperature these liquid diselenides are orange, but this coloration becomes weaker as the temperature is lowered. This is suggestive of a certain degree of dissociation into RSe radicals, increasing with temperature.[8]

From values obtained for d^{20}_4 and n^{20}_D, the atomic refraction of each selenium atom in these diselenides was 11.17 ± 0.11 ml. (sodium D light).[9]

Experimental

Materials.—The 1-bromoalkanes, each of which distilled within a two-degree range, were purchased from Columbia Organic Chemicals Co., Inc., Columbia, South Carolina. Powdered gray-black selenium, 99.5% pure, was obtained from Canadian Copper Refiners, Ltd., Montreal East, Quebec. The other compounds were chemically pure.

General Procedure.—In an atmosphere of nitrogen, 40 g. (0.50 g.-atom) of selenium was allowed to react for two hours with a mechanically stirred, hot solution of 119 g. (0.75 mole) of anhydrous potassium sulfite in 1200 ml. of 50% aqueous ethanol. Some undissolved matter was filtered from the hot mixture, and the filtrate was transferred immediately into a 5-liter, 3-neck flask. Without delay, 0.40 mole of the appropriate 1-bromoalkane was added portionwise during a period of one-half hour, while the mixture was kept refluxing in an atmosphere of nitrogen and mechanically stirred. An additional period of two hours under these conditions was allowed for the reaction. The solution of potassium alkylselenosulfate was cooled to room temperature and oxidized to the *n*-alkyl diselenide by iodine added portionwise until the color of the iodine persisted. The small excess of iodine was reduced by bubbling sulfur dioxide into the solution. The diselenide separated out as an orange oil.

In each case, the oil was washed with water and distilled at reduced pressure. Experimental data are given in Table I. Practically no unreacted 1-bromoalkanes were recovered in the purification of butyl, amyl, hexyl and heptyl diselenides. However, in the cases of octyl and nonyl diselenides, 10% of the original 1-bromoöctane and 27% of the original 1-bromononane were recovered. Hence, a period of reaction longer than two hours is indicated in the case of these higher 1-bromoalkanes.

All the diselenides had offensive odors, but those of heptyl, octyl, and nonyl diselenides were much less pronounced. All six of these compounds were orange at room temperature. Butyl and amyl diselenides remained liquid at −78°, at which temperature they were straw-colored. The higher diselenides formed yellow crystals below their melting points (Table I).

For the purpose of comparison, amyl diselenide also was prepared from 1-chloropentane (Sharples Chemicals, Inc., Philadelphia, Pa.). The period allowed for reaction was extended to twelve hours. In other respects the conditions were the same as those described above. After distillation, the yield of amyl diselenide was 65%, which is practically identical with the yield of 63% resulting from the use of 1-bromopentane (Table I).

Acknowledgment.—The authors are grateful to Phyllis K. Distelhorst and Justin S. McNulty, who performed the determinations of selenium.

Summary

Potassium alkylselenosulfates were used as intermediate compounds in conveniently preparing five new *n*-alkyl diselenides (amyl through nonyl). Several properties characterizing these homologs were determined. The value of the atomic refraction for each atom of selenium in such diselenides was found to be 11.17 ± 0.11 ml. (sodium D light).

Methylphenylpolysiloxanes

BY RICHARD N. LEWIS

Many compounds in the series of methylpolysiloxanes and phenylpolysiloxanes have been reported in the literature[1]; polymers containing both methyl and phenyl groups on the same silicon atom[2] and copolymers of methyl and phenylpolysiloxanes[3] have also been reported. However, few pure compounds containing both methyl and phenyl groups have been described. Kipping[4] has prepared dimethyltetraphenyldisiloxane, a solid melting at 51–52°. Daudt[5] has disclosed tetramethyldiphenyldisiloxane without describing its properties and has prepared pentamethylphenyldisiloxane, b. p. 206°.[6] Hexamethyldiphenyltrisiloxane was studied by Hurd[7] but has not been fully characterized.

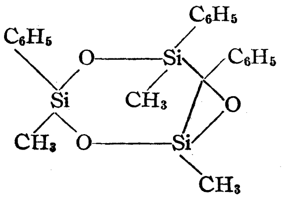
The shorthand notation used in this paper is based on that of Wilcock,[8] in which M and D represent mono- and difunctional units; primes are used to indicate phenyl groups, thus:

Unit	Formula	Unit	Formula
M	$(CH_3)_3SiO_{1/2}$	D	$(CH_3)_2SiO$
M′	$(CH_3)_2C_6H_5SiO_{1/2}$	D′	$CH_3C_6H_5SiO$
M″	$CH_3(C_6H_5)_2SiO_{1/2}$	D″	$(C_6H_5)_2SiO$

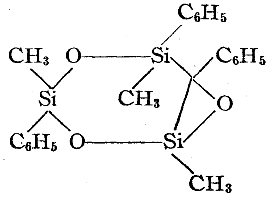
According to this system, the compounds mentioned above may be written, M''_2, M'_2, MM′, M_2D'', respectively.

A series of cyclic compounds was made by hydrolyzing methylphenyldichlorosilane[2] and distilling the resultant oil at a pressure of 2 mm. During the distillation the liquid was heated to 460°, at which temperature there is a strong possibility of thermal rearrangement of silicon–oxygen bonds.[9,10] The fact that there was no appreciable residue, therefore, does not mean that the original hydrolyzate was composed entirely of low molecular weight products. There was no indication, however, of rearrangement of the carbon–silicon bonds or of any other type of decomposition.

On fractional distillation of this oil there were obtained two forms of the cyclic trimer, D'_3, both solid at room temperature, and a cyclic tetramer, D'_4, as well as a non-volatile residue consisting of higher polymers of unusual thermal stability. Since the two forms of the trimer can be separated by distillation, they are apparently two distinct compounds. A type of *cis–trans* isomerism, in which the phenyl groups may or may not all lie on the same side of the ring, appears to be a reasonable explanation. The *cis*-configuration, which has a threefold axis of symmetry, is assigned to the higher melting isomer. This type of isomerism probably occurs with the tetramer as well. However, it was not possible to obtain any crystalline material from it, although four stereoisomers are theoretically present.



cis-Trimer, m. p. 99.5°



trans-Trimer, m. p. 39.5°

It is to be expected that these cyclic polysiloxanes can be converted to linear ones by equilibration with monofunctional units or "chain-stoppers." In the methyl series, M_2 and D_4, for instance, when shaken with sulfuric acid, produce compounds of the general formula M_2D_x.[9] Since the phenyl–silicon bond is known to be somewhat unstable toward acidic reagents,[11] it was considered desirable to use an alkaline catalyst in the present work. (Methods involving alkaline equilibration have recently been patented.[6,12])

It was found that compounds of the type D'_x, could be equilibrated with M'_2 and with M_2 by means of potassium hydroxide in isopropyl alcohol containing a small amount of water. In the first case, no other solvent was required, but when M_2 was used, it was necessary to add toluene because of the limited miscibility of D'_x with M_2 and isopropyl alcohol. This lack of solubility must be due to the presence of higher polymers as the tetramer is miscible with M_2. The phenyl–silicon bond is apparently quite inert toward this treatment as no appreciable quantity of benzene was produced.

In the reaction of D'_x with M_2 small amounts of dimethylphenylsilanol and dimethylphenylisopropoxysilane were formed; this means that the condensation of silanols and the hydrolysis of silyl ethers are reversible. Because of the acidic nature of silanols[13] some of the potassium salt must also have been formed. The following types of bonds are therefore present at equilibrium:

Alkoxysilane formation, which might have been predicted, has not been observed before. The formation of silanols from siloxanes was reported by Kipping and Robison.[14]

Experimental[15]

Hydrolysis of Methylphenyldichlorosilane.—Eleven and six-tenths moles (2210 g.) of redistilled methylphenyldichlorosilane (*Anal.* Calcd.: Cl, 37.10. Found: Cl, 36.69) was hydrolyzed in six portions by running it into ice water with vigorous stirring. The oil which was produced was distilled rapidly at 2 mm. from a Claisen flask, which was completely surrounded by an electric heater. The temperature outside the flask reached 460° while the vapor (probably superheated) reached 295°. No appreciable residue was left. The distillate (1318 g., 9.7 moles of D′) was redistilled at 1.5 mm. through a 1.5 inch by 18-inch column packed with stainless steel helices, and the resulting fractions were grouped as follows: I, forerun, 3%; II, 12% boiling at 165–185°; III, another 12% boiling chiefly at 190°; IV, 48% boiling chiefly at 237°; and V, 24% of residue.

Fraction II crystallized on cooling and was recrystallized from alcohol; flat plates, m. p. 99.5°; yield, 60 g.

Anal. Calcd. for $C_{21}H_{24}Si_3O_3$ (D'_3): C, 61.73; H, 5.92; mol. wt., 408. Found: C, 61.7, 61.7; H, 6.0, 5.9; mol. wt., 390.

Several fractions of the material boiling at 190° (1.5 mm.) were left at 0°. The first of these, apparently contaminated with the previous material, developed crystals in a few hours. After one week, however, the entire mass crystallized, and a portion of it was used successfully to seed the other fractions. Upon recrystallization from alcohol there were obtained small needles, m. p. 39.5°; yield, 137 g. There were also some intermediate fractions containing considerable amounts of both II and III. The following properties of III were determined on an unrecrystallized sample: n^{20}_D 1.5397, d^{20}_4 1.1062, R_D 0.2835, R_D (calcd.) 0.2826.

Anal. Calcd. for $C_{21}H_{24}Si_3O_3$ (D'_3): C, 61.73; H, 5.92; mol. wt., 408. Found: C, 61.6, 61.2; H, 6.2, 5.9; mol. wt., 437.

IV remained a viscous liquid well below 0° and could not be made to crystallize. It was miscible with *n*-heptane, acetone, M_2 and D_4, but not with alcohol. A middle fraction had the following properties: n^{20}_D 1.5461, d^{20}_4 1.1183, R_D 0.2832, R_D (calcd.) 0.2826. The yield of pure material was 453 g.

Anal. Calcd. for $C_{28}H_{32}Si_4O_4$ (D'_4): C, 61.73; H, 5.92; mol. wt., 544. Found: C, 61.8, 61.5; H, 6.0, 6.1; mol. wt., 545.

V was not characterized; it was assumed to consist of higher polymers of D′. It is a viscous liquid of high thermal stability as the following experiment shows: A 3-cc. portion was heated in a 6-cc. beaker in contact with zinc metal. There was no change, except for some fuming above 240°, until the melting point of zinc (419.4) was reached. After two hours in contact with molten zinc (average temperature about 450°) some thickening occurred; the material was then cooled to room temperature, at which point it was rubbery.

Dimethylphenylchlorosilane and Dimethylphenylbromosilane.—These two compounds were obtained together from the reaction of phenylmagnesium bromide with dimethyldichlorosilane.[16] From 3.0 moles of bromobenzene and 3.0 moles of dimethyldichlorosilane there were obtained 1.44 moles of the chloride, b. p. 197° at 766 mm., and 0.53 mole of the bromide, b. p. 215° at 766 mm. The combined yield of both halides was 65%. The chloride had a pleasant odor like that of the silanol described below, while the bromide was almost odorless.

Anal. Calcd. for $C_8H_{11}SiCl$: Cl, 20.77. Found: Cl, 20.5.

Anal. Calcd. for $C_8H_{11}SiBr$: Br, 37.15. Found: Br, 36.8.

Tetramethyl-1,3-diphenyldisiloxane (M'_2).—The above halides (1.93 moles) were hydrolyzed in ice water with vigorous stirring, and the product was diluted with ether, washed well, dried and distilled. The major portion of it distilled at 140–144° (5.7 mm.); yield, 250.5 g. (91%). A sample was redistilled at 110–111° (1.0 mm.); n^{20}_D 1.5122, d^{20}_4 0.9763, R_D 0.30745, R_D (calcd.) 0.3096.

Anal. Calcd. for $C_{16}H_{22}Si_2O$: C, 67.08; H, 7.74. Found: C, 66.2, 66.0; H, 7.6, 7.8.

Pentamethyl-1,3,5-triphenyltrisiloxane (M'_2D').—M'_2 (245 g., 0.857 mole) was mixed with 75 cc. of isopropyl alcohol and 38.8 g. (0.275 mole of D′) of cyclic polymers, D'_x, from which most of the tetramer had been distilled. A homogeneous solution resulted, although the cyclic compounds alone were immiscible with isopropyl alcohol. A solution of 10 g. of potassium hydroxide in 8 cc. of water was added and all but 5.3 cc. dissolved. The mixture was heated thirty-nine hours at 71°. After cooling it was washed, first with 10% sodium chloride (to help break the emulsion), then with 10% ammonium chloride and dried. On distillation the following fractions were obtained: 15.1 g., 60–119° at 1.8 mm.; 166.5 g., 120–138° at 2.0 mm. (recovered M'_2); 59.3 g., 130–173° at 0.5 mm. (0.140 mole, 51%, of M'_2D'); and a 25.3 g. residue of much lower viscosity than the original D'_x, presumably polymeric material of the general formula $M'_2D'_x$. The third fraction was redistilled at 169° and 0.7 mm.; n^{20}_D 1.5280, d^{20}_4 1.0227, R_D 0.3011, R_D (calcd.) 0.3009.

Anal. Calcd. for $C_{23}H_{30}Si_3O_2$ (M'_2D'): C, 65.36; H, 7.15. Found: C, 64.5, 64.9; H, 7.1, 7.2.

Dimethylphenylsilanol and Dimethylphenylisopropoxysilane.—The low-boiling fraction from the preceding preparation had a strong, pleasant odor similar to that of dimethylphenylchlorosilane and was therefore believed to contain the corresponding silanol. On redistillation 2.8 g. of material was obtained; b. p. 65–66° (3.5 mm.), n^{20}_D 1.4714, d^{20}_4 0.9074, R_D 0.3082, R_D (calcd. for silanol) 0.3034. The only other compound which seemed at all likely to be present was the isopropyl derivative; its calculated specific refraction, 0.3091, is closer to the observed value. A test-tube portion treated with sodium liberated hydrogen. Another portion treated with potassium hydroxide and potassium triiodide (the iodoform test) gave a precipitate, slowly on standing, more rapidly on warming to 70°, as would be expected from the slow formation of isopropyl alcohol. Similar tests with M'_2 and D_4 gave no precipitate. It was therefore concluded that the material was a difficultly separable mixture of dimethylphenylsilanol and dimethylphenylisopropoxysilane.

Heptamethyl-3-phenyltrisiloxane (M_2D').—A mixture of unfractionated cyclic methylphenylpolysiloxanes (13.6 g., 0.1 mole of D′) was dissolved in 48 g. (0.3 mole) of M_2 by adding 50 cc. of toluene and 25 cc. of isopropyl alcohol. To this was added 6.6 g. of 50% aqueous potassium hydroxide solution of which all but 1.5 cc. dissolved. The mixture was heated twenty-four hours at 60°. It was washed with water to remove alkali and alcohol, then dried and distilled through a 9-inch packed column. One cc. distilled from 76.4 to 89.5°. Of this only the first few drops had any odor of benzene; the rest appeared to be a mixture of water and M_2. The amount of benzene produced in the reaction was therefore considered to be negligible. A large fraction with an odor of toluene

distilled at 99.6° (750 mm.); n^{20}_D 1.3910. It was assumed to be an azeotrope between M_2 (b. p. 100.4°) and toluene (b. p. 110.8°). After the excess toluene was removed, the next fraction (10 g., 0.036 mole) was distilled at about 250°, leaving as a residue a low viscosity oil, which was assumed to consist of linear compounds of the type $M_2D'_x$. The 250° fraction was redistilled; b. p. 95° (5.0 mm.), n^{20}_D 1.4468, d^{20}_4 0.9080, R_D 0.2941, R_D (calcd.) 0.2929.

Anal. Calcd. for $C_{13}H_{26}Si_3O_2$ (M_2D'): C, 52.30; H, 8.78. Found: C, 52.8, 52.6; H, 8.9, 8.7.

Acknowledgment.—The author is indebted to Miss Mary L. Caldwell, who carried out the microanalyses for carbon and hydrogen.

Summary

1. Two stereoisomeric cyclic trimers and a cyclic tetramer have been obtained by the hydrolysis of methylphenyldichlorosilane.

2. Linear methylphenylpolysiloxanes have been prepared from the cyclic ones by means of hexamethyldisiloxane or tetramethyl-1,3-diphenyldisiloxane and an alkaline catalyst.

3. Evidence for an equilibrium between siloxanes, silanols and silyl ethers has been found.

Preparation and Properties of Trimethylsilylmethanol

BY JOHN L. SPEIER, B. F. DAUBERT AND R. R. MCGREGOR

Organo-silicon compounds containing organic functional groups such as the carbinol group are not readily prepared by the usual methods of synthesis of organo-silicon compounds. The literature records the preparation of only two compounds in which this group is contained. The first is triethylsilylethanol of uncertain structure[1] obtained by the chlorination of tetraethylsilane, conversion of the chloride to the acetate and hydrolysis of the acetate. The second is 1-trimethylsilyl-2-propanol prepared from trimethylsilylmethylmagnesium chloride and acetaldehyde.[2]

Since it was desired to investigate the properties of an α-hydroxyalkylsilane, trimethylsilylmethanol was synthesized in good yield through the sequence of reactions:

Me_3SiCH_2Cl[3] $\xrightarrow[\text{190°C.}]{\text{KOAc, HOAc}}$

$$Me_3SiCH_2OAc \xrightarrow[H_2SO_4]{\text{MeOH}} Me_3SiCH_2OH$$

The trimethylsilylmethanol so prepared was found to be approximately six times as reactive in forming a phenylurethan as its carbon analog, neopentyl alcohol, and approximately three times as reactive as methanol in the same reaction.

Experimental

Preparation of Trimethylsilylmethyl Acetate.—Chloromethyltrimethylsilane[4] (3.1 moles), potassium acetate (3.8 moles), and glacial acetic acid (420 ml.) were charged into a stainless steel high-pressure reactor and shaken at 190–192° for eighteen hours. The contents of the reactor were then washed thoroughly with distilled water. The water-insoluble liquid, after drying over anhydrous sodium carbonate, was slightly amber in color and weighed 416.5 g. (92%). The mixture was distilled through a three-foot Stedman column and was found to boil entirely between the temperatures of 136.2–136.8° at 748 mm., all but 5 ml. distilling at the higher temperature. The ester has the following constants: b. p. 136.8° at 748 mm., $[n]^{25}_D$ 1.4060, $[d]^{25}_4$ 0.8667. Molar refraction: Calcd.[5] for Me_3SiCH_2OAc, 41.31. Found: 41.37. Sapn. equiv.: Calcd., 146.2. Found: 146.5, 146.6. *Anal.* Calcd. for $C_6H_{14}O_2Si$: Si, 19.2. Found: Si, 19.3, 19.1.

Preparation of Trimethylsilylmethanol.—Trimethylsilylmethyl acetate (420 ml., 2.5 moles) was dissolved in absolute methanol (9 moles) and acidified with 10 drops of concentrated sulfuric acid. After standing at room temperature for two days, 165 ml. of the azeotropic mixture of methanol and methyl acetate was removed by distillation. The charge was then diluted with methanol (4 moles) and permitted to stand four days at room temperature before fractionation to yield 268 ml. (80%) of constant boiling trimethylsilylmethanol, b. p. 121.6° at 729 mm. The alcohol redistilled from lime had the following properties: b. p. 121.7–121.9° at 751 mm., $[n]^{25}_D$ 1.4169, $[d]^{25}_4$ 0.8261. Molar refraction: Calcd.[5] for Me_3SiCH_2OH, 31.83. Found, 31.71. The alcohol has a strong odor resembling that of menthol.

Preparation of Trimethylsilylmethyl 3,5-Dinitrobenzoate.—Trimethylsilylmethanol (1.1 g.) was added dropwise to 3,5-dinitrobenzoyl chloride (2.5 g.) and heated to 90° until no more hydrogen chloride was evolved. The mixture was cooled, and ground into a fine powder in the presence of two portions of warm 5–6% sodium carbonate solution. It was heated with a third portion of sodium carbonate solution until it fused. On stirring vigorously as it cooled, solidification occurred. The solids were washed with water in a suction filter, dissolved in boiling 95% ethanol, and filtered while hot. On cooling to room temperature, 2.3 g. of crystalline product was obtained which melted at 69.5–70°. The mother liquor was heated to boiling and diluted with water to the point of incipient turbidity. Again on cooling, 0.9 g. of crystalline product formed, m. p. 68.5–70°. The two crops of crystals were combined and recrystallized once from 95% ethanol. The recrystallized product melted at 70–70.5°. Further recrystallizations did not change this melting point.

Anal. Calcd. for $C_{11}H_{14}O_6N_2Si$: C, 44.26; H, 4.73; N, 9.33; Si, 9.41. Found: C, 44.04; H, 4.41; N, 9.33; Si, 9.47, 9.45.

Preparation of (Trimethylsilylmethoxy)-trimethylsilane.—Trimethylsilylmethanol (19.7 g.) dissolved in dry

[3] Whitmore and Sommer, *ibid.*, **68**, 481 (1946), first prepared chloromethyltrimethylsilane and showed that it reacted with potassium acetate in glacial acetic acid.

[4] Chloromethyltrimethylsilane was prepared for use in this work by the method of Whitmore, Sommer and Gold, *ibid.*, **69**, 1976 (1947).

[5] Warrick, *ibid.*, **68**, 2455 (1946).

chloroform–quinoline solution was treated with an equivalent amount of trimethylchlorosilane. The mixture, which was kept cool during the addition of the trimethylchlorosilane, separated into two layers. After the addition was complete, the mixture was shaken vigorously for fifteen minutes and then diluted with absolute ether (250 ml.). The quinoline hydrochloride was removed by filtration. The filtrate was distilled to yield a fraction (36 ml., 84%) boiling at 129.8° at 738 mm. which was found to be (trimethylsilylmethoxy)-trimethylsilane of the following properties: b. p. 129.8° at 738 mm., $[n]^{25}_D$ 1.3971, $[d]^{25}_4$ 0.7781. Molar refraction: Calcd.[5] for $Me_3SiCH_2OSiMe_3$, 54.00. Found, 53.91. *Anal.* Calcd. for $C_7H_{20}OSi_2$: Si, 31.81; C, 47.71; H, 11.42. Found: Si, 31.4, 31.4; C, 47.86; H, 11.61.

Reactivity of Trimethylsilylmethanol with Phenyl Isocyanate Relative to Other Alcohols.—The method of Davis and Farnum[6] for comparing the relative reaction rate constants of alcohols by means of the competitive reaction of one equivalent of each of two alcohols for one equivalent of phenyl isocyanate in benzene solution was adapted for use in studying the reactivity of trimethylsilylmethanol. These authors showed that the reaction of alcohols with phenyl isocyanate to form the phenylurethans is rapid, essentially irreversible, complete, and free from side reactions. Also, the products can be isolated quantitatively free from solvent and excess alcohol.

The methyl, ethyl, neopentyl and trimethylsilylmethyl alcohols used in this study were all carefully dried and purified. Commercial absolute methanol was refluxed over magnesium shavings and distilled. Commercial absolute ethanol was refluxed two days over amalgamated aluminum foil and distilled. The neopentyl alcohol[7] was prepared from *t*-butylmagnesium chloride and formaldehyde. Only the portion of the product distilled from lime boiling at 111.1° at 737 mm., m. p. 50–53° was used. The phenyl isocyanate was freshly distilled *in vacuo* immediately before use to ensure its being free of carbanilide.

An equivalent of phenyl isocyanate (*ca.* 1 g.) reacted with two equivalents of trimethylsilylmethanol in dry benzene (10 ml.) in a vial closed with a well-fitted ground-glass stopper. The vial was permitted to stand twenty-four hours at approximately 25°. The benzene and excess alcohol were then evaporated in a stream of filtered air with final drying under high vacuum for twenty-four hours. The product so obtained had a melting point of 80–80.5°. Repeated recrystallization from several solvents caused no change in this melting point. *Anal.* Calcd. for $C_{11}H_{17}O_2NSi$: Si, 12.57; C, 59.23; H, 7.68; N, 6.28. Found: Si, 12.59, 12.61; C, 58.89, 59.10; H, 7.37, 7.46; N, 6.15, 6.07.

The same technique was applied to a sample of neopentyl alcohol to produce a derivative melting sharply at 113°. Recrystallization from several solvents did not change this melting point. The phenylurethan of neopentyl alcohol is reported as melting at 114°.[8,9]

Trimethylsilylmethanol was made to compete with the alcohols mentioned essentially by the method of Davis and Farnum.[6] A dry benzene solution containing exactly equimolar amounts of trimethylsilylmethanol and neopentyl alcohol was prepared. From a buret there was added an amount of this solution calculated to contain exactly enough of each alcohol to react with 1.096 g. of phenyl isocyanate delivered from a carefully calibrated pipet into a glass-stoppered vial. The solution was quickly and thoroughly mixed and permitted to stand at least twenty-four hours at approximately 25°. In the same fashion solutions of trimethylsilylmethanol and methanol, trimethylsilylmethanol, and ethanol were prepared and reacted. The amounts of silicon in the nonvolatile products of the reaction were determined and the mole fraction of the silicon derivative present was calculated (Table I).

TABLE I

Competing alcohol	Trial	% Si in products of reaction				K_{Si}/K_{ROH}
Neopentyl	1	10.13	10.04	10.09	10.04	6.56
	2	10.12	10.10			
	3	10.07				
Methyl	1	9.53	9.56			2.92
	2	9.53	9.54			
	3	9.55				
	4	9.53				
Ethyl	1	9.68				3.57
	2	9.62				

The relative reaction rate constants were calculated according to the formula given by Davis and Farnum,[6] where K_{Si}/K_{ROH} is the ratio of the reaction rate constants of the silicon-containing alcohol and the other alcohol concerned.

Method of Analysis for Organo-silicon Compounds.—All determinations of silicon content in the compounds in this communication were carried out by the following procedure: A "Vycor" brand Kjeldahl flask (30-ml. capacity) was brought to constant weight at about 800° in a furnace. The flask was cooled in a desiccator, stoppered tightly to keep moisture from the interior, and permitted to stand in the balance case for from twenty to thirty minutes so that the exterior surfaces reached equilibrium with atmospheric moisture. The weight of the flask and stopper was determined accurately. A sample yielding between 500 and 1500 mg. of silica on oxidation was added to the flask and weighed carefully. About one and one-half ml. of 30% fuming sulfuric acid was added to the flask to dissolve the sample. Fuming nitric acid was cautiously added dropwise with gentle heating between additions until the oxidized material in the flask turned white. The flask was slowly brought to a high temperature to drive off all volatile material, and the flask and contents brought to constant weight at about 800°. The weighing procedure described above was employed again, the gain in weight of the flask being taken as due to silica formed by oxidation. The silica was quite hygroscopic. Therefore, the flask during weighing was stoppered to exclude moisture. All organo-silicon compounds may be analyzed in this manner except those that are volatile or not readily soluble in fuming sulfuric acid.

Discussion

The unusual reactivity of trimethylsilylmethanol in forming the phenylurethan indicates a pronounced activating influence by the silicon atom upon the O–H bond. Primary alcohols branched in the β position are generally less reactive than their normal homologs. The results of several different methods of determining the relative reactivities of alcohols agree quite well in that they usually place the alcohols in the same relative order. Table II shows some of the results of various workers, and the results of this study.

From the data in Table II it can be seen that the effect of branching in the β position is most apparent in neopentyl alcohol. The same effects of branching either are not present in the silicon analog of neopentyl alcohol or they are completely masked by a pronounced activating influence of the silicon atom upon the O–H bond. The large covalent radius 1.17 Å. for the silicon atom compared to 0.77 Å. for carbon causes less packing and thus less interaction between the methyl groups on

the silicon atom than would be the case for similar groups on a carbon atom, as has been pointed out by Whitmore and Sommer.[3] The interaction of the closely packed groups on a carbon atom probably is partly responsible for the inactivity of neopentyl alcohol. The lack of this effect, however, can scarcely explain the enhanced activity of its silicon analog which appears to be more active than any other alcohol. The explanation for the enhanced activity of this compound might be related to the highly electronegative nature of the Me_3SiCH_2-radical as found by Whitmore, Sommer and Bernstein,[3,13] who found that order of certain radicals was as follows: phenyl > Me_3SiCH_2- > Me- > Et- > n-Pr- > (n-Bu-, n-Hex-) > Benzyl > (Me_3CCH_2-, t-Bu-) as determined by the method of Kharasch and Marker.[14] This relationship of reactivity of alcohol to electronegativity of the radical seems to hold true for the normal alcohols but glaring exceptions are noticeable where branching in the alcohol occurs. Thus benzyl, neopentyl and t-butyl radicals are about equal in electronegativity, but the corresponding alcohols are quite different in relative reactivities. The reactivity of an alcohol probably is dependent upon the electronegativity of the radical as well as upon the steric effects of structure and the separation of the two effects is not possible.

Trimethylsilylmethanol dissolves sodium slowly at room temperature with the evolution of hydrogen. A sample (22 g.) containing a small amount of dissolved sodium was found to be unchanged by heating at 175° in a sealed tube for four days. The same sample diluted with a mixture of methanol (4 ml.) and water (0.5 ml.) was heated at 180° for sixteen hours followed by heating at 210° for two hours. No appreciable change was observed.

The alcohol dissolved slowly in boiling 75% potassium hydroxide solution over a period of several hours to form a clear solution from which an infusible combustible gel was precipitated by the addition of acid. Apparently cleavage of silicon–carbon bonds occurred resulting in the production of a polymeric siloxane material upon acidification of the solution.

Trimethylsilylmethanol dissolved clean amalgamated aluminum foil very quickly with the evolution of much heat when a trace of carbon tetrachloride was added to catalyze the reaction.

Summary

The synthesis of trimethylsilylmethanol and a study of its chemical reactivity is reported.

Kinetic Evidence for a Termolecular Mechanism in Displacement Reactions of Triphenylmethyl Halides in Benzene Solution

BY C. GARDNER SWAIN[1]

According to current theory there are only two commonly occurring mechanisms for nucleophilic displacement reactions. One is the bimolecular, kinetically second order (S_N2) substitution or "Walden Inversion."[2] In this mechanism the driving force is exclusively a "push" or *nucleophilic* attack by the entering atom or group, which has an unshared pair of electrons that it is eager to donate in bond formation. The attack is entirely from the back side. An example is the reaction of *primary* halides, such as methyl bromide, with pyridine in benzene solution.

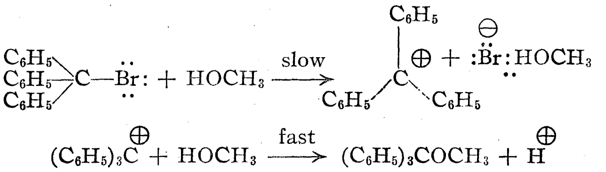
Soc.*, 1525 (1935); (d) A. G. Evans, "Reactions of Organic Halides in Solution," Manchester University Press (1946); *Trans. Faraday Soc.*, **42**, 719 (1946).

The other is the ionization (S_N1) mechanism,[3] which dominates for reactions of *tertiary* halides. It is with this second mechanism that the present paper is concerned. According to the most widely accepted interpretation,[3e] the driving force in this case is exclusively a "pull" or front side attack by the solvent or some *electrophilic* solute, which hydrogen bonds with or otherwise solvates the leaving atom or group due to simple electrostatic attraction or to formation of a coördinate bond with the unshared electron pair on the leaving group. This weakens the old bond, allowing it to ionize in the rate-determining step. The reaction is kinetically first order when it is with a solvent which is in large excess. An example is the solvolysis of trityl bromide in methanol solution.



$$(C_6H_5)_3\overset{\oplus}{C} + HOCH_3 \xrightarrow{\text{fast}} (C_6H_5)_3COCH_3 + \overset{\oplus}{H}$$

Previous workers have quite generally used a hydroxylic solvent as the reagent in studying the ionization (S_N1) mechanism, and hence have been unable to determine the kinetic order with respect to the reagent, since it was in large excess and did not change in concentration appreciably during the reaction.

There is a qualitative impression, arising from studies in mixed solvents, however, that more than one molecule of the hydroxylic solvent is involved in the rate determining reaction. Hammett considers that from one to three molecules may hydrogen bond with the halogen atom simultaneously, in a "polymolecular" solvolysis, still involving only attack on halogen. Others have proposed that dimers and trimers of the hydroxylic reagent may be involved. Nearly all are unanimous in declaring that there is no experimental evidence for any attack on carbon by the reagent in the rate-determining step.

By using reactants in low, approximately equivalent concentrations in an inert solvent, benzene, we have been able to determine the kinetic order with respect to all nucleophilic and electrophilic species present. As a model tertiary group we selected triphenylmethyl (trityl) rather than *t*-butyl, to avoid the possibility of elimination of hydrogen halide. The various nucleophilic and electrophilic reagents included tertiary amines, methanol and phenol, separately and in mixtures, with the concentration of each species being independently varied.

Our results indicate that the rate determining ionization step occurs by a termolecular mechanism. The ionization is a result of concomitant or "concerted" solvating attacks on carbon and halogen. Simultaneous attack on both atoms is required to effect any reaction. In the rate-determining step one and only one molecule forms a solvation bond (chiefly ionic) to carbon; similarly one and only one hydroxylic molecule becomes bound by a hydrogen bond (ionic bond) to halogen. The result is always a push–pull termolecular mechanism with exactly third order kinetics.

Data.—Triphenylmethyl (trityl) chloride or bromide (0.1 *M*) reacts with methanol (0.05–0.1 *M*) in dry benzene solution containing a tertiary amine (0.1–0.2 *M*) at 25° to give trityl methyl ether. The tertiary amine is used simply to take up the hydrogen halide formed and render the reaction irreversible. The reaction between trityl halides and tertiary amines is negligibly slow under these conditions, and the rate of the reaction with methanol is unaffected by changing the concentration of tertiary amine used. Triethylamine, a stronger base than pyridine by five powers of ten, gives approximately the same rate as pyridine.

Within experimental error the reaction with methanol is exactly third order (first order in trityl halide, second order in methanol). Rate "constants" calculated assuming that the reaction is second order (first order in each) decrease twofold within a kinetic run, while third order constants show less than 15% scatter and no trend. Comparing two runs having a two-fold ratio of initial concentration of methanol, the calculated average second order "constants" differ by twofold; while the average third order constants are the same within 5%. The fact that the order is so precisely third, rather than intermediate between second and third or between third and fourth, suggests that we are dealing with a pure mechanism which accounts for all of the reaction observed.

If phenol is used instead of methanol, the phenyl ether is obtained but at less than one-fiftieth the rate. The reaction appears to be still third order (second order in phenol), although an inverse, roughly first order dependence on pyridine concentration indicates that about half of the phenol is complexed by the pyridine. If the reaction proceeded by an ionization (S_N1) mechanism, one would have expected phenol to bring about a faster reaction than methanol, since it is known to form stronger hydrogen bonds with halogens.[4] The slower reaction of phenol can best be explained by assuming that a solvation of the carbon is required, in which phenol, due to its larger size, would be much less effective than methanol.

---

(c) Steigman and Hammett, THIS JOURNAL, **59**, 2536 (1937); Farinacci and Hammett, *ibid.*, **59**, 2542 (1937); **60**, 3097 (1938). (d) Hughes, *Trans. Faraday Soc.*, **37**, 604, 612 (1941). (e) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y., 1940, pp. 54, 172. Solvation of the carbon has generally been considered a negligible contribution to the driving force. However, theoretical arguments for it have been occasionally advanced (*cf.* Winstein and Buckles, THIS JOURNAL, **64**, 2780 (1942), and Evans, ref. 2d).

[4] Bartlett and Dauben, THIS JOURNAL, **62**, 1339 (1940) Hantzsch, *Ber.*, **58**, 627 (1925).

When both methanol and phenol are present, only methanol is consumed as long as the methanol lasts. However the rate of reaction is many times faster than in the absence of phenol. The rapid phase of the reaction ends when trityl chloride or bromide equivalent to the methanol present has been consumed. Beyond this point reaction proceeds further at the very slow rate characteristic of runs with phenol alone, until additional trityl halide equivalent to the phenol present has been consumed. An average third order rate constant calculated for the rapid phase of the reaction with trityl chloride in the same way as in the absence of phenol was twenty times larger in the presence of phenol equivalent to the methanol. However this constant increased three-fold within the run, indicating that this kinetic order was incorrect. The reaction was found to be exactly second order within a run (first order in trityl chloride, first order in methanol). However, when runs of different initial concentration of phenol were compared, it was found that the reaction was also first order in phenol, hence again exactly third order over-all. The lack of a kinetic dependence on phenol within a run was evidently due to the fact that phenol was not consumed until all methanol was exhausted. A new third order rate constant, calculated for $dx/dt = k_3'$ (RX) (CH_3OH)(C_6H_5OH), was seven times as large as the old third order constant for runs in the absence of phenol.

This seven-fold acceleration of the rate of reaction of trityl halides with methanol, caused by adding phenol, a substance which reacts only very slowly with trityl halides by itself, is best explained by assuming that a solvation of halogen is also required in these reactions. Phenol is an excellent reagent for solvating halogen, but a very poor one for solvating carbon. Since solvation of both halogen and carbon is required, it reacts very slowly. Methanol is moderate as a halogen reagent, excellent as a carbon reagent, hence reacts moderately rapidly by itself. However, when both are present, each performs independently the function to which it is best adapted and a very high rate results.

The data from typical runs is presented in Tables I and II. Figure 1 shows the course of the reaction of trityl chloride with methanol, phenol, and a mixture of the two. Tables III and IV give detailed data for the more important runs. It is by such tables that all the rate constants of Tables I and II were obtained. The constants are defined as follows. Let

τ = initial moles/liter of trityl halide
μ = initial moles/liter of methanol
ϕ = initial moles/liter of phenol
x = moles/liter of reaction
t = minutes
$Q = \tau/\mu$; $z = x/\mu$

For methanol

$$k_3 = \frac{dx/dt}{(\mu - x)^2(\tau - x)} = \frac{1}{\mu(Q-1)t}\left(\frac{z}{\mu(1-z)} - \frac{2.303}{\mu(Q-1)}\log\left[\frac{Q-z}{Q(1-z)}\right]\right)$$

For phenol the expression is the same except that μ is replaced by ϕ. For methanol and phenol

$$k_3' = \frac{dx/dt}{\phi(\mu - x)(\tau - x)} = \frac{2.303}{\phi\mu(Q-1)t}\log\left[\frac{Q-z}{Q(1-z)}\right]$$

These equations were applied to the data in their integrated rather than in their differential forms to obtain the maximum accuracy.

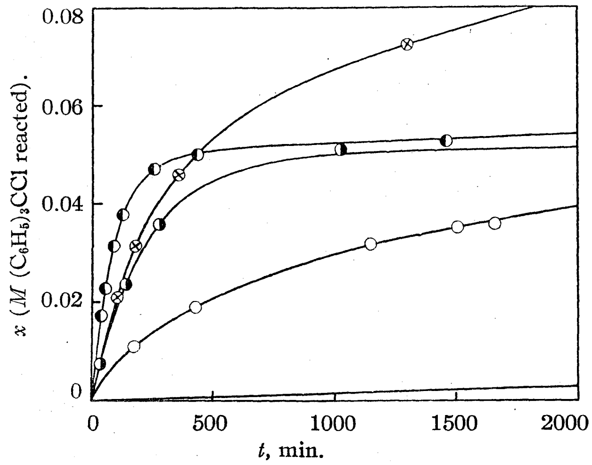


Fig. 1.—Reactions of 0.106 M trityl chloride in dry benzene solution in the presence of 0.108 M pyridine at 25°: lowest line for reaction with 0.056 M phenol; ⊙, 0.054 M methanol; ⊗, 0.109 M methanol; ◑, 0.054 M methanol plus 0.023 M phenol; ◐, 0.054 M methanol plus 0.056 M phenol.

The Salt Effect.—The concentration of dissolved pyridine hydrochloride is five times greater in the presence of phenol than with just methanol (see experimental section on procedure). However, the increased salt concentration caused by the presence of the phenol is not the cause of the greatly increased rate of reaction with methanol. It is true that there is a positive salt effect in this reaction, but it is of small magnitude. It was measured by substituting other tertiary amines having successively more soluble hydrochlorides for the pyridine, and observing the effect on the reaction with methanol in the absence of phenol. Quinaldine is less soluble by a factor of two and gave $k_3 = 0.21$ instead of 0.26. Quinoline is more soluble by a factor of three and gave $k_3 = 0.35$. With diethylaniline the salt dissolved indefinitely, giving $k_3 = 0.25$. A further check on this point was made by substituting quinaldine for pyridine in a reaction with methanol and phenol. In spite of the lower salt solubility, the same seven-fold acceleration was observed.

[a] At 60° rather than 25°. [b] Triethylamine used instead of pyridine. [c] Chloride ion titration necessitated only in this run was not as accurate as hydrogen ion titration used elsewhere. [d] Based on first (nine minute) point. Other points were too close to infinite titer to give accurate results.

One might argue that in the mixed methanol–phenol runs we might have an increased concentration of salt arising not only from the increased solubility of pyridine hydrochloride but also from the association of pyridine and phenol. However the latter type of complex, if it were a salt, should be even less effective electrically than the hydrochloride, because the charges would be buried in the middle of much organic material. To check this, the concentration of pyridine in a mixed methanol–phenol run was doubled, and it was observed, as expected, that the rate constant decreased to 64% of its previous value as a result of the decreased concentration of free phenol, in spite of an increased concentration of the dissolved pyridine–phenol complex.

The Mass Effect.—There is no indication of a mass effect, *i. e.*, of reversal of carbonium ion formation caused by chloride ion accumulating as a reaction product. In the experiments on the salt effect the rate at first showed a steady, though small, increase rather than decrease as the con-

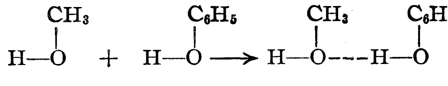
centration of dissolved tertiary amine hydrochloride was increased by varying the amine used.

Evidence Against a Methanol–Phenol Complex.—Another alternative interpretation of the increased rate of reaction with methanol caused by adding phenol must be ruled out before the picture of simultaneous solvation of carbon by methanol and solvation of halogen by phenol will be on a firm footing. One might interpret the increase by saying that only halogen solvation is involved, but that the solvating agent is a hydrogen bonded complex between methanol and phenol.

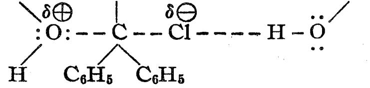


$$H-\overset{\overset{CH_3}{|}}{O} + H-\overset{\overset{C_6H_5}{|}}{O} \longrightarrow H-\overset{\overset{CH_3}{|}}{O}---H-\overset{\overset{C_6H_5}{|}}{O}$$

However, if this view were correct, this complex would have to form an even stronger hydrogen bond to halogen than phenol, to account for the much faster rate than in the case of solvolysis by phenol alone. That no complex having such hydrogen bonding ability exists in appreciable concentration can be shown by measurement of the enhancement of the acidity of hydrogen chloride dissolved in ether caused by methanol, phenol and a mixture of the two.[4] This enhancement depends on and is a measure of the extent of hydrogen bonding of the hydroxylic species with the chlorine of $(C_2H_5)_2O \cdot HCl$. This hydrogen bonding weakens the H–Cl bond and increases the extent of ionization. Evidently the system used for measuring the effect is very similar to our kinetic system where the C–Cl bond of $(C_6H_5)_3CCl$ is being weakened in the same way. Yet the results showed that phenol is much better at hydrogen bonding than methanol, rather than poorer, and that the mixture of the two is no better than the sum of phenol and methanol solutions taken separately. The above experiment argues against the existence of hydrogen bonding between methanol and phenol. The fact that the rate of reaction with methanol is completely independent of pyridine concentration shows that there is less than 15% hydrogen bonding between pyridine and methanol. However, the effect of pyridine concentration on the rate with phenol is probably due to hydrogen bonding.

Other Reagents.—*p*-Nitrophenol is almost entirely associated, probably in a hydrogen bonded complex, by excess pyridine in benzene solution at 25°, as shown by the inverse second order dependence of rate on pyridine concentration in reactions with trityl bromide. However, the small portion which is free, by reason of its great hydrogen bonding ability, is able to increase the overall rate to a higher value than phenol, in spite of the fact that a smaller concentration is acting. The constant k_3', calculated as if all the *p*-nitrophenol were uncombined and effective, is twenty times, rather than seven times, as large as k_3 with just methanol present.

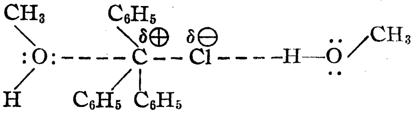
tris-(*p*-*t*-Butyl)-trityl chloride reacts with methanol in dry benzene solution thirty times as rapidly as does trityl chloride. According to Hammett's treatment[5] of the reactions of *m*- and *p*-substituted benzene derivatives, the *p*-*t*-butyl group has a substituent constant of −0.20. This gives a reaction constant of −7.5, or −2.5 per *t*-butyl group, representing a rather high sensitivity of the reaction to substituents. The direction of the change in rate is opposite to what one would expect if stabilization of the transition state



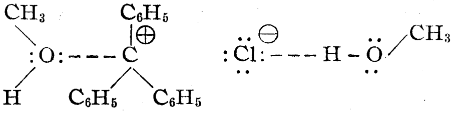
---

(5) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., N. Y., 1940, pp. 118–124, 184–228.

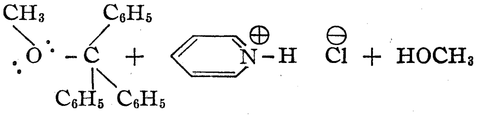
or formation of the covalent bond to oxygen were the most important factors determining the rate. However, it is what one would expect if the transition state were



and if the product formed by the rate-determining step is

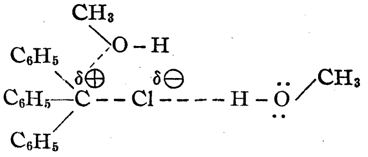


i. e., a solvated ion pair. The bonds with three dashes represent ion-dipole solvation bonds. The solvated ion pair may then react to form the products



in a fast follow-up step or succession of such steps. The methanol molecule which finally reacts, *i. e.*, becomes covalently bonded to carbon in the product determining step is not necessarily the same molecule that solvates the carbon in the rate determining step. The two steps are *independent*, and our study sheds light on only the rate-determining step. However, in this particular case it is possible that the same methanol molecule is involved in both steps.

We have pictured the solvation of halogen as a *front side* attack and the solvation of carbon as a *back side* attack. This stereo-relationship seems most likely but is not uniquely consistent with our experimental results. It is conceivable that the molecule solvating carbon may approach from the front side.



We are conducting experiments on displacement reactions of optically active halides in benzene solution which may shed light on the stereochemistry. However, pending further results we favor the picture of back side solvation of carbon.

Table II shows the relative reactivity of a number of different types of compounds toward trityl bromide. This series shows at least two forces at work.

(1) Steric Hindrance.—While methanol reacts very rapidly, triphenylcarbinol does not react detectably. Also pyridine does not react even when there is phenol in the system. Stuart molecular models, which have approximate interference radii, confirm the impossibility of back side collision of the oxygen or nitrogen with the trityl bromide carbon in these cases. On the other hand, phenol has less hindrance, and in the models its oxygen can just be caused to touch the carbon by proper orientation of groups. With methanol this is considerably easier and contact can be achieved with a large variety of orientations. The water molecule has the least steric hindrance of all. The relative rates for these compounds are the ones expected on the basis of these steric considerations.

(2) Basicity of the Atom Solvating Carbon.—On steric grounds *p*-toluidine and *p*-thiocreosol would be expected to react about as slowly as phenol. They are certainly much less hindered than pyridine but no less hindered than phenol. Actually *p*-toluidine reacts immeasurably fast (like water), and thiocresol almost as fast as methanol. We consider that solvation bonds are chiefly ionic in type. However the solvation bonds to carbon might have 25% covalent character, so that differences in nucleophilic tendency of the solvating atom could effect some difference in the rate of reaction. The high "reaction basicity" or nucleophilic character of S is a striking thing, since S is not a basic atom in the usual sense, *i.e.*, when an equilibrium measurement is made involving addition of a proton.

Examination of molecular models indicates that *t*-butyl halides would have the same high degree of back side hindrance as trityl halides, but no experiments were run on *t*-butyl halides.

Termolecular Reactions in Liquid Phase.—The evidence presented indicates that simultaneous solvating attacks on the carbon and halogen are necessary to effect reaction of the trityl halides in benzene solution. The reaction of trityl chloride with methanol has the surprisingly low activation energy of 6.6 ± 1.0 kcal. This means a frequency factor of only 300 $1.^2$ $/\text{mole}^2$ sec., or the large negative entropy of activation[6] of -49 ± 4 cal./mole, referred to a standard state of one mole/l., as compared with an activation entropy of about -15 ± 5 cal./mole, referred to the same standard state, calculated for a hypothetical termolecular reaction in the gas phase having a steric factor of unity and hence a frequency factor equal to the termolecular collision rate of 10^{10} $1.^2/\text{mole}^2$ sec. This indicates a very precise orientation requirement for reaction, but an energetically very easy reaction path once the proper steric relationships are satisfied.

Third order kinetics have been observed previously in the bromination of olefins,[7] the cleavage of ethers with hydrogen bromide,[8] and the hydrogen chloride catalyzed addition of hydrogen bromide to olefins.[9] These reactions very probably

also involve termolecular mechanisms. They too have abnormally low activation energies.

It is impossible kinetically to distinguish a termolecular reaction from a rapid bimolecular association of two of the reactants to give a low equilibrium concentration of a complex, followed by slow bimolecular reaction of the complex with the third reactant. Thus the rate determining step in our experiments might be a back side attack by methanol on a solvated trityl halide complex, $(C_6H_5)_3CCl---- HOR$. In the opinion of the author the distinction between this and a simultaneous back and front side attack, or termolecular reaction, lacks physical significance because the two pictures are so nearly identical. The complex, pictured above, would have a very short lifetime. The making and breaking of bonds between hydrogen and halogen, oxygen, sulfur or nitrogen is never activation controlled, and so cannot be postulated as a slow step in any organic reaction unless the reactants are in exceptionally minute concentration. If the back side attack must follow so quickly after the front side solvation, one might as well call the process a termolecular reaction.

Let us consider a trityl halide molecule and a methanol or phenol molecule which have just diffused together and collided for the first time. They are surrounded by a "cage" of benzene molecules which makes it difficult for them to separate again. Even if there were no attractive force between them, they might undergo a great many repeated collisions, perhaps a thousand or more, with the solvent molecules forming the wall of the cage, and with each other, before one of them would break out of the cage. The existence of a hydrogen bond of 3.0 to 6.0 kcal. strength between the halide molecule and the methanol or phenol will further significantly prolong (by a factor of 150 to 25,000) the period that a pair is associated together in one "encounter."[10] If at any time within this period another methanol or phenol molecule happens to break into the same cage, there is a minute but nevertheless finite probability of reaction, since a sizeable number of termolecular collisions may occur before one of the three molecules breaks out of the cage.

Bringing a new methanol dipole (1.7 Debye units, 1 Å. long) up to the interference distance (2.8 Å.) between oxygen and carbon would contribute 5.5 kcal./mole to the driving force of the reaction if one assumes an internal dielectric constant of 2.0. This added driving force is equivalent to a ten thousand-fold increase in rate, which must evidently outweigh the steric unlikelihood of a termolecular route as compared to a simple bimolecular reaction not involving solvation of carbon.

This double attack (or termolecular mechanism) is closely similar to the effects which were observed by Lowry in the mutarotation of tetramethylglucose.[11] Both an acid and a base appeared to be necessary in that reaction. The rate in a mixture of pyridine and cresol was far greater than that in either solvent alone.

Range of Applicability of this Mechanism.—Thus far the interpretation has been backed by experimental evidence. What follows is an extrapolation of the findings in the one particular system studied to other systems. The generalizations and predictions which follow seem probable now and should be helpful in planning future work, but must be recognized as speculative.

At most we have established this mechanism only for benzene solution, and it is hard to see how we could even go about determining the order with respect to methanol or water in methanol or aqueous solution with certainty. However, it seems inevitable that, as the concentration of hydroxylic reagent is increased, the higher order mechanism involving solvation of both carbon and halogen should still further outstrip a lower order mechanism involving only solvation of halogen. The ease of production of a solvated ion pair should reflect the internal dielectric constant of the halide ($\sim$2?), the polarizability of its electrons, and the specific nature and concentration of the solvating species. It does not seem reasonable to expect a large dependence on the dielectric constant of the medium, since internal dielectric constant should be much more important, and this is a function of only the halide and its two nearest neighbors, *e.g.*, two methanol molecules involved in back and front side solvation. On this view, methanol is not a much different medium than benzene containing 0.1 M methanol, for carrying out halide solvolyses. The large difference in rate is chiefly due to the difference in concentration of methanol in the two cases, although self-association of methanol in the pure solvent may have some small effect on the comparison.

Except for a generally higher reactivity, the situation with water should be similar to the situation with methanol.

Trityl halides are more strongly hindered with respect to attack on carbon than most other halides, yet these experiments indicate that such attack in the form of solvation is still required as part of the driving force which effects reaction. This suggests that attack on carbon is involved in the rate determining step of all displacements on carbon. According to this idea, attack on carbon is always necessary. Attack on the grouping to be displaced is optional; it occurs with tertiary halides; but there are certainly cases where it is not involved among the reactions of primary halides, *e.g.*, the reaction of methyl bromide with pyridine in benzene solution.[12]

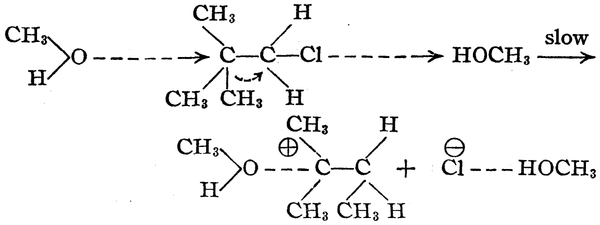
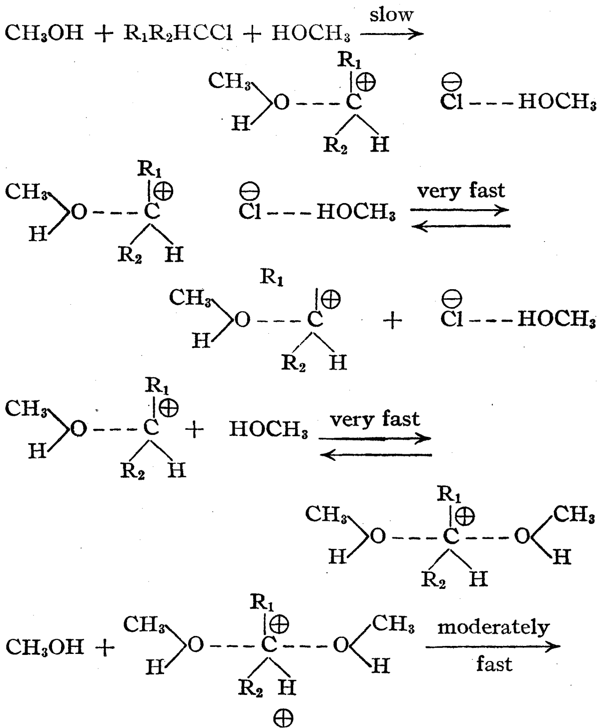
(12) We are neglecting solvation by benzene through van der Waals attractive forces, which, estimated by the heat of vaporization of benzene or methanol, may amount to 8 kcal./mole. This would be important in any comparison with the corresponding reaction run in gas phase. However, halide solvolyses have never been accomplished in homogeneous gas phase, and all real experiments compared in this paper were in liquid phase, for which these van der Waals forces are approximately constant.

The type of attack on carbon involved in the rate determining step may vary. With primary halides it gives a covalent bond; with tertiary halides it is a solvation giving a chiefly ionic or ion-dipolar bond. In other cases the attack on carbon may even be on a different carbon than that from which the leaving group is displaced, as in neopentyl chloride.



Here the whole process including the Wagner–Meerwein shift can be pictured as occurring in one step. Elimination (E_1) and displacement (S_N1) would both involve the same solvated carbonium ion intermediate. If this view is correct, it should be possible to substantiate the requirement of attack on carbon by demonstrating termolecular kinetics as we have done with trityl chloride.

First order racemizations in alcoholic or aqueous solution may be due to rapid formation of a disolvated carbonium ion, facilitated by dissociation of the ion pair in these polar solvents and by the high concentration of hydroxylic reagent present. These two factors would permit the existence of two very fast steps in alcoholic or aqueous solution which would not be probable steps in an inert solvent of low dielectric constant such as benzene.



Failure of hydroxide ion to accelerate the hydrolysis of tertiary halides in an aqueous solution is probably due to the ion's large solvation shell of water, which prevents it sterically from approaching very close to the central carbon.

Experimental

Reagents:—Trityl chloride was prepared from bromobenzene by the procedures of "Organic Syntheses."[13] The acetyl chloride was C. P. reagent grade. The white product was recrystallized from a benzene–pentane solution. All operations were designed to exclude atmospheric moisture. The product was washed with pentane and dried in a vacuum desiccator. The crystals (160 g., m. p. 109–111°) were as coarse as granulated sugar and had a very pale yellow tint. A 0.425 *M* solution in dry benzene was made up by weight, and this was used for kinetic experiments.

Trityl bromide was prepared from tritanol and dry hydrogen bromide gas. It was crystallized several times from benzene, m. p. 153–155°, with a yellow tint. The stock solution in benzene (0.392 or 0.412 *M*) was kept in a desiccator in the cold room at 4° whenever it was not in use.

Pyridine and methanol were reagent grade, dried over Drierite.

Phenol was reagent grade, dried over Drierite and recrystallized from petroleum ether, yielding snow white needles which were dried in a vacuum desiccator and kept protected from atmospheric moisture.

Benzene was thiophene-free reagent grade, dried over sodium wire.

The tris-(*p*-*t*-butyl)-trityl chloride was prepared by Dr. Marvel and his co-workers,[14] was white, and melted with decomposition at 263–266°.

Other reagents were repurified Eastman Kodak Co. chemicals.

Procedure.—Stock solutions of the reagents in dry benzene were kept in Pyrex glass-stoppered bottles in desiccators over potassium hydroxide to protect them from atmospheric moisture. All bottles, pipets and other glassware were dried in an oven at 130°, then packed while hot into a vacuum desiccator and evacuated to 2 mm. to remove surface moisture.

Run 35 is typical of the procedure used. Twenty cc. of benzene, 20 cc. of 0.430 *M* pyridine, 10 cc. of 0.435 *M* methanol and 10 cc. of 0.448 *M* phenol were pipetted into a dry glass-stoppered Erlenmeyer flask. At zero time 20 cc. of 0.425 *M* trityl chloride was added, and the flask thoroughly swirled to give a clear, homogenous solution. Five cubic centimeter aliquot samples were pipetted into each of ten 125 × 16 mm. soft-glass test-tubes which had been drawn out to give a neck 80 × 3 mm., 20 mm. below the lip, for easy sealing. The tubes were sealed off with a microburner and placed in a 25.0 ± 0.02° thermostat within five minutes. Turbidity first appeared after forty minutes. Eight tubes were saved for regular kinetic points, one tube was opened and analyzed after twenty-seven minutes, before any precipitation, to check the initial concentration, and one at 58,000 minutes to measure the total reaction.

The reaction was followed by taking advantage of the fact that pyridine hydrohalides are only very slightly soluble in benzene and precipitate out as the reaction proceeds. A separate sealed tube was used for each point. After filtering out the hydrohalide, the filtrate was shaken with water to hydrolyze the unreacted trityl halide, and the resulting hydrohalic acid titrated with standard sodium hydroxide. The filtration was performed in a special apparatus in an atmosphere of air which had been dried over potassium hydroxide and finally Drierite, and the sealed tube, filtered crystals and filter paper were washed with three 5-cc. portions of dry benzene and the washings

[a] The solubility of diethylaniline hydrochloride in this medium is 0.041. Consequently no salt precipitation occurred during run 49. The figure given refers to quinaldine, which was added as a precipitating agent just before analyses.
[b] Pyridine hydrobromide used instead of pyridine hydrochloride.

added to the filtrate. The filtrate was shaken with 20 cc. of ethanol and 20 cc. of water for five minutes, then with two successive 20-cc. portions of water. The combined lower layers were titrated with 0.0483 *M* carbonate-free sodium hydroxide using three drops of 0.2% brom thymol blue as indicator.

The data on trityl chloride tend to be more accurate because the reaction with methanol could be followed for two days, as compared to the reaction of trityl bromide with methanol which was half over in about ten minutes. On the other hand, pyridine hydrochloride is about ten times as soluble in the media used as pyridine hydrobromide. This is no longer a negligible solubility in some cases, and must be corrected for in the analysis by adding to the molarity calculated from the sodium hydroxide titer a figure equal to the solubility of pyridine hydrochloride in the particular medium used. Fortunately, these solubilities can be directly measured independently, and do not have to be derived from the kinetic data, although the latter derivation is possible and does give agreement with the direct solubility measurements. Only trityl chloride and the ethers which are reaction products were omitted in the solubility measurement, being replaced by benzene. These have much less effect on the solubility than do methanol or phenol in the solution. Replacement of 13% by volume of the benzene by diethyl ether, for example, had almost no effect on the solubility, whereas 0.1 *M* phenol increased it five-fold. The solubility determinations are given in Table V. All the analytical data for the experiments with trityl chloride have been corrected by these directly measured solubility figures, before plotting or obtaining rate constants such as those in Table I. No corrections for solubility were necessary in the trityl bromide runs.

Reaction Products.—No detectable reaction of trityl bromide occurred in fifty minutes in a solution of 0.103 *M* trityl bromide and 0.055 *M* methanol in dry benzene in run 29. The analytical method used here involved adding 15 cc. of benzene and excess pyridine (2 cc. of 0.440 *M* pyridine) to each 5-cc. aliquot at the end of the measured time interval, immediately filtering out any precipitated pyridine hydrobromide, shaking the filtrate with water to hydrolyze trityl bromide, and titrating with sodium hydroxide. Precipitation was uniformly negligible even when six minutes waiting time was allowed before filtering. Evidently in the absence of tertiary amines accumulating hydrogen bromide can cleave the trityl methyl ether formed, and an equilibrium is reached which is very far on the side of the reactants. Although the reaction may be moderately fast, no net reaction is observed because it is reversible.

A very slow irreversible reaction with a half life of about one year was subsequently observed to take place in these same tubes, however, which converted the bromine to a non-ionic, not readily hydrolyzable form, presumably methyl bromide

$$(C_6H_5)_3CBr + MeOH \underset{\text{fast}}{\rightleftharpoons} (C_6H_5)_3COMe + HBr$$

$$(C_6H_5)_3COMe + HBr \overset{\text{slow}}{\rightleftharpoons} (C_6H_5)_3COH + MeBr$$

The reaction with tertiary amines alone is probably irreversible but very slow. Only 4% reaction occurred between 0.103 *M* trityl bromide and 0.110 *M* pyridine in run 19 in 250,000 minutes (six months). The triethylamine used instead of pyridine in run 31 gave 24% reaction beyond the endpoint with methanol, which was obtained in a day, on waiting a further 250,000 min. The rates of these reactions with tertiary amines are negligible compared to the rates of the other reactions measured in Tables I and II.

This does not mean that the trityl halides cannot be caused to react with tertiary amines under different conditions than those which we have used in our kinetic study. Tritylpyridinium bromide monophenolate, $(C_6H_5)_3\overset{\oplus}{C}NC_5H_5\ \overset{\ominus}{Br}HOC_6H_5$, was actually obtained by mixing and immediately refrigerating 50 cc. of a homogeneous benzene solution of 0.078 *M* trityl bromide, 0.86 *M* pyridine and 0.038 *M* phenol in a Dry Ice-bath for five minutes. Apparently the solvent froze and gave a high local concentration of the three reactants. On warming to 10° a heavy white precipitate was found to be present. This was filtered out and dried in a vacuum desiccator. It was a white, odorless powder, not particularly hygroscopic. The yield was 0.90 g. (theoretical, 0.93 g.), dec. p., 80°. Molecular weight by sodium hydroxide titer using brom thymol blue, 492 (theoretical, 496). Pyridine concentration by hydrochloric acid titration of resulting neutral solution using methyl orange, 16.1% (theoretical, 15.9%) ionic bromide, 16.2% (theoretical, 16.1%). The phenol was shown to be present in quantity equivalent to the bromide by a comparison of bromine uptake by this material and by phenol itself in 1:1 benzene–ethanol solutions. Under these conditions pyridine, trityl bromide, and tritanol did not absorb bromine. The compound was unstable and spontaneously decomposed to a brown material with a strong odor of phenol when allowed to stand at room temperature overnight in a desiccator.

The above compound is interesting in that it probably contains a hydrogen bond between phenol and bromide ion. However, tritylation of pyridine occurs only when the concentrations of reactants are each several molar, never significantly under our kinetic conditions.

Occasionally kinetic points in the runs with methanol, phenol or both were titrated for bromide as well as for hydrogen ion. Agreement within the limits of experimental error was always obtained, demonstrating that the reaction was entirely a solvolysis by the hydroxylic component and not at all the formation of a quaternary ammonium salt.

Pyridine hydrobromide or hydrochloride precipitates out in the usual procedure as the reaction progresses. In the analysis of one of the tubes in run 37 between 0.106 *M* trityl chloride, 0.112 *M* phenol and 0.108 *M* pyridine, the benzene layer, after extraction with alcohol and water and separation of the water layers for titration with sodium hydroxide, was further extracted with dilute sodium hydroxide, then water, and dried over sodium sulfate. The benzene was evaporated and the flask evacuated at 2 mm. for several hours. There was obtained 0.148 g. (83%) of white crystalline *trityl phenyl ether*, m. p. 93–98°. The recorded m. p. is 103°, as contrasted to 282° for the *p*-tritylphenol. The same treatment applied to a tube from run 40 between 0.106 *M* trityl chloride 0.109 *M* methanol and 0.108 *M* pyridine yielded 0.101 g. (70%) of white crystalline *trityl methyl ether*, m. p. 77–79°. The recorded m. p. is 82°.

Enhancement of Acidity of Hydrogen Chloride in Ether by Methanol, Phenol and a Mixture.—The solutions were prepared by adding a total of 2 cc. of various dry benzene solutions to each of a number of 10-cc. samples of a dry ether solution containing 0.001 *M* butter yellow plus enough dry hydrogen chloride gas to turn the indicator from yellow to a very pale yellow orange. The color was measured with a Cenco "Photelometer" (photoelectric colorimeter) using a Corning No. 401 primary green filter, which gave the largest difference between red and yellow solutions of a number of filters tested. The results are presented in Table VI.

Acknowledgment.—The author wishes to thank Professors Linus Pauling, Paul D. Bartlett, Saul Winstein and Alwyn G. Evans for criticisms and suggestions which made a major contribution to this work.

Summary

Methanol reacts rapidly with triphenylmethyl chloride or bromide in benzene solution containing excess pyridine at 25° to give the methyl ether. When phenol is used instead of methanol, the phenyl ether is obtained at a slower rate. However, when both are present, the methyl ether is formed at a rate which is seven times as fast as the *sum* of the rates of reaction with methanol or phenol separately. Evidence is obtained to show that this cannot be a salt effect nor due to a complex between methanol and phenol. The kinetics are third order. In the mixed case this means that the rate is proportional to the product of concentrations of methanol, phenol and halide, although the phenol is not consumed in the rapid phase of the reaction.

This indicates that one molecule of alcohol or phenol hydrogen bonds with the halogen atom, weakening its bond to carbon, while another molecule simultaneously solvates the carbon which is becoming a carbonium ion. Phenol solvates halogen better than carbon; the converse is true for methanol. Therefore the concerted, termolecular attack proceeds at a high rate when both phenol and methanol are present and each can play the part to which it is best adapted.

The relative reactivity of a number of types of compounds toward triphenylmethyl bromide in benzene solution has been measured.

The Chemical Properties of Elements 94 and 93

BY GLENN T. SEABORG AND ARTHUR C. WAHL[1a,b]

This report describes the chemical experiments which we have performed on elements 94 and 93 and the chemical properties which we have deduced from these experiments.

Although these chemical experiments have been under way for 94 since December, 1940, when element 94 was discovered,[2] and for 93 since somewhat earlier than this, the investigation has not been a very systematic one. In the case of element 93, we have repeated most of the experiments reported by McMillan and Abelson[3] in their original publication and have confirmed their results. It has been of paramount importance to develop as quickly as possible methods of isolating in very thin precipitates elements 94 and 93 from large amounts of uranium in order to study the properties of 94^{239},[4] and, therefore, the experiments have been of a very practical and explora-

tory nature. It is only recently that we have begun a systematic investigation of the chemical properties; the description of these experiments is included also.

As the tracer for element 94 we have used the alpha-emitting, 50-year 94, whose production and properties are described elsewhere,[2] and for which the best isotopic assignment seems to be 94^{235} or 94^{238}.[5] As the tracer for element 93, we have used the beta-emitting 2.3-day 93^{239}.

The alpha-particles from 94^{238}, which have a range in air of about 4.1 cm., are detected with an ionization chamber connected to a linear amplifier and recording system. Only thin samples are prepared (< 1 mg. carrier material per sq. cm.). The weak samples are counted by placing them on one electrode of the ionization chamber, the "inside" chamber, for which the counting efficiency, as determined with a weighed sample of uranium, is about 45%. The strong samples are counted with poor geometry sometimes with screens interposed, depending upon the strength of the samples, by placing them near an ionization chamber with a screen window.

Although the beta-particles from 93^{239} have an upper energy limit of 0.78 Mev. (aluminum absorption end-point 260 mg.), the major portion of the radiation being rather soft,[6] with a half thickness of 9 mg. of aluminum and therefore demanding thin samples, a correction for self-absorption of the beta-particles is made. Correction for the back-scattering of the beta-particles from the backing material upon which the samples are mounted is always made in the quantitative experiments. The beta radiation is detected with (1) a Geiger–Müller counter connected to an amplifier, scaling and recording system, (2) an ionization chamber connected to an FP-54 electrometer tube or (3) a Lauritsen electroscope, depending on the strength of the sample and the type of experiment.

Naming the Elements.—Since formulas are confusing when the symbols "93" and "94" are used, we have decided to use symbols of the conventional chemical type to designate these elements. Following McMillan, who has suggested the name neptunium (after Neptune, the first planet beyond Uranus) for element 93, we suggest plutonium (after Pluto, the second planet beyond Uranus) for element 94. The corresponding chemical symbols would be Np and Pu. (The names ekarhenium and ekaosmium seem inappropriate in view of the marked dissimilarity of the chemical properties of elements 93 and 94 from those of rhenium and osmium.)

Experimental

General Remarks on Radiochemistry.—All of the experiments which we have performed have, of course, used exceedingly small amounts, in the macroscopic sense, of radioactive 94^{238} and 93^{239} as tracers, and great care must be exercised in deducing from these experiments the true chemical properties of macroscopic quantities of 94 and 93. Our experiments have employed amounts of 94^{238} and 93^{239} varying from about 10^{-7} microgram to about 1 microgram and concentrations of about 10^{-15} to 10^{-6} molal. The relationship of the chemical behavior of such small amounts to the behavior of macroscopic amounts of materials has been studied, using the natural radioactive isotopes as indicators, in the classical work of Fajans and Paneth and Hahn. The work of the numerous investigators in artificial radioactivity, which involves a great number of other elements, seems to lend confirmation to the rules of Hahn and Paneth and Fajans.

Precipitation reactions are among the most important reactions in studying the chemistry of an element by the use of microscopic amounts of a radioactive isotope of the element. It is well known that compounds of radioelements, though present in such dilution that their solubility is not exceeded, may be "carried down," even quantitatively, by a macroscopic precipitate of a non-isotopic element. Rules for this phenomenon have been formulated by Fajans and Paneth and Hahn. For example, Hahn[7] summarized Fajans' and Paneth's rule in a joint rule which he states as follows: "A radioelement, as cation, is more strongly adsorbed by a separating or a preformed precipitate, the less soluble is the compound it forms with the anion of the precipitate." From a study of these rules and the detailed discussion Hahn[7] gives them, it seems reasonably safe to assume that if a radioelement as cation is "carried down" by a precipitate formed in the presence of excess anion the compound between the radioelement and the anion is relatively insoluble, and if the radioelement is not "carried down" it is assumed that the compound is relatively soluble. That this is true has been confirmed in many instances since the discovery of artificial radioactivity in that many "pure" radioelements, that is, elements free from their stable isotopes, have been prepared and subjected to precipitation reactions of this sort. We believe that our conclusions as to the solubility and insolubility of the compounds of 94 and 93 are valid for macroscopic amounts, but it must be emphasized that in all the work there exists the possibility of drawing incorrect conclusions from such precipitation reactions.

It is remarkable, and it should be emphasized, that it has been found in many cases, when the radioelement is not "carried down" by the precipitate upon the addition of the precipitating

---

(5) Note added at time of publication: This alpha radioactivity was later shown to be due to the isotope 94^{238} with a slight admixture of alpha radioactivity due to the isotope 94^{236}; the isotopic assignment, of course, makes no difference from the standpoint of this paper. In order to avoid confusion this paper has been edited so that it always refers to this radioactivity as due to the isotope 94^{238}.

(6) Our work has shown that there are roughly as many conversion electrons as there are disintegration beta-particles in the 93^{239} radiation.

(7) O. Hahn, "Applied Radiochemistry," Cornell University Press, Ithaca, N. Y., 1936.

agent, it is not necessary that there be present some carrier material in the solution to "stabilize" the radioelement in order to prevent its precipitation. Thus, we have found in the case of elements 94 and 93 that we can make precipitations from solutions containing these elements leaving them behind in the solution with no carrier material in the solution with them.

It is well established that in the distribution between solvents, in the cases where there is no chemical combination with the solvents, these extremely small amounts (concentrations as low as 10^{-15} M) obey the same distribution coefficient as do macroscopic amounts of material; therefore it is quite possible to make deductions as to true thermodynamic distribution coefficients from experiments with solutions of pure radioelements. Similarly, it has been found that the properties of volatility can be correctly deduced from experiments performed with such microscopic amounts of radioelements. In addition, it has been found that a great deal of information about the oxidation and reduction properties of an element, and of the ions of this element, can be deduced from experiments performed with these small amounts (concentrations as low as 10^{-15} M) of radioelement material, when proper account is taken of the concentration of the ions and of the possibility of slow reactions.

Precipitation Reactions.—Since one of the most common precipitating agents which we use is hydrofluoric acid, it is often necessary to use platinum ware where heat is necessary and waxed glassware for room temperature reactions and precipitations. Coating the glassware with a mixture of paraffin and beeswax has given very satisfactory results. However, it is possible to use ordinary Pyrex glassware, instead of waxed glassware, if, instead of hydrofluoric acid, potassium fluoride is used in solutions of low acidity and the solutions do not stand in the glass for more than an hour or two. We have used waxed glassware and bakelite almost always because we wanted to be absolutely sure that no silica appeared in our very thin samples.

We found it to be very advantageous to use a centrifuge[8] rather than to filter precipitates, and a great number of our precipitation reactions were carried out right in the centrifuge tube in order to avoid loss by transfer. Where hydrofluoric acid is employed, waxed centrifuge tubes or "lusteroid" tubes should be used. In some experiments, particularly in the final precipitation in which the sample is isolated, it has been found convenient to centrifuge onto a platinum or cellophane plate in a clear bakelite centrifuge tube with a removable bottom. Similarly, some electrolysis reactions have been performed with the metallic cathodes in bakelite tubes with removable bottoms.

A number of qualitative precipitation reactions were carried out using various carriers and always having an excess of the anion present. As stated above, the radioactive isotopes used to follow the behavior of elements 94 and 93 were the alpha-emitting 50-year 94^{238} and the beta-emitting 2.3-day 93^{239}.

We have found that, similarly to element 93, element 94 has two oxidation states; in its lower oxidation state 94 forms an insoluble fluoride, but the fluoride of its higher oxidation state is soluble. Peroxydisulfate ion ($S_2O_8^{--}$), in the presence of silver ion (Ag^+) as catalyst, has sufficient oxidizing power to oxidize 94 to its higher oxidation state. This reaction takes place in about fifteen minutes in an acid solution (few normal) at a temperature just below boiling when the concentration of peroxydisulfate ion is of the order of 0.2–1.0 g. and the silver ion of the order of 50 mg. per 100 cc. A number of precipitation experiments on the oxidized and reduced states of 94 and 93 are summarized in Table I, where (i) indicates that the activity was "carried down" with the precipitate and therefore the transuranium compound is considered to be insoluble, (s) that the activity was not "carried" and therefore that the compound is considered to be soluble. The experiments on the oxidized state of 93 took place in an acid solution (few normal) of bromate ion (BrO_3^-), with about 0.5 g. of BrO_3^- per 100 cc.

TABLE I

SOLUBILITY OF 93 AND 94 COMPOUNDS

	93		94

Hydroxide (NH_4OH and CO_3^{--})	...	s	...	...
Carbonate	i	...	...	...

Elements 94 and 93 are precipitated quantitatively, in their reduced states, with lanthanum or cerous fluoride even from rather strong acid (6 N) solutions. This is in rather sharp contrast to the behavior of thorium, where we have found, using UX_1 as tracer, that the precipitation is not quantitative from solutions in which the acidity is as high as 6 N.

An experiment was performed in which 0.5 mg. of lanthanum was added last to a hydrofluoric acid solution containing 94 and 93 in their reduced states, in order to determine whether 94 and 93 would be carried down into the lanthanum fluoride precipitate under these conditions. After the precipitate was digested in the hot solution

---

[8] A convenient centrifuge, which handles 15 cc., 50 cc., 100 cc. and 250 cc. centrifuge tubes, is the Size 1 centrifuge of the International Centrifuge Company. This company also sells the "lusteroid," hydrofluoric-acid-proof, centrifuge tubes.

for about 20 min., the lanthanum fluoride precipitate was centrifuged out. It was found that this precipitate contained only about 50% of the 94 and about 90% of the 93. This would indicate that 94 and 93 are not precipitated quantitatively on "preformed" precipitates, and it is quite probable that the amount of 94 and 93 which is "adsorbed" would vary markedly with the conditions under which the precipitation was performed.

Oxidation and Reduction Reactions.—McMillan and Abelson[3] found that element 93 is not reduced to the metal by zinc. We have found the same to be true for element 94. To check the conditions of the experiment (stirring the acid solution over zinc amalgam for two hours at room temperature), very dilute solutions ($\sim 10^{-12}$ *M*) of polonium and 158-day $Cd^{107,109}$ were plated on zinc, proving (1) that if 94 had been plated out its alpha-particles could have been detected and (2) since no 94 was plated out it must be more difficult than cadmium to reduce to the metallic state.

The potential required to oxidize elements 94 and 93 from their "fluoride-insoluble" state to their "fluoride-soluble" state (see Table I) was studied in the following way: (1) 1 *M* sulfuric acid solutions of elements 94 and 93 were treated with various oxidizing agents (and with their reduction products) under varying conditions of time and temperature; (2) lanthanum fluoride, LaF_3, was precipitated from the solutions; and (3) the activity of the precipitate was measured on a Lauritsen electroscope to detect 93^{239} and ionization chamber plus linear amplifier to detect 94^{238}. The activity indicated whether the element had been in its lower, "fluoride-insoluble," state or its higher, "fluoride-soluble," state.

The results of these experiments are summarized in Table II. In this table "oxidized" indicates that less than 5% of the activity was carried with lanthanum fluoride; "not oxidized," that more than 85% was carried; "partially oxidized," that between 5 and 85% was carried.

TABLE II

OXIDATION OF 94 AND 93 SOLUTIONS

0.1 *M* Oxidizing agent in 1 *M* H_2SO_4	Approx. temp., °C.	Approx. time, min.	Effect on	
			93	94
$S_2O_8^{--}$, SO_4^{--} (Ag^+ catalyst)	20	10	Oxidized	Partially ox.
$S_2O_8^{--}$, SO_4^{--} (Ag^+ catalyst)	80	15	Oxidized	Oxidized
H_5IO_6, IO_3^-	80	60	Oxidized	Oxidized
MnO_4^-, MnO_2	20	10	Oxidized	Not oxid.
MnO_4^-, MnO_2	80	30	Oxidized	Oxidized
BrO_3^-, Br_2	20	10	Oxidized	Not oxid.
BrO_3^-, Br_2	80	20	Oxidized	Not oxid.
Ce^{+4}, Ce^{+3}	80	30	Oxidized	Partially ox.
$Cr_2O_7^{--}$, Cr^{+3}	20	25	Oxidized	Not oxid.
$Cr_2O_7^{--}$, Cr^{+3}	80	11 hr.	Oxidized	Oxidized
Br_3^-, Br^-	20	2 hr.	Not oxid.	Not oxid.
Br_3^-, Br^-	80	15	Not oxid.	Not oxid.
HNO_3 (concd.)	80	15	Not oxid.	Not oxid.

In the few reduction experiments that were tried, it was found that 93 is reduced to the "fluoride-insoluble" oxidation state at room temperature by sulfur dioxide, SO_2, bromide ion, Br^-, manganous ion, Mn^{++}, and partially by thallous chloride, TlCl, while 94 is reduced by sulfur dioxide, partially by bromide ion and not by manganous ion or thallous chloride. The oxidized form of 93 in these experiments was obtained by the use of a small amount of permanganate ion, MnO_4^-, or bromate ion, BrO_3^- (in 1 *M* sulfuric acid). To these oxidized solutions, there was added an excess of the reducing agent and after separating out any manganese dioxide that formed (which did not carry the 94 and 93), lanthanum fluoride was precipitated and the activity measured.

Although there occurs no oxidation of 94 by bromate ion in 20 min. at 80° in the absence of cerium, some rough experiments indicate that partial oxidation of 94 by bromate ion occurs when cerium is present. This would suggest that bromate ion is capable of oxidizing 94 from its lower to its higher oxidation state and that it is a very slow reaction and is catalyzed by the $Ce^{+3} \rightarrow Ce^{+4}$ couple. In the separation of 94 and 93, bromate ion is used under conditions where it oxidizes 93 and not 94, advantage being taken of the apparently slow rate of reaction between 94 and bromate ion; therefore, this separation is carried out in the absence of cerium.

A reaction of the oxidized form of 94 which should be emphasized is the following. If a sulfuric acid solution of the oxidized form of 94 containing peroxydisulfate ion is heated until fumes of sulfur trioxide appear, so as to decompose all of the peroxydisulfate ion, the 94 is reduced to its lower, "fluoride-insoluble," form. Evidently in a solution of this acidity the 94 is reduced by water. This reaction is important in that, when an oxidizing agent is present which can be completely reduced by heating the solution, such as is true in the case of peroxydisulfate ion, the 94 can be reduced by heating the sulfuric acid solution until fumes of sulfur trioxide appear and the addition of a reducing agent is not necessary. Element 93 is likewise reduced from its higher to its lower oxidation state when a sulfuric acid solution of 93 containing peroxydisulfate ion is heated until fumes of sulfur trioxide appear. However, it is not entirely certain how quantitative these reductions are under varying conditions of evaporation and time of heating, and therefore in most of our experiments we add some reducing agent such as sulfur dioxide, even when the oxidizing agent which is present is completely decomposed during the evaporation procedure, in order to ensure the complete reduction of the 94 and 93.

Electrolysis Experiments.—The primary purpose of the experiments on the electrolysis of elements 94 and 93 was to develop a method of preparing very thin adherent layers, containing these elements, suitable for the performance of physical measurements upon them. The aim was not to use electrolysis as a method of isolating these elements free from all of the fission products in this manner, but experiments in the future may show that electrolysis can be helpful in such a separation. Haissinsky[9] has shown that actinium, thorium and uranium can be deposited electrolytically from absolute ethyl alcohol solution of their nitrates. It seems quite certain that it is the oxides of these elements, and not the elements themselves, that are deposited in these experiments. We have found that elements 94 and 93, with 0.2 mg. of lanthanum carrier, can be electrolyzed out of absolute alcohol solution quantitatively under conditions similar to the experiments of Haissinsky in which no acid may be present. This procedure, however, has not yet solved for us the problem of the preparation of very thin adherent layers of material containing 94 or 93 because, (1) in order to transfer 94 or 93 at all quantitatively from the water solution, where it is present just before the final stage of its isolation into a thin layer, it is necessary to use an amount as large as a few milligrams of rare earth carrier material and (2) the rare earths are deposited electrolytically along with the 94 and 93. When 0.2 mg. of rare earth, which is the maximum amount wanted on the final plate, has been used, the transfer to absolute alcohol, which involves an evaporation to dryness in order to eliminate all the water and acid, has not been quantitative due to the difficulty of redissolving all the material in the absolute alcohol. However, as stated above, all of the 94 or 93 that is put into the alcohol is deposited quantitatively in this electrolysis procedure, and the problem of transferring the 94 or 93 from a water to an anhydrous alcohol solution is a separate problem with which we happen to be concerned only because we want to transfer these elements, with practically 100% yield, to extremely thin layers.

Experiments were also undertaken to electrolyze 94 and 93 out of water solution, where the rare earths can be completely removed by making a rare earth fluoride precipitation from an oxidizing solution, and procedures for the electrolytic deposition of 94 and 93 were developed. It has previously been found in work in this laboratory that thorium, protactinium and uranium could be deposited from an acetic acid solution in which the acidity was kept very low by the addition of sodium acetate. We found that elements 94 and 93 could be deposited from such solutions when they were originally present in their oxidized form, but the conditions for quantitative deposition have not yet been perfected. Element 94 was put into its oxidized form by use of periodate ion and element 93 by the use of bromate ion in these experiments. Again it seems quite likely that it is the oxides of these elements and not the elements themselves that are deposited. In these experiments the electrolytically deposited layer is extremely thin, consisting only of a very small amount of what is probably platinum black and which is present also in the blank experiments. In experiments similar to these, elements 94 and 93 are not deposited when they are originally present in such an acetic acid–acetate solution in their reduced form.

Other Experiments.—Since ruthenium and osmium form volatile tetroxides and since element 94 is directly below these elements in the same column of the periodic table, it seemed important to establish whether 94 also forms a volatile tetroxide, even though it was not expected that it should do so in view of the dissimilarity between the chemical properties of 94 and osmium. Experiments were performed with both 94 and 93 to see whether they could be distilled, presumably in the form of their tetroxides, from a nitric acid solution containing peroxydisulfate ion and silver ion, in which these elements probably exist in their highest oxidation states. The delivery tube from the distillation flask was immersed in an alkaline solution in which the distillate of osmium tetroxide, which was used as a carrier material in this experiment, was absorbed. Upon acidification, reduction with sulfur dioxide, and precipitation of rare earth fluoride from the distillate solution, it was found that none of the 94 or 93 had distilled over.

Experiments have been performed to measure the distribution of 94 and 93 in the lower oxidation state as their nitrates between diethyl ether and neutral water. These experiments were performed in the presence of high concentrations of uranyl nitrate. Less than 1% of the 94 and 93 were found to be present in the ether in experiments of this type.

Chemical Properties of 94 and 93

Because of the similarity, in their reduced states, of 94 and 93, in their precipitation reactions, to the trivalent rare earths and actinium and to quadrivalent cerium, thorium and uranium, it is extremely probable that the reduced state of these elements has an oxidation number of +3 or +4, and the formulas NpF_3 and PuF_3 or NpF_4 and PuF_4 for the fluorides. Whether the oxidation number is +3 or +4 cannot be decided on the basis of the experiments which have been performed to date. Comparison with the neighboring elements thorium and uranium suggests +4, but 94 and 93 resemble the +3 rare earths in that they are carried quantitatively with lanthanum fluoride from quite acid solution whereas quadripositive UX_1 is not carried quantitatively with lanthanum fluoride from acid solution.

Although it is again not possible to assign with

---

[9] S. Cotelle and H. M. Haissinsky, *Compt. rend.*, **206**, 1644 (1938).

certainty oxidation numbers to the oxidized states of 94 and 93 which exist in our experiments, it seems certain that the oxidation numbers will not exceed +7 and +8 for 93 and 94, respectively, and there may be intermediate oxidation states, such as, for example, +5 and +6 for 93 and +5, +6 and +7 for 94. It seems quite certain that the ions of the oxidized states of these elements will contain oxygen, similar to uranyl ion, UO_2^{++}, and because of their electropositive nature, the formulas may be of the type NpO_3^+ and PuO_3^{++}.

It should be possible, on the basis of our oxidation and reduction experiments, to assign some sort of values for the oxidation potentials of 94 and 93. We will attempt to assign values for these potentials in the system of standard oxidation potentials which is referred to the hydrogen–hydrogen ion couple as zero.[10] There are for each element the two oxidation potentials to be considered: (1) the potential for the oxidation of the element from its metallic to its reduced ionic (+3 or +4) state and (2) the potential for the oxidation of the element from its reduced ionic state (+3 or +4) to its oxidized ionic state (+5, +6, +7 or +8).

If the failure of zinc to reduce 94 and 93 to the metal is actually due to thermodynamic equilibria and not to slow rates, more than 0.75 volt must be needed to reduce the very dilute solutions ($\sim 10^{-12}$ *M*) of 94 or 93 to the metallic state. Assuming, for example, a three-electron change, more than 0.5 volt is required to reduce solutions at unit activities to the metals.

The experiments show quite strikingly that the reduced ionic state of 94 is oxidized very slowly and that the oxidized ionic state of 94 is reduced very slowly, while the corresponding reactions for 93 are quite rapid. Because 94 reacts so slowly with oxidizing and reducing agents, it is impossible from the existing data to assign an accurate potential to the change from the lower to the higher oxidation state of this element. However, since dichromate ion does oxidize 94 and bromide ion at last partially reduces it, some 1.0–1.4 volts must be needed to oxidize 94 from its "fluoride-insoluble" oxidation state to its "fluoride-soluble" state. These are not necessarily the "standard" oxidation potentials for these couples because we purposely neglected concentration effects which would be important if (1) the couple involves ions or molecules containing more than one 93 or 94 atom or (2) if the oxidation–reduction equilibrium is rapid enough so that it may be shifted by the adsorption of the reduced form (Np^{+4} or Pu^{+4}) by the rare earth fluoride. However, these are practical oxidation potentials in that they aid the experimenter in choosing a proper oxidizing agent when working with tracer amounts of these elements. The following couples summarize the oxidation–reduction data:

Couple	Volts
$Ac \longrightarrow Ac^{+3}$	+2.4 (?)
$Th \longrightarrow Th^{+4}$	$\sim +2.0$
$U \longrightarrow U^{+4}$	+1.4
$Np \longrightarrow Np^{+4}$	$> +0.5$
$Pu \longrightarrow Pu^{+4}$	$> +0.5$
$U^{+4} \longrightarrow UO_2^{++}$	−0.4
$Np^{+4} \longrightarrow NpO_3^{+}$ [11]	−1.35
$Pu^{+4} \longrightarrow PuO_3^{++}$ [11]	−1.0 to −1.4

In this table we have arbitrarily assigned an oxidation number of +4 to the "fluoride-insoluble" states and +7 and +8 to the "fluoride-soluble" states of 93 and 94, merely for the convenience of writing definite formulas.[11] The oxidation potentials for similar oxidations in actinium, thorium and uranium have been included for purposes of comparison.

The soluble and insoluble compounds of 94 and 93 in the reduced (+3 and +4) state are very similar to those of actinium, thorium and +4 uranium. For example, the fluorides and iodates and hydroxides of all five of these elements are insoluble in water and their sulfides are all soluble in acid. Likewise all five of these elements show quite a similarity in that their metals are all of an electropositive nature. On the other hand, there is little, if any, similarity between 94 and 93 and their homologs, osmium and rhenium. This supports McMillan and Abelson's suggestion and Mayer's calculations[12] that a new "rare earth" group may be starting at the upper end of the periodic table, *though from the present data we could just as well consider the group to be starting with actinium or thorium as with uranium.* In addition, it should be noted that uranium and 94 and 93 do differ in the values of their potentials for oxidation from the "fluoride-insoluble" to the "fluoride-soluble" state. It may be that in the chemistry that involves the higher oxidation states there will be marked differences between these three elements.

In the case of the electrolytic deposition of 94 and 93, it is probable that oxides of the formulas PuO_2 and NpO_2 are formed.

Yields

In this section we will discuss the yields of radioactive 94 and 93 which are obtained with the Berkeley 60-inch cyclotron. We have attempted no specific experiments to determine accurate yields, but, since it seems desirable to include in this report some yield data, we will summarize the rough yield data, obtained as incidental information, from our experiments. The isotope of 94 which can be formed most easily with the

Hildebrand in the "Handbook of Chemistry and Physics," The Chemical Rubber Publishing Co., Cleveland, Ohio.

(11) Note added at time of publication: It is now known that the "fluoride-soluble" oxidation states studied here correspond to the formulas NpO_2^{++} and PuO_2^{++}.

(12) M. Goeppert Mayer, *Phys. Rev.*, **60**, 184 (1941).

most intensity is the 50-year 94. This alpha-emitting isotope is the decay product of the beta-emitting 2.0-day 93^{238} which is formed in the deuteron bombardment of uranium. The production of these isotopes is described in another report.[2] The yield of 2.0-day 93^{238} is about 10 microcuries per microampere-hour of 15 Mev. deuterons, and the corresponding yield of 94^{238} is, therefore, about 10^{-3} microcuries per microampere-hour. A 1000-microampere-hour bombardment produces about 1 microcurie of 94^{238}, corresponding to about 1×10^6 counts per min. (on a chamber with 45% counting efficiency), which is a sufficient amount of activity to serve as a tracer in a very large number of chemical experiments. There will be mixed with about 1 microcurie of 94^{238} about 0.02 microcurie of 94^{239} which is also formed during the deuteron bombardment of uranium. This other isotope of 94, namely, 94^{239}, might conceivably be used as a tracer, but the intensity of readily prepared samples is considerably less. In the bombardment with neutrons of a rather large amount, about 2 kg., of uranyl nitrate hexahydrate, placed directly behind the beryllium target of the Berkeley 60-inch cyclotron we have found that the yield of 94^{239} is about 0.02 microcurie per 1000 microampere-hours of deuterons. Thus, it is seen that the best tracer isotope for 94 is the 50-year 94^{238} formed in the deuteron bombardment of uranium.

On the other hand, it is the neutron bombardment of uranyl nitrate rather than the deuteron bombardment of uranium which is the more suitable for the production of radioactive 93 for tracer experiments. The yield of 93^{239} in the neutron bombardment of two kilograms of uranyl nitrate hexahydrate amounts to about 80 microcuries per microampere-hour of deuterons. The yield of 93^{239} in the direct deuteron bombardment of uranium is about 80 microcuries per microampere hour, which is about the same as that obtained in the bombardment of kilogram amounts of uranyl nitrate with neutrons; however, the 93 formed in the deuteron bombardment of uranium, being a complex mixture of some 90% 93^{239} and 10% 93^{238}, may be undesirable for some experiments involving 93 as a tracer because of the growth, during the experiments, of the highly alpha-active 94^{238} from the 2.0-day 93^{238}. In addition, it is more convenient to perform neutron bombardment of uranium; for example, an easily performed bombardment, 100 microampere-hours of beryllium plus 15 Mev. deuteron neutrons on 200 g. of uranyl nitrate hexahydrate, produces of the order of a millicurie of 93^{239}, which is ample for a set of tracer experiments. For these reasons we believe that the best tracer isotope for 93 is the 2.3-day 93^{239} formed by the neutron bombardment of uranyl nitrate hexahydrate.

S. G. English and J. W. Gofman have given us valuable help in some of the experiments described in this paper.

Summary[13]

The chemical properties of elements 94 and 93 have been studied by means of the tracer technique using the radioactive isotopes 94^{238} and 93^{239}. Plutonium is suggested as the name for element 94 following the convention used in the naming of neptunium (element 93) and uranium. The chemical symbols Pu and Np are suggested for plutonium and neptunium. In the reduced states the precipitation reactions of neptunium and plutonium are similar to those of the tripositive rare earths and actinium, and of the quadripositive cerium, thorium and uranium. Neptunium and plutonium resemble actinium, thorium and +4 uranium in that their fluorides, iodates and hydroxides are insoluble in water; their sulfides are soluble in acid; and their metals are electropositive. Neptunium and plutonium exhibit a higher oxidation state with properties similar to those of uranium of oxidation state +6.

Probably the reduced state of both elements has an oxidation number of +3 or +4 and the formulas of the fluorides are NpF_3 and PuF_3 or NpF_4 and PuF_4. For both elements the standard oxidation–reduction potential from the metal to the reduced ionic state is greater than +0.5 v. For the reduced to the oxidized ionic state the standard potential for neptunium is about −1.35 v. and for plutonium, −1.0 to −1.4 v. Probably PuO_2 and NpO_2 are the oxides formed by electrodeposition.

There is practically no resemblance in chemical properties between neptunium and plutonium and rhenium and osmium. The chemical properties of neptunium and plutonium indicate that a "rare earth" type group of elements is starting at the upper end of the periodic table, and from the present data we can just as well consider the group to be starting with actinium or thorium, rather than with uranium which has been previously suggested as the starting point.

The Adsorption of Butane on Glass Spheres

BY R. T. DAVIS[1a] AND T. W. DEWITT[1b]

The Brunauer–Emmett–Teller theory of multilayer adsorption has had a considerable success in supplying a foundation for interpreting adsorption data. It has also been of great practical value in providing a relatively simple and reliable method for estimating the surface area of a wide variety of finely divided materials. While the theory admirably accounts for the major features of multilayer adsorption its more detailed behavior is not entirely satisfactory. It is well known that its range of applicability extends only over a relative pressure range of about 0.05 to 0.35 and that it consistently predicts excessive adsorption in the higher relative pressure range. In the low relative pressure region the theory predicts too low an adsorption and this has been generally[1c] attributed to neglect of a varying heat of adsorption over the first layer. Further than this, however, the heat of adsorption predicted by the theory is invariably appreciably lower than that measured calorimetrically or by use of the Clapeyron equation. It was suggested by Cassie[2] that this latter difficulty might arise from a constant entropy term associated with the adsorption energy and not determinable separately from it in the theory.

In the course of some other work rather extensive data have been obtained on the adsorption of butane on glass spheres. These data were extended to cover the region of very low partial pressures in order to obtain values for the heat of adsorption at very low surface coverages. There were thus obtained adsorption data over a wide range of partial pressures, surface coverages and temperatures. It was hoped that comparison of thermodynamic quantities, experimentally obtained, with those predicted by the Brunauer–Emmett–Teller theory might provide some clue to the origin of some of the difficulties mentioned above. Of particular interest is the form of the heat of adsorption curve at low surface coverages.

The system butane–glass is very convenient for such studies. The vapor pressure of butane is such that the system is readily investigated over the rather wide temperature interval of −78 to 0°. The net heat of adsorption is sufficiently low so that (at these temperatures) very low surface coverages are easily studied. Finally, glass beads produced by fusion would be expected to provide an inert and (it was hoped) a relatively smooth surface.

Experimental

The glass spheres were made by the method of Bloomquist and Clark.[3] Electron microscope pictures showed them to be for the most part well-formed spheres with only an occasional irregularly shaped particle. With the exception of a few thread-like appendages the surface appeared perfectly smooth. This does not, of course, eliminate the possibility of surface cracks of molecular dimensions. The beads were not sized. Particles were observed with diameters ranging from a few tenths of a micron up to as high as eight microns, with the average about 3 microns.

The butane used in the experiments was obtained from a tank of C. P. *n*-butane purchased from the Ohio Chemical Company. The gas was purified by condensing it at −78° and pumping off about a third of it. The remainder was used for the adsorption measurements. The vapor pressure of the purified gas at 0° checked satisfactorily with that given by Aston.[4]

Two adsorption systems were employed. One was of conventional design for operation up to pressures of one atmosphere,[5] except that all stopcocks were replaced by mercury cut-off valves. A separate system, equipped with two McLeod gages, was used for measurements in the pressure range 0.0005 to 17.0 mm. Hg pressure. Mercury cut-offs were also used in the low-pressure system. Approximately 10 g. of the glass spheres was used in the adsorption bulb of the high pressure system and about 3 g. in the low pressure sample tube. Samples were degassed for several hours at room temperature prior to adsorption measurements. Dead space calibrations were carried out in the usual way with helium.

Temperature control was achieved through the use of appropriate low temperature baths. A stirred ice-bath was used for 0°, a mixture of solid–liquid chlorobenzene was used for −46°, and a Dry Ice–acetone bath for −78°.

Results

Figure 1 is a plot of the adsorption of nitrogen at −195° on the glass spheres, together with a BET plot, from which the surface area may be calculated.

Figures 2, 3, 4, and 5 are plots of the adsorption of butane on the glass spheres. In Fig. 6 all the data are plotted on a single graph as log p/p_0 against log v/g. Only by such a plot can the wide range of values for p/p_0 be covered in a single figure of reasonable size. Straight line BET plots are shown in Fig. 7 and in Table I are collected the areas and heat values calculated from these plots, along with the corresponding quantities obtained from the nitrogen isotherm. The straight line form of the BET equation is

$$\frac{p/p_0}{v(1 - p/p_0)} = \frac{1}{v_m c} + \frac{c - 1}{v_m c} p/p_0 \qquad (1)$$

where v is the volume of gas adsorbed at pressure p, v_m is the volume of gas required to form a monolayer on the surface of the adsorbent, p_0 is the vapor pressure of the liquid adsorbate, and

$$c = \frac{a_1 b_2}{a_2 b_1} e^{(E_1 - E_L)/RT}$$

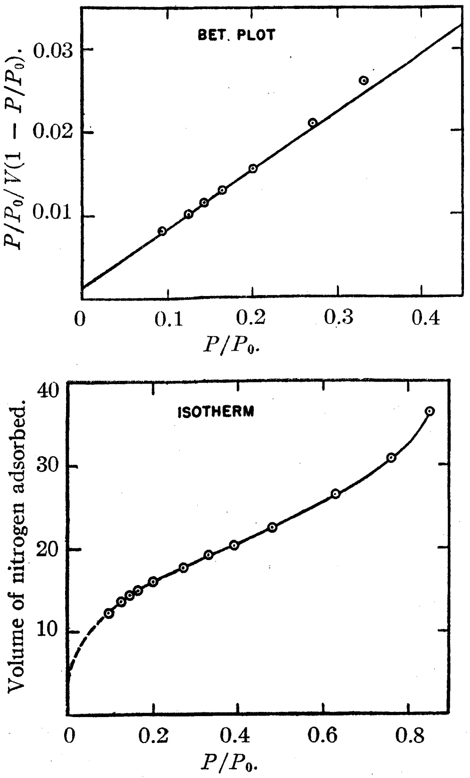

Fig. 1.—Adsorption of nitrogen on glass spheres at −195°.

The constant a_1b_2/a_2b_1 is the ratio of the evaporation–condensation coefficients for the first and higher layers. E_1 is the heat of adsorption in the first layer and E_L is the heat of condensation of the adsorbate. Areas are calculated from v_m, the volume of adsorbate corresponding to a monolayer, by obtaining cross-sectional areas for the adsorbate molecules from the liquid density and assuming hexagonal packing on the surface. For butane the value of 32 sq. Å. was used as the cross-sectional molecular area.

Harkins and Jura have used a method of calculating the surface area of various non-porous solids[6] which involves plotting the adsorption data according to the equation

$$\log \frac{p}{p_0} = B + \frac{A}{v^2} \qquad (2)$$

where A and B are constants. The square root of the slope of the straight line is proportional to the surface area. The proportionality constant was determined empirically for several gases by cali-

TABLE I

SURFACE AREA OF GLASS SPHERES

Gas	Temperature, °C.	c	Area, sq. m./g. by BET[a] method	Area, sq. m./g. by H. and J. method
C_4H_{10}	− 78	11.55	3.56	5.36[b] (4.51)
C_4H_{10}	− 46	8.47	3.34	4.81[b] (4.37)
C_4H_{10}	0	5.40	3.35	4.69[b] (4.69)
N_2	−195	55	5.82	4.47 ..

[a] Corrected for temperature variation of density of liquid butane. Cross-sectional area at 0° assumed to be 32 ss. Å. [b] Calculated using factor of 13.6 for all temperatures. Figures in parentheses calculated assuming factor is 13.6 for 0° and varies inversely with square root of absolute temperature. The factor 13.6 is equivalent to a cross-sectional area of 56.6 Å.[2]

bration against an absolute determination of the area.[7] The factor for butane at 0° is 13.6, which corresponds to a cross-sectional area for butane of 56.6 sq. Å. The butane data are plotted in this fashion in Fig. 8. Below relative pressures of 0.3 to 0.4 the plots are distinctly curves, but points in the higher pressure ranges yield reasonably straight lines from which areas may be calculated. The areas calculated using the Harkins and Jura method are given in Table I. The derivation of the Harkins and Jura equations involves a transformation through the Gibbs adsorption equation. This transformation inserts the absolute temperature in the denominator of the term involving $1/v^2$. It would be therefore expected that the constant relating the slope of the plot to the surface area, would vary inversely as the square root of the absolute temperature. For the figures in parentheses in Table I, it has been assumed that the constant 13.6 applies only to 0° and areas for −46° and −78° have been calculated assuming the constant varies as $1/\sqrt{T}$. The correction appears to be in the right direction and of approximately the right size since it yields fairly consistent area values for all three temperatures.

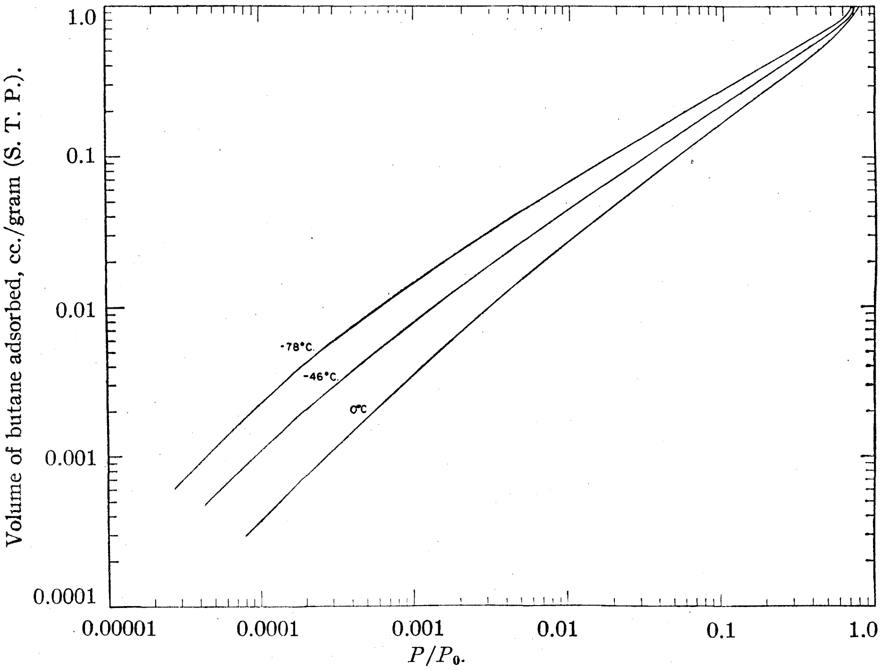

Fig. 6.—Adsorption of butane on glass spheres.

Thermodynamic Data.—The Clausius–Clapeyron equation is used for calculating the heat of adsorption. For convenience the equation was used in the form

$$\log\left(\frac{p}{p_0}\right)_2 - \log\left(\frac{p}{p_0}\right)_1 = \frac{-\Delta H_R}{2.303R}\left[\frac{1}{T_1} - \frac{1}{T_2}\right] \quad (3)$$

where $(p/p_0)_2$ is the relative pressure for a given value of volume adsorbed at T_2, $(p/p_0)_1$ that at T_1, and ΔH_R is the heat of adsorption referred to normal liquid. This equation directly incorporates the heat of liquefaction of the adsorbate, and the heats thus calculated are therefore not absolute but relative to the heat of liquefaction of normal liquid. Figure 6 provides a very easy way

---

(7) Harkins and Jura, THIS JOURNAL, **66**, 1362 (1944).

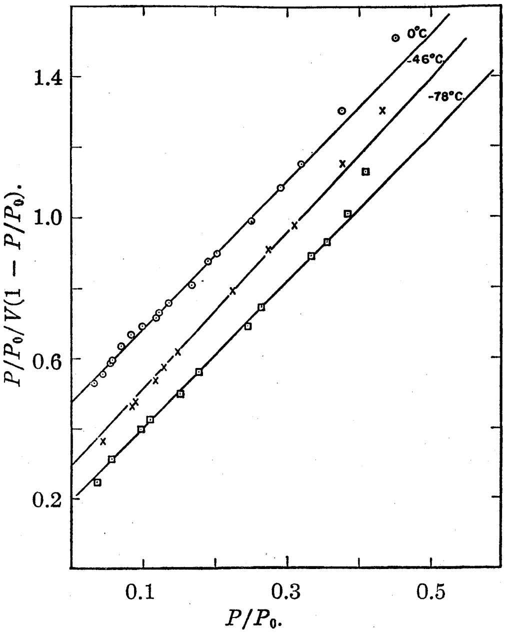

Fig. 7.—Adsorption of butane on glass spheres, B. E. T. plot.

of graphically carrying out these calculations. The heat of adsorption, ΔH_R, is directly proportional to log $(p/p_0)_2$ − log $(p/p_0)_1$. In Fig. 6 this quantity is proportional to the horizontal distance between any two isotherms at a given value of v. This distance then, multiplied by a factor determined by $2.303RT_1T_2/(T_2 - T_1)$ and the length of the logarithmic cycle, immediately gives the desired heat of adsorption. The heat values were obtained in this way from a large logarithmic plot of the data. The values thus obtained are shown in Fig. 9 on a logarithmic plot to spread out the values in the region of low p/p_0. The cross-hatching indicates the estimated limits of error. The tendency to constant values in the very low range will be noted. For comparison with these experimentally determined values, the heats of adsorption have been calculated from the BET equation with the appropriate values of c and v_m. The integral energy of adsorption, ΔE_I, relative to the energy of normal condensation is

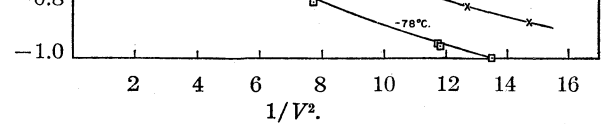

Fig. 8.—Adsorption of butane on glass spheres, Harkins and Jura plot.

$$[\Delta E_I = (E_1 - E_L)v_1] \qquad (4)$$

where E_1 is the molal energy of adsorption in the first layer, E_L the molal energy of liquefaction of normal liquid and v_1 is the number of moles of adsorbate in the first layer at the relative pressure at which the integral heat is desired. Differentiation of equation (4) with respect to V, the total number of moles of adsorbate, gives $\Delta E_R = (E_1 - E_L)\mathrm{d}v_1/\mathrm{d}V$, the differential molal energy of adsorption relative to normal liquid as a function of the total amount of gas adsorbed. This value should be directly comparable to ΔH_R determined experimentally since we are dealing with condensed phases throughout and there should be no difference between ΔH and ΔE. The quantity $E_1 - E_L$ was obtained in the usual way from the c value of the BET plots and $\mathrm{d}v_1/\mathrm{d}V$ was obtained by differentiation of the expression given by Hill[8] for the number of moles of adsorbate in the first layer as a function of total amount adsorbed. The experimental and calculated curves for the heat of adsorption are compared in Fig. 10.

The free energy change in going from condensed liquid having a vapor pressure p_0 to the adsorbed phase having a vapor pressure p, is given by $\Delta F = RT \ln p/p_0$. Free energy of adsorption values were thus calculated directly from the data and also from the BET equation. Of course, over the range of applicability of the BET equation, the experimental and calculated free energies must agree. From these free energy values and the corresponding heat values previously determined, entropies of adsorption, experimental and theoretical, were calculated through the relation $\Delta S = (\Delta H - \Delta F)/T$. Experimental and theoretical entropy values are compared in Fig. 11.

If values for c in the BET equation are available over a temperature range it becomes possible to determine separately the quantities a_1b_2/a_2b_1 and $E_1 - E_L$. Since

$$c = \frac{a_1b_2}{a_2b_1}\, e^{\frac{E_1 - E_L}{RT}}$$

a plot of log c against $1/T$ should be a straight line (assuming $E_1 - E_L$ is not strongly dependent on temperature). The slope of this plot serves for the evaluation of $E_1 - E_L$ and the intercept for

---

(8) T. L. Hill, *J. Chem. Phys.*, **14**, 268 (1946). Hill showed that the BET derivation leads to the conclusion that the number of moles of gas V_1 adsorbed in the first layer is given by the equation

$$\frac{V_1}{V_m} = \frac{c(V/V_m + 1) - [(1 - V/V_m)^2c^2 + 4V/V_mc]^{1/2}}{2(c - 1)} \qquad (5)$$

where the symbols are the molal equivalents of those used in equation (1). Differentiation with respect to the total number of moles of gas adsorbed gives

$$\frac{\mathrm{d}V_1}{\mathrm{d}V} = \frac{c}{2(c-1)}\left\{1 - \frac{V/V_m - 1 + 2/c}{[(1 - V/V_m)^2 4/cV/V_m]^{1/2}}\right\} \qquad (6)$$

Equations (4) and (6) were used to calculate the differential heats of adsorption that one would expect from the BET theory.

that of a_1b_2/a_2b_1. Such a plot for the butane on glass data is shown in Fig. 12. Values of $E_1 - E_L$ and a_1b_2/a_2b_1 determined from this plot are listed in Table II. The range of values shown indicates the outside limits obtainable from different straight lines through the three points, which are not quite in a straight line. Evidently the ratio a_1b_2/a_2b_1 is essentially unity and the slope of the plot yields a value for $E_1 - E_L$ in reasonable agreement with those obtained in the usual way from the individual c values.

Discussion

The system is quite normal in its behavior, and when viewed from the point of view of its pressure–volume adsorbed relations, requires little comment. The BET method for determining surface areas leads, as usual, to considerably lower surface area values, when the calculations are based on the butane isotherm than when they are based on the nitrogen isotherm, provided the values 32 and 16.2 Å.^{2} are used for the cross-sectional areas of the molecules of butane and nitrogen, respectively. With a smooth glass adsorbing surface it does not seem reasonable to assign this discrepancy to a screening out of the larger butane molecules from small holes. It must be that butane occupies a larger area on the surface than would be calculated from the liquid density. In calculating the area values recorded in Table I, corrections for the thermal expansion of the liquid were applied.

In the Harkins and Jura plots there is no straight line relation between the logarithm of the relative pressure and the reciprocal square of the volume adsorbed, as required in their theory, if the data in the relative pressure range 0.05 to 0.35, which is the region of usual validity of the BET equation, is used. For relative pressures above 0.3–0.4, however, the plots are relatively good straight lines and a reliable slope can be determined. The values for the areas thus determined are seen, from Table I, to be quite reasonable. It is interesting that the temperature correction demanded by the theory seems to operate in the right direction and to approximately the right extent. The factor 13.6 is equivalent to assuming a cross-sectional area for butane of about 56.6 Å.^{2} rather than the 32 Å.^{2} calculated from the liquid density and usually used in the application of the BET

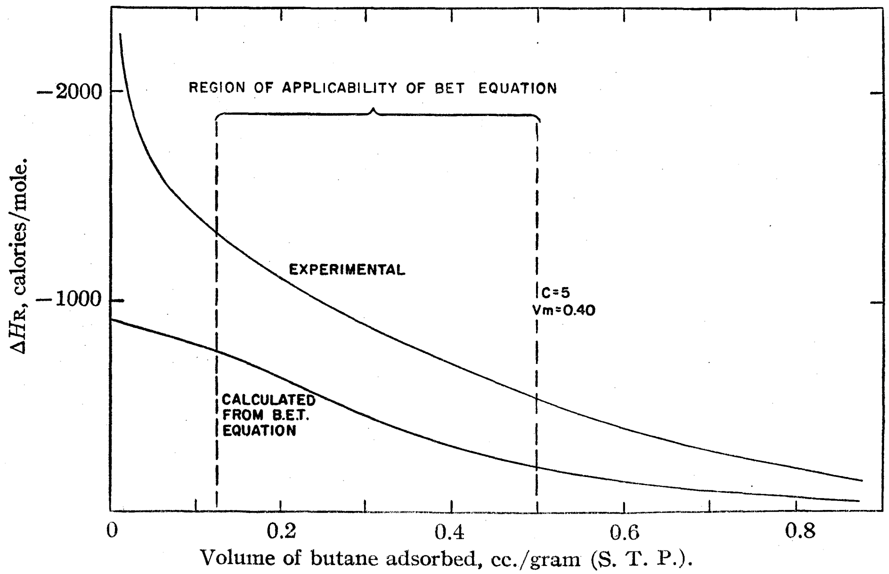

Fig. 10.—Adsorption of butane on glass spheres and heat of adsorption.

method. If a cross-sectional area of 56.6 Å.^{2} is used for butane in applying the BET method to the present work, good agreement with the nitrogen area is obtained but, as will be seen from Table I, the Harkins and Jura factor of 13.6 gives areas about 25% too low compared to the BET nitrogen area. The reason for this is readily seen to be that the BET and Harkins and Jura nitrogen areas do not agree. Nitrogen adsorption on glass beads has a low "c" value (55) and this constitutes a case wherein the nitrogen values for the two methods do not agree.[9] It will be noted from the table that there is good agreement between the area values calculated from butane and nitrogen data if the Harkins and Jura method and constants are used for both. Of course this should not be surprising since the constants were empirically determined to give such agreement. As has already been pointed out, equally good agreement could be obtained between the two gases using the BET method if a comparable procedure is used and the cross-sectional area of butane is chosen to give agreement with the nitrogen area. At the moment there seems to be no basis for making a choice between the BET method and the Harkins and Jura method for obtaining areas, if the Harkins and Jura method is applicable and yields a single straight line. The BET method when used to obtain absolute surface areas involves the assumption that the cross-sectional area of a molecule is independent of the substrate; the Harkins and Jura method assumes the same for its empirically chosen conversion factor. Probably such an assumption is not strictly justified for either method. Perhaps the best that can be done at the present is to admit that absolute areas cannot be relied on to better than 20–30% and regard both methods as adequate within these limits.

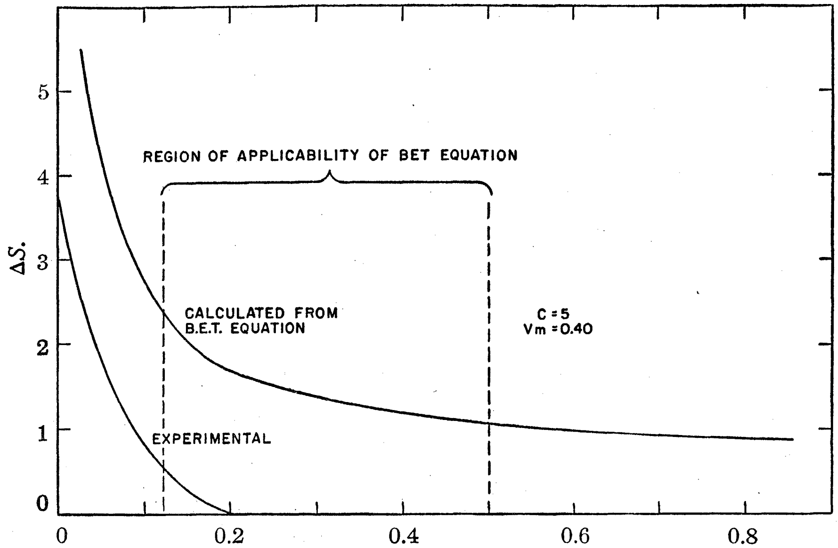

Fig. 11.—Adsorption of butane on glass spheres and entropy of adsorption.

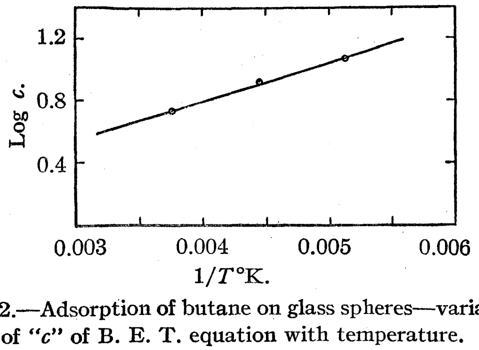

Fig. 12.—Adsorption of butane on glass spheres—variation of "c" of B. E. T. equation with temperature.

Thermodynamics.—The form of the heat curve is interesting, particularly at low surface coverages. Below about one per cent. coverage the heat appears to be constant at a rather high value. Beyond this it drops off at least approximately logarithmically with increasing adsorption. There is some uncertainty in the data in the low ranges; an unmistakeable departure, however, from its behavior at higher coverages occurs in this region. This is best illustrated by the logarithmic plot of Fig. 6 which spreads out the data at low partial pressures. It is also reflected in the nearly parallel straight line portions of the isotherms at the left in Fig. 6. Clausius–Clapeyron computations from parallel straight lines in this type of plot, of course, lead to constant heat values.

The sharp drop-off in the heat after about one per cent. of the surface is covered is difficult to explain. Roberts and Orr[10] and Orr[11] have made extensive theoretical calculations on the heat of adsorption of argon on alkali halide crystals and on the variation of the heat with amount adsorbed. Orr[12] determined the heats experimentally for the adsorption of oxygen, nitrogen and argon on potassium chloride and cesium iodide. Lateral van der Waals interaction invariably (as would be expected) contributes only in a way to increase the heat with surface coverage; only in the case of adsorption on the cesium positive ion faces of the crystal was there an electrostatic repulsive energy, arising from the oriented induced dipoles of the adsorbed atoms, sufficiently large to balance out the van der Waals attractive forces and give a net decrease in the energy of adsorption with increas-

ing coverage. In general, except for regions of very low coverage, agreement between experiment and theory was quite good. It is quite improbable that induced dipoles in butane adsorbed on glass could account for the observed decrease in heat of adsorption; indeed, the decrease in heats starts at such low surface coverages that no kind of lateral interaction would be expected to come into play. Frankenburg, in his study[13] of the adsorption of hydrogen on tungsten at elevated temperatures and also one of the authors (Davis) in the study of nitrogen adsorption on tungsten[13a] found the same behavior of the heat of adsorption at low surface coverages. Indeed, the behavior of the butane–glass system is so similar to that of the hydrogen–tungsten system that one is led to suspect the presence of something fundamentally general. In an attempt to account for the decreasing heat of adsorption, Frankenburg postulated a repulsive force operating between adsorbed atoms even at high dilutions that had its origin in the electron cloud that was assumed to exist in the substrate metal in the neighborhood of each adsorbed atom. No such device can be appealed to in the case of the butane–glass system, yet the experimental similarity of the data in the two cases tempts one to seek a common explanation. It does not seem probable that it will be found in the existence of lateral repulsive forces. Perhaps one is forced to the view that a heterogeneous set of adsorption sites is responsible. If so, the distribution of such sites must be of a remarkably universal form.

Reference to Figs. 10 and 11 makes it immediately apparent that the BET equation does not do too well in predicting individually the heat and entropy of adsorption. Although the form of the calculated heat curve approximates that of the experimental curve, it is everywhere much too low. Since the equation fits the data, and therefore the experimental and calculated free energies must agree, at least over the range of applicability, the entropy is everywhere correspondingly high. Experimentally, the entropy contribution has almost disappeared before a monolayer is completed and the heat contribution accounts for the free energy of adsorption thereafter. In the case of the BET equation the heat soon drops to a rather low value and the entropy continues to make an appreciable contribution to the adsorption free energy. It looks as though the theory incorporates too large an entropy contribution: this may be the origin of the excessive adsorption predicted by the theory for higher layers. A further indication of some basic difficulty is the recognized fact that the value for $E_1 - E_L$ obtained from the c value of the BET equation is so much smaller than the Clausius–Clapeyron heat. This cannot be blamed on a deviation of the factor a_1b_2/a_2b_1 from unity, at least in the present case, since it has been independently determined to be essentially unity. Even more disturbing is the result of plotting log c against $1/T$ for some other data. If the data of McGavack and Patrick[14] for the adsorption of sulfur dioxide on silica gel is thus plotted, the constant a_1b_2/a_2b_1 turns out to be about 6 and $E_1 - E_L$ about 700 calories instead of around 1700 as obtained directly from the c value. Several sets of data for the adsorption of nitrogen[15] at low temperature yield an average value of about 10 for a_1b_2/a_2b_1 and a value of about 400 calories for $E_1 - E_L$. Normally $E_1 - E_L$ determined from the c values for low temperature nitrogen adsorption is in the neighborhood of 700–800 calories. Thus in these cases, separate evaluation of a_1b_2/a_2b_1 has made agreement between $E_1 - E_L$ and the measured heat of adsorption considerably worse, rather than better.

Just wherein improvements are to be made to the simple BET theory is not clear. One obvious thing to do would be to attempt to take molecular interactions into account. Such a refinement has been approached by Hill.[16] The resulting equations are quite complicated and no application to experimental data has yet been published. As adsorption data accumulate, deficiencies in the simple theory become more apparent and the need for satisfactory refinements grows. The BET theory is theoretically sound and improvements will probably come through the use of an improved adsorption model and the incorporation of hitherto consciously ignored factors.

Summary

Data for the adsorption of butane on glass spheres has been reported for a relative pressure range from below 0.0001 up to near saturation at temperatures of −78, −46 and 0°. From these data heats of adsorption have been calculated through the Clausius–Clapeyron equation. The heat of adsorption tends to remain constant up to several per cent. surface coverage after which it decreases approximately logarithmically with increasing adsorption. Experimental heats and entropies of adsorption have been compared with the corresponding quantities calculated from the BET equation. The theory was found somewhat deficient in its ability to predict individually these thermodynamic functions. A plot of log c against $1/T$ was used for the independent evaluation of $E_1 - E_L$ and the coefficient a_1b_2/a_2b_1 in the expression for the constant c of the BET theory. In the case of butane on glass, a_1b_2/a_2b_1 was essentially unity. Some other data were thus treated and a_1b_2/a_2b_1 found to be larger than unity and $E_1 - E_L$ correspondingly lower than usual.

Magnetic Studies on the Dissociation and Disproportionation of Some Hexaarylethanes

BY WARD BYERLY,[1] HOWARD G. CUTFORTH AND P. W. SELWOOD

Previous communications from this Laboratory[1a] have given the heats of dissociation of hexylphenylethane, di-*o*-tolyltetraphenylethane, di-α-naphthyltetraphenylethane, and tetra-*o*-tolyldiphenylethane. Rate constants and activation energies have been given for the disproportionation of di-*o*-tolyltetraphenylethane.[2] To these results the present paper adds heats of dissociation and other thermodynamic constants for di-*o*-chlorophenyltetraphenylethane and for di-β-naphthyltetraphenylethane. Rate constants are given for the disproportionation of di-*p*-tolyltetraphenylethane. All the previously published results on heats of dissociation have been recalculated to correct an error in the method of calculating degrees of dissociation. Reference to this error has already been made.[2] Some of the data in Table I are not directly comparable with those published in 1941 because more experience with the magnetic susceptibility method has led us to reject certain data which we formerly believed were accurate. The conclusions drawn from the corrected results do not differ greatly from those originally reported, but all the reliable data, old and new, have been assembled in one table in the present paper.

Experimental

The magnetic measurements and the preparation of free radicals have already been described.[1,2] Again the authors are indebted to Professor Carl S. Marvel of the University of Illinois for supplying the triarylmethyl chlorides. All solutions were in toluene.

Results

All results on the five ethanes are summarized in Table I. Table II shows the best average values for free energy, heat and entropy changes for the various ethanes, as derived from the data of Table I.

These results confirm the general conclusions previously reached. It appears that the entropy change associated with dissociation is not independent of substituent, although the difference between hexaphenylethane and the other ethanes is not so large in this respect as previously reported.

It is also confirmed that the heats of dissociation are substantially independent of the substituent. On the other hand, large differences in percentage dissociation are produced by what must obviously be steric effects. However, the difference in de-

gree of dissociation produced by an α-naphthyl group as compared with an *o*-chloro group might be interpreted as being due to resonance. The difference between α-naphthyl and β-naphthyl supports the resonance theory of free radical stability.

The results obtained on di-*o*-tolylphenylmethyl are of little significance because of the high rate of disproportionation shown by this radical.

We turn now to a rate study on the disproportionation of *p*-tolyldiphenylmethyl. The problem is one of some difficulty because the solutions must be prepared and handled below 0°. It is complicated in another way. In our previous study on the dipproportionation of *o*-tolyldiphenylmethyl the ethane was at least 90% dissociated at the beginning of each run. But the degree of dissociation for *p*-tolyldiphenylmethyl is much less, and the changes in paramagnetism are correspondingly slight.

In Fig. 1 we show free radical concentrations plotted against time. The initial concentrations of ethane, and the temperatures at which disproportionation was observed are as follows: 0.0632 molal at 10°, and 0.0632 molal at 25°. For time intervals not in excess of ten hours these results give reasonably consistent velocity constants.

No difficulty is found in calculating the free radical concentration at any time, from the magnetic data, by the method previously used. But there is a difficulty in calculating the velocity constants because of the equilibrium, ethane $\rightleftarrows$ 2 radicals. The constants have been evaluated in the following way: Let $[A_2]$ be the concentration of the ethane, [B] and [C] those of the disproportionate.

We have

$$A_2 \underset{k_2}{\overset{k_1}{\rightleftarrows}} 2A \xrightarrow{k_3} B + C \tag{1}$$

$$d[A]/dt = k_1[A_2] - k\,[A]^2 - k_3[A]^2 \tag{2}$$

and

$$k_1/k_2 = [A]^2/[A_2] \tag{3}$$

eliminating A_2

$$d[A]/dt = -k_3[A]^2 \tag{4}$$

and integrating

$$1/[A]_2 - 1/[A]_1 = k_3(t_2 - t_1) \tag{5}$$

where $[A]_2$, $[A]_1$ are concentrations of free radical at times t_2, t_1.

Rate constants derived in this way from the first few hours of disproportionation are as follows: 0.0632 M at 10°, $k_3 = 12.92$; 0.0632 M at 25°, $k_3 = 41.8$. We find the activation energy to be 13.1 kcal. per mole of free radical. It seems probable that this is a maximum value, because disproportionation of *o*-tolyldiphenylmethyl required an activation energy of only 11.4 kcal. per mole, and the experiments and calculations in that case were much less complex.

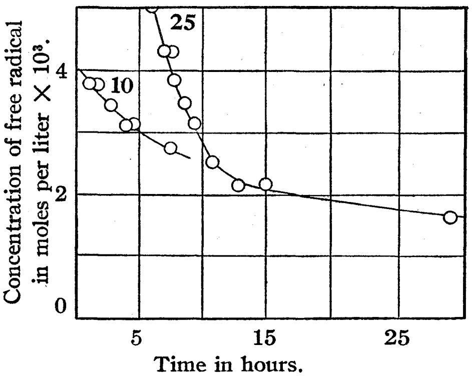

Fig. 1.—Disproportionation of *p*-tolyldiphenylmethyl.

An interesting observation was made during the work on *p*-tolyldiphenylmethyl. It will be recalled that the complete disproportionation of *o*-tolyldiphenylmethyl leaves the solution colored almost the same as when the free radical is present. The disproportionation of the *p*-tolyl also leaves the solution strongly colored *provided that the reaction is carried out in the dark.* If the disproportionation is carried out in the light, the loss of color parallels the loss of paramagnetism. But in the dark the solution remains colored even though all the free radical is destroyed. If now the solution is exposed to light the color fades in a few moments.

An attempt was made during this work to obtain the activation energy of the dissociation process by magnetic measurements on certain ethanes. The experimental difficulties proved insurmountable.

Water Absorption of Proteins. II. Lack of Dependence of Hysteresis in Casein on Free Amino Groups[2]

BY EDWARD F. MELLON, ALFRED H. KORN AND SAM R. HOOVER

Introduction

A series of benzoylated casein samples containing different amounts of free amino groups was used previously[3] to show that the amino group is responsible for the absorption of about one quarter of the total amount of water absorbed by casein, throughout the entire range of relative humidities. Furthermore, it appeared that the water absorbed by the amino group could be subdivided into three distinct portions. Since the amino group accounted for such a large proportion of the total water absorbed, we thought it would be interesting to know whether any of the water absorbed on the amino group is involved in the hysteresis phenomena. Therefore, the same series of benzoylated caseins was used to study the desorption phenomena of casein.

Experimental

The preparation of the benzoylated caseins, their analyses, the manipulations necessary to obtain a reproducible dry weight, and a detailed description of the apparatus and method for measuring the absorption or desorption over saturated salt solutions are given in the earlier paper.[3] The desorption experiments were made only at 30.0 ± 0.1°. The samples were thoroughly dried at 70° and then equilibrated at one of the higher humidities (51, 75, 84 or 93%). The water absorbed at these higher humidities was the same as that absorbed in the previous absorption experiments, where the absorption proceeded gradually from the lower to the higher humidities. The samples were then put into an atmosphere of the next lower relative humidity. It took the desorption samples about eighteen days to reach equilibrium—three times as long as the absorption samples—and there was a greater fluctuation in the equilibrium values obtained for different specimens of the same sample run at different times. When equilibrium was achieved at one humidity, the samples were moved to the next lower humidity until the value at 6% relative humidity was obtained. Then the samples were dried to check the starting weight.

Results and Discussion

Four desorption isotherms were determined for each of the benzoylated caseins. Each began at a different point on the absorption isotherm. From two to four determinations, made at different times, were averaged to determine each point on each isotherm. Figure 1 shows the four desorption isotherms of sample 1 only (purified casein) as compared with the absorption isotherm. The curves for the benzoylated samples are similar. All these curves show clearly that there is a marked hysteresis in the water-sorption phenomenon. It is also apparent that the total water content of the sample approaches a characteristic or limiting desorption curve regardless of the initial water content. Sets of isotherms similar to these have been obtained for wool by Speakman and Cooper[4] and for titania gels by Rao.[5]

Because the desorption isotherms from the higher humidities become identical at lower humidities, we can discuss the main desorption characteristics by discussing the upper limiting curve for each material. The data which fall on this upper curve for each sample at each humidity have been averaged, and the average value for each is reported in Table I. The standard deviation from these average values ranges from 0.002 to 0.004 g./g. of total nitrogen. The average values for the water content on absorption and the hysteresis values are also included in Table I. The water contents are reported on the basis of a gram of total nitrogen because this value relates the water content to the protein content and frees the calculations from the effects of the different weights of the benzoyl groups in the different samples. We have assumed that the benzoyl group does not absorb water.

TABLE I

WATER CONTENT OF BENZOYL CASEINS

Sample	NH_2-N, %[a]	Curve[b]	Water content[c] at relative humidity, % 5.9	11.8	31.4	50.9	75.1	83.6	93.3
1	0.93	A	159	227	465	660	981	1149	1441

[a] Moisture-free basis. [b] A = absorption, D = desorption, H = hysteresis. [c] g. H_2O/g. N × 1000.

The absolute magnitude of the hysteresis reaches an observed maximum of about 2.0 g. of water per 100 g. of protein at 51% R.H. This value is relatively large and wholly reproducible. The rapid approach of the 84% R.H. desorption isotherm to that of the 93% R.H. curve argues that the desorption curve would not be displaced

appreciably if desorption data from 100% R.H. were available. In our experience, reliable sorption data in the range 95–100% R.H. were difficult to obtain. The relative magnitude of the hysteresis is a maximum at the lowest humidity studied, where the hysteresis value is one half the amount absorbed. At intermediate humidities, the samples on desorption reach the same water content at relative humidities about 10–12% lower than on absorption. Speakman and Cooper[4] reported a comparable displacement of about 18% R.H. for wool.

The hysteresis values for the four samples are of similar magnitude, and, except for sample 1 at high humidities and sample 4 at low humidities, the variation is well within the experimental error (Table I), indicating that the amount of hysteresis is independent of the amino content of the sample and, therefore, cannot be due to the presence of the amino groups. This is in marked contrast to the high percentage of the water content held by the amino group both on absorption and desorption.

The nature of the hysteresis can be shown more clearly if the limiting desorption data for all four samples at the lower humidities are plotted (Fig. 2) against the absorption data. The data for the limiting curve of all four samples fall on a straight line with a slope of 1.12 and an extrapolated intercept of 0.059 (g. H_2O/g. N). This intercept is about half the magnitude of the maximum hysteresis obtained in these experiments. This would indicate that the water involved in the hysteresis consists of two types—a constant amount and a portion proportional to the amount absorbed.

The desorption data from 51% R.H., which do not approach the upper curve in Fig. 1 as rapidly as the higher humidity data, now become of particular importance. When these desorption values are plotted against the absorption values (Fig. 2), they fall on a straight line with a slope of 1.0 and an extrapolated intercept of 0.067 g. H_2O/g. N. The difference between these two slopes is statistically significant.

The intercept values appear to be associated with a type of water which is bound firmly at relatively low humidities. Its quantity is independent of the humidity from which the desorption is begun. The slope of 1.0 shows that it is the only type of water involved in the hysteresis, if desorptions are started from below about 60% relative humidity. This type of hysteresis has not been treated in any of the previous literature on the phenomenon.

The hysteresis indicated by the difference of the slope (Fig. 2) from 1.0 is associated with water absorbed above the upper break in the absorption curve, but it persists at the lower humidities, where it is proportional to the amount absorbed. Therefore, it might be attributed either to the capillary phenomena of Zsigmondy[6] and McBain[7] or to the swelling of the gel according to Urqu-

[6] Zsigmondy, *Z. anorg. Chem.*, **71**, 356 (1910).

[7] McBain, THIS JOURNAL, **57**, 699 (1935).

hart.[8] Smith[9] has recently proposed an extension of Urquhart's treatment, and applied it to cellulose, nylon and wool. However, our absorption and desorption data do not give the linear extrapolation characteristic of the approximate method of Smith. The excellent data of Wiegerink[10] on the sorption of wool give a curve of similar shape to that obtained from our data when plotted according to Smith; and it is quite possible that the protein gels require a more complicated swelling function than the simple weight function used by Smith. Moreover, several observations have been made which seem to indicate that the structure of casein is fairly open and most of the groups should be freely available to water vapor without swelling. The first of these is that even though the large benzoyl group has been introduced to modify the amino group there is apparently little disruption of the remainder of the molecule, as shown by the strict linearity of the absorption *versus* amino-content plots of the earlier paper.[3] This situation does not prevail in the cellulose–cellulose acetate system, where opening of the structure by intermediate degrees of acetylation is clearly demonstrable.[11] Secondly the lack of hysteresis in the absorption of the amino group indicates that no new amino groups are made available by swelling.

Summary

Desorption isotherms have been obtained for a number of benzoylated casein samples with various amounts of free amino groups.

A definite hysteresis in the sorption phenomena of about one-half the absorption value at 6% R.H. and about one-fifth at 50% R.H. was observed.

The hysteresis was independent of the content of free amino groups in the samples, although the amino group is responsible for one-fourth the water absorption in casein.

The hysteresis appears to be of two types: a constant hysteresis independent of the humidity from which desorption was started, and a hysteresis proportional to the amount absorbed and due only to absorption above the upper break in the absorption curve. This appears to be the first demonstration of the two-fold nature of the hysteresis phenomena.

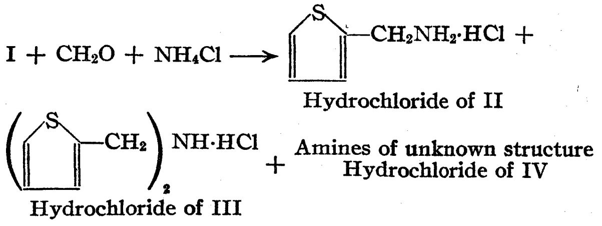
Aminomethylation of Thiophene. I. The Reaction of Thiophene with Formaldehyde and Ammonium Salts

BY HOWARD D. HARTOUGH, SIGMUND J. LUKASIEWICZ AND EVERETT H. MURRAY, JR.[1]

Recently the authors reported that thiophene possessed alpha hydrogens of sufficient reactivity to undergo a type of Mannich reaction.[2] At the same time Holdren and Hixon reported that the Mannich reaction had been extended to 2-methylfuran.[3] They also reported that only resinous products were obtained from the use of ammonium chloride with formaldehyde. Bachman and Heisey reported that pyrroles, azoles and their benzalogs which contain the —NH— group in the heterocyclic ring will undergo the Mannich reaction.[4]

The reaction of thiophene, I, with ammonium chloride and formaldehyde has been investigated and found to give a variety of products. Besides the formation of complex amines of unknown structure, IV, 2-thenylamine (2-aminomethylthiophene), II, and di-(2-thenyl)-amine, III, have been isolated.



The yields of II and III leave much to be desired and many unsuccessful attempts were made to improve the yields over those previously reported.[2] Lower yields were obtained when the reaction quantities were increased five-fold. Yields obtained from various molar ratios of reactants are listed in Table I.

TABLE I

EFFECT OF MOLAR CONCENTRATION ON YIELDS OF AMINES II, III AND IV

Moles of reactants				Weight % of total product

with thiophene in the same manner as ammonium chloride and formaldehyde.

In an effort to determine the molar ratios involved in the basic reaction, excess amounts of both ammonium chloride and thiophene were used with trioxymethylene and the unreacted portions recovered. Within reasonable limits the basic reaction was found to involve one mole of thiophene, one mole of ammonium chloride and two moles of formaldehyde. These observations are summarized in Table II.

TABLE II

DETERMINATION OF MOLAR RATIOS IN BASIC REACTION

Reactants used, moles			Reactants recov., moles			Mole ratio of basic reaction		
I	CH_2O	NH_4Cl	I	CH_2O	NH_4Cl	I	CH_2O	NH_4Cl
4	2	1	2.9	0	0	1.1	2	1
5	10	5	1.0	0	1.0	1	2.5	1
2	2	2	1.0	0	0.95	1	2	1
4	2	2	3.0	0	1.13	1	2	0.9

No successful degradation of polymeric amine IV types could be carried out by oxidation similar to the oxidation of polymers obtained from hydroxylamine, thiophene and formaldehyde.[5]

It is probable, however, that the polymeric linking takes place through the 2- and 5-positions. The structure of these polymeric materials will be discussed in later publications. The position of the —CH_2NH_2 group in the thenylamine was proven by oxidation of the 2-thenylamine to 2-thiophenecarboxylic acid.

No tri-(2-thenyl)-amine has been isolated. The failure to isolate this amine may be due to the fact that sub-resinous polymeric amines (IV) decompose to hard resinous masses at 180–210°. This is below the calculated boiling point of the tertiary amine under the reduced pressures used.

Blocking one of the reactive 2,5-positions in the thiophene nucleus leads to a somewhat less complicated reaction. 2-Methylthiophene reacts similarly to I in that the primary amine, 5-methyl-2-thenylamine (VI) as the hydrochloride, the secondary amine, di-(5-methyl-2-thenyl)-amine (VII) as the hydrochloride, are formed, along with a smaller amount of amines of unknown structure (X) as the hydrochloride. However, at 88° there were obtained appreciable amounts of the tertiary amine, tri-(5-methyl-2-thenyl)-amine (VIII) as the hydrochloride, and di-(5-methyl-2-thienyl)-methane (IX).

Not all the factors influencing this reaction are understood since it has been found that if the reaction is controlled at a lower temperature, 60–70°, less X is formed and VIII could not be isolated.

2-Chlorothiophene failed to react with aqueous formaldehyde and ammonium chloride but reacted with trioxymethylene and ammonium chloride to give di-(5-chloro-2-thenyl)-amine, XI. No other simple amine could be isolated and the reaction was complicated with amines of type IV.

A reaction with 2-*t*-butylthiophene, formaldehyde and ammonium chloride gave tri-(5-*t*-butyl-2-thenyl)-amine hydrochloride, XII. None of the secondary amine was isolated but a small amount of an unidentified product believed to be of type IV was obtained.

3-Methylthiophene was not investigated other than to determine that it reacted similarly to thiophene giving a series of amines including the sub-resinous type IV.

The alkylamine hydrochlorides have not been investigated to any great extent but in general they cause condensation of thiophene with aqueous formaldehyde. 2-Methylthiophene reacted with formaldehyde in the presence of dimethylamine hydrochloride to give a 45% yield of di-(5-methyl-2-thienyl)-methane, IX, along with higher polymers and a small amount of an unidentified amine containing sulfur. Similar reactions with thiophene gave high yields of polymers. Caesar and Sachanen reported that salts of weak bases and strong acids caused condensation of formaldehyde with thiophene thereby producing polymers.[6] No study has been made with polymeric formaldehyde and the alkylamine hydrochlorides and this may give the desired products rather than direct condensation of the formaldehyde and thiophene.

Superficially, at least, this reaction can be classified as a modified Mannich reaction. Although this reaction proceeds very readily with ammonium chloride to give the products listed above when alkylamine hydrochlorides are used it proceeds with reluctance and further investigation is needed to completely typify it.

Resins were obtained from the condensation of thiophene and formaldehyde with urea, ethylenediamine, and aniline (low yields) and with ammonium chloride. Morpholine hydrochloride caused no condensation with thiophene. A reaction occurred with thiourea but the oils obtained were so unstable and possessed such a stench that identification work was abandoned.

In general, when ammonium chloride is used, II, III, and IV are always obtained if the formaldehyde is used in amounts of two moles or less per mole of thiophene and ammonium chloride. Paraformaldehyde gave comparable results. For example, 11% II, 11% III, and 78% sub-resinous IV were obtained from a reaction involving 18 moles of thiophene, 18 moles of paraformaldehyde and 15 moles of ammonium chloride. II and III are not obtained when more than two moles of paraformaldehyde per mole of thiophene is used.

Ammonium chloride, ammonium bromide and, presumably, ammonium iodide undergo this reaction but other ammonium salts such as the acetate, phosphate, diacid phosphate, sulfate and acid sulfate do not react.

Experimental

Reaction of Thiophene, Aqueous Formaldehyde and Ammonium Chloride.—To a well-stirred mixture of 84

g. (1 mole) of thiophene and 162 g. (3 moles) of ammonium chloride was added 81 g. (1 mole) of 37% formaldehyde solution. After fifteen minutes heating at the reflux temperature, 72°, a yellow color appeared indicating the start of the reaction. The mixture was heated at reflux for one hour, cooled, the condenser inverted and the excess thiophene distilled off; 51 g. (0.63 mole) was recovered. The reaction mixture was then filtered to remove excess ammonium chloride, the filter washed with alcohol until colorless, the filtrate concentrated on the steam-bath to remove alcohol, cooled, made alkaline with 100 g. of 40% sodium hydroxide solution, and extracted three times with 50 ml. of benzene. The benzene was removed by distillation and the amines distilled *in vacuo;* 17.5 g. of 2-thenylamine, II, b. p. 82° at 17 mm.[7,8]; 7.0 g. di-(2-thenyl)-amine, III, b. p. 134–135° at 3 mm.; and 23 g. of sub-resinous amines, IV, were obtained. Refractionation of II and III through a 12-plate column to effect higher purity gave the following refractive indices; II, n^{20}D 1.5615; III, n^{20}D 1.6032. These products correspond to yields of 42% of II and 18.3% III based on the 0.37 mole of thiophene used in the reaction.

Anal. Calcd. for C_5H_7NS (II): N, 12.39. Found: N, 12.33. Calcd. for $C_{10}H_{11}NS_2$ (III): S, 30.62; N, 6.69. Found: S, 30.43; N, 6.65.

Analysis of typical samples of IV indicated that the nitrogen and sulfur ratios varied from 2:3 to 1:1.

II reacts rapidly with carbon dioxide in the air and a thin film on glass quickly forms a white solid, presumably the carbamate. II is soluble in water in all proportions but can be salted out conveniently with sodium chloride.

Oxidation of II with alkaline permanganate gave 2-thiophenecarboxylic acid, XIV, m. p. 129.5–130°. A mixed melting point with an authentic sample gave no depression.

The hydrochloride of II was prepared and crystallized from 20% hydrochloric acid solution by cooling in an ice-salt-bath; m. p. 188–189°.

Anal. Calcd. for C_5H_8ClNS: N, 9.30. Found: N, 9.30.

The hydrochloride of III was prepared and recrystallized from water; m. p. 252–253° with decomposition.

Anal. Calcd. for $C_{10}H_{12}ClNS_2$: S, 26.07; N, 5.66. Found: S, 25.59; N, 5.59.

The N-(2-thenyl)-N′-phenylthiourea, XV, was prepared by standard procedures from phenyl isothiocyanate and 2-thenylamine. After two recrystallizations from water and alcohol the product melted at 123.5–124°.[9]

Anal. Calcd. for $C_{12}H_{12}N_2S_2$: N, 11.28. Found: N, 11.36.

The di-(2-thenyl)-amine did not give a crystalline derivative with phenyl isothiocyanate.

The N-(2-thenyl)-benzamide, XVI, was prepared according to standard procedures, from II and benzoyl chloride; m. p. 121–122°.

Anal. Calcd. for $C_{12}H_{11}NOS$: N, 6.4. Found: N, 6.3.

The N-(2-thenyl)-stearamide, XVII, was prepared by refluxing 20 g. (0.177 mole) of 2-thenylamine and 50 g. (0.177 mole) of stearic acid in 200 ml. of xylene until 2.5 ml. (3.5 ml. calcd.) of water was collected in a water trap. After cooling, the white crystalline XVII was filtered off and recrystallized twice from benzene; 42 g. (67% yield), m. p. 92.5–93°.

Anal. Calcd. for $C_{23}H_{41}NOS$: N, 3.7. Found: N, 3.9.

Preparation of N-(2-Thenyl)-phthalimide, XVIII, and N,N′-Di-(2-thenyl)-phthalamide, XIX.—A mixture of 22 g. (0.2 mole) of 2-thenylamine and 14.8 g. (0.1 mole) of phthalic anhydride in 100 ml. of xylene was refluxed until 1.4 ml. (1.8 ml. calcd.) of water was collected in the water trap. Upon cooling 20 g. of XIX was filtered off, washed with cold benzene, and recrystallized twice from benzene, m. p. 169–169.5°. Removal of the xylene yielded 9 g. of XVIII, which after two recrystallizations from alcohol melted at 126–127°.

Anal. Calcd. for $C_{13}H_9NO_2S$ (XVIII): N, 5.76. Found: N, 5.65. Calcd. for $C_{18}H_{16}N_2O_2S_2$ (XIX): N, 7.81. Found: N, 7.86.

Preparation of N-(2-Thenyl)-urea, XX, and N,N′-Di-(2-thenyl)-urea, XXI.—A mixture of 20 g. (0.177 mole) of 2-thenylamine, 50 ml. of water, 17.6 g. of concentrated hydrochloric acid, and 12 g. (0.20 mole) of urea was heated at reflux for nine hours at the reflux temperature, 106°. The hot aqueous solution was decanted from the bottom organic layer (8 g., XXI), and 15 g. of XX was obtained by crystallization from the water solution. XX was purified by three treatments with decolorizing charcoal and recrystallization from hot water; m. p. 129.5–130.5°. XXI was purified by digesting once with water and three recrystallizations from hot alcohol; m. p. 164–165°.

Anal. Calcd. for $C_6H_8N_2OS$ (XX): N, 17.95; S, 20.51. Found: N, 17.45; S, 20.66. Calcd. for $C_{11}H_{12}N_2OS_2$ (XXI): N, 11.11; S, 25.39. Found: N, 11.01; S, 25.21.

The Reaction of Thiophene, Hexamethylenetetramine and Hydrochloric Acid.—To a well-stirred mixture of 168 g. (2 moles) of thiophene and 70 g. (0.5 mole) of hexamethylenetetramine was added 200 g. of hydrochloric acid (36%) over a period of forty minutes. After addition of the acid the mixture was maintained at a reflux temperature of 76–80° for one hour. The procedure from this point follows that previously described. Thirty-three grams of 2-thenylamine, II (identity established by mixed melting point of the N-(2-thenyl)-N′-phenylthiourea), 16 g. of di-(2-thenyl)-amine, III, and 100 g. of sub-resinous amine, IV, were obtained.

The Reaction of Thiophene, Formaldehyde and Ammonium Chloride.—To a mixture of 18 moles (1312 g.) of thiophene and 15 moles (803 g.) of ammonium chloride was added 18 moles (1460 g.) of 36% formaldehyde. The mixture was heated slowly over a two-hour period to 72° whereupon the reaction became vigorous and was controlled by means of an ice-bath. After twenty minutes the reaction was completed. The reaction mixture was cooled, 12 moles of sodium hydroxide as a 40% aqueous solution was added, the salt filtered off by suction, the oil layer decanted from the filtrate, the filter washed with thiophene (or benzene) and the filtrate extracted once with thiophene. The thiophene, I, was recovered by distillation and 123 g. of II, 97 g. of III, and 660 g. of IV were obtained.

Reaction of Thiophene, Urea and Hydrochloric Acid.—To a cooled mixture of 30 g. (0.5 mole) of urea, 42 g. (0.5 mole) of thiophene and 41 g. (0.5 mole) of formaldehyde (36%) was slowly added 50 g. of concentrated hydrochloric acid. A white solid material began to form immediately. The reaction mixture was heated to reflux for six hours, cooled, the resin washed with water, dilute sodium hydroxide, and then digested with hot water. The resin, 93 g., analyzed as follows: S, 14.2; N, 20.6.

Reaction of Thiophene, Formaldehyde and Ethylenediamine Dihydrochloride.—To 30 g. (0.5 mole) of ethylenediamine, cooled in an ice-bath, was added 100 g. of concentrated hydrochloric acid. To this dihydrochloride of ethylenediamine was added 84 g. (1 mole) of thiophene and 83 g. (1 mole) of formaldehyde (36%) and the mixture was refluxed for two hours at 75°. After cooling, the resinous material was washed with hot water several times, dried in an oven and analyzed (S, 19.0; N, 5.98).

Reaction of 2-Methylthiophene, Formaldehyde and Ammonium Chloride. Procedure A.—To a well-stirred mixture of 196 g. (2 moles) of 2-methylthiophene and 161 g. (3 moles) of ammonium chloride was added 162 g.

(8) Putokhin and Egorova, *J. Chem. Soc.* (*U.S.S.R.*), **10**, 1873 (1940); *C. A.*, **35**, 4377 (1941), gave b. p. of 88° at 26 mm., 77° at 16 mm.; n^{15}D 1.5678; d^{15}_4 1.1370.

(9) v. Braun, Fussgänger and Kühn, *Ann.*, **445**, 218 (1925), prepared this compound from the reaction of 2-thenyl isothiocyanate with aniline, m. p. 123°.

(2 moles) of formaldehyde (36%). The mixture was warmed to 40° where the reaction started and the temperature rose to 87° without further heating. When the rate of reaction decreased sufficiently the mixture was heated at the reflux temperature (85°) an additional thirty minutes, cooled, 200 ml. of benzene added, and the reaction mixture neutralized with 40% sodium hydroxide solution. After three more extractions with 100 ml. of benzene, the benzene was removed by distillation and the products fractionated under reduced pressure to yield 21 g. of 5-methyl-2-thenylamine, VI, b. p. 68–69° at 4 mm., $n^{20}\text{D}$ 1.5518; 21 g. of di-(5-methyl-2-thienyl)-methane, IX, b. p. 135–136° at 4 mm.; 39 g. of di-(5-methyl-2-thenyl)-amine, VII, b. p. 161–162° at 4 mm., $n^{20}\text{D}$ 1.5832; 32 g. of tri-(5-methyl-2-thenyl)-amine, VIII, b. p. 207–214° at 3 mm., m. p. 81–81.5°; and 83 g. of residue X. Extraction of the residue with boiling alcohol yielded an additional 10 g. of VIII.

Anal. Calcd. for $C_{12}H_{15}NS_2$, VII: S, 27.00; N, 5.91. Found: S, 27.03; N, 5.98.

Anal. Calcd. for $C_{18}H_{21}NS_3$, VIII: S, 27.68; N, 4.01. Found: S, 27.73; N, 4.04.

Anal. Calcd. for $C_{11}H_{12}S_2$, IX: S, 30.7. Found: S, 30.4.

The N-(5-methyl-2-thenyl)-N′-phenylthiourea, XXII, was prepared in order to properly identify VI since it picked up carbon dioxide from the air too rapidly to obtain good analyses. XXII melted at 133–134°.

Anal. Calcd. for $C_{13}H_{14}N_2S_2$, XXII: N, 10.69. Found: N, 10.45.

While VII appeared to form a thiourea derivative with phenyl isothiocyanate, no crystalline product could be obtained.

Procedure B.—To a well-stirred mixture of 490 g. (5 moles) of 2-methylthiophene and 535 g. (5 moles) of ammonium chloride was added 425 g. (5 moles) of 36% formaldehyde. The mixture was warmed to 40°, the heat was discontinued and the temperature controlled at 60–70° by means of an ice-bath. Crystals began to form and within a few minutes a slurry developed which became very hard to stir. After thirty minutes the ice-bath was no longer necessary and the reaction mixture was stirred an additional one and one-half hours. After cooling to 10° the mixture was filtered, the precipitate washed with benzene and recrystallized from six liters of water to yield 379 g. (56% yield) of di-(5-methyl-2-thenyl)-amine hydrochloride, XXIII, m. p. 216–217° with decomposition.

Anal. Calcd. for $C_{12}H_{16}ClNS_2$ (XXIII): S, 23.40; N, 5.12. Found: S, 23.54; N, 5.36.

The filtrate contained the benzene layer which upon evaporation yielded 82 g. of IX. A water and benzene insoluble oil, 66 g. XA, was not identified. It contained 16.3% S and 4.1% N, which cannot be reconciled with any simple structure. Neutralization of the water layer with sodium hydroxide followed by extraction of the products gave 15 g. of VI, and 109 g. of a light red viscous oil, XB (analysis showed S, 22.98; N, 7.87). Only a trace of VIII could be extracted from XB with hot alcohol.

Reaction of 2-Chlorothiophene, Paraformaldehyde and Ammonium Chloride.—To 119 g. (1 mole) of 2-chlorothiophene was added 30 g. (1 mole) of paraformaldehyde, 54 g. (1 mole) of ammonium chloride and 10 ml. of acetic acid. The mixture was heated with stirring at 85–90° for one and one-half hours, cooled, 50 ml. of water added and 34 g. of di-(5-chloro-2-thenyl)-amine hydrochloride, XI, was filtered off. After digesting twice in 700 ml. of hot water the product melted at 240–242° with decomposition.

Anal. Calcd. for $C_{10}H_{10}Cl_3NS_2$: S, 20.35; N, 4.45. Found: S, 20.30; N, 4.72.

The filtrate was neutralized with 40% sodium hydroxide solution, extracted three times with 50 ml. of benzene, the extracts combined, and upon evaporation of the solvent 19 g. of a viscous red oil was obtained (*Anal.* Found: S, 17.9; N, 5.04). This product reacted with phenyl isothiocyanate but no crystalline products could be obtained.

Reaction of 2-*t*-Butylthiophene, Formaldehyde and Ammonium Chloride.—To a mixture of 276 g. (2 moles) of 2-*t*-butylthiophene[10] and 161.5 g. (3 moles) of ammonium chloride heated to 75° was added 84 g. (1 mole) of formaldehyde (36%) over a period of thirty minutes. The mixture was heated at 85–90° for one hour, cooled and the organic layer separated. Upon dilution of the organic layer with petroleum ether 14 g. of XII separated out and was recrystallized from alcohol; m. p. 204–206° with decomposition. Recovery of 2-*t*-butylthiophene by distillation yielded an additional 44 g. of tri-(5-*t*-butyl-2-thenyl)-amine hydrochloride, XII, as a residue.

Anal. Calcd. for $C_{27}H_{40}ClNS_3$: S, 19.20; N, 2.81. Found: S, 18.94; N, 2.83.

Neutralization of the water layer with 40% sodium hydroxide solution followed by extraction with benzene yielded 4.5 g. of light yellow oil (*Anal.* Found: S, 15.9; N, 8.5).

Acknowledgments.—The authors wish to thank Dr. D. E. Badertscher for his advice and interest in this problem and Mrs. Josephine Sindoni Piel and Miss Loretta G. Conley for technical assistance.

Summary

Thiophene, formaldehyde and ammonium salts have been found to undergo a type of Mannich reaction to yield 2-thenylamine (2-aminomethylthiophene), di-(2-thenyl)-amine, and polymeric amines of unknown structure.

With 2-methylthiophene, formaldehyde, and ammonium chloride, 5-methyl-2-thenylamine, di-(5-methyl-2-thenyl)-amine, tri-(5-methyl-2-thenyl)-amine, two complex amines of unknown structure, and di-(5-methyl-2-thienyl)-methane have been isolated.

2-Chlorothiophene and 2-*t*-butylthiophene reacted to give both simple and complex amines.

The alkylamine hydrochlorides such as dimethylamine hydrochloride do not react in a similar manner to ammonium chloride. While unidentified amines were formed the major reaction is a coupling action of formaldehyde with thiophene forming polymers containing no nitrogen.

In addition to sixteen new aminomethyl derivatives of thiophene, N-thenylstearamide, -benzamide, -phthalamide, -phthalimide, N-(2-thenyl)-urea, di-N,N′-(2-thenyl)-urea, N-(2-thenyl)-N′-phenylthiourea and N-(5-methyl -2′-thenyl)-N′-phenylthiourea have been prepared and characterized.

The Preparation and Some Reactions of Ethyl α-Acetamidoacetoacetate

BY N. F. ALBERTSON, B. F. TULLAR, J. A. KING,[1] B. B. FISHBURN AND S. ARCHER

During the course of our investigations on useful intermediates for amino acid synthesis, we had occasion to prepare and study ethyl α-acetamidoacetoacetate, II. This compound was prepared in quantitative yield by reduction of ethyl α-oximinoacetoacetate, I, in acetic acid–acetic anhydride solution in the presence of a palladium–charcoal catalyst. Zinc dust reduction of I in the same solvent gave 79% of the theoretical yield of II, m. p. 47°.

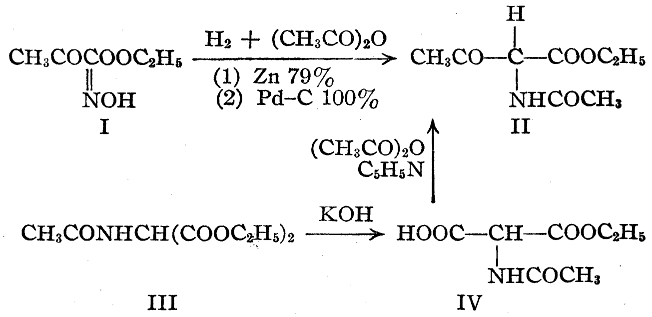
Cerchez and Colesiu[2] reported the preparation of II, m. p. 141°, by reduction of the acetate of I with aluminum amalgam. In view of the discrepancy in melting points we attempted to repeat this work, but were unable to obtain a substance whose properties corresponded with those of the one described. Aluminum amalgam reduction of acetyloximinoacetoacetic ester in the presence of moist ether gave 2,5-dimethyl-3,6-dicarbethoxypyrazine when the suggested method[3] of Cerchez and Colesiu[2] was followed. However, simultaneous addition of acetic anhydride and water to the reaction mixture gave II.[4]

Convincing proof that this low-melting solid, II, was indeed ethyl α-acetamidoacetoacetate was furnished by a fourth method of synthesis. Ethyl acetamidomalonate (III) was saponified to its half-ester with one equivalent of potassium hydroxide. The ester, IV, was then treated with acetic anhydride in the presence of pyridine according to the method of Dakin[5] for converting amino acids to acetamido ketones. The desired compound was obtained as a crystalline solid identical in all respects with the compound obtained in the other preparations. The reactions involved are given in the scheme.

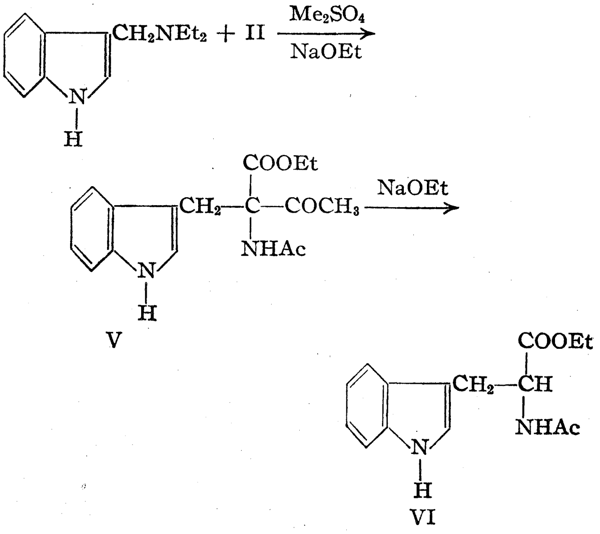
For the preparation of larger quantities of the ester, II, a method was employed whereby the isolation of the oximino-ester, I, was avoided. Aside from possessing the obvious advantage of eliminating several manipulations, the procedure is safer since it obviates the necessity of isolating the oxime. In one experiment the oxime, I, decomposed with explosive violence while being heated on the steam-bath to remove the last traces of solvent. It was possible to obtain II in 70% of the theoretical yield based on ethyl acetoacetate by following the zinc dust reduction procedure described in the experimental part.

The zinc dust method of reduction was also applied to the preparation of α-propionamidoacetoacetic ester.

When the acetamido ester, II was alkylated



with diethylaminomethylindole methosulfate under conditions similar to those used with ethyl acetamidomalonate and gramine[6] the alkylation product, V, was isolated in 83% yield. However,



when there was a delay in adding the dimethyl sulfate to the reaction mixture, no ester, V, could be obtained. When α-acetamidoacetoacetate was warmed with an alcoholic solution of sodium ethylate it cleaved into ethyl acetate and aceturic ester. It was found that V also underwent the same type of cleavage to give N-acetyl tryptophan ethyl ester, VI. This compound was also prepared from ethyl (3-indolylmethyl)-acetamidomalonate for purposes of comparison. Attempts to alkylate

II with benzyl chloride resulted only in cleavage to aceturic ester even when the sodium ethylate was added to the other reactants. Similar cleavage reactions have been observed with other substituted keto-esters.[7]

The behavior of ethyl α-acetamidoacetoacetate on catalytic reduction was examined, since Adkins and Reeve[8] reported that on reduction and subsequent hydrolysis ethyl O-ethyloximinoacetoacetate yielded a mixture of *dl*-threonine and *dl-allo*-threonine which was separated into its diastereomeric components by fractional crystallization from water and ethanol.

It was possible to reduce II in the presence of either Raney nickel or Adams catalyst so that hydrolysis of the intermediate hydroxy-ester led to a mixture of amino acids of approximately the same proportions of threonine and *allo*-threonine in each case. The fractional crystallization method of Adkins was used to separate the mixture into a more soluble fraction, m. p. 225–228°, and a less soluble fraction, m. p. 245–246°. The latter was largely *dl-allo*-threonine, since on benzoylation it gave a monobenzoyl derivative identical with that reported by Carter.[9] Some threonine could be separated from the soluble fraction by benzoylating and using β-phenethylamine according to the procedure of Carter,[10] but more than 75% of the crude hydrolysis mixture was recovered as substantially pure *dl-allo*-threonine. This method is a convenient one for preparing *dl-allo*-threonine since it is possible to obtain over-all yields of 43% based on ethyl acetoacetate via the catalytic reduction route and 41% by the somewhat shorter chemical reduction method.

Experimental[11]

Ethyl α-Oximinoacetoacetate (I).—The procedure of Adkins and Reeve[6] gave 75% yield when petroleum ether (b. p. 60–90°) was added to the toluene to decrease the solubility of the product.

Ethyl α-Acetamidoacetoacetate (II). A. Catalytic Reduction of Ethyl α-Oximinoacetoacetate.—One-tenth mole of ethyl α-oximinoacetoacetate was dissolved in a mixture of 50 ml. of acetic anhydride and 150 ml. of acetic acid, 1 g. of 5% palladium–charcoal catalyst[12] added and the mixture subjected to hydrogenation at 50 lb. pressure. After ninety minutes at room temperature the theoretical amount of hydrogen was absorbed. The catalyst and solvent were removed and the residual oil was triturated with petroleum ether (b. p. 60–90°). The crystalline solid thus obtained weighed 18.7 g. (yield quantitative). On crystallization from toluene at −15° it melted at 41–42°.

Anal. Calcd. for $C_8H_{13}NO_4$: N, 7.48. Found: N, 7.35.

When treated with 2,4-dinitrophenylhydrazine the ester yielded a yellow crystalline solid which melted at 199–200° after crystallization from ethanol. Analysis indicated that the derivative was a pyrazolone.

Anal. Calcd. for $C_{12}H_{11}N_5O_6$: N_{total}, 21.80: N_{NO_2}, 8.72. Found: N_{total}, 22.06; N_{NO_2}, 8.96 (by $TiCl_3$ reduction).

B. Reduction of Ethyl α-Oximinoacetoacetate with Zinc Dust.—To a cooled, well-stirred solution of 159 g. of ethyl α-oximinoacetoacetate in 250 ml. of acetic anhydride and 750 ml. of acetic acid, 275 g. of zinc dust was added portionwise during the course of thirty minutes. The temperature was kept at 40° by the addition of the metal. The suspension was stirred for an additional ten minutes and then 750 ml. of water was added at such a rate that the temperature remained at 40°. After stirring for an additional two hours the mixture was filtered and the filter cake washed with two 250-ml. portions of water. The filtrate was extracted with five 250-ml. portions of chloroform and the organic layer then washed with two 200-ml. portions of water. The chloroform was removed by distillation at 30 mm. pressure and the residue triturated with petroleum ether (b. p. 60–90°). The oil crystallized on cooling. The crystals were filtered and air dried, yield, 148 g., 79%, m. p. 47–49°. The dinitrophenylhydrazine derivative melted at 196–197°, undepressed on admixture with the sample prepared above.

C. From Ethyl Acetoacetate Directly.—The oximation of 64 ml. (0.5 mole) of ethyl acetoacetate was carried out according to the method of Adkins and Reeve[8] except that the mixture was not diluted with water. Instead 125 g. of ice and 100 ml. of acetic anhydride were added and the mixture was cooled in an ice-bath. During the course of one hour 125 g. of ice, 50 ml. of acetic anhydride and 65 g. of zinc dust were added to the stirred mixture, while the temperature was maintained below 20°. The product was isolated as in the previous experiment. The yield was 54–59% of the theoretical. When the amount of zinc was increased to 150 g., the yield increased to 71%. The product when recrystallized from acetone or ether melted at 47–49° and was identical with the compounds prepared by methods A or B.

D. From Ethyl Acetamidomalonate.—The ester, IV, was prepared by allowing a solution of 0.1 mole of ethyl-acetamidomalonate, 0.1 mole of potassium hydroxide in 50 ml. of water and 125 ml. of alcohol to stand for two days. The solvent was then removed, the residue partitioned between 50 ml. of chloroform and 20 ml. of water and the aqueous phase acidified with hydrochloric acid. The solid was collected on a filter, washed with ice water and air dried, m. p. 126–128° (d.).

Anal. Calcd. for $C_7H_{11}O_5N$: N, 7.40. Found: N, 7.15.

Nine and one-half grams of the above acid ester, IV, were slowly added to a mixture of 25 ml. of pyridine and 37 ml. of acetic anhydride with swirling. There was a yellow color produced immediately and carbon dioxide was evolved. The solution was allowed to stand overnight at room temperature and was then diluted with ice. The solvents were removed *in vacuo* to leave 9.2 g. of oil. This was distilled giving 6 g. of product boiling at 93–98° at approximately 1 mm. This product, m. p. 47°, was identical with the samples previously prepared.

When the pyridine and acetic anhydride were distilled from the reaction mixture without prior addition of ice the N-diacetylated compound was obtained as an oil. This gave the same derivative with 2,4-dinitrophenylhydrazine as the monoacetylated compound and could be converted to the monoacetylated compound by warming with sodium bicarbonate.

E. By Aluminum Amalgam Reduction.—Ten and three-tenths grams of Baker aluminum foil was amalgamated by the method of Vogel[13] and covered with 350 ml. of ether. A solution of 34.2 g. of acetyloximinoacetoacetic ester[2] and 35 ml. of acetic anhydride in 50 ml. of ether was dropped in over a ten minute period with simultaneous addition of 6 ml. of water. Two hours later an additional 10 ml. of water was added and the reaction allowed to

(13) Vogel, *J. Chem. Soc.*, 597 (1927).

stand overnight. It was then filtered and the insoluble material washed with ether. When several milliliters of the ether solution were shaken with an aqueous solution of ferric chloride the aqueous layer was colored a deep reddish purple color similar to that obtained with acetamidoacetoacetic ester prepared by the preceding methods.

The ether layer was dried and concentrated to give 17.7 g. of light orange oil. This gave a derivative with 2,4-dinitrophenylhydrazine melting at 201–202.5° and not depressed when mixed with the pyrazolone obtained from acetamidoacetoacetic ester. Nearly all of the oil distilled at 103–106° at 1 mm. and readily crystallized on cooling. It did not depress the m. p. of acetamidoacetoacetic ester prepared by other methods.

When the acetic anhydride was omitted in the above reaction no color with ferric chloride could be obtained and the only product which could be isolated was 2,5-dimethyl-3,6-dicarbethoxypyrazine. When five times as much aluminum was used and no acetic anhydride added, a small amount of *allo*-threonine (m. p. 249° after two recrystallizations from aqueous acetone) separated from the ether solution.

Ethyl α-Propionamidoacetoacetate.—Zinc dust reduction of α-oximinoacetoacetate in the presence of propionic acid and propionic anhydride gave α-propionamidoacetoacetate, m. p. 57° from acetone; b. p. 101–103° at slightly less than 1 mm.

Anal. Calcd. for $C_9H_{15}NO_4$: N, 6.96. Found: N, 7.14.

Ethyl α-Acetamido-α-(3-indolylmethyl)-acetoacetate (V).—To a solution of 0.58 g. of sodium in 50 ml. of absolute alcohol there were added in the order indicated 4.7 g. of ethyl α-acetamidoacetoacetate, 5.1 g. of diethylaminomethylindole and 4.7 ml. of methyl sulfate. The clear solution was warmed on a steam-bath and allowed to stand overnight. It was poured onto dilute acetic acid and the separated solid collected and air-dried, yield, 6.5 g. (83%), m. p. 152–154.5°. Crystallization from dilute ethanol raised the m. p. to 156–159°.

Anal. Calcd. for $C_{17}H_{10}O_4N_2$: N, 8.86. Found: N, 9.06.

Ethyl Aceturate.—To a solution of 1.6 g. of sodium in 40 ml. of ethanol was added 12.5 g. of acetamidoacetoacetic ester. The solution was warmed on a steam-bath. A precipitate started to form within several minutes and the solution darkened in color. After one hour the solution (strong odor of ethyl acetate) was poured onto crushed ice containing some acetic acid and the resulting solution extracted with chloroform. The product was distilled at 92–95° at about 0.5–1 mm. It melted at 44.5–47.5° (lit.[14] b. p. (2 mm.) 106°, m. p. 48°).

N-Acetyl-*dl*-tryptophan Ethyl Ester. (VI). A. From Ethyl Acetamido-(3-indolylmethyl)-malonate.—A mixture of 19.6 g. of ethyl acetamido-3-indolylmethylmalonate, 60 ml. of ethanol, 60 ml. of water and 3.2 g. of potassium hydroxide was allowed to stand at room temperature for two days. It was then concentrated *in vacuo* and partitioned between water (50 ml.) and chloroform. The water layer was acidified with 5 ml. of concentrated hydrochloric acid and the malonic acid collected and washed with water. It was decarboxylated at 160° and the residue taken up in chloroform and washed with 10% sodium carbonate solution and water. Removal of the chloroform gave crystals melting at 128–130°. Recrystallization from aqueous ethanol raised the m. p. to 133.5–135.5°.

Anal. Calcd. for $C_{15}H_{18}N_2O_3$: N, 10.21. Found: N, 10.20.

B. **From Ethyl α-Acetamido-α-(3-indolylmethyl)-acetoacetate.**—This reaction was similar to the preparation of aceturic ester except that the reaction mixture was refluxed for six hours and the product isolated by pouring onto ice and acetic acid and filtering. It proved to be identical with product "A" above.

dl-allo-**Threonine. A. Reduction with Raney Nickel Catalyst.**—A quantity of 319 g. of ethyl α-acetamidoacetoacetate in 500 ml. of alcohol was reduced at 1000 lb. pressure in the presence of approximately 10 g. of Raney nickel catalyst. The temperature rose to 68° in the course of the reaction, which was complete in ninety minutes. The catalyst was filtered off (filter-cel) and the solvent removed by distillation at 30 mm. pressure. There remained 315 g. of a colorless, viscous oil, $n^{25}D$ 1.4625. Concentrated hydrochloric acid (800 ml.) was added to this hydroxy ester and the mixture was heated under reflux for three and one-half hours before being concentrated to dryness *in vacuo*. One hundred milliliters of water was added and the mixture taken to dryness again. The crude mixture of hydrochlorides was dissolved in 300 ml. of water in which 70 g. of sodium hydroxide had been dissolved. The solution was made faintly acid to litmus with acetic acid, cooled to 10° and then filtered to yield 85 g. of crude *dl-allo*-threonine, m. p. 245–246°. The mother liquor was diluted with 500 ml. of alcohol and then set in ice for several hours. The crystals that separated were collected on a filter and dried, wt. 70 g., m. p. 225–228°.

The more soluble fraction was then taken up in 150 ml. of hot water, filtered (charcoal) and diluted with 200 ml. of alcohol. On cooling 14 g. more of the *allo* isomer, m. p. 245–248°, separated. The filtrate from this crop was concentrated to dryness and the crystallization repeated several times more. In this way it was possible to obtain a total of 40 g. of the higher-melting compound from the original, more soluble fraction. The crude crops were combined and recrystallized from aqueous ethanol to yield 117 g. of *dl-allo*-threonine, m. p. 251–252° (yield, 58%).

No *dl*-threonine could be isolated directly from the low-melting residue.

In another experiment the low-melting solid from the initial separation was benzoylated according to Carter's method.[9] The crude monobenzoate, m. p. 159–165°, was crystallized several times to raise the m. p. to 172–174°. The substance did not depress the m. p. of an authentic specimen of monobenzoyl-*dl-allo*-threonine. A sample of *dl*-threonine gave a monobenzoate, m. p. 147°, in agreement with the value reported by Carter.

B. **Reduction with Adams Catalyst.**—When 18.7 g. of ethyl α-acetamidoacetoacetate in 100 ml. of acetic acid was reduced in the presence of 0.3 g. of Adams catalyst, the theoretical amount of hydrogen was absorbed in six hours at room temperature. Removal of the catalyst and evaporation of the solvent left 18.9 g. of the hydroxy ester, $n^{25}D$ 1.4625. Hydrolysis and crystallization by the procedure described above gave 6.9 g. (55%) of pure *dl-allo*-threonine, m. p. 251–252°.

Summary

1. Ethyl α-acetamidoacetoacetate was prepared from ethyl α-oximinoacetoacetate by (a) reduction with hydrogen in the presence of palladium on charcoal in acetic acid–acetic anhydride solution, (b) reduction with zinc dust in acetic acid–acetic anhydride solution, and (c) reduction with aluminum amalgam in the presence of acetic anhydride. In addition it was prepared directly from acetoacetic ester and also from ethyl hydrogen acetamidomalonate by reaction with pyridine and acetic anhydride.

2. Alkylation of ethyl α-acetamidoacetoacetate with diethylaminomethylindole methosulfate gave ethyl α-acetamido-α-(3-indolylmethyl)-acetoacetate. Attempted alkylation with benzyl chloride resulted only in the formation of aceturic ester which was also produced when ethyl α-acetamidoacetoacetate was treated with sodium ethylate.

---

[14] Cherbuliez and Plattner, *Helv. chim. acta*, **12**, 320 (1929).

3. Reduction of ethyl α-acetamidoacetoacetate with either Raney nickel or Adams catalyst afforded, after hydrolysis, *dl-allo*-threonine in 55–58% yield. No *dl*-threonine could be isolated directly.

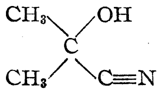
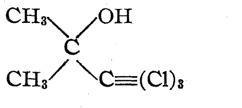
[Contribution from the Grosvenor Laboratory]

The Synthesis of α-Alkoxyisobutyric Acids and Alkyl Methacrylates from Acetonechloroform

By Ch. Weizmann, M. Sulzbacher and E. Bergmann

From the similarity of acetonecyanohydrin and acetonechloroform the latter appears a possible





starting material for the preparation of α-hydroxy-isobutyric and methacrylic acid. Equally, its analogs and homologs could be used for the synthesis of the analogs and homologs of these acids.

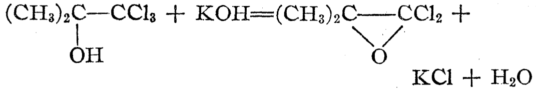
Literature data regarding the hydrolysis of acetonechloroform and similar compounds are scanty and contradictory: the formation of α-hydroxy-,[1] α-chloro-isobutyric acid and methacrylic acid,[2] *e. g.*, has been observed from acetonechloroform,[3,4] but most of the latter suffers undefined decomposition to acetone, carbon monoxide, phosgene and formic acid.[5]

When acetonechloroform is treated with a solution of four moles of potassium hydroxide or sodium butoxide in *butyl alcohol* at 0°, a vigorous reaction takes place; the alkaline reaction disappears, potassium (or sodium) chloride precipitates in the expected quantity, and the salt of a monobasic acid $C_8H_{16}O_3$ is formed which was identified as *α-butoxy-isobutyric acid.* Every alcohol investigated has given the same reaction which can be formulated as

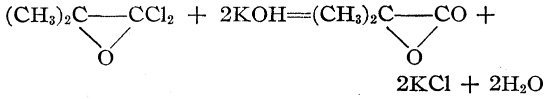
$$(CH_3)_2C(OH)CCl_3 + 4KOH + ROH = (CH_3)_2C(OR)COOK + 3KCl + 3H_2O$$

As it is surprising that under these conditions a tertiary alcoholic hydroxyl group should be alkylated, the following mechanism is suggested

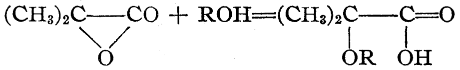
(A)



(B)

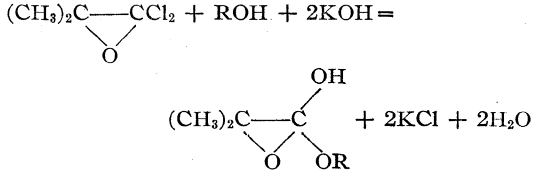


(C)

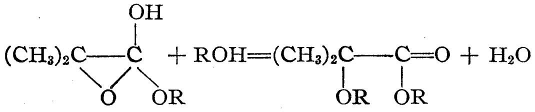


Analogously, the product of step (A) can be attacked by the alcohol ROH

(B′)

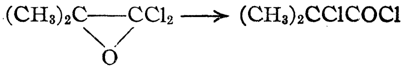


(C′)



Such esters, indeed, in which the alkyl radicals of the ester and of the ether group are identical, have been observed as by-products.[6]

The intermediary formation of an ethylene oxide from such trichlorinated alcohols and alkaline reagents has already been assumed by Jozicz[4] in order to explain the formation of α-chloroacids in the hydrolysis; this would be due to a pinacolonic re-arrangement, *e. g.*



One might be tempted to assume that the α-alkoxy acids in the above synthesis are formed through the intermediate of these α-chloroacids; however, the high yields obtained would imply that the rearrangement proceeds almost quantitatively, which is unlikely. Moreover, one would rather expect α-chloroacids of such structure to give the corresponding unsaturated acids, upon treatment with alcoholic potassium hydroxide. Methyl methacrylate does not add alcohols under the experimental conditions employed here.

That the acids obtained are actually the α- and not the isomeric β-alkoxy-compounds, can be

(3) The observations of Thomas and Oxley (British Patent 505,103 (1937) *C. A.* **33**, 7821 (1939)) could not be confirmed; they are theoretically most unlikely.

(4) Trichloromethyl-phenylcarbinol: Jozicz, *Chem. Zentrl.*, **68**, I, 1013 (1897). Rapson, Saunder and Stewart, *J. Chem. Soc.*, **74** (1944). It is doubtful whether the trichloromethylisopropylcarbinol studied by Jozicz actually had that structure; see Howard, This Journal, **49**, 1068 (1927).

(5) Compare Bressanin and Segre, *Gazz. chim. ital.*, **41**, I, 671 (1911). See also Peser, *C. A.*, **42**, 514 (1948).

(6) The opening of lactone rings by alcohols to form alkoxy acids is not without analogies. See F. E. Küng, U. S. Patent 2,352,641 (*C. A.*, **38**, 5500 (1944)). We owe this observation to one of the Referees. Compare also Aston and Greesburg, This Journal, **62**, 2590 (1940).

concluded from the observation that trichloromethylphenylcarbinol gives α-alkoxyphenylacetic acids. In this case, no β-alkoxylation is possible.

Primary alcohols give higher yields in alkoxyacids than secondary, secondary higher ones than tertiary alcohols in the reaction with acetonechloroform. The reaction is, also, not specific for acetonechloroform, but is applicable to its homologs and analogs. A number of examples are given in the Experimental Part.

"De-alkoxylation" of the α-alkoxyisobutyric acids to methacrylic acid is best carried out by heating the esters with the equivalent amount of phosphorus pentoxide. Oxalic acid and zinc chloride cause the same transformation with a lower rate of conversion and somewhat lower yield. Heating with anilinium hydrobromide is without effect on the alkoxyesters. Heating with alcoholic sulfuric acid also causes de-alkoxylation; therefore, frequently in the esterification of the alkoxyacids, some alkyl methacrylate is formed, and its quantity increases with increasing stringency of the conditions of esterification. The alkoxyacids containing secondary alkyl radicals are more easily converted into unsaturated compounds, and in the case of *t*-alkyl compounds, no alkoxy ester has been isolated from the esterification with alcoholic sulfuric acid.

The alkoxyacids are fairly stable; they are viscous liquids which can be characterized by crystalline derivatives, *e. g.*, the phenylhydrazides. Amides are best prepared from the esters; thus α-methoxyisobutyr-(β-hydroxyethyl)-amide was synthetized. An attempt to prepare the acid chlorides in pure state failed; however, the crude chlorides, obtained by means of thionyl chloride, can be used for the preparation of such substances as *phenyl α-butyoxyisobutyrate;* in this reaction, however, and still more in the preparation of phenyl α-isobutyoxyisobutyrate, substantial quantities of phenyl methacrylate were formed. This is somewhat surprising as the α-acyloxyisobutyric acids can easily be converted into the corresponding acid chlorides.[7]

An interesting parallel to our reaction is to be seen in the observation by Banti[8] that in presence of alcoholic potassium hydroxide solution, acetonechloroform and aniline give an anilinoisobutyric acid, m. p. 185°, or its anilide, m. p. 155–157°. The anilino-anilide (m. p. 122°) which is formed from methacrylic acid or methacrylanilide and aniline at 190°[9] is undoubtedly the β-anilino-compound, Banti's anilide, therefore, the α-anilino-anilide, also formed from α-bromoisobutyrylanilide and aniline at low temperature.[10,11]

Experimental

The experiments in the **α-methoxyisobutyric acid** series are described in detail; the analogous ones with its homologs are summarized in the tables.

To a cold and vigorously stirred solution of 448 g. of potassium hydroxide in 250 cc. of water and 1000 cc. of methyl alcohol, which was contained in a three-necked flask, fitted with mercury-sealed stirrer, reflux condenser and dropping funnel, a solution of 355 g. of acetonechloroform in 700 cc. of methyl alcohol was slowly added. The violent reaction, which was accompanied by the precipitation of potassium chloride, was checked by energetic cooling. The mixture was stirred for one hour at room temperature and then for two hours at boiling temperature. The inorganic salt was filtered off and washed with methyl alcohol (441 g., calcd. 447.1 g.).

The clear filtrate was freed from methyl alcohol at ordinary pressure and from most of the water *in vacuo*, and the residue was treated with a slight excess of dilute sulfuric acid (congo red). The inorganic precipitate was filtered, thoroughly washed with ether and the aqueous solution extracted with the same solvent. The residue of the combined and dried extracts distilled at 98–99° (20 mm.); yield, 167 g. (70.8%).[12,13] The same result is obtained when instead of aqueous-methanolic potassium hydroxide solution, methyl alcoholic sodium methoxide is used.

Anal. Calcd. for $C_5H_{10}O_3$: C, 50.8; H, 8.5; OCH_3, 26.3; mol. wt., 118. Found: C, 50.5; H, 8.6; OCH_3, 25.9; mol. wt., 117 (by titration).

Phenylhydrazide from 3 g. of the acid and 3.5 g. of phenylhydrazine at 120° (two hours): the melt solidified upon cooling. The product crystallized from boiling water in needles of m. p. 103°.

Anal. Calcd. for $C_{11}H_{16}O_2N_2$: C, 63.5; H, 7.7; N, 13.5; OCH_3, 14.9. Found: C, 63.2; H, 7.9; N, 13.2; OCH_3, 14.6.

Methyl Ester.—The solution of 118 g. of α-methoxyisobutyric acid in 125 cc. of methyl alcohol, containing 25 cc. of concentrated sulfuric acid, was refluxed for twelve hours. The excess of methyl alcohol was distilled off and the cold residue poured into the double volume of concentrated brine. The ester layer, which separated, was washed again with an equal volume of brine and dried over calcium chloride; b. p. 134–135° (lit. 144.8–145° (767 mm)); yield, 105 g. (79.6%). The use of larger quantities of sulfuric acid produced a dark resinous by-product.

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.5; H, 9.1; OCH_3, 47.0. Found: C, 54.1; H, 9.2; OCH_3, 46.9.

Methacrylates from α-Methoxyisobutyric Acid.—(a) A mixture of 39.6 g. of methyl α-methoxyisobutyrate and 30 g. of phosphorus pentoxide was heated in the presence of some hydroquinone for two hours. The liquid was directly distilled off from the brown resinous mass and redistilled. The methyl methacrylate boiled at 99–100°; yield, 28.4 g. (95%).

(b) A mixture of 39.6 g. of methyl α-methoxyisobutyrate and 20 g. of freshly fused zinc chloride was heated in presence of some hydroquinone for two hours. Fractional distillation in a Widmer column gave: b. p. 98–102°, methyl methacrylate, 18.0 g. (60%); b. p. 130–135°, methyl α-methoxyisobutyrate, 8.0 g. (20.4% of initial amount).

(c) A mixture of 39.6 g. of methyl α-methoxyisobutyrate and 30 g. of anhydrous oxalic acid was heated in the

[a] The quantities of potassium hydroxide are "pure KOH." The technical product, containing about 13% of water, was used. [b] By titration. [c] The crude product contained a small amount of ethyl ester, which was removed by treatment with soda solution and extraction with ether. Re-acidification gave the pure acid. Calcd.: OC_2H_5 34.1. Found: 33.9. [d] Small quantities of 2-ethylhexyl α-2-ethylhexoxyisobutyrate of b. p. 168° (4 mm.) were isolated. When the reaction was brought to completion at 130° (instead of 100°) and the crude product extracted with ether, before acidification, one third of the total reaction product consisted of that ester. [e] The reaction was begun at 35° and completed at 70°. [f] Besides the acid, 38 g. (17.3%) of dodecyl α-dodecoxyisobutyrate of b. p. 276° (15 mm.) were isolated. [g] The reaction was started at 0° and completed at room temperature.

presence of some hydroquinone for two hours. The liquid product was directly fractionated: b. p. 98–102°, methyl methacrylate, 10.0 g. (33.3%); b. p. 130–135°, methyl α-methoxyisobutyrate, 24.0 g. (60.6% of initial amount).

(d) When the amount of oxalic acid was doubled, the yield in methyl methacrylate rose to 13.0 g. (43.4%).

(e) **(β-Butoxyethyl) Methacrylate.**—A mixture of 32 g. of α-methoxyisobutyric acid with 120 cc. of butyl cellosolve and 10 cc. of concd. sulfuric acid was heated at 130° in presence of tannic acid for twelve hours. The reaction product was poured into water (in which butyl cellosolve and the methoxyacid are soluble) and the supernatant ester layer extracted with ether. (β-Butoxyethyl) methacrylate boiled at 122° under 12 mm. pressure; yield, 48 g. (80%). A small head fraction, b. p. 69–70° (13 mm.), was identified as butyl methacrylate. No ester of α-methoxyisobutyric acid was observed.

Table I lists the homolog α-alkoxyisobutyric acids, prepared from acetonechloroform.

The **phenylhydrazide of α-ethoxyisobutyric acid** was prepared, as described for the methoxy compound. It boiled at 195–200° (24 mm.) and solidified upon cooling. From dilute alcohol or isoöctane it crystallized in prisms, m. p. 84°.

Anal. Calcd. for $C_{12}H_{18}O_2N_2$: C, 64.1; H, 8.9; N, 12.6; OC_2H_5, 20.3. Found: C, 64.9; H, 7.9; N, 12.7; OC_2H_5, 19.9.

The **phenylhydrazide of α-butoxyisobutyric acid** boiled at 210° (24 mm.) and crystallized from petroleum ether in form of needles, m. p. 108–109°.

Anal. Calcd. for $C_{14}H_{22}O_2N_2$: C, 67.2; H, 8.8; N, 11.2. Found: C, 67.0; H, 8.7; N, 11.0.

Table II summarizes the preparation of analogous α-alkoxy acids from chlorinated alcohols.

The experiment, leading from trichloromethylphenylcarbinol (benzaldehydechloroform) to **α-methoxyphenylacetic** acid, is described in detail.

A solution of 56.4 g. of benzaldehydechloroform[18] in

[a] 6.9 g. (10.0%) of ethyl methacrylate was formed. [b] 6.0 g. (21.1%) of butyl methacrylate was formed. With 10 cc. of sulfuric acid, the quantity of butyl methacrylate rose to 18.0 g. (63.3%) while that of the butoxy ester decreased to 15.2 g. (35.2%). [c] The same result was obtained by ester interchange reaction when methyl α-butoxyisobutyrate was heated with ethyl cellosolve in a column until no more methanol distilled over. [d] The same result was obtained by ester interchange reaction between methyl α-butoxyisobutyrate and ethyl carbitol. [e] 8.5 g. (12.0%) of isobutyl methacrylate was formed. [f] 112.0 g. (70.0%) of 2-ethylhexyl methacrylate was formed. [g] The ester solidified slightly below room temperature and could be recrystallized by precipitation of its acetonic solution with alcohol. [h] 5.1 g. (20.2%) of allyl methacrylate was formed. This was resinified when the heating time and the amount of sulfuric acid were doubled; under these conditions, only 18.4 g. (50.0%) of allyl α-allyloxyisobutyrate was obtained. [i] 21.0 g. (73.9%) of butyl methacrylate was formed. This tendency of de-alkoxylation is still more outspoken for α-*t*-pentoxyisobutyric acid which (17.4 g.) with butyl alcohol (30 cc.) in presence of concentrated sulfuric acid (6 cc.) gave only butyl methacrylate (90.1%).

100 cc. of methanol was slowly added to a solution of 56 g. of potassium hydroxide in 200 cc. of methanol, the temperature being maintained at about 45°. The mixture was stirred for one hour at boiling temperature, allowed to cool and filtered from potassium chloride (56 g.). The clear solution was evaporated *in vacuo*, and the residue was treated with a slight excess of dilute sulfuric acid. The oily layer was separated and combined with the ether extract of the aqueous solution. α-Methoxyphenylacetic acid of b. p. 165° (18 mm.) and m. p. 72° (from ligroin) was obtained in a yield of 30 g. (72.2%).

Anal. Calcd. for $C_9H_{10}O_3$: C, 65.1; H, 6.0; OCH_3, 18.7. Found: C, 65.3; H, 6.2; OCH_3, 18.6.

The esters of the α-alkoxyisobutyric acids are listed in Table III. They were prepared by direct esterification of the acids with an excess of the alcohols in the presence of a small quantity of concentrated sulfuric acid as catalyst and of about 0.5% of tannic acid as polymerization inhibitor. It is, however, not necessary to isolate the α-alkoxyacids for the preparation of these esters. The following example shows that the same ultimate yields can be obtained without such isolation.

The solution obtained from 156.8 g. of potassium hydroxide in 750 cc. of butyl alcohol and 124.2 g. of acetonechloroform in 250 cc. of butyl alcohol (0°, two hours), and filtered from the potassium chloride (154.0 g.) formed, was acidified with concentrated sulfuric acid at 0° (congo red) and filtered again. The filtrate, containing the free α-butoxyisobutyric acid, was boiled with 50 cc. of concentrated sulfuric acid, 5 g. of tannic acid and 300 cc. of carbon tetrachloride (azeotropic distillation). After nine hours, the amount of water liberated became negligible. The greater part of the organic solvents was distilled off and the residue washed with water, 20% sodium carbonate solution and water, and dried. Fractional distillation gave three fractions: butyl alcohol, butyl methacrylate (20.0 g., 20.1%) and butyl α-butoxyisobutyrate (70.0 g., 46.3%).

The esterification of 52.2 g. of α-isobutoxymethylethylacetic acid with 80 cc. of isobutanol in the presence of 14 cc. of concentrated sulfuric acid gave 54.0 g. (78.2%) of isobutyl-α-isobutoxy methylethylacetate of b. p. 220° and 5.7 g. (12.2%) of isobutyl tiglate.

The esterification of 50.0 g. of 1-isobutoxycyclohexane-

TABLE IV

UNSATURATED ESTERS

Starting material	Conditions	Unsaturated ester	Yield, %	B. p. °C.	B. p. Mm.	Remarks
Ethyl α-ethoxyisobutyrate	P_2O_5, 80°, 2 hr.	Ethyl methacrylate	90.0	120	760	See Table III, note *a*

Methyl methacrylate	Butylcellosolve, 1% H_2SO_4, column	2-Butoxyethyl methacrylate	76.0	112	15	Alkyl exchange
Allyl α-allyloxyisobutyrate	P_2O_5, 60°, 1 hr.	Allyl methacrylate[21]	90.0	82	17	See Table III, note *h*
Methyl methacrylate	Diethylamino ethanol, 1% Na, column	β-Diethlaminoethyl methacrylate[22]	40.0	112	25	Alkyl exchange
Isobutyl α-isobutoxy-methylethylacetate	P_2O_5, 70°, 1 hr.	Isobutyl tiglate	95.0	180	760	See also esterification of acids
Isobutyl 1-isobutoxycyclohexanecarboxylate	P_2O, 100°, 2 hr.	Isobutyl 1-cyclohexenecarboxylate	85.0	140	28	
Isobutyl 2-isobutoxy-3-ethylheptoate	P_2O_5, 100°, 2 hr.	Isobutyl 3-ethyl-2-heptenoate	85.0	135	20	

carboxylic acid with 100 cc. of isobutanol and 15 cc. of concentrated sulfuric acid gave 18.5 g. (28.9%) of isobutyl 1-isobutoxycyclohexanecarboxylate of b. p. 154° (28 mm.) and 32 g. (70.3%) of isobutyl 1-cyclohexenecarboxylate.

The esterification of 46.0 g. of 2-isobutoxy-3-ethylheptoic acid with 100 cc. of isobutanol and 15 cc. of concentrated sulfuric acid gave 42.0 g. (73.4%) of isobutyl 2-isobutoxy-3-ethylheptoate of b. p. 155° (23 mm.) and 8.5 g. (20.0%) of isobutyl-3-ethyl-2-heptenoate.

The unsaturated esters, mainly methacrylates, encountered in this investigation, are listed in Table IV. It includes some esters of methacrylic acid which have not been prepared through the intermediary of α-alkoxyisobutyric esters but through alkyl exchange with methyl methacrylate.

In order to identify the unsaturated ester from isobutyl α-isobutoxymethylethylacetate, a sample was saponified with methyl alcoholic potassium hydroxide solution. The free acid obtained distilled at 197–203°, solidified and had m. p. 60°. These constants point to **tiglic acid** for which the literature records m. p. 65° and b. p. 199°.

When a carbon disulfide solution of the acid was kept for three days in the sunlight with a slight excess of bromine, an oily dibromide was formed which was brought to crystallization by the following treatment: dissolution in sodium carbonate solution, extraction with ether, acidification, re-extraction with carbon disulfide and evaporation, m. p. 85°.[23]

Of course, under these experimental conditions, angelic acid would also give the dibromide of its *trans*-isomer tiglic acid. The m. p. of the dibromide, however, excludes the possibility that the unsaturated ester formed was isobutyl α-ethyl-acrylate. The m. p. of the dibromide of α-ethylacrylic acid is 75°.[24]

α-Butoxy-isobutyryl Chloride and its Esterification with Phenol.—To a solution of 32 g. of freshly distilled α-butoxyisobutyric acid in 25 cc. of dry chloroform, 25 g. of thionyl chloride was slowly added, and the solution was kept at 18° during sixteen hours. After this time, the gas development had practically ceased. The weight increase of a trap showed that hydrogen chloride and sulfur dioxide had been liberated in a quantity of about 97%. The reaction mixture was a clear, brown liquid.

At 0°, a solution of 19.7 g. of phenol in 40 cc. of pyridine was added gradually. After twenty-four hours at room temperature, the product was diluted with 50 cc. of benzene, washed with water, dilute sulfuric acid and cold sodium hydroxide solution, and dried. The solvent was removed and the residue distilled under 20 mm. pressure in presence of hydroquinone. The liquid boiled, practically without residue, between 90 and 145°. It consisted of (a) b. p. 95–100° (16 mm.), phenyl methacrylate,[19] 10 g. (30.9%); (b) b. p. 138–140° (14 mm.), **phenyl α-butoxyisobutyrate**, 20 g. (42.4%).

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.2; H, 8.5. Found: C, 71.4; H, 8.7.

When the same reaction was carried out with 32 g. of α-isobutoxyisobutyric acid, 26 g. (80.2%) of phenyl methacrylate was the only product.

Aminolysis of Methyl α-Methoxyisobutyrate with Ethanolamine.—A mixture of 27.7 g. of methyl α-methoxyisobutyrate and 12.2 g. of monoethanolamine was heated on the steam-bath. After about fifteen minutes, it homogenized, and gentle refluxing (methyl alcohol) started. After three hours, the reaction was not yet quite complete, and fractional distillation gave: at 30–35° (10 mm.), methyl α-methoxyisobutyrate, 8.0 g. (28.7% of the initial quantity); at 63–70° (10 mm.), ethanolamine, 3.0 g. (24.5% of the initial quantity) and at 150–152° (16 mm.), **α-methoxyisobutyr-(β-hydroxyethyl)-amide**, 24.0 g. (74.5%).

The amide is a colorless, highly viscous oil which solidifies to a white crystalline mass at 0°.

Anal. Calcd. for $C_7H_{15}O_3N$: C, 52.1; H, 9.3; N, 8.7. Found: C, 51.8; H, 9.2; N, 8.7.

Summary

Acetonechloroform, when treated at 0°, with an alkali alkoxide or a solution of alkali hydroxide in an alcohol, gives the salt of an α-alkoxyisobutyric acid in good yield. Ten such α-alkoxyisobutyric acids have been prepared and their reac-

tions investigated. The reaction appears to be general for all analogs and homologs of acetonechloroform; three new α-alkoxyacids have thus been synthesized. A reaction mechanism has been suggested for this somewhat surprising reaction, and the analogous reaction of acetonechloroform and aniline has been discussed.

The dealkoxylation of the esters of the α-alkoxyacids to α,β-unsaturated esters has been investigated and a number of known and new esters of this series have been prepared.[25]

(25) (Note added February 19, 1948): In the November, 1947, issue of THIS JOURNAL (p. 2667), McElvain and Stevens describe the formation of ethyl α-ethoxyisobutyrate from acetonechloroform and 3 moles of sodium ethoxide in absolute alcohol. They also quote the British Patent 578,082 corresponding to the present paper (*C. A.*, **41**, 2075 (1947); applied in 1943; compare Weizmann, British Patent 587,545, applied in 1944).

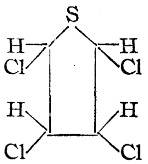
The Chlorination of Thiophene. I. Addition Products

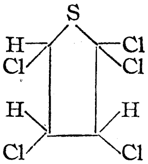
BY HARRY L. COONRADT AND HOWARD D. HARTOUGH

A study of the reaction of thiophene with chlorine was undertaken in these Laboratories when it became evident that the reaction was much more complex than had been indicated in the literature. Prior investigators reported[1] that when the reaction products were distilled, hydrogen chloride was evolved throughout the distillation and the presence of addition products was indicated since the substitution products distilled without decomposition. A study of addition products formed in the reaction was made by the present authors in order to determine, in part, their chemical potentialities since these compounds had been destroyed in the past by the methods used in processing the chlorinated mixtures.

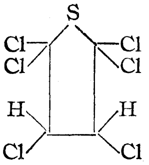
The addition compounds isolated from the reaction mixture were α-2,3,4,5-tetrachlorothiolane,[2] m.p. 111.5–113.5°, (I), β-2,3,4,5-tetrachlorothiolane, m.p. 44.5–46°, (II), 2,2,3,4,5-pentachlorothiolane (III), and 2,2,3,4,5,5-hexachlorothiolane (IV).



I, m. p. 111.5–113.5°
II, m. p. 44.5–46°



III



IV

The addition products were described previously by Steinkopf and Köhler[3] as "hydrogen chloride addition products." The assumption of addition products was based on the separation of a liquid material from exhaustively chlorinated thiophene, 2-thiophenecarboxylic acid or 4,5-dibromo-2-thiophenecarboxylic acid to which was assigned the structure of 2,3,4,5,5-pentachloro-2-thiolene or 2,3,4,4,5-pentachloro-2-thiolene. We isolated no such addition product from exhaustively chlorinated thiophene, and it seems probable that the material of Steinkopf and Köhler was not a single compound. The present work indicates that the addition compounds are chlorine addition products. Hydrogen chloride did not form addition products with 2,5-dichlorothiophene at 0° or −40° nor with 2,3,4,5-tetrachlorothiophene at 0°.

There are six possible geometrical isomers of 2,3,4,5-tetrachlorothiolane. Two were isolated and identified. These compounds may be viewed as the products of the addition of chlorine to thiophene. The *alpha* isomer, I, was obtained as a white crystalline product when partially chlorinated thiophene was cooled and filtered. The *beta* isomer, II, was obtained when partially chlorinated thiophene was distilled to remove the more volatile components, the residue cooled to crystallize and separate I, and the filtrate fractionated under reduced pressure. The higher boiling fractions contained II.

The structures of I and II were indicated by the method of synthesis and analysis. Further evidence for the structure assigned to I was obtained by dehydrohalogenation. Pyrolysis yielded hydrogen chloride and dichlorothiophenes composed of about 50% 2,3-dichlorothiophene, and 50% 2,4-dichlorothiophene with a trace of 2,5-dichlorothiophene. However, when I reacted with ethanolic potassium hydroxide, dichlorothiophenes composed of approximately 54% 3,4-dichlorothiophene, 44% 2,4-dichlorothiophene, 2% 2,5-dichlorothiophene, and no 2,3-dichlorothiophene were obtained. This conversion of I to all four possible dichlorothiophenes is evidence for the structure assigned. II upon treatment with ethanolic potassium hydroxide yielded a mixture of dichlorothiophenes.

The 2,2,3,4,5-pentachlorothiolane (III) was separated in low yield by the fractionation under reduced pressure of chlorinated thiophene. A superior method of preparation was found to be

[1] W. Steinkopf, "Die Chemie des Thiophens," Theodor Steinkopff, Dresden, 1941, p. 35.

[2] This terminology is in accord with that in Patterson, "The Ring Index," Reinhold Publishing Corp., New York, N. Y., 1940, p. 44. Other terminology, except that derived from thiacyclopentane, is cumbersome and occasionally misleading. The *alpha* and *beta* isomers of tetrachlorothiolane have been so designated by the present authors.

[3] Steinkopf and Köhler, *Ann.*, **532**, 250 (1937).

the chlorination of 2-chlorothiophene at low temperatures and subsequent crystallization of III at low temperatures from the reaction mixture. The structure assigned to III was based on the latter synthesis and on analysis. Further evidence for the structure assigned was the conversion of III to trichlorothiophenes by pyrolysis and by dehydrohalogenation with ethanolic potassium hydroxide. Of the trichlorothiophenes formed by pyrolysis, infrared absorption spectra indicated that 92% was 2,3,5-trichlorothiophene and 8% was 2,3,4-trichlorothiophene. However, of the trichlorothiophenes formed by the reaction of III with ethanolic potassium hydroxide similar analysis showed that 35% was 2,3,5-trichlorothiophene and 65% was 2,3,4-trichlorothiophene.

The 2,2,3,4,5,5-hexachlorothiolane (IV) was obtained from chlorinated thiophene by fractionation under reduced pressure. The same compound, IV, also was prepared by the direct addition of chlorine to 2,5-dichlorothiophene. The position of the two hydrogen atoms was indicated by the latter synthesis, and by the formation of 2,5-dichlorothiophene by the action of zinc on IV. IV reacted with ethanolic potassium hydroxide to give 2,3,4,5-tetrachlorothiophene. Pyrolysis of IV yielded hydrogen chloride and 2,3,4,5-tetrachlorothiophene.

The formation of the addition product, IV, as the principal product of the exhaustive chlorination of thiophene at 80–130° showed that at the latter stage of the reaction the ratio of addition to substitution products increased markedly. This is in contrast to the early stages of the chlorination where more chlorine reacted to form substitution than addition products. When two moles of chlorine was treated with one mole of thiophene at 70–80°, only 20% of the chlorine reacted to form addition products. The balance of the chlorine reacted to form substitution products as calculated from the weight of chlorine added and the weight of the reaction products.

The effect of temperature on the ratio of addition to substitution products was determined in part. When two moles of chlorine per mole of thiophene was used, the chlorine that reacted to form addition products was 20% at 70–80°, 30% at 30°, and 40% at −30°; the balance of the chlorine reacted to form substitution products. When the exhaustive chlorination of thiophene was conducted at reflux temperatures up to 200°, with concomitant pyrolysis, the yield of the addition product, IV, was low due to its dehydrohalogenation to tetrachlorothiophene. When the exhaustive chlorination was conducted at 80–130°, IV was obtained directly by distillation of the reaction product and was purer than the IV obtained when the chlorination was conducted at a lower temperature. This was clarified when I was found to react with chlorine at 115°, but not at 40°. The impurity in IV formed by chlorination near room temperature was thus indicated to be I and possibly other addition products which accumulated in the reaction mixture at lower temperatures and decomposed when IV was fractionated. I was found to react more readily than IV with cold sodium carbonate solution. Treatment of the crude reaction product with the alkaline solution destroyed the more unstable addition products so that IV could be distilled satisfactorily.

The purity of the addition products reported in this paper was indicated by the melting point, and infrared absorption spectrograms of carbon tetrachloride solutions of I, II and IV. Similar absorption spectrograms for I, II, IV and thiolane were obtained. The white crystalline addition products isolated had relatively high vapor pressures at room temperatures, but were quite stable under such conditions as was indicated by a constant melting point on standing. The addition products had a slight vesicant and lachrymatory action.

Experimental

Chlorination.—Thiophene of better than 99.5% purity, as determined by infrared absorption analysis, was used. The chlorinations were conducted in a flask fitted with stirrer, efficient condenser, thermometer and chlorine gas inlet tube that led below the surface of the liquid. The chlorine was measured by a rotameter.

α-2,3,4,5-Tetrachlorothiolane, I.—Five moles (420 g.) of thiophene was chlorinated at 30° with from two and one-half to ten moles of chlorine. The products were placed in stoppered flasks and immersed in a Dry Ice–acetone-bath at −70° for four hours. The cold reaction mixtures were filtered and the precipitates washed with cold petroleum ether. The white crystalline products so obtained had melting points of about 106–112° which were not substantially changed by repeated recrystallizations from ASTM naphtha. The moles of chlorine used per mole of thiophene and the yields of I, m. p. 106–112°, based on chlorine were as follows: 0.5, 9.9%; 0.8, 13.2%; 1.0, 11.1%; 2.0, 8.2%. The best yield of I based on thiophene was obtained with two moles of chlorine per mole of thiophene. The effect of the temperatures of chlorination on the yields under such conditions was as follows: 70–80°, 3.5%; 30°, 8.2%; −30°, 3.8%. Addition of petroleum ether to the more highly chlorinated mixtures before crystallization reduced coprecipitation and facilitated separation of I. Under such conditions the moles of chlorine used and the yields of I, m. p. 106–112°, based on chlorine were as follows: 3.0, 1.9%; 4.0, 0.0%. I of m. p. 111.5–113.5° was obtained by fractional crystallization from carbon tetrachloride by the addition of ASTM naphtha or from benzene by the addition of petroleum ether. I boiled at 111.5° (3.4 mm.) with partial decomposition, as was indicated by hydrogen chloride evolution and a distillate with a lower melting point. I gave an immediate precipitate with alcoholic silver nitrate.

Anal. Calcd. for $C_4H_4Cl_4S$: C, 21.26; H, 1.79; Cl, 62.8; S, 14.2; mol. wt., 226. Found: C, 21.27; H, 1.78; Cl, 62.5; S, 14.8; mol. wt., 226.

β-2,3,4,5-Tetrachlorothiolane, II.—Ten moles of chlorine was added to ten moles (840 g.) of thiophene over a two-hour period during which time the temperature was allowed to rise at a constant rate from 50 to 100°. Then nitrogen was passed through the reaction mixture for forty minutes while the mixture was heated at 90°. The cold reaction mixture was washed in turn with water, 5% sodium carbonate solution and water, and then dried over sodium sulfate. The mixture was distilled until the vapor temperature reached 150°. Hydrogen chloride was evolved during the distillation. The 404 g. of residue was divided. One-half (202 g.) was distilled directly under 4 mm. pressure. The major portion of the distillate was chlorine substitution products. In addition, there was a higher boiling fraction consisting of 8 g. of liquid, b. p. 112° (4 mm.), from which no II was obtained, and 74 g. of black tarry residue from which 7 g. of I was isolated by recrystallization from ASTM naphtha.

The other one-half (202 g.) of the mixture was kept at −30° for eighteen hours and then at room temperature for twenty-four hours. The precipitate, I (25 g.) that formed was separated by filtration. The filtrate was fractionated under reduced pressure (5 mm.) and gave, in addition to the chlorine substitution products, 47 g. of II, b. p. 110–118° (5 mm.), and 12 g. of black crystalline residue. The residue was recrystallized from ASTM naphtha and gave 2 g. of white crystalline product, m. p. 64–69°. II was recrystallized from ASTM naphtha; m. p. 44.5–46°; $n^{50}\mathrm{D}$ 1.5688.

Anal. Calcd. for $C_4H_4Cl_4S$: C, 21.26; H, 1.79; Cl, 62.8; S, 14.2. Found: C, 21.26; H, 1.87; Cl, 62.9; S, 14.2.

Pyrolysis of α-2,3,4,5-Tetrachlorothiolane, I.—Forty grams of I was refluxed at about 180° for thirteen hours. Hydrogen chloride was evolved throughout the heating period. The liquid product had a refractive index, $n^{30}\mathrm{D}$, of 1.5698. Distillation at atmospheric pressure gave 22 g. of dichlorothiophenes, b. p. 160–168°, and 8 g. of residue. The dichlorothiophene fraction was analyzed by infrared spectrograms which indicated the composition was 50% 2,3-dichlorothiophene and 50% 2,4-dichlorothiophene which contained a trace of 2,5-dichlorothiophene.

Reaction of α-2,3,4,5-Tetrachlorothiolane with Ethanolic Potassium Hydroxide.—A solution of 168 g. (3 moles) of potassium hydroxide in 504 g. of absolute ethanol was heated to 65–70°. The heater was removed and 226 g. (1 mole) of I, m. p. 106–110°, was added over a two-hour period so that the temperature was maintained at 65–70°. Considerable heat was evolved. The mixture then was refluxed at 80° for twenty-two hours. Water was added and the mixture was steam distilled into approximately 250 ml. fractions. Water was added to each fraction to precipitate an oil. The oily layers from the first three fractions were combined. The water layers were extracted twice with petroleum ether; the petroleum ether solution was distilled and the residual oil, 15 ml., added to the main body of the oil. The combined oil was washed with water to remove alcohol and then treated again with a mixture of 10 g. of sodium hydroxide and 10 g. of potassium hydroxide at 100–125° for five hours to react with any I that might remain. The excess alkali and any salt formed was removed by filtration and 124 g. (81%) of dichlorothiophenes was obtained as filtrate. The dichlorothiophenes, b.p. 155–185°, were separated by fractionation and analyzed by infrared absorption spectrograms. The analysis indicated a dichlorothiophene composition of approximately 2% 2,5-dichlorothiophene, 44% 2,4-dichlorothiophene, no 2,3-dichlorothiophene, and 54% 3,4-dichlorothiophene.

Reaction of α-2,3,4,5-Tetrachlorothiolane with Chlorine.—One mole of chlorine was passed into a solution of 34 g. (0.15 mole) of I, m.p. 110–112°, in 500 ml. of carbon tetrachloride at 40° during a two-hour period. The resultant product was evaporated on a steam-bath, and the crystalline residue, 34 g., m.p. 104–110°, showed no depression of the melting point with I.

Anal. Calcd. for $C_4H_4Cl_4S$: Cl, 62.8. Found: Cl, 63.3.

Four moles of chlorine was passed into 113 g. (0.5 mole) of I, m.p. 110–112°, at 115° during a one hundred-minute period. The product was a liquid which weighed 120 g., 7 g. more than the original I. The product was washed in turn with water, 5% sodium carbonate solution and water. The product gave 80 g. of distillate, b.p. 57–113° (4 mm.), and 10 g. of residue.

2,2,3,4,5-Pentachlorothiolane, III.—Two moles of chlorine was passed into 1 mole (119 g.) of 2-chlorothiophene at −30 to −35° during an eighty-minute period. Nitrogen was passed through the cold mixture for five minutes. The mixture was transferred to a stoppered flask and placed in a Dry Ice–acetone-bath at −70°, but crystallization was slow. The addition of 25 ml. of petroleum ether facilitated crystallization. After four hours the cold mixture was filtered. The precipitate (46 g.) after recrystallization from petroleum ether melted at 31–32°; $n^{35}\mathrm{D}$ 1.5755; $\Delta n\mathrm{D}/\Delta t = -0.0005$. The calculated refractive index, $n^{20}\mathrm{D}$, was 1.5830.

Anal. Calcd. for $C_4H_3Cl_5S$: C, 18.45; H, 1.16; Cl, 68.1; S, 12.3. Found: C, 18.32; H, 1.09; Cl, 67.9; S, 12.5.

Pyrolysis of 2,2,3,4,5-Pentachlorothiolane, III.—Twelve grams of III with refractive index, $n^{33}\mathrm{D}$, of 1.5740 was refluxed for twenty-four hours. Evolution of hydrogen chloride had practically ceased after that time. The condenser was inverted and 9 g. of light red oil was obtained by distillation. Redistillation gave a colorless product, b.p. 190–195°. Infrared absorption analysis indicated that of the trichlorothiophenes present 92% was 2,3,5-trichlorothiophene and 8% 2,3,4-trichlorothiophene.

Reaction of 2,2,3,4,5-Pentachlorothiolane, III, with Ethanolic Potassium Hydroxide.—Twelve grams of pentachlorothiolane with refractive index, $n^{33}\mathrm{D}$, of 1.5740 was refluxed with 50 ml. of 20% ethanolic potassium hydroxide for eight hours. The mixture was diluted with 100 ml. of water and steam distilled. The steam distillate was extracted with ether; the ether solution was washed with water, dried over calcium chloride, and then distilled. The distillate, b.p. 198–212°, weighed 8 g. and infrared absorption analysis indicated that of the trichlorothiophenes present 65% was 2,3,4-trichlorothiophene and 35% was 2,3,5-trichlorothiophene.

2,2,3,4,5,5-Hexachlorothiolane, IV.—Twenty-six and one-half moles of chlorine was added to 420 g. (5 moles) of thiophene over a five and one-half hour period. The temperature was maintained at 40° except during the last hour when it was lowered to 5°. The mixture evolved some chlorine at room temperature. A 400-g. sample of the 1284 g. of product was washed in turn with water, 5% sodium carbonate solution, and water. The alkaline and water solutions were extracted with carbon tetrachloride. The organic material was combined and dried over sodium sulfate. The carbon tetrachloride was distilled and the residue fractionated; the yield of IV was 354 g. (77%); b.p. 100–105° (1 mm.). The compound was recrystallized by adding just sufficient petroleum ether to dissolve the crystals and then cooling the solution slowly to 0°. The white crystalline product melted at 45–46°; $n^{50}\mathrm{D}$ 1.5590, $\Delta n\mathrm{D}/\Delta t = -0.0005$. IV gave an immediate precipitate with alcoholic silver nitrate.

Anal. Calcd. for $C_4H_2Cl_6S$: C, 16.29; H, 0.69; Cl, 72.2; S, 10.9. Found: C, 16.31; H, 0.64; Cl, 71.8; S, 10.8.

Chlorination of 2,5-Dichlorothiophene.—Five moles of chlorine was passed, during a two-hour period, into 100 g. (0.65 mole) of 2,5-dichlorothiophene at 5–10°. The product weighed 130 g. There was 20 g. of distillate, b.p. 115–120° (5 mm.), which after recrystallization from petroleum ether had a m.p. 45–46°. This material gave no depression of the melting point with IV prepared from thiophene as described above.

Pyrolysis of 2,2,3,4,5,5-Hexachlorothiolane, IV.—Forty-five grams of IV was refluxed (about 215°) for seventy-two hours. Hydrogen chloride evolution was rapid at first, but very slow near the end. Upon distillation there was obtained 7 g., b.p. 76–83 (3 mm.), and 17 g. of 2,3,4,5-tetrachlorothiophene, b.p. 75–77° (2 mm.), m. p. 29°. The latter material gave no depression of the melting point with pure tetrachlorothiophene, m. p. 29.09°.

Reaction of 2,2,3,4,5,5-Hexachlorothiolane, IV, with Ethanolic Potassium Hydroxide.—A solution of 20 g. of potassium hydroxide in 180 g. of absolute alcohol was heated to 60° and 45 g. of IV added over a ten-minute period. The mixture was refluxed for eighteen hours.

Water was added and the mixture steam distilled. The organic layer was separated and the water layer extracted four times with 30-ml. portions of petroleum ether. The combined organic material was dried over calcium chloride, filtered and fractionated. The 2,3,4,5-tetrachlorothiophene weighed 7 g., mixed m.p. 29°.

Reaction of 2,2,3,4,5,5-Hexachlorothiolane, IV, with Zinc.—A suspension of 150 g. of 90% zinc dust in 500 ml. of water was heated to 95°, and 250 g. of IV added over a one and one-quarter hour period. The unreacted metal was removed by filtration and the organic layer separated. The water layer was extracted with ether and yielded 21 g. of product. The organic material was combined and the ether distilled. The distilled 2,5-dichlorothiophene weighed 85 g.; b.p. 160–163°; $n^{20}D$ 1.5624.

Acknowledgment.—The authors are grateful to Dr. D. E. Badertscher and Dr. C. C. Price for their advice and interest in this problem, to Miss Emily Burns who carried out a great many of the laboratory experiments, and to Mr. J. G. Ehlers for infrared spectrographic analyses.

Summary

Thiophene reacts with chlorine to produce both addition and substitution products in proportions dependent upon the reaction conditions and the ratio of chlorine to thiophene.

Chlorine addition products were isolated. These are identified as α-2,3,4,5-tetrachlorothiolane, β-2,3,4,5-tetrachlorothiolane, 2,2,3,4,5-pentachlorothiolane and 2,2,3,4,5,5-hexachlorothiolane. The compounds are white crystalline materials stable at room temperature.

Pyrolysis of α-tetrachlorothiolane and of pentachlorothiolane gave mixtures of dichlorothiophenes and trichlorothiophenes, respectively, varying in composition from the chlorothiophenes formed by dehydrohalogenation with ethanolic potassium hydroxide.

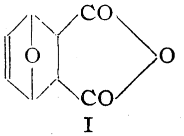
The Reaction of Furan with Maleic Anhydride[1]

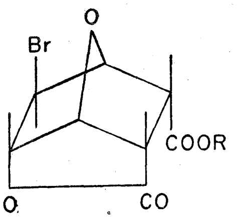
BY R. B. WOODWARD AND HAROLD BAER

In an attempt to synthesize cantharidine or cantharidine-like compounds, Diels and Alder[2] undertook the study of the reaction of furan with maleic anhydride. The two substances reacted in ether solution to give a crystalline adduct, m.p. 125°, which was shown to have the structure (I).

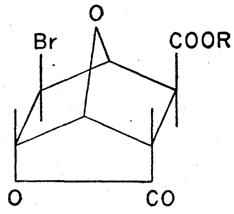


I

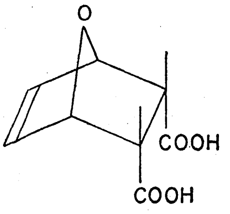
Subsequently, the same authors[3] observed that an aqueous solution of maleic acid dissolved furan on long shaking. When the resultant solution was treated with bromine a substance, $C_8H_7O_5Br$, m.p. 205°, was precipitated, to which the structure (II, R = H) was assigned. This bromolactonic acid was converted by diazomethane to a monomethyl ester (II, R = Me), m.p. 175°. Hydrobromic acid at 100° converted (II) to an isomer (III, R = H), from which an ester (III, R = Me), m.p. 168°, was obtained, while the same agent, at 160–170°, converted (II) to *o*-phthalic acid. These observations indicated that the solution of furan in aqueous maleic acid contained *endo-cis*-1,4-endoxo-Δ^5-cyclohexene-2,3-dicarboxylic acid (IV). It is significant that the German authors presented no evidence of the actual isolation from the solution of an adduct. *On the assumption that the acid obtained by the hydrolysis of the crystalline anhydride (I) was identical with the acid contained in the aqueous solution of furan in maleic acid, Diels and Alder assigned the structure (V) to the adduct, m.p. 125°.*



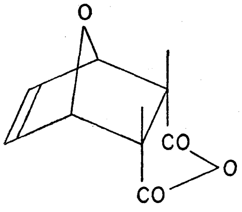
II



III



IV



V

In this communication, it is shown that that assumption was incorrect and that, in fact, the product of the addition of maleic anhydride to furan is *exo-cis*-3,6-endoxo-Δ^4-tetrahydrophthalic-anhydride (VI). When the anhydride, m.p.

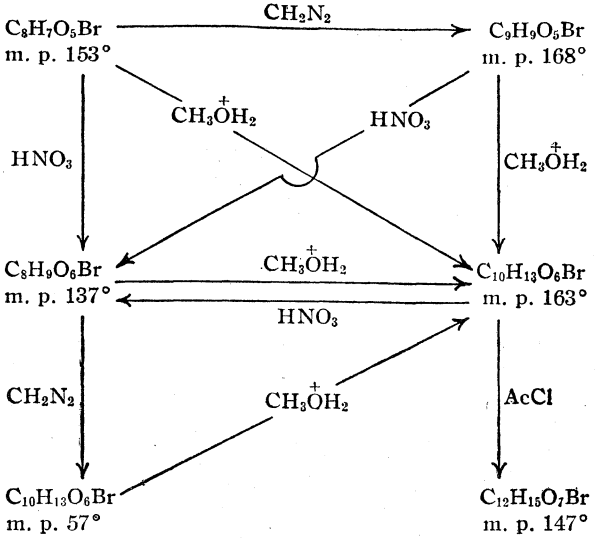
125°, is dissolved in water or dilute base and the resultant solution is treated with bromine, a new colorless crystalline substance $C_8H_7O_5Br$, m.p. 153° (d.), is precipitated,[4] in the latter case after acidification with hydrochloric acid. Careful evaporation of the mother liquor from the reaction yields a dibromide of the adduct acid, $C_8H_7O_5Br_2$, m.p. 155°. This substance, which was converted by catalytic esterification to a dimethyl ester, $C_{10}H_{12}O_5Br$, m.p. 116°, is of no great interest and needs no further comment.

Esterification of the new monobromo compound, m.p. 153°, with diazomethane gives a monomethyl ester, $C_9H_9O_5Br$, m.p. 168° (dec.) which is not identical with either of the isomeric esters, m.p. 175° and 168°, of Diels and Alder (*vide supra*) as evidenced by mixed melting point determinations and, further, by the striking differences between the chemical properties of the new ester, as contrasted with those of the previously described isomers. The latter melt without decomposition to clear liquids, which resolidify on cooling; they are stable to dilute alkalies, and to alkaline permanganate, and do not reduce Fehling solution or Tollens reagent. By contrast, the new ester melts with complete decomposition, it decolorizes cold aqueous permanganate instantly, reduces Tollens and Fehling solution readily when warmed slightly, and it is rapidly destroyed, with the formation of dark-colored intractable material, by the action of cold dilute weak bases or by short warming with dilute acids. Base liberates bromide ion instantaneously from the new ester, but, significantly, alcoholic silver nitrate fails to yield a precipitate of silver bromide.

Catalytic esterification, with methanol and sulfuric acid, converts either the monobromo compound, $C_8H_7O_5Br$, or the new ester, m.p. 168°, into a new substance, $C_{10}H_{13}O_6Br$, m.p. 163° (d.), from which an acetyl derivative, $C_{12}H_{15}O_7Br$, m.p. 147°, may be obtained. Any of the three substances, when boiled with dilute nitric acid,[5] is converted to an acid, $C_8H_9O_6Br$, m.p. 137° (d.). This acid is transformed by the action of methanol and sulfuric acid to the compound $C_{10}H_{13}O_6Br$, m.p. 163°, but *by the action of diazomethane, an isomeric substance, $C_{10}H_{13}O_6Br$, m.p. 57° (dec.) is obtained.* The new compound is inordinately unstable. It decomposes spontaneously within an hour, and it is the first substance of this series to yield a precipitate of silver bromide with alcoholic silver nitrate. Methanol containing sulfuric acid converts the 57° compound into its isomer, m.p. 163°. The accompanying chart will clarify this somewhat involved series of changes.



These transformations are explicable only on the basis that the original adduct (I), m.p. 125°, has the *exo-cis* configuration (VI). Attack at the double bond by bromine produces a carbonium ion (VII) or its equivalent. Unlike the corresponding *endo-cis* ion (VIII), which can undergo spontaneous stabilization by lactonization, to give (II, R = H), VII is incapable of direct lactonization, since the oxygen bridge blocks union between the positively charged carbon atom and an oxygen of the carboxyl group. However, after a normal Wagner–Meerwein rearrangement to (IX), the hitherto inaccessible carboxyl group may participate in lactonization, with the formation of (X, R = H); this expression represents the monobromo compound $C_8H_7O_5Br$, m.p. 153°, of the new series. This change is comparable to that involved in the transformation of *exo-cis*-Δ^5-bicyclo-[1,2,2]-heptene-2,3-dicarboxylic acid (XI) into the lactone (XII) on treatment with acid.[6] In our case, the circumstances are even more favorable for rearrangement, since the oxygen atom tends to stabilize the rearranged ion, through contributions

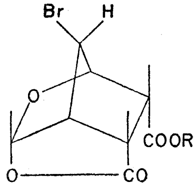
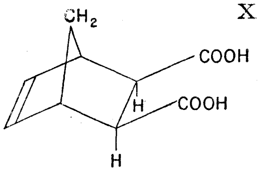
(4) Observation of Mrs. Virginia (Williams) Eager.

(5) Nitric acid only, of all acids tried, is effective, presumably because it oxidizes the decomposition products which are usually formed in reactions involving these very sensitive substances, and permits ready isolation of the desired product from reaction mixtures free of otherwise inseparable contaminants.

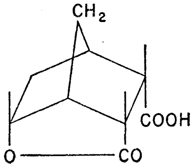
(6) Alder and Stein, *Ann.*, **514**, 1 (1934).



X



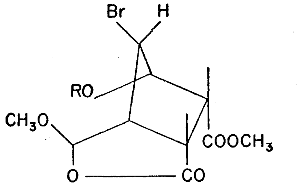
XI



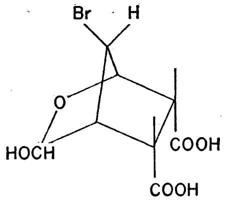
XII

of the type $-\overset{|}{C}=\overset{+}{O}-$. The presence in the rearranged ion of a carboxyl group in a position in which it may participate in lactonization undoubtedly provides additional driving force for the rearrangement; on the other hand the similar rearrangement in the hydration of dicyclopentadiene[7] indicates that this factor is not a necessary one. The occurrence of a Wagner–Meerwein rearrangement during bromination is not unexpected in the light of current views on the mechanism of halogenation[8] and, in any event, has been observed in other cases, *e.g.* in the reaction of pinene with bromine to give 2,6-dibromo-camphane.[9]

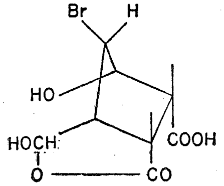
The structure (X, R = H) is compatible with all of the observed reactions of the 153° compound. The formulation of the mono-ester, m.p. 168°, as (X, R = CH_3) follows directly, while the compound $C_{10}H_{13}O_6Br$, m.p. 163°, may be represented as the pseudo-ester (XIII, R = H), a formulation supported by the formation of a mono-acetyl derivative (XIII, R = CH_3CO—). The acid, $C_8H_9O_6Br$, m.p. 137°, is (XIV) (or its ring-chain tautomer, XV), and finally, the isomeric substance $C_{10}H_{13}O_6Br$, m.p. 57° is the normal diester (XVI).



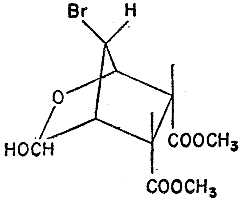
XIII



XIV

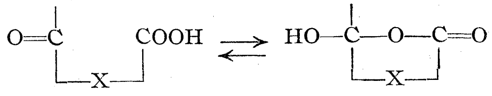


XV



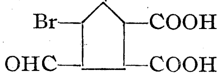
XVI

The formation of the isomeric esters, $C_{10}H_{13}O_6Br$, provides proof of the presence of a (potential) carbonyl group in this series, and in particular, the formation of the pseudo-ester (XIII, R = H) and the normal ester (XVI) respectively under catalytic esterification conditions and through the action of diazomethane, is consonant with the usual properties of substances capable of participation in ring-chain equilibria of the type XVII$a \rightleftarrows$ XVIIb.[10]

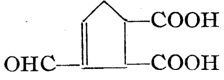


XVIIa XVIIb

The great sensitivity of the entire series arises from the circumstance that all of the substances are derived from the cyclopentane aldehyde (XVIII); once the lactone ring of any of the compounds is opened (say by alkali) with liberation of

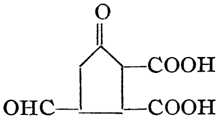


XVIII



XIX

the free aldehyde group, the β-halogen atom is eliminated with extreme ease. The resultant unsaturated aldehyde (XIX), itself very probably an unstable substance, may readily isomerize[11] to



XX

XX, which possesses manifold possibilities for auto-condensation.[12]

The ready elimination of bromide ion, and possibly also the potential aldehyde group, accounts for the facile oxidation by dilute permanganate solution, while the latter feature is responsible for the observed reducing action toward warm Fehling solution and Tollens reagent. In that connection, it is significant that while the substances are immediately oxidized by permanganate in the presence of the merest trace of base, dilute acid suppresses the reduction of that agent considerably; the somewhat greater stability of the acids of the series as compared with the esters is another consequence of the same effect. Finally, the fact that the ester of m.p. 57° is by far the most unstable compound of the entire series is a consequence of the fact that in it the potential aldehyde group is masked only as a simple hemiacetal function; mere prototropic change is necessary to initiate the series of degenerative reactions, while in

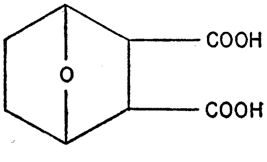
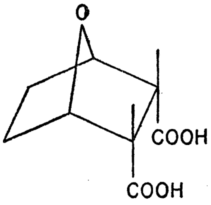
[12] *Cf.* the behavior of levulinic aldehyde, a simple analog of XX. When the acetal of the aldehyde is warmed with dilute acids the free aldehyde is liberated; attempts to neutralize the solutions with sodium carbonate result in very rapid and complete destruction of the substance [Harries, *Ber.*, **31**, 37 (1898)].

the other compounds, a more difficult reaction, initiated by an external reagent, must take place prior to decomposition.

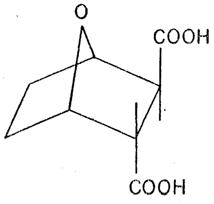
In addition to its ready elimination in the presence of base, the bromine atom in these compounds is remarkable in two further ways. The stability to alcoholic silver nitrate is traceable to the circumstance that while the bi-(or tri)-cyclic ring system is retained, stabilization of the carbonium ion intermediate which might otherwise result from the attack of silver ion is impossible. Finally, the bromine atom in (X) and its derivatives is stable toward zinc under conditions which normally transform dibromides and bromohydrin derivatives into olefins. However, it is known that this reaction is highly stereospecific, in that *trans* elimination takes place exclusively.[13] For instance, *dl*-2,3-dibromobutane gives only *cis*-butene-2, while *meso*-2,3-dibromobutane gives only the *trans*-olefin. No data are available on the reaction of zinc with a cyclic dibromide or bromohydrin derivative of known *cis*-configuration, but the above facts strongly indicate that the reaction, in such a case, in which the groups to be eliminated cannot assume a *trans* position with respect to one another, will proceed with difficulty, or not at all. Now in the formation of X, it is most probable that the initial attack of the bromine on the adduct (VI) takes place on the *exo* side[14]; consequently the bromine atom in (X), and the substances derived from it, will be *cis* to the oxygen attached to the contiguous carbon atom, and the sluggishness toward zinc may be accepted as confirmatory of the assigned structures.



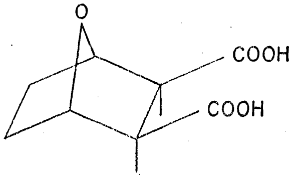
XXI



XXII



XXIII



XXIV

We turn now to a consideration of the configurations of the acids of the structure XXI. Three stereoisomeric forms, *viz.*, *endo–cis* (XXII), *trans* (XXIII) and *exo–cis* (XXIV), are possible. Alder and Backendorf, starting from the furan–maleic anhydride adduct (I or VI) have prepared three acids of the structure XXI, and *on the basis of the assignment of the erroneous configuration* (*V*) *to the original adduct*, deduced the configuration of the three saturated acids.[15] It is now clear that the previous configurational assignments, except for that of the intermediary *trans* acid, are invalid and must be revised. In Table I, the correct configurations are presented. In this connection it is noteworthy that the German workers were led to believe that in the *endoxo*-cyclohexane series, the melting point regularities observed in other (*e.g.* the [1,2,2]bicycloheptane) series were reversed, and that further, addition reactions (*e.g.*, hydrogenation), which normally occur with addition from the *exo* side,[16] also took an abnormal course, with *endo* addition. It is now clear that both the melting point regularities and the *exo* addition rule are obeyed in the *endoxo* cyclohexane series, and that the only reversal necessary is that which we have made in the configurational assignments.

TABLE I

CONFIGURATIONS OF THE 3,6-*endoxo*-HEXAHYDROPHTHALIC ACIDS AND ANHYDRIDES

		M. p., °C. Acid	Anhydride
exo–cis	(XXIV)	122–123	116–117
trans	(XXIII)	180	.....
endo–cis	(XXII)	169–170	158–159

The work described here demonstrates that the reaction of furan with dienophiles is similar to that of the fulvenes previously studied[1] in this Laboratory in that both *exo* and *endo* adducts may be formed, depending on the reaction conditions, and, in this particular case, on the nature of the addend. We are not prepared to discuss at this point the theoretical implications of the present work, but in any future discussion, the following points must be borne in mind. In the furan series, both addition reactions are readily reversible. Further, *the order of stabilities of the isomers is the same as that in the fulvene case*, as evidenced by the fact that while the *exo–cis* acid (XXV), obtained from the anhydride (VI), can be purified by recrystallization from warm water, all attempts so far made to isolate the *endo–cis* acid (IV) from its solutions have failed; since maleic acid is the only solid product obtained it

(15) Alder and Backendorf, *ibid.*, **535**, 113 (1938).

(16) It is worthy of note that the prevalence of *exo* addition in the catalytic hydrogenation of these bicyclic substances provides an excellent example of the operation of the catalyst hindrance effects postulated by Linstead, *et al.*, THIS JOURNAL, **64**, 1985 (1942).

appears that the furan–maleic acid reaction is extraordinarily readily reversible, with the result that attempts at removal of solvent, or extraction, result preferentially in removal of furan, by volatilization or extraction, with continuous displacement of the equilibrium until no adduct remains.

Experimental

Furan–Maleic Anhydride Adduct.—This substance was prepared according to the directions of Diels and Alder.[2] It is impractical to recrystallize the adduct because of the ease with which it dissociates in warm solvents.

Bromolactonic Acid (X, R = H).—Thirty-six grams of the furan–maleic anhydride adduct was dissolved in a solution containing 19 g. of sodium hydroxide in 600 ml. of water. The solution was cooled to about 8°, and bromine was added dropwise with constant stirring until a faint color persisted. Acidification with hydrochloric acid produced 49.5 g. of a white needle-like crystalline substance whose melting point was 153° (dec.) after recrystallization from water (not warmer than 40°). It is necessary to place the melting point capillary in the bath not more than 10° below the decomposition point or reproducible results cannot be obtained.

Anal. Calcd. for $C_8H_7O_5Br$: C, 36.5; H, 2.66. Found: C, 36.6, 36.3; H, 2.73, 2.70.

Concentration of the mother liquor *in vacuo* yielded 5.5 g. of the normal dibromide, m. p. 155° (from water).

Anal. Calcd. for $C_6H_6OBr(COOH)_2$: C, 27.9; H, 2.33; neut. equiv., 172. Found: C, 29.2, H, 2.79; neut. equiv., 170, 172.

Esterification of the dibromo acid (500 mg.) with 10 ml. of absolute methanol containing a few drops of fuming sulfuric acid (30%) yielded the dimethyl ester which, after two recrystallizations from water melted at 115.9–116.3°.

Anal. Calcd. for $C_{10}H_{12}O_5Br_2$: C, 32.3; H, 3.23. Found: C, 32.6; H, 3.51.

In order to obtain a maximum yield of the 153° compound it is necessary to add the bromine slowly and with rapid stirring as will be illustrated by Table II. The yield of dibromide is variable and of little significance because of the difficulty encountered in its isolation.

TABLE II

Adduct, g.	153° cpd.	Dibromide (155°)
9.2	8.2	2.2
30	28	7.3
36 rapid stirring	49.5	5.5

The 153° compound may also be obtained by dissolving the adduct directly in warm water (40–50°) and after cooling to 0° adding bromine until a slight color persists; the product, which has precipitated from the solution, is filtered off. In two typical experiments the weight of 153° compound obtained was approximately equal to that of the adduct used, and *ca.* one third as much dibromide was isolated.

If a small quantity of the 153° compound is dissolved in water and neutral or acid potassium permanganate added, no oxidation is observed. The addition of the slightest excess of carbonate results in instant decoloration of the solution.

Attempts at solution in caustic alkali or soda result in complete destruction of the compound if warmed; if the solution is kept cold, no decomposition is apparent until the solution is acidified, when a brown, amorphous solid is precipitated.

Schiff reagent fails to react but both Tollens solution and Fehling reagent give positive tests if the solution is warmed gently on the steam-bath. The addition of silver nitrate solution to a hot aqueous solution of the 153° compound produces an immediate precipitate of silver bromide; in alcoholic solution no reaction is observed.

Half-methyl Ester (X, R = CH_3).[4]—Diazomethane is distilled onto an ether suspension of the 153° acid (1 g.). After the reaction has ceased, the ether is boiled off and the solid that remains is recrystallized from methanol: 0.75 g. of fine, cotton-like needles, m. p. 167–168° (d.).

Anal. Calcd. for $C_9H_9O_5Br$: C, 39.1; H, 3.25. Found: C, 39.1, C, 39.1; H, 3.31, H, 3.39.

This substance is moderately stable to weakly acid permanganate solutions but once again, the addition of the merest trace of alkali results in instant decolorization of the permanganate.

This ester cannot be dissolved either in alkali or dilute sulfuric, hydrochloric, or acetic acids without complete decomposition. The reaction with nitric acid will be described under the preparation of the 137° compound.

If, however, nitrogen is bubbled through a saturated barium hydroxide solution and then the 168° ester rapidly added, the residue remaining, after warming for a half-hour to 50°, is mainly barium carbonate. While no organic product could be isolated from the solution, this result would indicate the presence of a β-keto acid in the solution which presumably resulted from the action of the base on the 168° ester. This observation may be considered as evidence for the change XVIII → XIX.

Pseudoester (XIII, R = H).—Into 10 ml. of methanol, containing a few drops of 30% fuming sulfuric acid, is placed 500 mg. of the 153° acid. After heating under reflux for three hours the solution is poured onto ice, whereupon the ester crystallizes (yield 300 mg.). After recrystallization from methanol the ester is obtained as plates, m. p. 163° (d.).

Anal. Calcd. for $C_{10}H_{13}O_6Br$: C, 38.9; H, 4.21. Found: C, 38.3, 38.3; H, 4.18, 4.14.

By making use of the above procedure the 168° ester (500 mg.) may be converted to the 163° ester (350 mg.); the 57° ester (*vide infra*) is also converted to the 163° ester by this procedure.

This ester is sensitive to alkali and alkaline potassium permanganate but relatively stable to acid and neutral permanganate.

Heating the 163° ester in methanol with zinc for twenty-four hours resulted in no change.

Acetyl Derivative (XIII, R = CH_3CO^-).—The 163° ester is dissolved in acetyl chloride and the solution heated under reflux for one hour. The solution was decomposed on ice and cooled in an ice-bath overnight: needles were obtained which, on recrystallization from methanol, melted at 146.5–147°.

Anal. Calcd. for $C_{12}H_{15}O_7Br$: C, 41.0; H, 4.27. Found: C, 41.1; H, 4.54.

Acid (XIV or XV).—Two grams of the 163° ester is added to a mixture of 10 ml. of concentrated nitric acid and 20 ml. of water and the mixture warmed in a water-bath (50°) with constant stirring until solution is complete. After warming for one more hour the solution is concentrated, by distillation *in vacuo*, and then cooled; the precipitated acid (600 mg.) is twice recrystallized from water and obtained as needles, m. p. 136–137° (d.) (this is not a true melting point and consequently varies somewhat with the rate of heating).

Anal. Calcd. for $C_8H_9O_6Br$: C, 34.1; H, 3.20. Found: C, 34.2, 34.0; H, 3.28, 3.56.

The same acid is obtained by treatment of either the 168° ester or the 158° acid in an analogous manner. From 1.4 g. of the 168° compound one obtains 450 mg. of acid.

Alkaline potassium permanganate attacks this substance with vigor. The Schiff test is negative but positive Tollens and Fehling tests are obtained.

This acid is readily converted to the 163° ester. To a solution of 300 mg. of acid in 10 ml. of methanol is added a few drops of fuming sulfuric acid (30%) and the whole heated under reflux for several hours. Decomposition of the solution on ice produces the characteristic silky plates of the 163° ester, m.p. 160° (d.).

Normal Ester (XVI).—Onto a suspension of 400 mg. of the 137° acid in ether diazomethane is distilled; the mixture is permitted to stand in ice until the evolution of nitrogen ceases. Removal of most of the ether on the steam-bath followed by cooling in ice results in the formation of 300 mg. of solid ester. Recrystallization from ether containing a little methanol produces clusters of transparent needles, m. p. 57° (dec.). This ester is estremely unstable, decomposing slowly in the cold room (5°) and very rapidly at room temperature (about an hour).

Anal. Calcd. for $C_{10}H_{13}O_6Br$: C, 38.9; H, 4.21; Br, 25.9. Found: C, 38.9; H, 4.43; Br, 26.3.

The Schiff test on this ester is negative but positive Fehling and Tollens tests are very readily obtained on only slight warming. Silver nitrate in alcoholic solution reacts slowly in the cold but rapidly on warming to produce a copious quantity of silver bromide.

Acid potassium permanganate does not effect a rapid oxidation but in an alkaline solution this reagent is instantly decolorized.

Summary

The reaction between furan and maleic acid in water, and that between furan and maleic anhydride in ether, take different stereochemical courses. In the former case, an *endo–cis* adduct is formed, while in the latter, an *exo–cis* product is obtained.

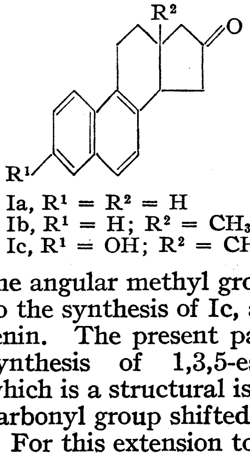
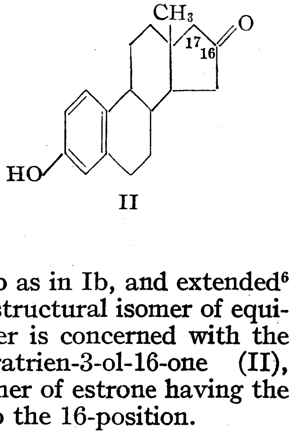
The Synthesis of 1,3,5-Estratrien-3-ol-16-one, A Structural Isomer of Estrone[1]

BY A. L. WILDS AND THOMAS L. JOHNSON[2,3]

Several years ago[4] a method of synthesis was developed for the ketone Ia, which possesses the basic ring system of the female sex hormones but with the ketone group at the 16 rather than the 17-position, and lacking the angular methyl and 3-hydroxyl groups. More recently[5] this synthetic approach was modified to permit incorporation of the angular methyl group as in Ib, and extended[6] to the synthesis of Ic, a structural isomer of equilenin. The present paper is concerned with the synthesis of 1,3,5-estratrien-3-ol-16-one (II), which is a structural isomer of estrone having the carbonyl group shifted to the 16-position.



Ia, R¹ = R² = H
Ib, R¹ = H; R² = CH₃
Ic, R¹ = OH; R² = CH₃



II

For this extension to compounds having ring B hydrogenated the key intermediate was the ketone VII,[7] for which an improved synthesis was developed by Bachmann, Kushner and Stevenson.[8]

In the present work the over-all yield in the conversion of the substituted malonic ester III to V could be raised from 28 to 45% by eliminating distillation of the intermediate keto ester IV and carrying out the cyclization with anhydrous hydrogen fluoride.[9] The remaining steps involving reduction of the dibasic acid to VI, conversion to the methyl ester, Dieckmann cyclization and methylation of the cyclic β-keto ester, followed by hydrolysis and decarboxylation, proceeded well to give mainly the crystalline isomeride of the octahydro ketone VII. Similar treatment of V led to the related hexahydro ketone VIII.[8] In each case the over-all yield of ketone from dibasic acid was 75–78%, or about 6.5 and 7.4%, respectively, for the 14–15 step synthesis from *m*-aminophenol.

In the earlier synthesis of the desoxy tetracyclic ketone Ib,[5] an acetic acid residue was introduced into the 2-position of 1-keto-2-methyl-1,2,3,4-tetrahydrophenanthrene by preparing the sodium enolate of the ketone with sodium amide and alkylating with methyl bromoacetate. Preliminary attempts to apply this procedure to the methoxy ketones VII or VIII (on a 0.5 g. scale) led to oily acidic mixtures after hydrolysis, from which no pure crystalline products could be isolated. Further work in the tetrahydro desoxy series showed that the original procedure, although quite satisfactory on a moderately large scale (71% yield on a 20 g. scale) was poor for small scale experiments (35–39% on a 0.5 g. scale). Triphenylmethylsodium, however, proved to be satisfactory as an enolizing agent even on a small scale, and when the optimum conditions for the reaction were developed it was possible to prepare the crystalline acetic acid derivatives IXa and Xa in 55–59% yields from the methoxy ketones VII and VIII.

With the hexahydroketone VIII the most probable position of alkylation was the 2-position.

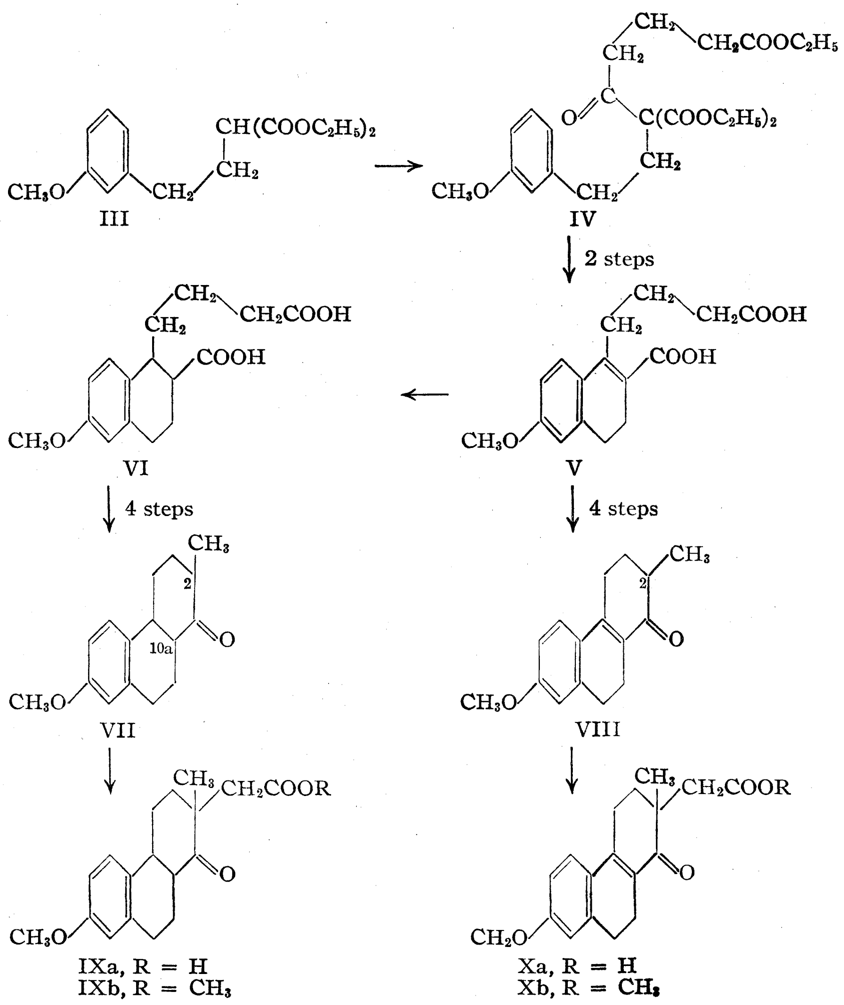
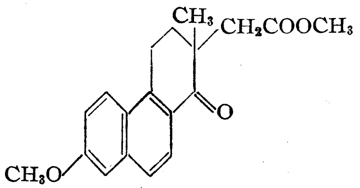
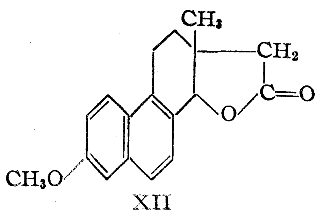
[9] Adkins and Hager have found this to be an excellent reagent for effecting the cyclization of somewhat analogous β-keto esters; Glenn F. Hager, Ph.D. Thesis, University of Wisconsin, 1943.



This structure for the acid Xa was proved by selective dehydrogenation of the methyl ester at 150° to the tetrahydro ester XI, which has been prepared[6] by a similar alkylation of the tetrahydro analog of VIII. The structure Xa for the acid also was supported by the ultraviolet absorption spectrum of the ester Xb, which was almost identical with that of the ketone VIII.



XI

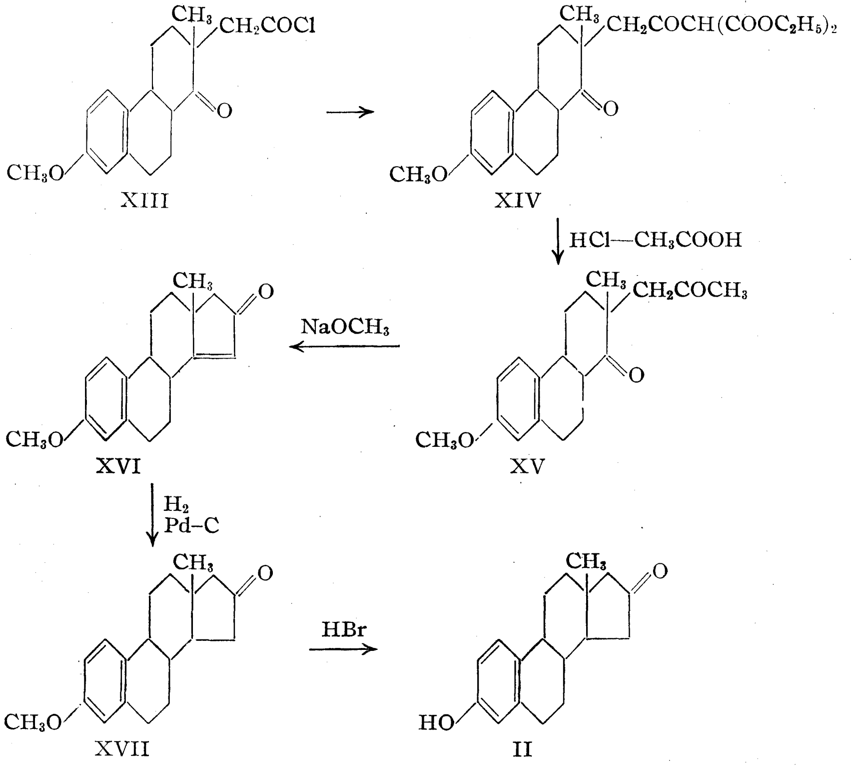


XII

In the case of the octahydro ketone VII not only the 2-position but also the angular 10a-position is available for alkylation. The results of dehydrogenation of the octahydro ester IXb were not so definitive as those for the hexahydro ester. The product after hydrolysis of the dehydrogenated ester contained considerable lactonic as well as acidic material. A small amount (5%) of the tetrahydro ester XI could, however, be isolated from the acidic product. The crystalline lactone, surprisingly enough, had the composition $C_{18}H_{20}O_3$ and thus apparently contained two hydrogen atoms more than the tetrahydro lactone XII, which was prepared by aluminum isopropoxide reduction of the ester XI. On the other hand, the ultraviolet absorption spectrum which closely resembled that of the tetrahydro lactone XII would indicate the presence of a naphthalene nucleus. Further work will be necessary to establish its structure.

Regardless of its own structure, however, the lactone obtained from the octahydro ester furnishes additional support for structure IXb, since a small amount of the same lactone was obtained by dehydrogenation of the hexahydro ester Xb at 225°. And finally, the hexahydro and octahydro series were linked by hydrogenation of the ester Xb. While the reaction was complex, it was possible to isolate a small amount (3%) of the crystalline octahydro ester IXb. Another product was the tetrahydro lactone XII, identical with that obtained from XI. Although in each of these reactions to establish the structure of IXa the yield of the critical derivative was low, the combined evidence affords reasonably good proof for the formula assigned.

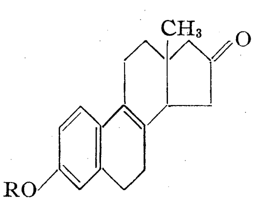
The next step of the synthesis involved converting the substituted acetic acids (IXa and Xa) into the corresponding methyl ketones. The reactions,[5] which involved formation of the acid chloride, condensation with sodiomalonic ester and acid hydrolysis of this intermediate to the diketone, proceeded well (78–83% yield) in the tetrahydro desoxy series regardless of the scale of the run (0.15 g. to 24 g.). Initial experiments in both the hexahydro and octahydro methoxy series, however, were unsuccessful and no crystalline products could be isolated. In the hexahydro series, starting with Xa, a large amount of *acidic* oil was obtained at the stage of the acyl malonic ester derivative. Part of the difficulty can be attributed to the step involving formation of the supposed acid chloride, for after hydrolysis of the latter, prepared with thionyl chloride or oxalyl chloride, only a small fraction of the starting acid could be recovered.



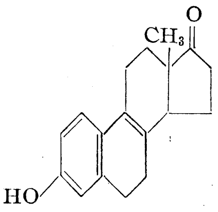
Early experiments with the octahydro acid IXa, using thionyl chloride to prepare the acid chloride, likewise led to an oily product at the diketone stage. However, in one run employing oxalyl chloride, 20% of the crystalline diketone XV was obtained. Here, too, the major difficulty consisted in forming the acid chloride. When the supposed acid chloride was hydrolyzed with water most of the product was a *neutral* oil, from which some of the starting acid could be obtained by alkaline hydrolysis. This indicated that the major product of this step was the ***enol*** lactone of IXa, rather than the acid chloride. By employing the sodium salt of the acid with oxalyl chloride,[10] the reaction was improved and the yield of the diketone increased to 42%. The sodium salt method, however, was unsuccessful in the hexahydro series, as were attempts to block the carbonyl group of IXb by conversion to a ketal with ethyl orthoformate or ethylene glycol.[11,12]

The cyclization of the diketone XV to the unsaturated ketone XVI was markedly influenced by the reaction conditions. The yield of the crystalline product was 90% using sodium methoxide in methanol as the condensing agent and heating for two and three-quarters hours. With shorter or longer times the yield was markedly decreased, in the latter case probably through isomerization of the crystalline ketone XVI. The ultraviolet absorption spectrum of the ketone (Fig. 1) showed bands typical for an α,β-unsaturated ketone (max. 227 mμ)[13] and for a phenol ether (max. 280 mμ).

Demethylation of the methoxy ketone XVI with hydrobromic and acetic acids gave a mixture from which a crystalline phenolic ketone could be isolated in 37% yield. The ultraviolet absorption spectrum of the latter (Fig. 1, max. at 273 mμ), different from that of the original methyl ether, indicated that the double bond had shifted from ring D into conjugation with ring A, most probably as shown in XVIIIa. This compound is then the 16-keto isomer (*dl*) of Hirschmann and Wintersteiner's isoequilin A (XIX, max. at 273 mμ)[14] which was prepared by a similar acid isomerization of the 7–8 double bond of equilenin to the 8–9 position.



XVIIIa, R = H
XVIIIb, R = CH_3



XIX

By hydrogenation with a palladium-on-carbon catalyst the unsaturated methoxy ketone XVI was converted into one of the isomeric forms of the reduced ketone XVII in 90% yield. Demethylation of this compound gave one of the eight possible racemic forms of the phenolic ketone II, m.p. 177.5–178°. The ultraviolet absorption

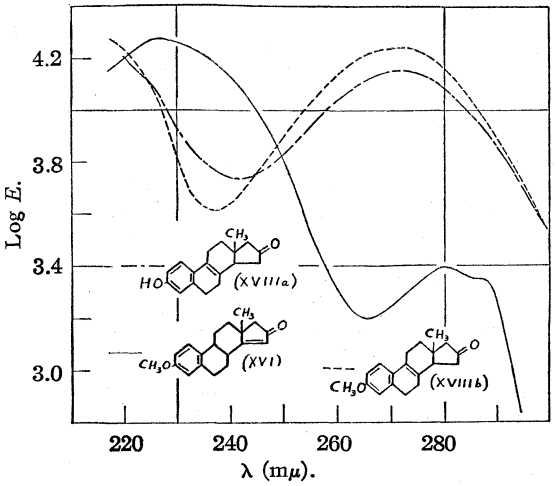

Fig. 1.

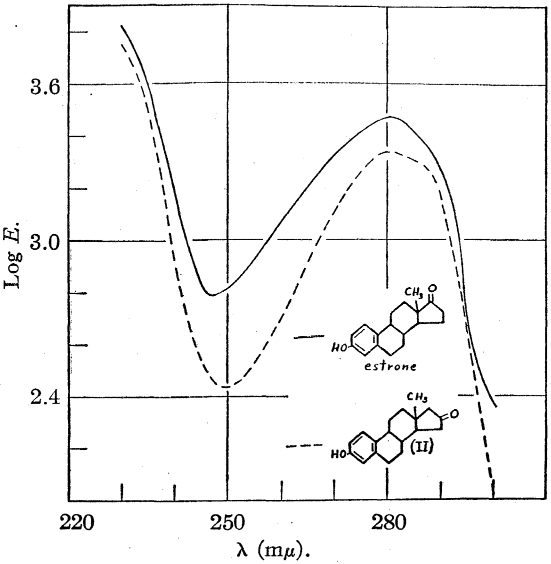

Fig. 2.

spectrum of the reduced phenolic ketone was in reasonably good agreement with that for estrone as can be seen from Fig. 2.

Tests for estrogenic activity, for which we are indebted to Drs. J. A. Leighty and E. D. Campbell of Eli Lilly and Co., indicated that this isomer of the phenolic ketone II possesses a low order of activity in ovariectomized mice. When injected as a solution in cottonseed oil, about 500 γ was equivalent to one mouse unit of estrone (0.066 γ). Since in the case of the analogous structural isomer of equilenin, reported recently,[6] the decrease in activity was much less (to about one-third that of *dl*-equilenin), it seems apparent that the present isomer of II does not possess the same stereochemical configuration as estrone. The unsaturated phenolic ketone XVIIIa was considerably more active, with one mouse unit equal to about 30 γ. This activity is the same as that for one of the isomers of Ic,[6] but is much lower (of the order of one-hundredth) than that for isoequilin A, which was reported[14] to be about one-fifth as active as estrone. Further work is in progress to prepare other stereoisomers of II by isomerization at various stages of the synthesis and by other suitable variations. The introduction of a keto group at C-17[5] in XVI with the goal of synthesizing the structures of estriol and estrone also is being investigated.

In view of the low yield at the stage of converting the acetic acid derivative IXa to the diketone XV, and the failure of the reaction in the hexahydro series, other approaches to the diketone and cyclic ketone which did not involve formation of the acid chloride, were investigated. Trial experiments were carried out first with the more readily available tetrahydro desoxy derivatives. Attempts to prepare the diketone directly from the ketone (corresponding to VII) by alkylation of the enolate with chloroacetone or iodoacetone were unsuccessful. Another route which appeared to offer considerable promise was the acetoacetic ester type of condensation between the keto ester XX and esters of acetic acid. Condensation reactions with ethyl acetate or acetonitrile, using sodium methoxide as the condensing agent, gave no positive results. Consequently the stronger base triphenylmethylsodium was used to prepare the enolate of the ester XX which was then condensed with phenyl acetate, a method employed with considerable success by Hauser and co-workers.[15] This led to an initial alkali-soluble product which underwent hydrolysis and decarboxylation with acid to give the cyclic ketone XXIIIa (in 23% yield) instead of the diketone. The yield could be raised by a retreatment of the neutral fraction to 37% (or 52% when corrected for recovered starting acid). The intermediate alkali-soluble material appears to be the cyclic keto ester XXII, previously prepared by Wilds and Beck[5] from XXIIIa through the glyoxalate reaction. The ultraviolet absorption spectrum of the compound closely resembled that of XXIIIa and other compounds having the same ring and conjugated double bond system.[16] The reaction of acetyl chloride with the enolate of the ester XX also was investigated. In this case the product (presumably XXI) was neutral, and after acid hydrolysis and decarboxylation the diketone corresponding to this was isolated in 19% yield using Girard's reagent P.

Application of the triphenylmethylsodium–phenyl acetate reaction to the methoxy hexahydro ester Xb gave an initial alkali-soluble product which led to a neutral oil upon hydrolysis and decarboxylation. Apparently this product unlike that in the tetrahydro desoxy series was not completely cyclized (if at all); upon heating with

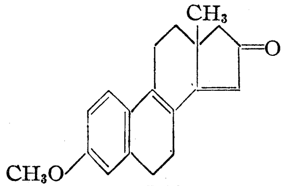
XXII

XXIIIa, R = H
(XXIIIb, R = CH_3O)

alkali, however, it gave the crystalline cyclic ketone XXIV in 11% yield. This material, a yellow solid, was not obtained entirely pure, judging from the melting point range, but the ultraviolet absorption spectrum, with the main maximum at 360 mμ, supports the structure with the double bonds as shown. Upon standing the filtrate from this ketone slowly deposited a small amount of a higher melting ketone which proved to be the dehydrogenated naphthalenic analog XXIIIb.[6] The reaction of acetyl chloride with the enolate of Xb gave after hydrolysis and cyclization about 2% of the same ketone XXIV as obtained from the phenyl acetate reaction.



XXIV

In the octahydro series the yields were even lower. In one run the reaction of phenyl acetate with the enolate of IXb gave after hydrolysis and decarboxylation 6% of the crystalline diketone XV, identical with that from the acid chloride–malonic ester procedure. In another run no crystalline diketone could be isolated, but after cyclization the crystalline compound obtained was similar in melting point and analysis to the cyclic ketone XVI; the mixed melting point, however, showed a 25° depression. The ultraviolet absorption spectrum (Fig. 1) indicated that in this isomer the double bond had shifted away from the carbonyl group and into conjugation with the aromatic ring as shown in XVIIIb.

Experimental[17]

Preparation of 1-Keto-2-methyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene and 1-Keto-2-methyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrene.[18]

—The method of Bachmann, Kushner and Stevenson[8] was employed for preparing these ketones with some modification in certain of the steps.

Ethyl 5-Keto-6,6-dicarbethoxy-8-*m*-anisyloctanoate (IV).—To 7.85 g. of powdered sodium in 230 cc. of dry, thiophene-free benzene was added 100 g. of diethyl β-*m*-anisylethylmalonate (III)[8] and the mixture was stirred and refluxed for twenty hours. Then the solution was cooled in an ice-bath and 76 g. of the acid chloride of ethyl hydrogen glutarate[8] was added. After four hours at room temperature and one hour at reflux the mixture was cooled and water added. The benzene layer and the ether extract of the aqueous layer were combined, washed with sodium bicarbonate solution and dried over sodium sulfate. Then the solvents and low boiling material were removed *as rapidly as possible* under reduced pressure (25 mm.), warming the residue finally to 100° in an oil bath. The residual yellow oil (134 g. corresponding to an apparent yield of 91%) was used in the next step without further treatment.[19]

γ-(6-Methoxy-2-carboxy-3,4-dihydro-1-naphthyl)-butyric Acid (V).[8]—To 25 g. of the crude undistilled keto ester (from the above procedure) in a 500-cc. platinum beaker cooled in an ice–salt mixture to −10°, was added approximately 150 g. of anhydrous, liquid hydrogen fluoride.[9] The mixture was kept in the bath at −10° for five hours, then the hydrogen fluoride was removed in a stream of air. Ice was added, most of the residual acid was neutralized with solid sodium bicarbonate, and the mixture was extracted twice with ether, washing the latter with water and evaporating. The residual triester was refluxed for three hours with 100 cc. of 45% potassium hydroxide and 100 cc. of methanol, most of the methanol was evaporated in a stream of air and the diluted mixture extracted with ether. The alkaline layer was acidified by pouring onto a mixture of ice and 110 cc. of concentrated hydrochloric acid and the tribasic acid was extracted with three portions of ether. Following removal of the ether the residue was heated with 250 cc. of water on the steam-bath for twelve hours. After cooling, the oily solid was filtered, triturated with about 30 cc. of ether, refiltered and washed with cold benzene, giving 8.15 g. of the dibasic acid, m. p. 185–187.5° (d.). A second crop of 0.10 g., m. p. 175–182°, brought the total yield to 50%, based upon the crude keto-ester, or an over-all yield of 45%, based on the diethyl β-*m*-anisylethylmalonate.

A third crop of 0.85 g., m. p. 135–143° (d.), proved to be β-*m*-anisylmalonic acid. After recrystallization from dioxane–benzene the compound melted at 143–144° (d.) and showed no m. p. depression when mixed with an authentic sample.

Anal. Calcd. for $C_{12}H_{14}O_5$: C, 60.5; H, 5.9. Found: C, 60.5; H, 6.0.

The above conditions represent the optimum determined from a number of cyclizations in which the time of standing with hydrogen fluoride and the temperature were varied.

1-Keto-2-carbomethoxy-2-methyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene.[8]—The dibasic acid (20 g., m. p. 185–188°) was converted to the dimethyl ester with diazomethane in ether (prepared from 30 g. of N-nitroso-N-methylurea), the ether was removed by distillation and the absence of water insured by adding dry benzene and again distilling the solvent. Meanwhile

---

(17) All melting points are corrected unless otherwise indicated; those marked "vac." were determined in sealed Pyrex melting point tubes evacuated to at least 0.5 mm.

18) Some of the early experiments in this section were carried out by Dr. Lloyd W. Beck.

(19) The earlier procedure[8] for this reaction included further purification by flash distillation at 340° (0.05 mm.) followed by fractional distillation. We have observed that this purification results in lower and more variable over-all yields of the dibasic acid V after cyclization, as indicated by the following example: crude keto ester obtained in 86% apparent yield gave a 43% over-all (from III) yield of the acid V; after the flash distillation the over-all yield of V dropped to 38%, after the fractional distillation to 16%, and after a second fractional distillation to 7%.

sodium methoxide was prepared from 3.2 g. of sodium and 70 cc. of anhydrous methanol, removing the excess solvent under reduced pressure at 100°. Dry benzene was added to the solid and again removed. The cake of sodium methoxide was broken up, the system filled with nitrogen, and the dimethyl ester was added in 250 cc. of dry benzene. The suspension was refluxed with occasional vigorous swirling; in one hour the sodio derivative of the cyclic keto ester began to separate as a voluminous precipitate. After eighteen hours at reflux, the mixture was cooled and 25 cc. of methyl iodide in 25 cc. of anhydrous methanol was added. After twenty-four hours at room temperature, the solid had completely dissolved, and an additional 10 cc. of methyl iodide and 10 cc. of methanol were added and the solution refluxed for one hour. The mixture was acidified with acetic acid, water and ether added and the organic layer was washed with sodium bicarbonate solution, dried and evaporated. The residue readily crystallized from methanol giving 15.6 g. of the keto ester, m. p. 96–97.5° and an additional 1.85 g., m. p. 90–96.5°, for a total yield of 84%. The pure compound is reported[8] to melt at 98–100°.

1-Keto-2-methyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene (VIII).—A mixture of 20.1 g. of the above keto ester, 200 cc. of acetic acid, 200 cc. of hydrochloric acid and 100 cc. of water was refluxed under nitrogen for two hours, then cooled, diluted and extracted twice with ether, washing with water, dilute potassium hydroxide and acid. From the ether extract by recrystallization from petroleum ether (b. p. 60–68°) was obtained 14.8 g. (91%) of the ketone, m. p. 67–69°. Further recrystallization gave material melting at 68–69° (reported 66–67°[8] and 67–68°[7]). The ultraviolet absorption spectrum was reported earlier.[16]

From the potassium hydroxide washings was obtained 0.52 g. of phenolic material, m. p. 183–189°. Two recrystallizations from methanol gave colorless prisms of what appears to be 1-keto-2-methyl-7-hydroxy-1,2,3,4,-9,10-hexahydrophenanthrene, m. p. 187–189°.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.9; H, 7.1. Found: C, 78.8; H, 7.0.

γ-(6-Methoxy-2-carboxy-1,2,3,4-tetrahydro-1-naphthyl)-butyric Acid (VI).—Reduction of the recrystallized unsaturated dibasic acid (5.03 g.) was carried out as described by Bachmann, Kushner and Stevenson,[8] with palladium-on-carbon catalyst.[20] A total of 4.64 g. (92%), m. p. 155–157.5°, of the reduced acid was obtained by crystallization from benzene (reported,[8] m. p. 156–157.5°).

1-Keto-2-methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene (VII).—The Dieckmann reaction was carried out on the dimethyl ester of the reduced dibasic acid (from 12.4 g. of acid and diazomethane) as described for the unsaturated analog, allowing twenty-one hours at reflux and using 25 cc. of methyl iodide in 50 cc. of methanol for the first addition and 10 cc. of methyl iodide in 25 cc. of methanol for the second. The mixture was allowed to stand for another twenty hours, followed by three hours at reflux, and the intermediate keto ester was isolated as an oil.[21] It was hydrolyzed and decarboxylated by refluxing with 120 cc. of acetic acid, 120 cc. of hydrochloric acid and 60 cc. of water for one and one-half hours under a nitrogen atmosphere. The cooled mixture, which showed an intense green fluorescence, was worked up as described for the hexahydro ketone. The product crystallized from methanol giving 5.74 g. of colorless ketone, m. p. 107–114°. The filtrate contained a preponderance of oily diastereoisomers which were partially converted to the crystalline isomeride by a repetition of the acid treatment for one and one-half hours using one-half the original quantity of reagents. In this manner an additional 1.71 g. of the crystalline ketone, m. p. 114–116°, was obtained, and from a third acid treatment another 0.26 g., m. p. 102–112°, for a total crude yield of 74%. Two recrystallizations of this material from methanol gave 5.1 g. of ketone, m. p. 116–118°, which was used in the subsequent reactions. By further recrystallization material of m. p. 118.5–119° was obtained (reported 116–117.5°[8] and 119–120°[7]).

Syntheses in the Desoxy Series (with 1-Keto-2-methyl-1,2,3,4-tetrahydrophenanthrene)

1-Keto-2-methyl-1,2,3,4-tetrahydrophenanthrene-2-acetic Acid.—For the preliminary experiments in the methoxy series it was essential to have a procedure suitable for small-scale runs. The procedure previously described by Wilds and Beck,[5] in which sodium amide was used in ether[22] suspension to enolize the ketone, gave considerably lower yields (35–39%) when the amount of ketone was reduced to 0.5 g.; with potassium amide (and allowing only 0.75 hour for enolization) the yield was slightly improved (49%). Triphenylmethylsodium[15] proved to be a suitable reagent for runs on a small scale, giving 74% yield of the acid in 0.5 g. runs (by a procedure similar to that described below in the octahydro series).

Condensation of Methyl 1-Keto-2-methyl-1,2,3,4-tetrahydrophenanthrene-2-acetate with Phenyl Acetate.—To a solution of 1 g. of the methyl ester XX (m. p. 72–73.5°) in 10 cc. of dry ether was added triphenylmethylsodium solution[25] in slight excess (11 cc. of 0.4 *M*) under nitrogen followed by 0.5 cc. of phenyl acetate.[23] The mixture was allowed to stand at room temperature for four hours with occasional swirling. Dilute acetic acid and ether were then added and the ether solution was washed with water and three times with 10% potassium hydroxide solution (the latter constitutes fraction a). The ether solution was evaporated and a crop of triphenylmethane (0.5 g., m. p. 91–93°) was crystallized from benzene. The filtrate was dried by repeated addition of dry benzene and distillation under reduced pressure, then the residue was treated again with the triphenylmethylsodium solution until a permanent red color remained (9 cc.). Phenyl acetate (0.5 cc.) was added and the above procedure repeated, giving a second portion of material in the alkaline extract (fraction b). Both fractions were worked up separately. The potassium hydroxide solution containing fraction a was acidified, extracted with ether and the latter washed with sodium bicarbonate solution. Evaporation of the ether left 0.48 g. of oil which was refluxed for two hours with 10 cc. of acetic acid, 10 cc. of hydrochloric acid and 4 cc. of water. After cooling, extracting with ether and washing with alkali and water, 0.23 g. of a yellow oil was obtained which crystallized immediately when stirred with petroleum ether, giving 0.203 g., m. p. 142.5–148°.

Fraction b gave in a similar manner an additional 0.120 g., m. p. 133–144°. This material proved to be $\Delta^{1,1'}$-2'-keto-2-methyl-3,4-dihydro-1,2-cyclopentenophenanthrene (XXIIIa); a recrystallized sample had the m. p. 148–150° alone and when mixed with a known sample.[5] From the neutral fraction after the second treatment was obtained 0.283 g. (30%), m. p. 148–151.5°, of the starting acid by alkaline hydrolysis and recrystallization of the bicarbonate-soluble fraction. The yield of the cyclic ketone corresponded to 37%, or 52% taking into account the recovered acid.

In another run, starting with 2 g. of the methyl ester, the intermediate alkali-soluble product was investigated. This material (950 mg. of oil which contained phenol)

---

[20] Linstead and Thomas, *J. Chem. Soc.*, 1130 (1940).

[21] Recently Anner and Miescher [*Helv. Chim. Acta*, **30**, 1427 (1947)] have reported isolation of three of the four possible crystalline *dl*-forms of this compound.

[22] Subsequent work has indicated toluene to be a more suitable solvent than ether for this reaction on a large scale, and in this case also the size of run can be reduced to at least 2 g. without lowering of yield. Using toluene at 55° for seven hours for the enolization of the ketone with sodium amide, the yield of crystallized acid (m. p. 148–150.5°) amounted to 71%; 5% of the starting ketone was recovered and none of the high melting by-product (m. p. 255–256°) was formed.

[23] Ethyl acetate was much less satisfactory, resulting in a lower yield of cyclic ketone, a trace of the uncyclized diketone and an appreciable amount of lactonic material.

would not crystallize until seeded in methanol with methyl $\Delta^{1,1'}$-2′-keto-2-methyl-3,4-dihydro-1,2-cyclopentenophenanthrene-3′-carboxylate (XXII, m. p. 148–154°) prepared earlier.[5] A total of 0.30 g. of yellow solid was obtained, m. p. 141–150°, which gave a green color with alcoholic ferric chloride. Repeated recrystallization from methanol gave a sample with the m. p. 149.5–158°. This material apparently retained solvent of crystallization since the analysis showed a low carbon value (76.4%). After drying at 80° and 0.1 mm. for forty hours, satisfactory analytical values were obtained.

Anal. Calcd. for $C_{20}H_{18}O_3$: C, 78.4; H, 5.9. Found: C, 78.3; H, 5.9.

The ultraviolet absorption spectrum[24] was very similar to that of the cyclic ketone XXIIIa[16] and showed maxima at 219 mμ (log E = 4.33), 238.5 mμ (4.10), 267 mμ (4.48), 276 mμ (4.56) and 315.5 mμ (4.40); minima at 230.5 mμ (4.05), 249 mμ (4.08), 270 mμ (4.45) and 287.5 mμ (4.06); and points of inflection at 245 mμ (4.09) and 360 mμ (3.75).

Syntheses in the Hexahydro Series (with 1-Keto-2-methyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene)

1-Keto-2-methyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene-2-acetic Acid (Xa).—The hexahydro ketone VIII (5.04 g.) was alkylated using triphenylmethyl sodium and methyl bromoacetate following the same procedure as described below for the octahydro ketone VII, except that ten minutes was allowed between the addition of the base and the bromo ester. The acid was crystallized from benzene to give 3.40 g. of acid (m. p. about 90–100°) containing benzene of crystallization. An additional 0.26 g. of crystalline material was obtained by chromatographic fractionation of the remaining acidic oil as the methyl ester (see below). The solvent of crystallization could be removed only by heating for one to two days at 70° and 0.2 mm., then giving a product melting at 105.5–106.5°. The loss in weight (10.4%) corresponded approximately to one-half molecule of benzene of crystallization (calcd. 11.5%). The yield of product, corrected for the benzene of crystallization, was 52%. Recrystallization of the combined acid from carbon tetrachloride (which is not suitable for crystallizing the crude product) gave 2.82 g. (45%) of nearly colorless, solvent-free material, m. p. 105.5–106.5° with slight softening at 104°. The purest sample was obtained from methanol as colorless clumps of prisms, m. p. 106.5–107.5°.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 72.0; H, 6.7. Found: C, 71.9; H, 6.9.

The **methyl ester Xb**, prepared with an ethereal solution of diazomethane, was obtained in practically quantitative yield as colorless blades from methanol, m. p. 66.5–68°.

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.6; H, 7.1. Found: C, 72.3; H, 6.9.

The ultraviolet absorption spectrum[24] of the ester showed maxima at 240 mμ (log E = 4.04) and 329 mμ (4.34) and a minimum of 262.5 mμ (3.04).

In addition to the acid some phenolic material also was obtained which crystallized when stirred with benzene, 360 mg. (7%), m. p. 119–125°. Repeated recrystallization from benzene raised the m. p. of the product to 124–126.5°; from the analytical values this material appears to be **2-methyl-7-methoxy-9,10-dihydro-1-phenanthrol**.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 80.0; H, 6.7. Found: C, 79.8; H, 6.6.

Chromatographic fractionation of the residual oily acid (as the methyl ester) was carried out on alumina. Elution with 60% benzene (in petroleum ether) gave 430 mg. of a nearly colorless oil which crystallized when stirred with petroleum ether; 204 mg., m. p. 140–160°. After two recrystallizations from methanol a compound, isomeric with the desired methyl ester, was obtained as colorless prisms, m. p. 161.5–163°.

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.6; H, 7.1. Found: C, 72.5; H, 7.0.

The ultraviolet absorption spectrum[24] of this ester was quite different from that of the methyl ester Xb, showing a maximum at 261 mμ (log E = 4.23), a minimum at 233 mμ (3.63) and a point of inflection at 292 mμ (3.51).

Subsequent eluates of the chromatogram, finally using pure benzene, gave material which upon saponification yielded 0.26 g. of the acetic acid derivative Xa mentioned above.

Dehydrogenation of the Hexahydro Methyl Ester Xb.—The ester (100 mg., m. p. 64–66°) and 100 mg. of palladium-on-carbon catalyst[20] were heated under nitrogen at 130–150° for a total of twenty minutes. The product was crystallized from methanol to give a total of 54 mg. of solid, m. p. 94–96°; after a second recrystallization the product melted at 97.5–99° alone and when mixed with a sample of the tetrahydro methyl ester XI (m. p. 98.5–99.5°).[6] Saponification gave the corresponding acid, m. p. 145–147° alone and when mixed with an authentic sample.[6]

In another run the same quantities of the methyl ester and catalyst were heated for five minutes in a bath preheated to 225°. The crude product gave 46 mg. of the tetrahydro ester, m. p. 94.5–97.5°. The material in the filtrate was hydrolyzed with 5% potassium hydroxide, extracted with ether and acidified. After warming the suspension of acid for one-half hour on the steam-bath it was taken up in ether and washed with sodium bicarbonate solution. The latter gave 22 mg. of acidic material and from the ether was obtained 16 mg. of neutral, lactonic material. Crystallization gave 11 mg. of a mixture, m. p. 123–133.5° (softening at 117°), from which a small amount of material, m. p. 131.5–134°, was obtained after five recrystallizations from benzene–petroleum ether. This showed no depression in m. p. when mixed with the lactone obtained below by dehydrogenation of the methyl ester of the octahydro acid.

$\Delta^{1,1'}$-2′-Keto-2-methyl-7-methoxy-3,4,9,10-tetrahydro-1,2-cyclopentenophenanthrene (XXIV).—To a solution of 634 mg. of the hexahydro methyl ester Xb (m. p. 64–66°) in 10 cc. of dry, thiophene-free benzene was added 1.4 equivalents of triphenylmethylsodium solution[25] (9 cc. of 0.3 *M*) under nitrogen; the red color of the reagent did not persist. Phenyl acetate (0.4 cc.) was added and the mixture allowed to stand for eighteen hours. Then it was worked up as described above for the desoxy series and the potassium hydroxide-soluble portion isolated. A retreatment of the neutral fraction (5 cc. of triphenylmethylsodium and 0.4 cc. of phenyl acetate) gave additional alkali-soluble material. These were hydrolyzed in a nitrogen atmosphere with acid; as the neutral fraction was not crystalline it was heated for fifteen hours under nitrogen with 2 cc. of 45% potassium hydroxide and 8 cc. of methanol, and the neutral portion was evaporatively distilled at 180–200° (0.1 mm.). The yellow distillate (105 mg.) was crystallized from methanol yielding 50 mg., m. p. 120–127°, and 14 mg., m. p. 116–127°, corresponding to an 11% yield. A sample with a sharp melting point could not be obtained. Repeated recrystallization of the cyclic ketone from methanol gave yellow prisms, m. p. 122.5–128° with a small residue remaining to 135°.

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 81.4; H, 7.2. Found: C, 81.1; H, 7.2.

The ultraviolet absorption spectrum[24] showed maxima at 257.5 mμ (log E = 4.03) and 360 mμ (4.44); minima at 230 mμ (3.74) and 293 mμ (3.53); and an inflection at 280 mμ (3.70).

The methanol filtrate from which the ketone XXIV had crystallized slowly deposited a small amount of solid which was filtered after five months. This material, which melted at 120–130° but with a residue up to 185°, gave after two recrystallizations from methanol a small sample of cream colored solid, m. p. 202–203°, which gave

---

[24] The ultraviolet absorption spectra were all determined in absolute alcohol solution using a Beckman quartz photoelectric spectrophotometer; $E = (1/c) \log (I_0/I)$ for a 1-cm. cell, where c = concentration in moles per liter.

no melting point depression (m. p. 202–204°) when mixed with $\Delta^{1,1'}$-2′-keto-2-methyl-7-methoxy-3,4-dihydro-1,2-cyclopentenophenanthrene (XXIIIb).[6]

Basic hydrolysis of the initial neutral material containing triphenylmethane gave 272 mg. of acidic oil from which 71 mg. of the starting acid could be crystallized using benzene.

Synthesis in the Octahydro Series (with 1-Keto-2-methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene)

1-Keto-2-methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-2-acetic Acid (IXa).—The following procedure represents the best of a number of runs in which the conditions were varied. To a solution of 5.47 g. of the octahydro ketone VII in 50 cc. of dry, thiophene-free benzene was added[25] at room temperature under nitrogen a 10% excess of triphenylmethylsodium[15] in ether (61 cc. of 0.4 *M*). After twenty minutes the reaction flask was cooled in ice, transferred to a nitrogen-filled condenser attached to a mercury trap and 10 cc. of methyl bromoacetate was added *all at once* through the condenser with swirling. The mixture was refluxed for one and one-half hours, then the ether and benzene were evaporated and the residue was saponified by refluxing for twelve hours with 75 cc. of 45% potassium hydroxide and 75 cc. of methanol. After evaporating most of the methanol, the alkaline solution was washed twice with ether and acidified. The product was extracted with ether and crystallized from carbon tetrachloride to give 4.96 g. of the acid containing solvent of crystallization; the latter was removed by heating at 65° for twelve hours, giving 3.40 g. of acid, m. p. 132.5–138°. The mother liquors were evaporated and the residue was treated with 25 cc. of saturated sodium bicarbonate solution and allowed to stand; more of the acid separated as the insoluble sodium salt from which, after acidifying and extracting with ether, an additional 0.41 g. of the crystalline acid, m. p. 136.5–140°, was obtained. By a second treatment with a smaller volume of bicarbonate solution another 0.15 g. of the acid, m. p. 127–135°, was obtained, bringing the total yield to 59%. The ether washings contained 0.18 g. of phenolic oil which could not be crystallized. The purest sample of the acid was obtained by recrystallization from methanol, giving clumps of colorless prisms, m. p. 139.5–140.5°.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.5; H, 7.3. Found: C, 72.0; H, 7.5.

The **methyl ester** IXb, obtained in 91% yield with diazomethane, crystallized from methanol as colorless leaflets, m. p. 97–97.5°.

Anal. Calcd. for $C_{19}H_{24}O_4$: C, 72.1; H, 7.6. Found: C, 72.0; H, 7.6.

Dehydrogenation of the Octahydro Methyl Ester IXb.—A mixture of 100 mg. of the ester (m. p. 94–96°) and 100 mg. of palladium-on-carbon catalyst[20] was heated at 200–205° for twenty-five minutes. Crystallization of the product from benzene–petroleum ether (b. p. 60–68°) gave 46 mg., m. p. 110–128°; after four recrystallizations was obtained 12 mg. of material, m. p. 133.5–134.5°, which proved to be a lactone. It gave no depression in m. p. when mixed with the lactone obtained by dehydrogenation of the hexahydro ester (see above), but showed depression to 110–120° with the tetrahydro lactone XII (m. p. 145–145.5°).

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.0; H, 7.1; for $C_{18}H_{18}O_3$: C, 76.6; H, 6.4; for $C_{18}H_{22}O_3$: C, 75.5; H, 7.8. Found: C, 76.1, 75.9; H, 7.1, 7.1.

The ultraviolet absorption spectrum[24] showed maxima at 229 mμ (log E = 4.66), 265 mμ (3.70), 274 mμ (3.71), 320 mμ (3.29), and 334 mμ (3.39); minima at 252–258 mμ (3.60), 269 mμ (3.66), 298 mμ (2.81) and 324 mμ (3.21); and inflections at 284 mμ (3.54), 308 mμ (3.01) and 329 mμ (3.26).

In another experiment 100 mg. of the ester was heated with the catalyst for ten minutes at 250°. A total of 37 mg. of the crude lactone and 32 mg. of acid, m. p. 125–131°, were obtained. The acid was treated with diazomethane and recrystallized five times from methanol to give about 5 mg. of the methyl ester of the tetrahydro acid XI, m. p. 95.5–96°. The mixed m. p. with an authentic sample[6] was 95.5–98.5°, while with the octahydro ester IXb (m. p. 94–96°) the m. p. was depressed to 72–96°.

Hydrogenation of the Hexahydro Methyl Ester Xb.—A solution of 489 mg. of the hexahydro ester Xb (m. p. 64–66°) in 16 cc. of purified dioxane was stirred with 200 mg. of palladium-on-charcoal catalyst[20] and hydrogen at atmospheric pressure and room temperature. After seven hours, when 1.1 mole-equivalents of hydrogen had been absorbed, reduction was still taking place at a steady rate and the reaction was stopped. The catalyst and solvent were removed, the residue hydrolyzed with 5 cc. of 45% potassium hydroxide and 20 cc. of methanol and separated into acidic (250 mg.) and lactonic (210 mg.) material as described above. A small portion (50 mg.) of the lactone crystallized from methanol, m. p. 114–138°. Recrystallization from benzene–petroleum ether gave a mixture of needles and clumps of microscopic crystals which were separated by hand. The former had the m. p. 162–171°, the latter 143–145°. A mixture of the latter with the lactone of 1-hydroxy-2-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-2-acetic acid (XII; see below) gave no m. p. depression. Apparently this lactone was formed by disproportionation.[26] The higher melting material was not investigated further.

The acidic fraction was dissolved in 5 cc. of hot sodium bicarbonate solution (saturated at room temperature) cooled and seeded with a trace of the sodium salt of the octahydro acid. After two days at 0° a small amount of precipitate had formed from which was obtained 15 mg. of acid which readily crystallized, m. p. 118–130°. The melting point was raised to 125–138° when the crude sample was mixed with the octahydro acid IXa. The crude acid was converted to the methyl ester (diazomethane) and recrystallized twice from methanol giving material melting at 95–97°. A mixture with the methyl ester of the octahydro acid IXb (m. p. 95.5–97°) showed no m. p. depression, while with the tetrahydro methyl ester XI (m. p. 98.5–99.5°)[6] the m. p. was depressed to 76–90°.

Aluminum Isopropoxide Reduction of the Tetrahydro Methyl Ester XI.—A solution of 100 mg. of the methyl ester[6] (m. p. 97.5–98.5°), and 300 mg. of aluminum isopropoxide in 5 cc. of anhydrous isopropyl alcohol was refluxed for sixteen hours. The solution was cooled, dilute acid added and the product was extracted with ether. The residue after evaporating the solvent was heated for two hours with 1 cc. of 45% potassium hydroxide and 4 cc. of methanol, diluted, acidified and warmed on the steam-bath for one-half hour. The product was extracted with ether, washed with bicarbonate solution (only 5 mg. of acidic material obtained) and crystallized from alcohol, giving 63 mg. of lactone, m. p. 144.5–145.5°, and an additional 11 mg., m. p. 142–144°, for a yield of 82%. The melting point of the pure lactone XII was 145–145.5°.

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.6; H, 6.4. Found: C, 76.3; H, 6.4.

The ultraviolet absorption spectrum[24] showed maxima at 236 mμ (log E = 4.84), 266.5 mμ (3.75), 275.5 mμ (3.77), 314 mμ (3.21), and 329 mμ (3.27); minima at 253.5 mμ (3.63), 270.5 mμ (3.73), 306 mμ (3.05) and 324

---

[25] The apparatus, designed by Dr. C. David Gutsche, was a convenient modification of that described by Baumgarten and Hauser [THIS JOURNAL, **66**, 1039 (1944)], which permitted the reagent reservoir and buret to be closed off from the rest of the system while this and the reaction flask were evacuated and filled with nitrogen. Measured amounts of the reagent solution were then added to the reaction flask from the buret.

[26] Disproportionation accompanying hydrogenation of somewhat related compounds has been observed before with equilin by Dirscherl and Hanusch, *Z. physiol. Chem.*, **233**, 13 (1935); **236**, 131 (1935), and with dihydroequilin by Serini and Logemann, *Ber.*, **71**, 186 (1938); for a recent example see Anner and Miescher, *Helv. Chim. Acta*, **29**, 1889 (1946).

mμ (3.08); and inflections at 285 mμ (3.62), 308 mμ (3.07), and 321 mμ (3.11).

1-Keto-2-methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-2-acetone (XV).—The octahydro acid IXa (1.34 g.) was converted to the sodium salt by means of 0.374 g. of sodium bicarbonate in 5 cc. of water, the water was evaporated in a stream of air and the solid residue was powdered and dried in an oven at 100° for twelve hours. Dry benzene (15 cc.), a drop of pyridine and 4 cc. of oxalyl chloride (b. p. 63–64°) were added to the sodium salt[10] at 0°. Immediate reaction took place and after standing at room temperature for two and one-half hours, the solvent was removed under reduced pressure without heating, and an additional 10 cc. of benzene was added and removed as before. The acid chloride was dissolved in 30 cc. of dry benzene and filtered through a plug of cotton into a suspension of sodiomalonic ester (from 0.5 g. of sodium powder and 5 cc. of diethyl malonate in 50 cc. of dry ether). After stirring at room temperature for fifteen hours and at reflux for two, the mixture was acidified with dilute acetic acid, extracted with ether, the ether removed and the residue heated for one and one-half hours under nitrogen with 10 cc. of water, 25 cc. of acetic acid and 25 cc. of hydrochloric acid. The cooled mixture, which showed an intense green fluorescence, was diluted, extracted with ether and washed with water, 10% potassium hydroxide and dilute acid. From the ether was obtained 1.02 g. of brown oil which crystallized from methanol to give 471 mg. of the diketone, m. p. 115–122°. Evaporative distillation of the material in the filtrate at 170–190° (0.05 mm.) and recrystallization from methanol gave an additional 76 mg., m. p. 114–117.5° and 18 mg., m. p. 107–117° for a total yield of 42%. One recrystallization of the combined material gave 422 mg. of the diketone, m. p. 121–122.5°. The pure compound crystallized from methanol as colorless blades, m. p. 122–122.5°.

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 76.0; H, 8.1. Found: C, 75.9; H, 8.1.

Acidification of the potassium hydroxide extracts gave 410 mg. of oil, from which 282 mg. of starting acid, m. p. 131–136°, was recovered through the insoluble sodium salt. The yield of crude diketone corrected for this recovered acid was 54%. When the acid chloride was prepared from the free acid, rather than the salt, the yield of crude diketone was only 20%.[27]

Condensation of Methyl 1-Keto-2-methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-2-acetate with Phenyl Acetate.—This reaction was carried out with 750 mg. of the octahydro ester IXb (m. p. 95–97°) in the same manner as described above for the hexahydro ester Xb, except that ether was used instead of benzene to dissolve the ester originally, and the reaction mixture was allowed to stand for six hours. After hydrolysis and decarboxylation of the potassium hydroxide-soluble material, the neutral oil was evaporatively distilled at 185–200° (0.1–0.4 mm.) giving 130 mg. of oil from which 41 mg. (6%) of solid diketone, m. p. 105–118°, could be crystallized using methanol. Recrystallization from methanol gave 19 mg. of material, m. p. 121.5–122.5°, which showed no depression in m. p. when mixed with the diketone XV prepared by the malonic ester procedure.

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 76.0; H, 8.1. Found: C, 75.5; H, 8.0.

A retreatment of the initial neutral fraction with triphenylmethylsodium and phenyl acetate gave only 7 mg. more of the crystalline diketone, m. p. 113–120.5°.

From another run starting with 700 mg. of the ester, the only variations being that benzene was used as the initial solvent and the reaction time was sixteen hours instead of six, no crystalline diketone was obtained. The oily diketone (135 mg., after evaporative distillation) was cyclized by heating with 1 cc. of 45% potassium hydroxide and 5 cc. of methanol for fifteen hours under nitrogen; 95 mg. of neutral oil was obtained which crystallized from methanol upon cooling to Dry Ice temperature, giving 26 mg. of solid, m. p. 103–109°. Recrystallization from methanol gave 7 mg., m. p. 108–111°. A mixture of this material with the cyclic ketone XVI (m. p. 110–111°) prepared by cyclization of the crystalline diketone XV (see below) gave a depression in melting point to 84–95°.

Anal. Calcd. for $C_{19}H_{22}O_2$: C, 80.8; H, 7.9. Found: C, 80.3; H, 7.7.

The ultraviolet absorption spectrum[24] of this substance (Fig. 1), which supported the structure XVIIIb as a result of a shift of the double bond, showed a maximum at 273 mμ (log E = 4.25) and a minimum at 237.5 mμ (3.62); a lower maximum and minimum in the region 320–370 mμ (log E = 2.7–2.9) were indicated but were not measured accurately.

3-Methoxy-1,3,5,14-estratetraen-16-one (XVI).—The optimum conditions for cyclizing the diketone XV were as follows: To a solution of 0.7 g. of sodium in 14 cc. of absolute methanol was added 284 mg. of the diketone (m. p. 120.5–122.5°) and the mixture was refluxed on the steam-bath in a nitrogen atmosphere for exactly two and three-quarters hours. The cooled mixture was diluted and extracted twice with ether and the extracts washed with water and dilute acid. After evaporating the ether the residue was stirred with petroleum ether (b. p. 60–68°), giving 239 mg. (90%) of solid, m. p. 107.5–111°. Recrystallization from alcohol gave 195 mg. of colorless blades, m. p. 110–111°, and 39 mg., m. p. 106.5–109°. The melting point of the first crop was not raised by further recrystallization.

Anal. Calcd. for $C_{19}H_{22}O_2$: C, 80.8; H, 7.9. Found: C, 80.8; H, 7.8.

The ultraviolet absorption spectrum[24] (Fig. 1) showed maxima at 227 mμ (log E = 4.27) and 280 mμ (3.40); a minimum at 265 mμ (3.21); and an inflection at 287 mμ (3.36).

The great importance of time in the above procedure was demonstrated by the following experiments, using the same concentration of sodium methoxide in methanol and starting with 100 mg. of diketone: two hours, 54% yield of crystalline cyclic ketone; two and three-quarters hours (above run on 284 mg.), 90%; three hours, 71%; four hours, 48%; and eight hours, no crystalline cyclic ketone isolated. In the last case the oily product was refluxed under nitrogen with 2 cc. of water, 5 cc. of acetic acid and 5 cc. by hydrochloric acid for one and one-half hours in order to effect isomerization if possible. When the neutral fraction was evaporatively distilled at 180–200° (0.05 mm.) and stirred with petroleum ether, it partially crystallized giving 22 mg. of an impure yellow solid, m. p. 110–145°. Further recrystallization from methanol gave material, m. p. 145–165°, which was still impure (*Anal.* Found: C, 79.1; H, 6.5); the ultraviolet absorption spectra suggested that it contains some of the methyl ether XXIIIb.

1,3,5,8(9)-Estratetraen-3-ol-16-one (XVIIIa).—A mixture of 75 mg. of the methoxy cyclic ketone XVI (m. p. 110–11°), 2.5 cc. of acetic acid and 2.5 cc. of 42% hydrobromic acid was refluxed under nitrogen for two and one-half hours. The cooled mixture, which exhibited a bright blue fluorescence, was diluted and made distinctly basic with 45% potassium hydroxide solution. Extraction with ether removed 12 mg. of oily neutral material. From the alkaline solution was obtained 60 mg. of phenolic oil which crystallized when stirred with a small amount of methanol yielding 26 mg. (37%) of a gray solid, m. p. 182–186°. Two recrystallizations from methanol gave the sample used for analysis which still melted over the range 188–193.5° (vac.).

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.6; H, 7.5. Found: C, 80.3; H, 7.5.

---

[27] Hydrolysis of the acid chloride prepared from the free acid gave only 17% of acidic material and 82% of a neutral oil, from which 24% of the solid starting acid was recovered by alkaline hydrolysis. When acid chloride prepared from the sodium salt was hydrolyzed, the acidic fraction was 40% and the neutral 56%. The latter probably is the enol lactone of the keto acid.

The ultraviolet absorption spectrum[24] (Fig. 1) showed maxima at 273 mμ (log E = 4.16), 336 mμ (2.36) and 362.5 mμ (2.22) and minima at 241.5 mμ (3.73), 332 mμ (2.35) and 355 mμ (2.20). The non-crystalline phenolic material, evidently a mixture, did not give crystalline material when converted to the benzoate.

3-Methoxy-1,3,5-estratrien-16-one (XVII).—A suspension of 200 mg. of palladium-on-carbon catalyst[20] in 10 cc. of purified dioxane was saturated with hydrogen at room temperature and atmospheric pressure, then 192 mg. of the methoxy ketone XVI, dissolved in 6 cc. of dioxane, was introduced and stirring continued for twenty hours until one mole-equivalent of hydrogen was absorbed. After removal of the catalyst and solvent, the product crystallized readily upon stirring with petroleum ether to give 168 mg. of colorless solid, m. p. 146–148°. An additional 6 mg., m. p. 143–148°, from the filtrate brought the yield to 90%. The pure material crystallized from absolute alcohol as colorless blades, m. p. 147.5–148°.

Anal. Calcd. for $C_{19}H_{24}O_2$: C, 80.2; H, 8.5. Found: C, 80.3; H, 8.4.

The compound was shown to be a ketone by reaction with Girard reagent P; 48 mg. (from 50 mg.) was recovered from the water-soluble fraction, m. p. 144–147.5°.

1,3,5-Estratrien-3-ol-16-one (II).—A mixture of 62 mg. of the saturated methoxy ketone XVII (m. p. 147–148°), 2 cc. of acetic acid and 2 cc. of 42% hydrobromic acid was refluxed under nitrogen for three hours. The cooled mixture (intense blue fluorescence) was diluted, extracted twice with ether, and the latter washed with water and three times with 10% potassium hydroxide; acidification of the alkaline layers and extraction with ether gave 52 mg. of phenolic product which crystallized upon stirring with petroleum ether to give 41 mg. (70%) of gray solid, m. p. 166–174.5°. An additional 2 mg., m. p. 158–170°, was obtained from the filtrate. Two recrystallizations of the material in the first crop from methanol gave the phenol II as colorless, irregular blades, m. p. 177.5–178°. Indications of polymorphism were obtained for this substance. When one sample was introduced in a bath preheated to 140°, it melted and immediately resolidified to melt again at 174–176°. If inserted at 100° and heated rather rapidly, the solid partially melted at 166–168°, followed by resolidification and remelting at 174–177°; if this melt was allowed to resolidify it remelted at 174–176.5° with no apparent change at the lower temperature.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 80.0; H, 8.2. Found: C, 79.7; H, 8.1.

The ultraviolet absorption spectrum[24] (Fig. 2) showed a maximum at 280.5 mμ (log E = 3.34) and a minimum at 249.5 mμ (2.43). For estrone the maximum was found at 279.5 mμ (3.48) and the minimum 247 mμ (2.79). The values for the extinction coefficient were somewhat higher than those found by Mayneord and Roe[28] and Dannenberg[29]—maximum at 280 mμ (log E = 3.3 and 3.36 respectively) and minimum at 248 mμ (2.5 and 2.58).

Digestion of the residue from the original ether extracts with 10% potassium hydroxide gave an additional 5 mg. of solid phenolic material, m. p. 135–150°, and 8 mg. of neutral oil.

The **benzoate** was prepared from the total crude phenolic material from demethylation of 50 mg. of the methyl ether by refluxing for three hours under nitrogen with a mixture of 0.25 cc. of benzoyl chloride and three drops of pyridine in 5 cc. of dioxane. After cooling and allowing to stand for several hours, the semi-solid material was filtered and washed well with water and alcohol, giving 43 mg. of nearly colorless benzoate, m. p. 213–225° (vac.). An additional 8 mg., m. p. 218–226° (vac.) was obtained from the filtrate for a total yield of 77% (from the methoxy ketone). Recrystallization of the material from acetone gave 32 mg., m. p. 227–229° (vac.). Another recrystallization gave the benzoate as colorless leaflets, m. p. 228–229.5° (vac.).

Anal. Calcd. for $C_{25}H_{26}O_3$: C, 80.2; H, 7.0. Found: C, 79.8; H, 7.0.

Summary

A twenty-step total synthesis of an isomer (II) of estrone having the keto group at C-16 instead of C-17 has been accomplished. Several alternative routes to 3-methoxy-1,3,5,14-estratetraene-16-one (XVI) from 1-keto-2-methyl-7-methoxy-1,2,3,4,4a,9,10,10a - octahydrophenanthrene - 2 - acetic acid (IXa) were explored. Hydrogenation and demethylation of XVI gave one of the eight possible isomers of II. Demethylation of the unsaturated ketone XVI resulted in a shift of the double bond to the 8–9 position, giving the 16-keto isomer (XVIIIa) of isoequilin A. The estrogenic activity of II was low (about 1/7600th that of estrone) indicating it to differ from estrone stereochemically as well as in the position of the keto group. XVIIIa was about 1/450th as active as estrone. The preparation of other stereoisomers is being investigated.

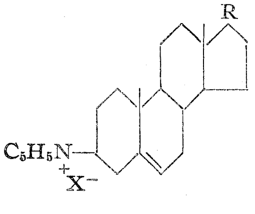
Preparation and Structure of Cholesteryl Quaternary Salts

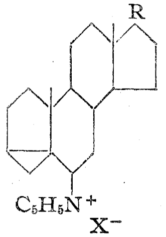
BY L. CARROLL KING, R. M. DODSON AND LEE A. SUBLUSKEY

Cholesterylpyridinium *p*-toluenesulfonate (I) was prepared in two ways: (a) by action of pyridine on cholesteryl *p*-toluenesulfonate and (b) by action of pyridine and *p*-toluenesulfonic acid on *i*-cholesteryl methyl ether. Cholesteryl isothiuronium *p*-toluenesulfonate (II)[1] was prepared (a) by action of thiourea on cholesteryl *p*-toluenesulfonate and (b) by action of thiourea and *p*-toluenesulfonic acid on *i*-cholesteryl methyl ether in alcoholic solution. Compound I was converted to the corresponding iodide on treatment with sodium iodide or on treatment with hydriodic acid. It was unchanged on refluxing twenty-four hours with pyridine and *p*-toluenesulfonic acid and displayed qualitative evidence for unsaturation. Compound II was converted to cholesteryl mercaptan and this in turn was converted to cholesteryl disulfide. These compounds were identical with the corresponding compounds reported by Wagner-Jauregg and Lennartz.[2]

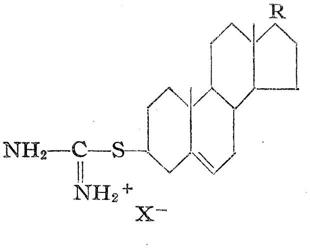
Of the structures considered for these quaternary salts, I and II are preferred over Ia and IIa.



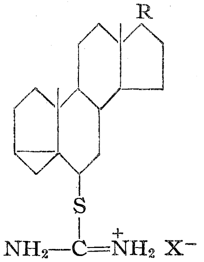
I



Ia



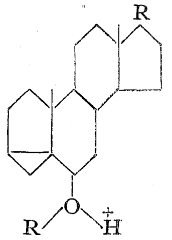
II



IIa

$X = CH_3C_6H_4SO_3^-$
$R = C_8H_{17}^-$

This preference is based on the fact that a single levorotatory salt is obtained from each of the reactions and on the fact that the salt when prepared from *i*-cholesteryl methyl ether is produced under conditions favoring rearrangement of the *i*-steroid structure. Structures Ia and IIa are further considered to be unlikely in view of their similarity to an oxonium structure such as III which may be involved when an *i*-steroid ether is rearranged to the normal steroid structure.[3]



III

Both cholesteryl *p*-toluenesulfonate and *i*-cholesteryl methyl ether are known to react readily with alcohol when a trace of acid is present. In the present paper they are shown to react selectively with thiourea in the presence of alcohol. A further study of this observation is in progress.

This investigation was partially supported by a Grant-in-Aid from the National Cancer Institute.

Experimental[4]

Cholesterylpyridinium *p*-Toluenesulfonate (I).—(a) A solution of 5.4 g. (0.01 mole) of cholesteryl *p*-toluenesulfonate[5] in 40 cc. of pyridine was heated on the steam-bath for five and one-half hours. The solution was diluted with acetone, cooled in ice, the product separated by filtration and washed with acetone-hexane. From this reaction 4.0 g. of product, m. p. 227–229°, was obtained. Two crystallizations from a mixture of chloroform and carbon tetrachloride raised the melting point to 231–232°; $[\alpha]^{26}\text{D}$ −6.1° in chloroform.

Anal. Calcd. for $C_{39}H_{57}O_3NS \cdot H_2O$: C, 73.44; H, 9.01; N, 2.20. Found: C, 73.73, 73.34; H, 9.10, 9.44; N, 2.56.

This compound is slightly soluble in acetone, soluble in chloroform but insoluble in carbon tetrachloride. It forms a colloidal solution on heating with water and can be crystallized from dilute alcohol. In chloroform solution this compound reacts rapidly with bromine forming a light yellow solution. A suspension of this compound in water slowly decolorized permanganate.

(b) A solution consisting of 1.0 g. of *i*-cholesteryl methyl ether,[6] 1.0 g. of *p*-toluenesulfonic acid and 10 cc. of pyridine was refluxed for two hours, then cooled and diluted with acetone. The crystalline material which was isolated from this reaction mixture was identical in all respects with the compound I; m. p. 230–232°, $[\alpha]^{25}\text{D}$ −4.5° in chloroform, yield 0.9 g.

Cholesterylpyridinium Iodide.—(a) A solution of 1.4 g. of cholesterylpyridinium *p*-toluenesulfonate (I) in absolute alcohol was treated with 2 g. of sodium iodide in alcohol. The cholesterylpyridinium iodide precipitated

(4) All melting points were observed on a Fisher-Jones melting point block. All rotations were determined with 100–105 mg. of sample in 3 cc. of solvent using a 1-dcm. tube of 2.5 cc. capacity. Analysis by P. Craig.

(5) Freudenberg and Hess, *Ann.*, **448**, 128 (1926).

(6) Stoll, *Z. physiol. Chem.*, **207**, 147 (1932).

at once. It was crystallized from alcohol; m. p. 260–261° dec., $[\alpha]^{27}D$ −7.4° in chloroform; yield 1.3 g.

Anal. Calcd. for $C_{32}H_{50}NI$: C, 66.75; H, 8.79; N, 2.44. Found: C, 66.59; H, 8.66; N, 2.12.

(b) A solution of 1.1 g. of I in absolute alcohol was treated with concentrated hydriodic acid. The iodide precipitated at once. It was crystallized from alcohol and was identical with that above, m. p. 260–261°; $[\alpha]^{25}D$ −7.8° in chloroform; yield 0.9 g.

Attempted Rearrangement of Cholesterylpyridinium *p*-Toluenesulfonate.—A solution consisting of 1.0 g. of cholesterylpyridinium *p*-toluenesulfonate and 1 g. of *p*-toluenesulfonic acid in 15 g. of pyridine was heated at the reflux temperature for twenty-four hours. The reaction mixture was worked up as described under the preparation of I. There was no evidence of decomposition and 0.9 g. of the starting substance was recovered unchanged; m. p. 229–231°. This was converted to the iodide, m. p. 260–261°; $[\alpha]^{24}D$ −7.5° in chloroform.

Cholesterylisothiuronium *p*-Toluenesulfonate (II).—(a) A solution of 5.4 g. (0.01 mole) of cholesteryl *p*-toluenesulfonate, 9.0 g. of thiourea and 5 cc. of pyridine in 50 cc. of absolute ethanol was heated under reflux for three hours. The resulting solution was diluted with water until a precipitate started forming, cooled and filtered. The residue was then suspended in acetone, the acetone heated to boiling, and the insoluble product filtered from the solution; yield 4.0 g. (65%) of salt; m. p. 230–234°. Recrystallization from alcohol raised the melting point to 233–235°; $[\alpha]^{24}D$ −27.1° in pyridine.

Anal. Calcd. for $C_{35}H_{56}N_2O_3S_2$: C, 68.15; H, 9.15; N, 4.54. Found: C, 68.26; H, 9.16; N, 4.31.

(b) From a similar reaction using 0.01 mole of cholesteryl *p*-toluenesulfonate, 0.02 mole of thiourea and 50 cc. of 95% alcohol, 2.26 g. (40%) of II, m. p. 231–233°, was obtained. This reaction mixture was acid to litmus and contained some cholesteryl ethyl ether, m. p. and mixed m. p. 89.0–89.5°.

(c) A reaction mixture consisting of 2.0 g. of *i*-cholesteryl methyl ether,[6] 2.0 g. of *p*-toluenesulfonic acid, 4.0 g. of thiourea in 50 cc. of ethyl alcohol was refluxed four hours. Compound II was isolated as described above; m. p. 233°; yield 1.3 g. (42%); $[\alpha]^{24}D$ −26.9° in pyridine. From this reaction mixture 0.3 g. of unchanged *i*-cholesteryl methyl ether, m. p. 75–77°, was also obtained.

Cholesteryl Mercaptan.—A solution of 2.46 g. (0.004 mole) of II and 0.68 g. (0.012 mole) of sodium hydroxide in 50 cc. of ethyl alcohol was heated under reflux. After the solution became homogeneous 5 cc. of water was added and the heating continued for two hours. The reaction mixture was then poured into 100 cc. of ice water and the resulting suspension acidified with 1 cc. of glacial acetic acid and stirred until the precipitate coagulated. The compound was separated and crystallized from acetone–methanol; m. p. 94–96°; yield 1.5 g. (93%). Recrystallization from acetone raised the melting point to 97.0–97.5°; $[\alpha]^{25}D$ −26.6° in chloroform.[7]

Anal. Calcd. for $C_{27}H_{46}S$: C, 80.53; H, 11.51. Found: C, 80.25; H, 11.80.

Cholesteryl Disulfide.—A solution consisting of 0.50 g. (0.00125 mole) of cholesteryl mercaptan in 10 cc. of hexane was oxidized with 0.32 g. (0.00125 mole) of iodine. Ten cubic centimeters of 5% potassium hydroxide was added and the mixture shaken. The mixture was then diluted and extracted with hexane. The hexane was then evaporated and the residue crystallized from benzene–ethyl alcohol and from acetone–benzene; m. p. 141–143°.[7]

Summary

Cholesterylpyridinium *p*-toluenesulfonate was prepared from cholesteryl *p*-toluenesulfonate and from *i*-cholesteryl methyl ether. Cholesterylisothiuronium *p*-toluenesulfonate was prepared from the same substances. The evidence indicates that these salts are derivatives of the normal cholesteryl structure.

---

[7] Wagner–Jauregg and Lennartz (ref. 2) reported for cholesteryl mercaptan m. p. 99.5°, $[\alpha]_D$ −23.85°; and for cholesteryl disulfide; m. p. 144.5°.

Substituted Styrenes. III. The Preparation of Some *m*- and *p*-Substituted α-Methylstyrenes

BY DEXTER SEYMOUR AND KATHERINE B. WOLFSTIRN

In connection with some studies undertaken in this laboratory on the effect of ring substituents in styrenes on their reactivity toward certain types of free radicals,[1a,b] it was necessary to synthesize a series of substituted α-methylstyrenes. *p*-Bromo, *p*-chloro and *p*-methoxy-α-methylstyrenes were synthesized by known methods. Some peculiarities in the preparation of the last mentioned were noted and are discussed further in the experimental part.

p-Fluoro-α-methylstyrene was prepared in a straightforward way from *p*-fluorobromobenzene and acetone through the Grignard reagent. *p*-Cyano-α-methylstyrene was prepared by taking advantage of the rather large difference in reactivity toward the Grignard reagent between a nitrile and a ketone grouping. A somewhat obscure paper[2] which came to our attention later records this fact also. Methylmagnesium bromide was added to a stoichiometric amount of *p*-cyanoacetophenone and the crude alcohol was dehydrated with acetic anhydride. Careful fractionation of the product gave 44% of *p*-cyano-α-methylstyrene, 20% of unreacted *p*-cyanoacetophenone and about 25% of non-volatile polymeric material. *m*-Bromo-α-methylstyrene was prepared in 54% yield by addition of two moles of methylmagnesium bromide to methyl *m*-bromobenzoate followed by dehydration with acetic anhydride.

Although the reaction is reported in the literature,[3] we were unable to prepare the Grignard reagent from *p*-dimethylaminobromobenzene even

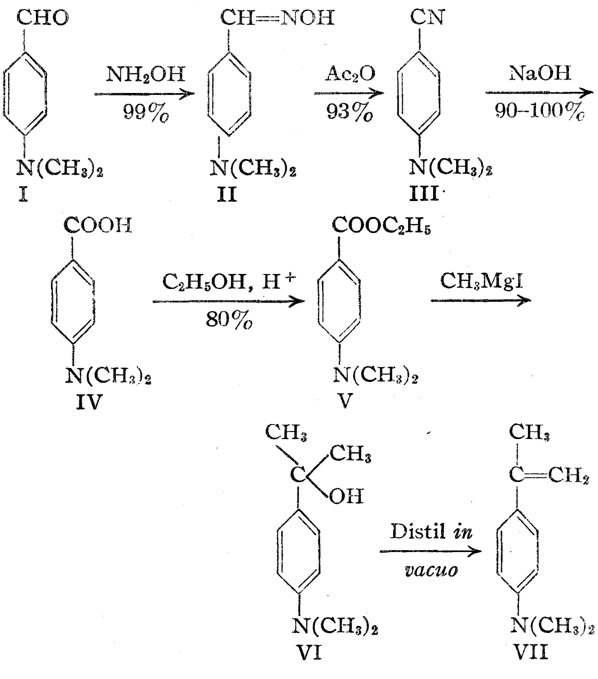
employing measures such as the "entrainment" method, and an alternative synthesis of *p*-dimethylamino-α-methylstyrene was carried out. The reactions employed were all straightforward and proceeded with the yields indicated. Several attempts to effect acid catalyzed alcoholysis of the nitrile III to produce the ester V directly met with no success and recourse was had to hydrolysis followed by Fisher esterification. The intermediate alcohol VI was not isolated but was dehydrated directly by vacuum distillation to the styrene VII. The over-all yield of recrystallized VII from V was 69%. The styrenes prepared, together with yields and physical properties, are listed in Table I.



Experimental[4]

***p*-Chloro-α-methylstyrene.**—This compound was prepared in 70% yield essentially by the method of Mowry, Huber and Ringwald.[5] The carbinol was dehydrated by refluxing sixty-four hours with about 100 mg. of iodine in toluene. After purification the product had b. p. 78.0–80.0° (8 mm.), $n^{20}D$ 1.5559, d^{20}_4 1.0723, *MR*D (calcd.) 44.56, *MR*D (found) 45.70.

***p*-Bromo-α-methylstyrene.**—This compound was prepared in 37% yield from *p*-bromophenylmagnesium bromide and acetone.[6] The best fraction had b. p. 114.5–117.5° (24 mm.), $n^{20}D$ 1.5834, d^{20}_4 1.3623, *MR*D (calcd.) 47.46, *MR*D (found) 48.34. Bergmann and Weigmann[6] give: b. p. 58–60° (2 mm.); $n^{20}D$ 1.5778.

***p*-Methoxy-α-methylstyrene.**—This compound was prepared from 249 g. (1.50 moles) of methyl anisate, 305 g. (3.20 moles) of methyl bromide and 81.6 g. (3.40 atoms) of magnesium.[6] The crude carbinol was dehydrated by distillation at reduced pressure.[7] The crude styrene so obtained was carefully redistilled through 17 cm. of glass helices with traces of *t*-butylcatechol and trinitrobenzene added as inhibitors. There was obtained 147 g. (66%) of pure product which had b. p. 63.0–65.5° (0.5 mm.), m. p. 34°, d^{40}_4 0.9860. The substance was observed to polymerize after several months even in the refrigerator in a brown bottle.

When methylmagnesium iodide was used in the preparation of the carbinol, or iodine or acetic anhydride were employed as dehydrating agents, the product was always what appeared to be the dimer of *p*-methoxy-α-methylstyrene with the following properties: b. p. 195–199° (1.5 mm.); $n^{20}D$ 1.5753.

Anal. Calcd. for $C_{20}H_{24}O_2$: C, 81.07, H, 8.11; mol. wt., 296. Found: C, 80.97; H, 8.91; mol. wt. (cryoscopic in benzene), 260.

Previous workers[6,7] apparently experienced little difficulty in this respect, however.[8]

***p*-Fluoro-α-methylstyrene.**—To the Grignard reagent prepared from 25.2 g. (1.05 atoms) of magnesium and 175 g. (1.00 mole) of *p*-fluorobromobenzene in 350 ml. of dry ether was added 63.8 g. (1.10 moles) of acetone in 700 ml. of ether and the mixture was allowed to stand two and one-half days. The mixture was hydrolyzed with saturated ammonium chloride solution and the ether removed from the product by distillation. Then 500 ml. of toluene and 100 mg. of iodine were added and the mixture was refluxed nineteen and one-half hours under a water separator. Fifteen milliliters (83%) of water separated. The toluene solution was washed with sodium thiosulfate and water and dried by distillation. The toluene was removed through a 17 cm. column packed with 1/8" single turn glass helices and the residue fractionated. The middle fraction had b. p. 97.5–101.5° (95 mm.), $n^{20}D$ 1.5120, d^{20}_4 1.0150, *MR*D (calcd.) 39.59, *MR*D (found) 40.20. The yield was 74.5 g. (55%).

Anal. Calcd. for C_9H_9F: C, 79.40; H, 6.66. Found: C, 78.66; H, 6.71.

[8] Yamashita, *J. Chem. Soc. Japan*, **62**, 1216 (1941); *cf. Chem. Abs.*, **41**, 3070 (1947), reports, however, that *p*-methoxy-β-methylstyrene readily forms a dimer on treatment with iodine in toluene.

A bromine analysis indicated the presence of not more than 2 wt. per cent. *p*-fluorobromobenzene as impurity.

p-**Cyano-α-methylstyrene.**—In a 2-liter three-necked flask previously flushed with dry nitrogen the Grignard reagent was prepared from 135 g. (0.95 mole) of methyl iodide and 24.0 g. (1.00 atom) of magnesium in 1250 ml. of dry ether. When reaction was complete, the reagent was filtered under nitrogen into a 2-liter dropping funnel attached to one neck of a 5-liter three-necked flask equipped with a Hershberg stirrer and a reflux condenser protected by a "Drierite" tube. In the flask was placed 133 g. (0.918 mole) *p*-cyanoacetophenone dissolved in 750 ml. of dry ether. The Grignard reagent was added to this solution dropwise over a period of one and one-half hours and the mixture was stirred two and three-quarter hours longer. The reaction mixture was worked up in the usual way and the crude carbinol dehydrated by boiling two hours with about 300 ml. of acetic anhydride. After hydrolysis of the excess anhydride, the products were taken up in chloroform, the solution dried, and the chloroform removed through 85 cm. of $^1/_8''$ glass helices. The residue was distilled at 1.5 mm. to separate volatile material from any polymeric products. The distillate was collected from 86–120° and there remained about 25 g. of non-distillable material in the flask. The distillate was fractionated at 2 mm. pressure using an 80-cm. 15-plate low hold-up column designed by Dr. H. Sargent of these Laboratories.[9] Three fractions were collected: (1) b.p. 82.0–86.0° (2 mm.), n^{20}_{D} 1.5618, wt. 4.4 g.; (2) b.p. 86.0–87.0° (2 mm.), n^{20}_{D} 1.5680, wt. 29.8 g.; (3) b. p. 87.0–87.5° (2 mm.), n^{20}_{D} 1.5680, wt. 28.0 g. The pot residue weighed 26.1 g. and gave 20.9 g. (15.7%) of *p*-cyanoacetophenone on crystallization from hexane-benzene. Fractions (2) and (3) of the distillate above which decolorized potassium permanganate in acetone and bromine in carbon tetrachloride were combined to yield 57.8 g. (44%) of *p*-cyano-α-methylstyrene, d^{20}_4 1.0017, MR_{D} (calcd.) 44.05, MR_{D} (found) 46.68.

Anal. Calcd. for $C_{10}H_9N$: C, 83.90; H, 6.34; N, 9.78. Found: C, 83.76, 83.98; H, 6.32, 6.31; N, 9.72.

m-**Bromo-α-methylstyrene.**—The Grignard reagent was prepared from 67.8 g. (2.83 atoms) of magnesium and 265 g. (2.79 moles) of methyl bromide and to this was added an ether solution of 294 g. (1.40 moles) methyl *m*-bromobenzoate. The reaction mixture was worked up in the usual way and the carbinol was dehydrated by the acetic anhydride technique. After hydrolysis of the excess anhydride, the neutral products were extracted with chloroform, dried and the solvent removed through 17 cm. of glass helices. Fractionation of the residue gave 150 g. (54%) of *m*-bromo-α-methylstyrene, b. p. 68.0–72.0° (2 mm.), n^{20}_{D} 1.5779, d^{20}_4 1.3560, MR_{D} (calcd.) 47.46, MR_{D} (found) 48.20.

Anal. Calcd. for C_9H_9Br: C, 54.86; H, 4.60. Found: C, 54.12; H, 4.54.

p-**Dimethylaminobenzaldoxime.**—This material was prepared from 75 g. (0.50 mole) *p*-dimethylaminobenzaldehyde by the method of Sachs and Steinert.[10] There was obtained 80.9 g. (99%) of oxime melting at 142.5–144.0° and it was used without purification.

p-**Dimethylaminobenzonitrile.**—Following the method of Sachs and Steinert,[10] 73.8 g. (0.45 mole) of *p*-dimethylaminobenzaldoxime was dehydrated with 300 ml. of 95% acetic anhydride to yield 61 g. (93%) of crude nitrile, melting at 74–75°. It was used directly in the next step.

p-**Dimethylaminobenzoic Acid.**—One-hundred twenty-eight grams (0.877 mole) of *p*-dimethylaminobenzonitrile was refluxed for nineteen hours with a mixture of 750 ml. of 2 *M* sodium hydroxide and 450 ml. of 95% ethyl alcohol. Most of the alcohol was removed by distillation and 500 ml. of water was added. The warm solution was acidified to *p*H 2 with concentrated hydrochloric acid and the suspension was allowed to stand for thirty-six hours. The acid was collected by filtration and washed with water. Neutralizing to about *p*H 7 with ammonia afforded a further small amount of product. The dry *p*-dimethylaminobenzoic acid weighed 148 g. (102%, probably due to inorganic salts), and was esterified without further purification.

Ethyl *p*-**Dimethylaminobenzoate.**—A mixture of 196.5 g. (1.19 mole) of crude *p*-dimethylaminobenzoic acid and 2 liters of absolute ethanol was saturated with dry hydrogen chloride and refluxed overnight. Most of the alcohol was distilled and the residue was thrown into iced sodium hydroxide solution (200 g. in 1 liter of water) with good stirring. The crude ester was collected by filtration; after drying it weighed 172.7 g. (79% based on recovered acid). From the mother liquor there was recovered 9.1 g. (4.6%) of unreacted acid.

The crude ester was distilled at 1–2 mm., the fraction boiling at 125–142° being collected. This weighed 159 g. and was crystallized from 400 ml. of 66% by volume ethanol. The first crop of shiny white plates weighed 124 g. (57%) and melted at 65–66°. A second crop of less pure material, weighing 27.0 g. (12%) and melting at 58–61°, was obtained, by concentration of the mother liquor.

p-**Dimethylamino-α-methylstyrene.**—The Grignard reagent was prepared from 341 g. (2.40 moles) of methyl iodide and 62.4 g. (2.60 atoms) of magnesium in 1200 ml. dry ether. To this refluxing solution was added 154.4 g. (0.800 mole) of ethyl *p*-dimethylaminobenzoate in 1200 ml. of ether over a period of one and one-half hours and refluxing was continued for twenty-one and one-half hours longer. The mixture was hydrolyzed with saturated ammonium chloride solution and worked up in the usual way. After removal of the ether, the crude product was distilled *in vacuo*, which caused the elimination of water. The styrene was collected from 95–121° at 1 mm.; it weighed 91.8 g. (71%). Recrystallization from 250 ml. of hexane gave 74.2 g. (58%) of *p*-dimethylamino-α-methylstyrene melting at 75.0–76.5°.

Anal. Calcd. for $C_{11}H_{15}N$: C, 81.95; H, 9.37; N, 8.69. Found: C, 82.08; H, 9.40; N, 8.64.

A further 14.6 g. (11%) of product melting at 72.0–74.0° was obtained from the mother liquor.

Summary

1. The preparation of *p*-chloro, *p*-bromo and *p*-methoxy-α-methylstyrenes is described.

2. *p*-Fluoro, *m*-bromo, *p*-cyano and *p*-dimethylamino-α-methylstyrenes have been prepared and their physical properties recorded for the first time.

The Use of Liquid Phase Oxidation for the Preparation of Nuclearly Substituted Styrenes. IV.[1] *m*-Chlorostyrene

BY WILLIAM S. EMERSON AND VICTOR E. LUCAS[2]

m-Chlorostyrene has been prepared by heating *m*-chlorophenylmethylcarbinol with potassium bisulfate at reduced pressure[3,4,5] in yields as high as 83%.[4] The carbinol was prepared by treating *m*-chlorobenzaldehyde with methylmagnesium iodide[4,5] or by treating acetaldehyde with *m*-chlorophenylmagnesium bromide.[3]

We have found that chlorobenzene can be alkylated with ethylene in the presence of aluminum chloride to give *m*-chloroethylbenzene in 37% conversion and 80% yield. Oxidation of *m*-chloroethylbenzene with air at 100 p. s. i, pressure in the presence of a chromium oxide catalyst gave *m*-chloroacetophenone in 26% conversion and 76% yield. This ketone was hydrogenated to *m*-chlorophenylmethylcarbinol in 94% yield by means of hydrogen and copper chromite. While this preparation of the carbinol from chlorobenzene involves three steps, the yields are good and the use of such difficultly available intermediates as *m*-chlorobenzaldehyde and *m*-chlorobromobenzene is avoided. The 84% yield of *m*-chlorostyrene, obtained by dehydrating *m*-chlorophenylmethylcarbinol in the vapor phase over alumina, is comparable to the 83% reported for the potassium bisulfate method.[4]

A still better method of synthesis was found to involve the chlorination of *m*-chloroethylbenzene in the presence of light and a phosphorus trichloride catalyst to give α,*m*-dichloroethylbenzene in 44% conversion and 91% yield. When the vapors of the latter compound, together with steam, were passed over a calcium sulfate catalyst, *m*-chlorostyrene was obtained in 93% yield.

Experimental

***m*-Chloroethylbenzene.**—Chlorobenzene was treated with ethylene in the presence of aluminum chloride in an autoclave equipped with a stirrer and gas inlet. The charge consisted of 3178 g. of chlorobenzene, 45.4 g. of ethyl chloride and 90.8 g. of anhydrous aluminum chloride. While the temperature was held at 100°, 454 g. of ethylene was introduced over a two-hour period. The mixture was then cooled, removed from the autoclave and poured into 5 kg. of ice water containing 100 cc. of concentrated hydrochloric acid. After the complex had decomposed, the organic layer was separated, dried over anhydrous potassium carbonate and distilled. In this way there was obtained 1702 g. (53.7% recovery) of chlorobenzene, b. p. <68° at 14 mm., $n^{25}\mathrm{D}$ 1.5213–1.5201; 1478 g. (37.3% conversion and 80.2% yield) of *m*-chloroethylbenzene, b. p. 68–74° at 14 mm.,[6] $n^{25}\mathrm{D}$ 1.5181–1.5160 (1103 g., b. p. 68–72° at 14 mm., $n^{25}\mathrm{D}$ 1.5171–1.5168); and 361 g. (7.6% calculated as chlorodiethylbenzene) of more highly alkylated material. The residue was 21 g.

***m*-Chloroacetophenone.**—Into a stirred autoclave equipped with a reflux condenser and gas outlet, thermowell and air inlet there was placed 500 g. of *m*-chloroethylbenzene and 5 g. of chromium oxide. While this mixture was stirred at a temperature of 140–155°, 3 cu. ft./hr. of air at 100 p. s. i. was introduced for a six-hour period. After cooling, the autoclave was opened, and the reaction mixture removed and filtered. By washing the solution with aqueous alkali and acidifying the extract there was obtained 8.1 g. (1.4%) of *m*-chlorobenzoic acid. The organic layer was distilled to obtain 331.5 g. (66.2% recovery) of *m*-chloroethylbenzene, b. p. 65–69° at 13 mm., $n^{25}\mathrm{D}$ 1.5181–1.5161, and 140.6 g. (25.6 % conversion and 76.0% yield) of *m*-chloroacetophenone, b. p. 76–92° at 3 mm., $n^{25}\mathrm{D}$ 1.5462–1.5491. The tarry residue weighed 13.7 g. (2.5%).

***m*-Chlorophenylmethylcarbinol.**—A standard American Instrument Company hydrogenation autoclave was charged with 100 g. of *m*-chloroacetophenone and 10 g. of copper chromite. The initial hydrogen pressure was 980 p. s. i. at 27°. Hydrogenation was conducted at 140° for seven hours. After the catalyst was removed by filtration, the product was distilled to give 94.9 g. (94%) of *m*-chlorophenylmethylcarbinol, b. p. 85–89° at 2 mm. (102–104° at 3 mm.),[4] $n^{25}\mathrm{D}$ 1.5418 ($n^{20}\mathrm{D}$ 1.5438).[4]

***m*-Chlorostyrene.**—A pyrolysis tube[7] was packed with activated alumina. Over a forty-minute period 74 g. of *m*-chlorophenylmethylcarbinol, together with some steam, was passed through the tube at 90 mm. pressure and 313–340°. Upon cooling, the tube was washed out with benzene and the distillate extracted with the same solvent. The combined washings and extracts were distilled from a trace of sulfur and hydroquinone to give 55 g. (84%) of *m*-chlorostyrene, b. p. 75–79° at 15 mm. (62–63° at 6 mm.),[4] $n^{25}\mathrm{D}$ 1.5612 ($n^{20}\mathrm{D}$ 1.5619).[4]

α,*m*-Dichloroethylbenzene.—A 1-liter three-necked flask equipped with a stirrer, condenser, thermometer and gas inlet tube was charged with 562 g. of *m*-chloroethylbenzene and 3 g. of phosphorus trichloride. While the temperature was maintained at 10–15° by means of an ice–salt-bath and the flask was illuminated with ultraviolet light, chlorine was introduced until a gain of 85 g. was observed. Direct distillation of the reaction mixture yielded 292.6 g. (52.1% recovery) of *m*-chloroethylbenzene, b. p. 70° at 17 mm.–74° at 16 mm., $n^{25}\mathrm{D}$ 1.5172–1.5183 and 306.2 g. (43.6% conversion and 91.4% yield) of α,*m*-dichloroethylbenzene, b. p. 63–70° at 2 mm., $n^{25}\mathrm{D}$ 1.5401–1.5423. The tarry residue weighed 8.7 g. (1.0%).

***m*-Chlorostyrene.**—The pyrolysis tube was packed with calcium sulfate (Drierite). Over a one hundred sixty-minute period 250 g. of α,*m*-dichloroethylbenzene, together with about three (liquid) volumes of steam, was passed through the tube at 90 mm. pressure and 425–475°. Upon cooling, the tube was washed out with 50

cc. of benzene and the combined distillate and washings were extracted three times with benzene. These combined extracts were washed free of acid with aqueous sodium bicarbonate and then distilled from a trace of sulfur and hydroquinone to give 183 g. (92.5%) of *m*-chlorostyrene, b. p. 76–81° at 17 mm. (62–63° at 6 mm.),[4] n^{25}_D 1.5616 (n^{20}_D 1.5619).[4]

Summary

The preparation of *m*-chlorostyrene from *m*-chloroethylbenzene by two routes has been described. The first involves oxidation to *m*-chloroacetophenone, hydrogenation to *m*-chlorophenylmethylcarbinol and dehydration in the vapor phase to *m*-chlorostyrene. The second involves chlorination to α,*m*-dichloroethylbenzene followed by dehydrochlorination in the vapor phase to *m*-chlorostyrene.

DAYTON, OHIO RECEIVED NOVEMBER 3, 1947

[CONTRIBUTION NO. 148 FROM THE GOODYEAR TIRE & RUBBER CO., RESEARCH LABORATORY]

The Synthesis and Reactions of Disazodicarboxylates[1]

BY NORMAN RABJOHN

The azo group in esters of azodicarboxylic acid is very reactive and will add to numerous compounds possessing active hydrogen atoms. Alder, Pascher and Schmitz[2] have shown that ethyl azodicarboxylate forms adducts with natural and synthetic rubbers.

The facility with which azo compounds of this type add to rubber and related polymers suggested that compounds containing two such active groups in the same molecule should be useful cross-linking agents. If current hypotheses concerning the nature of vulcanization are correct, then such compounds ought to be effective vulcanizing agents. They conceivably could be of value in quantitative vulcanization studies since they offer the possibility of introducing controlled numbers of cross-linkages between rubber molecules, or other similarly unsaturated polymers, by a comparatively simple addition reaction. Accordingly, the synthesis of disazodicarboxylates and the investigation of their properties was undertaken as described in the present paper.

A number of these azo esters have been obtained by the following series of reactions

$$\mathrm{HOROH} + 2\mathrm{COCl_2} \longrightarrow \mathrm{ClCO_2ROCOCl}\ (\mathrm{I}) + 2\mathrm{HCl}$$

$$\mathrm{H_2NNH_2} + (\mathrm{R'O})_2\mathrm{CO} \longrightarrow \mathrm{H_2NNHCO_2R'}(\mathrm{II}) + \mathrm{R'OH}$$

$$\mathrm{ClCO_2ROCOCl} + 2\mathrm{H_2NNHCO_2R'} \xrightarrow{\mathrm{R_3''N}} (\mathrm{R'OCONHNHCO_2})_2\mathrm{R}\text{—}\ (\mathrm{III}) + 2\mathrm{R_3''N{\cdot}HCl}$$

$$(\mathrm{R'OCONHNHCO_2})_2\mathrm{R}\text{—} \xrightarrow{[\mathrm{O}]} (\mathrm{R'OCON{=}NCO_2})_2\mathrm{R}\text{—}\ (\mathrm{IV}) + 2\mathrm{H_2O}$$

The nature of the R and R′ groups has been varied and their combinations are shown in Table II. The dichlorocarbonates (I) were prepared by two different procedures. Aromatic dichlorocarbonates were obtained by the method of Oesper, Broker and Cook[3]; aliphatic dichlorocarbonates were synthesized by merely adding a glycol to an excess of liquid phosgene. All of the aliphatic dichlorocarbonates are high-boiling liquids which can be distilled in some cases under reduced pressure without appreciable decomposition. Since they could not be obtained in an analytically pure condition, they were converted to the corresponding diurethans (Table I) for the purpose of identification.

The esters of hydrazine monocarboxylic acid were prepared according to the procedure of Diels.[4] The bis-hydrazodicarboxylates (III) (Table II) are all relatively high melting solids which were obtained in yields of 80–90%. They were oxidized to the corresponding disazodicarboxylates (IV) in good yields by means of nitric acid or hypochlorous acid. The dis-azo esters are in most instances viscous, orange-colored oils which are thermally unstable above 125° and cannot be distilled without decomposition; however, they appear to be stable at room temperature. The dis-azo esters prepared from aromatic dichlorocarbonates are solids. They decomposed within a few hours at room temperature or during attempts to purify them by crystallization. Only those disazodicarboxylates which are listed in Table III were obtained in a satisfactory state of purity. They absorbed the theoretical amount of hydrogen when shaken over platinum oxide catalyst, being regenerated to the bis-hydrazodicarboxylates.

All of the disazodicarboxylates reacted rapidly with natural and synthetic rubbers at relatively low temperatures; good vulcanizates were obtained without the aid of other ingredients. The vulcanization studies will be reported elsewhere.[5]

To gain an insight into the manner in which these dis-azo esters vulcanize rubber, a study was made of the reaction between ethyl azodicarboxylate (V) and 2-methyl-2-butene (VI). Although the former is monofunctional, its mode of addition should be analogous to that of a disazodicarboxylate. The 2-methyl-2-butene may be considered to be representative of an isoprene unit in natural

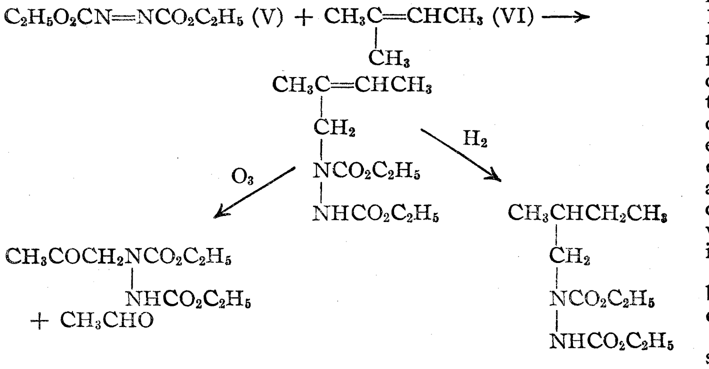
rubber. The following reactions indicate that the azodicarboxylate system adds to the olefin by attacking a carbon atom *alpha* to a double bond.



It can be argued then that the disazodicarboxylates vulcanize rubber by the establishment of cross-links between polymer chains caused by the attachment of azodicarboxylate systems at *alpha* methylenic carbon atoms. This agrees with the findings of Farmer[6] that many reagents undergo reaction with rubber at this position.

Experimental

Preparation of Dichlorocarbonates.—The following procedure is representative of the method employed for the preparation of aliphatic dichlorocarbonates. Twenty grams (0.22 mole) of tetramethylene glycol was added dropwise to 150 g. (1.5 moles) of liquid phosgene which was cooled in an ice-bath. The addition of the glycol was regulated so that the temperature remained below 10°. The excess phosgene was allowed to evaporate and the residue was warmed at 40–50° (20 mm.) to remove traces of phosgene and hydrogen chloride. There was obtained 47.5 g. (99%) of tetramethylene dichlorocarbonate as an almost colorless, slightly viscous liquid. Due to a tendency to decompose at the high temperature required for distillation, it was impossible to obtain a sample pure enough for analysis. The dichlorocarbonate was identified by shaking a small sample with aqueous ammonia to obtain the corresponding diurethan (Table I).

All of the aliphatic dichlorocarbonates prepared by this procedure were obtained in essentially quantitative yields.

The aromatic dichlorocarbonates were synthesized by condensing the diphenols with phosgene in the presence of a tertiary amine according to the method of Oesper, Broker and Cook.[3]

Preparation of bis-Hydrazodicarboxylates.—The procedure employed for the preparation of decamethylene bis-methyl hydrazodicarboxylate is general for this class of compounds. To a solution of 12 g. (0.134 mole) of hydrazine monocarboxylic acid methyl ester in 200 cc. of dioxane were added dropwise 20 g. (0.067 mole) of decamethylene dichlorocarbonate and 13.5 g. (0.134 mole) of triethylamine. The dichlorocarbonate was kept in excess during the addition. The reaction mixture was allowed to stir until it had cooled and the precipitate of triethylamine hydrochloride was removed by filtration. The filtrate was concentrated under reduced pressure and the residue was dissolved in a mixture of ethyl acetate and

---

(6) Farmer, *Trans. Faraday Soc.*, **38**, 340 (1942).

hexane. Upon standing for several hours a white solid precipitated; m. p. 109–111°; yield 23 g. (85%). After recrystallization from a mixture of ethyl acetate and hexane, the product melted at 112–113°.

Anal. Calcd. for $C_{16}H_{30}O_8N_4$: C, 47.29; H, 7.39. Found: C, 47.34; H, 7.59.

Preparation of Disazodicarboxylates.—The oxidation of decamethylene bis-methylhydrazodicarboxylate to the corresponding azo compound is typical. Sixteen grams of decamethylene bis-methylhydrazodicarboxylate was dissolved in 130 cc. of concentrated nitric acid. A slow oxidation took place and within about ten minutes an orange-colored oil formed as an upper layer. When this layer no longer appeared to increase, the reaction mixture was poured onto 500 g. of crushed ice. The azo compound was removed by extraction with benzene. The extract was washed with water, several times with 10% sodium bicarbonate solution and again with water. It was dried over anhydrous sodium sulfate and then concentrated under reduced pressure on a steam-bath. The residue was crystallized from a mixture of ethyl acetate and hexane. There was obtained 13 g. (82%) of decamethylene dis-methylazodicarboxylate as a bright, orange-colored solid; m. p. 38–39°.

Anal. Calcd. for $C_{16}H_{26}O_8N_4$: C, 47.76; H, 6.47. Found: C, 47.83; H, 6.52.

This compound was prepared also in satisfactory yield by passing chlorine into a well-stirred mixture of the bis-hydrazodicarboxylate and water.

Many of the disazodicarboxylates prepared by the nitric acid oxidation procedure did not form oil layers during the oxidation step. In such cases, the reaction became quite vigorous and was stopped by pouring onto ice.

Only those disazodicarboxylates which are solids (with the exception of diethylene dis-ethyl azodicarboxylate which was distilled at approximately 10^{-4} mm.) could be purified sufficiently for analysis. All of the disazodicarboxylates decomposed with the evolution of a gas when heated above 125°.

Preparation of Hydrazine Monocarboxylic Acid Esters.—The methyl and ethyl esters were obtained by the method of Diels.[4] The benzyl ester was prepared in a similar manner except that the condensation was carried out at steam-bath temperature and the ester was isolated as the hydrochloride salt; m. p. 186–187°. Neut. equiv. Calcd. for $C_8H_{11}O_2N_2Cl$: 202.5. Found: 205. Upon treating the hydrochloride with concentrated sodium hydroxide solution, the free ester resulted in 75% overall yield; m. p. 69–70°. It was purified by crystallization from a mixture of ethyl acetate and hexane. *Anal.* Calcd. for $C_8H_{10}O_2N_2$: C, 57.83; H, 6.02. Found: C, 57.83; H, 5.96. Hydrazine monocarboxylic acid *n*-decyl ester was obtained in 65% yield by heating di-*n*-decyl carbonate and 85% hydrazine hydrate at 115° for seventy-two hours. After crystallization from dilute alcohol, it melted at 58–59°. *Anal.* Calcd. for $C_{10}H_{24}O_2N_2$: C, 61.11; H, 11.11. Found: C, 61.35; H, 11.16.

Reduction of Decamethylene dis-Methyl Azodicarboxylate.—Two grams of the azo compound was dissolved in 100 cc. of dioxane and shaken with 0.1 g. of platinum oxide catalyst under hydrogen at a pressure of 50 lb./sq. in. The hydrogen uptake was rapid and within twenty minutes the solution was colorless. The drop in pressure corresponded to the theoretical amount of hydrogen required for reduction. The catalyst was removed by filtration and the filtrate was concentrated. The residue was dissolved in a mixture of ethyl acetate and hexane. There was obtained 1.9 g. of a white solid which melted at 112–113°. The melting point of a mixture of this substance and a known sample of decamethylene *bis*-methyl hydrazodicarboxylate was not depressed.

Condensation of Ethyl Azodicarboxylate with 2-Methyl-2-butene.—The ethyl azodicarboxylate was prepared according to the method of Ingold and Weaver.[7] 2-Methyl-2-butene was synthesized by dehydrating *t*-amyl alcohol after the procedure of Norris and Reuter.[8] The dehydration product (b. p. 36.5–38.5°) was purified[9] by careful fractionation with methyl alcohol through a 25 mm. × 72″ Podbielniak column. The product was washed with water to remove the methyl alcohol, dried over anhydrous potassium carbonate and then refractionated though a 13 mm. × 72″ Podbielniak column; $n^{20}D$ 1.3874.

A mixture of 41.5 g. (0.24 mole) of ethyl azodicarboxylate and 50 g. (0.71 mole) of 2-methyl-2-butene was allowed to stand at room temperature for nine days. The excess 2-methyl-2-butene was removed and the residue was distilled *in vacuo*. There was obtained 54 g. (92%) of a viscous, colorless oil which boiled at 128–129° (3 mm.); $n^{20}D$ 1.4613. *Anal.* Calcd. for $C_{11}H_{20}O_4N_2$: C, 54.10; H, 8.19. Found: C, 53.94; H, 8.22.

A 10-g. sample of this material was dissolved in 100 cc. of alcohol and reduced with hydrogen over Adams catalyst. The resulting product boiled at 115–116° (2 mm.); $n^{20}D$ 1.4507. *Anal.* Calcd. for $C_{11}H_{22}O_4N_2$: C, 53.66; H, 8.94. Found: C, 53.63; H, 9.01.

Seven grams of the adduct of ethyl azodicarboxylate and 2-methyl-2-butene was dissolved in 100 cc. of chloroform. A stream of ozonized air, containing about 2% of ozone, was bubbled through the solution for six hours at 0°. The solvent was removed under reduced pressure and the residue was boiled with 50 cc. of water for three hours. The flask was equipped with a column to keep back the water and the gases were led below the surface of 50 cc. of alcohol. After decomposition of the ozonide had been completed, the alcohol solution was treated with 2,4-dinitrophenylhydrazine. A yellow colored solid was obtained which melted at 147–148°. The melting point of a mixture of this material and a known sample of acetaldehyde 2,4-dinitrophenylhydrazone showed no depression.

The residue was extracted with chloroform and the extract was washed with water, with sodium bicarbonate solution and again with water. It was dried over anhydrous sodium sulfate and the solvent removed. The residue amounted to about 6 g. It was distilled *in vacuo*; b. p. 150–151° (3 mm.); $n^{20}D$ 1.4543.

Anal. Calcd. for $C_9H_{16}O_5N_2$: C, 46.55; H, 6.89. Found: C, 47.05; H, 7.14.

Summary

1. A method of synthesis of disazodicarboxylates has been described. These substances are capable of vulcanizing both natural and synthetic rubbers.

2. The condensation of ethyl azodicarboxylate with 2-methyl-2-butene has been studied. It has been shown that the azo ester system undergoes reaction at an α-methylenic carbon atom.

3. Accordingly, disazodicarboxylates must produce vulcanization by the establishment of cross-linkages between polymer chains.

The Oxidation of Catechol-type Substrates by Tyrosinase

BY MERCHANT L. CUSHING[1]

The fundamental function of the enzyme tyrosinase is thought to be the catalysis of the oxidation of the *ortho*-dihydroxy group of a catechol to an *ortho*-quinone. The enzyme is primed during this oxidation and after this priming is able to bring about the oxidation of monohydric phenols.[2] Robinson and McCance[3] first showed that the enzymatic oxidation of catechol requires two atoms of oxygen per mole. Since the production of an *ortho*-quinone from catechol requires only one atom of oxygen some explanation had to be made as to how the second atom was consumed. Onslow and Robinson[4] suggested that the second atom of oxygen resulted in the formation of hydrogen peroxide

$$C_6H_4(OH)_2 + O_2 \longrightarrow C_6H_4O_2 + H_2O_2$$

Several workers have expressed doubt concerning the validity of this postulate. The arguments advanced by these workers have been summarized in a paper by Dawson and Ludwig[5] who have presented additional evidence against the hydrogen peroxide postulate.

According to Dawson and Nelson[6] the oxidation of catechol takes place in two steps. Only the first step, the oxidation of catechol to *o*-benzoquinone, is catalyzed by the enzyme. This step consumes one atom of oxygen. The quinone reacts with water to form hydroxyhydroquinone, which in turn becomes oxidized to an *o*-quinone, thus consuming the second of oxygen. Later doubt was cast on this mechanism by Mason, Schwartz and Peterson[7] whose examination of the absorption spectrum of catechol undergoing oxidation in the presence of tyrosinase failed to detect hydroxyhydroquinone.

Since the oxidation of a monohydric phenol is through conversion to a catechol-type with the consumption of one atom of oxygen and subsequent oxidation of the catechol with the consumption of two atoms of oxygen, it follows that the oxidation of phenol requires three atoms of oxygen per mole.

Considerable data are recorded in the literature on the extent of oxidation of various phenolic substances but they are scattered and without attempted correlation. This is a natural result of their bit by bit presentation wherein little attention has been given to the effect of structure on the extent of oxidation. It would be an advantage to the advance of the knowledge of enzymatic oxidations if more were understood about the role variation of structure plays in extent and rate of oxidation.

This paper is a report of a study of the effect of variation in structure of the substrate on the extent of its oxidation. In approaching this problem the following postulates were used as guides:

1. It appears to be a general rule that addition to an ortho-quinone results principally in the formation of a 4-substituted catechol.
2. Dawson and Nelson[6] have suggested that water adds in the same way.
3. The use of a second atom of oxygen in the enzymatic oxidation of catechol depends upon the addition of water to *o*-benzoquinone.
4. It seemed likely that if substituents were placed in the 4-position of catechol this might prevent the hydration of the *o*-quinone and thus limit the oxygen consumption to one atom per mole.

Several catechol-type substrates were used to test the above postulates. These were allowed to oxidize in the presence of the enzyme until no more oxygen was consumed. The results are tabulated and discussed in the following section.

The Effect of Substituent Groups on the Total Oxygen Consumption of Catechol-Type Substances.—In Table I there is recorded the result of the oxidation to completion of several catechol-type substances when in the presence of tyrosinase. The oxygen consumption was measured by the technique of the Warburg respirometer, according to Graubard and Nelson.[8]

When the above results are considered in the light of the nature of the groups which are substituents the following generalizations seem permissible:

1. An *ortho*-directing group in the 4-position does not alter the amount of oxygen from that required by catechol.
2. A *meta*-directing group brings about a change in the oxygen consumption, only one atom of oxygen being used in place of the two of catechol.
3. When both the 4- and 5-positions are substituted by *ortho*-directing groups the oxygen consumption is only one atom per mole of substrate.

This would seem to indicate that the 4-position is of great importance in the consumption of the

Measurements were made at 25°. The reaction flasks were of 50 ml. volume and contained as the reaction mixture 1 ml. of enzyme added from the side-arm at zero time, 2 ml. of (0.2 *M*) phosphate–(0.1 *M*) citrate buffer to produce a *p*H of about 7, substrate solution, and water to bring the volume to 8 ml. The enzyme used was purified extract from the common mushroom, *Psalliota campestris*. When the absorption of oxygen ceased fresh enzyme was added. This was repeated until addition of enzyme failed to cause the absorption of more oxygen. The amount of substrate used was 1.0 × 10^{-5} mole, except in a few cases where it was less due to the low solubility of the substrate. The results are the average of three or more determinations.

second atom of oxygen by catechol. In those substances where the 4-position is occupied by a substituent, flanked by a *meta*-directing group, or by two *ortho*-directing groups the consumption of the second atom of oxygen does not occur. The result in all cases is the production of an *o*-quinone, without formation of hydrogen peroxide.

The Effect of Substituent Groups on the Total Oxygen Consumption of Monohydric Phenols.—Since the introduction of substituent groups onto the catechol ring has a marked effect on the extent of oxidation of catechols it was considered of interest to examine the effect of these substituents on the ability of the enzyme to introduce a second hydroxyl group into monohydric phenols.

Data from the literature on the extent of oxidation of monohydric phenols have been used in compiling Table II which classifies the phenols according to the nature and position of the substituent. Only two new substances have been studied here.

[a] After eight hours contact with the enzyme no oxidation had taken place. Attempts to prime the enzyme with traces of added catechol failed to bring about oxidation.

By comparison of the results presented in this table with those of Table I it can be seen that the same groups which act to limit the oxidation of catechols to a one-atom-per-mole stage here operate to prevent the introduction of a new or second hydroxyl group by the enzyme. The resulting substituted phenol is inert to tyrosinase oxidation. This seems to be true no matter what is the position of the substituent group. It also may be noted that there are some monohydric phenols which are not subject to the oxidative influence of tyrosinase even when their catechol analogs are substrates.

The oxidation of catechol and a few members of the catechol family by tyrosinase has been longsince well demonstrated. However, if tyrosinase is to play an important part in cellular respiration, as has been recently postulated,[10,14,15] it should possess the ability to catalyze the oxidation of a multitude of diverse and complexly substituted catechols, whose occurrence is widespread. This can now more certainly be considered to be a real property of the enzyme in the light of the findings of this paper.

The enzyme must also possess the property of being primed toward monohydric phenols when it

(11) D. Baker and J. M. Nelson, *J. Gen. Physiol.*, **26**, 269 (1943).

(12) J. Enselme and J. L. Vigneau, *Bull. soc. chim. biol.*, **27**, 387 (1945).

(13) M. W. Onslow and M. E. Robinson, *Biochem. J.*, **19**, 420 (1925), stated that this gave a positive test for catechol after it had stood twenty-four hours with potato tyrosinase.

(14) E. S. Robinson and J. M. Nelson, *Arch. Biochem.*, **4**, 111 (1944).

(15) E. M. Walter and J. M. Nelson, *ibid.*, **6**, 131 (1945).

catalyzes the oxidation of the more complexly substituted catechols. Without this property the enzyme would be devoid of power to aid in the utilization of the monohydric phenols in nature. The question as to whether the oxidation of a given substrate causes the enzyme to be primed for the oxidation of monohydric phenols must be tested by the use of a substance whose oxidation by tyrosinase alone is negligible. While hydroquinone is not a monohydric phenol it behaves as such toward the enzyme. Its oxidation is very slow and one can note the priming effect of adding traces of catechol. Gregg and Nelson[16] have shown that the oxidation of catechol primed the enzyme so that it could bring about the oxidation of hydroquinone. We have tested the priming of the enzyme during the oxidation of several of the substrates reported in this paper. The results are shown in Table III.

TABLE III

SHOWING THE ABILITY OF TYROSINASE TO EFFECT THE OXIDATION OF HYDROQUINONE DURING OXIDATION OF CATECHOL-TYPE SUBSTRATES

Substrate concentration, 0.25×10^{-5} mole; *p*H 6.40; hydroquinone, 5 mg.; gelatin, 5 mg.; enzyme, 2.75 catecholase units[16]

Substrate	Oxygen (cubic millimeters) Required	Oxygen (cubic millimeters) Consumed (30 min.)
Catechol	56.0	420
3,4-Dihydroxybenzenesulfonate Na	28.0	400
3,5-Dichlorocatechol	28.0	375
3,4,5-Trichlorocatechol	28.0	290
3-Nitrocatechol	56.0	225
3,4-Dihydroxy-ω-chloroacetophenone	28.0	130

The oxygen uptake in excess of that calculated as required for the catechols was consumed in the oxidation of the added hydroquinone. Thus it is seen that regardless of whether the substrate consumes one or two atoms of oxygen it can cause the enzyme to be primed to oxidize monohydric phenols.

Discussion

The question of hydrogen peroxide formation during the oxidation of catechols and phenols has been marked by controversy since the postulate of its formation was first advanced. In recent years the weight of evidence has been such that this postulate is being for the most part rejected. The finding of several substrates whose oxygen consumption is limited to a single atom of oxygen per mole adds confirmation to the work of those who reject the hydrogen peroxide postulate. In all cases where one atom of oxygen was consumed the product was found to behave as an *o*-quinone, and no hydrogen peroxide could be detected. The enzyme being free from catalase, the conclusion that there is no hydrogen peroxide formed appears well justified.

Studies on reaction rates of the system air–tyrosinase–catechol and air–tyrosinase–*p*-cresol are made difficult due to the complex nature of the reaction which each undergoes. The use of a substrate whose oxidation requires only one atom of oxygen per mole should eliminate many of these difficulties.

Experimental Details

Many of the catechol-type substrates used in this study were not available from commercial sources, thus necessitating their preparation according to the methods from previous literature as shown below.

4-Chlorocatechol.—By treating catechol with sulfuryl chloride; m. p. 90–92°.[17]

3,4-Dihydroxybenzaldehyde.—By treating piperonal with phosphorous oxychloride, followed by hydrolysis; yields very small; m. p. 152–153°.[18]

3,4-Dihydroxybenzoic Acid.—By fusion of vanillin with potash; m. p. 197–199°.[19]

3,4-Dihydroxyacetophenone.—By reduction of 4-chloroacetylcatechol; m. p. 116–117°.[20]

3,4-Dihydroxy-ω-chloroacetophenone.—By treatment of catechol with chloroacetic acid and phosphorous oxychloride.[21]

Sodium 3,4-Dihydroxybenzenesulfonate.—By treatment of guaiacol with sulfuric acid; m. p. 97–98°.[22]

4-Nitrocatechol.—By Dakin oxidation of 5-nitrosalicylaldehyde; m. p. 168–170°.[23]

3-Nitrocatechol.—By nitration of catechol; m. p. 86–90°.[24]

4,5-Dimethylcatechol.—From *o*-xylenol.[25]

4,5-Dichlorocatechol.—By treating catechol with sulfuryl chloride.[17]

4,5-Dibromocatechol.—By bromination of catechol in acetic acid.[26]

3,4,5-Trichlorocatechol.—By chlorination of catechol; m. p. 104–105°.[27]

Tetrabromocatechol.—Bromination of catechol; m. p. 192–193°.[28]

3,5,6-Tribromo-4-methylcatechol.—Bromination of 4-methylcatechol; m. p. 163–164°.[29]

3,5-Dibromocatechol.—By Dakin oxidation of 3,5-dibromosalicylaldehyde; m. p. 92–93°.[23]

3,5-Dichlorocatechol.—By Dakin oxidation of 3,5-dichlorosalicylaldehyde; m. p. 85–86°.[23]

3,5-Dinitrocatechol.—By nitration of catechol diacetate; m. p. 160–164°.[30]

Summary

1. It has been shown that the introduction of the *ortho*-directing groups —CH_3 and —Cl into the 4-position of the catechol ring produces a tyrosinase substrate whose oxygen consumption is the same as that for catechol, that is, two atoms of oxygen per mole.

2. The introduction into the 4-position of the catechol ring of such *meta*-directing groups as —CHO, —COOH, —$COCH_3$, —$COCH_2Cl$ and

—SO_3Na produces substrates whose oxygen consumption is one atom per mole.

3. For those substrates in which both the 4- and 5- positions are substituted the oxygen consumption is one atom per mole.

4. It was shown that the —NO_2 group in the 3-position of the catechol ring produces a substrate which consumes two atoms of oxygen per mole, whereas the —SO_3Na group in this position produces a substance inert to tyrosinase.

5. Leaving the 4-position open and substituting in the 3- and 5-positions produces a substrate which consumes one atom of oxygen per mole.

6. Analysis of the literature shows that the oxidation of a monohydric phenol by tyrosinase fails when there is in the 2-position any group other than —OH.

7. Analysis of the literature shows that an *ortho*-directing group (except —OH) in the 3-position of phenol produces a substrate which consumes three atoms of oxygen, whereas if the group is *meta*-directing the substance is inert to tyrosinase.

8. When there is in the 4-position of the phenol ring an *ortho*-directing group the substance consumes three atoms of oxygen per mole. This was demonstrated with *p*-chlorophenol. When the group is *meta*-directing the substance is inert toward tyrosinase.

9. 4,5-Dimethylphenol was oxidized by tyrosinase with the consumption of two atoms of oxygen per mole.

10. Oxidation of catechol-type substrates enabled the enzyme to bring about the oxidation of hydroquinone.

NEW YORK, N. Y. RECEIVED NOVEMBER 15, 1947

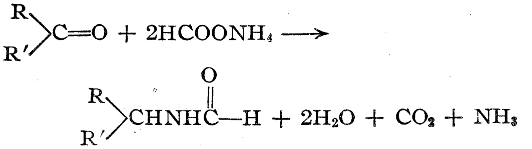
Studies on the Mechanism of the Leuckart Reaction

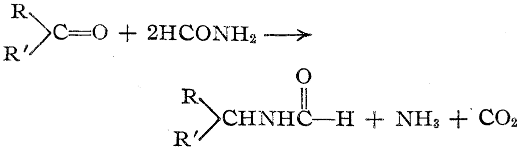
BY ELLIOT R. ALEXANDER AND RUTH BOWMAN WILDMAN

The conversion of carbonyl compounds into the corresponding amino derivatives by means of excess ammonium formate or formamide is usually called the Leuckart reaction. Recently this reaction has been used for the preparation of a rather large number of amines,[1] and the experimental conditions have been developed to the point where good yields can be obtained.

The mechanism of this reaction, however, is not definitely known. Superficially at least the equation may be written as in (1) or (2) in which either ammonium formate or formamide can be considered to be the essential reactant. It is quite interesting that both reagents have been used successfully, although ammonium formate appears to give somewhat better yields than formamide alone[1c,1d] or formamide in the presence of formic acid.[1b] These facts suggested that ammonium formate was the actual reactant, and it was therefore the object of this work to learn if there were conditions such that the reaction could be carried out with ammonium formate but not with formamide.



$$\begin{matrix}R\\R'\end{matrix}\!>\!C{=}O + 2HCOONH_4 \longrightarrow \begin{matrix}R\\R'\end{matrix}\!>\!CHNH\overset{O}{\overset{\|}{C}}{-}H + 2H_2O + CO_2 + NH_3 \quad (1)$$

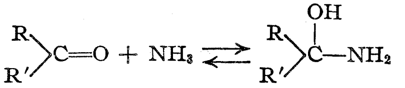


$$\begin{matrix}R\\R'\end{matrix}\!>\!C{=}O + 2HCONH_2 \longrightarrow \begin{matrix}R\\R'\end{matrix}\!>\!CHNH\overset{O}{\overset{\|}{C}}{-}H + NH_3 + CO_2 \quad (2)$$

In Table I are summarized the important data from a number of reactions carried out under different conditions using acetophenone as the carbonyl component. In experiments 4 and 5 it will be observed that when the reaction was carried out in diethylene glycol solution at 120–130°, no reaction occurred with formamide even after as long as fifteen hours, while a yield of 10% was obtained with ammonium formate after four hours. Thus, although formamide is capable of reacting at temperatures greater than 165° (Experiments 1 and 2), at 120–130° ammonium formate appears to the reagent which is both necessary and sufficient for reaction.[2]

One mechanism for the reaction of a carbonyl compound with ammonium formate is the one originally proposed by Wallach[3] which is outlined in equations 3–5.

$$HCOONH_4 \rightleftarrows HCOOH + NH_3 \quad (3)$$



$$\begin{matrix}R\\R'\end{matrix}\!>\!C{=}O + NH_3 \rightleftarrows \begin{matrix}R\\R'\end{matrix}\!>\!\overset{OH}{\overset{|}{C}}{-}NH_2 \quad (4)$$

Chem.*, **9**, 529 (1944); (c) Novelli, THIS JOURNAL, **61**, 520 (1939); (d) Johns and Burch, *ibid.*, **60**, 919 (1938); (e) Ingersoll, Brown, Kim, Beauchamp and Jennings, *ibid.*, **58**, 1808 (1936).

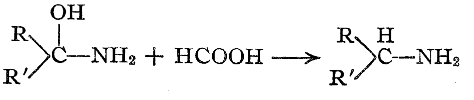
(2) At 165° there may exist an equilibrium between the systems.

$$HCONH_2 + O{=}\underset{|}{C}{-} \rightleftarrows HCON{=}\underset{|}{C}{-} + H_2O$$

$$H_2O + HCONH_2 \rightleftarrows [HCOO]^- + [NH_4]^+$$

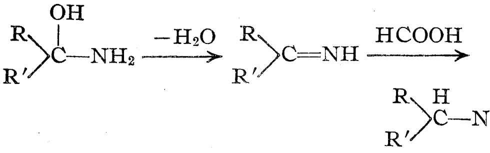
In support of this reaction series for the intermediate formation of ammonium formate, it will be observed that the yield was lowered from 30% to 17% by the introduction of anhydrous calcium sulfate into the reaction mixture (Experiments 1 and 2).

(3) Wallach, *Ann.*, **343**, 54 (1905).



(5)

It has also been suggested that an alternative path for primary and secondary alkyl ammonium formates might involve the reduction of an imine formed by the loss of water from the carbonylammonia[1b] (6).



(6)

TABLE I

THE LEUCKART REACTION WITH ACETOPHENONE

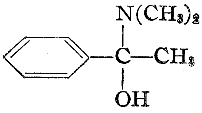
	Mole reactant/mole acetophenone[a]					
No.	Formamide	Ammonium formate	Solvent	Temp., °C.	Time, hr.	Yield, %
1	5.0			165–173	7.5	30[d]
2	5.0[b]			165–170	7.0	17[d]
3		5.2[c]		150–155	8.0	77[d]
4	2.3		Diethylene glycol[f]	120–130	15.0	0[e]
5		2.3	Diethylene glycol[f]	120–130[g]	4.0	10[e]

[a] Experiments 1–3 were carried out with 0.5 mole of acetophenone. Experiments 4 and 5 were carried out with 0.33 mole of acetophenone. [b] Anhydrous calcium sulfate (200 g.) was added to the reaction mixture. [c] Preheated at 160° until no more water came off. [d] Isolated as the formyl derivative of *dl*-α-phenylethylamine. [e] Isolated as *dl*-α-phenylethylamine. [f] 50 ml. [g] The reaction mixture became homogeneous at about 90°.

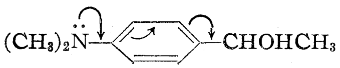
Except for the step involving the reduction of the carbonyl ammonia or imine by formic acid this reaction series seems most reasonable. However, no record of the reduction of a carbon–nitrogen double bond by formic acid could be found, and the reduction of a hydroxyl group by formic acid usually appears to require much more vigorous conditions than were employed in experiment 5. Thus, in a careful study of the minimum decomposition temperature of a number of formic esters, Bowden, Clarke and Harris[4] showed that methyl formate was stable at 440°, and that benzyl formate and benzhydryl formate began to decompose only at 320° and 206°, respectively.[5] Accordingly an investigation was undertaken to determine if intermediates such as those which are shown in equations 5 and 6 can be reduced with formic acid. As a model imine, benzalaniline (I) was chosen. Ketone ammonias, however, are well known to form only unstable addition compounds and for that reason *p*-dimethylaminophenylmethylcarbinol (II) was selected for study. *p*-Dimethylaminophenylmethylcarbinol, it will be observed, is a vinylog of the addition product of acetophenone and dimethylamine (III). Consequently, many of the electrical effects which might be conferred upon the α carbon atom as a result of the electron pair on the nitrogen atom in III would be expected to be relayed to the same atom by the electromeric mechanism shown in IV.

I

II



III



IV

Experiments showed that both benzalaniline and *p*-dimethylaminophenylmethylcarbinol produced resinous materials on boiling with 90% formic acid, but that when the acidity of the reaction mixture was reduced by employing triethylammonium formate, reduction occurred in both cases. Thus, on heating triethylammonium formate and the carbinol at 130–135° for twelve hours, a 6% yield of dimethylaminoethylbenzene was obtained (isolated as the methiodide). When benzalaniline was heated with the same reagent at 140–160° for two hours a 97% yield of N-benzylaniline hydrochloride was obtained. Although the yield in the case of the carbinol was very low, the fact that reduction occurred at all at 130° indicates that compounds of this type are much more susceptible to reduction with salts of formic acid than would normally be supposed.

Experimental[6]

The Leuckart Reaction with Acetophenone.—The procedure used for the runs given in Table I was a modification of the method described by Ingersoll.[7] The product was worked up by two methods. In one of them the formyl derivative of *dl*-α-phenylethylamine was hydrolyzed as described[7] and the product isolated was *dl*-α-phenylethylamine. In the other, the reaction mixture was poured into water and the resulting oil was extracted thoroughly with benzene. The benzene solution was then washed with water and dried over anhydrous magnesium sulfate. Distillation gave the formyl derivative as a thick yellow oil, b. p. 148–156° (4 mm.),[8] $n^{25}\text{D}$ 1.5420–1.5448. The material showed no tendency to crystallize.

Reduction of *p*-Dimethylaminophenylmethylcarbinol with Triethylammonium Formate.—*p*-Dimethylaminophenylmethylcarbinol was prepared by the method of F. Sachs and L. Sachs.[9] After three recrystallizations from high-boiling petroleum ether the material melted at 59–60°.

Triethylammonium formate was prepared by neutralizing 50% formic acid with triethylamine and evaporating the resulting solution on a steam-bath for twelve hours at 20 mm. The crude triethylammonium formate was used without further purification. It was a light brown sirup.

(5) Triphenylcarbinol, which forms no formate, can be reduced to triphenylmethane by boiling with formic acid; see Kauffmann and Pannwitz, *Ber.*, **45**, 767 (1912).

(6) All melting points and boiling points are uncorrected.

(7) A. W. Ingersoll, "Organic Syntheses," Coll. Vol. II, John Wiley and Sons, New York, N. Y., 1943, p. 503.

(8) DeLeeuw, *Rec. trav. chim.*, **30**, 241 (1911).

(9) F. Sachs and L. Sachs, *Ber.*, **38**, 512 (1905).

The reaction was carried out by heating 5.0 g. (0.03 mole) of the carbinol with 22.0 g. (0.15 mole) of crude triethylammonium formate in a distilling flask which was equipped with a receiver and water-cooled condenser. The heating was carried out at a temperature of 120–125° for two hours; then it was raised to 130–135° and allowed to run overnight. During the heating period droplets of oil could be observed throughout the reaction mixture and the odor of triethylamine could be detected. A few drops of oil and water collected on the receiver.

On cooling and rinsing the entire apparatus with water into a beaker, a gummy mass separated. This mixture was extracted with ether, evaporated to dryness and stirred thoroughly with three small portions of low-boiling petroleum ether. This solution was again evaporated to dryness and the residue steam distilled. From the distillate a small amount of oil was obtained by extraction with ether and evaporation of the excess solvent. It was characterized by warming with excess methyl iodide and recrystallizing the yellow quaternary salt formed from a mixture of alcohol and ether. After three recrystallizations 0.6 g. (6%) of a very faintly yellow material was obtained, m. p. 219–220° (dec.).[10] A mixed melting point of this material showed no depression with the methiodide of a sample of *p*-dimethylaminoethylbenzene prepared by the high pressure reduction of *p*-dimethylaminophenylmethylcarbinol over Raney nickel.[11]

Reduction of Benzalaniline with Triethylammonium Formate.—Benzalaniline (5.0 g., 0.0276 mole) and triethylammonium formate (13.0 g., 0.0884 mole) were heated with a small flame until the temperature of the reaction mixture reached about 140°. At this point a mild exothermic reaction took place; triethylamine was evolved and the reaction proceeded without further heating. In a very short time the reaction subsided and heating was continued at 140–160° for two hours.

After cooling the reaction mixture was poured into water, an oil separated, and the aqueous layer extracted with two small portions of benzene. The oil and the benzene extracts were then combined and heated with 10 ml. of concentrated hydrochloric acid in such a way that the benzene was allowed to evaporate. The residual oil was hydrolyzed in about ten minutes and the resulting solution was completely homogeneous. On cooling, the hydrolysis mixture completely solidified. It was broken up with a spatula, sucked as dry as possible on a Büchner funnel and rinsed with ice water and ether. After drying thoroughly, 6.9 g. (97.5%) of benzylaniline hydrochloride, m. p. 214–215°[12] was obtained. A second recrystallization from water did not improve the melting point. On regeneration with alkali, the free amine gave a benzamide, m. p. 107–108°, and a benzenesulfonamide, m. p. 118–119°.[13]

Summary

At 120–130° in diethylene glycol solution, acetophenone has been found to undergo the Leuckart reaction with ammonium formate but not with formamide. This indicates that at this temperature ammonium formate and not formamide is the essential reactant for the transformation.

Benzalaniline and *p*-dimethylaminophenylmethylcarbinol were reduced to N-benzylaniline (97%) and *p*-dimethylaminoethylbenzene (6%) by heating with triethylammonium formate at temperatures ranging from 130 to 160°. These compounds are analogous to the intermediates which were postulated by Wallach and by Crossley and Moore for the Leuckart reaction.

Preparation of Acetonechloroform and its Homologs

BY CH. WEIZMANN, E. BERGMANN AND M. SULZBACHER

For an investigation which is reported in the preceding paper, acetonechloroform ((trichloromethyl)-dimethylcarbinol) was needed in considerable quantities. Fishburn and Watson[1] concluded from a systematic investigation that the best method for its preparation was the condensation of acetone and chloroform by means of potassium hydroxide in excess acetone as solvent, and reported a yield of 25% under these conditions. Sodamide in anhydrous ether gives a yield of about 75%[2] but it has to be used in 50% excess and under strictly anhydrous conditions.

It has now been found that chloroform will condense with acetone and certain other ketones (see Experimental Part) in solutions of acetals containing potassium hydroxide to yield trichloromethyl carbinols. The yields are quite satisfactory, although some of the chloroform and/or the trichloromethyl carbinol formed reacts with the alkali to give potassium chloride, a side reaction which is the more pronounced the higher the water content of the potassium hydroxide used. The extent to which this side reaction occurs can be further reduced if one does not allow the reaction to go quite to the end.

The reaction can be extended to aldehydes, but only to those which are branched in α-position to the carbonyl group such as 2-ethylhexanal and isobutyraldehyde; straight-chain aldehydes undergo self-condensation more readily than condensation with chloroform. Benzaldehyde condenses with chloroform,[3] benzophenone does not.

While chloroform and bromoform condensed with the carbonyl compounds specified, methylene chloride failed to react at all, and 1,1,1,2,2,3,3-heptachloropropane was simply dehydrohalogenated to hexachloropropylene, even at low tem-

[l] Considerable quantities (40 g.) of relatively high boiling range (170–230°) were formed.

perature. It had been chosen for these experiments as it contains, according to Rebek and Mandrino, a mobile hydrogen atom.[4]

Experimental

Acetone and Chloroform. (a) **In Methylal** (Formaldehydedimethylacetal).—At −4°, 120 g. of powdered technical potassium hydroxide (102 g. KOH; 1.8 moles) was added to 500 cc. of dry methylal, with vigorous agitation. At about the same temperature (not higher than −1°), a mixture of 215 g. (1.8 moles) of chloroform and 116 g. (2.0 moles) of acetone was added in the course of two hours and the agitation continued for two hours. The pale yellow reaction product was then run into a mixture of crushed ice and dilute sulfuric acid, the top layer separated and the aqueous bottom layer extracted with methylal. Distillation removed the solvent and any unchanged chloroform. The residue, which crystallized at once, was steam-distilled; needles, melting at 91° (after drying). In two parallel experiments, 41.0 and 40.0 g. of chloroform (19.1 and 18.6% of the total quantity employed) were recovered and 175.0 and 177.0 g. of trichloromethyldimethylcarbinol were isolated, corresponding to 67.7 and 68.1% of the chloroform entered into reaction. Titration of the aqueous layer showed that 98 g. of potassium chloride had formed which accounts for 24.3% of the chloroform employed.

When the amount of potassium hydroxide was halved, 108.0 g. (50.2% of the initial) of chloroform was recovered and 130.0 g. of the chlorinated alcohol and 32 g. of potassium chloride were formed, amounting to 81.7 and 8.0%, respectively, of the chloroform entered into reaction. The yield was, therefore, better (the decomposition very much reduced), but the conversion was unsatisfactorily low. If on the other hand the amount of potassium hydroxide was doubled, only 24.0 g. (11.2% of the initial) of chloroform was recovered, but the yield of acetonechloroform was very much reduced.

As already pointed out, freshly molten potassium hydroxide gives considerably better results. In two parallel experiments, conducted as described above, but using 102 g. of freshly molten potassium hydroxide, 82.0 and 80.0 g. of chloroform (38.1 and 37.2% of the total) were recovered and 170.0 and 175.0 g. of acetonechloroform formed (86.0 and 87.2%, calculated on chloroform entered into reaction). Only 7.0 and 6.2% of the chloroform decomposed.

(b) **In Butyraldehydedibutylacetal.**—A suspension of 60 g. of potassium hydroxide flakes (51 g., 0.9 mole KOH) was heated in 300 cc. of butyraldehydedibutylacetal[5] (b. p. 218°; 100–103° (15 mm.)) at 150° until two liquid layers had formed. The mixture was then slowly cooled to −2° with violent agitation which produced a very fine suspension. At this temperature, a mixture of 107.5 g. (0.9 mole) of chloroform and 58 g. (1 mole) of acetone was added slowly, the agitation continued for two more hours, and the product poured into a mixture of cracked ice and dilute sulfuric acid; 32.5 g. (30.2% of the initial) of chloroform were recovered and 97.5 g. of acetonechloroform isolated. This corresponds to 87.5% of the chloroform consumed in the reaction.

All the other experiments are summarized in Table I. It refers to the reaction between 1 mole of carbonyl compound, 10.9 mole of chloroform and if not otherwise stated 60 g. of powdered potassium hydroxide of 85% KOH content.

Acetone and Bromoform.—A mixture of 227.5 g. of bromoform and 58 g. of acetone was slowly added to the suspension of 60 g. of potassium hydroxide (51 g. KOH) in 250 cc. of acetal at −2°. The reaction was extremely violent, and the temperature rose temporarily to +9°; 71.4% of the bromoform used was recovered, but only 10.5 g. of acetonebromoform (from petroleum ether, fine needles, m. p. 168–170°)[6] could be isolated, which corresponds to 13.1% of the bromoform consumed. The balance was decomposed to potassium bromide.

Summary

Good yields of acetonechloroform are obtained when the components are condensed by means of potassium hydroxide in acetals as solvent.

Methyl ethyl ketone, methyl isobutyl ketone, acetophenone, cyclohexanone and α-branched aldehydes (isobutyraldehyde, 2-ethylhexanal) condense with chloroform smoothly under the same

The Orienting Effect of Negatively Substituted Vinyl Groups in Aromatic Substitution

BY F. G. BORDWELL AND KENNETH ROHDE[1]

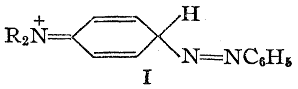
The orienting influence of groups on the course of aromatic substitution reactions was one of the first problems attacked in the development of the "English theory."[2] The directive properties of negatively substituted vinyl groups attracted attention during the early growth of the theory,[3,4] but groups of this nature have since been largely ignored in discussions and reviews. Baker and Wilson in their study of the nitration of ω-nitrostyrene found that the *p*- and *o*-isomers were formed almost exclusively. At that time they believed that the electron attracting effect of the nitro group was "damped out" by the electrons available in the olefinic bond, and that the substituted vinyl group was analogous to a methyl group in its directive properties. Since this early study, additional data concerning the orienting effect of substituted vinyl groups have become available, and the theory has also progressed.

The literature contains no mention of *m*-isomers from the nitration of such negatively substituted vinylbenzenes as α-methoxystyrene,[3] β-bromostyrene,[5] ω-nitrostyrene,[4] cinnamic acid,[6] α-chlorocinnamic acid,[7] α,β-dibromocinnamic acid[7] or 2-phenylethenesulfonyl chloride.[8,9] By careful analysis Baker and Wilson[4] found that the amount of *m*-isomer formed in the nitration of ω-nitrostyrene was less than 2%. Using a similar procedure, we have found that nitration in the *m*-positions of 2-phenylethenesulfonyl chloride also occurs to the extent of less than 2%. These data clearly illustrate the powerful *o*-*p*-directing effect of substituted vinyl groups.

In order to describe completely the orienting effect of a substituent on the course of aromatic substitution, it is necessary to know not only the positions taken by incoming groups under its direction, but also whether the substituent activates or deactivates the benzene nucleus. To determine the latter property for substituted vinyl groups, competitive nitration experiments were carried out by the method developed by Ingold, *et al.*[10] The competitive nitration of 2-phenylethenesulfonyl chloride and benzene was first studied, but the results obtained were not precise. Much better data were obtained from a study of the competitive nitration of cinnamic acid and benzene. The rates of nitration of 2-phenylethenesulfonyl chloride and of cinnamic acid were found to be appreciably lower than that of benzene, and of the same order as that of chlorobenzene. Negatively substituted vinyl groups, therefore, appear to belong with the halogen atoms in the class of strong *o*-*p*-directing groups which deactivate the benzene nucleus toward electrophilic substitution reactions.

Discussion

According to the most recent concepts of the role of orienting groups in aromatic substitution, the ability of a group to produce a more rapid reaction at *o*-*p*- than at *m*-positions is accounted for by assuming a resonance stabilization of the transition state for *o*-*p*- but not *m*-substitution.[11] Thus in the coupling of the benzenediazonium ion with dialkylaminobenzenes, Hughes and Ingold[11] attribute the *o*-*p*-directing influence of the dialkylamino groups to its ability to enhance the stability of the transition state by virtue of the contribution of structure I.



I

This concept of the role of orienting groups can be applied to all common *o*-*p*-directing groups, assuming a hyperconjugation effect for alkyl groups.[11] It is useful in explaining the fact that halogen atoms are strong *o*-*p*-directing groups despite their deactivating effect on the benzene nucleus. Al-

though the withdrawal of electrons from the benzene ring by the halogen atoms lowers the over-all rate of substitution in halobenzenes as compared to benzene itself, the rate of substitution at *o*-*p*-positions is greater than that at *m*-positions by virtue of resonance stabilization in the transition state.[12]

The transition state theory is particularly helpful in accounting for the orienting effects of negatively substituted vinyl groups, since predictions made on the basis of resonance possibilities in the initial states of these molecules are misleading. In the initial state the contribution of structures, such as II and III for ω-nitrostyrene, would be expected to be appreciable and to lead to *m*-substitution. The inductive effect of the nitro group transmitted through a vinyl group should also favor *m*-substitution. These effects are manifested by a lower rate of substitution for negatively substituted vinyl benzenes as compared to benzene. Structures of the type of IV probably would be relatively unimportant. However, in an electrophilic substitution reaction such as nitration of ω-nitrostyrene, which probably involves reaction with the NO_2^+ ion,[13] the energy of the transition state may be lowered appreciably when reaction occurs at the *o*-*p*-positions by the contribution of structures illustrated by V. No such resonance stabilization of the transition state can occur for reaction at the *m*-positions.

Experimental[14]

Percentage of Isomers Formed in the Nitration of 2-Phenylethenesulfonyl Chloride.—In earlier work[8] approximately 50% of the *p*-isomer and 20% of the *o*-isomer have been isolated from a 95% yield of crude nitration mixture. Repetition of the experiment gave a 94% yield of crude nitration product from which fractional crystallization gave 53.4% of *p*-isomer, 19.7% of *o*-isomer, and 10.7% of a mixture. A study was made of the reaction of 2-(*o*- and *p*-nitrophenyl)-ethenesulfonhydrazides with 90% aqueous hydrazine to see whether this reaction could be used to further resolve the mixture. This method has been used[15] to separate isomeric nitrobenzenesulfonhydrazides. The 2-(*o*- and *p*-nitrophenyl)-ethenesulfonhydrazides were readily prepared but not easily purified. The acetone derivatives were prepared for identification purposes. Crude 2-(*p*-nitrophenyl)-ethenesulfonhydrazide, m. p. 142–144°, was converted to the **2-(*p*-nitrophenyl)-ethenesulfonhydrazone of acetone**, m. p. 201–202°.

Anal. Calcd. for $C_{11}H_{13}N_3O_4S$: C, 46.60; H, 4.62. Found: C, 46.75; H, 4.64.

Crude 2-(*o*-nitrophenyl)ethenesulfonhydrazide, m. p. 116–119°, was converted to the **2-(*o*-nitrophenyl)-ethenesulfonhydrazone of acetone**, m. p. 157–159°.

Anal. Calcd. for $C_{11}H_{13}N_3O_4S$: C, 46.60; H, 4.62. Found: C, 46.58; H, 4.50.

Nitrogen was evolved in the reaction of the 2-(*o*- and *p*-nitrophenyl)-ethenesulfonhydrazides with 90% aqueous hydrazine, but no pure products could be isolated from the reaction.

The amount of *m*-isomer in the unresolved 10.7% of nitration product was determined by hydrolysis of the 2-(nitrophenyl)-ethenesulfonyl chlorides followed by oxidation with aqueous potassium permanganate to a mixture of nitrobenzoic acids. The nitrobenzoic acids, obtained in 84% yield, were converted to their barium salts. Fractional crystallization yielded only very small quantities of slightly soluble barium salts, and mixed melting points taken with the acid produced from these salts indicated that the *m*-nitrobenzoic acid thus produced was very impure. The oxidation product was almost exclusively *o*-nitrobenzoic acid, m. p. 128–132°, which gave mixed melting points of 90–95° and 132–134° with *m*- and *o*-nitrobenzoic acids, respectively.

Competitive Nitration of 2-Phenylethenesulfonyl Chloride and Benzene.—The nitrations were run by a method similar to that described by Bird and Ingold.[10] The "R values"[10] in ten determinations ranged from 0.04 to 0.2. The source of error was apparently in the method of separation of the nitration products.

Competitive Nitration of Cinnamic Acid and Benzene.—The nitrations were carried out by keeping a solution consisting of 0.015 mole of benzene, 0.015 mole of cinnamic acid, 0.012 mole of nitric acid and 30 ml. of acetic anhydride at a thermostatically controlled temperature of 25° for eighteen to twenty hours. The reaction mixture was then stirred with about 200 g. of ice and water for one hour, the temperature being kept below 20°. The resulting mixture was extracted with four portions of a 10% solution of benzene in ether, and the cinnamic and nitrocinnamic acids were removed from the combined ethereal solutions by four extractions with aqueous sodium carbonate. The quantity of nitrobenzene and nitrocinnamic acids formed in the reaction was determined by titration of separate solutions containing these substances with titanium trichloride according to the method developed by Francis and Hill.[16] In four determinations the moles of nitrobenzene produced were 0.0034, 0.0028, 0.0039 and 0.0041, respectively, and the moles of nitrocinnamic acids were 0.00043, 0.00034, 0.00048 and 0.00053, respectively. Using the correction formula developed by Ingold and his co-workers,[10] the mean value for the ratio of the rate constants, *k*(cinnamic acid)/*k*(benzene) was found to be 0.111. For the competitive nitration of 2-phenylethene-1-sulfonyl chloride and benzene the ratio of rate constants is approximately 0.07. Bird and Ingold[10] reported a ratio of rate constants of 0.0353 for the competitive nitration of chlorobenzene and benzene at 25°.

[15] Dann and Davies, *J. Chem. Soc.*, 1050 (1929); Davies, Storries and Tucker, *ibid.*, 624 (1931).

[16] Francis and Hill, THIS JOURNAL, **46**, 2498 (1924).

ride was found to give less than 2% of *m*-isomer, further illustrating the strong *o*-*p*-directing effect of negatively substituted vinyl groups.

2. The mean value for the ratio of rate constants, *k*(cinnamic acid)/*k*(benzene), determined by the competitive nitration of cinnamic acid and benzene was found to be 0.111. This ratio is of the same order as that obtained by Bird and Ingold[10] for the competitive nitration of chlorobenzene and benzene.

3. The *o*-*p*-orienting effect of negatively substituted vinyl groups has been accounted for by the assumption that resonance stabilization in the transition state, involving the electrons of the olefinic bond, is the determining factor.

Polysaccharide Acid Esters as Cation Exchange Media

BY FLOYD C. McINTIRE AND JAY R. SCHENCK

In the development of a method for the purification of histamine[1] there arose a need for a cation exchange medium with properties not possessed by the commercially available cation exchangers. It was found that if cotton were *partially esterified* with succinic acid the acid ester so produced would function very nicely as a cation exchanger. The preparation of acid esters by the partial esterification of cellulose and other polysaccharides was then studied further with a view toward a more general use of these materials as cation exchange media.

To this end we have partially esterified cotton with glutaric, maleic, phthalic, and succinic acids and wood cellulose and starch with succinic acid.

Experimental

Esterification of Polysaccharides.—Two methods of esterification were used: (1) The acid anhydride, 0.2 mole, was dissolved in 300 ml. of pyridine. Ten grams of polysaccharide was suspended in this solution and the temperature was maintained at 60° for eighteen to twenty-four hours. The insoluble product was washed successively with water, dilute hydrochloric acid, water and alcohol and then dried *in vacuo;* (2) the acid anhydride, 0.2 to 0.4 mole, and 10 g. of anhydrous sodium acetate were dissolved in 300 ml. of glacial acetic acid. Ten grams of polysaccharide was introduced and the temperature was maintained at 100° for forty-eight hours. The product was washed with dilute hydrochloric acid, water and alcohol and then dried. The latter method is preferable for most purposes as it produces little or no obvious changes in the gross structure of the materials esterified. Satisfactory preparations of cotton acid maleate could be made only by this method. Starch was esterified in this way. During the esterification of wood cellulose and starch the reaction mixture was stirred continuously.

Determination of Cation Binding Capacity and Degree of Esterification.—Free carboxyl groups were determined by shaking a given amount of polysaccharide acid ester with an excess of 0.05 *M* sodium carbonate for fifteen to twenty minutes and titrating an aliquot of the solution for either total sodium or carbonate sodium. In this determination the original concentration of the second sodium ion of sodium carbonate should exceed the sodium ion binding capacity of the acid ester. The values so obtained agreed closely with the values for free carboxyl groups obtained by electrometric titrations. Direct titration with sodium hydroxide in the presence o an indicator was less reliable.

The degree of esterification was calculated from the determination of free carboxyl groups on the assumption that the number of ester linkages was equal to the number of free carboxyls.

Results and Discussion

The esterification of polysaccharides with dicarboxy acids is not new. This was perhaps first claimed by Levy,[2] and since then such esters have been covered in numerous patents.

In nearly all previous reports the polysaccharides were almost completely esterified and the products were soluble in organic solvents as the free acids or in water as the sodium salts. To our knowledge there is no previous report of the partial esterification of polysaccharides with dicarboxy acids for the preparation of cation exchange media. By effecting only partial esterification of the polysaccharides under conditions which minimize changes in mechanical structure, one can obtain products with physical properties which are very desirable for many cation exchange procedures. These partially esterified products do not jel in organic solvents as the free acids or in water as the sodium salts. In appearance they resemble the original polysaccharides very closely. The fibers of cotton acid esters seem more wiry and more brittle than cotton. The starch acid esters have less affinity for water than does the original starch.

Table I shows some representative values for the degree of esterification and the sodium ion binding capacity of the polysaccharide acid esters. The degree of esterification has a rather wide range. As many as one-fourth of the available hydroxyls of cotton have been esterified without noticeable breakdown of the fibers; with starch nearly half of the available hydroxyls were esterified and the product did not jel in water or alcohol either as the sodium salt or as the free acid. The degree of esterification can be controlled within reasonable limits.

The polysaccharide acid esters participate

TABLE I

SODIUM ION BINDING CAPACITY AND DEGREE OF ESTERIFICATION OF TYPICAL POLYSACCHARIDE ACID ESTER PREPARATIONS

Acid ester	Sodium ion binding capacity, milliequivalents per gram	Available hydroxyls esterified, %
Cotton succinate	3.15	25
Cotton maleate	1.13	6.9
Cotton glutarate	0.80	4.8
Cotton phthalate	1.7	12.3
Starch succinate	4.9	52

rapidly in cation exchange reactions. Cations can be removed from them completely by washing with an equivalent (or slightly more) of dilute hydrochloric acid. For example: 5 ml. of a solution containing 0.4 mg. of histamine free base in 1.4×10^{-3} *M* trisodium phosphate (*p*H about 12) was filtered through 100 mg. of cotton acid succinate (sodium ion binding capacity 0.32 milliequivalent). The histamine was removed quantitatively from solution by the cotton acid succinate and then was removed completely from the cotton succinate by washing with 1 ml. of 0.4 *N* hydrochloric acid followed by 2 ml. of water.

The estimation of the acidic strength of the polysaccharide acid esters was approached in two ways:

(1) Measurements of *p*H were made on the aqueous phase at equilibrium (0.1 g. of polysaccharide acid ester in equilibrium with 10 ml. of water) after the polysaccharide acid ester had been half neutralized with sodium hydroxide. The *pKa* values so obtained are shown in Table II.

(2) The extent to which the polysaccharide acid esters would remove sodium ion from a sodium acetate solution was determined as follows: A quantity of each acid ester having 0.5 milliequivalent of free carboxyl group was suspended in 10 ml. of 0.05 *M* aqueous sodium acetate. One-half hour of shaking or mixing was allowed for the system to come to equilibrium. Duplicate 3-ml. samples of the aqueous phase were removed and the free acetic acid was determined by titration with 0.1 *N* sodium hydroxide. This titration may be considered a direct measure of the sodium ions removed from the sodium acetate solution by the polysaccharide acid ester. If it can be assumed that the acetate ion and the acid esters actually compete for sodium ion and that the distribution of sodium ion between the acetate ion and the polysaccharide acid esters will be dependent upon the strengths of the acids, these values should give an indication of the acidic strengths of the polysaccharide acid esters relative to acetic acid. In Table II the *pKa* values are shown along with the per cent. sodium ion bound by the polysaccharide acid esters at equilibrium, when the acid ester carboxyl, acetate ion, and sodium ion were present in equivalent amounts. That the polysaccharide acid esters are as weakly acidic as the *pKa* values indicate is difficult to believe. The data on competition with acetate ion are more in accord with expectations. The significance of the great quantitative differences between these two types of data is a matter for future consideration.

TABLE II

THE ACIDIC STRENGTH OF POLYSACCHARIDE ACID ESTERS

Acid ester	*pKa*	Na p. e.[a]/Total Na, %
Cotton glutarate	8.8	12
Cotton succinate	7.8	16.8
Starch succinate	7.5	18
Cotton maleate	5.7	40.4
Cotton phthalate	5.6	40.6

[a] Na p. e. = sodium bound by the polysaccharide acid ester.

The usefulness of the polysaccharide acid ester cation exchangers as compared to the ion exchange resins[3] is yet to be determined. Cations can be eluted with dilute solutions of strong acids much more readily from the acid esters than from the sulfonic acid exchange resins. A comparison with carboxy exchange resins has not been attempted. One attractive feature of the polysaccharide acid esters is the availability of exchangers of different acidic strengths. The acid esters have a high ion-binding capacity as compared to the carboxy resins available at present, and their mechanical properties are particularly suited for semi-micro or micro operations. It is likely that other polysaccharide acid esters may be produced which are either weaker or stronger acids than those reported here. The polysaccharide acid esters have one serious limitation to their use, *i. e.*, their ease of saponification. This fact prevents their extensive use in systems where an excess of strong bases may be encountered.

Summary

A series of new cation exchange media, the polysaccharide acid esters, have been reported. Their preparation and properties have been described.

Spectrophotometric Studies on Complex Formation with Sulfosalicylic Acid. I. With Iron III

BY ROBERT T. FOLEY AND ROBBIN C. ANDERSON[1]

Sulfosalicylic acid has long been known as an analytical reagent for iron,[2] giving characteristic colors with iron(III) solutions, apparently because of complex formation. The color variations, shading from violet through deep red or rose in acid solutions to yellow in alkaline, suggest that more than one complex may be involved. The present investigations were undertaken to obtain information concerning the nature of the complex or complexes responsible for these effects.

Experimental

Materials.—Standard iron(III) perchlorate solution was prepared by dissolving primary standard iron wire in hydrochloric and nitric acids. Perchloric acid was then added and the solution boiled slowly to drive off the more volatile acids.

C. P. sulfosalicylic acid (Eastman Kodak Co.) was dissolved in water, with sufficient perchloric acid to adjust to the same *p*H as that of the iron(III) perchlorate solution. The solution was standardized by titration with sodium hydroxide.

Sodium hydroxide solution for use in adjusting the *p*H was prepared from Merck Reagent grade sodium hydroxide. It was standardized with potassium acid phthalate. All solutions were prepared in calibrated apparatus at 25°.

Apparatus.—*p*H measurements were made with a Beckmann *p*H meter, Model G, with an accuracy of ±0.02 *p*H unit.

Light absorption measurements were made with an Automatic Recording General Electric Spectrophotometer of the Hardy type[3] over a range of 400 to 700 mμ with slit adjustment to measure a 10 mμ band. Per cent. transmission values for solutions of equal concentration prepared independently varied not more than 0.3 per cent.

Procedure.—Calculated volumes of iron(III) perchlorate and sulfosalicylic acid were mixed. Sodium hydroxide was then added if needed to adjust the *p*H and the whole diluted to the proper volume and allowed to stand one hour. The transmittance curve was then recorded, the absorption cells being rinsed very carefully before filling with each sample.

Preliminary experiments showed that the solutions reached equilibrium within one hour and showed no measurable variation thereafter for periods of less than twenty-four hours.

The absorption cell was not thermostated, but all solutions were brought to constant temperature before measurements were made.

Results

The composition of the complex was studied using Job's method of continuous variations,[4] the ratio of iron(III) to sulfosalicylic acid being varied with the total molarity of the two kept constant. Several typical transmittance curves for solutions at a *p*H of 2.38 are shown in Fig. 1.

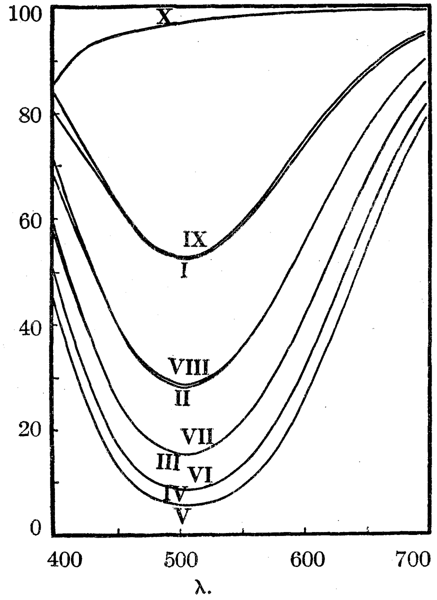

Fig. 1.—Method of continuous variations—absorption curves. The $[\mathrm{Fe^{III}}]/[\mathrm{Fe^{III}}]$ + [sulfosalicylic acid] ratio varied as I, 0.1; II, 0.2; III 0.3; IV, 0.4; V, 0.5; VI, 0.6; VII, 0.7; VIII, 0.8; IX, 0.9; X, 1.0.

From these curves values of the optical density ($D = \log_{10} 1/T$ where T = transmittance) for a particular wave length were calculated for each solution. Sulfosalicylic acid and perchloric acid show no absorption at the wave lengths used. The absorption for a system with no reaction is determined therefore by subtracting the optical density of iron(III) perchlorate determined from curve X of Fig. 1. Subtraction of this absorption for a particular wave length, from the optical density of the solution gives $\overline{D}$, a quantity which is proportional to the concentration of the complex and which passes through a maximum when the ratio of iron(III) to total sulfosalicylic acid in the solution is the same as that in which they react to form the complex.[4,5] $\overline{D}$ was plotted against the ratio

$$\frac{\text{concn. Fe(III) (moles/l.)}}{\text{concn. Fe(III)} + \text{concn. } \mathrm{HO_3SC_6H_3(OH)COOH}}$$

The results for wave lengths of 440, 500 and 540 mμ are shown in Fig. 2.

The occurrence of the maximum of $\overline{D}$ in the curves of Fig. 2 at a ratio of 0.5 indicates that un-

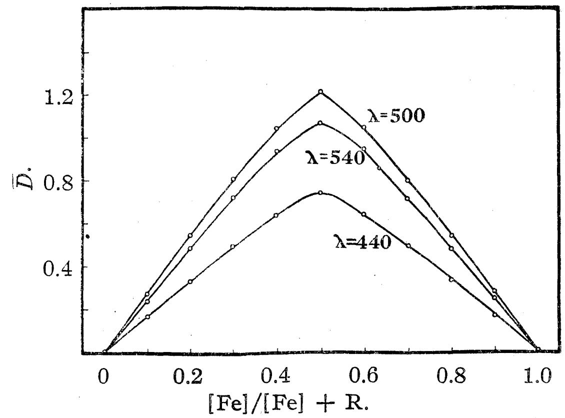

Fig. 2.—Method of continuous variations, *p*H 2.38.

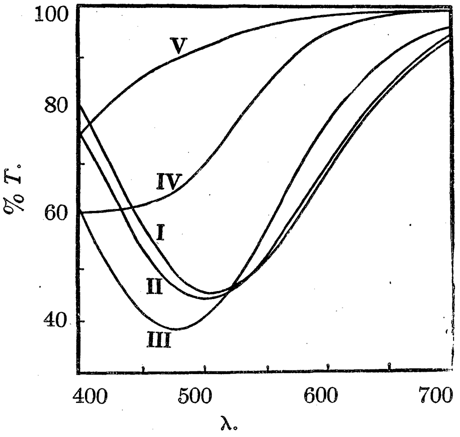
der these conditions the iron and sulfosalicylic acid react in a 1:1 ratio to form the complex.

It may be noted also that the absorption is essentially the same at the two extremes where the ratio of iron(III) to R (sulfosalicylate) is 9:1 and 1:9. Reasonable approximations for the extinction coefficients may be calculated by assuming that under such conditions essentially all of the reagent present in smaller proportion will react to form the complex. Correction can be made for absorption by excess iron(III). For the solution with ratio iron(III): R = 9:1, the value so obtained for the molar extinction coefficient of the complex was 753 at a wave length of 508 mμ. For solutions of ratios 1:9, 8:2, and 2:8, respectively, the corresponding values were 756, 761, 752. Thus there is no indication that in this *p*H range complex formation occurs with more than one iron (III) ion or R group. Similar agreement is obtained for absorption at other wave lengths.

With a change in *p*H, the results vary markedly. In more strongly acid solutions (*e. g.*, *p*H 0.9) $\bar{D}$ curves similar to those in Fig. 2 are obtained, except that the maximum tends to shift slightly to a concentration ratio of 0.46. Some variation is also apparent in solutions with excess sulfosalicylic acid as contrasted to excess iron; but, in general, solutions at *p*H values less than 2.5 show closely similar behavior.

From the curves of Fig. 1, values of the extinction coefficient may be calculated as indicated above. These can then be used to calculate the concentration of the complex in other solutions, *e. g.*, where equal concentrations of iron and sulfosalicylic acid are present. A better value for the extinction coefficient may then be calculated. By a series of successive approximations reasonably good values for the apparent dissociation constant (where R = sulfosalicylic acid concentration) K = [Fe(III)][R]/[FeR] may be determined. At *p*H 2.38 and ionic strength of 0.061 a value of 1.3 ($\pm$0.2) $\times 10^{-5}$ is obtained. At *p*H 0.9 and ionic strength 0.153 the value is 2.1 ($\pm$0.4) $\times 10^{-4}$.

Earlier workers[2] have referred to red or orange or yellow "complexes" in less acid solutions, but experiments at higher *p*H values in the present work indicate that information on such complexes based on ordinary color measurements alone is of doubtful significance. Typical results are shown in the curves of Fig. 3, for solutions of different *p*H and constant iron(III) and sulfosalicylic acid concentrations. The *position* of maximum absorption and thus the color of the solutions changes as well as the extent of absorption.



Effect of *p*H.

Fig. 3.—[Fe]^{III} = 1.791 $\times 10^{-4}$ mole/l. [sulfosalicylic acid] = 2.292 $\times 10^{-3}$ mole/l.: I, *p*H, 1.95; II, *p*H, 3.03; III, *p*H, 4.05; IV, *p*H 5.72; V, *p*H 9.38.

Graphs of $\bar{D}$ against concentration ratios show maxima shifted toward values less than 0.5. For *p*H 4.58, for example, the maximum $\bar{D}$ occurs at a concentration ratio of 0.25–0.30 and for *p*H 6.2 the maximum is between 0.1 and 0.2. These maxima might be taken as evidence of complexes with more R groups, but in some cases more than five sulfosalicylic acid molecules reacting per iron (III) ion would be indicated. It seems evident that other factors than complex formation are involved and that such maxima do not represent the compositions of real complexes.

It has been shown[6] that, even at *p*H 2.38, $FeOH^{++}$ is of major importance in iron(III) solutions; and, although dissociation constants for sulfosalicylic acid are not known exactly, experiments on buffers[7] have shown that the sulfonic acid group is highly ionized and that between *p*H 1 and *p*H 4 conversion in large measure to $^-O_3SCH_3(OH)COO^-$ should occur. These changes in ionic species might account in part for the effect of the hydrogen ion.

However, blank determinations show that in solutions of high *p*H, iron(III) perchlorate solutions absorb more strongly in the same regions as the iron(III)–sulfosalicylic acid mixtures, probably as a result of formation of hydrous iron(III) oxide sols. Where excess iron is present many of

[6] Rabinowitch and Stockmayer, THIS JOURNAL, **64**, 335 (1942); Bray and Hershey, *ibid.*, **56**, 1889 (1934).

[7] Private communication, U. S. Bur. Stds., Dr. R. G. Bates.

the mixtures form precipitates of hydrous iron (III) oxide on standing. The Job method may be applied successfully where other equilibria in solution are involved but any such sol formation makes uncertain the comparison and interpretation of absorption data for mixtures of varying concentrations.

Just recently, Babko's experiments on iron–salicylic acid systems, which might be expected to be closely analogous to the sulfosalicylic acid system, have been reported.[8] He found FeR^+ (violet) in acid solution, then FeR_2^- (red), and finally $FeR_3^{=}$ (yellow) at about *p*H 10, but abstracts available do not indicate what corrections were made for hydrolysis or dissociation.

Experiments are now under way to extend transmittance measurements on the iron–sulfosalicylate systems to the ultraviolet region in an attempt to determine concentrations of the various species, especially $FeOH^{++}$, so that their effects may be measured.

Effect of Temperature.—The instrument used is such that accurate control of temperature is not possible, but approximate measurement of the temperature effect showed that increased temperatures increase the extent of complex formation. The per cent. transmittance decreased about 7% on heating from 20 to 40°. A thermostated absorption cell has now been built so that the temperature effect may be measured more accurately in an attempt to determine the extent of dissociation of the complex.

The authors wish to express their appreciation to Mr. Leland L. Antes, Microscopy Specialist, Bureau Engineering Research, University of Texas, for his assistance in connection with use of the spectrophotometer.

Summary

1. Spectrophotometric studies of complex formation between iron(III) and sulfosalicylic acid were made over a *p*H range of 1 to 9.

2. In strongly acid solutions (to *p*H 2.4) iron (III) and sulfosalicylic acid react in a 1:1 ratio to form a violet complex. Stability of the complex is a function of the acidity.

3. Measurements at higher *p*H values indicate complexes of other mole ratios, but accurate formulas could not be determined from ordinary concentration measurements.

Some Reactions of Trisodium Monobismuthide in Liquid Ammonia[1,2]

BY GEORGE W. WATT AND THOMAS E. MOORE[3]

Although numerous intermetallic compounds of the alkali and alkaline earth metals have been prepared in liquid ammonia, the literature provides very little information concerning their reactions in this medium.[4] The present paper is concerned with the preparation of trisodium monobismuthide and the study of its properties as a reducing agent in liquid ammonia. Since there is no known method for the production of pure sodium bismuthate, it was of interest (particularly in view of the work of McCleary and Fernelius[5]) to determine whether trisodium monobismuthide could be oxidized to sodium bismuthate by treatment with molecular oxygen.

Trisodium monobismuthide was prepared by the reaction

$$BiI_3 + 6Na \longrightarrow Na_3Bi + 3NaI \tag{1}$$

Treatment of the purified monobismuthide with molecular oxygen leads not to sodium bismuthate but rather to an insoluble mixture of bismuth(II) oxide, sodium hydroxide and sodium peroxide

$$4Na_3Bi + 5O_2 + 6NH_3 \longrightarrow 4BiO + 6NaOH + 6NaNH_2 \tag{2a}$$

$$4Na_3Bi + 8O_2 \longrightarrow 4BiO + 6Na_2O_2 \tag{2b}$$

In addition, the following reactions of trisodium monobismuthide have been observed.

$$Na_3Bi + 2Bi \longrightarrow Na_3Bi_3 \tag{3}$$

$$2Na_3Bi + 6NH_4Br \longrightarrow 2Bi + 6NaBr + 6NH_3 + 3H_2 \tag{4}$$

$$Na_3Bi + 3AgI \longrightarrow Bi + 3Ag + 3NaI \tag{5}$$

$$Na_3Bi + BiI_3 \longrightarrow 2Bi + 3NaI \tag{6}$$

$$2Na_3Bi + Bi_2O_3 + 3NH_3 \longrightarrow 4Bi + 3NaOH + 3NaNH_2 \tag{7}$$

In the course of this work the conventional type of apparatus for the study of reactions in liquid ammonia at its boiling temperature has been modified extensively. The major improvements are concerned with techniques for filtration in a closed system.

Experimental

Apparatus.—With the exceptions noted below, the over-all details of construction and mode of operation of the equipment shown in Fig. 1 are similar to those described by Johnson and Fernelius.[6] Both reactors A

and B are provided with tubes b into which solid reaction products are transferred for removal from the system. These tubes are sealed off, evacuated, and opened in an inert atmosphere in a "dry box." At the start of a run, dry ammonia gas is admitted through stopcocks s_1 and s_2 as well as through tubes a in order to remove air more completely. Liquids may be added from *g* by means of an ammonia gas pressure applied at m, while gases may be added (with or without dilution with gaseous ammonia) *via* stopcock s_3.

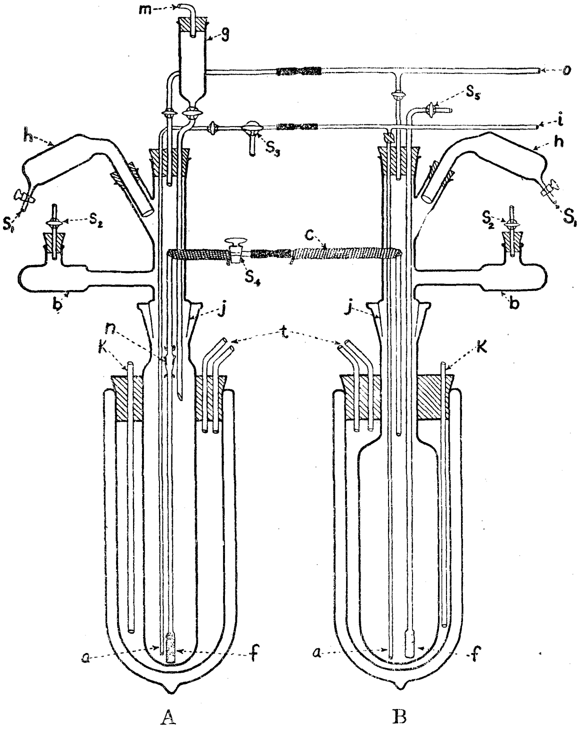

Fig. 1.

Reactor A is equipped with a fritted glass filter f attached by means of a ground glass joint n in order that change to filters of different porosity may be facilitated. The filter tube leads to reactor B through stopcock s_4 and a rubber connection tube.[7] The exposed connection tube between reactors A and B is wrapped with asbestos cord to provide the insulation necessary to prevent excessive "surging" during transfers. Filtration is accomplished by building up a gas pressure on the surface of the liquid in reactor A by admitting anhydrous ammonia gas through o (or less satisfactorily through stopcock s_1 or s_2) with stopcock s_4 open. Following filtration, solids remaining in reactor A may be washed by successive condensation of fresh portions of ammonia, followed by filtration. *Continuous washing* of a solid may be accomplished by balancing the rate of take-off through the filter with the rate of condensation of ammonia. This latter procedure is particularly advantageous when it is desired to extract an ammonia-soluble component of a mixture of solids in reactor A.

Reactor B may be made substantially identical with A although, as represented in Fig. 1, B does not include provision for addition of liquid reactants nor for interchangeable fritted glass filters. The filter tube shown for reactor B also differs in that it is supported through the rubber stopper at the top of the reactor rather than through a ring seal. This arrangement is shown for the reason that it is somewhat more flexible and less readily subject to breakage. For certain purposes, it is convenient to eliminate the fritted glass filter, f, in reactor B and to remove a slurry *via* the open tube through stopcock s_5 and into an external filter of the type shown in Fig. 2. This consists of a glass filter crucible r (having an extra fine porosity fritted glass filter plate) supported in a Dewar test tube w and connected to the tube bearing stopcock s_5 (Fig. 1) *via* a rubber connection e which carries a screw clamp d. With the screw clamp and stopcocks s and s_5 open and s′ closed, the pressure is lowered by a vacuum pump attached at x. After the insoluble material has been collected on the filter, washing is accomplished by means of successive fresh portions of liquid ammonia condensed in reactor B and subsequently drawn over into the external filter. Ammonia collected in the Dewar test tube is removed under reduced pressure *via* s or allowed to escape *via* the tube which bears stopcock s′ and which is connected to an ammonia absorber. Finally, s, s′, and d are closed, the entire assembly is detached and transferred to a "dry box" for removal of the solid on the filter and/or the residue in the Dewar test-tube.

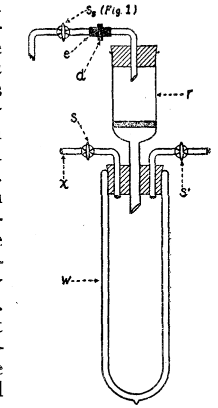

Fig. 2.

Numerous modifications of this equipment have been employed and are more or less obvious. Particular attention is called to the possibility of providing a third reactor which permits preparation, in separate vessels, of two liquid ammonia solutions that may then be brought together in the central unit.

Materials.—All apparatus and materials were thoroughly dried before use.

Bismuth(III) Iodide.—This material was prepared by the method of Birchenbach[8] and purified by three sublimations in an atmosphere of carbon dioxide.

Anal. Calcd. for BiI_3: Bi, 35.43. Found: Bi, 35.41.

Preparation of Trisodium Monobismuthide.—The black insoluble monobismuthide was prepared by reducing 1.5046 g. of bismuth(III) iodide in about 35 ml. of liquid ammonia with 0.3675 g. (6.26 equivalents) of sodium. The reaction was strongly exothermal and intermediate brown and violet colors characteristic of the ammonia-soluble tri and pentabismuthides[9] were observed. Analysis of the thoroughly washed precipitate showed that the Na/Bi ratio is 3.3.[10] Only traces of iodide ion and nitrogen were detected.

In order to show that bismuth is the *primary* product of reduction of the iodide, 1.4747 g. of bismuth(III) iodide was reduced with 0.1821 g. (3.17 equivalents) of sodium. The ammonia-insoluble product was found to contain 96.2% bismuth (pyrophoric) and 3.1% sodium hydroxide. When the bismuth was treated in liquid ammonia with an excess of ammonium bromide to remove sodium hydroxide, the final product contained 98.2% bismuth (non-pyrophoric) and 1.6% sodium hydroxide. This product gave X-ray diffraction patterns (Cu K_α radiation) that showed exactly and only the

---

(7) This and the other two rubber connections should be longer than shown in Fig. 1, in order to provide the flexibility necessary for tilting of the reactor during transfer of solid samples from the bottom of the reactor to tube b.

(8) Birchenbach, *Ber.*, **40**, 1404 (1907).

(9) Zintl, Goubeau and Dullenkopf, *Z. physik. Chem.*, **A154**, 1 (1931).

(10) This value corresponds exactly to that found by Kraus and Kurtz [THIS JOURNAL, **47**, 43 (1925)] in their study of the reduction of bismuth(III) chloride. Zintl, *et al.*,[9] however, found a ratio of 3.0 using a potentiometric titration method. If sodium in excess of that required by the formula Na_3Bi is assumed to be present as sodium hydroxide resulting from the ammonolysis of sodium monoxide [*cf.* Kraus and White, THIS JOURNAL, **48**, 1781 (1926)], formed by surface oxidation of the sodium used, the composition of the insoluble product is 97.0% Na_3Bi and 3.4% NaOH.

lattice spacings and relative intensities characteristic of bismuth.[11]

Preparation of Bismuth(II) Oxide.—Trisodium monobismuthide from the reduction of 1.7185 g. of bismuth (III) iodide by 0.4337 g. of sodium was washed, suspended in liquid ammonia and treated with oxygen[12] for three hours. Addition of 2.29 g. of ammonium bromide[13] resulted in the liberation of 4.4 cc. of oxygen[14] (0°, 760 mm.) and the color of the solid changed from gray to jet black. Several independent sets of analytical data showed that the final solid product had the following percentage composition: BiO (96.5); NH$_3$ (0.4); NaBr (1.8); NaOH (1.8).

Bismuth(II) oxide reacts with atmospheric oxygen at a negligible rate at room temperature but is converted to bismuth(III) oxide upon gentle ignition. The black product failed to form an amalgam when agitated with mercury and was unchanged when heated to 300° *in vacuo*. X-Ray diffraction patterns showed the presence of only a trace of bismuth and the absence of other oxides of bismuth.

Conversion of Trisodium Monobismuthide to Trisodium Tribismuthide.—The trisodium monobismuthide prepared from 1.0154 g. of bismuth(III) iodide by reaction (1) was agitated in 30 ml. of liquid ammonia for two hours with 0.4231 g. of bismuth prepared by reduction of bismuth(III) iodide with three equivalents of sodium. The violet colored ammonia solution[9] was transferred from reactor A to reactor B and found to contain 0.1323 g. of bismuth. This corresponds to the utilization [in accordance with equation (3)] of 21% of the elemental bismuth used.

Reduction of Ammonium Bromide with Trisodium Monobismuthide.—Trisodium monobismuthide from 1.5137 g. of bismuth(III) iodide and 6.23 equivalents of sodium was suspended in 30 ml. of liquid ammonia and treated with 1.5060 g. of ammonium bromide. The insoluble products were a black precipitate and hydrogen (found, 80.6 cc.; calcd., 86.2 cc.). The precipitate was washed ten times and found to contain 98.3% bismuth and only traces of sodium and ammonia.

Reduction of Silver(I) Iodide with Trisodium Monobismuthide.—To 0.7880 g. of silver(I) iodide dissolved in 30 ml. of liquid ammonia was added 0.3040 g. of trisodium monobismuthide. A rapid exothermal reaction led to the formation of a heterogeneous mixture of a gray and a black solid which was washed thoroughly.

Anal. Calcd. for a 1:1 mixture of Ag and Bi: Ag, 61.3; Bi, 38.7. Found: Ag, 59.6; Bi, 37.5; Na, 0.6; I, 1.5.

Reduction of Bismuth(III) Iodide with Trisodium Monobismuthide.—In a similar manner, 1.3375 g. of bismuth(III) iodide was treated with 0.6242 g. of trisodium monobismuthide. The rapid exothermal reaction resulted in a black precipitate which was washed free of iodide ion.

Anal. Found: Bi, 96.7; NaOH, 2.8; NH$_3$, 0.4.

Reduction of Bismuth(III) Oxide with Trisodium Monobismuthide.—Bismuth(III) oxide (0.4900 g.) was agitated vigorously with 0.5800 g. of trisodium monobismuthide in liquid ammonia for three hours. The yellow color of the oxide was progressively replaced by a gray-black mixture of insoluble solids. Unreacted bismuthide was determined by addition of an excess of ammonium bromide, whereupon 40.0 cc. of hydrogen was liberated (see equation 4). By difference, this corresponds to the reduction of 43% of the oxide used. X-Ray diffraction patterns showed all of the lines characteristic of bismuth and bismuth(III) oxide[11] and only these lines.

Substantially identical results were obtained when the oxide was added slowly to a suspension of the tribismuthide in liquid ammonia.

Discussion

The formation of bismuth(II) oxide by oxidation of bismuth in a lower oxidation state has not been reported previously. In the present work, both physical and chemical evidence showed that the black solid did not contain more than traces of elemental bismuth, that the compound contained oxygen and that no other known oxide of bismuth was present.

Bismuth(II) oxide has been reported as a product of the reduction of bismuth(III) oxide with tin(II) chloride,[15,16] hydrogen or carbon monoxide,[17] and the reduction of bismuth(III) dioxyoxalate with carbon monoxide.[18-20] Early work purportedly leading to the formation of bismuth(II) oxide has been criticized by Neusser[21] who contends that the product is probably a mixture of bismuth(III) oxide and elemental bismuth. In the present work, it is significant that the observed properties of bismuth(II) oxide are in generally good agreement with those reported by earlier workers, and that the X-ray diffraction studies rule out the possibility of a mixture of the type suggested by Neusser except for the remote possibility that both of the components of such a mixture might be produced in an amorphous condition.

Summary

1. Improved apparatus and procedures for use in the study of reactions in liquid ammonia at its boiling temperature are described.

2. The reduction of bismuth(III) iodide by three equivalents of sodium in liquid ammonia leads to the formation of elemental bismuth which is essentially unreactive toward molecular oxygen in the same medium.

3. Bismuth(III) iodide is reduced to trisodium monobismuthide by six equivalents of sodium, and the monobismuthide reacts with molecular oxygen to form bismuth(II) oxide and a mixture of oxides of sodium.

4. The reducing properties of trisodium monobismuthide are demonstrated by its use in the partial reduction of bismuth to tribismuthide ion and bismuth(III) oxide to bismuth, and

The Catalytic Reaction of Hydrogen and Oxygen on Plane Faces of a Single Crystal of Copper[1]

BY HENRY LEIDHEISER, JR., AND ALLAN T. GWATHMEY

Introduction

The determination of the positions of different activity on a catalyst surface is a question of primary importance. The two great difficulties in determining these positions are the preparation of a surface of known structure and the development of a method for following changes in the structure as the reaction takes place.

Most studies made in the past on the activity of a solid catalyst surface have consisted of measuring the amounts of materials consumed and produced by powdered metal catalysts. Such catalysts generally consist of many crystals randomly arranged and exposing faces, edges and corners of many kinds. Measurements made on such materials are composite quantities and give little direct information about the reactivity of the various types of structure exposed.

In an effort to obtain simple, reproducible surfaces of known structure, large single crystals with surfaces prepared parallel to special planes were selected. Furthermore, previous studies with large single crystals[2] have shown that the rate of many surface processes varies with the crystal face exposed at the surface. Therefore in order to determine the influence of crystal plane on catalytic activity and to extend our knowledge of metal surfaces in general, studies have been made of the reaction of hydrogen and oxygen on several plane faces of a large single crystal of copper.

In the study of the reaction of gases on the surface of metallic crystals, it has been found that the reactions may be divided into two classes, those which readily produce rearrangements in the surface and those which do not, at least on a microscopic scale. The reaction of hydrogen and oxygen on copper belongs to the first class. The nature of the rearrangements produced by the action of hydrogen and oxygen will first be described, and then the measurement of rates on several faces will be presented. An important feature of these studies is the correlation between catalytic activity and surface structure which can be observed.

Method of Experiment

Preparation of Surface of Catalyst.—There is a tendency in catalytic studies to underrate the importance of the preparation of the surface. Very fine measurements are often of limited value because they are made on surfaces, about the structure and composition of which little is known. Emphasis was placed in these studies on the preparation of the surface.

Single crystals of copper in the form of rods, $^5/_8$ in. in diameter and 4 in. long, were grown by the method previously described.[2,3] For use in the studies of rearrangements, spheres were machined from the $^5/_8$ in. rods and polished mechanically and electrolytically. For the rate measurements thin slices, about $^1/_8$ in. thick and parallel to the (100) and (111) planes were cut from a 1-inch crystal. In order to assure that there could be no difference in the chemical composition of the two crystal faces on which rates were measured, a sphere was machined from a 1-inch rod, and two flat faces, one parallel to the (100) face and one to the (111) face, were cut on the sphere. This was done by the same method used in cutting the slices. Photographs of the several specimens are shown in Figs. 2 and 14. The flat faces for rate measurements were polished as follows. The face was mechanically polished with metallographic polishing papers nos. 1 through 0000, and after each paper it was electrolytically etched in the polishing solution at a current density of about 0.02 amp./sq. cm. for a sufficient length of time to remove the strained layer produced by the last mechanical polishing. The time varied from about thirty minutes after the no. 1 paper to about ten minutes after the last paper. After the last etching the surface was slightly roughened on a microscopic scale but plane on a macroscopic scale and in a strain-free condition. The final step consisted of polishing mechanically on a felt wheel moistened with levigated alumina. In order to prevent subsequent recrystallization of the surface it was necessary to keep the cloth wet, to operate the wheel at a slow speed of about 150 r.p.m., and to press the specimen only lightly against the felt. After the first treatment with the reacting gases, it was only necessary to repolish with the 0000 paper and alumina, or with alumina alone. The surface was swabbed with a soft tissue under a stream of water in order to remove traces of alumina. Surfaces prepared by this method gave essentially the same results as those prepared by careful electrolytic polishing but the method described above was generally used because of the tendency of large surfaces to become pitted during electrolytic polishing. In order to reduce oxide and remove any distortion in the surface, all crystals were annealed in hydrogen at 550° for at least sixteen hours immediately prior to study of rearrangements or measurement of rates of reaction.

The Study of Rearrangements.—Since the surface of a monocrystalline sphere of copper exposes every crystal plane in at least six places, the (100) face appearing six times, most of the rearrangement studies were carried out on $^5/_8$ in. spheres. Also the symmetry of the patterns on a sphere make it easy to identify the location of the crystal faces. For the study of rearrangements the sphere was supported, generally with shaft downward, within the bulb of a glass apparatus connected with suitable inlet and exit tubes. The sphere was placed in the apparatus through a ground glass joint at the top and was suspended from the upper half of the joint by means of a no. 20 B. and S.

gage copper wire. When it was desired to protect the supporting wire from the action of the gases in order to prevent a change in concentration of the gases before they reached the crystal, the wire was enclosed in a glass tube and the shaft of the sphere, pointing upward, was inserted into the lower end of the tube. The appearance of the crystal as the reaction proceeded was observed through a glass window in the side of the furnace, the inside of which was illuminated by a small light at the top. Different crystal faces could be brought into view opposite the window by rotating the upper half of the ground glass joint to which the supporting wire was attached. It was found convenient, in identifying crystal regions during the early states of formation of the pattern, to have three adjacent (100) pole positions previously marked on the sphere by means of a deep pin prick. One great advantage of this method of study is that it is possible to follow changes in surface structure as the reaction proceeds.

The crystals were finally removed from the reaction chamber and examined under a microscope and in a darkened room with the aid of a flashlight. The methods of examining the patterns, identifying the planes and recording the results have been previously described.[2] The temperature of the reaction was assumed to be the temperature of the air just outside of the reaction vessel as measured by a mercury thermometer. The question of the exact temperature of the catalytic surface will be discussed later. In all reactions with the spheres the rate of flow of gas approximated 200 ml./minute.

Measurement of Rates of Reaction.—In order to determine rates on a surface prepared parallel to one particular crystal plane, it is necessary to prevent from exposure to the reacting gases other parts of the crystal, such as other faces, edges, and corners. Several different methods of accomplishing this were tried, but the simple apparatus shown in Fig. 1 was found to be satisfactory for the reaction under consideration. The surface of the crystal was ground flat and placed on top of the enclosed tube A, which had been flanged on the upper end and likewise ground exceedingly smooth. The crystal was placed in position and the outer glass cover tube was vacuum sealed to the base of the apparatus with the aid of a ground glass joint. The incoming gases consisting of purified tank hydrogen and electrolytic oxygen passed up the center tube, reacted on the surface of the crystal, passed down the middle tube, and out through a drying train of calcium chloride and Dehydrite where the water formed was absorbed. The rate of flow of the gases was measured with the aid of orifice meters and was 40 ml./min. unless stated otherwise. A furnace was placed over the top of the apparatus and extended down to within about 6 in. of the upper ground glass joint. The temperature was kept constant in the final experiments by means of a thermoregulator. In the experiments with thin slices an iron weight sealed in glass was placed on the slice to hold it in place. In experiments with the spheres on which the two faces had been cut, this was unnecessary. The failure of the polished surface to rearrange in the region of the crystal not exposed to the action of the flowing gases indicated that the amount of gas which leaked by the metal-flange joint was negligible. A photograph showing the difference in the appearance of the region exposed to the direct action of the gas and that of the region in the dead space surrounding the inner reaction chamber is given in Fig. 2. The apparent surface of the metal exposed to the action of the gases was always 2.69 sq. cm. Through the aid of this apparatus it is possible to measure the rates of reaction on surfaces prepared parallel to special crystal planes and containing always the same apparent area. At the completion of a run the surface of the crystal was examined under the microscope and in a darkened room with the aid of a flashlight. During preliminary studies, whenever inconsistent rate measurements were obtained because of such reasons as recrystallization of the surface or the presence of an accidental impurity, it was found that the final appearance of the surface was always abnormal.

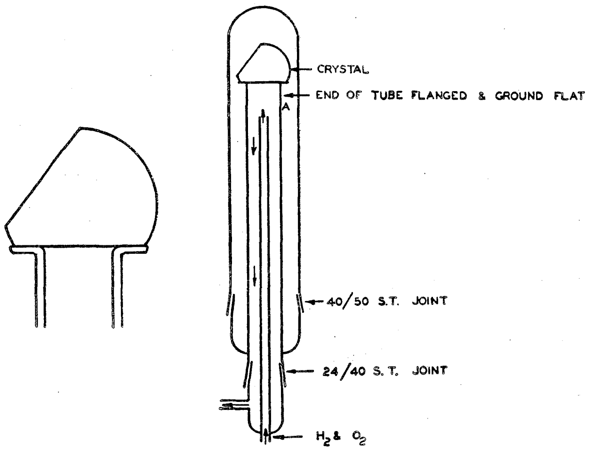

Fig. 1.—Apparatus for measuring rate of catalytic reaction of hydrogen and oxygen on plane faces of a metallic single crystal.

Results

Rearrangements of the Surface.—Rearrangements of the metallic surface under the action of reacting gases have been found to take place with a number of metals and gases. The nature and the intensity of the rearrangement depend on the metal, the gases, and the conditions of the experiment such as temperature and gas flow. Only rearrangements produced by the action of hydrogen and oxygen on copper will be described, although a photograph of the hydrogen–oxygen reaction on nickel is shown in Fig. 3 to illustrate the complicated fine structure of a pattern produced by another system. Brief mention has previously been made that such rearrangements take place on the surface of a copper crystal serving as a catalyst for the reaction of hydrogen and oxygen.[4]

Experiments were carried out over a temperature range of 360–440° and an oxygen concentration of 1–20%. The rearrangements which took place with 14% oxygen at a temperature of 400° will be described. Within a few seconds after oxygen was added to the stream of hydrogen in which the crystal was being heated, the surface of the crystal became slightly foggy in certain preferred crystal regions. After about fifteen minutes a definite pattern of light reflections from certain regions could be seen when a beam of light was directed through the window in the furnace wall, and after sixteen hours the striking pattern shown in Figs. 4 and 5 was obtained. Photomicrographs of the final surface structures on several different faces are shown in Figs. 6–10. The surface immediately at the (111) face remained quite smooth, while that at the (100) became very rough. Still another type of structure developed at the (110). Not only did the (111) face remain relatively smooth but (111) planes developed in large three-armed areas adjacent to each (111) pole as shown by the photograph in Fig. 5 taken when a beam of

---

(4) Gwathmey and Benton, *J. Chem. Phys.*, **8**, 569 (1940).

light was directed normally to the surface at the (111) pole. (110) planes were slightly developed in the (100) regions as shown by faint reflections obtained from these regions when a light beam was directed normally to the surface at the (110) pole. The facets developed parallel to these special planes as described above could also be identified by examination under the microscope. Figure 11 shows a microscopic view of a polycrystalline surface exposed to a hydrogen–oxygen mixture at 400°. Structures characteristic of the various surface regions on a monocrystalline sphere may be observed on the individual grains. The specimen shown in Fig. 11 was formed by recrystallization of a single crystal, although similar surface structures have been observed on many polycrystalline samples of copper.

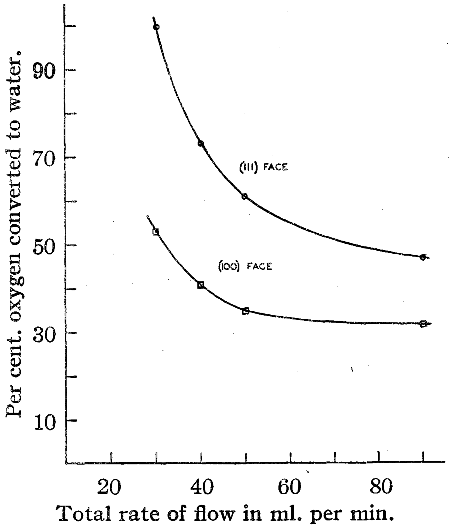

Fig. 12.—Curves showing change in rate of reaction with change in rate of flow: 400°, oxygen flow = 0.5 ml. per min., hydrogen flow varied.

Although many features of the patterns were the same over a temperature range of 360–440° and an oxygen concentration of 1–20%, there were some variations depending on the oxygen concentration and the time of reaction. With an oxygen concentration of 14% after sixteen hours, (111) planes were developed in large areas surrounding the (111) poles, but after about twenty-four days the development of (111) planes had decreased and (110) planes had developed in large areas surrounding the (110) poles. After seven days at this concentration a reddish-brown powder had formed over the entire surface. When this powder was wiped off with a tissue at the end of twenty-four days, the typical pattern with the exception noted above was observed. When the powder was removed, the contrast between the smooth (111) and the rough (100) areas was not as striking as it had been before the powder formed. The formation of this powder appears to be similar to the disintegration of copper tubes by heating in ammonia as observed by Beilby and Henderson.[5]

The presence of a small amount of a second metal, such as zinc or nickel, when electrodeposited on a copper sphere greatly influenced the pattern formed by the catalytic reaction of hydrogen and oxygen.

Measurement of Rates of Reaction.—Since the rate of reaction depends on the type and total area of surface exposed as a result of rearrangement, it is essential that the nature of the surface be known to some degree of approximation when the rates of reaction are measured. The change in the nature of the surface with the conditions of the experiment makes it difficult to present a complete picture of all events taking place in this reaction. A detailed study of each individual surface might reveal much additional information about its structure, but in the studies herein reported the structure was examined by the methods described, primarily for the purpose of showing the differences in structure of the various faces and the influence of these differences on the rates of the catalytic reaction.

No powder was ever observed on either face over a period of seven days with an oxygen concentration of 1.25% or less. Therefore experiments carried out within this range should give results which are dependent on the rearranged structure of the individual faces and are independent of the influence of the powder which forms at higher oxygen concentrations. As will be shown later, when a large amount of copper powder forms on the surface, the specific influence of the crystal face will be obscured.

With oxygen concentrations in the range of 0.6–2.5% and temperatures from 250–420°, the rate of reaction on the (111) face was approximately twice that on the (100) face, although the latter face had become much rougher and therefore exposed more surface area than the (111) face. All rates of reaction for both faces are referred to the same amount of apparent starting surface, 2.69 sq. cm. A plot of the rates of reaction on the (111) and (100) faces for various rates of flow of the reacting gases is shown in Fig. 12. The variations in the rates of reaction with temperature are shown in Fig. 13. The difference in the roughness of the (100) and (111) faces after reaction had taken place is shown in Fig. 14. The photograph was taken looking down on the sphere with the flat (100) face on the left side of the sphere and the (111) face on the right side, both faces making the same angle with the plane of the photograph. The crystal was illuminated from both sides, the beams of light pointing down and making an angle of about 45° with the plane of the photograph. The part of the (100) face on which the reaction took place appears as the light elliptical-shaped region in the center of the face on the left since the light was scattered upward by the rough surface. The part of the (111) face on which reaction took

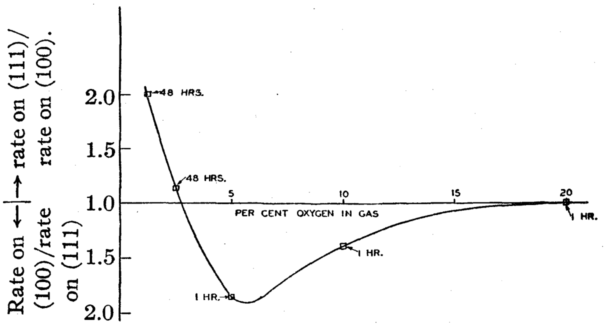
place appears as the dark elliptical-shaped region in the center of the face on the right since little light is reflected upward into the camera by the relatively smooth (111) surface. Microscopic views of the two faces are shown in Figs. 15 and 16.

Several experiments were carried out to determine the effect of the method of preparation of the starting surface on the rate of the reaction. It was found that within limits, as long as the base single crystal metal was exposed, the rates were independent of the exact surface preparation at the start. The reaction tended to form a surface characteristic of the face and reaction under consideration. For example, surfaces polished mechanically with alumina on felt, surfaces polished electrolytically, and surfaces roughened by etching electrolytically in a copper sulfate–sulfuric acid solution gave similar results after rearrangement. With an oxygen concentration of 1.25% and at a temperature of 400° the rate on the (111) face was twice that on the (100). In the case of the roughening of the surface by electrolytic etching, the area of the (111) face which had been exposed to the hydrogen and oxygen reaction for twenty-seven and one-half hours had become much smoother than the surrounding surface which had not been so exposed. The contrast between the two areas was very marked. In the case of the (100) face, since it is roughened by the catalytic reaction, the contrast between the two types of areas was not great, although a definite line of demarcation could be seen. When the (100) face was examined with a flashlight in a darkened room, brilliant reflections were visible from (110) facets in the reactive area but no reflections from (110) facets were obtained from the etched external area. Thus surfaces characteristic of the hydrogen and oxygen reaction were finally obtained regardless of the several different initial treatments given to the surface.

As the oxygen concentration was increased, the speed with which the rearrangement took place and the surface area exposed, especially on the (100) face, increased greatly. Figure 17 shows the ratio of the rates of reaction on the (111) and (100) faces with changes in oxygen concentration at 400°. As the oxygen concentration was increased below 5%, the rate on the (100) face relative to the (111) increased rapidly on account of the great increase in surface on the (100) face. No red powder formed within at least forty-eight hours. With oxygen concentrations of about 5% at which the powder began to form, the difference in rates between the two faces became increasingly less, until at 20% oxygen within one hour so much powder had formed on both faces that the inherent difference between the two faces was not detected. In order to obtain comparisons of the activity of the two faces as free as possible from powder, measurements were made at the higher oxygen concentrations after one hour of reaction. With an oxygen concentration of 20% the powder formed very rapidly at temperatures as low as 300°.



Hydrogen–oxygen reaction on plane faces of copper single crystal.

Fig. 17.—Ratio of rates of reaction on (100) and (111) faces with changes in oxygen concentration at 400°: total gas flow = 40 ml. per min.

Figure 18 shows the change in rates of reaction with time at 400° for two single crystal slices, for a single crystal slice which had been mechanically polished, and for an ordinary piece of polycrystalline copper which had been electrolytically polished. The increase in the rate of reaction on all samples corresponds to the visual observation of the formation of powder. As the reaction proceeded on the mechanically polished single crystal slice, the disturbed layer recrystallized to produce a polycrystalline surface which had a greatly increased rate.

A qualitative comparison of the degree of roughness on the (100) face at different oxygen concentrations was determined by the following procedure. The (100) face was exposed to definite mix-

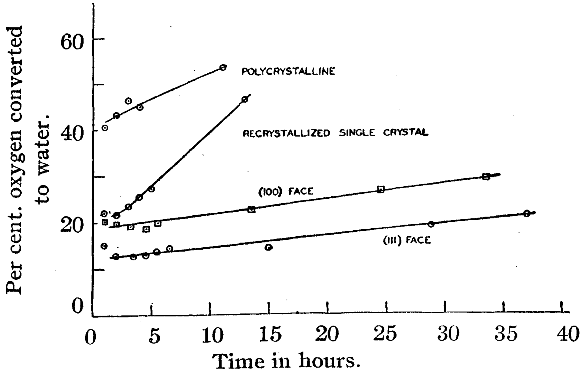


Fig. 18.—Change in rate of reaction with time at 400° and 10% oxygen concentration: gas flow = 40 ml. per min.

tures of hydrogen and oxygen for seven hours at 400°, and the surface was polished after each run with a suspension of levigated alumina on felt. The time necessary to polish away the roughened region was determined. Care was taken to insure equal conditions of polishing in each determination, and the results are shown in Table I.

TABLE I

% Oxygen in mixture	Time of polishing
1.25%	Less than 30 seconds
5.0	Approximately 50 seconds
10.0	Approximately 120 seconds
20.0	Greater than 240 seconds

In the case of the (111) face it took less than fifteen seconds to remove all traces of roughness under conditions at which no powder formed within seven hours.

Discussion

The discovery of a regular rearrangement of the catalyst surface under the influence of a gaseous reaction was made possible by the use of the catalyst in the form of a highly polished single crystal sphere exposing all possible crystal faces. The rearrangements showed themselves as highly complicated and symmetrical patterns which should be considered as records of the structure of the surface for a particular gas–metal reaction. On some faces definite facets parallel to one or more planes developed, on other faces a general roughening took place showing the development of no special planes, while other faces seemed to remain highly polished and apparently undisturbed. Although there were often similar features in the different patterns, in that the (100) face roughened greatly and the (111) remained relatively smooth, no two patterns for different gas–metal systems were found to be exactly the same.

In order to appreciate the significance of these regular surface rearrangements, it should be understood that they have been found with a number of reactions. The complications of these beautiful patterns and the differences between the patterns of different systems emphasize the complications of surface reactions and explain in part why they are so difficult to understand.

Not only does the pattern depend on the nature of the reactants, but for any one gas–metal system the pattern also depends on the conditions of experiment, such as temperature, concentration and rate of flow of the reacting gases, and time of reaction. As regards the latter, the planes developed in certain regions varied with time, emphasizing the importance of both rate and equilibrium factors in the rearrangement process. For example, with 14% oxygen at 400° (111) facets developed over a large region surrounding the (111) pole within twenty-four hours of reaction, but after a week of operation the size of the region containing the (111) facets had decreased considerably and the size of the region containing (110) facets had correspondingly increased. Also during the early period of the reaction a fine structure developed in many parts of the pattern, showing a variation in activity of many different faces, but after the reaction had proceeded for several days the complexity of the pattern was reduced and a fewer number of planes appeared. The crystal planes developed also depended on a certain critical angle between the plane in question and the surface of the metal specimen. In this connection it might be expected, if the rearrangement resulted simply from the heat evolved, that the most stable plane would be developed over the entire surface of the sphere, but facets parallel to a particular plane developed in one region, and, when the angle between the plane in question and the surface reached a certain value, facets parallel to another plane developed. In some regions several planes seemed to compete with each other for their existence.

It is surprising that these rearrangements, involving in some cases movement of the metal atoms over tremendous distances in terms of atomic dimensions, would take place so readily on massive metal at measured gas temperatures of only 400°, which is 680° below the melting point of the metal. The evaporation of considerable metal which deposited on the walls of the glass vessel suggested that the temperature of the metal surface was considerably higher than the measured gas temperature, but heating a crystal in hydrogen at 1000° failed to produce any rearrangement or evaporation. In fact a surface which has been roughened by this reaction may be "heat polished" by heating in hydrogen at such a high temperature. Therefore, high temperatures alone would not cause rearrangement or appreciable evaporation. Furthermore rearrangements have been obtained with an endothermic reaction. The evaporation of copper during the reduction of polycrystalline copper oxide has been attributed to the formation of steam between the grains and the expulsion of copper by the steam. In the copper single crystal surface used in these experiments there were no grain boundaries and no visible film of oxide. However, the (100) face which roughened greatly during the catalytic reaction is a face having a high rate of oxidation when heated in air.[6] The oxygen may possibly diffuse more rapidly down into the lattice of the (100) face and react to form steam which may then expel metal. Although the exact nature of such a catalyst surface was not known, these rearrangements indicated that the surface was in a state of great agitation, at least during the initial stages of rearrangement which lasted over a number of days for this particular reaction. These rearrangements which take place with catalytic reactions but not with adsorption indicate that the nature of the surface during such reactions may be quite different from that during adsorption. This fact in turn indicates that great care must be exercised in using adsorption measurements to interpret the nature of a catalytic surface of this kind.

One important experimental feature of these studies was that the reaction in effect prepared its own surface, and therefore reproducible surfaces exposing the structure of the base metal were obtained. In this method of study the use of light reflections, against a background of a single crystal sphere whose orientation was known, made it possible to identify the plane exposed right at the surface. The actual planes exposed at the surface cannot be determined by the diffraction of X-rays or electrons which penetrate the surface. The preparation of a catalyst surface with the aid of a gaseous reaction which produces a characteristic surface of a relatively well-known structure offers the possibility of standard surfaces for experimental studies.

One interesting effect of these rearrangements is that a surface originally prepared parallel to an unreactive plane may finally become a very active surface per unit starting area since both a greater total area and/or different facets may be finally produced. This suggests the possibility of preparing a surface parallel to one plane and then activating it by reaction with one set of gases for use with another set. In order to obtain appreciable adsorption on platinum Langmuir[7] found that it was necessary to activate the surface by means of the reaction of hydrogen and oxygen. Obviously this treatment increased the surface area, but it was not known whether special facets developed.

The alteration of the pattern on copper by the addition on the surface of small amounts of a second metal, such as zinc or nickel, indicates that the action of a promoter in some cases is to control the planes developed.

During the study of rates several different slices as well as the spherical specimen containing both faces were used. Similar results were obtained on all samples of the same face.

Since the structure of the surface continued to rearrange over a considerable length of time depending on the conditions of the experiment, the rate measurements must be considered in relation to these structural changes. There is no simple method of measuring the true surface area of small specimens, and it was elected to report the rate measurements, unless otherwise stated, in terms of the apparent starting area which in all cases was 2.69 sq. cm. This method of reporting rates enabled the more important facts to be arrived at and the minimum values for the relative rates on the two faces to be given. It is planned to measure surface areas, but this in itself is a major undertaking for these small specimens.

At low concentrations of oxygen in the neighborhood of 1%, where the rearrangements were relatively slight, the rate on the (111) face was approximately twice that on the (100) face. Since it can be seen in Figs. 14–16 that the surface on the (100) face was much rougher, and therefore had a much greater final surface than the (111), the actual rate on the (111) face per unit of final surface must have been considerably greater than twice the rate on the (100) face per same unit. It would appear that the surface on the (100) face was at least twice that on the (111) face at this concentration, and this estimate would make the rate on the (111) face per unit of final surface at least four times that on the (100). The rates on only two different faces were measured in these studies, and there may be others which have greater or lower rates.

As the concentration of oxygen was increased and the (100) face became much rougher than the (111), it would be expected that the rate on the (100) would become greater than that on the (111), although the rate per unit of final surface might still be greater on the (111) face. As the oxygen concentration was increased still higher and powder began to form, the surface of the powder was so much greater than that of the base metal that most of the reaction took place on the powder and the rates on the two faces became approximately equal as would be expected. The underlying pattern could still be seen when most of the powder was removed.

Summary

The catalytic reaction of hydrogen and oxygen on a single crystal of copper has been studied. Single crystals in the form of spheres exposing all possible faces and in the form of slices parallel to a particular face were used. The crystals were mechanically and electrolytically polished and annealed in hydrogen so that the surface of the base crystal was exposed to the action of the gases. With oxygen concentrations of 1–20% at 400° regular rearrangements were found to take place in the surface of the metal, exposing certain facets on some faces, roughening others without the development of particular planes, while other faces remained quite smooth and were apparently undisturbed. Rate measurements were made on

[7] Langmuir, THIS JOURNAL, **40**, 1361 (1918).

(100) and (111) faces, and it was found that appreciable differences in rates existed between the two faces. These differences depended on both the differences in activity per unit of surface and on the differences in total surface area exposed on the two faces. The rate measurements were correlated with the structure of the surfaces as the surfaces rearranged under the action of the catalytic reaction.

The Selective Deposition of Carbon on the (111) Face of a Nickel Crystal in the Catalytic Decomposition of Carbon Monoxide[1]

BY HENRY LEIDHEISER, JR., AND ALLAN T. GWATHMEY

Previously reported results[2] have shown that the catalytic reaction of hydrogen and oxygen leads to rearrangement of a copper surface and proceeds at a rate dependent on the crystal face exposed to the reacting gases. Results reported herein give an example of a catalytic process which does not lead to visible rearrangement of the surface initially and which proceeds at a rate dependent on crystal face.

A monocrystalline sphere[3] of nickel, 0.5 in. in diameter, with a shaft, $^3/_{16}$ in. in diameter and $^3/_8$ in. long, on one side was mechanically polished and then electrolytically polished by the method of Hothersall and Hammond[4] in order to give a smooth and strain-free surface. It was heated to 550° in carbon monoxide at a pressure of one atmosphere in an electric furnace provided with a window for continuous observation. After ten hours the pattern shown in Fig. 1 (see insert facing page 1203) began to develop. Black deposits had formed in large areas around the (111) poles but not in areas at the (100) and (110) poles. As the reaction continued the diameter of the (111) areas increased until the deposit covered the entire surface with the exception of a small square at each (100) pole and a narrow band between neighboring (100) poles and running through (110) poles. The photograph shows in a striking manner that the decomposition of carbon monoxide to form carbon on nickel at 550° proceeds at widely different rates on the (100) and (111) faces. The black deposit was readily removable by rubbing with tissue within several hours after it was first observed. As the reaction continued, however, the deposit tenaciously adhered to the surface, and it could not be removed by rubbing.

Evidence summarized by Hofer[5] indicates that when nickel is treated with carbon monoxide above 500° the major product left on the surface is carbon, although the presence of an intermediate carbide is not excluded. In order to obtain a sufficient amount of deposit for analysis, a polycrystalline nickel foil of larger surface area was treated with carbon monoxide under identical conditions as the single crystal. The analysis of the product on the surface was as follows: carbon 88.52 wt. %, nickel 11.01 wt. %. This analysis corresponds to approximately 97.5 atom % carbon and 2.5 atom % nickel.

Results similar to those shown in Fig. 1 were obtained at 550° in mixtures of hydrogen and carbon monoxide when the carbon monoxide was in excess. When the carbon monoxide was present in low concentrations in the neighborhood of 10%, no carbon deposit was observed and rearrangement patterns resulted.

It is interesting that the crystal lattice of graphite may be superimposed on the (111) face of nickel with only slight distortion. No similar match is possible on the (100) or (110) faces of nickel. It should be pointed out, however, that even though the (111) face of copper would give almost as good a match, no carbon deposits were visible after forty-eight hours at 550°.

Information on the deposition of carbon is important in an understanding of the Fischer–Tropsch catalytic process, and the results herein reported indicate the importance of crystal face in reactions of this type.

A Kinetic Study of the Oxidation of Uranium Tetrachloride

BY JOHN VAN WAZER AND GEORGE JOHN

A novel method for kinetic studies of solid–gas reactions in which the solid undergoes a color change has been used in this Laboratory for determining the activation energy for oxidation of uranium tetrachloride. The oxidation process consists of two independent steps which can be described by the equation

$$UCl_4\text{(green)} + O_2 \longrightarrow UO_2Cl_2\text{(yellow)} + Cl_2 \quad (1)$$
$$3UO_2Cl_2\text{(yellow)} + O_2 \longrightarrow U_3O_8\text{(black)} + 3Cl_2 \quad (2)$$

There is also a side reaction in which the uranium tetrachloride reacts with the chlorine evolved to form volatile uranium pentachloride.

Experimental

Working in a dry box a thin layer of uranium tetrachloride was dusted on the top of a rectangular copper bar which could be heated electrically at one end and cooled by a water coil at the other (see Fig. 1). The bar was then put into an air-tight glass envelope and purified helium was passed over it while the temperature of the hot end was raised to about 600°. The temperatures were measured by the thermocouples soldered to the bar at several points along its length. Then oxygen instead of helium was allowed to stream over the bar. This caused the green uranous chloride to change into yellow uranyl chloride at the hot end of the bar and a boundary separating the green from the yellow region was seen to move at an approximate velocity of 1 cm. in several seconds from the hot toward the cold end of the bar. This boundary was soon followed by another separating the yellow region from one of black uranium oxide. These boundaries were quite sharply defined and the kinetics of the reaction was studied by measuring the velocity at which the boundaries moved.

Interpretation of Results

The rate constant for either of the over-all reactions is inversely proportional to the time, *t*, required for the material to undergo a given color change at any particular temperature. Thus the rate constant in the Arrhenius equation can be replaced by B/t to give

$$t = (B/A)e^{E/RT} = Ke^{E/RT}$$

where E is the activation energy and A is the frequency factor. As the positions of the boundaries along the bar are determined as a function of time and each position corresponds to a definite temperature, values of time and temperature can be found which when substituted in the above equation will give the activation energy. Since time in these experiments was measured from the instant oxygen was allowed to flow into the system, the time origin was displaced from experiment to experiment and the data were best interpreted by plotting log t against $1/T$.

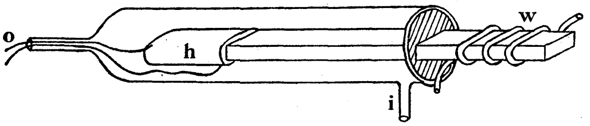

Fig. 1.—Reaction bar: w, water coil for cooling; i, gas inlet; h, heating element; o, gas outlet with wires to heating element.

In the oxidation of uranium tetrachloride to uranyl chloride the activation energy was found to be 12 (±2) kcal. and the lowest temperature for measurable reaction is 230 ± 5°. In the conversion of uranyl chloride to the black oxide the activation energy was 45 (±5) kcal. and the lowest temperature for observable reaction is 250 ± 10°. The mechanism of these reactions can be divided into three steps: (1) transport of oxygen to the reacting surface, (2) diffusion of oxygen into a uranium tetrachloride particle coated over with oxidation product, and (3) the rate at which oxidation will occur when the oxygen molecules reach the unreacted solid. From kinetic theory it can be shown that step (1) does not determine the rate. Also, since varying the rate of gas flow over the bar did not change the oxidation rate, diffusion of oxygen through a concentration gradient of chlorine near the surface does not affect the measured rate.

Diffusion of the oxygen through a thick surface layer is probably not the rate determining process either since the color of such a surface layer is used as the criterion of completion of the reaction. It also seems doubtful that a tight skin such as is found on passive metals can be formed over a salt. Thus it appears that step (3) is the rate determining process and that plenty of oxygen is available for the reaction.

Acknowledgment.—We wish to thank Dr. C. E. Larson for his permission to undertake this problem and his interest in it. This document is based on work performed under Contract No. W-7401-eng-23 for the Atomic Energy Project at the Tennessee Eastman Corporation, Oak Ridge, Tennessee.

Summary

A simple procedure for studying the kinetics of a heterogenous reaction involving color change of the solid phase has been applied to the investigation of uranium tetrachloride oxidation.

The Thermal Decomposition of Benzoyl Peroxide

BY D. J. BROWN

In continuation of our studies[1] we investigated the effects of the temperature, of the solvent and of halide substitution on the benzene nucleus on the rate of decomposition of benzoyl peroxide.

The best procurable peroxides and solvents were further purified. *o*-Chlorobenzoyl peroxide alone was not obtained in the pure state; it appeared to contain some of the decomposition products. The purity of the peroxides was determined and the course of the decomposition was followed iodometrically.

In all cases, as previously observed[1], there was a preliminary period during which the rate of decomposition increased to a maximum. This was followed by two parallel reactions whose calculated order is n. The first order rate constant, k, as calculated from the observed molarity, $C - x$, the elapsed time and the initial observation, is included.

In Table I we have data representative of the results for the decomposition of benzene solutions of benzoyl peroxide in sealed bomb tubes at 90° ± 0.05.

TABLE I

DECOMPOSITION OF BENZOYL PEROXIDE IN BENZENE AT 90° ($n = 1.33$)

Time, min.	$(C - x)$ mole/l.	k min.$^{-1}$	$(C - x)$ mole/l.	k min.$^{-1}$
10	0.3260		0.1730	
20	.2902	0.0121	.1586	0.0087

Discussion

The results presented in the preceding article[1] indicated that benzoyl peroxide in benzene, following a "preliminary period," decomposed as if two parallel reactions were occurring, a first order and a second order. This decomposition was interpreted as an initial dissociation of the peroxide followed by the further dissociation of the hemimer and the parallel reaction of the hemimer as an oxidizer. The final products of the reaction were determined by the reactions of the hemimer. The almost constant order of reaction with changing environment (Tables I, IV and V) and with halogen substitution on the benzene nucleus (Table VI) indicate a uniform mechanism of decomposition.

If the initial dissociation were ionic, $(RO)_2 = RO^+ + RO^-$, we would expect a large solvent effect on the rate of reaction in relation to the dielectric constant.[3] The increase in the rate of decomposition for a twelve-fold increase in the dielectric constant of the solvent is relatively small (Table V). The temperature coefficient for a reaction involving an ionized substance is usually relatively low.[3] The large variation of the rate constant with temperature and the comparative insensitivity to changes in dielectric constant may be further evidence that the decomposition proceeds via an uncharged radical mechanism, as was previously advanced[4,1] and is now accepted by many workers in the field.

The degree of the initial dissociation may be determined in part by the relative "negativity" of the radicals R and R′ of the peroxide R–O–O–R′ exactly as found by Gomberg[5] for the formation of trivalent carbon. The rate of reaction of the peroxide is determined by the degree of the dissociation which precedes and thus controls the subsequent rate determining reactions. Of those studied *o*-chlorbenzoyl peroxide decomposes the most rapidly. The rate constants for the *o*- and *p*-chlorobenzoyl peroxides have approximately the same ratio as the ionization constants of the two chlorobenzoic acids (Table VI), but no such simple relationship is found among the corresponding constants in the unsubstituted, *p*-chloro and *m*-bromo derivatives.

The data are correlated by the postulate that the initial reaction is a simple dissociation of the peroxide with the formation of radicals which contain monovalent oxygen as a constituent followed by two parallel reactions. The products of the decomposition are determined by these parallel reactions.

Summary

The rates of decomposition of benzoyl peroxide in benzene and the order of reaction at two temperatures are reported.

A study of the relation of the rate of reaction and order of reaction to the dielectric constant of the solvent was made.

The effect of substitution on the benzene nucleus of the benzoyl peroxide was studied.

Hydrolysis of Fluoboric Acid in Aqueous Solution

BY CHRISTIAN A. WAMSER

Aqueous fluoboric acid, which is now commercially available in the form of a 40% concentrate, is prepared[1] by treating aqueous hydrofluoric acid with the calculated amount of boric acid according to the equation

$$4HF + H_3BO_3 = HBF_4 + 3H_2O$$

It has been well known that aqueous solutions of fluoboric acid are more or less strongly hydrolyzed depending on the dilution, temperature and length of time they have been standing after preparation. Such solutions always contain more H ion than can be accounted for by the fluoboric acid they are calculated to contain.

Any successful explanation of the net changes occurring on hydrolysis must be capable of accounting for the following experimentally observable facts:

(1) When four moles of hydrofluoric acid and one mole of boric acid are mixed in aqueous medium, an immediate sharp increase in conductance occurs and heat is evolved, yet the solution contains no fluoboric acid immediately after the preparation (no precipitate with nitron). The total titratable acidity (as measured by the volume of standard alkali consumed to the phenolphthalein end-point in the presence of mannitol) of such a mixture immediately after preparation corresponds to five equivalents of acid, the solution at the end-point containing only F^- and BO_2^- anions.

(2) After preparation, the fluoboric acid content gradually increases to a final (equilibrium) value, while the total acidity decreases to a definite value. The only anions present at the titration end-point are BF_4^-, F^- and BO_2^-.

(3) When a fluoboric acid concentrate (which is itself appreciably hydrolyzed) is diluted with water, the total acidity gradually increases to a final (equilibrium) value.

---

[1] F. Fischer and K. Thiele, *Z. anorg. Chem.*, **67**, 304 (1910).

According to Wilke-Dörfurt and Balz[2] the fluoborate ion hydrolyzes

$$BF_4^- + 3H_2O \rightleftarrows H_3BO_3 + 3H^+ + 4F^-$$

so that a hydrolyzed solution contains hydrofluoric and boric acids as well as fluoboric acid. Assuming this reaction, Ryss and Bakina[3] have determined the hydrolysis constant from *p*H data. It has been found, however, that except in the case of very dilute solutions, hydrolyzed aqueous fluoboric acid solutions probably do not contain any free boric acid because the addition of mannitol to such solutions does not result in any increase in conductance.

According to Travers and Malaprade[4] hydrofluoric acid and boric acid react immediately to form a fluoboric acid, not HBF_4, and the latter is only formed slowly at the expense of the first-formed complex until finally an equilibrium between the two acids is reached.

It will be shown herein that when 4HF and H_3BO_3 are mixed in aqueous solution an immediate reaction occurs and HBF_3OH is formed. This is followed by a slower reaction involving this first-formed complex and hydrofluoric acid and resulting in the formation of fluoboric acid

(1) $H_3BO_3 + 3HF \longrightarrow HBF_3OH + 2H_2O$ (very fast)
(2) $HBF_3OH + HF \rightleftarrows HBF_4 + H_2O$ (slower)

Reaction (2) continues until finally a state of equilibrium is reached.

The Reaction $H_3BO_3 + 3HF \rightarrow HBF_3OH + 2H_2O$.—If an aqueous solution of boric acid is titrated conductometrically with hydrofluoric acid, it will be found that the conductance increases sharply until the point representing the addition of between three and four moles of hydrofluoric acid per mole of boric acid has been reached; further additions of hydrofluoric acid cause a much more gradual increase. Figure 1 is a plot of such a titration and the data for it were obtained as follows:

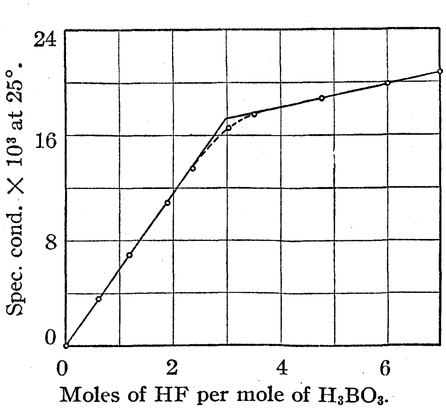

Fig. 1.—Conductance of H_3BO_3–HF mixtures immediately after preparation.

For each point on the curve a separate mixture was made up by treating a solution containing a fixed amount of recrystallized boric acid with a measured volume of a standard hydrofluoric acid solution in a calibrated polystyrene volumetric bottle at 25°. Immediately after preparation the mixture was transferred to a polystyrene conductance cell. The concentration of boric acid in each case was 0.0522 *M*.

Figure 1 is the plot of the conductance of the mixtures against the number of moles of hydrofluoric acid added per mole of boric acid. The well-defined break corresponds to a ratio of 3 to 1, and the reaction is probably

$$H_3BO_3 + 3HF \longrightarrow HBF_3OH + 2H_2O$$

Boric acid here behaves as a base analogous to aluminum hydroxide

$$Al\,(OH)_3 + 3HF \longrightarrow AlF_3 + 3H_2O$$

The acid HBF_3OH is known in the anhydrous state (Meerwein's acid, $BF_3 \cdot H_2O$)[5] and probably does not exist in aqueous solutions except in equilibrium with fluoboric acid. It is apparently able to form salts, for, as will be shown, KBF_3OH may be easily prepared.

The conductance plot of Fig. 1 indicates that HBF_3OH is a strong acid, although its specific conductance at this concentration (0.0522 *M*) is 17.3×10^{-3} at 25° compared with 20.3×10^{-3} for fluoboric acid at this same concentration (corrected for hydrolysis from data presented in a later section). HBF_3OH is hence somewhat weaker than fluoboric acid.

The reaction deduced from the previous data is probably oversimplified; it does not represent all the important changes that can take place, and the following may also occur

$$\begin{array}{lr} H_3BO_3 + HF \longrightarrow HBF(OH)_3 & \text{(rapid)} \\ HBF(OH)_3 + HF \longrightarrow HBF_2(OH)_2 + H_2O & \text{(rapid)} \\ HBF_2(OH)_2 + HF \longrightarrow HBF_3OH + H_2O & \text{(rapid)} \end{array}$$

If HBF_3OH were the only acid formed immediately after boric acid and hydrofluoric acid are mixed, it would be expected that the specific conductance of the mixture $H_3BO_3 + 3HF$ would be 17.3×10^{-3} (the intersection of the lines of Fig. 1). Actually about 3.3 moles of hydrofluoric acid per mole of boric acid are required to give this conductance and this seems to indicate that a weaker acid is in rapid reversible equilibrium with HBF_3OH, and present in appreciable amount. It is therefore possible that appreciable amounts of $HBF_2(OH_2)$ (probably a slightly weak acid) and $HBF(OH)_3$ (probably weak) exist in rapid reversible equilibrium with boric acid, hydrofluoric acid and HBF_3OH. The acid $HBF_2(OH)_2$ is in fact known in the anhydrous state (dihydroxyfluoboric acid[6]). The author has also prepared a salt from concentrated solutions of equimolar proportions of potassium bifluoride and boric acid which has a

ratio of K:B:F of 1:1:2 and the analysis of which corresponds closely to $KBF_2(OH)_2$. The salt further gives a well-defined X-ray diffraction pattern different from potassium fluoborate and KBF_3OH.

Preparation of Potassium Hydroxyfluoborate (KBF_3OH).—In their attempts to identify the first-formed complex acid in $4HF–H_3BO_3$ mixtures in aqueous solution, Travers and Malaprade[4] isolated a salt from cold, concentrated mixtures of potassium bifluoride and boric acid. Their chemical analyses of this salt indicated a ratio of K:B:F of 1:1:3 and they ascribed to it the formula $K_2B_2F_6 \cdot 1.5H_2O$. They found that the salt hydrolyzes readily and that the volume of standard alkali consumed by an aqueous solution of it up to the phenolphthalein end-point (in the presence of mannitol) corresponded closely to that calculated to decompose it to fluoride and metaborate.

This salt is, however, probably KBF_3OH, produced in accordance with the following equation, which also explains the increase in alkalinity that occurs when strong solutions of potassium bifluoride are treated with boric acid

$$2KHF_2 + H_3BO_3 \longrightarrow KBF_3OH + KF + 2H_2O$$

Travers and Malaprade[4] do not offer an equation to explain the formation of their salt, for no simple reaction (not involving an oxidation or reduction) presented itself.

Several samples of KBF_3OH were prepared as follows: 100 grams of potassium bifluoride was dissolved in 250 ml. of water in a polystyrene beaker. After standing for several hours at room temperature, the solution was freed from potassium fluosilicate and undissolved potassium bifluoride by filtering through paper in a polystyrene funnel. The solution, in polystyrene, was placed in an ice–water-bath and 40 g. of powdered boric acid added with continual stirring. The boric acid dissolved readily and within an hour, during which time the solution was occasionally stirred, small crystals deposited. These were filtered off on a sintered glass funnel (this liquor has a *p*H of about 6 and does not attack glass appreciably), washed sparingly with ice–water, then with larger amounts of 95% ethanol and acetone and dried at 120°. The analysis of two lots of crystals thus obtained is given in Table I.

TABLE I

ANALYSIS OF CRYSTALS OBTAINED FROM $2KHF_2 + H_3BO_3$

	Theoretical for KBF_3OH	Theoretical for $K_2B_2F_6 \cdot 1^1/_2 H_2O$	Lot 1	Lot 2
% K[a]	31.56	32.47	31.85	31.68
% B[b]	8.73	8.98	8.90	8.81
% F[c]	46.00	47.34	45.82	46.10
Milli-eq. weight[d]	0.0413	0.0401	0.0410	0.0411

[a] By repeated evaporation with sulfuric acid in platinum crucible and ignition to potassium sulfate. [b] By methyl alcohol distillation method of Chapin. [c] By lead chlorofluoride method. [d] Weight of a sample divided by the number of ml. of 1 *N* sodium hydroxide required to the phenolphthalein endpoint (in presence of mannitol).

The product obtained by the method described above and that obtained by following the directions of Travers and Malaprade[4] give identical X-ray diffraction patterns.

The salt KBF_3OH is distinguished from potassium fluoborate as follows: (1) The hydroxyfluoborate is much more soluble in water. (2) An aqueous solution of the hydroxyfluoborate gives no precipitate with nitron acetate. (3) An aqueous solution of the hydroxyfluoborate hydrolyzes readily in the presence of alkali, at room temperature: ($KBF_3OH + 3KOH \rightarrow 3KF + KBO_2 + 2H_2O$, while salts of fluoboric acid hydrolyze only very slowly in the presence of alkali (rapidly only at the boiling point and in the presence of excess calcium ions[7]).

The ease with which KBF_3OH decomposes in the presence of alkali explains why a mixture of $4HF + H_3BO_3$ immediately after preparation and though a reaction has taken place, requires five equivalents of alkali in a titration of total acidity and why the only anions present at the end-point are F^- and BO_2^-.

It was also found that KBF_3OH may be fused without suffering any decomposition or loss in weight, a property which would not be expected of a hydrate of the form assumed by Travers and Malaprade.[4]

Attempts to recrystallize the hydroxyfluoborate from aqueous solutions were unsuccessful, the product obtained being contaminated with fluoride and boric acid (extractable with ether–alcohol).

The Reaction $HBF_3OH + HF \rightarrow HBF_4 + H_2O$.—This reaction is slow enough, at concentrations of the order of 0.1 *M* at 25°, to permit of accurate estimation of the acids present based on total acidity, from which the amount of fluoboric acid formed can be easily calculated and the kinetics of the reaction studied. That the total acidity may be used for calculating the proportion of the three acids present has been proved over a wide range of concentration by the comparison of fluoboric acid concentrations thus calculated with direct gravimetric determinations of fluoboric acid as nitron fluoborate, as will be indicated in a later section.

For studying the kinetics of $HBF_3OH + HF \rightarrow HBF_4 + H_2O$, the reaction mixture is conveniently prepared from four moles of hydrofluoric acid and one mole of boric acid. Immediately after preparation, *i. e.*, at time $t = 0$, the total acidity is equal to five times that theoretically equivalent to the (stoichiometrically possible) fluoboric acid. If this latter calculates to T_1 and the observed titration at any time t is T_2, then the fraction of the possible fluoboric acid which is actually present at that time is $(5T_1 - T_2)/4T_1$.

The kinetics of this reaction was investigated at 25° at a concentration of 0.1105 *M* by mixing a solution of 3.805 g. of pure boric acid and one con-

taining 4.922 g. of hydrogen fluoride in a calibrated polystyrene bottle (volume at mark 556.8 ml.) which was allowed to remain suspended in a thermostat bath. At recorded intervals of time, aliquots of the mixture were removed and quickly titrated for total acidity. Table II contains the data for this reaction. T_1 is here 2.62 ml. and the final (equilibrium) value of T_2 = 4.07 ml. indicates that at this concentration there is present, at equilibrium, 86.2% of the stoichiometrically possible fluoboric acid (or that the solution is hydrolyzed to the extent of 13.8% when the reaction is considered in the reverse direction). When the mixture had come to equilibrium, an aliquot was analyzed directly for fluoboric acid by precipitation with nitron acetate, using essentially the procedure described by Lange[8] except that the precipitate was filtered off within five minutes. There was obtained, from 25 ml. of the mixture, 0.9515 g. of $C_{20}H_{16}N_4 \cdot HBF_4$, corresponding to 86.1% of the total possible fluoboric acid.

TABLE II

KINETICS OF $HBF_3OH + HF \rightarrow HBF_4 + H_2O$ AT 25°

t = time in minutes. T_1 = 2.62 (ml. 1.054 N NaOH) per 25 ml. aliquot. T_2 = observed titration (ml. 1.054 N NaOH ≎ total acidity). a = initial concn. of HBF_3OH (and HF) in moles/liter = 0.1105. x = concn. of HBF_3OH (or HF) reacting in time t.

163	4.36	83.4	.280
218	4.19	85.0	.236
equil.	4.07	86.2	

The last column of Table II lists values of a specific reaction rate calculated on the basis of the reaction being of second order. The average value of K_1 obtained from the earlier part of the reaction is 0.392 liters moles^{-1} min.$^{-1}$ at 25°.

The Reaction $HBF_4 + H_2O \rightarrow HBF_3OH + HF$.—This reaction represents the hydrolysis of fluoboric acid in aqueous solution, and its kinetics were investigated at the same concentration (0.1105 M) as the reverse reaction considered in the previous section. The reaction mixture was prepared from equivalent quantities of barium fluoborate dihydrate and sulfuric acid: $Ba(BF_4)_2 + H_2SO_4 \rightarrow 2HBF_4 + BaSO_4$. This device was used by Travers and Malaprade[4] in their studies of solutions containing fluoboric acid free from its hydrolysis products.

Pure barium fluoborate dihydrate was prepared by the method of Funk and Binder[9] and analyzed as follows: Calcd. for $Ba(BF_4)_2 \cdot 2H_2O$: Ba, 39.59; BF_4, 50.04. Found: Ba, 39.65; BF_4, 49.66 (BF_4 by nitron method). The kinetics of this hydrolysis reaction was investigated as follows:

A solution of 10.675 g. of $Ba(BF_4)_2 \cdot 2H_2O$ in water was mixed with a solution containing 59.27 ml. of 1.038 N H_2SO_4 in the polystyrene bottle mentioned previously. The mixture was maintained at 25° in a thermostat bath and aliquots were withdrawn at recorded intervals of time. Total acidity was determined by titration in the usual manner. The precipitated barium sulfate was not removed since it is inert with respect to the hydrolysis reaction and to the titrations. The degree of hydrolysis at any time t will be $(T_2 - T_1)/4T_1$, the symbols having the same significance as in the case of the reverse reaction. Here T_1 is 4.87 ml. and the final (equilibrium) value of T_2 = 7.53 ml. indicates a degree of hydrolysis of 13.7% which is in good agreement with the result obtained from the measurements of the equilibrium approached from the opposite direction.

Table III contains the data obtained and the last column lists a specific rate calculated on the basis of the reaction being of first order. The average value of K_2 obtained from the earlier part of the reaction is 0.00090 min.$^{-1}$ at 25°.

The ratio $K_2/K_1 = 2.3 \times 10^{-3}$ thus represents the equilibrium constant for the hydrolysis of fluoboric acid: $HBF_4 + H_2O \rightleftarrows HBF_3OH + HF$ at 25°.

TABLE III

5.41	(concentrate)	0.5881	0.9636 g.	5.47	17.6×10^{-3}

The specific reaction rates K_1 and K_2 have also been determined at other concentrations using the experimental methods previously described.

The variation of K_1 and K_2 with concentration may be in part an ionic strength effect and in part a result of the hydrogen ion concentration change which simultaneously takes place.

It has been observed that an increase in hydrogen ion concentration (such as occurs for example if hydrochloric acid be added to the reaction mixture $HBF_3OH + HF$) results in an increase in the specific rate K_1. This explains why KBF_4 is rapidly precipitated from the reaction mixture $[2KHF_2 + H_3BO_3 \rightarrow KBF_3OH + KF + 2H_2O]$ on acidification with, say, hydrochloric acid.

Degree of Hydrolysis of Aqueous Fluoboric Acid Solutions.—The degree of hydrolysis of aqueous fluoboric acid solutions (at equilibrium) was determined over the concentration range 0.001 *M* to 5.41 *M* at 25° by diluting weighed amounts of a fluoboric acid concentrate with water. These solutions were stored in sealed polyethylene bottles for three months (a 0.001 *M* solution requires about two months to come to equilibrium), and then suspended in a thermostat bath at 25° for a day. Appropriate aliquots were withdrawn and titrated with standard alkali for total acidity. In those cases where a blank on the mannitol used was significant, it was carefully determined and deducted.

Table V lists the concentration of the solution (always with respect to stoichiometrically possible fluoboric acid), the method of preparation, and the analytical data on which the degree of hydrolysis is based.

Equilibrium constants calculated from the degree of hydrolysis are listed in the final column of Table V. The assumption is here made that the HBF_3OH is itself not appreciably hydrolyzed and therefore $[HF] = [HBF_3OH]$. An examination of these values shows that only that calculated for the most dilute solution measured is appreciably different from the average of the next nine (2.04×10^{-3}). This figure is in good agreement with the constant derived from rate data. At the higher concentrations, the values in the final column increase rapidly, due probably to the increasing difference between activity and concentration as the latter increases.

If the hydrolysis of HBF_3OH proceeds according to $HBF_3OH + H_2O \rightleftarrows HBF_2(OH)_2 + HF$, and the constant is of the same order of magnitude as that for the hydrolysis of fluoboric acid, the amount of $HBF_2(OH)_2$ will be significant only in very dilute solutions. The equilibrium constant would have to be modified from

$$\frac{A \times A}{HBF_4} = \frac{A^2}{HBF_4}$$

where $A = [HF] = [HBF_3OH]$ to

$$\frac{(A + X)(A - X)}{HBF_4} = \frac{A^2 - X^2}{HBF_4}$$

where X = the decrease of $[HBF_3OH]$ due to its hydrolysis = the increase of [HF]. The effect of ignoring the hydrolysis of HBF_3OH is to neglect the X^2 term, and since X is probably of the order of 10^{-3}, the value of the constants as previously calculated will not be appreciably affected until A is of the order of 3×10^{-3}.

Conductometric and *p*H Titrations of Hydrolyzed Fluoboric Acid Solutions.—Several hydrolyzed fluoboric acid solutions were titrated conductometrically and potentiometrically, and in the case of the former method, comparison was made with (a) unhydrolyzed fluoboric acid solution and (b) a solution prepared from salts of the three acids involved.

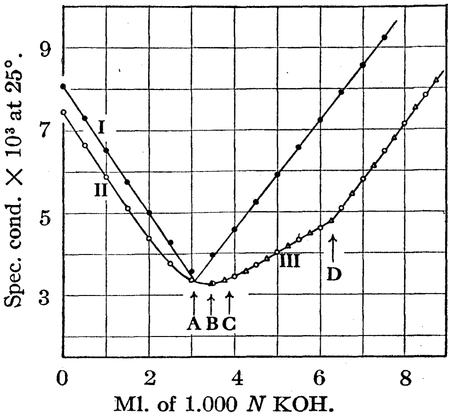

Fig. 2.—Conductometric titrations of aqueous fluoboric acid solutions: I, ●, unhydrolyzed HBF_4 solution; II, O, hydrolyzed HBF_4 solution; III, △, solution of KBF_4 + KBF_3OH + KHF_2.

Figure 2 summarizes graphically the results of three conductometric titrations: I. The titration of 150 ml. of 0.02036 *M* fluoboric acid (prepared from barium fluoborate and sulfuric acid and titrated immediately after preparation) with 1.000 *N* potassium hydroxide. II. The titration of 150 ml. of 0.02036 *M* fluoboric acid solution at equilibrium, with 1.000 *N* potassium hydroxide. This curve shows the effect of the hydrolysis products on the titratable acidity, the end-point having been displaced from 3.08 to 6.30 ml. This titration (point D on curve II of Fig. 2) corresponds to 26.6% hydrolysis. The point *A* = 3.06 ml. corresponds to the neutralization of the strong acids fluoboric acid and HBF_3OH and very nearly coincides with the end-point of titration I, indicating that the conductance of potassium fluoborate is not appreciably changed by the replacement of a large part of it with an equivalent amount of KBF_3OH (neglecting the conductance of the relatively weak hydrofluoric acid which is present at the point A). It was also found that in this case and in the case of other titrations of fluoboric acid solutions (at equilibrium) at various concentrations, the point of minimum conductance corresponds very closely to the stage of the titration at which KBF_4, KBF_3OH and KHF_2 are present in solution, *i. e.*, point B on curve II. The segment CD = 2.43 ml. which represents the decomposition of KBF_3OH, was found to be a straight line at various concentrations.

III. It was found that the last part of curve II (BD) could be exactly reproduced by titrating a solution containing 0.283 of KBF_4, 0.100 g. of KBF_3OH, and 0.0312 g. of KHF_2 dissolved in water and diluted to the volume of the solution corresponding to this point (B) on curve II (*i. e.*, 153.5 ml.). This is evidence of the correctness of the assumed hydrolysis reaction.

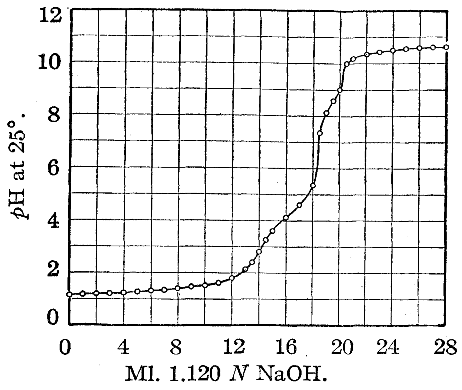

Fig. 3.—*p*H titration of 100 ml. of 0.1512 *M* fluoboric acid at equilibrium.

Figure 3 represents a *p*H titration of 100 ml. of 0.1512 *M* fluoboric acid at equilibrium (hydrolysis 12.4%) with 1.120 *N* sodium hydroxide at 25°. The first inflection corresponds closely to the neutralization of HBF_4 + HBF_3OH, the second to the stage of the titration corresponding to the decomposition of the $NaBF_3OH$ to sodium fluoride and boric acid, and the final inflection to the total acidity. It is interesting to note here that when a hydrolyzed fluoboric acid solution is treated with iodate–iodide mixture as in the standard iodimetric determination of acidity, the iodine liberated is equivalent to the second inflection in the *p*H curve.

This *p*H titration was performed in a polystyrene beaker using glass and calomel electrodes and although this cell combination may not be well suited to such a titration, it enables the measurements to be extended over the desired range.

Effect of Excess Boric Acid or Hydrofluoric Acid on the Hydrolysis Equilibrium.—A series of solutions containing the same concentration of fluoboric acid concentrate but various amounts of added excess boric or hydrofluoric acid were allowed to come to equilibrium at 25° in sealed polyethylene bottles. Total acidity was determined on appropriate aliquots and after correcting for the known added amount of either acid, the remaining titration was considered as due to fluoboric acid and its hydrolysis products and the degree of hydrolysis so calculated. Some of the solutions were also analyzed directly, by the nitron method, for fluoboric acid.

Figure 4 is a plot of the degree of hydrolysis of a 0.0527 *M* HBF_4 solution against the indicated concentrations of added boric or hydrofluoric acid. Excess hydrofluoric acid markedly decreases the hydrolysis while boric acid increases the equilibrium ratio of HBF_3OH to fluoboric acid.

Conductance of Aqueous Fluoboric Acid Solutions.—The conductances at 25° of aqueous solutions of fluoboric acid were measured in polystyrene cells over the concentration range 0.005 to 0.1 *M*. The curves of Fig. 5 were plotted from measurements made on the following

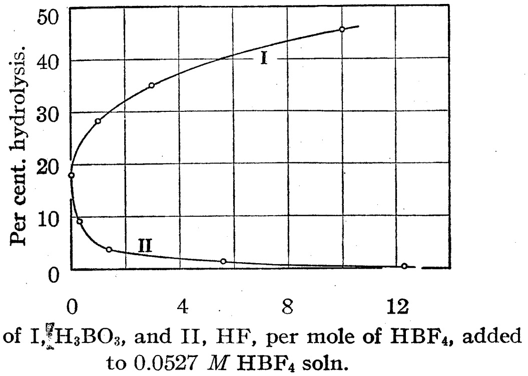

Fig. 4.—Influence of added excess H_3BO_3 and HF on the degree of hydrolysis (at equilibrium) at 25°.

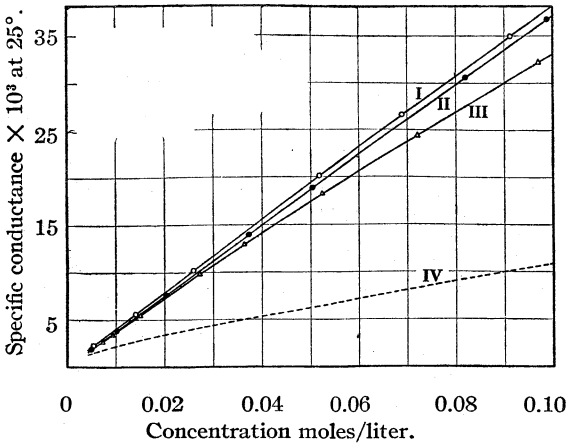

Fig. 5.—Conductance of aqueous fluoboric acid solutions: I, O, no hydrolysis; II, ●, equilibrium hydrolysis; III, △, complete hydrolysis; IV, ----, 4 HF.

solutions: I. Mixtures of equivalent amounts of barium fluoborate and sulfuric acid immediately after preparation. II. Aqueous fluoboric acid solutions at equilibrium. III. Mixtures of four moles of hydrofluoric acid and one mole of boric acid immediately after preparation. A curve of the conductance of 4HF has been included for comparison (IV).

The measurements from which curve I was obtained are uncorrected for the barium sulfate contained or for any adsorption or other possible effects caused by its presence in the solutions.

It was found that the addition of pure recrystallized mannitol did not appreciably alter the conductance of any of the solutions, indicating that no appreciable amount of free boric acid was present.

Acknowledgment.—The author acknowledges his indebtedness to Thomas L. Allen of the California Institute of Technology for helpful suggestions.

Summary

Conductance measurements show that when four moles of hydrofluoric acid and one mole of boric acid are mixed in aqueous solution, three moles of the hydrofluoric acid react immediately with the boric acid to form HBF_3OH.

HBF_3OH then reacts more slowly with hydrofluoric acid to form fluoboric acid until an equilibrium is reached.

The kinetics of the reaction $HBF_3OH + HF \rightleftarrows HBF_4 + H_2O$ was measured (1) from left to right (second order), and (2) from right to left (first order).

The equilibrium constant at 25° for the hydrolysis of fluoboric acid in aqueous solution is about 2.3×10^{-3}.

The salt KBF_3OH was prepared from $2KHF_2$ and boric acid and is the same as that reported by Travers and Malaprade[4] as $K_2B_2F_6 \cdot 1^1/_2H_2O$.

The degree of hydrolysis of aqueous fluoboric acid solutions at equilibrium at 25° has been determined over the range 0.001 to 5.41 *M*.

The conductance of aqueous fluoboric acid solutions at 25° has been determined over the range 0.005 to 0.1 *M* for the cases (1) no hydrolysis, (2) equilibrium hydrolysis and (3) complete hydrolysis.

The Interaction of Manganic Ion and Oxalate. Rates, Equilibria and Mechanism

BY HENRY TAUBE

Recent observations[1] on the manganic ion catalysed reaction of chlorine and oxalic acid were shown to be consistent with a mechanism in which the slow step is the oxidation of oxalic acid by manganic ion. Accepting this assumption, the rate data fixed the rate law for this reaction and its specific rate in solutions at high hydrogen ion concentration. In the present work, the interpretation of the catalytic data has been checked by direct measurements of the rate of the manganic ion–oxalic acid reaction

$$2\mathrm{Mn(III)} + \mathrm{H_2C_2O_4} = 2\mathrm{Mn(II)} + 2\mathrm{H^+} + 2\mathrm{CO_2}$$

Measurements of the rate of this reaction in solutions at low hydrogen ion concentration have been reported.[2,3,4] However, since there are important differences in the conclusions reached by some of the observers,[2,3] and since in no case did the conditions sufficiently approach those obtaining in the catalytic work, unambiguous comparisons of rate could not be made. While the present measurements do not extend to solutions as acidic as those employed in the catalytic work—the rate of reduction of manganic ion at high hydrogen ion concentration being so rapid as to make direct measurement difficult—a comparison is still possible since the rate law established in the catalytic work predicts the variation of reaction rate with hydrogen ion concentration for conditions under which the assumed mechanism operates. The measurements reported here have been extended also to solutions at low hydrogen ion, and conclusions about the mechanisms operative over the whole hydrogen ion concentration range are offered.

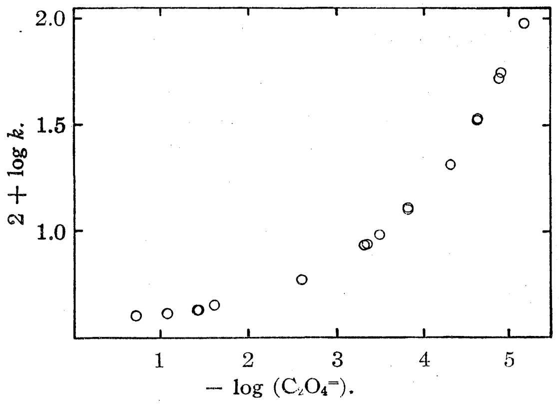

Fig. 1.—The variation of specific rate with oxalate ion concentration. Data are from Table I, experiments 1 to 17.

Method

To the solution containing oxalate, hydrochloric acid and manganous ion, a small volume of a solution of potassium permanganate was added. After sufficient time (*ca.* 1 min.) had elapsed to ensure complete reduction by the excess manganous ion of permanganate ion to Mn(III), a sample was withdrawn and quenched by discharging it into a solution of potassium iodide. Other samples were withdrawn at measured intervals of time and quenched in like manner, and the Mn(III) content determined by titrating the liberated iodine. The initial concentration of Mn(III) was of the order of 3.0×10^{-3} *M* in most cases, much less than the concentration of added oxalate, and, during the course of the run, the concentration fell to one-third to one-sixth of the original value. The first order specific rates calculated from the several samples, usually four, measured at intervals agreed within 1 to 2% of the mean, and in no case showed a significant drift. Over the concentration range covered, 3.0×10^{-3} *M* down to about 0.5×10^{-3} *M*, the reaction is strictly first order with respect to the concentration of Mn(III).

To remove oxygen, carbon dioxide was swept through the more acidic solutions, and nitrogen, from which residual oxygen had been scrubbed, through those in the range of low acid concentration. Except where otherwise noted, the reactions were carried out at 25.2°. The ionic strength was maintained at 2 in the majority of experiments by the addition of potassium chloride.

Results and Discussion

The Rate Determining Steps.—In Table I are recorded the results of a series of experiments, 1–17, in which the concentration of total oxalate and of acid have been varied, the ionic strength and temperature being constant. Each specific rate tabulated in column 6 is the mean of the several which were obtained during a single run. The specific rate is defined by the equation

$$k = \frac{2.303}{t} \log \frac{(\mathrm{Mn(III)})_0}{(\mathrm{Mn(III)})_t}$$

The time being expressed in minutes. The data show that at high acid concentration (low oxalate ion concentration) the specific rate increases rapidly as the acid concentration is raised, approaching variation with the second power, and that the specific rate at high oxalate ion concentration reaches a limiting value, which is independent of the oxalate ion or acid concentration. The important features are more strikingly portrayed in Fig. 1, in which log *k* for experiments 1–17 is plotted against log $1/(\mathrm{C_2O_4^=})$. The specific rate is observed to be fixed by the oxalate ion concentration, and does not depend directly on the hydrogen ion, oxalic acid or binoxalate ion concentrations.

These observations can be interpreted quantitatively by the simple mechanism in which each of the ions $\mathrm{MnC_2O_4^+}$, $\mathrm{Mn(C_2O_4)_2^-}$, $\mathrm{Mn(C_2O_4)_3^{\equiv}}$ known to be in rapid equilibrium,[1,5] undergoes

TABLE I

KINETICS OF THE REACTION AT 25.2°

Columns 2, 3 and 4 express the compositions of the solutions in terms of the reagents initially added; column 5 presents the equilibrium concentration of oxalate ion at the time of withdrawing the first sample. All concentrations are expressed in moles per liter. [$MnCl_2$] was 0.01 *M* except in experiment 18, [$KMnO_4$] *ca.* 7×10^{-4} *M*, $(Mn(III))_0$ from 2×10^{-3} to 3×10^{-3} *M*. The ionic strength was 2 (maintained by KCl) except in experiment 19. The content of columns 7, 8, 9 and 10 is described in the text.

No.	$[HCl]_0$	$[H_2C_2O_4]$	$[K_2C_2O_4]$	$(C_2O_4^=)_0$	k	Fraction[c] of Mn(III) as $Mn(C_2O_4)_3^=$	Contribution to k by $MnC_2O_4^+$ path	Contribution to k by $Mn(C_2O_4)_2^-$ path	k calcd.

[a] [$MnCl_2$] = 0.05 *M*. [b] No added KCl; ionic strength = 0.65. [c] Solutions in experiments 1–6 are a deep straw color; a reddish tint appears in experiments 7 and 8; at high oxalate ion concentration, the solutions are a wine red color.

decomposition. Thus to cover the whole oxalate ion concentration range, the three independent paths below are assumed

$$MnC_2O_4^+ \xrightarrow{k_1'}$$

$$Mn(C_2O_4)_2^- \xrightarrow{k_1''}$$

$$Mn(C_2O_4)_3^= \xrightarrow{k_1'''}$$

The contribution by each path depends on the concentration of the ion in question and on its specific rate of decomposition.

$$-\mathrm{d}\,Mn(III)/\mathrm{d}t = k(Mn(III)) = 2k_1(MnC_2O_4^+) + 2k_1'(Mn(C_2O_4)_2^-) + 2k_1''(Mn(C_2O_4)_3^=)$$

The factor 2 is introduced into the equation above since it may reasonably be supposed, as in fact the comparison of the results at high acid with those of the catalytic experiments show, that the reducing intermediate formed in the rate determining step rapidly reacts with a second manganic ion, as for example

$$C_2O_4^- + Mn(III) = 2CO_2 + Mn(II)$$

This mechanism has been tested by assigning values to the specific rates k_1, k_1' and k_1'' and to the equilibrium quotients governing the distribution of Mn (III) among the three manganic species, and from these parameters, knowing the compositions of the solutions, calculating the values of k for each of the experiments 1–17 of Table I. The values of the above mentioned parameters which give close agreement between the experimental and calculated values for k were chosen as follows: k_1 has been measured[6] in the catalytic work as 11.8 min.$^{-1}$; k_1' has been selected as 0.046 min.$^{-1}$ to fit the present data; k_1'' is fixed by the present data at high oxalate ion concentration as 0.0205 min.$^{-1}$; K_b, the quotient governing the equilibrium

$$MnC_2O_4^+ + H_2C_2O_4 = Mn(C_2O_4)_2^- + 2H^+$$

was determined in the catalytic work as 42; $1/K_c$, governing the equilibrium

$$Mn(C_2O_4)_3^= = Mn(C_2O_4)_2^- + C_2O_4^=$$

has been selected[7] to fit the present data as 1.4×10^{-3}. Values for the first and second dissociation constants of oxalic acid (K_1 and K_2) are also required, these in order to calculate the equilibrium concentrations of $H_2C_2O_4$, $HC_2O_4^-$, $C_2O_4^=$ and H^+ in each experiment; these constants are reported by Dawson[8] as 6.3×10^{-2} and 1.66×10^{-4} for a medium 2*M* in potassium chloride.

In making the calculations, allowance has been made for the changes produced in oxalate and acid by the net reduction of MnO_4^- to Mn (II)

---

(6) The data on the catalysis of the oxalic acid–chlorine reaction gave for k_1 and K_b values of 11.4 min.$^{-1}$ and 44, respectively; more recent data on bromine and oxalic acid catalyzed by manganic ion give for k_1 and K_b values of 11.9 min.$^{-1}$ and 41. Weighted means were chosen for the comparisons with the present results. Results obtained in the bromine–oxalic acid work furthermore show that there is no interference by chloride ion in the Mn(III)–oxalic acid reaction, if the oxalate ion concentration is as high as that used in the present work.

(7) The value of Cartledge and Ericks for 0° and lower ionic strength is 3.8×10^{-3}.

(8) Dawson, *J. Chem. Soc.*, 1889 and 2534 (1929).

and to the mangani–oxalate complexes. No corrections were applied for the oxalate consumed by association with Mn (II) since the pertinent equilibrium constants are not known; in any case, the effects due to this cause are small since the concentration of manganous ion is low in comparison to the total oxalate.

Data for a typical experiment are present below, and the calculation of the equilibrium oxalate ion concentration and of the specific rate outline to illustrate the factors which have been considered.

Experiment 9, Table I.—Square brackets denote stoichiometric, round brackets equilibrium concentrations.

$$[H_2C_2O_4] = 0.100\ M$$
$$[K_2C_2O_4] = 0.02\ M$$
$$[KMnO_4] = 6.9 \times 10^{-4}\ M$$

Since the concentration of oxalate ion in the solution will be low, it is convenient to express the concentrations in terms of $H_2C_2O_4$ and KHC_2O_4; thus: $[H_2C_2O_4] = 0.080\ M$ and $[KHC_2O_4] = 0.040\ M$

Time in minutes	0.00	3.33	7.00	11.12	15.38
$(Mn(III)) \times 10^3$	2.350	1.710	1.195	0.800	0.525
k		0.0963	0.0968	0.970	0.974

The concentrations of oxalic acid and potassium oxalate are altered by the oxidation of Mn^{++} to Mn(III), and of oxalic acid to carbon dioxide (from one-quarter to one-half of the added total oxidizing power is lost by the time of the first sampling). Allowing for these changes, $[H_2C_2O_4]_{t=0}$ and $[KHC_2O_4]_{t=0}$ become 0.0797 M and 0.0352 M, respectively; allowing then for the dissociation of oxalic acid, the stoichiometry and equilibrium constants are satisfied by: $(H^+) = 0.0374\ M$, $(H_2C_2O_4) = 0.0426\ M$, $(HC_2O_4^-) = 0.0720\ M$ and $(C_2O_4^=) = 3.20 \times 10^{-4}\ M$.

The specific rate is calculated making use of the equation

$$k_{\text{calcd.}} = 2k_1 \frac{1}{1 + b + c} + 2k_1' \frac{b}{1 + b + c} + 2k_1'' \frac{c}{1 + b + c} \qquad \text{I}$$

where

$$b = \frac{K_b}{K_1K_2}(C_2O_4^=) = 4.02 \times 10^6(C_2O_4^=)$$

and

$$c = \frac{K_bK_c}{K_1^2K_2^2}(C_2O_4^=)^2 = 2.87 \times 10^9(C_2O_4^=)^2$$

In deriving the equation, the principal manganic ion species are considered to be the complexes with oxalate ion; even for the solution at lowest oxalate ion concentrations used in the present study, it is a sufficiently close approximation to neglect the species Mn_{Cl}^{+++}. The quotients in the three terms on the right-hand side of the equation I represent the fractions of the total manganic ion present as $MnC_2O_4^+$, $Mn(C_2O_4)_2^-$ and $Mn(C_2O_4)_3^{\equiv}$, respectively. The fraction present as $MnC_2O_4^+$ is in every case small, being 0.04 in the maximum case of experiment 1. The fraction present as $Mn(C_2O_4)_3^{\equiv}$ has been entered in column 7 of Table I. The three terms of equation I give the contributions to the total specific rate by the decompositions of $MnC_2O_4^+$, $Mn(C_2O_4)_2^-$ and $Mn(C_2O_4)_3^{\equiv}$, respectively, and were calculated by substituting the value of $(C_2O_4^=)$ appropriate for each experiment into the terms of equation 1. The values of the first and second terms are recorded in columns 8 and 9 of Table I, and the sum of the three terms, representing the calculated values k to be compared to the experimental values, in the final column.

Some features of the data may require special emphasis. In the more acidic solutions, most of the reaction proceeds by decomposition of $MnC_2O_4^+$, which was the only path exposed by the catalytic data in the highly acid solutions there studied. Since the calculated values of k in experiments 1–5 are not very sensitive to the values assumed for k_1', k_1'' and K_c the quantitative agreement of the experimental and calculated values of specific rate in these experiments confirms the earlier cited conclusions about the character of the rate determining step in the catalytic work. The results also show definitely that at high oxalate ion concentration the rate becomes independent of this variable. This conclusion agrees with that reached by Lidwell and Bell,[3] but is at variance with that reached by Launer.[2] Not much emphasis can be placed on the agreement of the experimental and calculated values of k for intermediate ranges of oxalate ion concentration since both k_1' and K_c are adjustable parameters, and the limits of error on these constants are judged to be about 10 and 30%, respectively.

An additional feature of the manganic ion-oxalic acid reaction which was exposed by the catalytic work[1,6] has been checked by observations (qualitative only) on the direct reaction. Where the principal manganic species in solution is $Mn(C_2O_4)_2^-$, the rate of reaction is expected, and is observed, to rise rapidly as the oxalate ion concentration is reduced. If, however, the oxalate ion is reduced to such low values, that the dissociation of $MnC_2O_4^+$ to Mn^{+++} and $H_2C_2O_4$ takes place, the rate of reaction will *diminish* as the concentration of oxalate ion (proportional to oxalic acid) is decreased, and in the limit will be first order with respect to oxalic acid. These effects were observed in the manganic catalyzed chlorine–oxalic and bromine–oxalic reactions. In the present work it was shown that in a solution about $10^{-3}\ M$ in oxalic acid and 7 M in perchloric acid, the half-life of manganic ion is about fifteen seconds; if all the manganic ion were present as $MnC_2O_4^+$, a half-life of about three seconds would be expected. Furthermore, the half-life of manganic ion was observed to increase as the concentration of oxalic acid diminished.

Experiment 18 in comparison with 17 shows that a moderate change in Mn (II) concentration has only a minor effect on the rate of decomposition of $Mn(C_2O_4)_3^{\equiv}$; the slight increase observed when the prevailing manganous concentration is increased about eight-fold may however be real. A 20% reduction in rate of $Mn(C_2O_4)_3^{\equiv}$ decomposition is produced by changing the ionic strength from 2 to 0.65. The limiting Brönsted equation predicts no variation of specific rate with ionic strength for a reaction of this type. Since however the act of decomposition involves a separation of charged particles, it would not be surprising if the activity coefficients of the original ion and the activated, deformed ion are differently affected by media of high ionic strength.

Calculations of the type made above were applied also to the data of Lidwell and Bell[3] and of Bradley and van Praagh.[4] The calculated values of specific rate in typical cases, experiment 7, reference 3, and experiment 105, reference 4, for example, exceed by a factor of about 3 those observed by Lidwell and Bell. Part of the difference may be due to the differences in ionic strength and part to differences in temperature. No mention of removal of oxygen was made in the papers mentioned, and if this precaution was not taken, part of the difference may also be attributed to this cause.[9]

Temperature Coefficients of the Mangani-oxalate Decomposition.—The temperature coefficient of the rate of decomposition of $MnC_2O_4^+$ has already been measured[1]; in the present work new data for $Mn(C_2O_4)_3^{\equiv}$ are presented. These are recorded in Table II.

TABLE II

VARIATION OF THE RATE OF DECOMPOSITION OF $Mn(C_2O_4)_3^{\equiv}$ WITH TEMPERATURE

Initial Mn(II) = 0.01 *M*; E_3 is defined by $k_1'' = ae^{-E_3/RT}$

No.	$(C_2O_4^{=})$	Temp., °C.	$2k_1''$	E_3
1	0.120	17.9	0.0163	
2	.192	25.2	.0410	21,900
3	.180	35.6	.1455	22,200
4	.095	36.3	.156	22,500
			Mean	22,200 ± 500

Only the decomposition of $Mn(C_2O_4)_3^{\equiv}$ contributes appreciably to the reaction at the concentrations of oxalate ion used in the experiments above, and the activation energy measured may therefore be ascribed to this reaction.

The data on the specific rates, activation energies and frequency factors (*a* in the equation above Table II) for the mangani–oxalate decompositions are presented below.

	$MnC_2O_4^+$	$Mn(C_2O_4)_2^-$	$Mn(C_2O_4)_3^{\equiv}$
k_1 at 25.2°, min.$^{-1}$	11.8 ± 0.5	0.046 ± 0.005	0.0205 ± 0.001
E	18,300 ± 500		22,200 ± 500
a	2×10^{14}		3×10^{14}

An interpretation of the decrease in the rate of decomposition of the complexes as the number of associated oxalate ions increases, has been advanced elsewhere.[1] This interpretation attributes the decrease primarily to an effect on the activation energies and thus is supported by the data recorded in the table above. It may be noted that the interpretation is also consistent with the observation that a greater decrease in specific rate occurs for the first stage of the stepwise addition of oxalate ion than for the second.

The Products Formed in the Rate Determining Step.—It was observed in the catalytic work[1,10] that the reducing intermediate formed on decomposition of $MnC_2O_4^+$ reacts with Mn(III), Fe(III), Cl_2 and Br_2. Launer[9] has shown that the reducing intermediate reacts also with oxygen, and that it thereby induces the reaction

$$H_2C_2O_4 + O_2 = H_2O_2 + 2CO_2$$

This observation has been checked in the present work for more acidic solutions; in a solution 0.15 *M* in oxalic acid and 0.45 *M* in hydrochloric acid, with initial manganic ion sufficiently low, as many as twenty equivalents of hydrogen peroxide are produced for each equivalent of manganic ion consumed when oxygen is present. None of these observations, however, distinguish between the alternatives[1]

$$MnC_2O_4^+ = Mn^{++} + C_2O_4^- \text{ (or } CO_2 + CO_2^-\text{)} \quad (1)$$

$$MnC_2O_4^+ = Mn^+ + 2CO_2 \quad (2)$$

Evidence is offered below that part at least of the reaction must proceed to produce an organic radical, step 1, but some participation also by step 2 is not excluded by the new results.

It has been found that hydrogen peroxide is produced even in the absence of oxygen for solutions over a limited range of acidity (*ca.* 0.4 *M*–1 *M* hydrochloric acid). This was shown by experiments in which oxygen was removed by a current of carbon dioxide, and more rigorously by experiments in which the solutions were degassed by repeated freezing and evacuation, the solutions being mixed to initiate reaction after the system was sealed off. The amounts of hydrogen peroxide which appear, while not great, are great enough to make precise[11] determination of the rate of the mangani-oxalate decomposition difficult in the critical acid range. In the optimum case observed, a solution 0.45 *M* in hydrochloric acid with the initial manganic ion 1.2×10^{-3} *M*, about one-eighth of the oxidizing capacity appeared as hydrogen peroxide after the complex ion had decomposed. The residual oxidizing agent was identified as hydrogen peroxide by comparing its specific rate of reaction with iodide ion with that observed for hydrogen peroxide when this was added to the same iodide solution.

---

(9) Launer, THIS JOURNAL, **55**, 865 (1933).

(10) Publication of the data on Br_2—$H_2C_2O_4$ reaction catalyzed by manganic ion will be forthcoming.

(11) In experiment (1), Table I, the samples were quenched by using a solution low in iodide concentration cooled to 0°. The oxidation of iodide by the peroxide within the time of titration was small. Residual peroxide was determined and a correction applied for the fact that not each molecule of reducing intermediate accounted for a second molecule of mangani-oxalate ion.

There appears to be no chemically reasonable way of explaining the appearance of hydrogen peroxide if only Mn^+ is formed as the reducing intermediate. With the first alternative however, the observation can readily be understood. Two radicals $C_2O_4^-(HC_2O_4)$ or $CO_2^-(HCO_2)$ may be expected to form a peroxide on association. In the acid solutions the perdioxalic acid or perdiformic acid would hydrolyze to form hydrogen peroxide and regenerate the organic acid. Hydrogen peroxide is not produced in very acidic solutions presumably because the reducing intermediate reacts rapidly with $MnC_2O_4^+$, and the concentration of this ion increases with increasing acid concentration. At low acid, where the rate of decomposition of the mangani–oxalate complexes is low, the stationary concentration of the organic radicals will be similarly low, and the reaction of the radicals with Mn(III), being first order with respect to the radical concentration, will be favored over the association of the radicals. The decrease in peroxide production as the acidity is decreased however seems too sharp to be completely explained in this way, and it seems possible that effects due to an equilibrium

$$HC_2O_4 = H^+ + C_2O_4^-$$

become important when the hydrogen ion concentration is about 0.5 *M*. This would attribute to HC_2O_4 a dissociation constant about 0.5, and this value seems not unreasonable in comparison with 1.7×10^{-4} for $HC_2O_4^-$.

Summary

Kinetic data on the oxidation of oxalate by manganic ion over the range 6×10^{-6} *M* oxalate ion to 0.19 *M* oxalate ion are presented. These data are interpreted if it is assumed that the first order decomposition of each of the ions $MnC_2O_4^+$, $Mn(C_2O_4)_2^-$, $Mn(C_2O_4)_3^{=}$ contributes to the reaction. Values for the specific rates of decomposition of these ions, for the activation energy of the decomposition of $MnC_2O_4^+$ and $Mn(C_2O_4)_3^{=}$, and for the equilibrium quotients relating the complexes, are presented.

The rate of decomposition of $MnC_2O_4^+$ deduced from experiments on catalysis by manganic ion agrees quantitatively with that directly observed in the present work.

When the oxalate ion concentration is sufficiently great, *ca.* 0.1 *M*, the rate of reaction is independent of this variable.

Hydrogen peroxide is produced in the oxidation of oxalic acid by manganic ion within a limited acid concentration range, and conclusions about the detailed mechanism of reaction based on this observation are offered.

Phenyl Silicon Isothiocyanates

BY HERBERT H. ANDERSON

Five monoisothiocyanates remain the sole stable members of the corresponding ternary series. They are: $(CH_3O)_3Si(NCS)$,[1] $SiCl_3(NCS)$,[1] $PCl_2(NCS)$,[1] $POCl_2(NCS)$[1] and $PF_2(NCS)$.[1]

Introduction of the small, neutral methyl group allowed isolation of the first complete ternary series—$(CH_3)_3Si(NCS)$, $(CH_3)_2Si(NCS)_2$ and $(CH_3)Si(NCS)_3$.[2] Apparently the normal boiling point of the compound was not an important factor in determining stabilities; the "acidity" of the other group seemed to be the criterion.

To test this further, the author has now synthesized a complete series of phenyl silicon isothiocyanates, in which the phenyl groups are definitely more acidic than the neutral methyl groups of the only previously known complete series, and less acidic than methoxyl and the halogens. Moreover, phenyl is a group of rather large molar volume, approximately double that of isothiocyanate.

Steric effects may be encountered in proposed future syntheses of isopropyl and tertiarybutyl silicon isothiocyanates; the planar phenyl ring was no steric hindrance to introduction of isothiocyanate groups.

Preparation of New Compounds.—Dr. E. G. Rochow of the General Electric Company, Schenectady, N. Y., kindly furnished samples of phenyltrichlorosilane and diphenyldichlorosilane, which were used after distillation at 200–202.5° and 301–303°, respectively. Triphenylchlorosilane, prepared from the diphenyl analog, was distilled at 189° under 3 mm. pressure.

Silver isothiocyanate in 30% excess converted each of the three phenylchlorosilanes, in benzene solution, into the corresponding isothiocyanate; after an hour at 80–90°,[3] the suspended silver salts were filtered and washed with benzene. After distillation of benzene at atmospheric pressure, each compound was distilled at 3 mm. pressure through a plain column 4 mm. i. d. and 300 mm. long. Middle fractions used in physical measurements and analyses were collected at the following temperatures: phenyl silicon triisothiocyanate, 153.5–154.5°; diphenyl silicon diisothiocyanate, 173–174°; triphenyl silicon isothiocyanate, 188.5–189.5°. Yields varied from 72 to 90%.

Analyses.—A weighed sample of each compound was decomposed in methanol; after addition of water, thiocyanate was determined by titration with silver nitrate solution in the presence of ferric iron. The slow rate of solution of triphenyl silicon isothiocyanate in methanol

was a hindrance. In two cases silica was obtained, with some difficulties, by hydrolysis, oxidation with nitric or sulfuric acids, and ignition. One compound was burned in oxygen in a tube containing lead chromate and silver wire, and hydrogen estimated thereby. Molecular weights, obtained through lowering of the freezing point of camphor, confirmed monomeric formulas. Calcd. for $(C_6H_5)Si(NCS)_3$: NCS, 62.4; Si, 10.0; mol. wt., 279.4. Found: NCS, 62.0, 61.5; Si, 10.0; mol. wt. 318. Calcd. for $(C_6H_5)_2Si(NCS)_2$: NCS, 38.9; Si, 9.4; mol. wt., 298.4. Found: NCS, 38.7; Si, 9.5; mol. wt., 307. Calcd. for $(C_6H_5)_3Si(NCS)$: NCS, 18.3; H, 4.8; mol. wt. 317.4. Found: NCS, 18.2, 18.1; H, 4.9; mol. wt., 296.

Physical Properties (see Table I).—Dynamic vapor pressure measurements were made on the day of final purification, with calibrated mercury thermometers, and according to the method described by Mack and France.[4] Heats of vaporization and Trouton constants were calculated from the data.

Supercooling, apparently characteristic of compounds of this general type, occurred to the following extents: monophenyl, 52°; diphenyl, 46°; triphenyl, 20°. After formation of crystals during vigorous stirring, the samples showed rather sharp freezing points and melting points.

All the purified compounds were colorless. A solution of diphenyl silicon diisothiocyanate in phenyl silicon triisocyanate[5] furnished, upon application of the law of mixtures, a molar refraction (n^2 formula) of 90.1 ml., compared with 90.0 ml. calculated for $(C_6H_5)_2Si(NCS)_2$ and 85.5 ml. calculated for $(C_6H_5)_2Si(SCN)_2$. Assumptions made previously[2] were followed in these estimations of molar refractions.

Chemical Properties.—Tetraphenylsilane was inert to pure water; triphenylsilicon isothiocyanate was practically inert, since a sample stood for a week in open air during the summer without discoloration; the diisothiocyanate, triisothiocyanate and tetraisothiocyanate hydrolyzed with progressively increasing ease in water.

Benzene and carbon tetrachloride were good solvents for these isothiocyanates. Ethanol dissolved readily all save the triphenyl compound, which dissolved slowly even in methanol. Decomposition occurred, of course.

Discussion

1. A provisional conclusion from the existing information is that the stability of mixed isothiocyanates is associated with the "acidity" of the other group attached to the central atom rather than with the molar volume of that group, or the normal boiling point of the compound. Neutral methyl and the slightly acidic phenyl permit complete series, whereas acidic methoxyl, chloride and fluoride allow only monoisothiocyano derivatives. (The investigation of possible steric effects is planned.) At this time the existence of certain new related isothiocyanates is known: benzyl silicon triisothiocyanate, *n*-butyl silicon triisothiocyanate and triethoxy silicon isothiocyanate, of boiling points 349°, 300° and 206°, respectively. The stability of the last three compounds is consistent with the interpretation made in this paragraph.

2. Supercooling is encountered in the phenyl silicon isothiocyanates, while the analogous methyl silicon isothiocyanates do not do this.[2]

3. Triphenyl silicon isothiocyanate resists hydrolysis almost as markedly as does the inert tetraphenylsilane.

The author thanks Professor George S. Forbes of this Laboratory for sustained interest in these investigations.

Summary

1. Phenyl silicon isothiocyanates were formed through reaction of silver (iso)thiocyanate with phenylchlorosilanes. All three possible ternary compounds were isolated: phenyl silicon triisothiocyanate, $(C_6H_5)Si(NCS)_3$, melting at 52° and boiling at 340°; diphenyl silicon diisothiocyanate, $(C_6H_5)_2Si(NCS)_2$, melting at 46° and boiling at 376°; triphenyl silicon isothiocyanate, $(C_6H_5)_3Si(NCS)$, melting at 76° and boiling at 396°.

2. Measurements of physical properties included vapor pressures, and two densities and one molar refraction obtained in solution. The resistance of triphenyl silicon isothiocyanate to hydrolysis was striking.

3. All the evidence available at present indicates that the non-existence of certain diisothio-

Methyl Silicon Isocyanates and *n*-Butyl Silicon Triisocyanate

BY GEORGE S. FORBES AND HERBERT H. ANDERSON

This paper on the methyl silicon isocyanates describes the first isolation of organosilicon pseudo halides; the introduction of methyl groups into silicon tetraisocyanate was first attempted, unsuccessfully, using methylmagnesium iodide, and also dimethylmercury. All three methyl silicon isocyanates and also *n*-butyl silicon triisocyanate were then prepared through reaction of silver isocyanate with the appropriate alkylchlorosilanes, with yields of at least eighty per cent.

Preparation of Alkyl Silicon Isocyanates.—The homogeneity of their reaction products indicated that the methylchlorosilanes, obtained from the Dow Corning Corporation of Midland, Michigan, had been carefully purified. A thirty-gram sample of each methylchlorosilane was treated with a 25% excess of silver isocyanate, added in three portions; benzene was the solvent used in preparation of the monomethyl and dimethyl compounds, while isopropylbenzene proved more suitable for the trimethyl derivative. After the usual half-hour at 90°,[1] the suspension of silver salts was filtered and washed. After distilling off the benzene, the triisocyanate and diisocyanate were recovered; the monoisocyanate was distilled directly from the higher-boiling isopropylbenzene. Each individual compound was distilled at least twice in a plain column, 4 mm. i. d. and 500 mm. long, and final fractions were taken at the following (uncorrected) temperatures: $(CH_3)Si(NCO)_3$, 169.2–169.6° at 755 mm.; $(CH_3)_2Si(NCO)_2$, 138.3–138.5° at 760 mm.; $(CH_3)_3Si(NCO)$, 90.5–90.8° at 760 mm.

n-Butyltrichlorosilane, prepared from tetrachlorosilane and the alkylmagnesium bromide and boiling at 148.7–149.3°, was gradually added to an excess of silver isocyanate suspended in benzene, in a reaction of moderate vigor. The middle fraction, boiling at 134.6–135.4° under 59 mm., was used for all measurements.

Chemical Properties.—The monoisocyanate floats on water and hydrolyzes slowly at the interface; the diisocyanate hydrolyzes slowly at first and finally at a moderate rate. *n*-Butyl silicon triisocyanate hydrolyzes at a moderately fast rate; when shaken with an equal volume of water, the temperature rise is only about 20°—much less than in the vigorous hydrolysis of silicon tetraisocyanate.

These four new liquids are easily soluble in petroleum ether (30–60°), carbon disulfide, carbon tetrachloride, benzene and isopropylbenzene.

vapor pressure measurements, following a standard method,[4] always made on the day of final purification, employed mercury thermometers which had been calibrated in the same apparatus with boiling water, bromobenzene or aniline; the apparatus was of Pyrex glass, and included stopcocks and ground joints in non-critical positions. Errors in temperatures could not have exceeded 0.3°; the four vapor pressure equations predicted the observed points with an average error of approximately three mm. All three methyl silicon isocyanates showed sharp melting points, and freezing points without perceptible supercooling; on the other hand, *n*-butyl silicon tended to supercool and form a glass to such an extent that the use of liquid nitrogen and vigorous stirring were necessary to obtain a crystalline solid of fairly sharp melting point. Due to incomplete drainage and other uncertainties, the readings of the toluene thermometer used in obtaining some of the melting points appeared subject to errors possibly as great as three degrees. Densities were obtained using a special 2-ml. micropycnometer.

Discussion

Swarts' rule of linear progression in boiling points[5] does not fit the new methyl compounds satisfactorily. Calculations based on the "increment method," by adding 32.0° to the boiling point of the corresponding chloride[6] for each replacement of one chlorine by isocyanate, predicted the following boiling points: monoisocyanate, 89.7° (57.7 + 32.0); diisocyanate, 134.0° (70.0 + 64.0); triisocyanate, 161.7° (65.7 + 96.0).

After this isolation of the complete series of methyl silicon isocyanates, and of *n*-butyl silicon triisocyanate, the stable existence of at least a part of the ethyl and *n*-propyl series can be inferred.

Summary

1. Certain alkylchlorosilanes yielded the corresponding (new) isocyanates upon treatment with silver isocyanate.

The complete methyl series consisted of trimethyl silicon isocyanate, $(CH_3)_3Si(NCO)$, boiling at 91.0°, dimethyl silicon diisocyanate, $(CH_3)_2Si(NCO)_2$, boiling at 139.2°, and methyl silicon triisocyanate, $(CH_3)Si(NCO)_3$, boiling at 170.8°.

n-Butyl silicon triisocyanate, $(n\text{-}C_4H_9)Si(NCO)_3$, boiling at 215.5°, showed a marked tendency to supercool.

2. Physical data included vapor pressure equations, melting points, refractive indices, densities and molar refractions. The heat of hydrolysis seems to decrease as the number of alkyl groups increases.

Actidione, an Antibiotic from Streptomyces Griseus[1]

BY JARED H. FORD AND BYRON E. LEACH

It has been found in this Laboratory that the beers from streptomycin-producing strains of *Streptomyces griseus* contain another antibiotic which we have named actidione. In contrast to streptomycin, actidione is very effective against many yeasts but has little or no activity against bacteria.

Simultaneous bio-assays for actidione and streptomycin on a series of production beers demonstrated a wide variation in the ratio of concentrations of the two antibiotics. In a few cases the actidione content was as high as 200-250 mg. per l. but the average was about 80–100 mg. per l. A number of strains of *S. griseus* which produce actidione but little or no streptomycin and vice versa have been obtained by irradiating the conidia with X-rays.[2]

The crude product was isolated from the filtered beer by extracting with chloroform either directly or after a preliminary concentration step which involved adsorption on activated carbon, elution with 80% acetone and removal of acetone from the eluates by distillation. The chloroform extracts were orange-brown or an intense green, depending on the culture medium employed, but most of the color was removed by treatment with carbon. After removing the chloroform by distillation *in vacuo*, the resulting crude products were orange-brown sticky oils having a moldy odor. Bio-assays indicated a purity of 30–60% based on crystalline actidione as the standard.[3]

(1) An outline of this work was reported in a preliminary communication: Leach, Ford and Whiffen, THIS JOURNAL, **69**, 474 (1947).

(4) Observations of Drs. George M. Savage and Alma J. Whiffen of these Laboratories.

(3) The assay method was developed by Dr. Alma J. Whiffen. It is a modification of the paper-disc plate method for streptomycin[4] and employs *Saccharomyces pastorianus* ATCC 2366 as the test organism. The medium consists of 10 g. of glucose, 2.5 g. of Difco yeast extract, 1.0 g. of potassium dihydrogen phosphate and 20 g. of agar made up to 1.0 l. with distilled water and adjusted to *p*H 6.0. The inoculation was at the rate of 1.8 × 10^5 yeast cells per ml. of medium. The *p*H of the aqueous test solutions is not critical and the samples may also be assayed in methanol, ethanol or acetone.

[a] Calculated as a monohydrate for the C_{15} formula and as a dihydrate for the C_{27} formula. [b] Analysis by Oakwold Laboratories. Other analyses by our Analytical Department under the supervision of Mr. Harold Emerson. [c] Averages of two or more determinations. Individual results given in Experimental.

These crude products proved to be highly irritating to the skin.

Crystalline material was first obtained by counter-current distribution[5] between benzene and water, using separatory funnels. A comparison of the experimental curve with the theoretical curve (Fig. 1) would indicate that the central band was composed, in the main part, of one material. Since the activity was also located in this band, it can be concluded that the material in this band is primarily actidione. The emulsions that were encountered by this method proved to be troublesome. For the isolation of larger amounts of crystalline material carbon chromatography was found to be more convenient. The crude product was put on the column in 20% acetone, developed with 20% acetone and eluted from the column with 60–100% acetone. The peak eluate fractions gave solids that could be crystallized readily by adding amyl acetate and seeding. Several recrystallizations from amyl acetate gave a constant melting point of 115–116.5°. Further recrystallization from water or 30% methanol gave a melting point of 115–117°. The specific rotation is −3.0° in methanol (c = 10) and +6.8° in water (c = 2). The crystalline product is very soluble in all the common organic solvents with the exception of the saturated hydrocarbons. At 2° the solubility is 2.1 g. per 100 ml. in water and 7 g. per 100 ml. in amyl acetate.

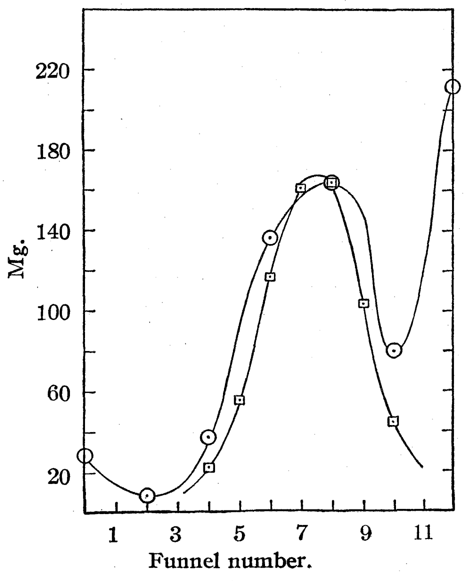

Fig. 1.—⊙, experimental; ⊡, theoretical.

Treatment of the compound with acetic anhydride and pyridine at room temperature produced a biologically inactive acetate, m.p. 148–149°. The oxime, m.p. 203–204°, was also inactive but the semicarbazone, m.p. 182–183°, was found to be about one-twentieth as active as actidione. The melting points of the acetate and semicarbazone are somewhat higher than those reported previously.[1]

Analytical data for carbon, hydrogen and nitrogen on actidione and its derivatives are listed in Table I. It will be noted that the majority of the data is in better agreement with a $C_{15}H_{23}NO_4$ formula for actidione[6] than for our previously suggested $C_{27}H_{42}N_2O_7$ formula. The only values which differ greatly enough to be of much use in distinguishing between the two formulas are the carbon percentages of the semicarbazones and nitrogen contents of the oximes and semicarbazones.

Our previous cryoscopic molecular weight data, using benzene as the solvent, were inconclusive, apparently because of association. The values ranged from 420 to 875, depending upon the concentration. We have now obtained satisfactory molecular weight determinations on actidione and its oxime by the Rast method and on the acetate by a cryoscopic determination in benzophenone (the acetate decomposed at the melting point of camphor). The results (listed in Table II) are in good agreement with the C_{15} formula and appear to exclude any C_{27} or C_{30} formula.

TABLE II

CRYOSCOPIC MOLECULAR WEIGHT DETERMINATIONS

Compound	Formula	Solvent	Molecular weight Calculated	Found
Actidione	$C_{15}H_{23}NO_4$	Camphor	281	254
Acetate	$C_{17}H_{25}NO_5$	Benzophenone	323	334
Oxime	$C_{15}H_{24}N_2O_4$	Camphor	296	291

---

(5) Craig, Golumbic, Mighton and Titus, *J. Biol. Chem.*, **161**, 321 (1945).

(6) This formula was first suggested by Dr. Reuben G. Jones of the Lilly Research Laboratories, Indianapolis, Indiana.

Degradation studies on actidione are being carried out by Drs. Reuben G. Jones and Edmund C. Kornfeld of The Lilly Research Laboratories.

The acute toxicity of actidione has been found to vary widely with the species of test animals employed. In addition to our previously reported value of 150 mg. per kg. for the LD_{50}, intravenously in mice, the following results have been obtained: subcutaneously in guinea pigs, 60 mg. per kg.; intravenously in rabbits, 17 mg. per kg.; intraperitoneally in cats, 4 mg. per kg.; subcutaneously in rats, 2.7 mg. per kg.; intravenously in rats, 2.5 mg. per kg.

Acknowledgments.—The authors wish to express thanks to Dr. W. G. Jackson for helpful suggestions concerning the chromatography, to Mr. George C. Prescott and Mrs. Alice Sterk for technical assistance, to Dr. Alma J. Whiffen for bioassays, to Messrs. William DeVries, Malcolm Bergy and Russell Heald for isolation of the crude products, and to Dr. M. J. Vander Brook for the toxicity studies.

Experimental

Isolation of Crude Actidione.—Eleven hundred liters of seventy-two hour *S. griseus* beer which assayed 110 mg. of actidione per liter was acidified[7] with sulfuric acid to *p*H 2 and stirred with a mixture of 2 kg. of carbon (Nuchar C-190NU) and 5 kg. of Celite #545[8] and then filtered. The press cake was eluted successively with 40 l. of acetone, three 30-l. volumes of acetone and 20 l. of water. The combined eluates were concentrated *in vacuo* to 38 l. and extracted with 5 l. of chloroform followed by three extractions with 3 l. volumes of chloroform. The combined extracts were decolorized with 300 g. of carbon (Nuchar C-190NU), concentrated *in vacuo* to a sirup, and warmed to 30° under 200–500 μ pressure overnight to remove chloroform. The resulting very thick sirup weighed 97.5 g.; purity, as indicated by bioassay, 59%; 48% yield of activity from beer to crude product.

Counter-Current Distribution Studies on Crude Actidione.—Preliminary tests indicated that crude actidione could be distributed between benzene and water with a partition coefficient of approximately 0.70. Nine-hundred and eighty milligrams of crude actidione was dissolved in 40 ml. of benzene and equilibrated with an equal volume of water in separatory funnels. Twelve such transfers were carried out using the aqueous layer as the traveling phase according to the method described by Craig, Golumbic, Mighton and Titus.[4] The emulsions that were encountered during these transfers were broken by centrifugation. Figure 1 shows the weight curve obtained from this 12-transfer distribution. The biologically active fractions very closely approximated the peak fractions (nos. 6, 7, 8 and 9) and these were combined and dried. One hundred and twenty-seven milligrams of this dried product was dissolved in 4 ml. of anhydrous ethyl ether and poured into 150 ml. of low boiling petroleum ether. The milky suspension crystallized slowly after vigorous scratching with a glass rod. After standing overnight in the refrigerator the crystals were collected and dried; weight 43 mg. Recrystallization from ether–petroleum ether gave crystals melting at 112–115°.

Carbon Chromatography.—Ten grams of crude actidione (bio-assay, 53% actidione) was dissolved in sufficient acetone to give 80 ml. of solution. The acetone solution was diluted with 320 ml. of water and poured into a 4-foot length of 2-inch Pyrex pipe containing a mixture of 100 g. of Darco G-60 and 100 g. of Celite that had been slurried with 20% acetone and packed under pressure. Using a flow rate[9] of 12 ml. per minute the column was developed with 1500 ml. of 20% acetone followed by 500 ml. of 60% acetone, 500 ml. of 80% acetone, 500 ml. of 90% acetone and 500 ml. of 100% acetone. The eluates were collected in 100-ml. volumes. The first 2000 ml. contained a total of 0.92 g. of light yellow gummy solids, none of which yielded crystals when treated with amyl acetate (2 ml. per g.) and seeded. The next three 100-ml. eluates yielded 1.28 g., 1.31 g. and 0.88 g. of white fluffy solids which crystallized readily when treated with amyl acetate. The next six 100-ml. eluates also gave solids which could be crystallized but were rather gummy in appearance. The total recovery of solids was 9.33 g., of which 7.53 g. was in fractions that could be crystallized. The combined weight of crystals was 4.05 g.; m. p. 113–115°.

Preparation of Pure Actidione.—Two recrystallizations from amyl acetate (2 ml. per g.) raised the melting point of the above-described product to 115–116.5° but subsequent recrystallizations from this solvent caused no change. The analytical sample was recrystallized twice from 30% methanol; m. p. 115.5–117°; $[\alpha]^{25}_{D}$ −3.0° (*c* 10, methanol); +6.8° (*c* 2, water).

Anal. Calcd. for $C_{15}H_{23}NO_4$: C, 64.02; H, 8.24; N, 4.98. Found: C, 64.17, 64.02, 64.23, 64.24; H, 8.00, 8.53, 8.25, 7.91; N, 5.17, 5.10.

Actidione Acetate.—One gram of actidione was dissolved in 5 ml. of acetic anhydride by warming on the steam-bath. After the solution had cooled to room temperature 5 ml. of dry pyridine was added. After standing eighteen hours at room temperature the volatile products were removed *in vacuo*. The residue crystallized upon standing. When recrystallized from 99% isopropanol the yield was 0.83 g.; m. p. 143–149°. Two recrystallizations from hot water gave glistening plates; m. p. 148–149°; $[\alpha]^{25}_{D}$ +22° (*c* 2.3, methanol).

Anal. Calcd. for $C_{17}H_{25}NO_5$: C, 63.14; H, 7.79; N, 4.33. Found: C, 63.04, 63.22; H, 7.45, 7.61; N, 4.50, 4.45.

Actidione Oxime.—A solution of 1.0 g. of actidione in 2.5 ml. of methanol was added to a solution of 1.4 g. of hydroxylamine hydrochloride and 2.4 g. of anhydrous sodium acetate in 10 ml. of water. Upon standing overnight at room temperature 0.80 g. of white crystals was obtained; m. p. 194–196° (dec.). The analytical sample was recrystallized from methanol; m. p. 203–204° (dec.).

Anal. Calcd. for $C_{15}H_{24}N_2O_4$: C, 60.79; H, 8.16; N, 9.46. Found: C, 60.79, 60.52; H, 8.26, 8.32; N, 9.65, 9.59.

Actidione Semicarbazone.—A solution of 1.0 g. of actidione in 5 ml. of methanol was added to a solution of 1.0 g. of semicarbazide hydrochloride and 1.3 g. of anhydrous sodium acetate in 5 ml. of water. Upon standing overnight at room temperature 1.13 g. of white crystals was obtained; m. p. 175–178°. Recrystallization from methanol raised the melting point to 182–183°.

Anal. Calcd. for $C_{16}H_{26}N_4O_4 \cdot H_2O$: C, 53.92; H, 7.92; N, 15.72; H_2O, 5.05. Found: C, 53.72, 53.74; H, 7.95, 8.37; N, 16.08, 16.30; H_2O (by drying to constant weight at 60–80° in high vacuum), 5.09.

Summary

1. Actidione appears to have the formula $C_{15}H_{23}NO_4$ rather than $C_{27}H_{42}N_2O_7$ as previously suggested.

2. Methods for its isolation and purification are described.

3. Acute toxicities vary greatly with the species of test animals employed.

KALAMAZOO, MICHIGAN RECEIVED SEPTEMBER 27, 1947

---

[7] The acidification aids the subsequent filtration of the carbon-mycelium cake. It is unnecessary for adsorption of the actidione.

[8] A filter aid composed of diatomaceous earth.

[9] The rate of flow was regulated by adjustment of the pressure at the top of the column.

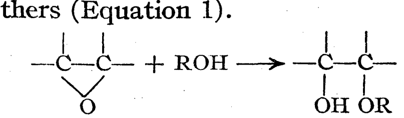
Chemistry of Epoxy Compounds. V.[2] Preparation of Some Hydroxy-ethers from 9,10-Epoxystearic Acid and 9,10-Epoxyoctadecanol

BY DANIEL SWERN, GERALDINE N. BILLEN AND JOHN T. SCANLAN

The reaction of oxirane compounds with compounds containing a hydroxyl group offers a convenient way of preparing many types of hydroxy-ethers (Equation 1).



$$\underbrace{-\overset{|}{C}-\overset{|}{C}-}_{O} + ROH \longrightarrow -\underset{OH}{\overset{|}{\underset{|}{C}}}-\underset{OR}{\overset{|}{\underset{|}{C}}}- \quad \text{(Equation 1)}$$

Acidic or alkaline materials are usually employed to catalyze this reaction, although for the more reactive oxirane compounds, a catalyst is not necessary. The reaction is generally applicable, and numerous hydroxy-ethers which contain a variety of functional groups can be readily prepared. Most of the published work has described the reaction of short-chain oxirane compounds with saturated aliphatic alcohols, and little information is available on the reaction of long-chain oxirane compounds with hydroxyl compounds. In this paper, the preparation of some hydroxy-ethers by the reaction of 9,10-epoxystearic acid and 9,10-epoxyoctadecanol with methyl, ethyl, *n*-propyl, *n*-butyl, *iso*-butyl, *n*-octadecyl, allyl, and β-chloroallyl alcohol and phenol, respectively, is reported. (Mixtures of products are obtained, since it is equally probable that the oxirane ring is opened between the oxygen atom and C_9 or C_{10}.)

The reaction of 9,10-epoxystearic acid (prepared from oleic acid by hypochlorination followed by dehydrohalogenation) with a large excess of ethyl, *n*-propyl and *n*-butyl alcohol, respectively, in the presence of catalytic quantities of sulfuric acid, has been reported by Nicolet and Poulter.[3] The reaction products which they obtained were saponified with aqueous alkali, and the three compounds isolated were mixtures of the 9- and 10-monoalkyl ethers of 9,10-dihydroxystearic acid. Yields were not reported. The oxirane ring of 9,10-epoxystearic acid can best be opened by heating the acid with a large molar excess of the alcohol and catalytic quantities of sulfuric acid, and under these conditions the carboxyl group is quantitatively esterified. By omitting the saponification step we obtained the hydroxy-ethers shown in Table I, in which the alkyl radicals in the ester and ether groups are identical. These products were isolated by vacuum distillation of the reaction products. We also treated 9,10-epoxystearic acid with *n*-octadecyl alcohol, phenol and β-chloroallyl alcohol under the conditions described above in an attempt to prepare *n*-octadecyl 9,10(10,9)-octadecoxyhydroxystearate, 9,10(10,9)-phenoxyhydroxystearic acid, and β-chloroally-9,10(10,9)-chloroalloxyhydroxystearate, respectively, but we were unable to purify the products completely. The analytical data which we obtained indicated, however, that in the main the reaction had proceeded in the expected manner.

We were unable to find any literature references to the reaction of 9,10-epoxyoctadecanol with hydroxyl compounds. We prepared the compounds shown in Table II in 25 to 65% yields, by heating 9,10-epoxyoctadecanol with a large molar excess of the appropriate alcohol in the presence of sulfuric acid as catalyst, and subsequently distilling the reaction products. We were unable to isolate pure 9,10(10,9)-*n*-octadecoxyhydroxyoctadecanol, 9,10(10,9)-phenoxyhydroxyoctadecanol and 9,10(10,9)-β-chloroalloxyhydroxyoctadecanol, although as mentioned earlier, the reactions proceeded in the expected manner.

The purified hydroxy-ethers are colorless, odorless, high-boiling liquids, soluble in all the common organic solvents and insoluble in water. They do not solidify when stored at 0° for long periods of time. Yields and characteristics of the products are shown in Tables I and II. Their high boiling points, insolubility in water, and stability suggest their possible use as plasticizers.

Allyl 9,10(10,9)-alloxyhydroxystearate (Table I) was co-polymerized in various proportions (from 1 to 40% by weight of total monomers) with vinyl acetate, according to the procedure of Guile and Huston.[4] Over the entire percentage range, insoluble, infusible products were obtained which ranged in physical appearance from hard, glass-like resins to soft, rubbery gels, thereby indicating that cross-linking probably had occurred and that both allyl groups must have reacted. That the fatty derivative was probably completely chemically bound was demonstrated by the fact that no oil was extruded when the co-polymers were squeezed in thin layers between sheets of absorbent paper.

In the reactions of 9,10-epoxystearic acid with hydroxyl compounds, small quantities of by-products, tentatively identified as esters of 9,10-dihydroxystearic acid,[5] were formed, and in the re-

actions of 9,10-epoxyoctadecanol, the by-product was 9,10-dihydroxyoctadecanol. These side-reaction products were separated from the hydroxy-ethers by crystallization from acetone.

Experimental

Starting Materials.—9,10-Epoxystearic acid, m. p. 59.5°, and 9,10-epoxyoctadecanol, m. p. 54°, were prepared by epoxidation of pure oleic acid and oleyl alcohol, respectively.[2] The short-chain aliphatic alcohols were the purest commercial grades, and they were distilled through an efficient fractionating column (40 to 50 theoretical plates) before use. The *n*-octadecyl alcohol, m. p. 57–58°, was the Eastman Kodak purest grade. The phenol was the U. S. P. grade.

Preparation of Hydroxy-ethers from 9,10-Epoxystearic Acid.—A typical reaction procedure suitable for the short-chain alcohols is given: 9,10-Epoxystearic acid (29.9 g., 0.1 mole) was dissolved in the freshly distilled anhydrous alcohol (4 ml. per gram), with gentle heating. The solution was cooled below 30°, and 0.3 g. of 95% sulfuric acid was added dropwise while the reaction mixture was shaken by hand. A temperature rise of several degrees was always observed during the addition of the catalyst. The solution was heated on the steam-bath for two hours, and a quantity of sodium bicarbonate equivalent to the sulfuric acid was then added. The reaction mixture was fractionally distilled, first at atmospheric pressure to recover unreacted alcohol and then under high vacuum to isolate the hydroxy-ether. A short Vigreux column was employed during the vacuum distillation, which was carried out as rapidly as possible, otherwise some dehydration of the product occurred. The hydroxy-ether was dissolved in acetone (2 to 3 ml. per gram), and the solution was cooled to −20° to precipitate the ester of 9,10-dihydroxystearic acid, which was always obtained as a by-product. This was separated by filtration and rejected. The acetone was evaporated from the filtrate, and the residual oil consisted of almost pure hydroxy-ether without further treatment (yield 60 to 95%). This residue was rapidly redistilled, and fractions having the same refractive index were combined for analysis. The results are summarized in Table I.

Preparation of Hydroxy-Ethers from 9,10-Epoxyoctadecanol.—These were prepared and isolated as described under the preparation of hydroxy-ethers from 9,10-epoxystearic acid. The results are summarized in Table II.

Benzoyl Peroxide-Catalyzed Co-polymerization of Allyl 9,10(10,9)-Alloxyhydroxystearate with Vinyl Acetate.—This was conducted as recommended by Guile and Huston,[4] a maximum content of allyl 9,10(10,9)-alloxyhydroxystearate of 40% by weight of the total monomers and 0.5% by weight of benzoyl peroxide being used. Solubility tests on the co-polymers were conducted in acetone at the boiling point and in acetic acid and amyl acetate at 100°. When thin layers of the co-polymers were squeezed between sheets of absorbent paper, no extrusion of oil was observed.

Summary

Twelve hydroxy-ethers have been prepared from 9,10-epoxystearic acid and 9,10-epoxyoctadecanol by reaction with methyl, ethyl, *n*-propyl, *n*-butyl, isobutyl and allyl alcohol, respectively. The high boiling points of the products, their insolubility in water and their stability suggest their possible use as plasticizers.

The benzoyl peroxide-catalyzed co-polymerization of allyl 9,10(10,9)-alloxyhydroxystearate (prepared from 9,10-epoxystearic acid and allyl alcohol) with vinyl acetate has been studied. Over the entire percentage range investigated (allyl 9,10(10,9)-alloxyhydroxystearate content from 1 to 40% by weight of total monomers), insoluble and infusible co-polymers which ranged from hard, glass-like resins to rubbery gels were obtained, thereby indicating that cross-linking probably occurred and that both allyl groups take part in the co-polymerization reaction.

The reaction of 9,10-epoxystearic acid and 9,10-epoxyoctadecanol with *n*-octadecyl alcohol,

phenol and β-chloroallyl alcohol was also investigated. Although pure hydroxy-ethers were not obtained, analytical data indicated that the reaction proceeded mainly in the expected manner.

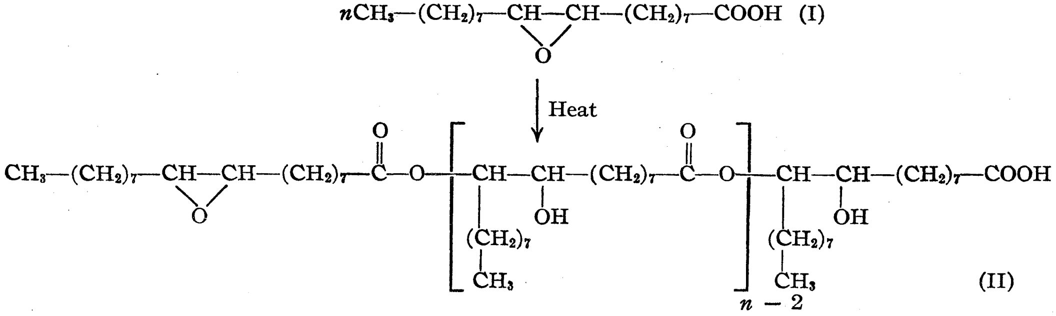
Chemistry of Epoxy Compounds. VI.[2] Thermal Polymerization of the Isomeric 9,10-Epoxystearic Acids[1a]

BY DANIEL SWERN, GERALDINE N. BILLEN AND C. ROLAND EDDY



(I)

(II)

The isomeric 9,10-epoxystearic acids[3,4] (I), m. p. 59.5° and 55.5°, contain two very reactive functional groups, and theoretically they should yield linear polyesters of structure II on thermal polymerization at relatively low temperatures. (Mixtures of isomers would be obtained, since it is equally probable that the oxirane ring would be opened between the oxygen atom and C_9 or C_{10}). Since no product of reaction would be eliminated in their formation and since the molecular formula of the recurring unit would be identical with that of the monomer, they would resemble addition polymers, but on hydrolysis they would yield a monomer whose molecular formula is not identical with that of the recurring unit, and in this respect they would resemble condensation polymers.[5] This interesting point, coupled with the fact that convenient methods for the laboratory preparation of the isomeric 9,10-epoxystearic acids in a high degree of purity were available,[3,4] prompted us to study the quantitative thermal polymerization of these compounds.

A limited amount of work on the thermal polymerization of the 9,10-epoxystearic acids has been published,[6] but the starting materials were apparently impure and, in general, higher temperatures than necessary were employed, thereby encouraging side reactions.

Experimental

Starting Materials.—The isomeric 9,10-epoxystearic acids, m. p. 59.5° and 55.5°, were prepared from pure oleic and elaidic acids, respectively, by epoxidation with peracetic or perbenzoic acids.[3,4] *Anal.* Calcd. for $C_{18}H_{34}O_3$: neutralization equivalent, 298.5; oxirane oxygen,[6,7] 5.36. Found: neutralization equivalent, 297.5–299.5; oxirane oxygen, 5.32–5.37.

Polymerization Procedures.—Approximately 5-g. portions of the 9,10-epoxystearic acids were weighed into a series of test-tubes. The tubes were flushed with nitrogen, tightly stoppered and immersed in a constant temperature oil-bath which maintained the desired temperature to ±0.2°. Fifteen minutes was allowed for the establishment of temperature equilibrium before polymerization times were counted. At selected time intervals, a tube was removed from the oil-bath and rapidly cooled to room temperature. The required analytical information was usually obtained within twenty-four hours.

Analytical Procedures.—Acid numbers were determined by means of 0.1 *N* aqueous sodium hydroxide on 0.15–0.30 g. of sample dissolved in neutralized 95% ethanol, phenolphthalein being employed as indicator. Oxirane oxygen was determined by the modified method of Nicolet and Poulter.[6,7] Carbonyl oxygen analyses were conducted by the method described by Leithe,[8] except that a *p*H meter was employed to determine the end-point.

Discussion

The course of the polymerization of 9,10-epoxystearic acid, m. p. 59.5°, at 65°, 75° and 85° is shown in Tables I, II and III, and that of its isomer, m. p. 55.5°, at 75°, 100° and 120° is shown in Tables IV, V and VI. The rate of disappearance of the oxirane and carboxyl groups is plotted in

Figs. 1 and 2 for the high-melting isomer and in Figs. 3 and 4 for the low-melting isomer.

Examination of the tables and figures reveals several significant points. First, both epoxy-acids may be polymerized to form gels. Second, in the polymerization of the high-melting isomer, m. p. 59.5°, the oxirane group disappears more rapidly than the carboxyl group throughout the reaction. In fact at the gel point more than 90% of the oxirane group has been consumed, whereas only about 73–76% of the carboxyl group has disappeared. Third, in the polymerization of the low-melting isomer, m. p. 55.5°, the rates of disappearance of both the oxirane and carboxyl groups are almost the same over the entire period investigated. This is best observed when Figs. 3

and 4 are superimposed, although it is fairly evident from Tables IV, V and VI. Fourth, the polymerization of the high-melting isomer proceeds at a more rapid rate than that of the low-melting isomer.

The fact that both epoxy-acids may be polymerized to gels indicates that these compounds have a higher functionality than two. Consideration of the possible addition and condensation reactions which may occur makes this point evident. These reactions are listed below:

1. Reaction between the oxirane and carboxyl groups (addition reaction).
2. Reaction between the hydroxyl groups, formed as a result of reaction 1, and carboxyl groups, with the elimination of water (condensation reaction).

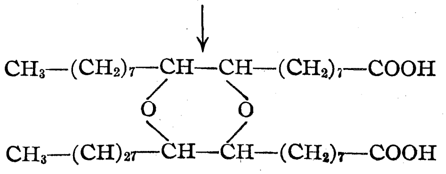
b.



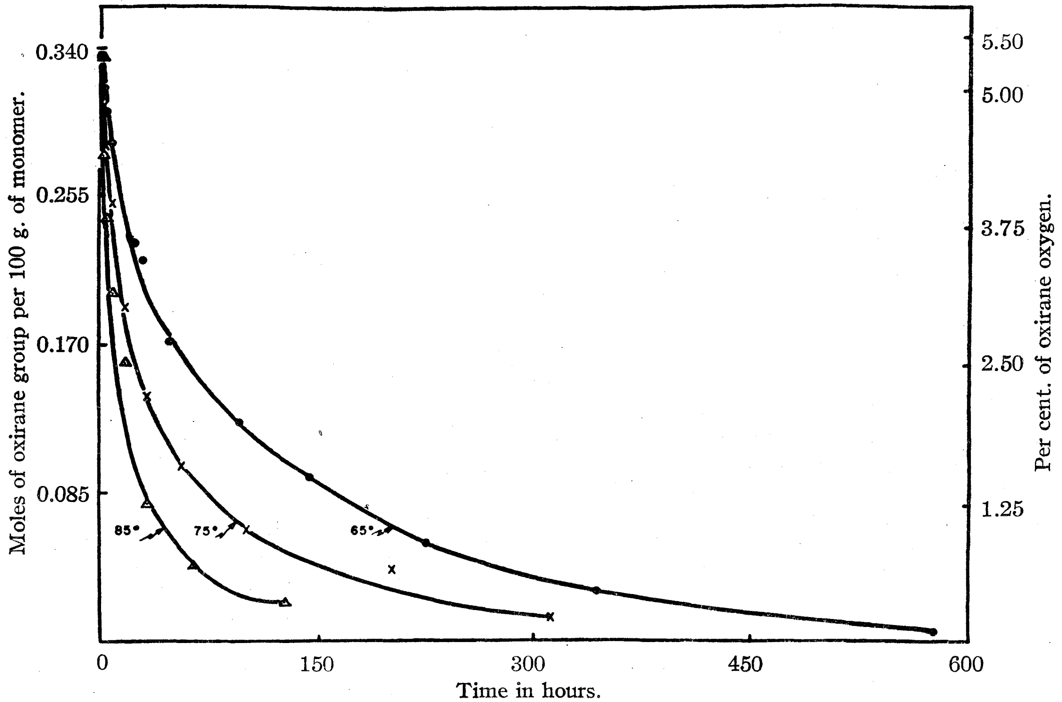


Fig. 1.—Thermal polymerization of 9,10-epoxystearic acid, m. p. 59.5°.

3. Reaction between the hydroxyl groups, formed as a result of reaction 1, and oxirane groups (addition reaction).

4. Reaction between oxirane groups (addition reactions).

5. Reaction between the hydroxyl groups, formed as a result of reaction 1, with the elimination of water (condensation reaction).

Reaction 1 is undoubtedly the main polymerization reaction, since carboxyl groups react readily with oxirane groups at moderate temperatures without catalysts, but such a reaction cannot ac-

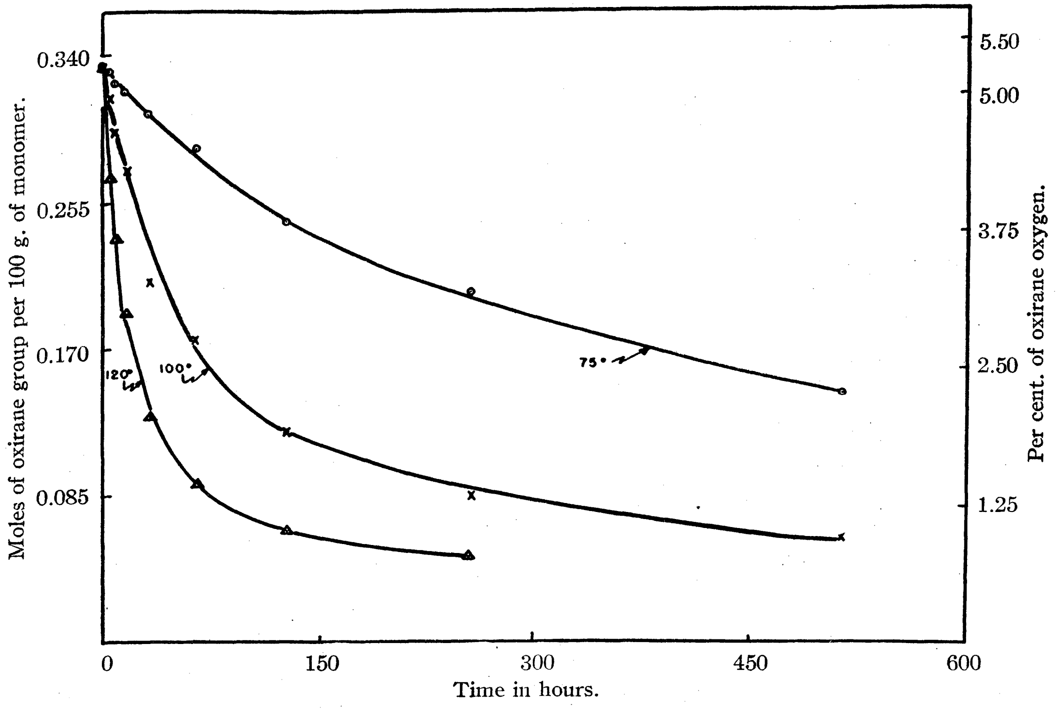

Fig. 3.—Thermal polymerization of 9,10-epoxystearic acid, m. p. 55.5°.

count for gel formation, since it yields only linear polyesters. Likewise, reaction 4b, which yields a difunctional dimer, cannot account for gel formation. The concept that reaction 4b may account for the oxirane group's disappearance at a more rapid rate than the carboxyl group's in the high-melting isomer, is not tenable because such a reaction requires high temperatures and acid catalysts. Reactions 2, 3 and 5, however, are cross-linking reactions, and reaction 4a yields a polyfunctional product capable of cross-linking. Reactions 4a and 5, however, in common with reac-

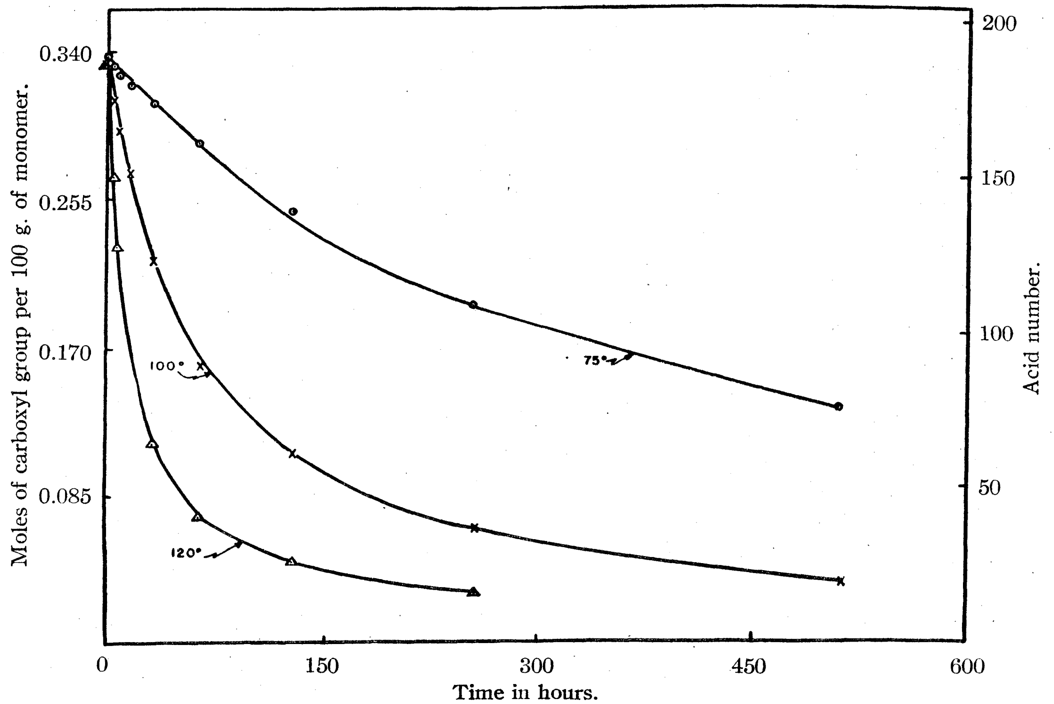

Fig. 4.—Thermal polymerization of 9,10-epoxystearic acid, m. p. 55.5°.

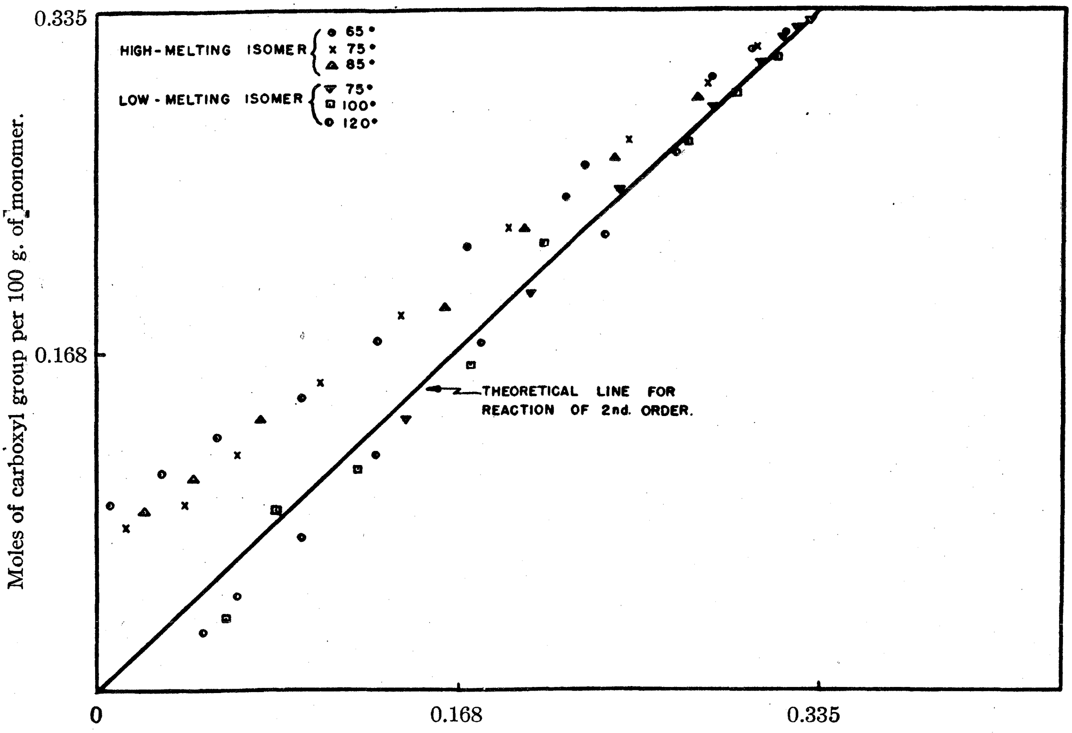

Fig. 5.—Thermal polymerization of the 9,10-epoxystearic acids, m. p. 59.5° and 55.5°.

tion 4b, require catalysts and high temperatures and probably do not account for cross-linking in either isomer or for the oxirane group's disappearance at a greater rate than the carboxyl group's in the high-melting isomer. Although we cannot state positively which of the remaining cross-linking reactions predominate, in the high-melting isomer it is probably reaction 3, and in the low-melting isomer it is probably reaction 2. These reactions can account not only for gelation, but reaction 3 also accounts for the oxirane group's disappearance at a more rapid rate than the carboxyl group's in the high-melting isomer, and reaction 2 accounts for the carboxyl group's disappearance at a slightly more rapid rate than the oxirane group's in the low-melting isomer, noticeable toward the end of the reaction. The assumption that reaction 3 accounts for gelation in the high-melting isomer is consistent with the fact that the oxirane group in this isomer reacts considerably faster with various simple secondary alcohols than the oxirane group in the low-melting isomer.

It was thought that the disappearance of the oxirane group at a more rapid rate than the disappearance of the carboxyl group in the high-melting isomer might be explained on the assumption that this group was isomerizing to the carbonyl group. Carbonyl oxygen analyses,[8] however, carried out on the polymers just prior to the gel point indicated that this reaction would account for only about one-third of the oxirane groups which had disappeared in excess of the carboxyl groups. In the low-melting isomer, carbonyl oxygen values were negligible, as would be expected from the data already discussed.

Cross-linking reactions must occur to only a limited extent in the low-melting 9,10-epoxystearic acid, since the disappearance of the carboxyl and oxirane groups proceeds at nearly the same rate throughout the entire polymerization and gelation does not occur until about 85% of the oxirane groups have disappeared. The parallel disappearance of these two functional groups suggested that the polymerization of this isomer might be a simple second order reaction. In Fig. 5, the concentration of carboxyl group is plotted against the concentration of oxirane group both for this isomer and the high-melting one. If the only process is a second order reaction between oxirane and carboxyl groups, a straight line which makes an angle of 45° with the co-ordinate axes, should be obtained. In the low-melting isomer, the points fall almost exactly on this line during the early stages of the polymerization, and diverge slightly toward the later stages. The best straight line drawn through these points makes an angle of 47° with the abscissa. It was fairly obvious from an inspection of the data in Tables I, II and III and by superimposition of Figs. 1 and 2, that a simple second order reaction was not the sole process occurring in the high-melting isomer, but this fact was strikingly illustrated when the points for this isomer, m. p. 59.5°, were also plotted in Fig. 5.

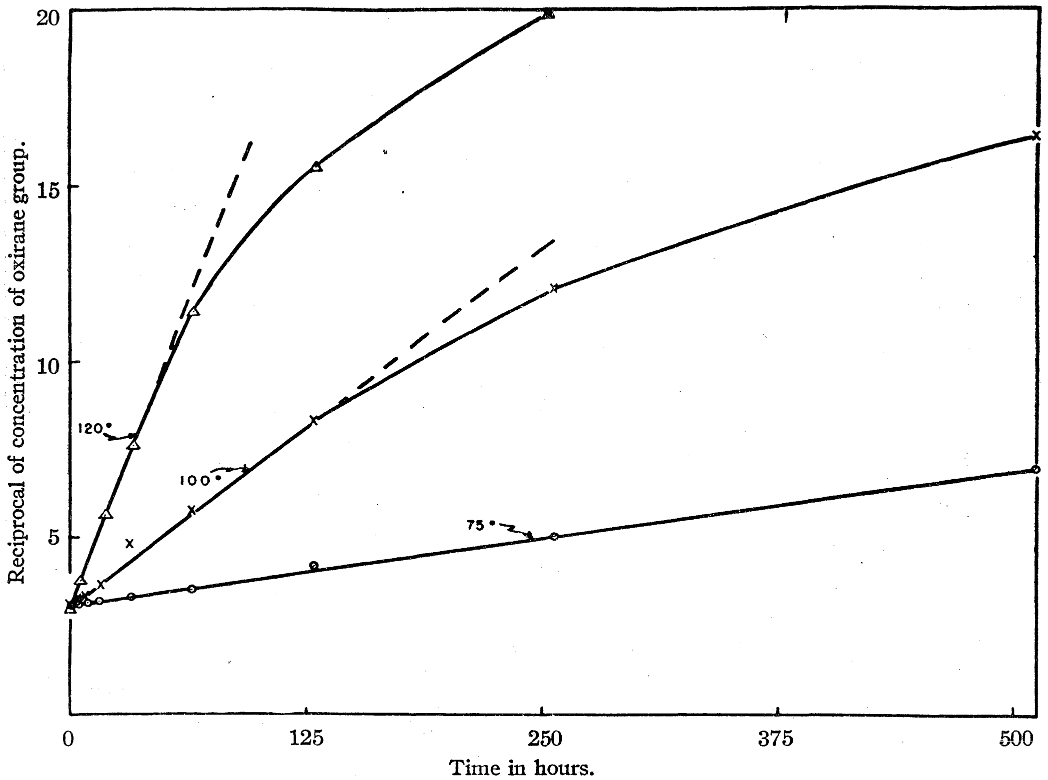

Fig. 6.—Thermal polymerization of 9,10-epoxystearic acid, m. p. 55.5°.

These points diverge from the line for equimolar disappearance of the oxirane and carboxyl groups even during the early stages of the reaction, and the best straight line drawn through these points makes an angle of about 36° with the abscissa.

Furthermore, if the second order reaction between oxirane and carboxyl groups is the only process occurring, plotting the reciprocal of the concentration of either the oxirane or carboxyl group against time should give a straight line, since both groups are initially present in equimolar amounts, and the slope of the line is the reaction rate constant, k. This is shown in Fig. 6 for the low-melting isomer only. At 75°, an almost perfect straight line is obtained over the entire range investigated, whereas at 100° and 120°, the first seven and five points, respectively, appear to fall on straight lines. These early points were replotted on larger graph paper, and the broken lines in Fig. 6 represent the extensions of the best straight lines for these points, as obtained from the plots on the larger graph paper. The rate constants at 75, 100 and 120° for the low-melting isomer are 0.00781, 0.0412 and 0.161, respectively (time in hours, concentration in moles per 100 g.). The energy of activation was calculated from the slope of the line in Fig. 7, in which log k is plotted against $1/T$. The value of E thus obtained is 18,600 calories per mole. The equation for correlating k with T is shown below

$$\log k = -4081/T + 9.59$$

Just prior to the gel point, the polymers are highly viscous, colorless oils, which are soluble in ethanol, diethyl ether, butanol, acetone, xylene, ethylene dichloride and ethyl acetate, and insoluble in water and in aliphatic hydrocarbons. At the gel stage, the polymers are insoluble in all these solvents at their boiling points.

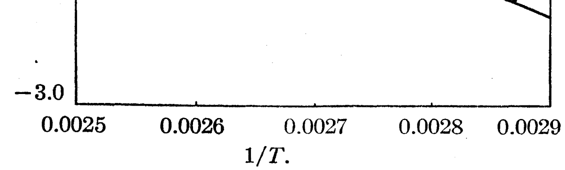

Fig. 7.—Thermal polymerization of 9,10-epoxystearic acid, m. p. 55.5°.

Acknowledgment.—We are indebted to Rudolph Speiser, Thomas W. Findley and John T. Scanlan for valuable discussions in connection with this problem.

Summary

The thermal polymerization of the isomeric 9,10-epoxystearic acids, m. p. 59.5° and 55.5°, derivable from oleic and elaidic acids, respectively, has been quantitatively studied. Both isomers can be polymerized to the gel stage, the high-melting isomer yielding a gel when about 75% of the carboxyl groups and 95% of the oxirane groups have disappeared, the low-melting isomer when about 85% of the oxirane groups and 90% of the carboxyl groups have disappeared. The main process appears to be the formation of linear polyesters by the reaction of the oxirane with the carboxyl group.

In the high-melting isomer, side reactions, which take place from the beginning of the reaction, cause the oxirane group to disappear at a more rapid rate than the carboxyl group, thereby preventing a kinetic analysis of the polymerization. In the low-melting isomer, the approximately parallel disappearance of both functional groups permits calculation of reaction rate constants as well as activation energy. This latter value is 18,600 cal. per mole. For both isomers, the reaction rate approximately doubles for each ten-degree rise in temperature.

The polymers just prior to the gel stage are highly viscous, colorless oils, soluble in many common organic solvents, and insoluble in water and in aliphatic hydrocarbons. At the gel stage they are insoluble at the boiling point in all the solvents tested.

Chemistry of Epoxy Compounds. VII.[2] Stereochemical Relationships between the 9,10-Epoxy-, Chlorohydroxy- and Dihydroxystearic Acids

BY DANIEL SWERN

The stereochemical relationships involved in the conversion of oleic and elaidic acids (*cis*- and *trans*-9-octadecenoic acids, respectively) to the 9,10-dihydroxystearic acids by way of the intermediate oxirane and chlorohydroxy compounds have been studied by King[3] and also by Atherton and Hilditch.[4] These investigators have proposed reaction schemes which not only differ on several fundamental points but which are at variance with accepted thinking on the Walden inversion[5] and double bond addition reactions[5] in some important respects.

A satisfactory reaction scheme must be in agreement with the following experimentally determined facts: (1) The 9,10-epoxystearic acid obtained from oleic acid by epoxidation with organic per-acids and that obtained by hypohalogenation and subsequent dehydrohalogenation are identical, and therefore have the same configuration; (2) the 9,10-epoxystearic acid obtained from elaidic acid by epoxidation and that obtained by hypohalogenation and dehydrohalogenation are also identical, and differ from the 9,10-epoxystearic acid described under (1) above; (3) the 9,10-dihydroxystearic acid obtained from oleic acid by oxidation with potassium permanganate and that obtained from elaidic acid by epoxidation and subsequent hydrolysis are identical; (4) the 9,10-dihydroxystearic acid obtained from elaidic acid by oxidation with potassium permanganate and that obtained from oleic acid by epoxidation and hydrolysis are also identical and differ from the 9,10-dihydroxystearic acid described under (3) above; (5) the chlorohydroxystearic acids obtained from oleic acid by reaction with hypochlorous acid and those obtained by epoxidation of oleic acid and subsequent treatment of the 9,10-epoxystearic acid with hydrochloric acid are identical; (6) the chlorohydroxystearic acids obtained from elaidic acid by reaction with hypochlorous acid and those obtained by epoxidation of elaidic acid and treatment of the 9,10-epoxystearic acid with hydrochloric acid are also identical and differ from the chlorohydroxystearic acids described under (5) above; and (7) treatment of either 9,10-dihydroxystearic acid with hydrochloric acid, followed by dehydrohalogenation and hydrolysis, yields the other isomer.

For some time we have been studying the reactions discussed above, and in this paper we are suggesting a scheme which correlates configurational relationships involved, in harmony with accepted theories of the Walden inversion and double bond addition reactions. This reaction scheme is shown in Fig. 1 (the + and − signs do not refer to optical rotations but are employed to correlate configurational relationships and to demonstrate the inversions more clearly).

Although it is generally agreed that opening and closing of the oxirane ring is accompanied by inversion,[6,7,8,9] and this rule has been followed in re-

Fig. 1.

actions 2, 3, 4, 6 and 7 of Fig. 1, Atherton and Hilditch[4] have suggested that inversion may not occur when the oxirane ring of 9,10-epoxystearic acid is hydrated. One of the reasons offered to explain this is the fact that hydrolysis of the oxirane ring by alkaline or by acidic hydrolytic agents yields the same isomeric form of dihydroxystearic acid, although the mechanisms of hydrolysis differ. Thus, in acid hydrolysis the oxirane compound is converted to the glycol by a two-step process in which a hydroxy-ester is an intermediate, whereas in alkaline hydrolysis the glycol is obtained directly in one step. We believe that the formation of the same 9,10-dihydroxystearic acid can be adequately accounted for on the assumption that in both types of hydrolysis only *one* inversion occurs, namely, at the time that the oxirane ring is opened. This is shown in Fig. 2, in which the conversion of 9,10-epoxystearic acid, m. p. 59.5°, to 9,10-dihydroxystearic acid, m. p. 95°, is em-

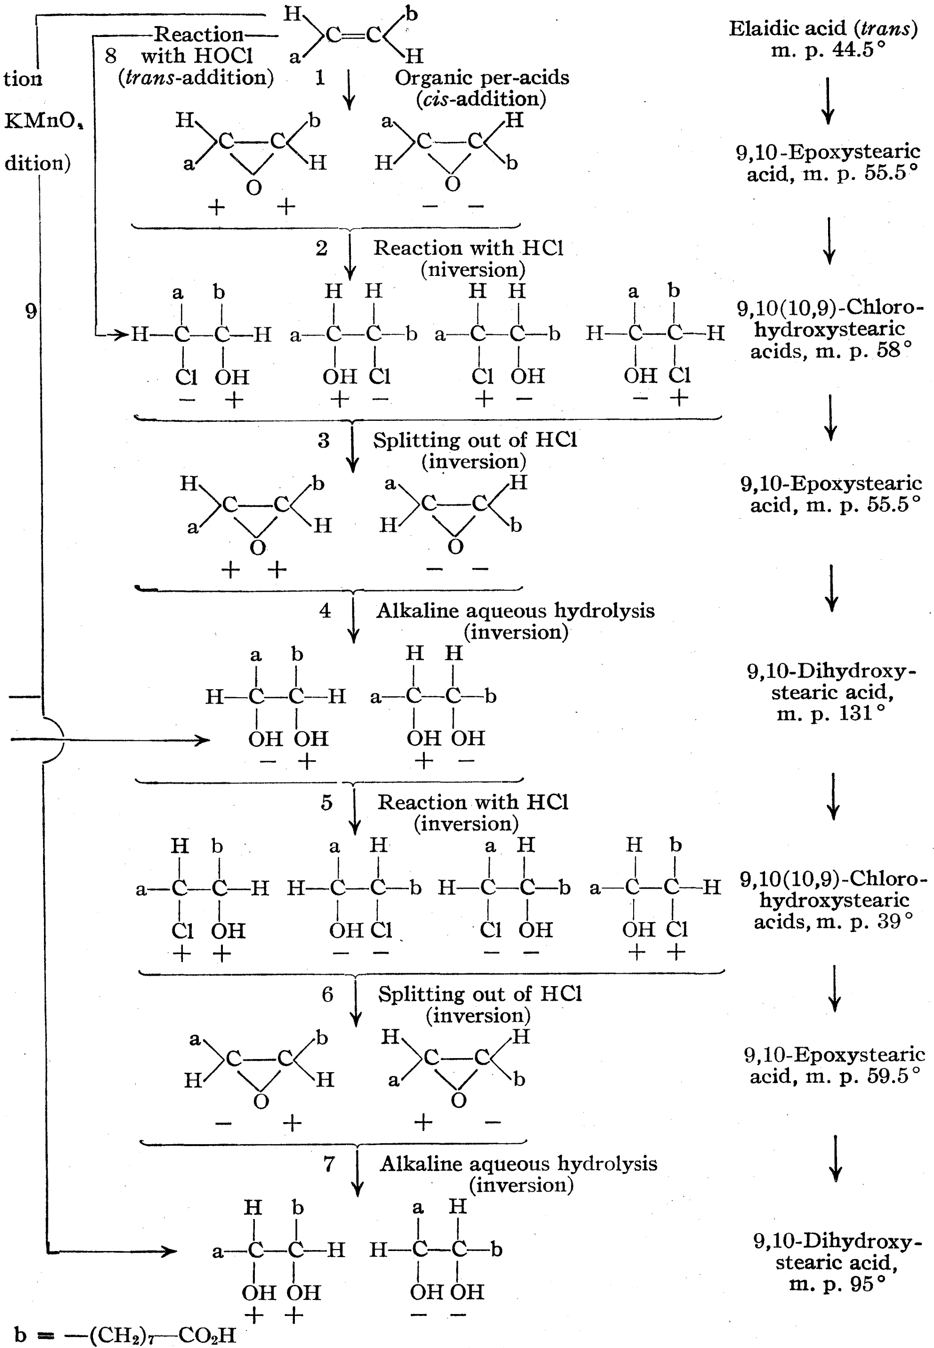

Fig. 1.

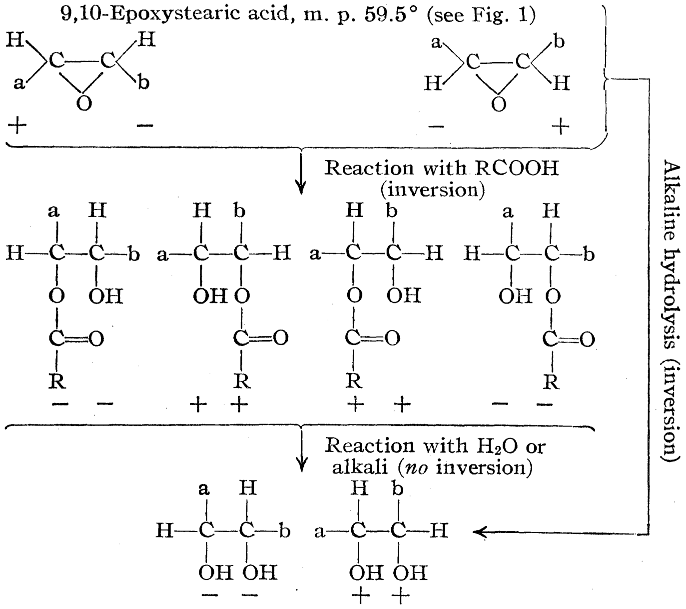
ployed as the example, although the same reasoning applies to the conversion of its isomer, m. p. 55.5°, to 9,10-dihydroxystearic acid, m. p. 131°. It is important to note that inversion cannot occur in the hydrolysis of the intermediate hydroxyester obtained by treatment of the oxirane compound with acid because the carbon–oxygen bond of the alcoholic component, in this case 9,10-dihydroxystearic acid, is not ruptured.[5] Identical results are obtained when sulfuric acid is employed instead of organic acids, or when concentrated or dilute alkali is used.

As further evidence that the oxirane ring may be hydrated without inversion, Atherton and Hilditch[4] have referred to the work of Abderhalden and Eichwald,[10] but we believe that this work is inapplicable to the present problem. Thus, inversions may not occur during the opening or closing of an oxirane ring which is attached to a

---

[10] Abderhalden and Eichwald, *Ber.*, **48**, 1847 (1915).

Fig. 2



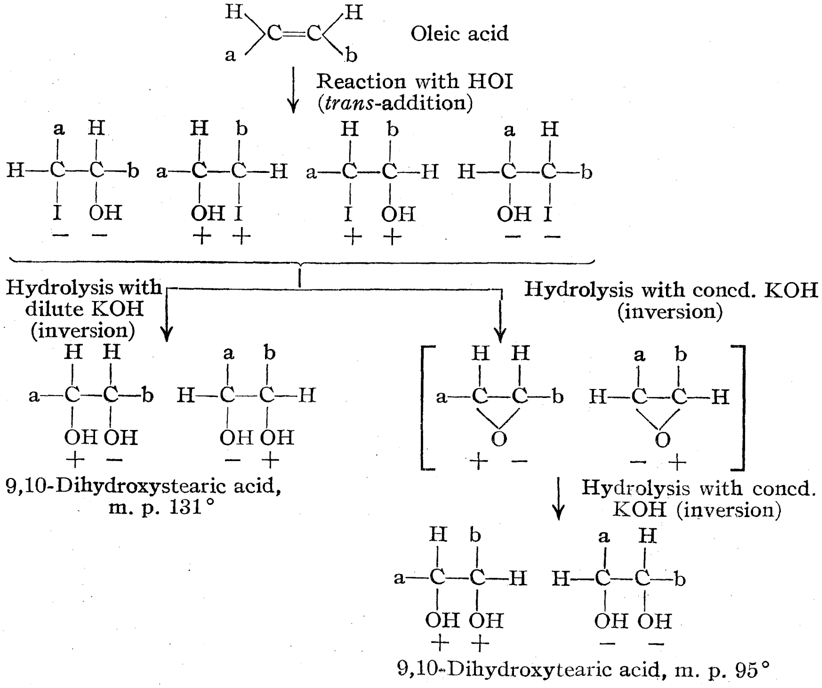
9,10-Dihydroxystearic acid, m. p. 95°

terminal, non-asymmetric carbon atom,[11] as is the case in the three-carbon systems studied by Abderhalden and Eichwald, but inversions occur during ring opening and closure when the oxirane group is attached to a pair of asymmetric carbon atoms[6,9] as is the case in the isomeric 9,10-epoxystearic acids.

Halohydrins of the same configuration (see later discussion) may be prepared either by treating the oxirane compound with hydrogen chloride, hydrogen bromide or hydrogen iodide (reaction 2), or by treating the appropriate unsaturated acid with a hypohalous acid (reaction 8). The form of dihydroxystearic acid obtained by alkaline hydrolysis of these halohydrins is determined by the concentration of the alkali used, since oxirane compounds may be formed as intermediates when the concentration of alkali exceeds a certain value. Thus, Esafov[8] has shown that iodohydroxystearic acid, prepared from oleic acid, yields 9,10-dihydroxystearic acid, m. p. 131°, on hydrolysis with dilute potassium hydroxide, whereas the isomeric 9,10-dihydroxystearic acid, m. p. 95°, is obtained when concentrated potassium hydroxide is employed. According to the scheme proposed in this paper, when dilute alkali is employed, the iodine atom is replaced directly by the hydroxyl group, with inversion,[5] and the 9,10-dihydroxystearic acid, m. p. 131°, is obtained. With concentrated alkali, the oxirane compound is formed as an intermediate, accompanied by inversion,[9] and this on hydrolysis also accompanied by inversion,[9] yields 9,10-dihydroxystearic acid, m. p. 95°. Thus, in the latter case two inversions must occur, whereas in the former only one takes place. This is shown in Fig. 3.

The chlorohydroxystearic acids obtained directly from the unsaturated acids by reaction with hypochlorous acid (reaction 8) and those obtained by treatment of the oxirane compounds with hydrogen chloride (reaction 2) have the same configuration, since they (the chlorohydrins) yield the same oxirane compound on ring closure. Since opening of the oxirane ring is accompanied by inversion,[6,7,8,9] it follows that hypohalogenation of the unsaturated acids must take place by *trans*-addition, as would be expected,[5] and epoxidation (reaction 1), therefore, must occur by *cis*-addition. That epoxidation occurs by *cis*-addition was also concluded by Braun[12] from a study of the perbenzoic acid oxidation of crotonic and isocrotonic acids.

Fig. 3



Furthermore, hydroxylation with potassium

---

[11] Sowden and Fischer, THIS JOURNAL, **64**, 1291 (1942).

[12] Braun, *ibid.*, **51**, 228 (1929).

permanganate (reaction 9) must also occur by *cis*-addition, which is in accord with accepted views on such oxidations,[6,7,13] and photochemical addition of hydrogen peroxide to the double bond, as well as the catalytic hydroxylation of the double bond with *t*-butyl hydroperoxide, must also take place by *cis*-addition.[14] The hydroxylation of maleic and fumaric acids to meso and racemic tartaric acids, respectively, by these reactions is excellent proof that a *cis*-addition mechanism is operative.

The interconversion of the 9,10-dihydroxystearic acids[3,4] (reactions 5, 6 and 7) must proceed, therefore, as shown in Fig. 1. The postulation of an inversion when a hydroxyl group is replaced by a halogen atom, or when the reverse change occurs, is substantiated by extensive experimental evidence.[5]

Experimental

Preparation of the Isomeric 9,10-Epoxystearic Acids.—The high-melting isomer, m. p. 59.5–59.8°, was prepared in good yield by the epoxidation of pure oleic acid[15] with perbenzoic[16] or peracetic acids.[17] It can also be prepared by treating oleic acid with hypochlorous acid followed by dehydrohalogenation with alkali,[4,18] although the yields are poor.

The low-melting isomer, m. p. 55.5°, was similarly prepared[4,16,17,18] from pure elaidic acid.[19]

Preparation of the Isomeric 9,10-Dihydroxystearic Acids.—The high-melting isomer, m. p. 131°, was prepared in excellent yield from oleic acid by oxidation with alkaline potassium permanganate[20] or from elaidic acid by epoxidation,[16,17] yielding 9,10-epoxystearic acid, m. p. 55.5°, as an intermediate product, followed by alkaline aqueous hydrolysis.[18] It was also prepared in more than 95% yield by heating 5 g. of 9,10-epoxystearic acid, m. p. 55.5°, for several hours at 100° with 100 ml. of glacial acetic acid, removing the solvent by vacuum distillation and treating the residual hydroxyacetoxystearic acids with an excess of 1 to 6 *N* aqueous sodium hydroxide for one hour at 100° (or overnight at room temperature), followed by acidification with dilute hydrochloric acid. The high-melting isomer was also prepared under milder reaction conditions by allowing 9,10-epoxystearic acid, m. p. 55.5°, to stand overnight at room temperature in anhydrous formic acid solution or in glacial acetic acid solution containing 1 to 5% of 95% sulfuric acid, or by allowing it to stand for several weeks at room temperature in glacial acetic acid solution, followed by removal of the solvent and aqueous hydrolysis. The best over-all procedure for preparing the high-melting isomer, which does not require isolation of the intermediate oxirane compound, involves oxidation of elaidic acid with 25 to 30% hydrogen peroxide in formic or acetic acid solution.[21] Yields are over 95%.

The low-melting isomer, m. p. 95°, was prepared in excellent yields from elaidic acid by oxidation with alkaline potassium permanganate,[20] from oleic acid by epoxidation[16,17] and hydrolysis,[18] from 9,10-epoxystearic acid, m. p. 59.5°, as described above, or from oleic acid by oxidation with 30% hydrogen peroxide in formic or acetic acid solution.[21]

Preparation of the Isomeric 9,10(10,9)-Chlorohydroxystearic Acids.—Although the 9,10(10,9)-chlorohydroxystearic acids can be prepared from oleic and elaidic acids by reaction with hypochlorous acid (prepared from gaseous chlorine and sodium hydroxide and utilized *in situ*,[4,18,22]) in our experience the yields may be low and the products are usually contaminated with polychlorinated materials. The best procedure for their preparation is to dissolve 2.98 g. (0.01 mole) of 9,10-epoxystearic acid (either isomer) in 100 ml. of a 0.2 *N* solution of anhydrous hydrogen chloride in absolute ether[22,23] contained in a 250-ml. separatory funnel, and allow the solution to stand at room temperature for three hours. The ether solution is washed with cold water until acid-free, dried over anhydrous calcium sulfate and filtered. Distillation of the ether yields 3.30 to 3.35 g. (99 to 100% yield) of 9,10(10,9)-chlorohydroxystearic acids as a non-volatile residue. Neutralization equivalent, calcd., 334.5; found, 334 to 335. 9,10-Epoxystearic acid, m. p. 59.5°, yields 9,10(10,9)-chlorohydroxystearic acids, m. p. 39–40° (lit.[22] 35°), which are reconverted to 9,10-epoxystearic acid, m. p. 59.5°, on treatment with concentrated alkali.[4,18] The chlorohydroxystearic acids, m. p. 39–40°, are identical with those obtained by the hypochlorination of oleic acid, since they both yield 9,10-epoxystearic acid, m. p. 59.5°, on dehydrohalogenation.[4] 9,10-Epoxystearic acid, m. p. 55.5°, yields 9,10(10,9)-chlorohydroxystearic acids, m. p. 58.0–58.8° (lit.[4] 58°), which are reconverted to 9,10-epoxystearic acid, m. p. 55.5°, on treatment with concentrated alkali.[4] The chlorohydroxystearic acids, m. p. 58–58.8°, are identical with those obtained by the hypochlorination of elaidic acid, since they both yield 9,10-epoxystearic acid, m. p. 55.5°, on dehydrohalogenation.[4]

Acknowledgment.—The author wishes to thank Thomas W. Findley and John T. Scanlan for thought-provoking discussions which helped to clarify some of the ideas presented in this paper.

Summary[24,25]

A reaction scheme is described which correlates the configurational relationships in the conversion of oleic and elaidic acids (*cis*- and *trans*-9-octadecenoic acids, respectively) to 9,10-dihydroxystearic acids by way of the intermediate oxirane

(24) NOTE ADDED IN PROOF: In the recent paper by McKay and Bader, *J. Org. Chem.*, **13**, 75 (1948), it was assumed that oxidation of oleic and elaidic acids with alkaline potassium permanganate proceeds by a *trans* hydroxylation mechanism. This was based on infrared absorption studies of the isomeric methyl 9,10-dihydroxystearates, Davies, *J. Chem. Phys.*, **8**, 577 (1940), and on the difference between the rates of reaction of the 9,10-dihydroxystearic acids with lead tetraacetate, Hilditch and Jasperson, *Nature*, **147**, 327 (1944). In these papers no conclusions regarding the absolute configuration of the dihydroxystearic acids and their relationship to oleic and elaidic acids were made. It is our belief, based upon the information presented in our paper and also in literature references 3, 6 and 13 cited therein, that the conclusions drawn by McKay and Bader regarding the configurations of the dihydroxy and tetrahydroxystearic acids are unjustified [see also Wittcoff and Miller, THIS JOURNAL, **69**, 3138 (1947)]. Furthermore, the terms *cis* and *trans*, employed by McKay and Bader and some earlier investigators, should not be applied to the hydroxy acids since these compounds are diastereoisomers and not geometric isomers, for which the terms are intended.

(25) This paper was presented at the meeting of the American Chemical Society held in New York, N. Y., on Sept. 15–19, 1947.

and chlorohydroxy compounds. This scheme is self-consistent and is in harmony with accepted theories of the Walden inversion and double bond addition reactions.

According to this scheme, epoxidation of the unsaturated acids with organic per-acids, or oxidation with alkaline potassium permanganate, takes place by *cis*-addition, whereas reaction with hypochlorous acid proceeds by *trans*-addition. Furthermore, it is postulated that opening (either in alkaline or acidic media) and re-forming of the oxirane ring, as well as replacement of a hydroxyl group of 9,10-dihydroxystearic acid by halogen, are each accompanied by an inversion. An inversion is also postulated when halogen is replaced by hydroxyl in the 9,10(10,9)-halohydroxystearic acids, and an explanation is offered for the formation of high- or low-melting 9,10-dihydroxystearic acid when 9,10(10,9)-iodohydroxystearic acids (from oleic acid) are treated with dilute or concentrated alkali, respectively.

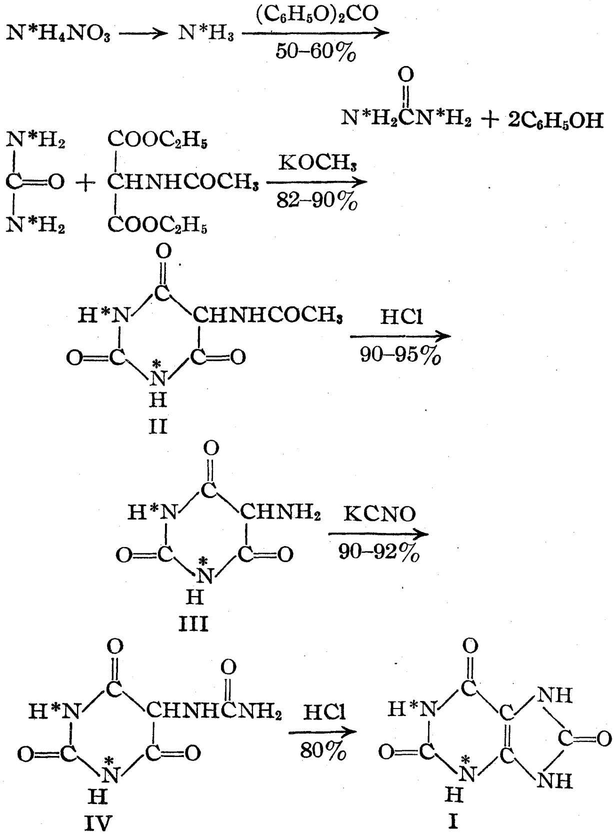
The Synthesis of Uric Acid Containing Isotopic Nitrogen

BY LIEBE F. CAVALIERI, VIRGINIA E. BLAIR AND GEORGE BOSWORTH BROWN

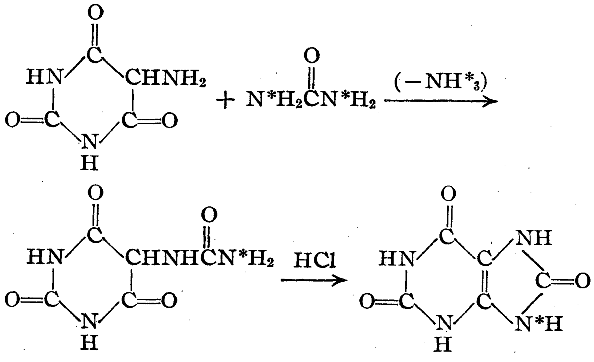
The existing procedures[1,2,3,4,5,6] for the synthesis of uric acid involve many steps and the over-all yields are low, based upon the urea used. For the introduction of isotopic nitrogen a modified synthesis has been developed in order to insure optimum utilization of the isotope. This synthesis introduces N^{15} in the pyrimidine ring (positions 1 and 3) (I) as shown in the following equations:



IV I

The over-all yield in this synthesis was 55%, based upon the urea used. The yields afforded by the older procedures can be estimated to be about 27%.

A second synthesis of uric acid (V) incorporating N^{15} presumably in position 9 was carried out according to the method of Grimaux.[2]



V

It will be noted that one amino group of the urea molecule was eliminated in the initial reaction. Cyclization with hydrochloric acid produced uric acid (V) containing about 1 atom of isotopic nitrogen. Since in the analogous reaction of 2,6-dioxy-4,5-diaminopyrimidine with urea[7] both of the amino groups of the urea were eliminated and no isotopic nitrogen was introduced into the uric

acid it may be presumed that in the uric acid (V) formed from urea and uramil the isotopic nitrogen was introduced chiefly in position 9.

Experimental

Urea.—The preparation of urea from diphenyl carbonate and ammonia was reported by Hentschel.[8] Bloch and Schoenheimer[9] introduced the use of copper powder as the catalyst. The preparation is described here since the technique used was more reproducible, in our hands, than that of Bloch and Schoenheimer.

A three-necked flask was equipped with a reflux condenser, dropping funnel and an inlet tube for nitrogen. A potassium hydroxide drying tower was placed on top of the condenser and a wide-mouth tube from this was led into a glass bomb tube, 15 cm. above the bottom of the bomb. An outlet tube from the bomb tube was passed through an acid trap containing a known quantity of standard acid. A flask of liquid nitrogen was placed around the bomb tube to condense and freeze the isotopic ammonia.

A solution of 4.088 g. (0.0511 mole) of $N^{15}H_4NO_3$ (32.0 atom % excess N^{15}) in 25 cc. of water was introduced into the three-necked flask. The bomb tube was charged with an intimate mixture of 4.95 g. (0.0231 mole) of diphenyl carbonate and 130 mg. of copper powder. Before the ammonia was liberated from the ammonium nitrate, the apparatus was swept with nitrogen for ten minutes. The bomb tube was then immersed in the liquid nitrogen. While continuing the slow stream of nitrogen, an excess of sodium hydroxide was slowly introduced from the funnel and the generating flask was heated to boiling. Care must be exercised not to allow the ammonia to be liberated too rapidly since the inlet tube in the bomb may become clogged with crystalline ammonia. The generating flask was heated for three hours and about 5% of uncondensed ammonia was collected in the acid trap. The bomb tube was transferred to a solid carbon dioxide-bath and sealed. It was then heated in a water-bath at 90–100° for four hours. The contents of the tube were dissolved in a minimal amount (about 50-cc.) of warm water and the copper powder was removed by filtration. The filtrate was extracted with six 50-cc. portions of chloroform. The aqueous layer was decolorized and evaporated to dryness on a water-bath. The yield of crude urea was 0.977 g. Recrystallization from acetone gave 0.830 g. of urea (57%, based upon the ammonia condensed); m. p. 133.5–135° (stage).

Acetyluramil (Potassium Salt).—A three-necked flask was equipped with a Hershberg stirrer, reflux condenser and glass stopper. The apparatus was dried and potassium methylate was prepared by adding absolute methanol (dried over Drierite) to 0.9 g. (0.23 mole) of clean potassium under benzene. The solvents were removed under reduced pressure and to the dry residue was added 1.180 g. (0.0197 mole) of urea in 4 cc. of absolute methanol. Ethyl acetamidomalonate[10] (4.3 g., 0.02 mole) was dissolved in 8 cc. of methanol and added in one portion to the urea solution. The mixture was refluxed and stirred for four hours. The white precipitate of potassium acetyluramil was collected by filtration; yield 3.74 g. (85%). An analytical sample of acetyluramil was prepared as follows: potassium acetyluramil (500 mg.) was dissolved in 15 cc. of concentrated hydrochloric acid at room temperature. The solution was added to 100 cc. of ethanol and cooled overnight. The precipitate which formed weighed 400 mg.

Anal. Calcd. for $C_6H_7O_4N_3$: N, 22.70. Found: N, 22.50.[11]

Uramil.—The potassium acetyluramil (3.61 g., 0.0161 mole) was hydrolyzed to uramil in 30 cc. of concentrated hydrochloric acid. The mixture was heated to boiling for about five minutes at which time all the solid had gone into solution. The uramil was precipitated by diluting with 70 cc. of water; yield 2.16 g. (94%). An analytical sample was prepared by dissolving 100 mg. of uramil in dilute sodium hydroxide and reprecipitating with hydrochloric acid; recovery 72 mg.

Anal. Calcd. for $C_4H_5O_3N_3$: C, 33.57; H, 3.52. Found: C, 33.01; H, 3.60.

Pseudouric Acid (Potassium Salt).—Potassium pseudourate was prepared by a modification of the procedure of Baeyer.[1] Uramil (2.16 g., 0.0151 mole) was added in one portion to a boiling solution of 55 g. of potassium cyanate in 260 cc. of water. The uramil dissolved producing a clear pink solution and potassium pseudourate precipitated almost immediately. The solution was refluxed for one-half hour while stirring. Upon cooling, 3.14 g. (92%) was obtained.

Uric Acid.—Potassium pseudourate was converted to uric acid according to the procedure of Fischer.[3] Yields of 72 to 80% were obtained, after two recrystallizations.

Anal. Calcd. for $C_5H_4O_3N_4$: C, 35.71; H, 2.39; N, 33.33. Found: C, 35.81; H, 2.50; N, 33.25.

The isotopic preparation contained 34.05% total nitrogen (calcd. 33.52% with allowance for the N^{15} present), and 16.1 atom % excess N^{15} (expected 16.0%).[12]

Absorption Spectra of Uric Acid.—The ultraviolet absorption spectrum of synthetic samples prepared by either method (determined upon a solution of 0.013 mg. per cc. at *p*H 7.0; 0.1 *M* phosphate buffer) showed maxima of ϵ 12,700 at 292 mμ and of ϵ 10,100 at 235 mμ. A commercial sample of uric acid,[13] purified in the same manner as the synthetic sample, exhibited slightly lower maxima (ϵ = 11,500 and 8,820) at the same wave lengths. The data on the commercial sample agree with the values previously reported.[14,15]

Uric Acid from Urea and Uramil (Isotopic Nitrogen in the 9 Position).—Urea (550 mg., 0.0092 mole, 0.97 atom % excess N^{15}) was fused with 500 mg. (0.0035 mole) of uramil[16] at 150–170° for forty-five minutes. The cooled melt was extracted with 20 cc. of boiling water and the insoluble material was removed by filtration. The filtrate was decolorized and evaporated to about 6 cc. Upon cooling, 355 mg. (50%) of ammonium pseudourate precipitated. This was dissolved in aqueous sodium hydroxide and pseudouric acid was precipitated by acidification with hydrochloric acid; yield, 200 mg. (35%). This pseudouric acid contained 0.28 atom % excess N^{15}. This was converted to uric acid (calcd. N, 33.34; found 33.18) which also contained 0.28 atom % excess N^{15}. This is slightly more than the theoretical of 0.24 atom % N^{15} excess for the introduction of one nitrogen atom from the urea used.

Uric Acid from 2,6-Dioxy-4,5-diaminopyrimidine.—Urea (700 mg., 0.0117 mole, 0.97 atom % excess N^{15}) was fused with 468 mg. (0.0011 mole) of 2,6-dioxy-4,5-diaminopyrimidine sulfate[9] for one hour at 150–170°. The cooled melt was washed with 10 cc. of water and filtered. The residue was dissolved in dilute sodium hydroxide, decolorized with charcoal and precipitated by the addition of acetic acid. It was dissolved again in alkali and precipitated by the addition of hydrochloric acid. The product was then recrystallized from water and the 163 mg. of uric acid obtained was shown to contain no excess isotopic nitrogen.

Summary

An improved synthesis of uric acid, suitable for

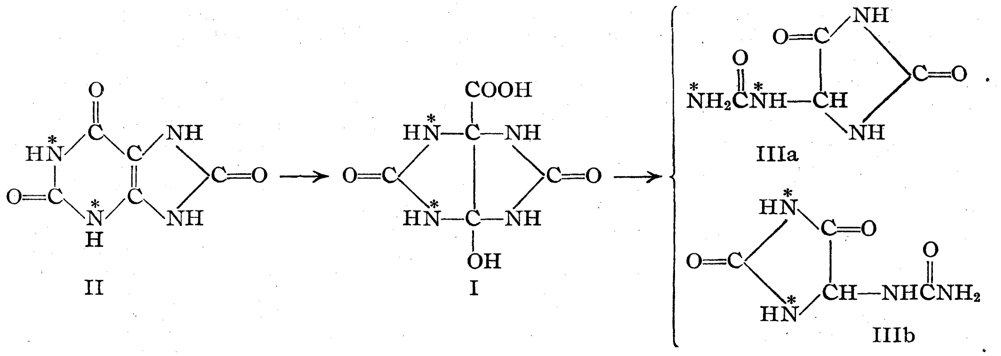
The Mechanism of the Oxidation of Uric Acid Studied with Isotopic Nitrogen as a Tracer[1]

BY LIEBE F. CAVALIERI AND GEORGE BOSWORTH BROWN

The oxidation of uric acid with potassium permanganate in alkaline solution results in the formation of allantoin,[2,3,4] while oxidation with nitric acid or chlorine produces alloxan.[5,6] In the alkaline permanganate oxidation it has been suggested[3] that the reaction proceeds *via* the symmetrical intermediate I. In support of this hypothesis, Fischer and Ach[7] have shown that both 1- and 7-methyluric acids yield upon oxidation 3-methylallantoin and that both 3- and 9-methyluric acids yield 1-methylallantoin. Schuler and Reindel[8] isolated the silver salt of an intermediate compound to which they assigned the symmetrical structure (I) originally postulated by Behrend. Klemperer[9] has also obtained what is believed to be this compound by the action of uricase on uric acid.

We have studied the oxidation of uric acid (II) containing an excess of isotopic nitrogen in positions 1 and 3. II was oxidized to allantoin with alkaline permanganate. If the symmetrical intermediate I is formed, the N^{15} will be present in only one pair of the nitrogen atoms of the molecule. The cleavage of either ring of this molecule will result in the formation of allantoin. The result in one case will be the introduction of the isotopic nitrogen into the urea moiety of the allantoin (IIIa) and in the other case into the ring of the allantoin (IIIb).[10] The allantoin isolated will contain the same number of molecules of each of IIIa and IIIb. Statistically, therefore, the allantoin will have the isotopic nitrogen distributed uniformly among all four nitrogens of the molecule.



A sample of the allantoin obtained (IIIc) was oxidized to potassium oxonate (IV) with potassium permanganate, while a second portion was converted by reduction with hydriodic acid to hydantoin (V). Isotope analyses showed that the nitrogen of the potassium oxonate and that of the hydantoin contained the same atom per cent. excess of N^{15} as the allantoin. The isotopic nitro-

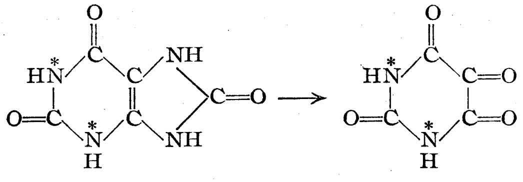
(9) Klemperer, *J. Biol. Chem.*, **160**, 111 (1945).

(10) In the work of Fischer and Ach[7] only the substituted allantoins with the methyl group on the hydantoin ring were isolated. This may have been due to failure to isolate an accompanying allantoin with the methyl substituent on the urea moiety, or it may be that no such allantoin is formed because of a preferential cleavage of the unsubstituted ring of a methylated I.

gen originally present in the 1 and 3 positions of the uric acid was thus proven to have become distributed equally between the imidazolone and the urea moieties of the allantoin and the isotope in the urea moiety was shown to be equally distributed between its two nitrogens. This evidence furnishes direct proof of the formation of a symmetrical intermediate in this oxidation of uric acid to allantoin.

When the uric acid, labelled with isotopic nitrogen in the 1 and 3 positions, was oxidized either with nitric acid or with chlorine, the atom per cent. excess of N^{15} in the alloxan (VI) formed was twice that of the uric acid from which it was derived.



II VI

This demonstrates that the nitrogen atoms of the alloxan were derived solely from the 1 and 3 nitrogens of the uric acid. Thus the oxidation in acid media is a direct cleavage of the imidazolone ring with the formation of the alloxan from the pyrimidine ring alone.

Experimental

Uric Acid.—Two samples of uric acid containing N^{15} in the 1 and 3 positions, synthesized according to the directions given in another communication,[11] were shown to contain, respectively, 0.43 and 0.34 atom per cent. excess N^{15}.[12]

Allantoin.—Uric acid (1.20 g., 0.43 atom per cent. excess N^{15}) yielded 866 mg. of allantoin when oxidized according to the procedure of Hartman, Moffett and Dickey.[4] Recrystallization from water yielded 647 mg., (57%); 0.41 atom per cent. excess N^{15}.

Anal. Calcd. for $C_4H_6O_3N_4$: N, 35.4. Found: N, 35.3.[13]

Potassium Oxonate.—Allantoin was oxidized to potassium oxonate according to Biltz and Giesler.[14] Allantoin (100 mg.) yielded 85 mg. of potassium oxonate. Recrystallization from water gave 50 mg., (40%); 0.41 atom per cent. excess N^{15}.

Anal. Calcd. for $C_4H_2O_4N_3K$: N, 21.5. Found: N, 21.8.

Hydantoin.—The procedure of Baeyer[15] for the reduction of allantoin to hydantoin was simplified as follows. Allantoin (200 mg.) was refluxed with 2 cc. of hydriodic acid, containing a trace of hypophosphite, for eight minutes. The mixture was then evaporated to dryness with a stream of air. Three cc. of acetone was added to the dry residue and the solution was placed in an ice-box for one-half hour. The hydantoin (70 mg.) was collected by filtration and washed with fresh acetone and then recrystallized from ethyl alcohol. Yield was 57 mg. (45%); 0.43 atom per cent. excess N^{15}.

Anal. Calcd. for $C_3H_4O_2N_2$: N, 28.0. Found: N, 28.6.

Alloxan (a) Nitric Acid Oxidation.—The procedure for the oxidation of uric acid was similar to that of Nightingale[16] for the oxidation of alloxantin to alloxan. Uric acid (400 mg., 0.34 atom per cent. excess N^{15}) yielded 50 mg. of alloxan, 0.67 atom per cent. excess N^{15}.

Anal. Calcd. for $C_4H_2O_4N_2 \cdot 4H_2O$: N, 13.1. Found: N, 13.2.

(b) **Chlorine Oxidation.**—Uric acid (400 mg., 0.34 per cent. excess N^{15}) was treated with 107 mg. of potassium chlorate, 0.67 cc. of concentrated hydrochloric acid and 1.1 cc. of water.[17] After all the solid had gone into solution, the mixture was evaporated with a stream of air to about one-half the volume. After standing in the ice-box overnight, 100 mg. of alloxan crystallized, 0.69 atom per cent. excess N^{15}.

Anal. Calcd. for $C_4H_2O_4N_2 \cdot 4H_2O$: N, 13.1. Found: N, 13.5.

Summary

By the use of isotopic nitrogen as a tracer, it has been demonstrated that the oxidation of uric acid to allantoin with alkaline potassium permanganate proceeds through a symmetrical intermediate. Oxidation with either nitric acid or chlorine results in a direct cleavage of the imidazolone ring to produce alloxan.

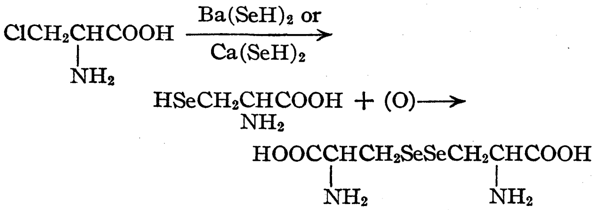
Syntheses of the Selenium Analog of *dl*-Cystine

BY LORING R. WILLIAMS AND ABRAHAM RAVVE

Several methods for the synthesis of the selenium analog of cystine have been previously described. Fredga[1] prepared a seleno-cystine by treating the methyl ester of α-amino-β-chloropropionic acid hydrochloride with potassium diselenide in an aqueous solution. A yellow, crystalline compound was obtained, m. p. 215° with decomposition. A 30% yield was reported. Painter[2] reported several methods for preparing the compound. Methods were sought which would avoid the prolonged use of diselenides in aqueous alkali as they are generally unstable. In these syntheses the methyl ester of α-amino-β-chloropropionic acid hydrochloride was used as the starting compound. The best yields were obtained by the use of the following method: The amino acid, β-(benzylseleno)-alanine was prepared by treating the ester with sodium benzyl selenide. The acid was reduced with sodium in liquid ammonia and the product formed by the cleavage of the benzyl group was oxidized to give the selenium analog of *dl*-cystine. Small plates (some hexagonal, some rectangular) were obtained, m. p. 222° with decomposition.

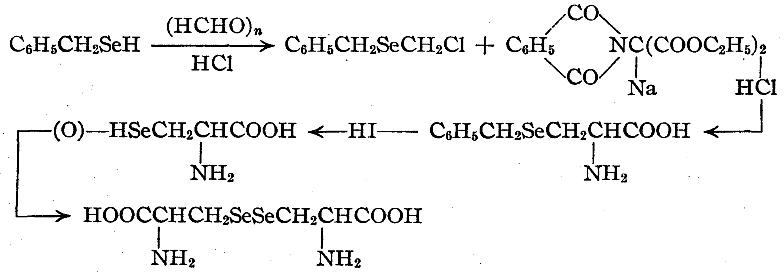
In the present investigation the selenium analog of cystine was prepared by substituting selenium analogs for the sulfur compounds used in the methods of preparation described by Abderhalden[3] and Wood and du Vigneaud[4] for the preparation of *dl*-cystine. The modifications may be summarized as follows:

(I) Abderhalden Modification.—α-Amino-β-chloropropionic acid reacted with barium hydrogen selenide or calcium hydrogen selenide and the product was oxidized.



$$Cl\underset{NH_2}{CH_2CH}COOH \xrightarrow[Ca(SeH)_2]{Ba(SeH)_2\text{ or}} HSeCH_2\underset{NH_2}{CH}COOH + (O) \longrightarrow HOOC\underset{NH_2}{C}HCH_2SeSeCH_2\underset{NH_2}{C}HCOOH$$

(II) Wood and du Vigneaud Modification.—Benzyl selenol was condensed with polyoxymethylene and hydrogen chloride according to a reaction carried out by Böhme[5] in the synthesis of the ethyl homolog. Benzyl chloromethyl selenide was obtained which was condensed with sodium phthalimidomalonic ester. The resulting compound was hydrolyzed to give β-(benzylseleno)-alanine. After the benzyl group was cleaved with hydriodic acid the resulting seleno-acid was oxidized and the β,β'-diselenodialanine was separated by the procedure described by Fredga.[1]



$$C_6H_5CH_2SeH \xrightarrow[HCl]{(HCHO)_n} C_6H_5CH_2SeCH_2Cl + C_6H_5\langle(CO)_2\rangle N\underset{Na}{C}(COOC_2H_5)_2 \xrightarrow{HCl} C_6H_5CH_2SeCH_2\underset{NH_2}{C}HCOOH \xrightarrow{HI} HSeCH_2\underset{NH_2}{C}HCOOH \xrightarrow{(O)} HOOC\underset{NH_2}{C}HCH_2SeSeCH_2\underset{NH_2}{C}HCOOH$$

Experimental

Method (I).—**Barium Hydrogen Selenide.**—Barium hydrogen selenide and calcium hydrogen selenide were both prepared by saturating a solution of the hydroxides with hydrogen selenide. The solutions that were formed were used as no attempts were made to isolate the compounds.

Serine.—Prepared by the method of Wood and du Vigneaud.[6]

Methyl Ester of Serine Hydrochloride.[7]—Fifteen grams of pulverized serine was suspended in 450 g. of absolute methyl alcohol and dry hydrogen chloride added until saturated. The alcohol was removed *in vacuo* and the ester remained as a white crystalline mass, m. p. 133°; yield 8.7 g., 58%.

α-Amino-β-chloropropionic Acid.—The methyl ester of α-amino-β-chloropropionic acid hydrochloride was prepared by the method of Fischer and Raske[8] and was subsequently hydrolyzed in sodium hydroxide solution. The resulting salt was carefully neutralized with hydrochloric acid to produce α-amino-β-chloropropionic acid, m. p. 160°.

β,β'-Diselenodialanine.—One gram of α-amino-β-chloropropionic acid was digested with a water solution of barium hydrogen selenide at the boiling point for two hours. The solution was filtered and just neutralized (litmus) with ammonium hydroxide. A yellow, crystalline precipitate was formed after thirty-six hours in the refrigerator, which was filtered, washed with water, alcohol and ether. The crystals were thin, yellow, hexagonal plates which turned gray upon heating to 175–180°. The crystals melted with decomposition at 213–215°; yield, 0.55 g., 20%.

The same results were obtained when calcium hydrogen selenide was used instead of barium hydrogen selenide.

Anal. Calcd. for $C_6H_{12}O_4N_2Se_2$: Se, 47.27. Found[9]: Se, 47.09.

Method (II).—**Benzyl Chloromethyl Selenide.**—Seventy-three grams of benzyl selenol[2] was placed in a flask with 25 g. of polyoxymethylene. The mixture was

cooled in an ice-bath and saturated with dry hydrogen chloride. To this, 30 g. of calcium chloride was added, the mixture was allowed to stand at room temperature for twenty-four hours and the solid material was removed by filtration. The liquid was a yellow oil with a very unpleasant odor. The compound was unstable at high temperatures, boiling at 158–160°, 16 mm.

β-(Benzylseleno)-alanine.—Ten grams of benzyl chloromethyl selenide was refluxed for four hours with 15 g. of sodium phthalimidomalonic ester in the presence of toluene. The toluene was removed *in vacuo*, the compound recrystallized and the white crystals were collected. The compound was unstable at high temperatures and a melting point could not be determined. Fifteen grams of the compound was suspended in 100 ml. of an ethyl alcohol and water mixture (1:1) and 10 ml. of dioxane added. Two drops of phenolphthalein solution was added and the mixture was heated to 50°. Fifteen ml. of 5 N sodium hydroxide solution was added dropwise with stirring at a rate to maintain a temperature of 55–60°. When all of the alkali had been added the temperature of the solution was brought up to 70°. The solution was stirred constantly while the temperature was allowed to drop to room temperature. Hydrochloric acid was added until the solution was acid to phenolphthalein and the solution was distilled to half volume *in vacuo*. Water was added to make a total volume of 150 ml. and 20 ml. of concentrated hydrochloric acid was added with the evolution of carbon dioxide. The solution was heated for one and one-half hours, more hydrochloric acid added and heating continued for two more hours. The solution was taken to dryness, the residue dissolved in water and ammonium hydroxide was added until a neutral reaction was obtained with congo red. The precipitate which consisted of β-(benzylseleno)-alanine and phthalic acid was removed by filtering, suspended in boiling ethyl alcohol and again filtered. This was repeated until all of the phthalic acid had been removed leaving the β-(benzylseleno)-alanine as a white, crystalline residue, m. p. 185°; yield, 59%.

Anal. Calcd. for $C_{10}H_{13}O_2NSe$: Se, 30.52; C, 47.0; H, 5.07; N, 5.41. Found: Se,[9] 30.03; C, 47.0; H, 5.5; N,[10] 5.42.

β,β'-Diselenodialanine.—Three and one-half grams of β-(benzylseleno)-alanine was cleaved with concentrated hydriodic acid after digesting for forty-eight hours while air was bubbled through the mixture. Yellow hexagonal plates were obtained, m. p. 215° with decomposition; yield, 0.32 g.

Anal. Calcd. for $C_6H_{12}O_4N_2Se_2$: Se, 47.27. Found: Se, 47.10.

Summary

Two syntheses of the selenium analog of cystine are described which furnish additional evidence that selenium analogs may be substituted for the sulfur compounds used in published methods for the preparation of *dl*-cystine. In the first method α-amino-β-chloropropionic acid was treated with barium hydrogen selenide or calcium hydrogen selenide and the product was oxidized to produce the selenium analog of cystine. In the second method, the Gabriel synthesis of amino acids was used to produce the selenium analog from benzyl chloromethyl selenide and sodium phthalimidomalonic ester.

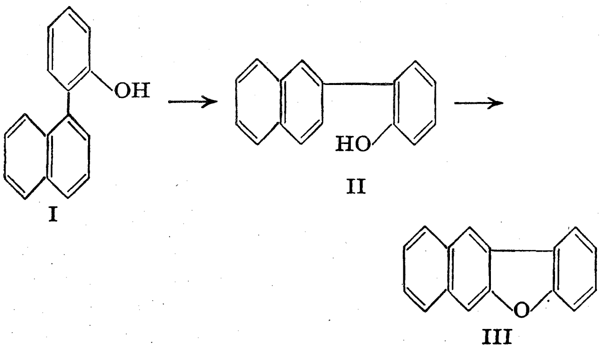
Aromatic Cyclodehydrogenation. VII. Rearrangements in the Phenylnaphthalene Series[1]

BY MILTON ORCHIN[2] AND LESLIE REGGEL[2]

It was shown previously[3] that liquid-phase treatment of 2′-hydroxy-1-phenylnaphthalene, I, with a palladium-on-charcoal catalyst resulted in cyclodehydrogenation to 1,9-benzoxanthene. It was of interest to study the behavior of I under the vapor-phase conditions used in earlier cyclodehydrogenation studies.

Treatment of I with a chromia–alumina catalyst at 490° gave a mixture of conversion products. The first compound to be isolated from this mixture had properties and composition consistent with its formulation as the hitherto unknown 2′-hydroxy-2-phenylnaphthalene, II. It had a higher melting point than I and on treatment with diazotized p-nitroaniline gave a color identical with that observed for I under the same conditions. The ultraviolet absorption spectrum of II differed from that of I in the same manner as the spectrum of 2-phenylnaphthalene differed from that of 1-phenylnaphthalene.[4] Although none of this evidence fixes the position of the hydroxyl group, the isolation of compound III supports its placement in the *ortho* position, as shown in II.



A second compound isolated from the reaction mixture had properties identical with those reported[5] for benzo[b]naphtho[2,3-*d*]furan, III

(brazan); direct comparison with a sample of brazan kindly furnished by Dr. E. Mosettig confirmed the identity. The formation of III from I can be explained by the rearrangement of I to II followed by the intramolecular loss of hydrogen between the hydroxyl group and the naphthalene nucleus.[3] The ultraviolet absorption spectrum of brazan is shown in Fig. 1.[6]

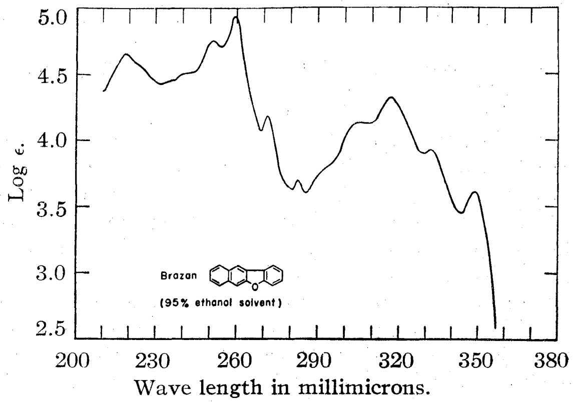

Fig. 1.—Ultraviolet absorption spectrum of brazan.

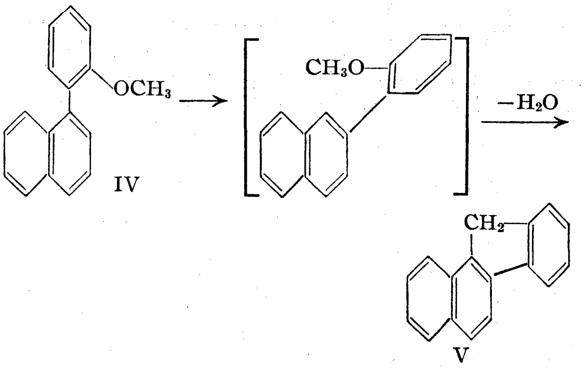
2-Phenylnaphthalene was also isolated from the reaction products.

Treatment of 1-*o*-anisylnaphthalene, IV, with a chromia–alumina catalyst at 510–520° gave a mixture of products from which it was exceedingly difficult to separate pure compounds. The hydrocarbon fraction of the products appeared to be a mixture of 1,2- and 2,3-benzfluorene (ultraviolet absorption spectra) and indeed one fraction, on oxidation, gave a ketone the color and melting point of which were identical with that reported[7] for authentic 1,2-benzfluorenone. The transformation of IV to 1,2-benzfluorene, V, may be explained by assuming the shift of the anisyl group in IV to the *beta* position to give the indicated intermediate, followed by a most unusual intramolecular loss of water (cyclodehydration) to V. The presence of 2,3-benzfluorene can be accounted for by assuming cyclodehydration of the intermediate into the beta position of the naphthalene nucleus.



Although the various fractions from IV were examined intensively by ultraviolet spectra, no evidence was found for the presence of fluoranthene or a substituted fluoranthene. We have previously shown[8] that 1-phenylnaphthalene undergoes cyclodehydrogenation to fluoranthene in good yield, and that there is only slight migration of the phenyl group to give 2-phenylnaphthalene. The present work makes it appear probable that in some cases migration of a group from the 1- to the 2-position of the naphthalene nucleus takes precedence over cyclodehydrogenation involving the 8-position.

Experimental[9]

Apparatus and Catalysts.—The apparatus used was similar to that employed in earlier experiments.[10] The catalyst tube was vertical and was heated by means of a standard combustion furnace. A detailed drawing and photograph of the apparatus will be found in a Bureau of Mines publication.[11] The catalyst, designated as Cr-181, was purchased from the Harshaw Chemical Company, Cleveland, Ohio.[8]

Conversion of 2′-Hydroxy-1-phenylnaphthalene, I.—During the course of two hours, 7.1 g. of molten I[3] was passed over 76 g. of catalyst at 490°. The partly crystalline material in the receiver weighed 6.18 g. This material was refluxed for a short time with a small volume of petroleum ether and the insoluble material filtered to give 1.4 g., melting point 78–91°. Three recrystallizations gave 0.47 g. of colorless crystals, m. p. 96.2–96.8°. *Anal.* Calcd. for $C_{16}H_{12}O$: C, 87.2; H, 5.5. Found: C, 87.7; H, 5.7. When this compound was tested with diazotized *p*-nitroaniline,[12] it produced a deep color identical with that obtained when I was similarly treated. The infrared absorption spectrum of the compound showed a strong band in the 2.8 micron region, indicating the presence of a hydroxyl group. The compound is regarded as 2′-hydroxy-2-phenylnaphthalene, II. The ultraviolet absorption spectrum of this compound has been reported.[4] Ferric chloride tests in aqueous and alcoholic solutions were negative with both 2′-hydroxy-1-phenyl- and 2′-hydroxy-2-phenylnaphthalene.

All mother liquors were combined and chromatographed on alumina–celite. Two percolate fractions were collected, the column extruded, and arbitrarily cut into four fractions. The first percolate fraction on evaporation gave a small (unweighed) quantity of material with the odor and appearance of naphthalene; it was discarded. Evaporation of the second percolate fraction gave 0.7 g. of material which after one crystallization from methanol was obtained as colorless crystals, m. p. 99.4–102.2°; mixed melting point with authentic 2-phenylnaphthalene[4] showed no depression. The fractions on the chromatographic column were called 3, 4, 5, and 6 in order of increasing strength of adsorption. Fraction 3 on elution gave 0.22 g. of an obvious mixture which was not investigated. Fraction 5 (0.10 g.) was also not investigated. Fraction 6 consisted of 4.57 g. of a very viscous liquid which was probably a mixture of I and II. Frac-

tion 4 gave 0.12 g. of material, which, after two recrystallizations from ethanol, was obtained as colorless plates, m. p. 209.2–209.8°. *Anal.* Calcd. for $C_{16}H_{10}O$: C, 88.1; H, 4.6. Found: C, 88.3; H, 5.1. This material was identical (melting point, mixed melting point, ultraviolet absorption spectrum) with a sample of brazan obtained from Dr. E. Mosettig (secured from the Gesellschaft fur Teerverwertung).[13] It has been reported[5] that brazan does not form a picrate. We have found that the *s*-trinitrobenzene complex of brazan is very unstable, but that it readily forms a complex with 2,4,7-trinitrofluorenone[14] in the usual manner. The complex crystallized from benzene–alcohol in orange needles, m. p. 215.2–216.0°. *Anal.* Calcd. for $C_{29}H_{15}N_3O_8$: C, 65.3; H, 2.8. Found: C, 66.5; H, 3.0.

Conversion of 1-*o*-Anisylnaphthalene, IV.—During two and one-half hours, 11.25 g. of molten IV[3] was passed over 98 g. of catalyst at 510–520°. The partly crystalline product weighed 6.4 g. Four recrystallizations gave 0.22 g. of material which still had not reached a constant melting point. The material was converted to the trinitrofluorenone[14] complex, the orange needles recrystallized twice, and then decomposed by chromatography on alumina. The recovered hydrocarbon portion, melting point 203.0–205.2°, was still impure and was shown by ultraviolet absorption spectra (Fig. 2) to be a mixture of 1,2-benzfluorene and 2,3-benzfluorene.[15] About 0.08 g. of the impure material was refluxed with 0.20 g. of sodium dichromate dihydrate in 5 cc. of acetic acid for fifteen minutes, the mixture poured into water, and extracted with benzene. The benzene solution was extracted with sodium carbonate and the neutral portion chromatographed on alumina. Two bands were observed, separated, and eluted. The bottom orange colored band consisted of 29 mg.; recrystallization gave orange crystals, m. p. 129.4–132.4°. *Anal.* Calcd. for $C_{17}H_{10}O$: C, 88.7; H, 4.4. Found: C, 88.4; H, 4.3. The analysis, melting point, and appearance of this compound are consistent with that of 1,2-benzfluorenone.[7] The upper yellow band from the chromatography of the oxidation products consisted of 27 mg. and could not be recrystallized. The ultraviolet absorption spectrum was very similar to that of authentic 2,3-benzfluorenone.

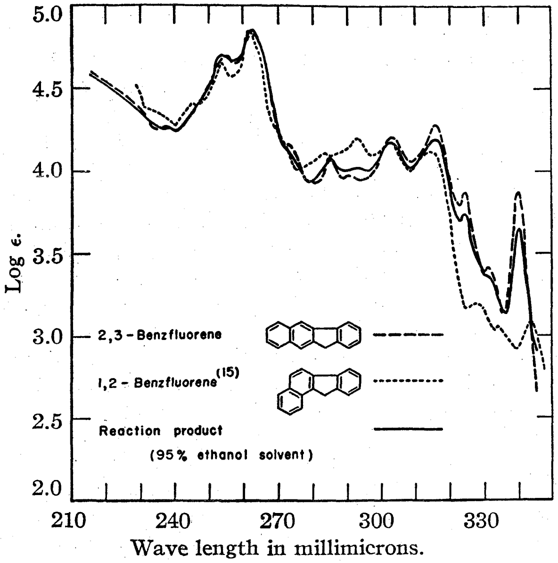

Fig. 2.—Ultraviolet absorption spectra.

The mother liquor containing 6.3 g. of the conversion product was evaporated to dryness. A methoxyl determination indicated that only a very small amount (2%) of this mixture could be unchanged starting material. All the product was dissolved in benzene and extracted with Claisen alkali. The alkali-soluble fraction weighed 2.5 g.; ultraviolet absorption spectrum indicated it was principally 2′-hydroxy-1-phenylnaphthalene, I. Chromatography of the neutral fraction (4.0 g.) gave 0.02 g. of naphthalene, 0.06 g. of 2-phenylnaphthalene, a third fluorescent fraction of 2.7 g. and a fourth fraction of 0.3 g. The ultraviolet absorption spectrum of fraction 4 indicated that it was a mixture of 1,2- and 2,3-benzfluorenes. The ultraviolet absorption spectrum of fraction 3 indicated principally a mixture of 1,2- and 2,3-benzfluorenes with some 1,9-benzoxanthene, but no pure compounds could be isolated by crystallization of the mixture, of the T. N. F. complexes, chromatography, or crystallization of the T. N. B. complexes.

Summary

Vapor phase treatment of 2′-hydroxy-1-phenylnaphthalene over a chromia–alumina catalyst gave a mixture of products from which a compound of the probable structure of 2′-hydroxy-2-phenylnaphthalene was isolated. There was also obtained benzo[b]naphtho[2,3-*d*]furan (brazan).

Vapor phase treatment of 1-*o*-anisylnaphthalene gave a mixture of products among which 1,2- and 2,3-benzfluorene were shown to be present. These compounds were probably formed by the migration of the anisyl group to the *beta* position followed by an unusual type of cyclodehydration between the methoxyl group and the aromatic nucleus.

PITTSBURGH, PENNSYLVANIA RECEIVED OCTOBER 14, 1947

---

(13) A strictly unambiguous proof of structure of brazan is still lacking since, as Robinson and Mosettig have indicated, their synthesis gave two isomers, one of which was identical with the German commercial sample and to which they therefore assigned the structure of benzo[b]naphtho[2,3-*d*]furan (brazan).

(14) Orchin and Woolfolk, THIS JOURNAL, **68**, 1727 (1946).

(15) The ultraviolet absorption spectrum of 2,3-benzfluorene was obtained from a carefully purified authentic sample in our possession. The spectrum of 1,2-benzfluorene was obtained from the work of Mayneord and Roe, *Proc. Roy. Soc.* (*London*), **A158**, 634 (1937). Since the latter spectrum was determined in chloroform solution, we determined the spectrum of 2,3-benzfluorene in both alcohol and chloroform; band shifts were of the order of 1–3 mμ, and extinction coefficients were practically identical. On this basis the small band shifts could be safely applied to the corresponding bands in 1,2-benzfluorene, to produce a reliable spectrum of this compound in alcohol for comparison purposes. The spectra of the two benzfluorenes are very similar; the chief differences are not found in the location of band maxima, but in the extinction coefficients. The coefficients of our sample are intermediate between those of the two benzfluorenes.

Preparation of New Derivatives of Diethylstilbestrol and Hexestrol. II. Extension of the Claisen Rearrangement

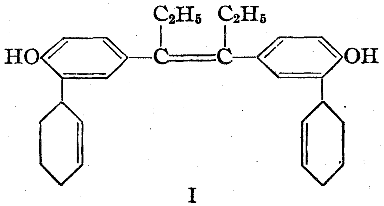
BY EMIL KAISER, A. L. ANDERSEN, JR., AND J. J. SVARZ

Rearrangement of the diallyl ethers of diethylstilbestrol and hexestrol to the corresponding 3,3'-disubstituted derivatives has been reported.[1]

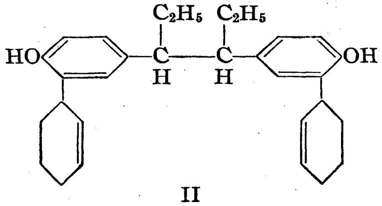
These investigations were extended to the study of the behavior of the di-2-cyclohexene-1-yl ethers of synthetic estrogens. Heretofore only one other application of the Claisen rearrangement to 2-cyclohexene-1-yl phenol ethers has been described.[2] The 2-cyclohexene-1-yl ether of phenol was pyrolyzed at 215° yielding 5% of *o*-cyclohexene-2-phenol.

The di-2-cyclohexene-1-yl ether of diethylstilbestrol was prepared by two different methods: Method I, the reaction between 1-bromocyclohexene-2, diethylstilbestrol and potassium carbonate in methyl ethyl ketone; Method II, the reaction between 1,2-dibromocyclohexane and diethylstilbestrol in the presence of sodium alcoholate. Method I yielded 12% of the theoretical amount of di-2-cyclohexene-1-yl ether of diethylstilbestrol. Method II, an adaptation of the procedure of Solonina,[3] yielded 25 to 35% of the same compound. Method II was therefore used to prepare the dicyclohexene ether of hexestrol.

The di-2-cyclohexene-1-yl ethers were rearranged to the 3,3'-disubstituted derivatives by refluxing in diethylaniline in an atmosphere of nitrogen. 3,3'-Di-(2-cyclohexene-1-yl)-diethylstilbestrol (I) was isolated in a 25% yield and 3,3'-di-(2-cyclohexene-1-yl)-hexestrol (II) in a 38% yield.



I



II

A better yield of rearrangement products averaging 65 to 67% was obtained by the use of benzoic anhydride in the reaction mixture. The dibenzoates of the 3,3'-disubstituted products were formed in this reaction. Saponification of the dibenzoates yielded 3,3'-di-(2-cyclohexene-1-yl)-diethylstilbestrol and 3,3'-di-(2-cyclohexene-1-yl)-hexestrol, respectively. These compounds were identical to those formed by the rearrangements of the di-2-cyclohexene-1-yl ethers without the use of benzoic anhydride.

Experimental[4]

Di-2-cyclohexene-1-yl Ether of Diethylstilbestrol. Method I.—Diethylstilbestrol and 1-bromocyclohexene-2 were treated in the same manner as described for allyl phenyl ether.[5]

The di-2-cyclohexene-1-yl ether of diethylstilbestrol was crystallized from methanol, m. p. 118–119°, yield 12.1%.

Method II.—Twenty grams of 1,2-dibromocyclohexane was added to a solution prepared by dissolving 4 g. of sodium and 10.72 g. of diethylstilbestrol in 100 ml. of absolute ethanol and the mixture refluxed for twenty-four hours. The solution was then concentrated under reduced pressure and treated with a solution of 10 g. of sodium hydroxide in 100 ml. of water. The alkaline solution was extracted with ethyl ether and the ether layer washed with 100 ml. of 10% aqueous sodium hydroxide and water. The ether was removed by distillation and the residue crystallized twice from 100-ml. portions of 95% ethanol; m. p. 117–119°; yield 4.43 g. (25.3%).

Anal. Calcd. for $C_{30}H_{36}O_2$: C, 84.08; H, 8.46. Found: C, 84.08; H, 8.57.[6]

Preparation of 3,3'-Di-(2-cyclohexene-1-yl)-diethylstilbestrol.—Two grams of the di-2-cyclohexene-1-yl ether of diethylstilbestrol was dissolved in 15 ml. of diethylaniline and the solution refluxed for seven hours in an atmosphere of nitrogen. The diethylaniline was removed and the product crystallized from an ethyl ether–petroleum ether mixture as described for 3,3'-diallyldiethylstilbestrol.[1] The substance was recrystallized by dissolving in 10 ml. of ethanol and adding 10% of water to the hot solution; yield 0.5 g. (25%), m. p. 154–156°.

Anal. Calcd. for $C_{30}H_{36}O_2$: C, 84.08; H, 8.46. Found: C, 83.62; H, 8.86.[7]

Preparation of the 3,3'-Di-(2-cyclohexene-1-yl)-diethylstilbestrol Dibenzoate.—One and a half grams of the di-(2-cyclohexene-1-yl)-diethylstilbestrol and 3 g. of benzoic anhydride were dissolved in 15 ml. of diethylaniline and refluxed for six hours in an atmosphere of nitrogen. After cooling 100 ml. of 2 *N* hydrochloric acid was added and the mixture extracted with ether. The ether layer was washed with 2 *N* acid, water, and dried over sodium sulfate. It was then concentrated to about 15 ml. and 30 ml. of methanol added. The dibenzoate crystallized in the cold. It was recrystallized by dissolving in 15 ml. of carbon tetrachloride and adding 30 ml. of methanol; yield 1.5 g., m. p. 188–199°.

[6] Analysis made at the California Institute of Technology, Pasadena, California.

[7] Figures obtained for the percentage of carbon were consequently lower than the calculated values, regardless whether the compound was obtained by rearrangement of the ether or by saponification of the dibenzoate. The carbon values of the dibenzoate checked well with the calculated values. Such irregularities have been reported previously for 4,4'-dioxy-2,2-methyl-α,β-diphenylbutane by Bretschneider, de Ionze Bretschneider and Ajtai, *Ber.*, **74**, 571 (1941).

Anal. Calcd. for $C_{44}H_{44}O_4$: C, 82.98; H, 6.97. Found: C, 82.96; H, 7.15.[6]

Saponification of 3,3′-Di-(2-cyclohexene-1-yl)-diethylstilbestrol Dibenzoate.—One-half gram of 3,3′-di-(2-cyclohexene-1-yl)-diethylstilbestrol dibenzoate was refluxed for two hours in an atmosphere of nitrogen with 10 ml. of a 10% potassium hydroxide–isopropanol solution. After cooling the mixture was diluted with 30 ml. of water and acidified with *N* hydrochloric acid. An oil precipitated which solidified on standing at room temperature. This was filtered, washed with water and dissolved in 10 ml. of ethanol. The solution was clarified with a small amount of charcoal. After filtration 10% of water was added and the solution cooled. Crystals were obtained which melted at 153–156° and were identical to the 3,3′-di-(2-cyclohexene-1-yl)-diethylstilbestrol obtained by rearrangement of the ether; yield 0.15 g.

Anal. Calcd. for $C_{30}H_{36}O_2$: C, 84.08; H, 8.46. Found: C, 83.25; H, 8.56.[8]

Di-2-cyclohexene-1-yl Ether of Hexestrol.—Ten and eight-tenths grams of hexestrol was treated in the same manner as described in Method II for the preparation of the di-2-cyclohexene-1-yl ether of diethylstilbestrol. The product obtained after treatment with alkali was crystallized twice from 95% ethanol; m. p. 123–124°, yield 5.86 g. (34.1%).

Anal. Calcd. for $C_{30}H_{38}O_2$: C, 83.66; H, 8.89. Found: C, 83.57; H, 8.68.[6]

3,3′-Di-(2-cyclohexene-1-yl)-hexestrol.—This compound was prepared in the manner described for 3,3′-di-(2-cyclohexene-1-yl)-diethylstilbestrol. One and a half grams of the di-2-cyclohexene-1-yl ether of hexestrol yielded 0.58 g. of rearranged product; m. p. 169–171°.

Anal. Calcd. for $C_{30}H_{38}O_2$: C, 83.66; H, 8.89. Found: C, 83.4; H, 9.06.[6]

3,3′-Di-(2-cyclohexene-1-yl)-hexestrol Dibenzoate.—This compound was prepared in the manner described for 3,3′-di-(2-cyclohexene-1-yl)-diethylstilbestrol dibenzoate. One gram of the di-2-cyclohexene-1-yl ether of hexestrol when treated with 2 g. of benzoic anhydride in diethylaniline and crystallized from a carbon tetrachloride–methanol mixture yielded 0.98 g. of a product melting at 198–201°. Repeated analysis showed the existence of one mole of methanol of crystallization.

Anal. Calcd. for $C_{44}H_{46}O_4 \cdot CH_3OH$: C, 80.56; H, 7.51. Found: C, 80.64,[6] 80.51,[8] 80.80[9]; H, 7.06,[6] 7.25,[8] 6.95.[9]

The methanol of crystallization was removed by drying in high vacuum.

Anal. Calcd. for $C_{44}H_{46}O_4$: C, 82.72; H, 7.29. Found: C, 82.04; H, 7.47.[9]

3,3′-Di-(2-cyclohexene-1-yl)-hexestrol Dipropionate.—Twenty-seven hundreths of a gram of 3,3′-di-(2-cyclohexene-1-yl)-hexestrol was refluxed with 10 ml. of propionic anhydride for two and one-half hours. The product obtained after hydrolysis of the mixture with water was crystallized twice from 95% ethanol; yield 0.15 g., m. p. 133.5–135°.

Anal. Calcd. for $C_{36}H_{46}O_4$: C, 79.66; H, 8.54. Found: C, 79.5; H, 8.46.[8]

Summary

The di-2-cyclohexene-1-yl ethers of diethylstilbestrol and hexestrol have been prepared by two methods. Application of the Claisen rearrangement to these compounds produced the corresponding 3,3′-disubstituted derivatives. Use of benzoic anhydride in the rearrangement of the ethers increased the yield considerably.

Structure Determination and Synthesis of a Plant Growth Inhibitor, 3-Acetyl-6-methoxybenzaldehyde, Found in the Leaves of *Encelia Farinosa*

BY REED GRAY AND JAMES BONNER

Introduction

In a recent publication[1] it was demonstrated that the leaves of *Encelia farinosa* when applied to tomato and to other plants exert a marked inhibition of growth. The toxic principle was removed by extracting the dry *Encelia* leaves with purified ether. Water and ether extracts of the *Encelia* leaves, when fed to tomato seedlings in solution culture, caused death of the plants within one day. Fractionation of the leaf extracts led to the isolation of a pure crystalline compound which was toxic when fed to tomato seedlings in solution culture. It was suggested that the presence of the growth inhibitor in the leaves may be responsible for the fact that only few individuals of desert annuals are found growing in close relationship with the *Encelia* shrub on the desert.

The present work is concerned with the characterization and synthesis of this new toxic compound which was isolated from the *Encelia* leaves.

Experimental

Physical and Chemical Properties.—The toxic material crystallizes in colorless needles from ether or alcohol, m. p. 144°. Sublimation causes no change in melting point. The compound has no odor but when the crystals are heated a pleasant perfume-like odor is detected. It burns with a smoky flame leaving no residue after ignition. A sodium fusion showed the absence of nitrogen, sulfur and halogens. Evidently the compound is composed only of the elements carbon, hydrogen and oxygen. The compound is soluble in hot water, warm ether, alcohol, acetone, benzene and chloroform. It is insoluble in cold water, 5% hydrochloric acid, 5% sodium hydroxide, petroleum ether and carbon tetrachloride. It dissolves in

---

(1) Gray and Bonner, *Am. J. Bot.*, Jan. (1948).

concentrated sulfuric, hydrochloric, and hydrobromic acids producing orange-colored solutions.

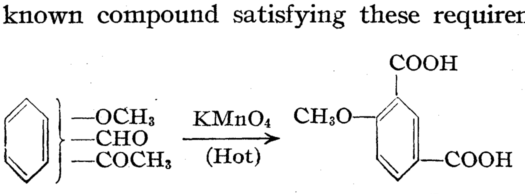
Classification tests[2] carried out on the toxic compound gave the following results: A red color with anhydrous aluminum chloride and chloroform, a substitution reaction with bromine in chloroform, a brown precipitate with cold permanganate solution, a precipitate with 2,4-dinitrophenylhydrazine reagent, a green color with Fehling solution, a black precipitate with Tollens reagent, a violet color with Schiff reagent, a positive test for methyl ketones with both sodium nitroprusside[3] and *o*-nitrobenzaldehyde,[3] no color with ferric chloride, or with the hydroxamic acid test[4] for esters. When heated in alkaline solution a new compound is formed as a result of condensation, m. p. 260–265° with decomposition. These tests show that an aldehyde and a methyl ketone group may be present in the toxic compound which also contains a benzene ring.

2,4-Dinitrophenylhydrazine Derivative.—A cold saturated solution of 2,4-dinitrophenylhydrazine in 95% ethyl alcohol was added to 5 mg. of the compound dissolved in 1 cc. of alcohol. After adding a drop of conc. hydrochloric acid, an orange precipitate formed immediately. The derivative was filtered off, washed twice with alcohol and dried, m. p. 258–261°. The derivative was insoluble in most organic solvents, and could be recrystallized only from nitrobenzene.

Quantitative Analysis.—A micro analysis[5] of the pure compound gave results agreeing closely with the empirical formula $C_{10}H_{10}O_3$. Calcd. for $C_{10}H_{10}O_3$: C, 67.14; H, 5.82; mol. wt., 178. Found: C, 67.41; H, 5.62; mol. wt. (Rast), 192; $-OCH_3$, 17.98.

A calculation of the molecular weight assuming one methoxyl group per molecule gives 172. A quantitative precipitation with 2,4-dinitrophenylhydrazine using the method described above shows that two moles of the reagent combine with one mole of the toxic compound giving 184 for the molecular weight. A Zerewitinoff determination showed the absence of active hydrogen.

The results indicate that the toxic compound is a benzene derivative containing an aldehyde, methyl ketone, and a methoxyl group, and having a molecular weight in the range 172–192. Considering the molecular formula ($C_{10}H_{10}O_3$) to be correct, no other groups could be present. A search in the chemical literature revealed no known compound satisfying these requirements, therefore, degradation to simpler known compounds was undertaken.



I II (1)

Oxidation with Hot Permanganate.—A 20-mg. sample of the toxic compound was mixed with 2 cc. of saturated potassium permanganate solution in a small reflux tube. The tube was sealed and heated on a steam-bath until the color of the permanganate had disappeared; this took two and one-half hours. The tube was cooled, opened, and the contents emptied into a centrifuge tube. After centrifuging, the clear supernatant was drawn off. Upon acidifying with dilute hydrochloric acid, a white precipitate formed. The precipitate was filtered off, recrystallized from hot water, dried and sublimed, m. p. 264–267°.

Examination of the carboxylic acid derivatives of anisole found in the literature gave the following possibilities for the oxidation product of the toxic compound: 5-methoxyisophthalic acid, m. p. 265,[6] 270°,[7] 4-methoxyisophthalic acid, m. p. 245,[8] 261,[9] 275°[10]; 2-methoxyterephthalic acid, m. p. 274–276, 277–279°, 281°.[11] The melting points of these acids vary considerably as determined by different investigators. Therefore, the acids were synthesized in order that mixed melting points with the oxidative product of the toxic compound could be taken.

5-Methoxyisophthalic Acid.—This compound was prepared by methylating 5-hydroxy-1,3-dimethylbenzene with dimethyl sulfate and oxidizing the side chains with permanganate as described above. After recrystallizing from hot water and subliming it melted at 269–270°. A mixed melting point with the oxidation product of the toxic compound gave a considerable depression.

4-Methoxyisophthalic Acid (II). (a) Prepared from *p*-Cresol.—An aldehyde group was substituted in the position ortho to the phenolic group of *p*-cresol using chloroform and alkali (Reimer–Tiemann reaction). The resulting 3-methyl-6-hydroxybenzaldehyde was methylated with dimethyl sulfate and then the side chains were oxidized to acids with permanganate. The product was recrystallized from hot water, dried and sublimed, m. p. 264–267°. A mixed melting point determination with the oxidation product of the natural toxic compound gave no depression in melting point.

(b) Prepared from 2,4-Dimethylphenol.—By methylating 5 g. of this compound with dimethyl sulfate in strong alkali, the methyl ether was obtained, b. p. 192°. To 2.72 g. of the ether in a round-bottomed flask fitted with a reflux condenser was added 200 cc. of water containing 12.64 g. of potassium permanganate. The mixture was heated on a steam-bath until the color of the permanganate had all disappeared (eight hours). The manganese dioxide was filtered off and the filtrate acidified with hydrochloric acid. The white crystals which separated were filtered off, recrystallized from hot water, and dried in an oven, m. p. 273–275°, yield 1 g., 25% of theoretical. After subliming the melting point was lowered to 264–267°.

The above reaction tentatively establishes the identity of the oxidative product of the toxic compound with 4-methoxyisophthalic acid (II). This indicates that the toxic compound which contains an aldehyde and a methyl ketone group must be either 3-acetyl-6-methoxybenzaldehyde,

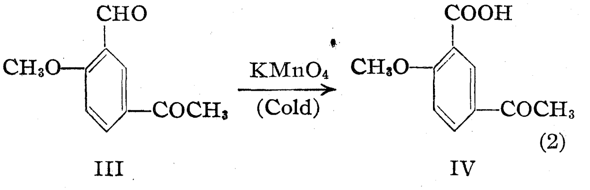
or 3-acetyl-4-methoxybenzaldehyde. The question as to which isomer is the correct one was answered by a selective oxidation of the aldehyde group with cold potassium permanganate solution.[2]



(2)

Selective Oxidation of the Aldehyde Group.—A sample of 30 mg. of the toxic compound was mixed in a small test-tube with 1 cc. of saturated potassium permanganate solution. The mixture was shaken for forty-five minutes, centrifuged and the supernatant drawn off. A few drops of ethyl alcohol were added to reduce the excess permanganate. A drop of 5 *N* sodium hydroxide solution hastened the reaction. After the violet color had disappeared the solution was heated to 60° on a water-bath and centrifuged. The clear supernatant was drawn off and concentrated to 0.33 cc. by bubbling air through the solution while heating on a water-bath. The solution was acidified with dilute hydrochloric acid. After standing for a few minutes, crystals began to separate and after two hours the crystals were filtered off and recrystallized from hot water. The yield was approx. 10 mg., m. p., 150–151°. This product gave a positive test for methyl ketones but gave a negative test for aldehydes.

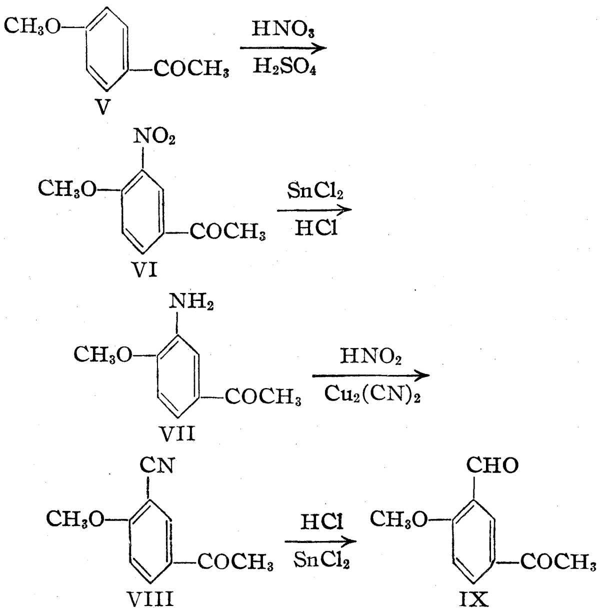
The identity of this cold permanganate oxidative product was established by its synthesis. The literature[12] reports 152° as the melting point of 3-acetyl-6-methoxybenzoic acid. (IV) This compound was synthesized and a mixed melting point determination made with the cold permanganate oxidative product of the toxic compound.

3-Acetyl-6-methoxybenzoic Acid (IV).—The corresponding phenol was prepared according to the directions of Bialobrzeski and Menki[13] and methylated as described by Krannichfeldt.[12] The product after recrystallization from hot water melted at 150–151°, and a mixed melting point with a cold permanganate oxidative product of the toxic compound showed no depression.

This determination shows that the aldehyde group is ortho to the methoxyl group and that the methyl ketone group must be in the para position. Therefore the structure of the toxic compound isolated from the *Encelia* leaves is established as 3-acetyl-6-methoxybenzaldehyde (III). This compound has not been reported in the chemical literature.

Synthesis

Since more of the toxic compound was needed for physiological testing, and since it had not been prepared before, synthesis of the compound was undertaken. A number of methods for synthesis of aromatic aldehydes and ketones were tried without success. A method was found by which the compound could be prepared, however, starting with *p*-methoxyacetophenone, according to the scheme



4-Methoxy-3-nitroacetophenone (VI).—The preparation of this compound was accomplished by nitration of 50 g. of *p*-methoxyacetophenone (V) according to the procedure of Bogert and Curtin[14]; yield 61.6 g., 95%; m. p. 96–98°.

3-Amino-4-methoxyacetophenone (VII).—The preparation of the amino compound from the corresponding nitro compound using tin and hydrochloric acid has been mentioned by Bogert and Curtin.[14] Directions were not given. In the present work poor yields and a colored product were obtained using tin and hydrochloric acid. It was found that stannous chloride in hydrochloric acid gave better yields and a colorless product.

Powdered stannous chloride dihydrate (180 g.) was dissolved in 180 cc. of concd. hydrochloric acid contained in a 1-liter Erlenmeyer flask. The solution was cooled to 0° in an ice–salt-bath and 40 g. of 4-methoxy-3-nitroacetophenone was added all at once with stirring. The ice-bath was removed, and the nitro compound dissolved as the reaction proceeded. When the heat of the reaction had raised the temperature to 95°, the flask and contents were cooled to 85° in the ice-bath and then the ice-bath was removed.

Light yellow crystals of the double salt of the hydrochloride of the amine and stannic chloride started to separate immediately. The mixture was stirred and allowed to cool slowly to room temperature. The mixture was cooled in the ice-bath and the double salt was filtered off. The amine was released by adding 50 cc. of water to the salt and then adding an excess of 40% sodium hydroxide solution. The amine was filtered off by suction, washed with cold water, and recrystallized from alcohol. Small colorless platelets were obtained which melted at 100–101°; yield, 25.7 g., 76% of theoretical.

3-Acetyl-6-methoxybenzonitrile (VII).—The nitrile was also prepared by Bogert and Curtin[14] using the Sandmeyer method, but no details were given. Borsche and Barthenheier[15] prepared this compound from *o*-methoxybenzonitrile using the Friedel–Crafts synthesis. The original Sandmeyer method with some modification was found to give a reasonably good yield.

To 20 g. of cuprous chloride suspended in 80 cc. of water was added a solution containing 30 g. of sodium cyanide dissolved in 50 cc. of water. Heat was evolved and after cooling, the solution was filtered. An additional 160 cc. of water was added and the solution cooled to 0°

in an ice–salt-bath. Meanwhile, 18 g. of 3-amino-4-methoxyacetophenone was mixed with 100 cc. of water. To this mixture was added 20 cc. of concentrated hydrochloric acid. The amine dissolved and 18 cc. more of concd. hydrochloric acid was added. The solution was cooled to 0° in an ice–salt-bath with stirring. Fine crystals of the amine hydrochloride separated. The cold solution was diazotized by adding from a dropping funnel a cold solution of 11 g. of sodium nitrite dissolved in 50 cc. of water, until an excess was indicated by starch iodide paper. The temperature was kept at 0° during the reaction. The diazonium solution was poured slowly with vigorous shaking into the cold cuprous cyanide solution contained in a 2-liter Erlenmeyer flask. A yellow-brown precipitate formed. Both solutions were kept at 0° until the addition was complete. The mixture was stirred for two hours longer while allowing the contents to reach room temperature. The mixture was then heated on a water-bath for thirty minutes and finally heated to boiling over a burner. The reaction was carried out under a hood, as hydrogen cyanide is given off. The mixture was cooled, filtered, and the residue dried in the room. The residue was extracted with hot benzene. A white copper salt remained behind. From the hot benzene solution light yellow needles of 3-acetyl-6-methoxybenzonitrile (VIII) crystallized, m. p. 157–158°; yield, 13.1 g., 68.5% of theoretical. Bogert and Curtin[14] report the m. p. 159.5°, while Borsche and Barthenheier[15] report 155° for the melting point of the nitrile.

3-Acetyl-6-methoxybenzaldehyde (IX).—This compound has not been reported previously. The aldehyde was prepared from the corresponding nitrile using Stephen's reaction. After a number of experiments it was found that the following conditions gave the best yield.

To 20 g. of anhydrous stannous chloride (prepared by the action of acetic anhydride on stannous chloride dihydrate) contained in a 3-necked flask fitted with a reflux condenser, a mercury sealed stirrer, and an inlet tube reaching nearly to the bottom of the flask, was added 200 cc. of absolute ether. Dry hydrogen chloride was passed in through the inlet tube while stirring the mixture. After four hours a clear lower layer separated, and the inlet tube was replaced by a dropping funnel. A solution of 12.7 g. of 3-acetyl-6-methoxybenzonitrile dissolved in 80 cc. of warm chloroform was added in a small stream from the dropping funnel while stirring vigorously. After a few minutes crystals of the aldimine-stannichloride began to separate. Dry hydrogen chloride was again passed into the solution for one and one-half hours. Stirring was continued one-half hour longer and the flask and contents were allowed to stand overnight. The yellow precipitate of the aldimine-stannichloride was filtered off and washed with 50 cc. of dry ether. The salt was heated with 100 cc. of water and filtered. The residue and filtrate were both extracted with benzene. The aldehyde was removed from the benzene by extracting with 20% sodium bisulfite solution. The aldehyde was released upon acidifying and heating the bisulfite solution. After cooling, the 3-acetyl-6-methoxybenzaldehyde (IX) was filtered off and dried. It was recrystallized from alcohol, m. p. 141–143°, yield, 5.05 g., 39% of theoretical. After recrystallizing from ether the melting point was 143–144°. This compound gave an aldehyde test with Schiff reagent and a positive test for methyl ketones with sodium nitroprusside reagent.[3] A mixed melting point with the natural toxic compound isolated from *Encelia* leaves showed no depression in melting point.

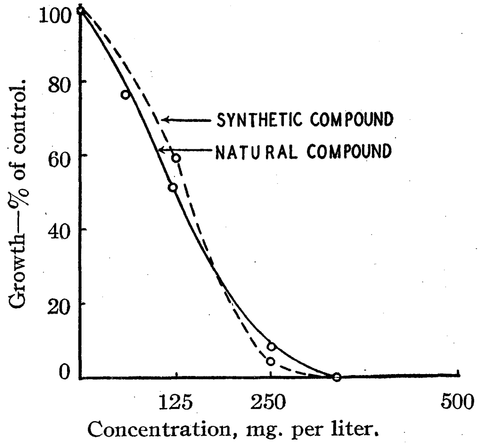

Fig. 1.—Effect of varying concentrations of synthetic and natural 3-acetyl-6-methoxybenzaldehyde on the growth of tomato seedlings in solution culture.

Thus the identity of the toxic compound has been confirmed by its synthesis. This method provides a way by which other aromatic compounds containing an aldehyde and a ketone group on the same ring may be synthesized.

Inhibitory Effect of Synthetic and Natural Compound and Activity of Related Compounds.—The inhibitory effect of the synthetic compound was compared to that of the natural compound. Both compounds were tested in the same concentrations using the toxic assay test described earlier,[1] in which the compounds to be tested are supplied to young tomato seedlings in solution cultures. The results are shown in Fig. 1. It may be seen that the inhibitory effect of the synthetic aldehyde is essentially the same as that of the natural aldehyde. Concentrations of 250 mg. per liter caused death of most of the plants and concentrations of about 125 mg. per liter caused 50% inhibition of growth of the tomato seedlings in both cases.

Substances related to the toxic compound which was isolated from *Encelia* leaves were tested to determine which group or combination of groups is responsible for the toxic effect. The pure compounds were weighed out and dissolved in a known volume of distilled water, the difficultly soluble solid compounds being taken up in hot water. These solutions were mixed with an equal volume of Hoagland's nutrient solution and fed to tomato seedlings contained in vials. The plants were measured at the time of transplanting and again after growing in the greenhouse at a constant temperature of 80° F. for one week. Four or five dilutions of each substance (1000, 500, 250, 125, and 0 mg. per liter) were tested using ten plants for each dilution. Concentration of inhibitor was plotted against growth in height as percentage of control for each substance as in Fig. 1, and the values for 50% inhibition determined by interpolation. The results are shown in Table I.

It may be seen from the table that benzene itself is not toxic and that substitution of a methyl ether group in the ring does not increase the toxicity. Introduction of an aldehyde group greatly increases the inhibitory activity, whereas a methyl ketone (acetyl) group is much less inhibitory than the aldehyde group. Combination of a methyl ketone group with a methoxyl group is more inhibitory than the combination of aldehyde and methoxyl groups. The toxic compound isolated

TABLE I

INHIBITORY ACTIVITY OF PURE COMPOUNDS ON GROWTH OF TOMATO SEEDLINGS

(3-acetyl-6-methoxybenzaldehyde) which contains all three groups is more toxic than combinations of any two of the other groups. The substitution of a cyano, nitro, or amino group for the aldehyde group causes increased inhibition, the amino group having the most toxic effect. The last two columns in the table show that most of these compounds do not cause death of the plants even though they may cause more inhibition in height growth than the naturally occurring inhibitor. Only the nitro, cyano, and amino substituted analogs brought about as high a mortality as the natural substance itself.

Acknowledgment.—The authors wish to express their appreciation to Dr. E. R. Buchman and to Dr. David R. Howton, Gates and Crellin Laboratories of Chemistry, California Institute of Technology, for their advice, assistance and encouragement in the prosecution of this work.

Summary

1. The structure determination and synthesis of a new compound, 3-acetyl-6-methoxybenzaldehyde, which was isolated from the leaves of *Encelia farinosa* is given.

2. The inhibitory activity of the toxic compound and other related compounds on the growth of tomato seedlings in solution culture is demonstrated.

Crystalline Vitamin A Methyl Ether[1a]

BY A. R. HANZE, T. W. CONGER, E. C. WISE* AND D. I. WEISBLAT

The increased interest in vitamin A syntheses has placed vitamin A methyl ether in a position of considerable prominence, since its synthesis should be less difficult than that of the alcohol or its esters. The synthesis of vitamin A ethers recently has been the subject of numerous papers and patents.

Kipping and Wild[1] were the first to outline a possible synthesis of vitamin A methyl ether but no further work has appeared giving the results of this proposed synthesis. Oroshnik[2] reported a synthesis of vitamin A methyl ether which gave two fractions whose absorption maxima differed from that of vitamin A by 10 and 13 $m\mu$. No methoxyl analysis or biological assay of these fractions has been published. Milas[3] has published the synthesis of a product having a reproducible activity of 1.5 to 3.0% that of vitamin A. Cornwell[4] reported a synthesis of an ether of vitamin A, identifying the product by spectrophotometric data only. Isler, *et al.*,[5] reported the synthesis of a product having a potency greater than that of β-carotene.

In spite of the large amount of work done on vitamin A methyl ether, no one had reported the preparation of a product of sufficient purity for the property determination of its properties. For this reason we undertook the synthesis of pure vitamin A methyl ether and in a preliminary report have given[6] its physical properties and biological potency. The complete experimental details as to its preparation as well as the behavior of vitamin a methyl ether under various experimental conditions are given here.

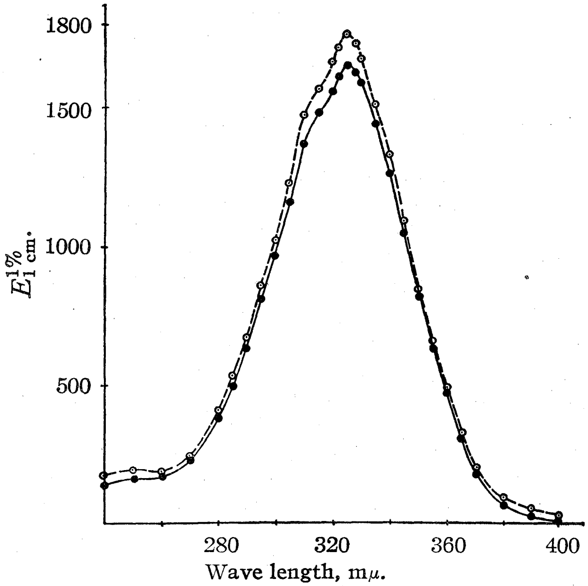

Fig. 1.—Spectrophotometric curves of vitamin A methyl ether, ●, and of vitamin A alcohol, ⊙, in isopropanol.

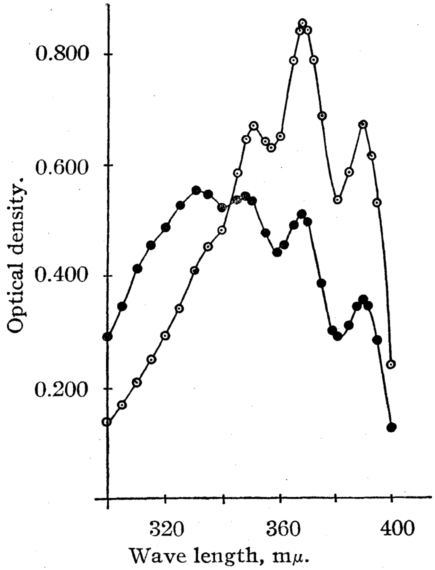

Fig. 2.—Spectrophotometric curves in isopropanol of vitamin A methyl ether, ●, and of vitamin A alcohol, ⊙, after treatment with 0.033 N hydrogen chloride in ethanol.

Subsequent to our initial publication[6] Cawley[7] reported the preparation of a vitamin A methyl ether for which he records a melting point of 33–33.5°, an extinction coefficient $E^{1\%}_{1\,\text{cm.}}$ at 328 mμ of 1800 and a biological potency of 4,800,000 units per gram.

Vitamin A methyl ether was prepared by the action of dimethyl sulfate on the lithium derivative of the vitamin. The lithium derivative was prepared by the reaction of *n*-butyl lithium[8] with crystalline vitamin A alcohol.[9] Attempts were made to form a metallic vitaminate using triphenylmethyl sodium, a Grignard reagent or potassium metal. The former possesses the disadvantage of giving triphenylmethane which is extremely difficult to separate from the desired product, while the latter two destroy the vitamin A molecule, the Grignard reagent with the formation of a product with absorption maxima at 333, 348 and 366 mμ and the metallic potassium generating hydrogen which probably reduces the molecule. Milas[10] has reported the preparation of metallic salts of vitamin A, using sodium amide, triphenylmethyl sodium and potassium *t*-butoxide.

The methyl ether obtained by the action of dimethyl sulfate on the lithium salt was purified by chromatography on activated alumina[11] and was obtained as an orange oil which crystallized from methanol at −70°. The spectrophotometric curve (Fig. 1) of vitamin A methyl ether is identical in all respects with that of vitamin A alcohol, both having absorption maxima at 326 mμ on the Beckman spectrophotometer (model DU). The extinction coefficient ($E^{1\%}_{1\,\text{cm.}}$) in isopropanol is 1660, which corresponds to an equivalent extinction coefficient of 1742 for vitamin A alcohol. We found an extinction coefficient of 1769 for crystalline vitamin A alcohol. Crystalline vitamin A methyl ether was found to have a provisional biological potency of 3,500,000 U.S.P. XII units per gram. This value was obtained as the average of three biological assays (a total of 30 rats used) made by Miss Elizabeth Musser of these Laboratories. Baxter and Robeson[12] reported 4,300,000 U. S. P. XI units per gram for crystalline vitamin A alcohol. A value of 3,500,000 for vitamin A alcohol is obtained consistently in our Laboratories.

Since the final step in most of the reported vitamin A ether syntheses involves dehydration, the stability of the ether under these conditions is of particular interest. Although vitamin A methyl ether was found to be more stable than the alcohol toward alcoholic hydrogen chloride by the method of Shantz, *et al.*,[13] absorption spectra studies (Fig. 2) showed that some anhydro vitamin A is formed. Similarly the ether possesses a greater stability than the alcohol toward the action of *p*-toluenesulfonic acid in boiling benzene. For example, at a molar ratio of one part of *p*-toluenesulfonic acid to 218 parts of vitamin A alcohol or its methyl ether, the ether is unaffected, whereas anhydro formation is observed with the alcohol (Fig. 3). However, at a molar ratio of 1:92 anhydro formation is observed with the vitamin A ether, whereas vitamin A acetate is little affected (Fig. 4).

The biological utilization of vitamin A methyl

ether in the rat is now being investigated and will be reported at a later date.

Experimental

Crystalline Vitamin A Methyl Ether[14]

Crystalline vitamin A alcohol (500 mg., 1.75 millimoles) was dissolved in 60 cc. of dry benzene and the solution further dried by distillation of 10 cc. of benzene. To the solution, at room temperature, was added 6.0 cc. of 0.38 *N* *n*-butyllithium (2.28 millimoles)[8] in low boiling petroleum ether (30–40°). A sharp color change from yellow to deep cherry red occurred immediately. The solution was shaken and allowed to stand at room temperature for five minutes. Then dimethyl sulfate (560 mg., 4.52 millimoles) in 20 cc. of dry benzene was added, followed by a return of the yellow color. The solution was heated at 70° for one hour, cooled in ice, transferred to an amber separatory funnel where it was washed successively with cold solutions of 0.5 *N* sulfuric acid, 1 *N* ammonium hydroxide (twice) and water (three times). The solution was dried over anhydrous sodium sulfate, filtered and concentrated at 40° under reduced pressure to give an orange oil. The last traces of benzene were removed from the residual oil by the repeated addition of purified Skelly Solve B[15] followed by its removal under reduced pressure. An antimony trichloride blue color assay on the above oil showed a 92.5% recovery.

The orange oil was dissolved in 25 cc. of purified Skelly Solve B and put on a 15 × 5 cm. activated alumina column.[11] All reaction products were absorbed at the top of the column. After washing well with Skelly Solve B, the yellow vitamin A methyl ether was eluted with 1% acetone in Skelly Solve B. This gave a sharp separation from an orange pigment which remained at the top of the column. An antimony trichloride blue color assay on the ether fraction showed an over-all yield of 90%.

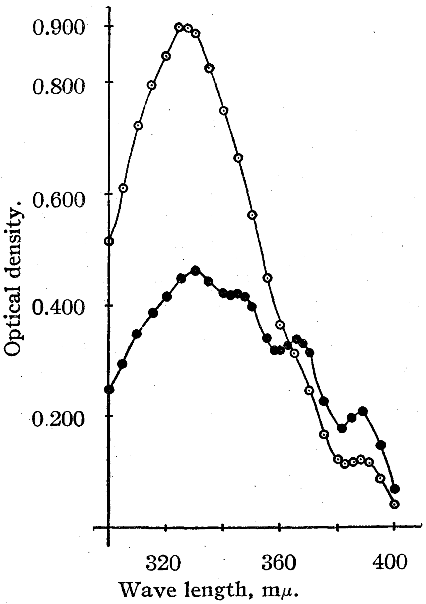

Fig. 4.—Spectrophotometric curves in isopropanol of vitamin A methyl ether, ●, and of vitamin A acetate, ⊙, after treatment with 0.011 mole of *p*-toluenesulfonic acid.

The oil, obtained on removal of the solvent at 40° under reduced pressure, crystallized from methanol after standing several months at −70°; m. p. 31–33°. Three recrystallizations from methanol and two from Skelly Solve B gave yellow crystals of vitamin A methyl ether; m. p. 33–34°. The yield of crystalline ether from 1 g. of alcohol was 660 mg. (62.7%).

Anal. Calcd. for $C_{21}H_{32}O$: C, 83.95; H, 10.74; OCH_3, 10.34. Found: C, 83.96, 83.76; H, 11.16, 11.07; OCH_3, 10.00, 9.94. The antimony trichloride blue color assay was 100% of the expected value.

Crystalline vitamin A methyl ether is soluble in the common organic solvents such as alcohol, ether, benzene, etc., and is insoluble in water. It has been successfully crystallized from methyl alcohol, ethyl formate and Skelly Solve B, the former being the preferred solvent. For best crystallization results the oil obtained upon chromatography of a 1-g. run is dissolved in 5 cc. of absolute methanol, the solution cooled in ice, seeded, and allowed to stand in a refrigerator overnight, whereupon large crystals are formed. The mixture is then cooled in an ice–salt mixture for four hours, and then at about −70° (solid carbon dioxide) twenty hours. The crystals are filtered on a sintered glass funnel which has been cooled with Dry Ice. Recrystallizations are carried out in the same manner.

Behavior of Vitamin A Methyl Ether in $^1/_{30}$ *N* Dry Hydrogen Chloride in Alcohol (Fig. 2).—Crystalline vitamin A methyl ether (11.5 mg.) was dissolved in 0.75 cc. of absolute alcohol, after which 0.25 cc. of 0.132 *N* dry hydrogen chloride in absolute ethanol was added. The solution was shaken and allowed to stand at room temperature for fifteen minutes. Water (5 cc.) was added and the mixture extracted twice with 10-cc. portions of benzene. The combined benzene solutions were washed once with cold saturated sodium bicarbonate solution and three times with cold water, dried over anhydrous sodium sulfate, filtered and the solvent removed at 40° under reduced pressure to give an oil. The last traces of benzene were removed by repeatedly adding isopropanol followed by its removal under reduced pressure. The spectrophotometric curve was determined on this oil in isopropanol.

---

(14) All experiments were carried out in an atmosphere of dry nitrogen in subdued light.

(15) Purified by treatment with concentrated sulfuric acid, neutralization and distillation.

Vitamin A alcohol (10.5 mg.) was treated in exactly the same manner.

Behavior of Vitamin A Methyl Ether with *p*-Toluenesulfonic acid

1. In a Molar Ratio of 218 to 1 (Fig. 3).—A solution of 26 micrograms of *p*-toluenesulfonic acid monohydrate in 20 cc. of benzene was dried by distillation of 10 cc. of benzene. To this solution crystalline vitamin A methyl ether (8.9 mg.) was added and the solution refluxed for thirty minutes after which it was cooled in ice, and then poured onto cold saturated sodium bicarbonate contained in a separatory funnel. The benzene solution was washed well with the bicarbonate solution and then three times with cold water, dried over anhydrous sodium sulfate, filtered and concentrated. After the last traces of benzene were removed as above, an ultraviolet absorption curve was run on the residual oil.

Crystalline vitamin A alcohol (8.5 mg.) was run under identical conditions.

2. In a Molar Ratio of 92 to 1 (Fig. 4).—Vitamin A methyl ether (9.4 mg.) was treated with 65 micrograms of *p*-toluenesulfonic acid monohydrate exactly as in (1) above. Definite anhydro formation is indicated in the spectrophotometric curve.

Vitamin A acetate (10.6 mg.) under identical conditions was little affected.

Summary

1. Crystalline vitamin A methyl ether has been prepared by the action of dimethyl sulfate on the lithium salt of the alcohol.

2. Crystalline vitamin A methyl ether has a provisional biological potency of 3,500,000 U. S. P. XII units per gram.

3. The behavior of vitamin A methyl ether under dehydration conditions has been studied and a comparison is made between the stability of the vitamin A alcohol, ether and acetate under these conditions.

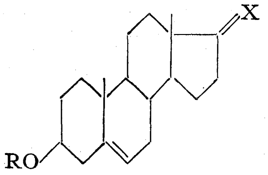
[CONTRIBUTION FROM THE RESEARCH DEPARTMENT OF SYNTEX S. A.]

Mercaptols of 17-Keto Steroids

BY L. NORYMBERSKA, J. NORYMBERSKI AND A. OLALDE

In a recent paper by Hauptmann[1] the reaction of estrone acetate with ethanedithiol was reported. Since the reactions of 17-keto steroids with mercaptans have been the object of investigation in our laboratory for a considerable period of time, we wish to communicate some of the results obtained.[2]

By condensation of dehydroisoandrosterone acetate (II) with benzyl and ethyl mercaptan in the presence of fused zinc chloride and anhydrous sodium sulfate, we were able to prepare the respective mercaptols III and V.



I. $R = H, X = O$
II. $R = CH_3CO, X = O$
III. $R = CH_3CO, X = (C_6H_5CH_2S)_2$
IV. $R = H, X = (C_6H_5CH_2S)_2$
V. $R = CH_3CO, X = (C_2H_5S)_2$
VI. $R = H, X = (C_2H_5S)_2$
VII. $R = CH_3CO, X = H_2$
VIII. $R = H, X = H_2$

Acid hydrolysis of dehydroisoandrosterone acetate dibenzylmercaptol (III) led to the formation of dehydroisoandrosterone (I); alkaline hydrolysis to dehydroisoandrosterone dibenzylmercaptol (IV); boiling with cadmium carbonate and mercuric chloride in acetone or acetic acid solution to dehydroisoandrosterone acetate (II); hydrogenolysis with Raney nickel to desoxo-dehydroisoandrosterone acetate (VII).

The last-mentioned reaction is of some special interest: Butenandt and Surányi[3] and recently Heard and McKay[4] described the Wolff–Kishner reduction of dehydroisoandrosterone semicarbazone and the product obtained has been proved to consist of a hard to separate mixture of desoxo-dehydroisoandrosterone, etiocholan-3(α)-ol and androstan-3(β)-ol. On the other hand, by hydrogenolysis of the dibenzylmercaptol, as well as of the diethylmercaptol of dehydroisoandrosterone acetate (III and V, respectively) with Raney nickel, we have obtained the pure desoxo-dehydroisoandrosterone acetate (VII) in excellent yield and by its saponification the desoxo-dehydroisoandrosterone (VIII).

Acknowledgment.—The microanalyses have been carried out by L. N. at the microanalytical laboratory of the Escuela Nacional de Ciencias Biológicas, Instituto Politecnico Nacional, with the kind permission of Dr. P. Hope, to whom we wish to express our thanks for his obligingness. Dr. G. Rosenkranz of our laboratory we thank for his kind interest in this work.

Experimental

Dibenzylmercaptol of Dehydroisoandrosterone Acetate (III).—A mixture of 15 g. of dehydroisoandrosterone acetate, 15 cc. of benzylmercaptan, 10 cc. of dioxane and 15 g. of anhydrous sodium sulfate is ice-cooled and 15 g. of freshly fused and pulverized zinc chloride is added.

(2) Further communications on this subject will be reported soon.

(3) Butenandt and Surányi, *Ber.*, **75**, 591 (1942).

(4) Heard and McKay, *J. Biol. Chem.*, **165**, 677 (1946).

The mixture solidifies in few minutes and is kept at room temperature overnight. The reaction product is extracted with chloroform, the chloroform solution washed with water, dried over sodium sulfate and evaporated. The residue crystallizes from a mixture of chloroform and methanol in the form of prismatic plates, m. p. 148–149°, yield 20 g. (78.5%).

Anal. Calcd. for $C_{35}H_{44}O_2S_2$: C, 74.95; H, 7.91. Found: C, 74.81; H, 7.95.

Diethylmercaptol of Dehydroisoandrosterone Acetate (V).—The preparation proceeds in the manner described above for dibenzylmercaptol. The crude product crystallizes from acetone, m. p. 147–149°.

Anal. Calcd. for $C_{25}H_{40}O_2S_2$: C, 68.76; H, 9.23. Found: C, 69.00; H, 9.33.

Acid Hydrolysis of the Dibenzylmercaptol Acetate (III).—One hundred milligrams of the compound (III) is refluxed for one hour with 5 cc. of dioxane, 5 cc. of methanol and 0.4 cc. of concentrated hydrochloric acid. The warm solution is diluted with water and the precipitated needles are filtered off, m. p. 138–140°. The product gives no depression with dehydroisoandrosterone.

Alkaline Hydrolysis of the Dibenzylmercaptol Acetate (III).—One and one-tenth grams of the compound (III) is dissolved in 10 cc. of dioxane and a solution of 0.5 g. of sodium hydroxide in 20 cc. of methanol is added. The dibenzylmercaptol of dehydroisoandrosterone is precipitated by dilution with water and recrystallized from acetone; prismatic needles, m. p. 185–186°.

Anal. Calcd. for $C_{33}H_{42}OS_2$: C, 76.40; H, 8.16. Found: C, 76.48; H, 8.31.

Acetylation of the compound with acetic anhydride in pyridine at room temperature gives the original acetate.

Reaction of the Dibenzylmercaptol Acetate (III) with Mercuric Chloride and Cadmium Carbonate.—Two-hundred-fifty milligrams of the compound (III), 300 mg. of mercuric chloride and 400 mg. of cadmium carbonate are refluxed in 10 cc. of acetone and 1 cc. of water for eight hours. The inorganic salts are filtered off, the crude reaction product purified by adsorption on activated alumina, the benzene fraction yielding crystals of dehydroisoandrosterone acetate of the melting point 165–166°. The resulting dehydroisoandrosterone acetate may be isolated from the crude product by recrystallization from methanol if the reaction is carried out in acetic acid instead of acetone.

Desoxo-dehydroisoandrosterone Acetate (VII).—To a suspension of 40 g. of Raney nickel[5] in 120 cc. of methanol is added a solution of 4 g. of dibenzylmercaptol of dehydroisoandrosterone acetate in 120 cc. of acetone and the mixture is refluxed for two hours. The nickel is filtered off, washed with methanol, the filtrate evaporated and the residue (2 g., m. p. 86–91°) recrystallized from methanol, yielding leaflets of constant melting point, 96–97°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19. Found: C, 79.56; H, 10.03.

Hydrogenolysis of the diethylmercaptol (V) is carried out in the same manner and gives an identical product.

Desoxo-dehydroisoandrosterone (VIII).—Nine-tenths gram of the acetate (VII) is refluxed with 1 g. of potassium hydroxide in 20 cc. of methanol for one hour. The hot solution is diluted with water until the first crystals appear and the mixture is cooled to complete the precipitation; long needles, m. p. 136–137°. Repeated recrystallization from aqueous methanol or from hexane does not change the melting point.

Anal. Calcd. for $C_{19}H_{30}O$: C, 83.15; H, 11.02. Found: C, 83.16; H, 11.16; $[\alpha]_D$ $-75.8°$ (in dioxane).

Summary

1. The dibenzylmercaptol and the diethylmercaptol of dehydroisoandrosterone acetate have been prepared; conditions are described under which the selective hydrolysis of either the acetyl or mercaptol group may be carried out.

2. Desoxo-dehydroisoandrosterone and its acetate have been prepared by the hydrogenolysis of the mercaptols of dehydroisoandrosterone acetate with Raney nickel and the advantages of this method over the Wolff–Kishner reduction for this particular case have been shown.

Pyrazine Chemistry. III. Derivatives of 3-Amino-5,6-dimethylpyrazinoic Acid

BY RUDOLPH C. ELLINGSON AND ROBERT L. HENRY

3-Amino-5,6-dimethylpyrazinoic acid[1] can be obtained in excellent yield by the alkaline hydrolysis of 6,7-dimethyllumazine. The decarboxylation of this acid according to a modification of the described method[1] gives 2-amino-5,6-dimethylpyrazine (I) in good yield.

Bromination of I gives 2-amino-3-bromo-5,6-dimethylpyrazine (II). The structure of II was established by amination to the hitherto unknown diamine (III) followed by conversion of the diamine by reaction with glyoxal into the unknown 2,3-dimethylpyrazinopyrazine (IV). The structure of IV was established by its synthesis from diacetyl and the known 2,3-diaminopyrazine.[2] This series of reactions proves that in II the bromine atom is in position 3.

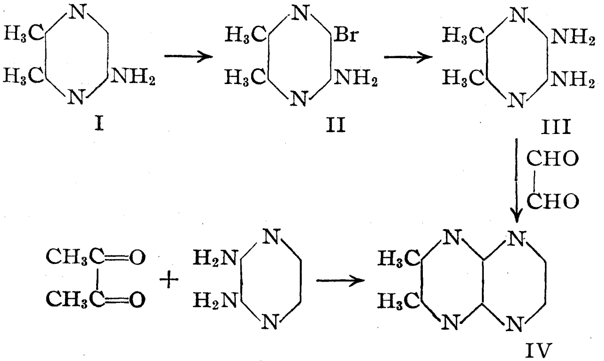

CHART 1

Condensation of III with diacetyl gave tetramethylpyrazinopyrazine. 2,3-Dimethylpyrazinopyrazine and tetramethylpyrazinopyrazine are

(2) McDonald and Ellingson, *ibid.*, **69**, 1034 (1947).

members of a little known class of heterocyclic compounds, the basic ring structure of which is pyrazinopyrazine. The only compound found in the literature which might be considered to belong to this class is quinoxalo[2,3-b]quinoxaline.[3]

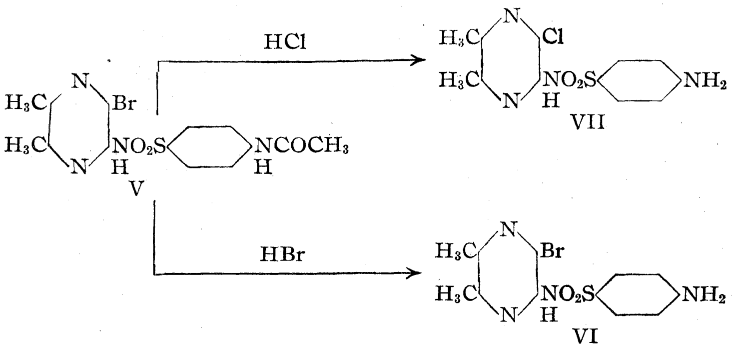

CHART 2

2-Amino-3-bromo-5,6-dimethylpyrazine (II) on reaction with acetylsulfanilyl chloride gave 2-(N^4-acetylsulfanilamido)-3-bromo-5,6-dimethylpyrazine (V). Deacetylation of V with hydrobromic acid gave the expected 2-sulfanilamido-3-bromo-5,6-dimethylpyrazine (VI), but deacetylation with hydrochloric acid gave the unexpected 2-sulfanilamido-3-chloro-5,6-dimethylpyrazine (VII). Even compound II is converted into 2-amino-3-chloro-5,6-dimethylpyrazine (VIII) when treated under similar conditions with a solution of ethanol and hydrochloric acid.

The replacement of carbon-linked halogen atoms in aliphatic and aromatic compounds by ionic halogen is not to our knowledge a frequently occurring phenomenon. Hepp[4] recorded the rapid conversion of chlorotrinitrobenzene into the iodo compound by treatment with a hot alcoholic solution of potassium iodide. Bennett and Vernon[5] reported the conversion of chloro-2,4-dinitrobenzene into the iodo compound by boiling it in a solution of sodium iodide in ethylene glycol. In compounds II, V and VI we have found that the bromine atom is readily replaced by chlorine on being treated with a solution of ethanol and hydrochloric acid.

Reaction between 2-amino-3-chloro-5,6-dimethylpyrazine (VIII) and acetylsulfanilyl chloride gives a mixture of the mono- and di-coupled compounds, the greater portion of which is the mono-coupled compound. Note that in the reaction[2] between 2-amino-3-chloropyrazine and acetylsulfanilyl chloride largely di-coupling occurred.

When III reacts mole for mole with acetylsulfanilyl chloride, the major portion of the product is the di-coupled compound from which 2,3-disulfanilamido-5,6-dimethylpyrazine (IX) may be obtained by deacetylation. Its solubility in dilute aqueous alkali indicates the 2,3-disulfanilamido structure. For an analogous case of 2,3-disulfanilamido substitution refer to paper II[2] of this series. A more soluble fraction which consists of a mixture of III and the mono-coupled compound, 2-(N^4-acetylsulfanilamido)-3-amino-5,6-dimethylpyrazine (X), was obtained by concentration of the mother liquors after removal of the di-coupled compound. X was separated from III by virtue of its greater solubility in aqueous alkali. This method, however, is unsatisfactory for preparing 2-sulfanilamido-3-amino-5,6-dimethylpyrazine (XI). XI is more readily obtained from VI by replacement of the bromine atom with the amino group.

The value of compounds VI, VII, IX and XI as anti-bacterial agents has been investigated by others and will be reported elsewhere. In preliminary studies 2-sulfanilamido-3-chloro-5,6-dimethylpyrazine (VII) proved to be the most interesting.

Experimental

3-Amino-5,6-dimethylpyrazinoic Acid.—This acid was prepared from 6,7-dimethyllumazine as described by Weijlard, *et al.*[1] The conversion of this acid into the methyl ester and amide was done by essentially the same procedure as was used for making 2-amino-3-carbomethoxypyrazine and 3-aminopyrazinamide.[6] The yield of crude ester was 51%. For analysis[7] the product was crystallized from water and came out as light yellow needles; m. p. 170–171° (cor.).

Anal. Calcd. for $C_8H_{11}N_3O_2$: C, 53.03; H, 6.12; N, 23.19. Found: C, 53.06, 52.78; H, 6.28, 6.24; N, 23.80, 23.66.

The yield of crude amide was low, 19.3%. The product was purified by crystallization from 85 parts of a 16% dioxane–water solution (v/v). The yellow, finely granular solid melted at 243–245° (dec.).

Anal. Calcd. for $C_7H_{10}N_4O$: C, 50.59; H, 6.07; N, 33.72. Found: C, 50.51, 50.41; H, 6.33, 6.22; N, 34.75, 34.57.

2-Amino-5,6-dimethylpyrazine (I).—This amine was prepared by Weijlard, *et al.*,[1] by decarboxylation of 3-amino-5,6-dimethylpyrazinoic acid in sulfuric acid. We made I by decarboxylation of the acid in carbitol acetate in much the same manner as the above-mentioned authors prepared aminopyrazine from 3-aminopyrazinoic acid. Pure 2-amino-5,6-dimethylpyrazine (I) exists as slightly yellow, brittle plates; m. p. 151° (cor.).

2-Amino-3-bromo-5,6-dimethylpyrazine (II).—One mole (123 g.) of crude 2-amino-5,6-dimethylpyrazine (I) was dissolved in 400 cc. of warm glacial acetic acid. After complete solution 54 cc. of bromine (5% excess) was added dropwise with stirring over a period of one hour. After five hours 1200 cc. of ethyl ether was added and the orange precipitate was collected. Without drying it was dissolved in 1600 cc. of hot water and the solution was decolorized with Norite. After filtration, the filtrate was made weakly alkaline by the addition of about 325 cc. of a 20% sodium hydroxide solution. The yellow granular solid was collected and air-dried. The yield was 154–163 g. (70.2–80.7%); m. p. 111–114°. For analysis a sample was crystallized three times from a 1 to 3 mixture

(7) Dr. Carl Tiedcke, Laboratory of Microchemistry, New York, N. Y., performed the analyses recorded in this paper.

of ethanol and water. This compound crystallized as light yellow cubes; m. p. 114.7° (cor.). The compound sublimes readily in vacuum.

Anal. Calcd. for $C_6H_8BrN_3$: C, 35.66; H, 3.99; Br, 39.55; N, 20.80. Found: C, 35.65, 35.57; H, 3.84, 3.91; Br, 39.58, 39.84; N, 20.39, 20.31.

2,3-Diamino-5,6-dimethylpyrazine (III).—In each of four Carius tubes were placed 8.08 g. (0.04 mole) of crude 2-amino-3-bromo-5,6-dimethylpyrazine (II), 24 cc. of concentrated ammonium hydroxide and a trace of copper powder and the tubes were heated at 128° for twenty-four hours. After cooling, each tube was rinsed out with 75 cc. of water and the suspensions were combined and heated to dissolve all the crystalline solid. The hot solution was decolorized and filtered. After refrigeration the yellow needles were collected; they weighed 17.1 g. (77.4%); m. p. 211–214°. On repeated crystallizations of this diamine from water almost colorless needles were obtained; m. p. 216° (cor.).

Anal. Calcd. for $C_6H_{10}N_4$: C, 52.15; H, 7.29; N, 40.55. Found: C, 52.30, 52.08; H, 7.48, 7.38; N, 41.11, 40.90.

2,3-Dimethylpyrazinopyrazine (IV). A. (From glyoxal and 2,3-diamine-5,6-dimethylpyrazine).—A mixture of 4.14 g. (0.03 mole) of 2,3-diamino-5,6-dimethylpyrazine (III), 10 g. of glyoxal di-sodium bisulfite and 75 cc. of water was boiled under reflux for one hour. After cooling to room temperature, 20 cc. of concentrated ammonium hydroxide was added. On refrigeration long yellow needles separated; they weighed 1.83 g. (38.1%); m. p. 212–216° (dec.). On crystallization from 95% ethanol small, light yellow needles were obtained, m. p. 219° (dec.).

Anal. Calcd. for $C_8H_8N_4$: C, 59.98; H, 5.03; N, 34.98. Found: C, 59.97, 59.90; H, 4.87, 4.89; N, 36.14, 36.02.

B. (From diacetyl and 2,3-diaminopyrazine).—In 25 cc. of hot water were dissolved 0.75 g. of 2,3-diaminopyrazine[2] and 1.0 cc. of diacetyl. The solution was boiled under reflux for thirty minutes. On refrigeration yellow crystals separated; they weighed 0.5 g. (45.9%); m. p. 215–217° (dec.). On crystallization from ethanol, light yellow needles were obtained; m. p. 216–218° (dec.). There was no depression of the melting point on mixed melting of this compound with that obtained in A.

Anal. Calcd. for $C_8H_8N_4$: C, 59.98; H, 5.03; N, 34.98. Found: C, 59.23; H, 5.01; N, 36.24.

Tetramethylpyrazinopyrazine.—To a warm solution of 4.0 g. (0.028 mole) of 2,3-diamino-5,6-dimethylpyrazine (III) in 400 cc. of water was added 4.0 cc. of diacetyl. The solution was boiled under reflux for twenty-five minutes. As the clear orange solution cooled, long needles separated; they weighed 1.1 g.; m. p. 261–262°. By concentration of the mother liquors a second crop weighing 1.8 g. and melting at 260° was obtained. The total yield was 2.9 g. (55%). On two crystallizations from water, bright yellow needles were obtained; m. p. 261° (cor.).

Anal. Calcd. for $C_{10}H_{12}N_4$: C, 63.80; H, 6.43; N, 29.77. Found: C, 63.20, 63.51; H, 6.31, 6.19; N, 30.30, 30.16.

2-(N^4-Acetylsulfanilamido)-3-bromo-5,6-dimethylpyrazine (V).—A suspension of 156 g. (0.773 mole) of crude 2-amino-3-bromo-5,6-dimethylpyrazine (II) (dried over phosphorus pentoxide) in 980 cc. of dry pyridine was cooled to about 5° in an ice-bath. With constant stirring of the chilled suspension 190 g. (5.4% excess) of crystalline acetylsulfanilyl chloride was added over a period of forty-five minutes. After holding the reaction mixture at about 5° for five hours, it was allowed to come to room temperature and to stand overnight. The red-brown reaction mixture was poured into water and the pyridine removed by steam distillation in vacuum. After thorough cooling at 0°, the solid was collected and dried. The yield was 210 g. (68.2%) of a tan, light-weight powder; m. p. 204–206° (dec.). After one crystallization from a mixture of dioxane and water the melting point rose to 216° (dec.). For analysis the compound was crystallized from a mixture of ethanol and water; it came out in fluffy clusters of almost colorless small needles; m. p. 218° (dec.).

Anal. Calcd. for $C_{14}H_{15}BrN_4O_3S$: C, 42.11; H, 3.79; Br, 20.02; N, 14.03; S, 8.03. Found: C, 42.16, 42.13; H, 3.64, 3.71; Br, 19.76, 19.91; N, 14.90, 14.97; S, 8.00, 8.02.

2-Sulfanilamido-3-bromo-5,6-dimethylpyrazine (VI).—A mixture of 10 g. (0.025 mole) of 2-(N^4-acetylsulfanilamido)-3-bromo-5,6-dimethylpyrazine (V), 20 cc. of 40% hydrobromic acid and 60 cc. of 95% ethanol was boiled under reflux for thirty minutes. To the solution 200 cc. of water and 25 cc. of concentrated ammonium hydroxide then Darco-G60 were added. After filtration the filtrate was made weakly acid by the addition of hydrobromic acid. After thorough cooling the yellow granular solid was collected and dried. It weighed 7.7 g. (86%); m. p. 183–185°. After two crystallizations from 95% ethanol, the sulfonamide existed as small, light yellow crystals; m. p. 185° (cor.).

Anal. Calcd. for $C_{12}H_{13}BrN_4O_2S$: C, 40.34; H, 3.67; Br, 22.37; N, 15.68; S, 8.97. Found: C, 40.22, 40.13; H, 3.78, 3.79; Br, 22.70, 22.53; N, 16.67, 16.70; S, 8.40, 8.83.

2-Sulfanilamido-3-chloro-5,6-dimethylpyrazine (VII).—A. A mixture of 179 g. (0.449 mole) of 2-(N^4-acetylsulfanilamido)-3-bromo-5,6-dimethylpyrazine (V), 1000 cc. of 95% ethanol and 360 cc. of concentrated hydrochloric acid was boiled under reflux for forty-five minutes. Then Norite was added and the solution boiled five minutes longer. After filtration the hot solution was diluted with five liters of water and enough concentrated ammonium hydroxide was added to bring the *p*H to about 4. After thorough cooling the yellow granular solid was collected and dried. It weighed 119 g. (84.8%); m. p. 182–184°. After two crystallizations from 95% ethanol, large yellow crystals were obtained; m. p. 185° (cor.).

Anal. Calcd. for $C_{12}H_{13}ClN_4O_2S$: C, 46.08; H, 4.19; Cl, 11.34; N, 17.91; S, 10.25. Found: C, 45.82; H, 4.50; Cl, 11.70, 11.52; N, 17.90; S, 10.12.

B. To 50 cc. of pyridine at 55–60° a mixture of 6.0 g. (0.038 mole) of crystalline 2-amino-3-chloro-5,6-dimethylpyrazine (VIII) and 9.2 g. (5.0% excess) of acetylsulfanilyl chloride was added over a period of thirty minutes. The reaction mixture was held at that temperature for a total of four and one-half hours; then it was allowed to stand overnight at room temperature. The pyridine was removed by steam distillation in vacuum and after thorough cooling of the solution, the solid was collected and dried. The light yellow, fluffy product weighed 6.35 g. and melted at 195–207° (dec.). It was dissolved in 100 cc. of dioxane; the solution was filtered and the filtrate was diluted with 100 cc. of boiling water. The undissolved solid weighed 0.85 g. and melted at about 240° (dec.). As the filtrate cooled to room temperature a small quantity of solid separated; this was collected and dried; 0.7 g. melting at about 250° (dec.). The filtrate was then chilled in an ice-bath for several hours whereupon an almost colorless precipitate filled the solution. It weighed 4.4 g.; m. p. 208–210° (dec.).

The two portions of high melting material (0.85 g. and 0.7 g.) were combined and crystallized from 440 cc. of a 1 to 1 mixture of dioxane and water. After a second crystallization the small colorless crystals were analyzed; m. p. 269–270° (dec.). The analytical data show that some di-coupling has occurred; this compound is probably 2-di-(N^4-acetylsulfanilyl)-amino-3-chloro-5,6-dimethylpyrazine.

Anal. Calcd. for $C_{22}H_{22}ClN_5O_6S_2$: C, 47.87; H, 4.02; Cl, 6.42; N, 12.69; S, 11.60. Found: C, 47.70; H, 4.16; Cl, 6.20; N, 13.51; S, 11.54.

The 4.4-g. fraction was crystallized from a mixture of 150 cc. of dioxane and 300 cc. of water; 3.4 g. of slightly yellow granules was obtained; m. p. 210–212° (dec.). On another crystallization from a 2 to 1 mixture of water and ethanol the compound came out as light yellow, glistening plates; the melting point remained unaltered. Analysis shows it to be 2-(N^4-acetylsulfanilamido)-3-chloro-5,6-dimethylpyrazine.

Anal. Calcd. for $C_{14}H_{15}ClN_4O_3S$: C, 47.39; H, 4.26; Cl, 9.99; N, 15.79; S, 9.04. Found: C, 47.18, 47.01; H, 4.22, 4.40; Cl, 10.02, 9.96; N, 16.66, 16.42; S, 8.88, 9.03.

Deacetylation of this compound gave a slightly yellow crystalline substance which melted at 185° and showed no depression on mixed melting with 2-sulfanilamido-3-chloro-5,6-dimethylpyrazine (VII) obtained in A.

2-Amino-3-chloro-5,6-dimethylpyrazine (VIII).—A mixture of 10 g. (0.0495 mole) of crude 2-amino-3-bromo-5,6-dimethylpyrazine (II), 60 cc. of 95% ethanol and 20 cc. of concentrated hydrochloric acid was boiled to effect solution. The solution was then diluted with 250 cc. of water and made weakly alkaline by the addition of ammonium hydroxide. After cooling the colorless granules were collected and dried; they weighed 3.5 g. (45%); m. p. 97–100°. The compound crystallizes from water in long colorless prisms; m. p. 98° (cor.).

Anal. Calcd. for $C_6H_8ClN_3$: C, 45.72; H, 5.12; Cl, 22.50; N, 26.66. Found: C, 45.60, 45.84; H, 5.22, 5.06; Cl, 22.63, 22.40; N, 27.40, 27.15.

2,3-Disulfanilamido-5,6-dimethylpyrazine (IX).—The reaction between 13.8 g. (0.1 mole) of 2,3-diamino-5,6-dimethylpyrazine (III) and 48 g. (0.206 mole) of crystalline acetylsulfanilyl chloride was carried out in pyridine under essentially the same conditions as those used for the preparation of V. The yield of crude 2,3-di-(N^4-acetylsulfanilamido)-5,6-dimethylpyrazine was 40.9 g. (76.8%) of yellow granules; m. p. 253–257° (dec.). Before analysis the compound was crystallized three times from a 2 to 1 mixture of water and ethanol (v/v). Small yellow crystals were obtained; m. p. 264° (dec.).

Anal. Calcd. for $C_{22}H_{24}N_6O_6S_2$: C, 49.61; H, 4.54; N, 15.78; S, 12.04. Found: C, 49.53, 49.40; H, 4.46, 4.35; N, 16.53, 16.32; S, 11.92, 11.90.

The deacetylation was carried out in an alcoholic solution of hydrochloric acid as described for the deacetylation of V. The yield was 90% of a yellow granular product melting at 257° (dec.). 2,3-Disulfanilamido-5,6-dimethylpyrazine (IX) was purified by solution in 31 parts of a 4 to 1 mixture of dioxane and water and, after decolorization and filtration, dilution with an equal volume of hot water; light yellow granular crystals were obtained. IX is insoluble in ethanol and in water and only slightly soluble in dioxane. It dissolves both in weakly acidic or basic aqueous solutions.

Anal. Calcd. for $C_{18}H_{20}N_6O_4S_2$: C, 48.20; H, 4.49; N, 18.74; S, 14.30. Found: C, 48.90, 48.80; H, 4.55, 4.58; N, 18.67, 18.73; S, 14.11, 13.99.

2-Sulfanilamido-3-amino-5,6-dimethylpyrazine (XI).—**A.** In a Carius tube were sealed 5.35 g. (0.015 mole) of 2-sulfanilamido-3-bromo-5,6-dimethylpyrazine (VI), 25 cc. of concentrated ammonium hydroxide and a trace of copper powder. The tube was heated at 105° for eight hours. The contents of the tube were diluted with 40 cc. of water and filtered. The filtrate was chilled and then neutralized by the gradual addition of dilute hydrochloric acid.[8] A yellow solid separated; it weighed 3.6 g. (84.7%); m. p. 204–207°. It was crystallized from a 10 to 1 mixture of ethanol and water. After three crystallizations large, slightly yellow crystals which melted at 207° (cor.) were obtained.

Anal. Calcd. for $C_{12}H_{15}N_5O_2S$: C, 49.13; H, 5.15; N, 23.88; S, 10.93. Found: C, 48.90, 48.71; H, 5.30, 5.27; N, 24.01, 24.04; S, 10.80, 10.98.

More drastic reaction conditions such as higher temperatures and/or longer reaction times lowered the yield of the desired compound. Since 2,3-diamino-5,6-dimethylpyrazine was then also isolated, the more drastic conditions cause cleavage of either the starting sulfonamide, VI, or the product, XI.

B. To a mechanically stirred suspension of 6.9 g. (0.05 mole) of 2,3-diamino-5,6-dimethylpyrazine (III) in 100 cc. of dry pyridine cooled to about 2° was added gradually over a period of thirty minutes 12 g. (0.051 mole) of crystalline acetylsulfanilyl chloride. One hour after the addition had been completed a solution of 2 g. of sodium hydroxide in 100 cc. of water was added and the pyridine was removed by steam distillation in vacuum. The aqueous solution, freed from pyridine, was diluted with water to a volume of 1.5 liters and then cooled to room temperature. The light yellow, granular solid was collected and dried. It weighed 4.5 g. and melted at 258–260° (dec.). It is 2,3-di-(N^4-acetylsulfanilamido)-5,6-dimethylpyrazine as there was no depression of the melting point on mixed melting of it with an authentic sample of 2,3-di-(N^4-acetylsulfanilamido)-5,6-dimethylpyrazine.

The filtrate was concentrated in vacuum to a volume of about 500 cc. and then cooled overnight in the refrigerator. The tan, partially crystalline solid (9.8 g.) melted at 205–230° and evidently was a mixture.

The 9.8 g. of mixture was suspended in 100 cc. of a 2.5 per cent. aqueous sodium hydroxide solution; 2.3 g. of solid remained undissolved. It melted at 215–217° and gave no depression of the melting point on mixed melting with an authentic sample of 2,3-diamino-5,6-dimethylpyrazine (III). Evidently it is unreacted diaminodimethylpyrazine, III.

The clear yellow filtrate was carefully neutralized with dilute hydrochloric acid. On scratching the solution, a yellow solid separated. It weighed 2.7 g.; m. p. 225–231°. Crystallization from 150 cc. of a 2 to 1 ethanol–water solution (v/v) gave 2 g. of slightly pink crystals; m. p. 235–236°. This substance we believed to be 2-(N^4-acetylsulfanilamido)-3-amino-5,6-dimethylpyrazine (X). To confirm this belief we deacetylated the material in aqueous alcoholic hydrochloric acid and obtained 1.15 g. of colorless granules melting at 203–205°. There was no depression of the melting point on mixed melting of this compound with an authentic sample of 2-sulfanilamido-3-amino-5,6-dimethylpyrazine (XI) prepared from 2-sulfanilamido-3-bromo-5,6-dimethylpyrazine (VI). Obviously the way to prepare XI is by reaction of VI with ammonium hydroxide in the presence of copper rather than from III and acetylsulfanilyl chloride.

Summary

1. The preparation of five new simple pyrazine derivatives, namely, methyl-3-amino-5,6-dimethylpyrazinoate, 3-amino-5,6-dimethylpyrazinamide, 2-amino-3-bromo-5,6-dimethylpyrazine, 2-amino-3-chloro-5,6-dimethylpyrazine and 2,3-diamino-5,6-dimethylpyrazine, is described.

2. The chemical structures of 2-amino-3-bromo-5,6-dimethylpyrazine and 2,3-diamino-5,6-dimethylpyrazine have been established.

3. Two new members, 2,3-dimethylpyrazinopyrazine and tetramethylpyrazinopyrazine, of a little known class of heterocyclic compounds have been prepared and characterized.

4. Four new derivatives of sulfapyrazine have been synthesized, namely, 2-sulfanilamido-3-bromo-5,6-dimethylpyrazine, 2-sulfanilamide-3-chloro-5,6-dimethylpyrazine, 2-sulfanilamido-3-amino-5,6-dimethylpyrazine, and 2,3-disulfanilamido-5,6-dimethylpyrazine.

---

[8] If the acid is added too rapidly, and/or the solution has not been thoroughly chilled (0°), the compound may separate as a gray gummy mass which soon solidifies. It can be purified by crystallization from aqueous ethanol.

5. The replacement of the bromine atom in 2-amino-3-bromo-5,6-dimethylpyrazine and some of its derivatives with chlorine on treatment with aqueous hydrochloric acid in ethanol was unexpected.

Strains in Methyl Amines and Hydrocarbons[1]

BY RALPH SPITZER AND KENNETH S. PITZER

H. C. Brown and co-workers have written a series of interesting articles on the anomalous basic strength of the methyl amines.[2] In order to eliminate complicating effects due to hydration, they worked in the gas phase and used trimethylboron as reference acid. They concluded that trimethylamine was weakened, in comparison with ammonia or mono- or dimethylamine, by a type of steric effect to which they referred as B-strain and which resulted from spreading of the methyl groups. We propose to show, by a semiquantitative calculation, that the magnitude of the B-strain is far too small to account for the observed anomaly and that the anomaly is probably due to ordinary steric effects of the type referred to by Brown as F-strain.

Perhaps a brief description of our understanding of Brown's use of the term F-strain is in order at this time. Under this heading are lumped all types of steric strain resulting from the interference of groups attached to two adjacent atoms, including van der Waals repulsion, increase in the bonded distance, and interference with the preferred rotational configuration about the bond. It is our opinion that strains of this type are primarily responsible for the weakness of trimethylamine.

Let us quote from Dr. Brown's paper his definition of B-strain: "There are theoretical reasons for believing that the three bonds of a trivalent nitrogen atom should be directed in space at angles of 90° to each other. In all cases which have been investigated, however, the angles are considerably greater, probably because they must be increased to accommodate the attached groups. An electron diffraction investigation of trimethylamine led Brockway and Jenkins to the conclusion that the C–N–C angle in this molecule is 108 ± 4°.[3a] In the explanation here proposed, it is assumed that the bond angle in trimethylamine is somewhat greater than the normal tetrahedral angle, probably close to the upper limit set by Brockway and Jenkins. In other words, the three rather bulky methyl groups spread the bonds of the nitrogen atom from their preferred configuration (90°) to a value greater than the tetrahedral angle.

"In the trivalent nitrogen derivative, such spreading of the bond angles is relatively easy since the fourth position in the valence shell is not occupied. However, the addition of a fourth group to the vacant position, be it a proton or a trimethylboron molecule, forces the nitrogen atom toward a tetrahedral configuration and results in a reduction of the expanded angles. The methyl groups are, therefore, crowded toward each other, setting up a strain which reduces the stability of the addition compound.

"The term B-strain is proposed for this effect. (The letter B is used to indicate that the interference which causes the strain is localized at the "back" of the molecule—trimethylamine in the case under discussion—away from the entering group; it is thus contrasted to F-strain which results from interference at the front of the molecule, at the interface between the two components of the addition compound."

Our problem is thus to calculate the energy needed to crowd the methyl groups together to tetrahedral angles. This will be accomplished by calculating the energy needed to bend trimethylamine into the tetrahedral configuration. As long as the C–N–C bond angles remain the same, the actual addition of the acid can introduce only F, not B strain. Also any B strain already in the free base at its expanded angles is not significant since it is the change in B-strain on addition of the acid which would affect the energy or equilibrium in that reaction.[3b]

Total Strain in Amines.—In order to discuss this concept, it is necessary to estimate the amount of the B-strain. Brown estimates that the total strain is about 9000 kcal. per mole in the free energy of the trimethylamine–trimethylboron complex. Although he does not divide this into B-strain and ordinary steric strain (F-strains), he implies that the B strain is of considerable im-

[3a] L. O. Brockway and Jenkins, *ibid.*, **58**, 2036 (1936). More recently V. Schomaker (private communication) has obtained for the C–N–C angle, 109 ± 2° for trimethylamine, 111 ± 3° for dimethylamine, 112 ± 3 for diethylamine and 113 ± 3° for triethylamine.

[3b] We have discussed this matter at considerable length because Dr. Brown does not agree that our calculation is in accord with his definition quoted above.

portance. We shall use energy rather than free energy in our discussion in order to eliminate the complicating effects of entropy changes, and it is therefore necessary to re-estimate the strain.

Table I shows the energy of dissociation of the trimethylboronamine complexes. The addition of one methyl group increases dissociation energy by 3.9 kilocalories per mole. If we assume, with Brown, that the effect of adding more methyl groups is linear in the number of methyl groups, we may derive the third column in Table I, which shows expected dissociation energy. The last column then gives the difference between expected and observed dissociation energies, and this difference may be attributed to a steric strain of some sort. Actually, these estimates are probably high. If we accept Brown's hypothesis that methylamine is a stronger base than ammonia because of the positive inductive effect, we really should not expect the strength of the amines to increase linearly with number of methyl groups added. Whereas the dipole moment of ethyl chloride is about 10% higher than that of methyl chloride—presumably because of the positive inductive effect of the added methyl group—we find little or no additional increase in the dipole moments of isopropyl and *t*-butyl chlorides. This fact would indicate that the positive inductive effect of methyl groups falls off beyond the first. If we arbitrarily assume that the second methyl may have as little as one-half the effect of the first and that the third one-third the effect, we would obtain 0.35 and 3.3 kcal./mole for the strain energies of the last two compounds in the table. These values are used as lower limits to the strain energies in Table III.

Table I

Summary of Dissociation Energies

	Kcal. per mole		
Compound	ΔH of dissociation	Expected dissociation	Strain energy
NH_3—$B(CH_3)_3$	13.7	13.7	(0)
CH_3NH_2—$B(CH_3)_3$	17.6	17.6	(0)
$(CH_3)_2NH$—$B(CH_3)_3$	19.3	21.5	2.2
$(CH_3)_3N$—$B(CH_3)_3$	17.6	25.4	7.8

Calculation of B-Strain.—We are now ready for an approximate calculation of B-strain in the trimethylamine complex. Inasmuch as the C–N–C angle changes only a few degrees when boron trimethyl is added to trimethylamine, the energy increment due to the change in this angle should be calculable to good approximation by use of the angle bending constant for trimethylamine. It should be noted that the use of an empirical potential constant accounts for energy of methyl group compression as well as pure angle bending. If we make the extreme assumptions that the C–N–C angles in the trimethylamine and the trimethylamine–boron trimethyl complex are, respectively, 112° and 109$^1/_2$°, the angle change is 2$^1/_2$°.

Although the bending potential constants for similar molecules are known to range near 1×10^{-11} erg./radian^2, there seemed to be no good literature value for trimethylamine. We calculated the C–N–C bending constant from the Raman frequencies[4] 368, 827 and 1179 cm.$^{-1}$ which are to be identified as primarily C–N–C bending, C–N stretching and CH_3 wagging, respectively, all in the symmetry class A_1. We set up the exact equations for the A_1 class and then reduced them by making the CH_3 groups rigid and of the generally accepted dimensions. Then assuming a valence force potential, we obtained the constants 1.17×10^{-11} erg./radian^2 for C–N–C bending, 4.77×10^5 dynes/cm. for C–N stretching, and 0.70×10^{-11} erg./radian^2 for the C–C–H angles in CH_3 wagging. This result may be compared, *e. g.*, with Sutherland's[5a] estimate of the stretching and bending constants for isobutane of 4.5×10^5 dynes/cm. and 0.95×10^{-11} erg./radian.^{2}

With the bending constant 1.17×10^{-11} erg./radian^2, we find that the energy of trimethylamine increases by $25(\Delta\theta)^2$ calories per mole per C–N–C angle where $(\Delta\theta)$ is the change in degrees from the equilibrium value of the C–N–C angle. Taking the upper limit $\Delta\theta = 2^1/_2°$, we obtain a destabilization of 156 calories per angle or a total destabilization for the molecule of three times this amount. The resulting maximum value of about 0.5 kcal. per mole is certainly small compared with the 3–8 kcal. per mole estimated in Table III. This calculation indicates that B-strain is not primarily responsible for the anomalous weakness of trimethylamine.

Comparison with Related Hydrocarbons.—Having indicated that the effect of B-strain is small in the methylamines, we shall now show that hydrocarbons with structures related[5b] to the structures of the compounds discussed here show a corresponding increase in strain energy as the complexity of the structures increases. This strain must be a manifestation of F-strain, because, even if B-strain is present in the hydrocarbons which we shall discuss, it must not vary greatly from one to another because the number and nature of bonds attached to carbon is essentially constant. As we have seen in the preceding discussion, B-strain becomes manifest in such a situation as the change from trivalent to tetravalent nitrogen in which the methyl groups attached to nitrogen are forced back toward the tetrahedral angle. Table II shows the heats of formation of some hydrocarbons in the gas phase at 25°.[6] Column 3 gives the difference between the heat of formation of the given hydrocarbon and the normal hydrocarbon with the same num-

ber of carbon atoms. We observe that the iso hydrocarbons are about 1.7 and the neo hydrocarbons about 4.6 kcal. per mole more stable than the related normal hydrocarbon. If we assume that the effects of branching would be additive in more complex molecules, we obtain the results in column 4 of Table II for the expected difference from the heat of formation of the normal hydrocarbon. For example, 2,2,3-trimethylbutane contains both iso and neo type configuration, and so should be more stable than *n*-heptane by 1.7 + 4.6 = 6.3 kcal. per mole. The difference between columns 4 and 3 represents destabilization which we shall attribute to steric strain of the F type. The assumption of additivity is no doubt an oversimplification. Some justification for the assumption may be derived from a consideration of 2,5-dimethylhexane. In this compound, where two iso groups are widely separated, additivity is strict. We were unable to test the assumption with regard to combinations with neo groups due to lack of data on compounds in which these groups are separated sufficiently.

TABLE II

HEATS OF FORMATION OF HYDROCARBONS IN THE GAS PHASE AT 25° AND RELATED DATA

Hydrocarbon	$-\Delta H_f$	Kcal. per mole Difference from normal hydrocarbon	Expected difference from normal hydrocarbon	Steric strain
n-Butane	29.8	0.0	0.0	0.0
Isobutane	31.5	−1.7	−1.7	.0
n-Pentane	35.0	0.0	0.0	.0
Isopentane	36.9	−1.9	1.7	− .2
Neopentane	39.7	−4.7	−4.6	− .1
n-Hexane	40.0	0.0	0.0	.0
2-Methylpentane	41.7	−1.7	−1.7	.0
2,2-Dimethylbutane	44.4	−4.4	−4.6	.2
n-Heptane	44.9	0.0	0.0	.0
2-Methylhexane	46.6	−1.7	−1.8	.0
2,2,3-Trimethylbutane	49.0	−4.1	−6.3	2.2
n-Octane	49.8	0.0	0.0	0.0
2,2,3,3-Trimethylbutane	54.0	−4.2	−9.2	5.0
2-Methylheptane	51.5	−1.7	−1.7	0.0
2,5-Dimethylhexane	53.2	−3.4	−3.4	.0

The skeletons of the hydrocarbons 2,2-dimethylpropane, 2,2-dimethylbutane, 2,2,3-trimethylbutane and 2,2,3,3-tetramethylbutane are identical, respectively, with those of the addition compounds of trimethylboron with ammonia, mono-, di-, and trimethylamines if we consider B + N atoms as equivalent to C atoms, as the first two columns of Table III show. Columns 3 and 4 of the same table summarize the steric strains of the hydrocarbons and of the amine–boron compounds. This agreement as to order of magnitude makes it probable that this steric effect in the hydrocarbons, in which B-strain should be substantially eliminated, is of the same nature as that in the amine complexes.

TABLE III

COMPARISON OF STERIC STRAINS OF AMINE–TRIMETHYLBORON COMPLEXES AND RELATED HYDROCARBONS

Amine–boron complex	Hydrocarbons	Estimated strain of amine, kcal.	Estimated steric strain of hydrocarbon
 $H_3N-B(CH_3)_3$	 $H_3C-C(CH_3)_3$	0.0	−0
 $CH_3NH_2-B(CH_3)_3$	 $CH_3CH_2-C(CH_3)_3$	0.0	0.2
 $(CH_3)_2NH-B(CH_3)_3$	 $(CH_3)_2CH-C(CH_3)_3$	0.3–2.2	2.2
 $(CH_3)_3N-B(CH_3)_3$	 $(CH_3)_3C-C(CH_3)_3$	3.3–7.8	5.0

Discussion.—The comparison with the hydrocarbons does not apply to the formation of ammonium salts in water solution, in which a parallel trend has been found.[2b] Inasmuch as the situation in water is much more complex, as was recognized by Brown, it is probable that the parallelism is to some extent fortuitous. Indeed correction[7] for symmetry number changes on proton addition spoils the exact parallelism by making methylamine the strongest base. Possibly hydration energy effects are responsible for the effect in water solution.

It is clear, then, as was pointed out by Lewis (and also by Brown in his later experiments on F-strain) that the reference acid is very important in determination of the order of basic strengths.

With hydrochloric as a reference acid, Brown[8] found a regular order of base strength for the methylphosphines. His conclusion that this result supports his theory is not necessarily correct. It is quite possible that if experiments could be performed in the gas phase, the alkylamines would show the normal order of basic strength against hydrochloric acid. In any event, the structure of the hydrochlorides is so different from that of the trimethyl boron complexes that any comparison between the two must be made with caution. Also, it should be pointed out that in compounds such as the phosphines, in which the bond angles are less than tetrahedral, B-strain should have a base-strengthening effect. The change from p to sp^3 bonds caused by the addition of the acid and consequent expansion of the bond angles should relieve the B-strain, thereby making the salt or addition complex more stable compared with the free base.

---

[7] We are indebted to Prof. V. Schomaker for suggesting this point.

[8] H. C. Brown, THIS JOURNAL, **67**, 503 (1945).

B-strain may become important when groups much larger than methyl are attached to the central atom because both the angles of distortion and the angle force constant will increase.

Summary

1. It is shown, by a semi-quantitative calculation, that the B-strain postulated by H. C. Brown is too small to account for the observed weakness of trimethylamine as an acid.

2. A comparison of ordinary steric forces (F-strain) in hydrocarbons of related structure shows that the steric strains in trimethylboron-alkyl amine compounds are probably of the same nature as those in the hydrocarbons.

3. The importance of the reference acid in establishing basic strengths is re-emphasized.

4. It is pointed out that B-strain will be base-strengthening rather than base-weakening when the angles are less than tetrahedral.

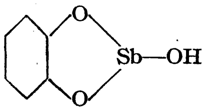
Antimonylcatechol. I. Coördination of Simple Amines and Alcohols

BY L. M. WHEELER AND C. K. BANKS

The combination of inorganic, trivalent antimony with phenols and α-hydroxyacids has long been known, but only a few derivatives with alcohols have been reported[1] and these compounds are unstable in the presence of water. Since antimonylcatechol[2] (I) appeared to be of interest in the treatment of filariasis,[3] efforts were made to solubilize this compound. It is insoluble in water, aqueous ammonia, alcohol, ether, chloroform and other solvents and dissolves only in strong sodium hydroxide and concentrated hydrochloric acid. However, it was noted that in the presence of both an alcohol and an amine, antimonylcatechol readily formed solutions from which crystalline products could be isolated. Both the alcohol and the amine were combined, in some fashion, with the antimonylcatechol in the isolated products. That such combinations were not fortuitous was readily demonstrated. The ratios of combination were always the same regardless of the reactants and experiments showed that no combination occurred in aqueous solution when only the alcohol or the amine was present.



I

The atomic ratio of antimony to nitrogen was always one within experimental limits. The products dissolved readily in water to give nearly neutral solutions which could be decomposed with strong acids to yield antimonylcatechol, the alcohol and the amine salt. When both the alcohol and amine were low-boiling, prolonged heating at 100° in a high vacuum resulted in the loss of these fragments, leaving antimonylcatechol. Preparations containing ammonia or other volatile amines would lose the nitrogenous constituent during prolonged shelf storage, resulting in decreased solubility and altered crystalline properties. If the amines were relatively non-volatile, the products were stable to heat and storage.

Solutions of these compounds in water appeared to undergo hydrolysis on standing and a hydrated form of antimonylcatechol was separated. An excess of any amine would stabilize the solutions indefinitely. Aqueous solutions appeared to have all the properties of salt solutions, particularly in that they were excellent conductors of electricity, showing about forty per cent. the conductance of equimolar sodium chloride solutions.

Determinations of carbon and hydrogen in the presence of antimony were extremely variable, but both antimony and nitrogen were readily determined. To further elucidate the structures, inductive postulations were necessary.

The alcohols used were methanol, propanol, glycols, glycerol, sorbitol, mannitol, dextrose, galactose and levulose. The amines studied consisted of ammonia, diethyl- and triethylamine. The properties of the resulting products are given in Table I.

The reaction product of antimonylcatechol and tartaric acid[4] was also investigated. When equimolar amounts of the two substances were heated in water containing a four-fold excess of sodium bicarbonate, a product similar in every respect to the alcohol–amine complexes was formed.

Experimental

Alcohol–Amine–Antimonylcatechol Complexes.—Antimonylcatechol (0.2 mole) was suspended in 100 ml. of water in which had been dissolved 0.2 mole of the alcohol and 0.5 mole of amine in a 500-ml. round-bottomed flask equipped with stirrer and condenser. The temperature of the vigorously stirred solution was raised to 80–90° and was maintained at this temperature for fifteen minutes after complete solution occurred. The hot solutions were filtered rapidly and cooled. The products crystallized on cooling or on adding acetone to the cold solution. They were recrystallized from hot water, methanol or

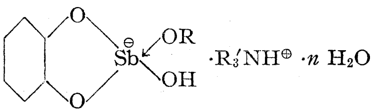
acetone–water mixtures. The properties of the compounds are listed in Table I.

Sodium Antimonyltartratecatechol.—Tartaric acid (16 g.) and sodium bicarbonate (32 g.) were dissolved in 180 ml. of water and heated to 80°. Antimonylcatechol (27.6 g.) was added slowly. After the reaction was completed, the solution was filtered hot and cooled. The product crystallized on standing and was recrystallized from water.

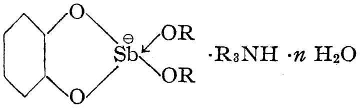
Anal. Found: Sb, 29.91, 29.92.

Discussion of Structure

The structure of antimonyl compounds has not been investigated extensively. Doak[5] has shown that arylstibonic acids and their salts conform to a coördinate ion structure which may be represented as $RSb(OH)_5^-\cdot M^+$ in which antimony exhibits a coördination number of six. Similarly, it was suggested in previous work that some benzenearsonous acids are best represented as $RAs(OH)_3^-\cdot H^+$ where arsenic has a coördination number of four.[6] Triethoxystibine in ethanol forms the ion $(C_2H_5O)_4Sb^-$ which has strong acid properties[1] and the antimony-bis-catecholates have been postulated by Bodendorf[7] to have a coördinate ion structure. By analogy, these compounds might have structures II or III.

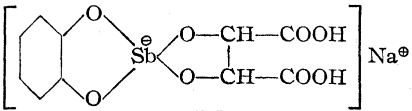


II



III

The strict one-to-one ratio of antimony to nitrogen, the water solubility, ionic type of conductance, all favor such a structural interpretation. Furthermore, the tartaric acid–antimonylcatechol complex (IV), can be explained by a similar postulation.



IV

A comparison of the experimental data with the postulated structures is given in Table II.

While these structures appear to satisfactorily explain the antimonylcatechols and related compounds, all postulations as to the structures of the antimony derivatives of tartaric, citric and malic acids are inadequate to explain the large number of variations obtained. While previous work has suggested that the compounds form complex ions, it is possible that reëxamination of the data in the light of the requirements for coördinate structures may elucidate the nature of the chemical linkages.

Summary

1. Antimonylcatechol was found to react with alcohols and amines to form antimonylcatechol–alcohol–amine complexes having the properties of salts. Fourteen such compounds involving various alcohols and amines are reported.

2. The compounds are best explained as amine salts of an antimonylcatechol coördinate acid.

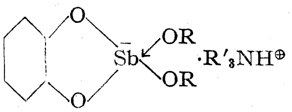
Antimonylcatechol. II. Coördinates with Aminoalcohols

By L. M. Wheeler and C. K. Banks

In the previous paper of this series[1] it was shown that antimonylcatechol would react with alcohols in the presence of amines to form compounds which could be represented by formula III. It was considered of interest to determine if aminoalcohols would also form similar compounds, and under what specific conditions.



III

Antimonylcatechol was dissolved by aqueous solutions of amino-alcohols when the aminoalcohol was in molecular excess.[2] It was frequently difficult to isolate the products directly from such reaction mixtures. They were easily isolated, however, when antimonylcatechol and the aminoalcohol reacted in aqueous suspension in the presence of an excess of ammonia or diethylamine. The product appeared to be independent of the amine used to catalyze the reaction. When the ratios of reactants were varied, the isolated products were more complex and appeared to incorporate a portion of the catalytic amine.

The products resulting from equimolar reaction were stable as solids and dissolved in water to give solutions which hydrolyzed slowly on standing. An excess of any amine appeared to prevent this hydrolysis. Like the products derived from amines and alcohols, the compounds appeared to have the properties of salts. When two moles of antimonylcatechol reacted with one of a poly-

hydric aminoalcohol in the presence of another amine, the products were less stable, tending to decompose in solid form. Solutions of these compounds had the same properties as before. The condensation products and their postulated structures are listed in Table I.

Experimental

Equimolar Compounds.—Antimonylcatechol (0.1 mole) was suspended in 100 ml. of water containing the aminoalcohol (0.1 mole) and 0.5 mole of ammonia or diethylamine. The temperature was raised to 80° while stirring. As soon as the reaction was complete, the solution was filtered and chilled. The products crystallized on standing and were recrystallized from acetone–water mixtures.

Antimonylcatechol (2): **Aminoalcohol** (1).—Antimonylcatechol (0.2 mole) and the aminoalcohol (0.1 mole) reacted in 100 ml. of water and 0.5 mole of diethylamine as before. The products were recrystallized from water or acetone–water mixtures.

Summary

Six coördinate complexes of antimonylcatechol with amino-alcohols have been described as to preparation, properties and possible structure.

Some Chemotherapeutically Active Sulfones.[1] III. Azido Substituted Sulfones

BY C. K. BANKS AND O. M. GRUHZIT

The activity of 4,4′-diaminodiphenylsulfone against β-hemolytic streptococcal infections in mice has resulted in the preparation of innumerable sulfone derivatives of varying types. A survey of variously substituted sulfones[2] indicated that derivatives easily hydrolyzed to the parent 4,4′-diaminodiphenylsulfone, such as the di-dextrose bisulfite (Promin) and the di-formaldehyde sulfoxylate (Diamidin, Diasone), retained the same type of therapeutic activities as the parent sulfone. When groups which would hydrolyze only with difficulty were substituted on the amine groups, the activity was generally retained when one amino group remained unsubstituted, but was lost if both amine groups were substituted.

It was thought of interest to prepare related compounds in which the character of the amino group was completely changed. The triazo group was chosen since it resembles the amino group in some respects but also has some greatly different reaction properties. 4,4′-bis-Triazo-, 4-amino-4′-triazo, 4-succinylamino-4′-triazo- and 2-sulfamyl-4,4′-bis-triazodiphenylsulfone were prepared by variations in standard procedures. Both hydroxylamine and hydrazine were investigated as reactants with diazonium salts and hydrazine was found to be superior for these preparations. While the compounds generally separated from the reaction mixtures in better than 99% purities, special recrystallization techniques were necessary to remove traces of diazotizable amines. All of the compounds had very sharp explosion points when pure.

Experimental[3]

4,4′-*bis*-Triazodiphenylsulfone.—4,4′-Diaminodiphenylsulfone (25 g.) was worked into a paste with 60 g. of concentrated sulfuric acid and then poured over 100 g. of ice. The resulting suspension was cooled in an ice-bath and diazotized by the slow addition of 14 g. of sodium nitrite in 100 ml. of water. When the diazotization was nearly completed, the nitrite was added dropwise, testing the diazonium solution after each drop until an excess was indicated by starch-potassium iodide strips. A coupling solution of 100 g. of sodium acetate, 20 ml. of 85% hydrazine hydrate, 100 g. of ice and 200 ml. of water was prepared and placed in a 4-liter beaker. The diazonium solution was added all at one time with vigorous stirring, resulting in violent foaming which required octyl alcohol to prevent overflow.[4] After four hours, the yellow product was filtered off and dissolved in 600 ml. of acetone. The acetone solution was treated with two types of charcoal (Darco G 60 and Norite) and then diluted with 2 liters of water. The resulting precipitate was recrystallized from glacial acetic acid and then dissolved in a minimum of acetone, charcoaled and the solution filtered directly into a large volume of air-free water. The acetone recrystallization was repeated until no diazotizable amine was present. The product was filtered off and dried *in vacuo* over phosphorus pentoxide; yield 70%, nearly white, explosion point 156–157°.

Anal. Calcd. for $C_{12}H_8N_6O_2S$: N, 28.02. Found: N, 27.94.

4-Amino-4′-triazodiphenylsulfone.—4-Acetoamino-4′-aminodiphenylsulfone (60 g.) was suspended in 100 ml. of water, 50 ml. of concentrated hydrochloric acid added and 100 g. of ice. The hydrochloride salt precipitated and was diazotized slowly with 14 g. of sodium nitrite in 100 ml. of water using the same precautions as above to avoid an excess. The diazonium solution was added all at once to a solution of 100 g. of sodium acetate and 25 ml. of 85% hydrazine hydrate in 200 ml. of water and 200 g. of ice. The crude product was filtered off and hydrolyzed by refluxing in 300 ml. of 3 *N* hydrochloric acid until solution occurred. The solution was cooled and neutralized with ammonia to precipitate a nearly white product which was purified further by recrystallization from 70% alcohol; yield 40%, white, m. p. 130–131°, explodes immediately after melting.

Anal. Calcd. for $C_{12}H_{10}N_4O_2S$: N, 20.44. Found: N, 20.49.

4-Succinylamino-4′-triazodiphenylsulfone.—4-Amino-4′-succinylaminodiphenylsulfone (7 g.) was diazotized in 60 ml. of water and 4 ml. of concentrated sulfuric acid with 1.4 g. of sodium nitrite. The coupling was performed with a solution of 10 g. of sodium acetate, 2 ml. of 85% hydrazine hydrate, 50 ml. of water and 100 g. of ice. After coupling was completed, the solution was made alkaline to phenolphthalein paper, filtered and acidified. The product was recrystallized from 70% acetone until no diazotizable amine was found; yield 60%, white, explosion point 182–185°.

Anal. Calcd. for $C_{16}H_{14}N_4O_5S$: N, 14.92. Found: N, 14.95.

2-Sulfamyl-4,4′-*bis*-triazodiphenylsulfone.—4,4′-Diamino-2-sulfamyldiphenylsulfone (18.2 g.) was diazotized in 50 ml. of water, 50 ml. of concentrated hydrochloric acid and 100 g. of ice as in the other preparations. Coupling was performed with 50 g. of sodium acetate, 15 ml. of 85% hydrazine hydrate and 100 g. of ice in 100 ml. of water. Recrystallized from 70% acetic acid, then repeatedly from an acetone–alcohol–water (40–40–20) until no diazotizable amine test was obtained; yield 50%, nearly white, explosion point 176–178°. *Anal.* Calcd. for $C_{12}H_9N_7O_4S_2$: N, 25.88. Found: N, 25.42.

Chemotherapy

The chemotherapeutic activity of the triazosulfones was determined in albino mice injected intraperitoneally with about 5,000–10,000 lethal doses of β *Streptococcus hemolyticus* or about 750 lethal doses of pneumococcus Type I cultures, as based on the titration for virulence at the time of the tests. A "lethal dose" of either culture resulted in the death of all control animals in thirty-six hours. Treatment of the pneumococcus-infected mice was begun immediately following inoculation, and in one to one and one-half hours after *Streptococcus hemolyticus* inoculation. The mice were treated orally by cannula twice daily for three days when infected with pneumococci and

2-Sulfamyl-4,4'-bis-triazodiphenylsulfone	>500	2.5	83	20.0	0

[a] Calcd. by the method of Dragstedt, *J. Pharmacol.*, **32**, 217 (1927–1928). [b] Lancefield's Group A, 01625. [c] Type I, 02444. [d] M. E. D. = minimal effective dose permitting survival of 80 to 90% of mice. [e] Promin. [f] Diamidin, Diasone.

once daily for three days when infected with streptococci. The animals were observed for twenty-eight days; however, the comparison of compounds was made on the basis of fourteen and seven day survival rates, respectively. Except for 4,4'-diaminodiphenylsulfone, the results tabulated in Table I are based on one or two routine tests for each compound, using ten to fifteen animals per dose level. Diaminodiphenylsulfone was used as a reference standard in all tests and the values given are the statistical average of all tests. Only those minimal doses which achieved comparable therapy are reported. The oral LD_{50} in mice was also determined for each compound.

The activities of the triazo compounds against mouse streptotoccal infections resembled those of the analogous aminosulfones but the pneumococcal activities were much less. 4,4'-bis-Triazodiphenylsulfone was of greatest interest. The acute toxicity of the triazo compound given orally in mice was much less than that of the analogous amino compound, yet the minimal dose of triazosulfone to achieve comparable therapy was only twice that required for the aminosulfone. Furthermore, no free or hydrolyzable amine could be detected in the blood of mice given up to 10 mg./mouse of 4,4'-bis-triazodiphenylsulfone orally, while the minimum oral therapeutic dose of 4,4'-diaminodiphenylsulfone (0.25 mg./mouse) gave demonstrable blood levels, indicating that conversion of any triazo group to amino *in vivo* was of a very low order.

Summary

1. Four new triazodiphenylsulfones are described. These compounds had antistreptococcal activity in mice comparable to that of the corresponding aminodiphenylsulfones.

2. 4,4'-bis-Triazodiphenylsulfone, although absorbed orally in sufficient amounts to achieve demonstrable antistreptococcal activity, was not converted *in vivo* to an amino compound in detectable amounts. It is possible that the activity of this compound functions through a different mechanism than that common to sulfa drugs in general.

Reactions of Atoms and Free Radicals in Solution. XIII. The Reactions of Diacetyl Peroxide with Aliphatic Ketones. A New Synthesis of 1,4-Diketones

BY M. S. KHARASCH, HENRY C. MCBAY AND W. H. URRY

Attention has been called[1] to the fact that the free primary or secondary alkyl radicals (formed by the decomposition of the diacyl peroxides of low molecular weight) remove hydrogen atoms from solvents to form new free radicals. The relations between the structure and the properties of the new free radicals thus formed are of considerable interest. A good deal of information regarding the behavior of the free radicals formed by the removal of hydrogen atoms from acids,[1] esters,[2] nitriles,[3] acid halides,[2] alkylbenzenes and ring-substituted alkylbenzenes[4] has already been recorded. The present paper deals with the reactions of the free radicals formed by the removal of hydrogen atoms from aliphatic and aryl-substituted aliphatic ketones.

Discussion

The products and the yields of such products obtained by the decomposition of diacetyl peroxide in aliphatic ketones, can be best explained by assuming that the free methyl radical, formed by the decomposition of the diacetyl peroxide, abstracts an *alpha* hydrogen atom from the ketone molecule, and that the new free radical, thus formed, dimerizes.

$$(1)\quad \underset{\text{(A)}}{\text{RR}'\text{CHCOCHRR}'} + \text{H}_3\text{C}\cdot \longrightarrow \underset{\text{(B)}}{\text{RR}'\underset{\cdot}{\text{C}}\text{OCHRR}'}$$

(2) 
$$\mathrm{RR'\dot{C}COCHRR'} \longrightarrow \begin{array}{l} \mathrm{R\overset{R'}{C}{-}COCHRR'} \\ \;\;| \\ \mathrm{R\underset{R'}{C}{-}COCHRR'} \end{array}$$

(C)

R is an alkyl radical, an aryl radical, or a hydrogen atom, and R′ is an alkyl or an aryl radical. Furthermore, since the "dimer" (C) contains hydrogen atoms (secondary or tertiary) susceptible to attack by free methyl radicals, it is to be expected that "trimers" (formed by a combination of the free radical (B) and the free radical produced by removal of a hydrogen atom from (C)) and "tetramers" (formed by the combination of two free radicals produced by removal of a hydrogen atom from (C)) should occur among the reaction products. In most of the reactions studied, both of these types of reaction product were isolated. The yields of the "dimers," "trimers" and "tetramers" are strongly influenced by the molecular ratio of ketone to peroxide. When this ratio is very high (*e. g.*, 10:1), the "dimer" predominates. With lower ratios (*e. g.*, 3:1) the yields of the "trimers" and "tetramers" are fairly high. These findings illustrate the selective action of free methyl radicals to which attention has been called in previous articles. In closely related series of compounds, the ease of removal of hydrogen atoms by free methyl radicals follows the order tertiary > secondary > primary. If the radical R in compound (A) is a hydrogen atom (that is, if the compound is $\mathrm{R'CH_2COCH_2R'}$), then its "dimer" (C), because it contains tertiary hydrogen atoms, should have a strong tendency to form "trimers" and "tetramers." A large ratio of ketone to diacetyl peroxide would therefore be required to ensure the formation of an appreciable quantity of the "dimer" (C).

Furthermore, the selective action of free methyl radicals in removing secondary or tertiary rather than primary hydrogen atoms is well illustrated by the products formed from the action of free methyl radicals on the following ketones: butanone, 3-methylbutanone, 2,4-dimethyl-3-pentanone, 2,6-dimethyl-4-heptanone, 1-phenylpropanone, methyl acetoacetate, and 3,3-dimethylbutanone. No evidence of attack on primary hydrogen atoms was found in any of these compounds (except in the case of 3,3-dimethylbutanone). It should, however, be stated that, with the methods used, even careful examination of the reaction products may have failed to detect small quantities of the substances formed by removal of primary hydrogen atoms. To settle this point another experimental procedure is needed. It is proposed to study the comparative reactivity of primary, secondary, and tertiary hydrogen atoms by labeling one of the hydrogen atoms, that is, by replacing it by a deuterium atom and determining the amounts of CH_4 and CH_3D formed.

The products formed by the decomposition of diacetyl peroxide in various ketones are indicated in Table I.

Whenever the 1,4-diketones ("dimers"), formed by the decomposition of diacetyl peroxide in ketones, were new compounds, their structure was established by conventional methods. The experimental part of this paper should be consulted for the procedures used in individual cases. This part also contains a full list of the gaseous and other products (methane, carbon dioxide, methyl acetate) formed from the diacetyl peroxide when that compound is decomposed in aliphatic ketones. Since these products are the same as those formed when diacetyl peroxide is decomposed in other solvents (acids, esters, nitriles, etc.), the mechanism of their formation is presumably the one discussed in previous articles.

"Dimers" (1,4-diketones), "trimers" (triketones), and "tetramers" (tetraketones) are formed by the action of a diacyl peroxide on ketones whenever the ketones are either aliphatic or of the type Aryl-CHR-CO-Alkyl, (in which R is a hydrogen atom or an alkyl group); they are not formed from ketones in which an aryl group is directly attached to a carbonyl group. Thus, no polymers of low molecular weight, but only higher polymers were formed when acetophenone, propiophenone, or phenyl isopropyl ketone was treated with diacetyl peroxide. Furthermore, judging by the nature of the gaseous products produced in these

TABLE I

DECOMPOSITION OF DIACETYL PEROXIDE IN KETONES

	Ketone	Major reaction product	Other products
1	Butanone	3,4-Dimethyl-2,5-hexanedione	Heavy oil, probably "trimer" and "tetramer"
2	3-Methylbutanone	3,3,4,4-Tetramethyl-2,5-hexanedione	"Trimer" and some higher polymer
3	2,4-Dimethyl-3-pentanone	2,4,4,5,5,7-Hexamethyl-3,6-octanedione	"Trimer" and some higher polymer
4	2,6-Dimethyl-4-heptanone	2,9-Dimethyl-5,6-diisopropyl-4,7-decanedione (*meso* and racemic)	Some "trimer"
5	1-Phenylpropanone	3,4-Diphenyl-2,5-hexanedione (*meso* and racemic)	Some polymer
6	2,4-Pentanedione	*sym*-Tetraacetylethane	Some polymer
7	2,5-Hexanedione		Mostly "trimer" and "pentamer"
8	3,3-Dimethylbutanone	2,2,7,7-Tetramethyl-3,6-octanedione (about 15%)	"Tetramer" and polymer
9	Cyclohexanone	2,2′-Dioxobicyclohexyl (*meso* and racemic)	High polymer

reactions (high carbon dioxide to methane ratio), it is probable that some of the free methyl radicals attach themselves to the benzene ring. If such is the fact the benzene ring must be greatly activated by the adjacent carbonyl group, for in the ketones mentioned, it competes successfully for free methyl radicals with such active atoms as the secondary and tertiary hydrogen atoms in the alkyl groups of propiophenone and phenyl isopropyl ketone, respectively. Further examination of such ketones is in progress.

Experimental

The general method for the preparation, isolation, analysis and decomposition of diacetyl peroxide in organic solvents is described in previous articles of this series.

I. The Decomposition of Diacetyl Peroxides in Organic Solvents. A. The Preparation of 3,4-Dimethyl-2,5-hexanedione, $[CH_3(CH_3CO)CH]_2$.—Diacetyl peroxide (61.0 g., 0.517 mole) was dissolved in butanone (129 g., 1.79 mole), and this solution was introduced into butanone (159 g., 2.21 moles) heated to 75°. Carbon dioxide (34.76 g., 0.79 mole), methane, (14 liters, S. C., 0.62 mole, mol. wt. 16.95), and methyl acetate (6.09 g., 0.08 mole, b. p. 56–7°) were collected and identified in the usual manner.

The first fraction obtained when the contents of the reaction flask were distilled was unchanged butanone (237.0 g., 3.30 moles, b. p. 78.5°, n^{20}_{D} 1.3800). The second fraction was collected at 57° (1 mm.) (38.3 g.). The residue in the flask weighed 4 g. The second fraction was then fractionated through a 10-plate column, and the fraction boiling at 92° (30 mm.) (n^{20}_{D} 1.4330) was collected.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.44; H, 9.56.

The analysis and the observation that the compound gave positive ferric chloride and iodoform tests suggested that the substance was the expected 3,4-dimethyl-2,5-hexanedione. The structure of the compound was established in the following manner. (a) When a sample of the presumed diketone was treated with an excess of sodium hypobromite a nearly quantitative yield of α,α'-dimethylsuccinic acid (*meso* and racemic) was obtained. The melting point of the *meso* dimethylsuccinic acid thus obtained was 206°. The recorded melting point of this acid is 209°. (b) The compound when heated with ammonium hydroxide and methyl alcohol gave 2,3,4,5-tetramethylpyrrole, which upon crystallization from methyl alcohol melted at 110°. The recorded melting point of 2,3,4,5-tetramethylpyrrole is 114°.[5] (c) The compound when treated with phenylhydrazine in ethyl alcohol gave a pyridazine derivative which melted at 127–128°. The recorded melting point for this pyridazine derivative is 130°.

Anal. Calcd. for $C_{14}H_{18}N_2$: N, 13.1. Found: N, 12.6.

B. The Preparation of 3,3,4,4-Tetramethyl-2,5-hexanedione, $[CH_3CO(CH_3)_2C]_2$.—Diacetyl peroxide (67.0 g., 0.57 mole) was dissolved in 3-methylbutanone (260 g., 3.0 moles), and this solution was introduced into 3-methylbutanone (131.0 g., 1.52 mole) heated to the boiling point of the solvent (93°). Carbon dioxide (42.25 g., 0.96 mole), methane (18.2 liters, S. C., 0.81 mole; mol. wt. 18.4), and methyl acetate (1.6 g., 0.02 mole, b. p. 57°) were collected and identified in the usual manner.

The unchanged ketone (333 g.) was recovered by distillation at ordinary pressure. The residue (64 g.) was distilled at 0.5 mm. pressure. The following fractions were collected: Fraction 1: b. p. 40° (0.5 mm.), n^{20}_{D} 1.4522, colorless oil, 23 g.; Fraction 2: b. p. 40–55° (0.5 mm.), n^{20}_{D} 1.4559, 9 g.; Fraction 3: b. p. 103–125 (0.5 mm.); n^{20}_{D} 1.4713, pale yellow sirup, 6.5 g. The residue weighed 7.0 g.

Fraction 1.—This material was shown to be the "dimer" of 3-methylbutanone (3,3,4,4-tetramethyl-3,5-hexanedione) by analysis and by the fact that it reacts with sodium hypobromite to give tetramethylsuccinic acid.

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65; mol. wt., 170. Found: C, 70.94; H, 10.34; mol. wt., 179.

Fraction 1 ("the dimer") (9 g.) was treated with the calculated amount of sodium hypobromite. The white solid which separated (9 g.) was crystallized from methyl alcohol. Beautiful white needles of a compound which melted at 117° were thus obtained. The compound contained bromine and was undoubtedly the tetrabromo derivative of the "dimer" (3,3,4,4-tetramethyl-2,5-hexanedione).

Anal. Calcd. for $C_{10}H_{14}O_2Br_4$: Br, 65.79. Found: Br, 65.71.

The appearance of this type of bromo derivative when a hindered methyl ketone is treated with sodium hypobromite has been noted previously.[6]

The hypobromite oxidation was repeated using 0.5 mole of sodium hypobromite in 300 cc. of solution and 2.5 g. (0.015 mole) of the diketone. The reaction mixture was stirred for twenty-four hours at room temperature, and eight hours at 60–80°. The reaction mixture gave 2.0 g. of the tetrabromide (m. p. 113–15°) described in the preceding paragraph, and 0.25 g. of an acid which, upon recrystallization from water, melted at 200°. The melting point of this acid was not depressed by mixture with an authentic sample of tetramethylsuccinic acid. Reflux of the tetrabromoderivative of the diketone (1 g.) in a 20% solution of potassium hydroxide in ethylene glycol for five hours and subsequent acidification gave a small quantity of tetramethylsuccinic acid.

Fraction 2.—This material is probably a mixture of the "dimer" and small amounts of the "trimer."

Fraction 3.—This material is mostly the "trimer" (mol. wt. 280; calcd. mol. wt. 255) contaminated with small amounts of the "tetramer." The structure of this compound was not established, but, on the basis of previous experience in this field, we favor the structure assigned to the "trimer" in the theoretical part.

C. The Preparation of 2,4,4,5,5,7-Hexamethyl-3,6-octanedione, $[i\text{-}C_3H_7CO(CH_3)_2C]_2$. Diacetyl peroxide (64.5 g., 0.546 mole) was dissolved in 230.5 g., 2.0 moles, of 2,4-dimethyl-3-pentanone, and this solution was added to the ketone (312.5 g., 2.74 moles) heated to 135°. Carbon dioxide (40.4 g., 0.92 mole), methane (16.34 liters, S. C., 0.73 mole, mol. wt. 17.0), and methyl acetate (2.7 g., 0.036 mole, b. p. 56.5–57°; n^{20}_{D} 1.3599) were collected and identified in the usual manner.

The unchanged ketone (477 g.) was recovered by distillation at reduced pressure (40° (35 mm.)). The straw-colored residue (62.5 g.) was fractionated at a pressure of 1.5 mm. through a six-inch Vigreux column. The following fractions were collected: Fraction 1: b. p. 75–77° (1.5 mm.), n^{20}_{D} 1.4520, 30 g.; Fraction 2: b. p. 77–85° (1.5 mm.), n^{20}_{D} 1.4583, 8 g.; Fraction 3: b. p. 100–140° (1.5 mm.), n^{20}_{D} 1.4694, 10 g. The residue weighed 5 g.

Fraction 1.—This material was shown to be the "dimer" of 2,4-dimethyl-3-pentanone (2,4,4,5,5,7-hexamethyl-3,6-octanedione) by analysis and by the fact that it gave upon oxidation tetramethylsuccinic acid and acetone.

Anal. Calcd. for $C_{14}H_{26}O_2$: C, 74.28; H, 11.58; mol. wt., 226. Found: C, 74.54; H, 11.79; mol. wt., 229.

Two grams of Fraction 1 ("dimer") was added at 0° to 100 cc. of glacial acetic acid containing 8 g. of chromic anhydride. The mixture was kept at 0° for five hours, at the end of which time it was heated to 100° and kept at that temperature for one hour. The reaction mixture was then cooled, diluted with 900 cc. of water, and the whole was extracted with 200 cc. of ether. The ether extraction was repeated five times, and the ether extracts

---

(5) Ciamician and Silber, *Ber.*, **45**, 1542 (1912); Démètre-Vladesco, *Bull. soc. chim.*, [3] **6**, 807 (1891).

(6) Fuson and Bull, *Chem. Rev.*, **15**, 275 (1934).

were combined. The ether extract was then shaken three times with a dilute solution of sodium hydroxide (20 cc. of 2% sodium hydroxide), and the alkaline extracts were combined. Upon acidification with hydrochloric acid 0.8 g. of a solid separated. When crystallized from hot water the material melted at 201°, and its melting point was not depressed by the addition of an authentic sample of tetramethylsuccinic acid.

The original aqueous solution (from which the tetramethylsuccinic acid was removed by extraction with ether) was distilled. The first 75 cc. of the distillate was collected and tested for acetone, the other expected oxidation product of the "dimer." The solution in fact gave with 2,4-dinitrophenylhydrazine a yellow crystalline product which did not depress the melting point of a known sample of the 2,4-dinitrophenylhydrazone of acetone.

D. The Preparation of 2,9-Dimethyl-5,6-diisopropyl-4,7-decanedione, $[i\text{-}C_3H_7(i\text{-}C_3H_7CH_2CO)CH]_2$.—Diacetyl peroxide (31.0 g., 0.26 mole) was dissolved in 2,6-dimethyl-4-heptanone (230.0 g., 1.62 mole), and this solution was introduced into the ketone (48.0 g., 0.34 mole) heated to 115°. Carbon dioxide (20.7 g., 0.47 mole), methane (9.0 liters, S. C., 0.40 mole, mol. wt. 17.69), and methyl acetate (2.0 g., 0.027 mole, $n^{20}D$ 1.3614) were collected and identified in the usual manner.

The unchanged ketone (232 g.) was removed at reduced pressure (b. p. 30° (1 mm.)), and the residue (48 g.) was distilled through a 6-inch Vigreux column. The following fractions were collected: Fraction 1: b. p. 95–97° (1.5 mm.), $n^{20}D$ 1.4430, clear oil, 8 g.; Fraction 2: b. p. 98–110° (1.5 mm.), mixture of crystals and an oil, 3 g.; Fraction 3: b. p. 110–114° (1.5 mm.), white crystalline material, 9 g.; Fraction 4: b. p. 114–24° (1 mm.), yellow oil, 4 g. The residue ($n^{20}D$ 1.4705) weighed 7 g.

The solid material which comprises Fraction 3 crystallizes from methyl alcohol in long white needles which melt at 87–90°. This material and the substance of Fraction 1, which is an oil, are assumed to be the *meso* and racemic forms of the "dimer" of 2,6-dimethyl-4-heptanone, namely, 2,9-dimethyl-5,6-diisopropyl-4,7-decanedione. The evidence for this assumption is based upon the difference in their boiling points, the fact that one of the isomers is a solid and the other a liquid (which resisted all our efforts to transform it into a solid), their identical analyses for carbon and hydrogen, their almost identical molecular weights, and the fact that an alcoholic solution of the liquid material of Fraction 1 could be transformed by sodium ethoxide into the solid material (m. p. 87–90°) of Fraction 3. (Note that these substances contain enolizable hydrogen atoms on the carbon atoms adjacent to the carboxyl groups.)

Anal. Calcd. for $C_{18}H_{34}O_2$: C, 76.54; H, 12.13; mol. wt., 282. Found: (solid, m. p. 87–90°) C, 76.45; H, 11.53; mol. wt., 292. (Fraction 1) C, 76.32; H, 11.41; mol. wt. 300.

Fraction 2 is probably a mixture of the two stereoisomers of Fractions 1 and 3. The residue is a tan-yellow sirup. The molecular weight of this material is 466. It is probably a "trimer" (mol. wt. 432) admixed with some of the "tetramer."

E. The Preparation of 3,4-Diphenyl-2,4-hexanedione, $[CH_3CO(C_6H_5)CH]_2$.—Diacetyl peroxide (19.6 g., 0.17 mole) was dissolved in 1-phenylpropanone (69.4 g., 0.52 mole) and this solution was introduced dropwise into the ketone (40 g., 0.3 mole) heated to 125–30°. Carbon dioxide (11.7 g., 0.27 mole), methane (4.79 liters, S. C.; 0.21 mole; mol. wt. 18.4), and methyl acetate (2.0 g., 0.03 mole; b. p. 56.5°; $n^{20}D$ 1.3615) were collected and identified in the usual manner.

The reaction mixture, upon standing overnight, deposited white crystals. These were collected on a filter. They weighed 6.5 g. When crystallized from a mixture of methyl and ethyl alcohols they melted at 201–202°. This material is quite insoluble in methyl alcohol.

The filtrate obtained when the reaction mixture was freed of the solid material was subjected to distillation at reduced pressure (5–6 mm.), and the unchanged ketone (86 g., 0.638 mole) thus recovered. The residue in the flask when allowed to stand overnight deposited some crystals. These were collected on a filter (6.0 g.). This material when crystallized first from methanol, in which it is very soluble, and then from ligroin, melted at 98–100°.

It is submitted that the compound which melts at 201–202°, and the compound which melts at 98–100°, are stereoisomers (*meso* and racemic, respectively) of 3,4-diphenyl-2,5-hexanedione. The evidence is based upon analyses, oxidation of the material to *sym*-diphenylsuccinic acid, and the fact that both materials when treated with aniline gave the identical substituted pyrrole.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81. Found: (solid m. p. 201–202°) C, 81.37; H, 6.88 (solid m. p. 98–100°) C, 80.93; H, 6.56.

The high-melting material (201°) when treated with sodium hypobromite gave a solid which upon crystallization from water melted at 253°. The melting point of this material was not depressed when mixed with an authentic sample of *meso* diphenylsuccinic acid.

The high-melting and the low-melting forms of the 3,4-diphenyl-2,5-hexanedione were converted to the same pyrrole (m. p. 135°) when treated with aniline. The procedure employed was as follows. About 0.7 g. of the material was dissolved in 20 cc. of glacial acetic acid to which 0.5 g. of aniline had been added. The mixture was refluxed for six hours and then allowed to cool. About 200 cc. of water was then added, and the whole was extracted with ether. The ethereal solution upon evaporation gave a solid which upon crystallization from methyl alcohol separated in the form of pale straw-colored needles which melted at 133–135°. Furthermore, no depression in the melting point was noted, when the pyrroles from the two compounds were mixed. For analysis the 1,3,4-triphenyl-2,5-dimethylpyrrole was further purified by sublimation. The melting point of the sublimed material was 135°.

Anal. Calcd. for $C_{24}H_{21}N$: C, 89.12; H, 6.55; N, 4.33. Found: C, 88.95; H, 6.32; N, 4.44.

Besides the *meso* and racemic forms of 3,4-diphenyl-2,5-hexanedione there is formed a sirupy polymer. The weight of the polymer is about equal to the weight of the two stereoisomers. All efforts to obtain a crystalline material from the sirupy polymer have been unsuccessful.

F. Preparation of *sym*-Tetraacetylethane, $[(CH_3CO)_2CH]_2$.—Diacetyl peroxide (65.0 g., 0.55 mole) was dissolved in 2,4-pentanedione (229.0 g., 2.29 moles) and this solution was introduced into the diketone (191.0 g., 1.91 mole) heated to 125°. Carbon dioxide (35.80 g., 0.81 mole), methane (14.75 liters S. C., 0.66 mole, mol. wt. 17.0), and methyl acetate (4.0 g., 0.05 mole; b. p. 55–6°; $n^{20}D$ 1.3605) were collected and identified in the usual manner.

The unchanged diketone (350 g.) was removed at reduced pressure (about 25 mm.). When the residue (64 g.) was allowed to stand overnight a solid separated. This was collected on a filter, and the filtrate ("A") was reserved for further treatment. The solid material when crystallized from ethyl alcohol melted at 189–191°. The melting point of tetraacetylethane, as recorded in the literature, is 189 or 191°. The identity of the 189–191° melting material, obtained in this reaction, was further confirmed by the fact that the melting points of its furan and pyrrole derivatives corresponded with those described in the literature.

The filtrate "A" began to decompose when an attempt was made to distill it in a molecular still. Its average molecular weight as determined in carbon tetrachloride was 326.

G. Preparation of 2,2,7,7-Tetramethyl-3,6-octanedione, $t\text{-}(C_4H_9COCH_2)_2$.—Diacetyl peroxide (59.5 g., 0.50 mole) was dissolved in 3,3-dimethylbutanone (316.0 g., 3.16 moles), and this solution was introduced into the ketone (58.0 g., 0.58 mole) heated to 104°. Carbon dioxide (37.9 g., 0.86 mole), methane (16.52 liters, S. C., 0.74 mole; mol. wt. 17.12), and methyl acetate (1.2 g., 0.016 mole) were collected and identified in the usual manner.

The unchanged ketone (330 g.) was recovered from the reaction mixture at reduced pressure (35 mm.), and the residue remaining in the distilling flask (44 g. of a yellow oil) was distilled at reduced pressure through a 6-inch Vigreux column. The following fractions were collected: Fraction 1: b. p. 55–60° (0.5 mm.), $n^{20}D$ 1.4400, colorless oil, 6.5 g.; Fraction 2: 60–115° (0.5 mm.), $n^{20}D$ 1.4545, mol. wt. 258, 7.5 g.; residue: red sirup, mol. wt. 347, 20 g.

Fraction 1 was shown to be the expected "dimer," 2,2,7,7-tetramethyl-3,6-octanedione, by its reactions and analyses.

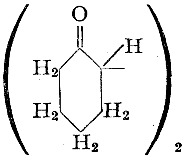
Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18; mol. wt., 198. Found: C, 73.67; H, 11.09; mol. wt., 199.

The "dimer" when treated with a methyl alcohol solution of ammonium hydroxide and allowed to stand for several days gave an oil. This oil gave a positive pyrrole test with a pine splint. Furthermore, the "dimer" gave no iodoform when treated with iodine and a base.

The "dimer" (Fraction 1) (1.5 g.) when treated with phenylhydrazine (1.0 g.) and heated for several hours at 120° gave compound which upon crystallization from alcohol melted at 144–147°. This white crystalline compound is probably the di-phenylhydrazone of 2,2,7,7-tetramethyl-3,6-octanedione.

Anal. Calcd. for $C_{24}H_{34}N_4$: N, 14.83. Found: N, 14.73.

As would be expected from the considerations discussed in the theoretical part, the "dimer" should be more readily attacked than the starting material since it contains secondary hydrogen atoms, while the hydrogen atoms in the original ketone are all primary. The low yield of the "dimer" is thus readily explained. Furthermore, it follows that Fraction 2 contains some dimer and some higher polymer, while the residue is probably a "tetramer" contaminated with some "dimer." No work was done with these higher condensation products.



H. Preparation of 2,2′-Dioxobicyclohexyl.—Diacetyl peroxide (46.0 g., 0.39 mole) was dissolved in cyclohexanone (404.5 g., 4.13 moles), and this solution was introduced into the ketone (274.5 g., 2.80 moles) heated to 130°. Carbon dioxide (25.3 g., 0.57 mole), methane (10.71 liters, S. C., 0.48 mole; mol. wt. 17.79), and methyl acetate (3.4 g., 0.04 mole, b. p. 55.5–56°, $n^{20}D$ 1.3599) were collected and identified in the usual manner.

The unchanged cyclohexanone (6.22 g., 6.25 moles) was recovered from the reaction mixture by distillation at reduced pressure (1 mm.). The residue remaining in the flask (47 g.) was distilled at reduced pressure through a 6-inch Vigreux column. The following fractions were collected: Fraction 1: b. p. 114–117° (1 mm.), $n^{20}D$ 1.4958, orange oil which darkens on standing in air, 15 g; residue, dark-red glassy material, mol. wt. 605, 13 g.

The analysis and molecular weight of Fraction 1 show it to be the "dimer" of cyclohexanone.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34; mol. wt., 194. Found: C, 74.42; H, 9.21; mol. wt., 215.

If the "dimer" of cyclohexanone is 2,2′-dioxobicyclohexyl, then the compound should exist in two stereoisomeric forms. As a matter of fact, Fraction 1 upon standing deposited a crystalline material which upon crystallization from low-boiling (60°) ligroin melted at 70–71°. This melting point is that recorded by Plant[7] for 2,2′-dioxobicyclohexyl.

To confirm the structure of the solid from Fraction 1, it was converted to the 9-methyloctahydrocarbazole by heating it with methylamine in acetic acid. The melting point of the compound thus obtained was 94–95°. The recorded melting point of 9-methyloctahydrocarbazole is 94–95°.

As indicated, the residue left in the flask was a dark-red glassy material. Its high molecular weight (605) indicated that it is either a "hexamer" of cyclohexanone or a mixture of a very high molecular weight material with some materials of lower molecular weight. No further work was done with this polymer.

Decomposition of Diacetyl Peroxide in 2,5-Hexanedione.—Diacetyl peroxide (56.0 g., 0.47 mole) was dissolved in 2,5-hexanedione (273 g., 2.39 moles), and this solution was introduced into the diketone (297.5 g., 2.61 moles) heated to 145°. Carbon dioxide (34.08 g., 0.77 mole), methane, (14.47 liters, S. C., 0.64 mole; mol. wt. 17.56), and methyl acetate (5.5 g., 0.07 mole, b. p. 56°) were collected and identified in the usual manner.

The unchanged diketone (495 g.) was recovered by distillation at reduced pressure. The reddish-brown oil (72 g.) was distilled through a 6-inch Vigreux column, and the following fractions were collected: Fraction 1: b. p. 35–55 (1 mm.), 5 g.; Fraction 2: b. p. 145–155° (1 mm.), 38 g.; residue, dark-red gummy material.

Fraction 1 is the unchanged diketone.

From the molecular weight of Fraction 2 (330) it would appear that this substance is a "trimer" of the diketone (calcd. mol. wt. 338). The residue had a molecular weight of 552. The calculated molecular weight for a "pentamer" of the diketone is 562. No further chemical work was done with either Fraction 2 or the residue.

Decomposition of Diacetyl Peroxide in Acetophenone.—Diacetyl peroxide (70.0 g., 0.60 mole) was dissolved in 183 g., 1.52 mole, of acetophenone, and this solution was introduced dropwise into acetophenone (152.3 g., 1.26 mole) heated to 125°. Carbon dioxide (41.47 g., 0.94 mole), methane (8.57 liters, S. C.; 0.382 mole; mol. wt. 16.43), and methyl acetate (7.4 g., 0.10 mole, b. p. 58°, $n^{20}D$ 1.3620) were collected and identified in the usual manner. Note, however, that the amount of methane formed is about one-half of the amount formed when diacetyl peroxide is decomposed in ketones in which the carbonyl group is not adjacent to a benzene ring.

The unchanged acetophenone (300 g.) was recovered from the reaction mixture by distillation at low pressure. The residue (35 g.) was a dark red-brown gummy substance. The molecular weight of the residue was 648.

Decomposition of Diacetyl Peroxide in Propiophenone.—Diacetyl peroxide (57.8 g., 0.49 mole) was dissolved in propiophenone (187.5 g., 1.40 mole), and this solution was introduced into propiophenone (164.5 g., 1.22 mole) heated to 115°. Carbon dioxide (31.56 g., 0.717 mole), methane (10.44 liters, S. C., 0.466 mole, mol. wt. 16.38) and methyl acetate (5.4 g., 0.08 mole, b. p. 56–57°) were collected and identified in the usual manner.

The unchanged propiophenone (301 g.) was removed from the reaction mixture by distillation at reduced pressure. The residue (50 g.) was an orange-colored semi-solid resin. The molecular weight of this material (in carbon tetrachloride) was 389.

The Decomposition of Diacetyl Peroxide in Phenyl Isopropyl Ketone.—Diacetyl peroxide (72.0 g., 0.61 mole) was dissolved in phenyl isopropyl ketone (140.0 g., 0.946 mole), and this solution was introduced dropwise beneath the surface of phenyl isopropyl ketone (75.0 g., 0.51 mole) heated to 115°. Carbon dioxide (40.05 g., 0.91 mole), methane (11.41 liters, S. C., 0.509 mole, mol. wt. 22.4), and methyl acetate (11.0 g., 0.15 mole, b. p. 55–56.4°; $n^{20}D$ 1.3610) were collected and identified in the usual manner.

The unchanged phenyl isopropyl ketone (171 g.) was recovered from the reaction mixture by distillation at reduced pressure. The residue (44 g.) remaining in the flask was an orange-red sirupy material which could not be crystallized. The molecular weight of this material (in carbon tetrachloride) was 784.

---

Summary

1. A new method for the preparation of 1,4-diketones is described.
2. A number of new 1,4-diketones have been prepared and characterized.
3. The mechanism of the formation of the 1,4-diketones is discussed.

CHICAGO, ILL. RECEIVED NOVEMBER 15, 1947

NOTES

Studies on the Mechanism of the Sulfonation of Aromatic Amines. III. Rearrangement of Barium Phenylsulfamate

BY ELLIOT R. ALEXANDER

In earlier communications, it has been shown that freezing point data and kinetic data[1] support a bimolecular mechanism for the sulfonation of aromatic amines rather than an intramolecular rearrangement of phenylsulfamic acid which has been postulated as an intermediate. There is one fact, however, that appears to be an anomaly: The dihydrate of barium phenylsulfamate can be transformed into sulfamic acid on heating at 180°.[2] It therefore seemed advisable to repeat Bamberger's experiments with carefully purified materials and to determine whether the reaction would proceed with the anhydrous salt.

On heating the dihydrate of barium phenylsulfamate in a closed vessel four and one-half hours at 175–185°, sulfonation of the aromatic nucleus was indeed found to have occurred to the extent of 26%. When the reaction was carried out with *anhydrous* barium sulfamate, however, no sulfonation occurred.

While these facts do not necessarily preclude an intramolecular rearrangement of the hydrate (since the water of hydration might have weakened and labilized certain bonds in the molecule permitting rearrangements which would not be possible in the anhydrous material), nevertheless it is interesting that this reaction is not characteristic of the anhydrous salt.

Experimental

Rearrangement of the Dihydrate of Barium Phenylsulfamate.—Barium phenylsulfamate dihydrate[3] (5.0 g., 0.00965 mole) was crushed into a fine powder and heated for four and one-half hours at 175–185° in a stoppered round-bottomed flask partially immersed in a metal heating bath. At the beginning of the heating moisture could be seen to condense on the cooler portion of the flask. As heating was continued the solid became streaked with purple but did not melt. After the heating period was completed, the flask was cooled and a mixture of 15 ml. of concentrated hydrochloric acid in 100 ml. of water was added. This mixture was digested fifteen minutes on a steam-bath and attached to a Kjeldahl apparatus. The solution was then made basic with sodium hydroxide solution and steam distilled quantitatively into 10 ml. of concentrated hydrochloric acid and 25 ml. of distilled water. The aromatic amine content of the distillate and the non-volatile portion was determined by titrating with standard sodium nitrite solution.[4] The steam-volatile portion required 28.91 ml. of 0.484 *N* sodium nitrite solution (72.6%) while the non-volatile portion required 10.38 ml. (26.1%).

Attempted Rearrangement of Anhydrous Barium Phenylsulfamate.—Anhydrous barium phenylsulfamate was prepared by drying the dihydrate for eight hours at 100° and 1 mm. It was analyzed by titration with sodium nitrite solution.[4]

Anal. Calcd. for $C_{12}H_{12}N_2S_2O_6Ba$: NH_2, 6.58. Found: NH_2, 6.55.

This salt (5.0 g., 0.00104 mole) was treated exactly as described above. Three drops of the sodium nitrite solution was required for the non-volatile portion while 42.87 ml. (99.6%) was required for the portion volatile with steam.

The Preparation of 2-Amino-4-hydroxy-6-keto-5,5-dichlorodihydropyrimidine

BY R. B. ANGIER, J. H. MOWAT, J. H. BOOTHE, C. W. WALLER, J. SEMB, B. L. HUTCHINGS, E. L. R. STOKSTAD AND Y. SUBBAROW

In connection with the investigation of the synthesis of pteroylglutamic acid[1] the compound, 2-amino-4-hydroxy-6-keto-5,5-dichlorodihydropyrimidine (III), became of some interest. The corresponding 2,4-dihydroxy-6-keto-5,5-dichlorodihydropyrimidine (IV) has been prepared by several methods[2,3,4] including the direct chlorination of barbituric acid (II) in water solution.[4] Several attempts to chlorinate 2-amino-4,6-dihydroxypyrimidine (I) by the use of chlorine in a water solution were unsuccessful. A good deal of decomposition occurred and the small yield of product usually obtained was apparently a mixture of the starting material and the monochloro and dichloro substitution products. When a potassium chlorate and hydrochloric acid mixture was used as a chlorinating agent a reasonably pure

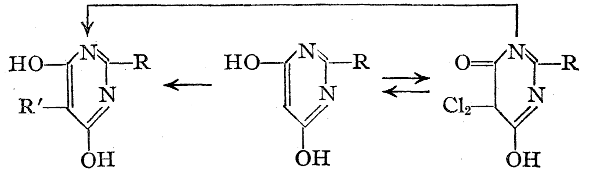
sample of the monochloro derivative, 2-amino-4,6-dihydroxy-5-chloropyrimidine (V), was obtained.



V R = NH$_2$, R′ = Cl
VI R = NH$_2$, R′ = I
I R = NH$_2$
II R = OH
III R = NH$_2$
IV R = OH

Johnson[5] has described the use of a mixture of 30% hydrogen peroxide and concentrated hydrochloric acid to convert 2-amino-4-hydroxypyrimidine to 2-amino-4,6-dihydroxy-5,5-dichlorodihydropyrimidine. By applying this procedure to 2-amino-4,6-dihydroxypyrimidine (I) the desired product was obtained. Unlike the monochloro derivative or the starting material this compound was rather unstable. In hot water it dissolved and decomposed rapidly with the production of carbon dioxide.[6] Therefore in order to demonstrate that the pyrimidine ring was still intact the compound was reduced by two methods. Reduction with hydriodic acid and glacial acetic acid gave 2-amino-4,6-dihydroxy-5-iodopyrimidine (VI) while stannous chloride and hydrochloric acid gave 2-amino-4,6-dihydroxypyrimidine (I).

Experimental[7]

2-Amino-4,6-dihydroxy-5-chloropyrimidine (V).—2-Amino-4,6-dihydroxypyrimidine (2.5 g.) was suspended in a solution of 10 cc. of concentrated hydrochloric acid and 15 cc. of water; 1.6 g. of potassium chlorate was added slowly while keeping the temperature at 25–35°. After thirty minutes the product was filtered off, washed with water and dried; yield 1.0 g. This was nearly pure but to obtain an analytical sample it was dissolved in dilute ammonium hydroxide, filtered, and precipitated by adding acetic acid. This was repeated and a white crystalline product was obtained.

Anal. Calcd. for $C_4H_4N_3O_2Cl$: C, 29.74; H, 2.50; N, 26.01; Cl, 21.95. Found: C, 29.36; H, 2.52; N, 25.70; Cl, 22.38.

2-Amino-4-hydroxy-6-keto-5,5-dichlorodihydropyrimidine (III).—2-Amino-4,6-dihydroxypyrimidine (10.0 g.) was suspended in 70 cc. of cold 30% hydrogen peroxide (Superoxol) and 70 cc. of concentrated hydrochloric acid was added. While stirring or shaking the solid slowly dissolved and the solution became warm. This was allowed to react for ten to twenty minutes while keeping the temperature between 40° and 60° by cooling. During this time a crystalline precipitate appeared. (It was necessary to control the temperature of the reaction since if the solution became too hot the reaction became violent and the product decomposed. Even when the temperature was controlled during the initial reaction period if the mixture was allowed to stand at room temperature overnight the product would redissolve and decompose.) The reaction mixture was then well cooled, filtered and the precipitate washed with water, ethanol and ether and dried; yield 6.5 to 8.0 g. (42–52%). The product did not require purification.

Anal. Calcd. for $C_4H_3N_3O_2Cl_2$: C, 24.51; H, 1.54; N, 21.44; Cl, 36.18. Found: C, 24.50; H, 1.65; N, 21.63; Cl, 35.81.

This compound is insoluble in cold water and in most organic solvents but is somewhat soluble in pyridine. It is insoluble in all concentrations of cold hydrochloric acid. It dissolves in hot water or hot dilute acid solutions and immediately decomposes giving off carbon dioxide. A sample of the compound was recrystallized by dissolving it in cold ammonium hydroxide and then acidifying the cold solution with acetic acid. The product crystallized as platelets. Analytical data on this material were the same as before recrystallization.

Reduction of 2-Amino-4-hydroxy-6-keto-5,5-dichlorodihydropyrimidine (III). A. Hydriodic Acid in Glacial Acetic Acid.—2-Amino-4-hydroxy-6-keto-5,5-dichlorodihydropyrimidine (0.5 g.) was suspended in 5 cc. of glacial acetic acid; 5 cc. of hydriodic acid (sp. gr. 1.7) was added and the resulting solution was heated on the steam-bath for thirty minutes. It was then diluted to 50 cc. with water and enough sodium hydroxide added to neutralize the hydriodic acid present. The resulting precipitate was filtered off, redissolved in dilute sodium hydroxide, filtered and precipitated again by the addition of acetic acid; yield 0.4 g. (62%) of a white powder insoluble in water. This material gave a good qualitative test for iodine.

Anal. Calcd. for $C_4H_4N_3O_2I$: C, 19.00; H, 1.59; N, 16.61. Found: C, 19.37; H, 2.02; N, 16.74.

B. Stannous Chloride in Hydrochloric Acid.—To a suspension of 1.0 g. of 2-amino-4-hydroxy-6-keto-5,5-dichlorodihydropyrimidine in 10 cc. of water were added 4 g. of stannous chloride dihydrate and 15 cc. of concentrated hydrochloric acid. This was warmed to 70° for fifteen minutes, cooled, neutralized, and then made distinctly alkaline with ammonium hydroxide. This was centrifuged and filtered to remove the stannous hydroxide. The filtrate was neutralized with acetic acid and a white crystalline product appeared; yield 0.3 g. (47%). This contained no halogen and had physical properties resembling 2-amino-4,6-dihydroxypyrimidine. To further purify it, it was dissolved in dilute ammonium hydroxide, filtered, and crystallized by adding acetic acid.

Anal. Calcd. for $C_4H_5N_3O_2$: C, 37.80; H, 3.97; N, 33.06. Found: C, 37.67; H, 4.35; N, 33.19.

All of these products are characteristic of this type of pyrimidine compound in that they have no melting point but decompose slowly at high temperatures. Also they are all insoluble or only slightly soluble in water and most organic solvents.

The Reaction of 2-Amino-2-methyl-1-propanol with Sulfuric Acid[1]

BY ROBERT E. BUCKLES AND GENE V. MOCK

The synthesis[2] of 2,2-dimethylethyleneimine by the dehydration of 2-amino-2-methyl-1-propanol would be expected to be analogous to Wenker's[3] synthesis of ethyleneimine. In the latter case the first step of the reaction has been shown to be the esterification of monoethanolamine by sulfuric

---

(5) Johnson, THIS JOURNAL, **65**, 1218 (1943).

(6) Although 5,5-dichlorobarbituric acid (IV) can be recrystallized from water, Blitz and Hamburger[3] have shown that it decomposes slowly in boiling water.

(7) The microanalyses were carried out by Mr. Louis Brancone and staff of this Laboratory.

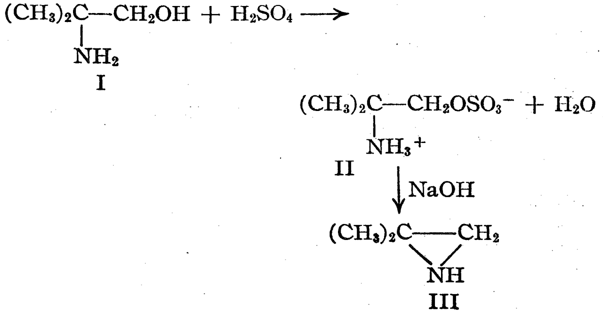
acid to give aminoethylsulfuric acid.[4] A similar procedure is used as the first step in the synthesis of 2,2-dimethylethyleneimine, but no published report of the actual identification of the reaction product has been made.

It has now been found that 2-amino-2-methyl-1-propanol (I) is esterified directly by sulfuric acid to give the expected 2-amino-2-methyl-1-propylsulfuric acid (II).



The mixture of the amine I, water and sulfuric acid was distilled slowly to remove the water according to the method of Cairns.[2a] The solid product obtained was identical with that formed during a more rapid distillation of the water similar to that described by Leighton, Perkins and Renquist[5] for the synthesis of β-aminoethylsulfuric acid. Both products yielded 2,2-dimethylethyleneimine (III) when treated with alkali.

The pure salt II was found to give no precipitate with barium chloride. This behavior parallels that of β-aminoethylsulfuric acid.[4] It was possible, however, to hydrolyze completely either β-aminoethylsulfuric acid or II in hot dilute hydrochloric acid containing barium chloride. This hydrolysis in the case of II yielded the hydrochloride of the amine I.

The possibility that the imine III might be an intermediate in the formation of the salt II was investigated. When 2,2-dimethylethyleneimine III reacted with sulfuric acid under conditions similar to those used in the preparation of II, a dark viscous product was obtained. None of the salt II could be isolated from the product, and no imine III was generated from it by alkali. It is clear from these results that the imine is not an intermediate in the preparation of II. The salt II, is formed directly from I, and III is produced by an intramolecular alkylation of II in the presence of alkali.

Experimental

2-Amino-2-methyl-1-propylsulfuric Acid (II).—A hundred grams (1.12 moles) of 2-amino-2-methyl-1-propanol (I) in 200 ml. of water was heated with 110 g. (1.06 moles) of sulfuric acid in 200 ml. of water until most of the water was distilled from the mixture. The temperature of the heating bath was then slowly raised to 175°, while the rest of the original water and that formed from the reaction was removed under the reduced pressure obtained with an aspirator. A modified method[5] was also carried out. Only about a quarter of the original amount of water was used. The solution of I was mixed with the slightly diluted sulfuric acid with cooling. The water was removed by distillation at reduced pressure over a free flame. In either case the light brown solid product was softened with 500 ml. of 95% alcohol, filtered and washed with absolute alcohol. Recrystallization from 50% alcohol yielded a white crystalline material which gave only a slight milkiness with aqueous barium chloride. The yield of purified product from the first procedure was 113 g. (63%); m. p. 253–255° (dec.).

Anal. Calcd. for $C_4H_{11}O_4NS$: C, 28.4; H, 6.56; N, 8.29. Found: C, 28.5; H, 6.48; N, 8.35.

Hydrolysis.—Two grams of II was dissolved in 25 ml. of water and 10 ml. of concentrated hydrochloric acid and 10 ml. of a saturated solution of barium chloride were added. The solution was heated overnight on a steam-bath. The barium sulfate was removed by filtration, and the filtrate was evaporated to dryness. The residue was recrystallized from absolute alcohol. The product had a m. p. 200–201° as compared with an authentic sample of 2-amino-2-methyl-1-propanol hydrochloride, m. p. 199–201°. There was no lowering of the m. p. on mixing the two. The recorded m. p. for the hydrochloride is 203–206°.[6]

Determination of Sulfur by Hydrolysis.—From 0.2 to 0.4 g. of the sulfuric ester was weighed and dissolved in 10% barium chloride solution so that there was 100% excess of barium chloride. Ten milliliters of 6 *N* hydrochloric acid was added and the solution was heated twenty hours on the steam-bath. The barium sulfate was determined gravimetrically. This analytical procedure was applied to the determination of sulfur in both II and β-aminoethylsulfuric acid.

Anal. Calcd. for $C_4H_{11}O_4NS$: S, 19.0. Found: S, 19.4, 19.8. Calcd. for $C_2H_7O_4NS$: S, 22.7. Found: S, 22.7.

Reaction of 2,2-Dimethylethyleneimine (III) with Sulfuric Acid.—A mixture of 57 g. (0.80 mole) of 2,2-dimethylethyleneimine[2] in 100 ml. of water and 79 g. (0.78 mole) of 96% sulfuric acid in 100 ml. of water was distilled with a water pump until the residue was a very viscous, black material. Treatment of some of this residue with alcohol gave no appreciable amount of crystalline product. Distillation of the residue from 40% sodium hydroxide (*ca.* 300% excess) gave some volatile material but little which distilled below 120°. 2,2-Dimethylethyleneimine boils at 70–72°.

Addendum.—It has been brought to our attention by one of the referees that J. V. Karabinos[7] has isolated 2-amino-2-methyl-1-propylsulfuric acid and β-aminoethylsulfuric acid from the reactions of the amino alcohols with sulfuric acid. Analysis of the esters for amino nitrogen by the Van Slyke method checked with the theoretical values.

The Friedel–Crafts Reaction on Highly Methoxylated Compounds

BY H. R. FRANK[1] AND D. S. TARBELL

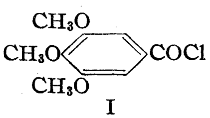
The following observations give some information about the behavior of derivatives of anisole

---

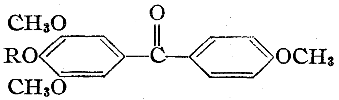
[1] Abbott Laboratories Fellow, 1946–1947.

and 1,2,3-trimethoxybenzene in the Friedel–Crafts reaction.

3,4,5-Trimethoxybenzoyl chloride (I) and anisole gave, with one and one-half moles of aluminum chloride, a mixture of the expected ketone (II) and a phenolic ketone. The position of the



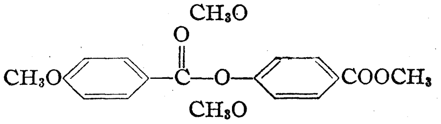
I



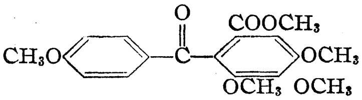
II, R = CH_3
III, R = H

phenolic group in III was not established, but was assumed to be para to the carbonyl group, since the para methoxyl in 3,4,5-trimethoxybenzoic acid is cleaved in concentrated sulfuric acid, to give syringic acid (3,5-dimethoxy-4-hydroxybenzoic acid).[2] Aluminum chloride usually cleaves the methoxyl group ortho to the carbonyl in a substituted aromatic ketone or, if no ortho methoxyl is present, a para one. Ether linkages meta to a negative group are cleaved only at higher temperatures.[3]

When the acylation of methyl 3,4,5-trimethoxybenzoate with anisoyl chloride was attempted, no reaction was observed in the presence of one mole of aluminum chloride. The addition of a second mole caused reaction to occur; the product was a neutral compound, which, on hydrolysis, yielded anisic acid and syringic acid, and hence had structure IV. None of the desired keto ester V was obtained. Similar cleavage of ether linkages



IV



V

with ester formation has been observed before in attempted acylation of aromatic ether esters.[4] In the present case, the activating effect of the methoxyl groups in methyl trimethoxybenzoate is evidently not enough to compensate for the deactivating effect of the ester group, and make the ring susceptible to Friedel–Crafts acylation. However, Friedel–Crafts acylation of a substituted benzoic ester can occur if the substituents are more favorably placed than in the present case; thus, methyl 2,6-dimethoxy-4-methylbenzoate is reported to be acylated by acetyl chloride and aluminum chloride to yield methyl 2-hydroxy-3-acetyl-4-methyl-6-methoxybenzoate.[5]

Experimental[6]

3,5,4′-Trimethoxy-4-hydroxybenzophenone (III) and 3,4,5,4′-Tetramethoxybenzophenone (II).—Freshly distilled 3,4,5-trimethoxybenzoyl chloride (I, 11.5 g., 0.05 mole) was dissolved in 10 cc. of anisole and 50 cc. of carbon disulfide. To this cooled solution was added 10 g. of aluminum chloride (0.075 mole, 50% excess) in small portions. Vigorous evolution of hydrogen chloride commenced, and a red complex formed in the solution. After refluxing on the steam-bath for ninety minutes, the reaction mixture was decomposed by ice-cold 1:3 hydrochloric acid, and the organic layer subjected to steam distillation to remove carbon disulfide and unreacted anisole. The residue was taken up in ether and extracted with dilute sodium hydroxide solution; a voluminous precipitate of the bright yellow sodium salt of the phenolic ketone, which appeared in the aqueous layer, was separated by filtration and the phenolic ketone regenerated with dilute acid. Crystallization from ethanol yielded 6.5 g. (45% yield) of colorless cubes of the phenolic ketone III, m. p. 163°. The product on methylation with dimethyl sulfate yielded the tetramethoxybenzophenone II.

Anal. (III). Calcd. for $C_{16}H_{16}O_5$: C, 66.66; H, 5.60. Found: C, 66.59; H, 5.52.

Evaporation of the ether layer from the Friedel–Crafts reaction resulted in a sticky oil which partly crystallized when triturated with benzene or alcohol. Repeated recrystallization from methanol or ethanol yielded II, m. p. 75–77°. Since this material analyzed 1% low on carbon, it was refluxed with alcoholic alkali to remove any ester or phenolic compound. The recovered ketone melted at 76–77°, but the carbon percentage was unchanged; the phenylhydrazone was therefore prepared and analyzed. It melted at 170° after crystallization from alcohol.

Anal. Calcd. for $C_{23}H_{24}N_2O_4$: C, 70.39; H, 6.16. Found: C, 70.22; H, 6.35.

3,4,5,4′-Tetramethoxybenzhydrol.—Reduction of 3,4,5,4′-tetramethoxybenzophenone in alcohol with zinc and concentrated ammonia, or zinc and sodium hydroxide, yielded after refluxing for two hours almost the theoretical quantity of the substituted benzhydrol, m. p. 106°, after crystallization from ethanol.

Anal. Calcd. for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62. Found: C, 67.13; H, 6.57.

The compound dissolves in concentrated sulfuric acid with a deep red color, which disappears on dilution with water.

2,6-Dimethoxy-4-carbomethoxyphenyl 4′-Methoxybenzoate (IV).—To a solution of 36.2 g. of methyl 3,4,5-trimethoxybenzoate in 75 cc. of benzene and 50 cc. of carbon disulfide was added 27 g. (0.16 mole) of anisoyl chloride in 100 cc. of carbon disulfide and 21.3 g. (0.16 mole) of aluminum chloride in small portions. The reagent dissolved, but no reaction was observed, even on refluxing. After cooling, another 21.3 g. of aluminum chloride was added to the reaction mixture. Evolution of hydrogen chloride took place smoothly. After the mixture had refluxed for one hour, the carbon disulfide was removed by distillation, and the residue decomposed with cold 1:1 hydrochloric acid. The neutral compound which separated was removed by filtration and washed with small portions of acetone. The benzene layer and acetone washings contained mainly starting material. The product after several crystallizations from ethanol melted at 171–173°.

Anal. Calcd. for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24. Found: C, 61.93; H, 4.93.

The structure was proved by hydrolysis with alcoholic alkali, which yielded two acids differing in their water solubility. The mixture of acids was dissolved in the minimum amount of boiling water, and cooled to 50°; anisic acid, m. p. 184°, separated. The solution, when cooled to room temperature yielded a small intermediate

ROCHESTER, NEW YORK RECEIVED NOVEMBER 21, 1947

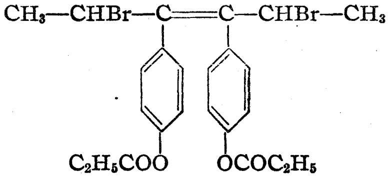
Introduction of Double Bonds into Diethyl Stilbestrol

BY M. J. FREIMAN

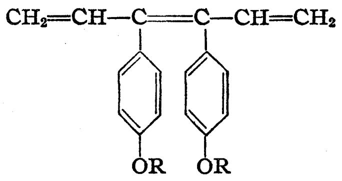
In the course of some work in this Laboratory on synthesizing substances with estrogenic activity, a 3,4 conjugated triene was prepared.

Diethylstilbestrol dipropionate was treated with 2 moles of N-bromosuccinimide to yield 3,4-bis-(*p*-propionoxyphenyl)-2,5-dibromohexene-3 (I). Two moles of hydrogen bromide were then eliminated by treatment with diethylaniline and the resulting 3,4-bis-(*p*-propionoxyphenyl)-hexatriene-1,3,5 (II) saponified to yield the free phenol (III).

The structural formulas of the new compounds are



I



II and III

II, R = C_2H_5CO—
III, R = H—

Absorption spectra of the conjugated triene dipropionate and the free phenol showed two peaks for each substance. The ester showed peaks at 273 and 280 mμ with a rather high molecular extinction coefficient of 22,860 at 280 mμ. The free phenol showed peaks at 223 and 257 mμ with a molecular extinction coefficient of 20,570 at 257 mμ.

Experimental

3,4-bis-(*p*-Propionoxyphenyl)-2,5-dibromo-hexene-3.—Thirty grams of diethylstilbestrol dipropionate dissolved in 300 ml. of carbon tetrachloride and 28.2 g. of N-bromo-succinimide were refluxed for thirty minutes in an atmosphere of nitrogen. The hot mixture was filtered and the crystals of succinimide washed with 15 ml. of carbon tetrachloride. The dried succinimide weighed 15.4 g. (theoretical recovery, 15.7 g.). The filtrate was washed with water to remove the last traces of succinimide, dried over sodium sulfate, filtered, concentrated to a volume of 85 ml. and cooled overnight. The precipitated white crystals were washed with carbon tetrachloride and dried in a vacuum desiccator at room temperature; yield, 27.3 g., m. p. 149°, green melt with decomposition. One recrystallization from carbon tetrachloride yielded small white crystals, m. p. 149.5°.

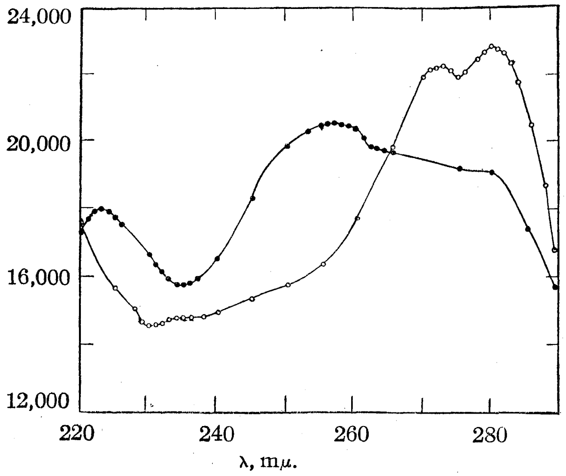


Fig. 1.—Ultraviolet absorption spectra of 3,4-bis-(*p*-propionoxyphenyl)-hexatriene-1,3,5, –○–; 3,4-bis-(*p*-hydroxyphenyl)-hexatriene-1,3,5, –●–.

Anal. Calcd. for $C_{24}H_{26}O_4Br_2$: C, 53.54; H, 4.97; Br, 29.71. Found: C, 53.48; H, 5.10; Br, 30.32.

3,4-bis-(*p*-Propionoxyphenyl)-hexatriene-1,3,5.—Twenty-one and eight-tenths grams of the above dibromo compound was heated at 150–160° for ten minutes with 220 ml. of diethylaniline. The solution darkened considerably and then was cooled to room temperature, after which it was acidified with concentrated hydrochloric acid and extracted three times with 250-ml. portions of ether. The combined ether extracts were washed with water until neutral, dried over sodium sulfate, and concentrated to a volume of 75 ml. This was then cooled to −50°, filtered and washed with a small amount of cold ether. The seven and one-tenth grams of crude crystals (m. p. 128–132°) after recrystallization from 150 ml. of petroleum ether yielded 5.4 g. of long, white needles, m. p. 134–136°.

Anal. Calcd. for $C_{24}H_{24}O_4$: C, 76.58; H, 6.43. Found: C, 76.70; H, 6.59.

When treated with bromide–bromate reagent, the triene dipropionate took up 3.84 atoms of bromine.

3,4-bis-(*p*-Hydroxyphenyl)-hexatriene-1,3,5.—Two grams of the dipropionate was refluxed for twenty minutes with 65 ml. of 10% potassium hydroxide in methanol. After this time, three volumes of water was added, and the solution made slightly acid with concentrated hydrochloric acid. At this point, the free phenol which had precipitated out, was filtered off and crystallized from ether–petroleum ether yielding 1.3 g. of slightly yellowish crystals, m. p. 196–198°. After recrystallization from aqueous isopropanol, 0.8 g. of white needles was obtained, m. p. 202–203°.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.82; H, 6.11. Found: C, 81.70; H, 6.14.

Absorption Spectra.—The spectra were determined with a Beckman quartz spectrophotometer, density readings being made at 5 mμ intervals, except when in the region of maxima or minima when the readings were made at 1 mμ intervals.

The solvent used for both curves was 99% isopropanol (Carbide & Carbon). This solvent was not purified in any way since readings could be obtained when the wave length was as low as 217 mμ.

The concentration of the conjugated dipropionate was 7 mg. per liter and that of the free phenol was 7.6 mg. per liter, and the thickness of the silica absorption cells was 1.000 ± 0.002 cm.

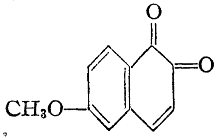
VITAMINS, INC.
CHICAGO, ILLINOIS RECEIVED SEPTEMBER 2, 1947

6-Methoxy-1,2-naphthoquinone[1]

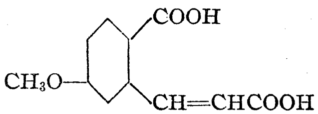
By H. E. French and Kern Sears[2]

6-Methoxy-1,2-naphthoquinone (I), required as an intermediate for a series of compounds, was prepared by the usual coupling process from 6-methoxy-2-naphthol.[3] The route to this intermediate by methylation of 2,6-dihydroxynaphthalene derived from 2-naphthol-6-sulfonic acid appeared unsatisfactory as a preparative method.[4] The claimed preparation by the hydrolysis of 6-bromo-2-naphthol with aqueous base under pressure[5] gave a tar from which a small amount of β-naphthol was isolated. Similar treatment of 6-bromo-2-methoxynaphthalene gave only traces of the desired 6-methoxy-2-naphthol. These poor results may be attributed to the positive character of the halogen.

6-Methoxy-2-naphthol was obtained in fairly good yield from 6-methoxy-2-bromonaphthalene by oxidation of the corresponding Grignard reagent according to the procedure of Kharasch.[6] Oxidation of the naphthoquinone (I) with peracetic or monoperphthalic acid gave 2-carboxy-5-methoxycinnamic acid (II). The oxidation was much less vigorous in this case than with the unsubstituted naphthoquinone.[7] When 6-methoxy-2-naphthol was oxidized with peracetic acid prepared from a mixture of acetic acid and acetic anhydride it gave a 7.4% yield of the cinnamic acid (II), whereas none of this product was obtained with peracetic acid prepared from pure acetic anhydride. On the basis of these results the oxidation may be due to unreacted hydrogen peroxide in acetic acid solution, although Böeseken obtained 2-carboxycinnamic acid from 2-naphthol by the action of peracetic acid.[8]



I



II

Experimental

6-Bromo-2-methoxynaphthalene.—6-Bromo-2-naphthol (1 mole)[9] dissolved in a solution of 80 g. of sodium hydroxide in 3000 ml. of water was methylated by heating with two portions of methyl sulfate (126 g. and 63 g.) to 70°. The mixture was thoroughly cooled after the addition of each portion. The product was filtered with suction and distilled under reduced pressure. The material boiling at 189–199° (20 mm.) weighed 170 g. (71.7%) and melted at 102–104° after crystallization from alcohol. Most of the unchanged naphthol was recovered from the aqueous solution.

6-Methoxy-2-naphthol.—A solution of 500 ml. of dry ether, 118.5 g. of 6-bromo-2-methoxynaphthalene, 123 g. of isopropyl bromide, and 300–400 ml. of dry benzene was added with stirring to a mixture of magnesium turnings (36.5 g.), 50 ml. of dry ether, and a trace of iodine. After completed reaction the mixture was stirred two hours at room temperature and one hour at reflux temperature. Dry oxygen was passed through this mixture until the visible chemiluminescence disappeared and ten minutes longer. The reaction mixture gave a negative test with Michler ketone at this point. A solution of 45 ml. of concentrated sulfuric acid in 200 ml. of water was added to the mixture with cooling, and the resulting liquid layers were separated. The naphthol was extracted from the organic layer with 1000 ml. of 10% aqueous potassium hydroxide containing some sodium hydrosulfite. It was precipitated with acid, filtered off and dried. The yield of dark yellow product was 35–37 g. (40–42%). Crystallization from water or from benzene–petroleum ether gave a white product melting at 150–151°. The m. p. has been reported as 136–137[4a] and 140.[4b]

2,6-Dimethoxynaphthalene.—Methylation of the above material with methyl sulfate in aqueous potassium hydroxide gave the known dimethyl ether which melted at 149–150.5[5] after crystallization from petroleum ether. The mixed melting point with 6-methoxy-2-naphthol (150–151°) was 118–140°.

1-Amino-6-methoxy-2-naphthol Hydrochloride.—Sulfanilic acid (42 g.) diazotized in the usual way,[3a] was added to a cold solution of 34.8 g. of 6-methoxy-2-naphthol and 61.6 g. of potassium hydroxide in 500 ml. of water. The red reaction mixture was allowed to stand for several hours and was heated to 45°. Sodium hydrosulfite (92 g.) was added, and the light yellow reaction mixture was heated to boiling, cooled to 20° in an ice-bath, and filtered. The product was crystallized and decolorized with Norite in portions from the same solution of 200 ml. of concentrated hydrochloric acid and 2 g. of stannous chloride in 800 ml. of water. The hydrochloride formed colorless needles which gradually turned purple. The yield was 30.5 g. (67.2%).

6-Methoxy-1,2-naphthoquinone.—The above aminonaphthol hydrochloride (30.3 g.) was dissolved in 2500 ml. of 0.1% aqueous hydrochloric acid by warming. The solution was filtered, cooled, and oxidized with a solution of 95 g. of ferric chloride in 75 ml. of water and 34 ml. of hydrochloric acid.[3b]

The dark orange precipitate was filtered, washed thoroughly with water and dried. The quinone, melting at 135–140°, weighed 22 g. (53.6%). Crystallization from alcohol gave red-orange needles melting at 124–127°.

Anal. Calcd. for $C_{11}H_8O_3$: C, 70.21; H, 4.23. Found: C, 69.82; H, 4.65.

3-Methoxybenzo[a]phenazine.—6-Methoxy-1,2-naphthoquinone (0.5 g.) in 20 ml. of hot glacial acetic acid was treated with a solution of 0.6 g. of *o*-phenylenediamine and 0.5 g. of sodium acetate in 20 ml. of glacial acetic acid. The crystalline phenazine was filtered off and recrystallized from aqueous acetic acid. It melted at 160–161°.

Anal. Calcd. for $C_{17}H_{12}N_2O$: C, 78.45; H, 4.66. Found: C, 78.45; H, 4.70.

2-Carboxy-5-methoxycinnamic Acid. A. Peracetic Acid Oxidation.—6-Methoxy-1,2-naphthoquinone (9.12 g.) suspended in 50 ml. of acetic acid was treated with 25 ml. of 1.4 molar peracetic acid in acetic acid.[10] A yellow

A Peptide Derivative Related to Gramicidin

BY JOSEPH S. FRUTON

The studies of Hotchkiss[1] and of Gordon, *et al.*,[2] have shown that gramicidin is a cyclopeptide which is characterized by an unusually high content in D-leucine and L-tryptophan, these two components accounting for approximately one half of the total amino acids found after complete hydrolysis of gramicidin. In the course of our studies on the effect of peptides and peptide derivatives on bacterial growth, the substance D-leucyl-L-tryptophan diketopiperazine was synthesized. The synthesis involved the reaction of carbobenzoxy-D-leucyl azide with L-tryptophan methyl ester, followed by the catalytic hydrogenation of the coupling product. Treatment of the resulting dipeptide ester with ammonia gave the diketopiperazine.

If the antibacterial action of gramicidin were due solely to the presence of D-leucine or L-tryptophan residues, the synthetic diketopiperazine might have been expected to exhibit some inhibition of the growth of organisms affected by gramicidin. It has been found, however, that the diketopiperazine, when tested at concentration levels of 1 to 10 μg. per ml. of culture medium, shows no appreciable action on *Escherichia coli*, *Staphylococcus aureus*, *Clostridium welchii* or *Brucella abortus*, and only a slight antibacterial effect was noted with *Streptococcus hemolyticus*. Control experiments with gramicidin, at 1 and 5 μg. per ml., showed complete inhibition of the growth (in 12 hours) of *S. hemolyticus*. Further experiments on the antibacterial activity of peptide derivatives related to gramicidin and tyrocidine are in progress.

Experimental

N-Carbobenzoxy-D-leucyl-L-tryptophan Methyl Ester.—Three grams of carbobenzoxy-D-leucinhydrazide[3] was dissolved in a mixture of 25 ml. of water, 10 ml. of glacial acetic acid and 5 ml. of concentrated hydrochloric acid. The solution was chilled to 0° and, with shaking, there was added, in small portions, a solution of 0.7 g. of sodium nitrite in 10 ml. of water. The azide separated as an oil and was extracted with ether. The ethereal solution was washed successively with cold water, cold aqueous bicarbonate solution, and again with cold water. The ethereal layer (60 ml.) was dried briefly over sodium sulfate and added to a solution of 2.5 g. of L-tryptophan methyl ester[4] in 60 ml. of ether. The reaction mixture was left at room temperature for eighteen hours, and then washed successively with dilute hydrochloric acid, water, aqueous bicarbonate solution, and water. After being dried over sodium sulfate, the solution was concentrated to a small volume under reduced pressure. The careful addition of petroleum ether (30–60°) gave a sirup which crystallized readily. After recrystallization from ethyl acetate–petroleum ether, the substance (2.7 g.) melted at 125–127°.

Anal. Calcd. for $C_{26}H_{31}O_5N_3$: N, 9.0. Found: N, 9.2.

D-Leucyl-L-tryptophan Diketopiperazine.—One gram of the above carbobenzoxydipeptide ester was dissolved in a mixture of 15 ml. of methanol and 0.2 ml. of glacial acetic acid and was hydrogenated at atmospheric pressure in the presence of palladium black. The hydrogenation required two hours, after which time the catalyst was removed by filtration. The filtrate was added to 30 ml. of methanol which had previously been saturated with dry ammonia at 0°. The mixture was left at room temperature for two days, then concentrated under reduced pressure, and the resulting crystalline product was dissolved in 10 ml. of hot absolute alcohol. On chilling the alcoholic solution, 0.56 g. of the diketopiperazine crystallized; m. p. 218–219° (dec.).

Anal. Calcd. for $C_{17}H_{21}O_2N_3$: C, 68.2; H, 7.1; N, 14.0. Found: C, 67.9; H, 7.1; N, 14.0.

Indole from Formyl-toluidine

BY ALEXANDER GALAT AND HARRIS L. FRIEDMAN

Of the numerous methods of preparation of indole described in the literature, ring closure of *o*-formyltoluidine is the most direct and convenient. Tyson[1] has shown that yields up to 79% may be obtained with potassium alkoxides, whereas sodium alkoxides give little or no product. This is a peculiarity of the formyl group, for the higher acyl derivatives are readily dehydrated by sodium alkoxides.[2]

The use of potassium metal in the dehydration of *o*-formyltoluidine adds both expense and an element of danger to large scale preparations. It occurred to us that if the potassium *ion* had a catalytic effect in the reaction, it would be possible to use an inexpensive potassium salt with sodium alkoxide.

This possibility was tested as follows: sodium (4.6 g.) was dissolved in 100 ml. of anhydrous methanol and 27 g. of *o*-formyltoluidine was added. Complete solution resulted on warming.

---

(1) Tyson, THIS JOURNAL, **63**, 2024 (1941).

(2) Madelung, *Ber.*, **45**, 1130 (1912).

The potassium salt used was then added and methanol was distilled off with stirring to obtain a uniform dispersion. Complete removal of methanol was effected by applying reduced pressure (20–30 mm.) and the resulting solid was heated in a solder-bath between 300 and 350°. The reaction occurs at the internal temperature of 300–310° as evidenced by rapid distillation of toluidine. Reduced pressure (20–30 mm.) was applied toward the end of the reaction to remove all toluidine. The reaction mass was cooled, treated with water and the indole steam-distilled over. The product crystallized in the cooled distillate in the form of lustrous plates. Any trace of toluidine was removed by acidification and the indole was filtered, washed with water and dried; m. p. 50–51.5°.

Since half of the toluidine was recovered in every case, the yield was calculated on the basis of this recovery. The results obtained are contained in Table I.

TABLE I

g.	Added salt,	K atoms	Yield, %	Observations
None		..	6.0	
17	Anhydrous K_2SO_4	1	14.5	No stirring used; melt appears heterogeneous
35	Anhydrous K_2SO_4	2	21.0	
70	Anhydrous K_2SO_4	4	14.5	
35	Anhydrous K_2SO_4	2	34.0	Mechanical stirring used
20	Anhydrous KOAc	1	27.0	Homogeneous fluid melt
39	Anhydrous KOAc	2	37.5	

Whether the potassium acts as a catalyst or as a reactant is open to question. The data show that a potassium salt does effect a marked increase in yield, the maximum effect being obtained apparently with two atoms of potassium.

Although the yield is not as high as when potassium metal is used, the procedure is safer and much less expensive.

The Preparation of 2,2,2-Trifluoroethanol

BY HENRY GILMAN AND R. G. JONES

In connection with studies of compounds containing the trifluoromethyl group, we had need of trifluoroethanol. This substance had been described by Swarts[1] who prepared it by the catalytic reduction both of trifluoroacetic anhydride and of trifluoroacetamide. Since the former method afforded him a yield of only 23%, we attempted in vain its preparation from both ethyl and *n*-butyl trifluoroacetate by hydrogenation over copper chromite catalyst at pressures up to 3500 lb./sq. in. and temperatures up to 250°. No hydrogen was absorbed and we recovered unchanged 70% of the ethyl, and 32% of the butyl ester.

In view of this failure we resorted to the latter method of Swarts, who unfortunately gave no details of his procedure other than that he hydrogenated the ethereal solution under a pressure of 40 atmospheres.

Trifluoroethanol.—A solution of 113 g. (1.0 mole) of pure amide (m. p. 74.5–75.0°) in 100 cc. of anhydrous ether in a bomb of 490-cc. capacity with 3.5 g. of Adams catalyst was agitated with hydrogen at 1500 lb./sq. in. at 90° for seven hours, the pressure dropping to 670 lb./sq. in. To the cooled bomb 1.5 g. of fresh catalyst was added and agitation at the previous temperature and pressure was continued for four hours longer, the pressure then dropping to 1080 lb./sq. in. The contents of the cooled bomb with the ether washings was fractionated in a small packed column of about 10 equivalent plates, yielding a fraction weighing 76.5 g. (76.5%) and boiling at 75–77° (740 mm.). It was necessary to heat the distilling flask with a free flame in order to drive over the trifluoroethanol. Apparently the latter forms an unusually stable solvate with the unchanged trifluoroacetamide and ammonium trifluoroacetate present. The released hydrogen in each case was allowed to bubble through concentrated hydrochloric acid, whereby a total of 36 g. of ammonium chloride (66% yield), identified by analysis, was obtained.

The platinum catalyst seemed to quickly lose its activity. In all of the runs the rate of reduction became very slow after about four hours and it was necessary to add fresh catalyst.

From several preparations, the general reaction for which may be represented as

$$CF_3CONH_2 + 2H_2 \xrightarrow{Pt} CF_3CH_2OH + NH_3$$

none of the recently described[2] trifluoroethylamine was isolated. The only products were trifluoroethanol, ammonia, unchanged trifluoroacetamide, and ammonium trifluoroacetate. The small quantity of ammonium trifluoroacetate obtained may have resulted from hydrolysis of trifluoroacetamide.[3]

Trifluoroisopropanol.[4]—Seventy-five grams (0.67 mole) of trifluoroacetone,[5] 5 g. of Adams catalyst, and 3 cc. of water, were added to the bomb previously cooled to −15°, and the whole agitated at room temperature with hydrogen at 760 lb./sq. in. pressure. The absorption of hydrogen began at once and in three hours the pressure had dropped to 250 lb./sq. in. The bomb was then opened and the contents and ether washings were dried over calcium sulfate and

Preparation of Schiff Bases by Condensation of 2-Acylthiophenes with Amines

BY HOWARD D. HARTOUGH

In contrast to the circuitous procedure involved in the preparation of Schiff bases from acetophenone,[1] 2-acetylthiophene condenses directly with aniline and primary aliphatic amines, without the aid of a catalyst, in boiling toluene or xylene. 2-Butanoylthiophene condenses very slowly with aniline and the reaction apparently can be catalyzed by addition of iodine. Zinc chloride could not be used to catalyze this reaction since an insoluble complex formed with the 2-acylthiophenes. Although the best yields obtained were not greater than 46%, the original reactants could be completely recovered and the product distilled without loss due to high boiling residues.

These ketimines are readily hydrolyzed with moisture to the original components. A loosely stoppered bottle of pure crystalline N-phenyl 2-thienyl methyl ketimine stored in a humid atmosphere became semi-crystalline at the top of the bottle and the odor of 2-acetylthiophene was prevalent.

Experimental

N-Phenyl 2-Thienyl Methyl Ketimine.—A mixture of 0.5 mole each of aniline and 2-acetylthiophene was heated at reflux in 150 ml. of toluene in a flask to which was attached a conventional water take-off trap and a reflux condenser. After thirteen hours, 5 ml. of water (9 ml. calcd.) was collected in the trap. Heating at reflux an additional six hours did not increase the amount of water. The toluene was recovered by distillation at atmospheric pressure; the aniline and 2-acetylthiophene at a reduced pressure. The bright yellow product, 45 g. (46%), boiling at 155° at 5 mm. crystallized on standing and after one recrystallization from absolute alcohol melted at 69–70°.

Anal. Calcd. for $C_{12}H_{11}NS$: N, 7.0; S, 16.0. Found: N, 7.1; S, 16.1.

N-(2-Ethylhexyl) 2-Thienyl Methyl Ketimine.—An equimolar mixture (0.325 mole) of 2-acetylthiophene and 2-ethylhexylamine in 500 ml. of toluene was refluxed for twenty-two hours as above. The liquid product, 30 g. (40%), boiled at 150–157° at 4 mm.

Anal. Calcd. for $C_{14}H_{23}NS$: N, 5.91. Found: N, 6.07.

N-Phenyl 2-Thienyl Propyl Ketimine.—A mixture of 2-butanoylthiophene (0.25 mole) and aniline (0.50 mole) in 500 ml. of toluene was refluxed for four hours, but only 0.3 ml. of water was collected. The mixture was cooled, 3 g. of iodine added, and refluxed five hours more, 1.0 ml. of water being collected. The liquid product, 16 g. (28%), boiled at 128–130° at 1 mm.

Anal. Calcd. for $C_{14}H_{15}NS$: N, 6.12. Found: N, 6.19.

Low Temperature Nitrogen Adsorption Studies of Silica Gel

BY ISIDOR KIRSHENBAUM AND RICHARD K. GROVER

Recently a number of papers have appeared upon the effect of sintering *in vacuo* and of grinding upon the surface area and average pore size of gel type materials. Milligan and Rachford[1] have reported that sintering a silica gel causes destruction of pores but no change in average pore size. Van Nordstrand, Kreger and Ries[2] have found that grinding Thermofor Catalytic Cracking beads to a fine powder results in a considerable decrease in both surface area and pore volume. Apparently, however, this latter phenomenon is not restricted to silica–alumina cracking catalysts. Similar observations have recently been made in our laboratories, using a Davison silica gel, activated at 650° and having a surface area of 655 sq. m./g. Upon grinding from 80+ microns to a powder containing about 40% 0–80 micron and 60% 80+ micron particles, the surface area was decreased by 8.6% to 599 sq. m./g. Typical data are summarized in Table I. Both ground and unground samples were evacuated for four hours at 290° before the nitrogen adsorption isotherms were obtained, previous work having indicated that this pretreatment is sufficient to give results reproducible to better than about 1%. The changes observed upon grinding may be due to a partial collapse of pore structure effected by the heat and/or pressure of grinding.

TABLE I

EFFECT OF GRINDING ON ACTIVATED SILICA GEL

Sample	Roller analysis		Weight loss on evacuation, %	Surface area sq. m./g.
	Microns	%		
Unground	0–20	2.8	5	655
	20–40	1.7		
	40–80	1.7		
	80+	93.8		
Ground	0–20	14.7	5	599
	20–40	10.3		
	40–80	13.7		
	80+	60.9		

This effect of grinding was also observed with a silica gel containing about 64% water. A sample of the gel was ground and then both ground and

unground samples were evacuated at 290° for four hours. The surface area of the unground catalyst, as determined from the nitrogen adsorption isotherm, using the weight after evacuation, was 1061 sq. m./g., whereas that of the ground catalyst was 991 sq. m./g., a difference of 6.7%. Little, if any, effect was observed on the average Kelvin pore radius, as determined from the relative pressure corresponding to the steepest portion of the desorption curve. The unground sample had an average pore size of 21.1 A., whereas the ground sample had an average pore radius of 20.7Å.

Preparation and Characterization of β-Dibutylaminoethyl Chloride Hydrochloride

BY HOWARD C. KLEIN[1] AND IRVING A. KAYE

β-Dibutylaminoethyl chloride hydrochloride has been prepared by the dropwise addition of 47.2 g. (0.4 mole) of thionyl chloride to 51.9 g. (0.3 mole) of β-dibutylaminoethanol, dissolved in 150 ml. of benzene. After removal of the solvent and excess thionyl chloride under diminished pressure, the tarry residue was dissolved in dry acetone, the solution decolorized with Darco G-60, and then cooled with Dry Ice. The precipitated white hydrochloride (57.9 g., 85%) melted at 86–88°.

Anal. Calcd. for $C_{10}H_{23}NCl_2$: Cl^-, 15.41; Cl (total), 30.82. Found: Cl^-, 15.30; Cl (total), 30.92.

Recrystallization of the hydrochloride from acetone–hexane gave pearly leaflets, m.p. 87–89°.

The basic chloride boiled at 119–120° (30 mm.).[2]

Synthesis of Amino-substituted Phosphonic Acids. II. α-Aminobenzylphosphonic Acid

BY GENNADY M. KOSOLAPOFF

As it was reported earlier[1] the synthesis of α-aminobenzylphosphonic acid by the reduction of *p*-nitrophenylhydrazone of diethyl benzoylphosphonate by means of hydrogen, followed by sodium sulfide, failed to yield the pure product. The contamination of the final product was caused principally by the products of incomplete reduction and led to the unusually low melting point of the substance. In order to secure the pure material it was necessary to find another reduction method which was usable in this instance. Such a procedure using the method of Fischer and Groh[2] for the reduction led to the pure substance.

The hydrazone (4 g.) in 500 cc. of ethanol was added to 10 g. of amalgamated aluminum foil immersed in 1 liter of ethanol and 200 cc. of water. The mixture was allowed to stand overnight in a loosely stoppered flask. After filtration, the precipitate was washed with 500 cc. of ethanol and the combined filtrates were treated with 300 cc. of concentrated hydrochloric acid. The solution was slowly distilled (six hours) through a Vigreux column until the volume in the still-pot amounted to approximately 50 cc. On cooling, the *p*-phenylenediamine hydrochloride was filtered off, the filtrate was evaporated to dryness by an infrared lamp and the residue was taken up in 200 cc. of ethanol. Neutralization with aniline gave the crude product which was taken up in 30 cc. of warm water, made strongly alkaline with 10% sodium hydroxide and extracted twice with 50 cc. of benzene. The aqueous solution was made just acid to congo red with 1:1 hydrochloric acid and concentrated to incipient crystallization. After cooling, the product was filtered off, washed with 5 cc. of ice-water, dissolved in 50 cc. of hot water, treated with charcoal, filtered and concentrated to 10 cc. On cooling there was obtained 1.0 g. (50%) of *dl*-α-aminobenzylphosphonic acid, in the form of tiny bunched colorless needles, which melted at 272–273°.

Anal. Calcd.: N, 7.5; P, 16.6. Found: N, 7.46; P, 16.7.

Copolymerization Rate Constants in the System 2,5-Dichlorostyrene–Methyl Acrylate

BY F. LEONARD, W. P. HOHENSTEIN AND E. MERZ

During the course of an investigation of the copolymerization of the isomeric dichlorostyrenes and acrylic esters, it became of interest to determine the copolymerization rate constants in the system 2,5-dichlorostyrene and methyl acrylate. The results of this determination are herein presented.

Experimental

2,5-Dichlorostyrene.—This monomer was obtained from the Monsanto Chemical Co. and was purified by washing with 5% sodium hydroxide solution and then with distilled water until the washes were neutral to litmus. The monomer was allowed to dry over calcium chloride overnight. It was then filtered and checked for the presence of polymer by adding a sample to methanol. If no turbidity was observed, the monomer was used *per se*.

Methyl Acrylate.—This monomer obtained from Rohm and Haas was distilled *in vacuo* through a 12″ column packed with glass helices in an all-glass system. The first 10 cc. to distil was rejected and a residue of 50 cc. was left in the distilling flask.

Polymerization and Purification.—The requisite quantities of 2,5-dichlorostyrene, methyl acrylate and benzoyl peroxide (0.5% by weight based on monomers) were weighed into Pyrex glass test-tubes. The tubes were sealed, and immersed in a water-bath held at 70 ± 0.1°. The per cent. conversion was estimated approximately by the rate of rise of air bubbles through the polymerizing mixture when the tubes were inverted. When it appeared that the desired conversion, <5%, had been reached, the tubes were immediately chilled, and the seal broken. The contents of the tubes were dissolved in methyl ethyl ketone containing hydroquinone, and this solution was slowly added with stirring to a 3 times excess of methanol. The precipitated polymer was filtered, washed copiously with methanol and allowed to dry to constant weight in a vacuum oven at 60°.

Chlorine Analysis.—The per cent. chlorine was determined using the Parr bomb.

Results and Discussion

The experimental data are summarized in Table I. The copolymerization rate constants were calculated according to the method of Alfrey and Goldfinger[1] in the usual manner.

TABLE I

DETERMINATION OF r_1 AND r_2

THE COPOLYMERIZATION RATE CONSTANTS SYSTEM 2,5-DICHLOROSTYRENE–METHYL ACRYLATE

Monomer composition: Mole fraction 2,5-dichlorostyrene	Monomer composition: Mole fraction methyl acrylate	Yield, %	Chlorine, %	Polymer composition (Exp.): Mole fraction 2,5-dichlorostyrene	Polymer composition (Exp.): Mole fraction methyl acrylate
0.90	0.10	4.4	39.95	0.950	0.050
.75	.25	3.0	39.15	.913	.087
.50	.50	3.7	37.20	.829	.171
.25	.75	4.4	32.15	.643	.357
.10	.90	4.9	22.30	.371	.629
.05	.95	4.3	14.15	.206	.794

The smooth curve in Fig. 1 represents the theoretical curve calculated from the values $\alpha = 0.25$ and $\beta = 0.15$. These correspond to the values, according to the latest nomenclature,[2] $r_1 = 4$ and $r_2 = 0.15$, respectively. The encircled points are experimentally determined from the data in Table I.

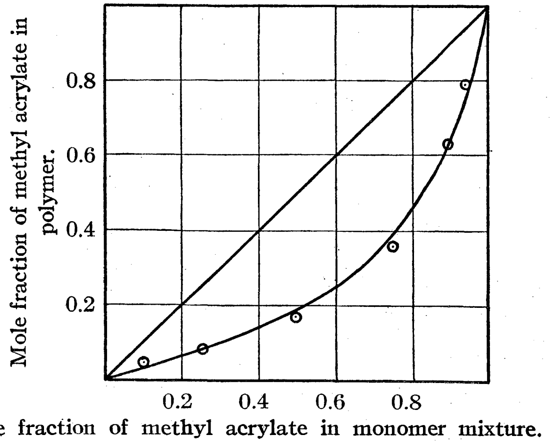

Fig. 1.—Copolymerization composition curve.

The value $r_1 = 4$ indicates that the 2,5-dichlorostyrene monomer adds to the 2,5-dichlorostyrene free radical four times as fast as the methyl acrylate monomer adds. The value $r_2 = 0.15$ indicates that the methyl acrylate monomer adds to the methyl acrylate free radical 0.15 as fast as the 2,5 dichlorostyrene monomer adds to the methyl acrylate free radical.

The Preparation of 2,3,5-Triphenyltetrazolium Chloride

BY A. M. MATTSON, C. O. JENSEN AND R. A. DUTCHER

Synthesis of 2,3,5-triphenyltetrazolium chloride by the method of Pechman and Runge as modified by Bamberger and Billeter and by Kuhn and Jerchel[1] resulted in poor yields of preparations which had a greater chloride content than the desired monobasic compound. A better yield of the compound with the theoretical chloride content and a saving of time were achieved by modifying the previous procedures.

Experimental

Triphenylformazan.—Twenty-one and two-tenths grams (0.2 mole) of freshly distilled benzaldehyde was dissolved in 125 ml. of methanol. To this solution 21.6 g. (0.2 mole) of phenylhydrazine was added during mechanical agitation. The hydrazone, dissolved in one liter of methanol, was added to a solution of 50 g. of sodium hydroxide and 70 g. of sodium acetate in one liter of methanol. To this solution, cooled to 20°, benzenediazonium chloride prepared from 18.6 g. of aniline (0.2 mole), 50 ml. of concentrated hydrochloric acid, 50 ml. of water and 14–15 g. of sodium nitrite, was added slowly during agitation. Formazan was precipitated as small red crystals. A yield of 15.8 g. (23%) of triphenylformazan was obtained, m. p. 170°.

2,3,5-Triphenyltetrazolium Chloride.—Fifteen grams (0.05 mole) of triphenylformazan were dissolved in 100 ml. of chloroform and the solution was cooled to 20°. Lead tetraacetate (30 g.) was added until the red color disappeared. The chloroform was evaporated and the residue taken up in water. Hydrochloric acid was added and the lead chloride was removed by filtration. The monobasic triphenyltetrazolium chloride was removed from the filtrate by three successive extractions with chloroform (water–chloroform ratio of 3:1), leaving the more acid salt in the water. The chloroform solution was concentrated on the steam-bath. Addition of ether to this solution precipitated the tetrazolium salt in long, silky needles. Nine and seven-tenths grams (57.7% based on formazan) of 2,4,5-triphenyltetrazolium chloride was obtained, m. p. 245° (d.) (Pechman and Runge 243°).

Effects of Inhibitors on the Polymerization of Styrene[1]

BY FRANK R. MAYO AND R. A. GREGG

Inhibitors of free radical polymerization are regarded as materials which, by transfer or addition, are converted to radicals so stable they do

---

(1) This paper was presented before the Division of Organic Chemistry at the New York City Meeting of the American Chemical Society, September 15, 1947.

not add to double bonds. This note will show that benzoquinone is not an inhibitor in this sense and that even the stable radical triphenylmethyl adds readily to styrene.

Foord[2] and Goldfinger, Skeist and Mark[3] found the period of inhibition of styrene polymerization by benzoquinone was proportional to the initial quinone concentration. Assuming the consumption of inhibitor to be a direct measure of the rate of chain initiation, they calculated the activation energy for chain initiation. Since the present work shows that most of the quinone radicals add to styrene, the above assumptions are not justified. At 100°, the rate of uncatalyzed polymerization of styrene is 2.23% per hour yielding a polymer of degree of polymerization 4030.[4] The total moles of polymer per gram per hour is 5.32×10^{-8}, and is equal to the maximum number of chains which could have been initiated. At 100°, 10^{-4} g., 9.3×10^{-7} mole, of benzoquinone inhibits the polymerization of 1 g. of styrene for one hour.[3] Hence, at least 17 molecules of quinone are consumed per radical chain initiated.

Since the inhibition period, the time required to consume quinone, is directly proportional to the initial concentration of quinone, its rate of disappearance is independent of its concentration and quinone cannot be reacting directly with monomer. Let us consider the possible reactions, denoting monomer and quinone by M and Q, and the derived radicals by M* and Q*

$$2M \longrightarrow 2M^* \qquad (1)$$
$$M^* + Q \longrightarrow Q^* \qquad (2)$$
$$Q^* + M \longrightarrow M^* \qquad (3)$$
$$\left.\begin{array}{ll} 2Q^* \longrightarrow & (4) \\ Q^* + M^* \longrightarrow & (4a) \\ 2M^* \longrightarrow & (4b) \end{array}\right\} \text{non-radical products}$$

If we assume the mechanism to be described completely by Equations 1, 2, 3 and 4, then

$$-\mathrm{d}Q/\mathrm{d}t = M^2(2k_1 + k_3\sqrt{k_1/k_4})$$

The rate of disappearance of quinone should then be independent of the quinone concentration, as observed, and about 16 out of 17 quinone radicals react by Equation 3 instead of Equation 4. At higher radical concentrations Equation 4 may predominate since it is of second order while Equation 3 is of first order with respect to radicals.[5] Equation 2 may represent either chain transfer or addition of quinone to the chain (copolymerization). Reaction 4b must be unimportant or quinone would not be an inhibitor. If the termination step were 4a, then the rate of disappearance of quinone would depend on the quinone concentration.

It is desirable to have an inhibitor which will not initiate or continue chains, each molecule of which will terminate one reaction chain. Then the rate of chain initiation could be determined and, from our data,[4] the number of polymer molecules formed per chain initiated, *i. e.*, the extent of chain transfer with styrene monomer.[6] Hence, we investigated the radical triphenylmethyl hoping it would terminate chains without starting any.

Hexaphenylethane was dissolved in styrene and heated in narrow diameter tubes sealed under nitrogen. The length of the inhibition period was determined from the viscosity of the reaction mixture, measured as the time for a bubble to traverse a measured distance in the tube. Figure 1 shows that the solution viscosities after the induction period follow essentially the same course as in the blank run. The induction periods were taken as the times required for the solutions to attain a "bubble time" of thirty seconds, minus the eight and three-tenths hours required to reach this stage in the blank. The essential data and conclusions are summarized in Table I and Fig. 2. The results show that the inhibition period increases with the initial concentration of inhibitor, but less rapidly; a large concentration of inhibitor is relatively less effective than a small concentration.

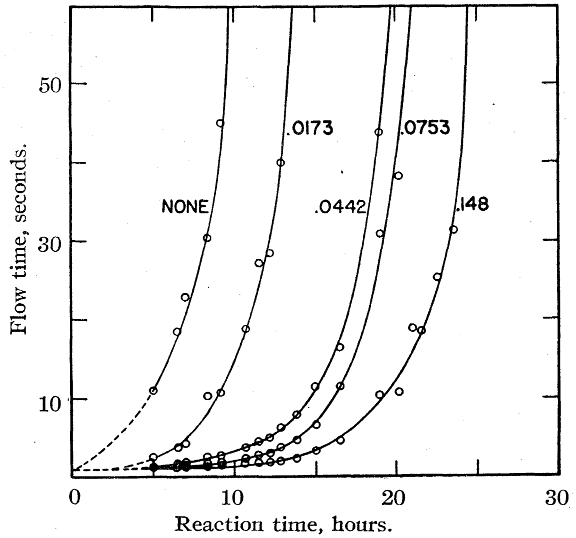

Fig. 1.—Polymerization of styrene at 100° with various initial concentrations of hexaphenylethane, as indicated in moles/liter.

TABLE I

INHIBITION OF THE POLYMERIZATION OF STYRENE AT 100° BY HEXAPHENYLETHANE

Inhibitor moles/l.	Inhibition period, hours	Hours per unit inhibitor concentration
None	None	240–300[a]
0.0173	3.9	225
.0442	9.7	219
.0753	10.9	145

[6] While this attempt failed, the transfer constant of polymerizing styrene with styrene monomer has been determined and will be published shortly.

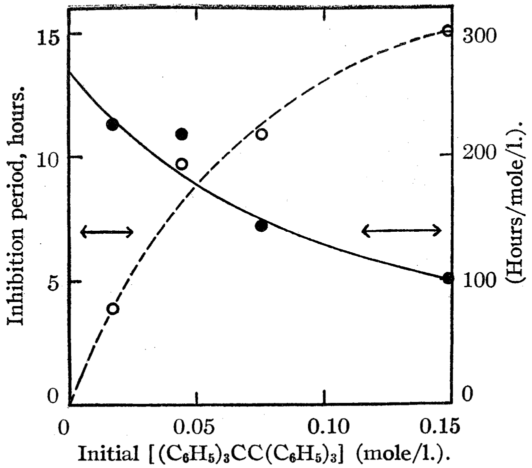

Fig. 2.—Inhibition periods in the polymerization of styrene, in hours (broken line), and in hours per unit concentration of hexaphenylethane (solid line).

This result may be due to the disappearance of hexaphenylethane in a side reaction, such as the addition to styrene; the addition of tri-biphenylmethyl to styrene to give a 2:1 product has been observed.[7] However, since our data are not consistent enough to permit analysis of the kinetics, the inhibition period per unit concentration of inhibitor has been plotted against the concentration of inhibitor in Fig. 2 and extrapolated to estimated zero concentration of inhibitor. Making the reasonable assumption that this extrapolation minimizes complications due to side reactions which consume hexaphenylethane, the results show that the induction period is of the order of two-hundred-forty to three-hundred hours per mole of substituted ethane initially present. Thus, such a solution would consume about 1/270 or 0.0037 mole of hexaphenylethane per hour. Normally, $5.32 \times 10^{-8} \times 905 = 4.8 \times 10^{-5}$ mole of polymer per liter per hour would have been produced. Hence, about 77 molecules of hexaphenylethane disappear (at zero ethane concentration) for each molecule of polystyrene that would have been formed in its absence. It follows that triphenylmethyl radicals must start nearly as many chains as they stop. The addition of hexa-arylethanes to double bonds seems to be the result of an initiation of "polymerization" by free radicals, and an even more effective termination by the same kind of radicals or by undissociated ethane, so that only *very* low molecular weight polymer is formed while triarylmethyl radicals, or undissociated ethane, remain.

We consider that this work leads to the following conclusions: Any free radical may start or terminate the polymerization of a styrene chain. Neither benzoquinone nor hexaphenylethane is suitable for measuring the spontaneous rate of chain initiation, nor for calculating its activation energy. Whether a source of free radicals will behave as a catalyst or an inhibitor depends on the balance between the rate of addition of these radicals to monomer, the rate of interaction of radicals and the rate of growth of the polymer radicals at the chosen temperature. If the radicals do not add rapidly or if they are supplied too fast, then a high radical concentration results and chain growth is restricted. If the radicals add very rapidly, or are supplied slowly enough, polymerization will result. These statements mean simply that the dividing line between catalysts and inhibitors is not clear cut; the differences between them are quantitative rather than qualitative.

The Periodate Oxidation of Some Dihydroxyaminoalkanes[1]

BY J. F. MEAD AND E. A. BARTRON

It has been reported previously[2] that two of the contiguously substituted dihydroxyaminoalkanes and possibly dihydrosphingosine[3] can be partially identified by the periodate or lead tetraacetate oxidation of the N-acetyl derivatives with measurement of the amount of oxidizing agent consumed.

A simpler method applicable to a wide variety of related compounds is the periodate oxidation[4] of the amino glycols themselves, with isolation of at least two of the oxidation products.

The reactions of the various types of isomeric compounds with periodate can be represented as follows

Type I $R—CHNH_2—CHOH—CH_2OH + 2IO_4^- \longrightarrow R—CHO + HCOOH + HCHO + NH_3 + 2IO_3^-$

Type II $R—CHOH—CHNH_2—CH_2OH + 2IO_4^- \longrightarrow R—CHO + HCONH_2 + HCHO + 2IO_3^-$

Type III $R—CHOH—CHOH—CH_2NH_2 + 2IO_4^- \longrightarrow R—CHO + HCOOH + HCHO + NH_3 + 2IO_3^-$

Type IV $CH_2OH—C(R)NH_2—CH_2OH + 2IO_4^- \longrightarrow R—CONH_2 + 2HCHO + 2IO_3^-$

Type V $CH_2OH—C(R)OH—CH_2NH_2 + 2IO_4^- \longrightarrow R—COOH + HCHO + NH_3 + 2IO_3^-$

It will be noticed that if R is different from H (as in the case of sphingosine) all five types give different products except I and III, which can be distinguished by oxidation of the N-acetyl derivatives[2] and measurement of the amount of formaldehyde produced.

In testing the method, the simplest substrates were used, and the products isolated or identified were those most easily isolated or determined quantitatively. As can be seen from Table I, the

[2] C. Niemann, A. A. Benson and J. F. Mead, *J. Org. Chem.*, **8**, 397 (1943).

[3] After completion of this note a paper appeared by Carter, Glick, Norris and Phillips, *J. Biol. Chem.*, **170**, 1 (1947), who oxidized dihydrosphingosine to obtain formaldehyde, formic acid and ammonia.

[4] E. L. Jackson, "Organic Reactions," Vol. II, John Wiley & Sons, Inc., New York, N. Y., 1944, Chap. 8, p. 341.

method is both qualitative and quantitative. The yields, which in some cases would be greater than 100% if calculation were made on the basis of substrate actually oxidized can be explained by the differences in temperature of the oxidizing solutions resulting from the addition of the dimethyldihydroresorcinol in hot water (see below). Only one serious difficulty was experienced. In the cases in which both ammonia and formaldehyde were produced, only small yields of either could be obtained because of the formation of hexamethylenetetramine. This difficulty was partially overcome in the case of formaldehyde by an earlier addition of dimethyldihydroresorcinol, with which the formaldehyde apparently reacts preferentially. The compounds used for the reactions were selected because of availability and as examples of each type of product. Formaldehyde was isolated in each case, while acid or ammonia were titrated if the theoretical equation required their formation. If the equation and a qualitative test (for ammonia)[5] indicated the formation of an amide (II and IV), the solution was treated under hydrolytic conditions, and the acid formed was distilled and titrated.

TABLE I

Compound	% oxidized	% of theoretical amount of products isolated (based on substrate taken)			
		HCHO	NH_3	HCOOH	CH_3COOH
$CH_2OH—CHOH—CH_2OH$	94.2	91.7		93.7	
$CH_2OH—CH_2NH_2$	84.4	69.2	59.0		
$CH_2OH—C(CH_3)NH_2—CH_3$	88.0	91.2	84.0		
$CH_2OH—C(CH_3)NH_2—CH_2OH$	89.2	92.6			73.5
$CH_2OH—CHOH—CH_2NH_2$	82.2	82.1		90.8	

Experimental

Determination of Completeness of Oxidation.—The substrate, about 10^{-4} mole, in water solution or emulsion was treated with a 10% excess over the theoretical amount of a saturated solution of potassium metaperiodate (1.66×10^{-2} mole per liter) for twenty minutes. To the resulting solution was added borax–boric acid buffer solution, and potassium iodide, and the liberated iodine was titrated with standard arsenite solution.

Determination of Formaldehyde.—In the absence of ammonia, the oxidation mixture, after standing for twenty minutes, was treated with a 10% excess over the theoretical amount of dimethyldihydroresorcinol[6] in alcohol solution, brought to *p*H 4, warmed to 60°, and allowed to stand in the ice-box until precipitation was complete. The formaldehyde dimethone was collected and weighed, and the melting point taken to determine the purity of the sample.

In case ammonia was formed in the reaction, the following procedure was adopted. The substrate and periodate solutions were mixed, and dimethyldihydroresorcinol in hot water solution was added after about three minutes. After twenty minutes, the solution was brought to *p*H 4 and treated as before.

Determination of Acid.—If no ammonia was formed in the reaction, the oxidation mixture, after twenty minutes, was titrated with standard alkali. If ammonia was formed, the solution was acidified with sulfuric acid and about three-fourths of it distilled. Water was added, and the distillation repeated. The distillate was then titrated with standard alkali.

Determination of Ammonia.—If no acid was formed in the reaction, the oxidation mixture, after twenty minutes, was titrated with standard acid.

Determination of Amides.—If the formation of amide was indicated (see above), the solution, after completion of the oxidation, was made strongly acidic with sulfuric acid, refluxed for two hours and then distilled to about one-fourth volume. Water was added, and the solution was again distilled to one-fourth volume, and the distillate titrated with standard alkali. If the acid formed was known, it was necessary to distill and titrate only 10% of the solution, and calculate the total amount originally present.[7]

Crystalline Procaine Penicillins

BY CHARLES J. SALIVAR, F. HOWARD HEDGER AND ELLIS V. BROWN

There is an urgent need for a penicillin dosage form which will give prolonged penicillin blood levels with more certainty and without the objectionable features of the currently available preparations.

We have prepared procaine salts of two penicillins and have milled them in vegetable oil to give injectable mixtures. Preliminary animal and clinical trials have indicated that significant and prolonged penicillin blood levels are obtainable with these preparations. These data will be published later.

For the preparation of procaine benzylpenicillin, 10 g. of sodium benzylpenicillin dissolved in 10 ml. of water is treated with a solution of 7.6 g. of procaine hydrochloride in 10 ml. of water and the reaction product is allowed to crystallize slowly. After crystallization is completed, the product is filtered, washed with water and dried in a vacuum drier at 50°.

The practically colorless crystalline procaine salt of benzylpenicillin melts (capillary) at 129–130°. *Anal.* Calcd. for $C_{29}H_{38}N_4O_6S{\cdot}H_2O$: N, 9.52; S, 5.44. Found: N, 9.78; S, 5.35.

The biological potency obtained by the Oxford plate method[1] against *S. aureus* is 1020 U./mg. The potency as determined iodometrically[2] is 1007 U./mg. The calculated value based on 1667 U./mg. for sodium benzylpenicillin is 1008 U./mg. The optical rotation is $[\alpha]^{25}\text{D}$ +173° (1% in 50% aqueous acetone).

Procaine *n*-amylpenicillin was also prepared in the same manner from sodium *n*-amylpenicillin.[3] It melts at 113–115°. *Anal.* Calcd. for $C_{27}H_{42}N_4O_6S{\cdot}H_2O$: N, 9.86; S, 5.63. Found: N, 9.79; S, 5.97.

The Friedel–Crafts Reaction of Benzene and 3,4-Dichlorohexane

BY KEIITI SISIDO AND HITOSI NOZAKI

The condensation of benzene with 3,4-dichlorohexane has been studied. The dichlorohexane was prepared from divinylacetylene by catalytic hydrogenation followed by chlorination.[1] The reaction product obtained by the usual procedure was composed of two fractions.

The analysis and molecular weight determination of the first fraction agreed with the formula $C_{12}H_{16}$, showing that it was a mono-cyclialkylated benzene. The dehydrogenation of this hydrocarbon with sulfur or with selenium under the condition not to be accompanied with anomalies[2] gave an oily product, whose picrate formed orange needles melting at 144–144.5°, alone or admixed with an authentic specimen of 1,4-dimethylnaphthalene picrate. It has often been observed, however, in the case of the picrates of naphthalene derivatives, that a mixture of two different isomers shows no depression of the melting point. But as all of the isomers of dimethylnaphthalene are already known, an examination of the literature about the characteristic data of the hydrocarbons and their picrates made it clear that the dehydrogenation product above mentioned was nothing else but 1,4-dimethylnaphthalene. From these observations, we concluded that the hydrocarbon $C_{12}H_{16}$ was a new compound, 1,4-dimethyltetralin.

In the alkylation of benzene with alkyl halogenides catalyzed by aluminum chloride, the isomerizations of the alkyl radicals are often observed. The mechanism of the present condensation is explained from this view-point that the chlorine atoms of the 3,4-positions migrate to the 2,5-positions and the resulting dichloride cyclialkylates benzene to form a six-membered carbon ring.

The second reaction product formed colorless liquid. Several attempts to crystallize it were unsuccessful. The results of its analysis and molecular weight determination gave a formula $C_{18}H_{26}$, showing that it was not 3,4-diphenylhexane[3] as expected at first, but a di-cyclialkylated benzene, *i. e.*, 1,4,5,8-tetramethyl-1,2,3,4,5,6,7,8-octahydroanthracene, -phenanthrene or a mixture of them.

Experimental

The Condensation of 3,4-Dichlorohexane with Benzene.—To a mixture of 105 g. of benzene and 24 g. of aluminum chloride was added 42 g. of 3,4-dichlorohexane in the course of about one hour under stirring, during which time the reaction temperature was maintained at 5–10°. After additional fifteen minutes the mixture was heated slowly so as to insure a uniform evolution of hydrogen chloride gas. Heating was continued for about two hours until the reaction temperature reached 25° and practically no more evolution of gas was observed. The reaction mixture was poured over crushed ice acidified with hydrochloric acid and treated as usual. The solvent was removed and the residue was distilled under reduced pressure. The following fractions were obtained.

Fraction	B. p., °C.	Pressure, mm.	Yield, g.	Appearance
I	107–131	37	11	Colorless liquid
II	79–110	9	5	Colorless liquid
III	112–140	9	1	Colorless liquid
IV	140–170	9	5	Colorless viscous oil
V	170–184	9	3	Viscous sirupy oil
VI	Residue	..	3	Viscous sirupy oil

The Mono-cyclialkylated Product: 1,4-Dimethyltetralin.—Fractions I and II were combined and the mixture was redistilled. The main fraction boiling at 216–227° under atmospheric pressure weighed 14 g. occupying 50% of the total condensate. It formed a colorless liquid with characteristic odor. The boiling point determined by the Emich method was 226°.

Anal. Calcd. for $C_{12}H_{16}$: C, 89.94; H, 10.06; mol. wt., 160. Found: C, 89.74; H, 10.21; mol. wt. (cryoscopy in benzene), 152.

The Dehydrogenation of 1,4-Dimethyltetralin with Sulfur.—A mixture of 2.4 g. of the hydrocarbon and 1.0 g. of sulfur was heated on a metal-bath at 180–250° for two and a half hours. The reaction product was immediately distilled and yellowish oil, boiling at 260–300° (bath temperature), was obtained. It was dissolved in hot alcohol and added a hot alcoholic solution of picric acid. On cooling, orange needles separated. After one recrystallization from alcohol, the picrate melted at 144–144.5° and repeated crystallizations changed the melting point no more. This fact showed that the material was already quite pure. When admixed with an authentic specimen of 1,4-dimethylnaphthalene picrate (m. p. 143–144°) it melted at 144–144.5°.

Anal. Calcd. for $C_{12}H_{12}\cdot C_6H_3O_7N_3$: C, 56.10; H, 3.92. Found: C, 55.39; H, 4.17.

The Dehydrogenation of the Dimethyltetralin with Selenium.—To 1.58 g. of the substance was added 1.62 g. of selenium and the mixture was heated on a metal-bath at 250–300° for one hour. The reaction product was shaken out and heated for additional six and a half hours at 300–350° (bath temperature). Distillation of the dehydrogenation product gave 0.57 g. of yellowish oil, which yielded the same picrate as described above.

The Di-cyclialkylated Product.—Fraction IV was redistilled under reduced pressure and the main fraction boiling at 145–160° at 9 mm. was subjected to the following experiments.

Anal. Calcd. for $C_{18}H_{26}$: C, 89.19; H, 10.81; mol. wt., 242. Found: C, 89.20; H, 10.81; mol. wt. (cryoscopy in benzene), 220.

A mixture of 4.5 g. of the substance and 2.3 g. of sulfur was heated for about three hours at 180–260°. The resulting black mass was distilled under reduced pressure. The red viscous oil, which distilled at 230–300° (bath temperature) at 5–6 mm., solidified immediately. On recrystallizations from alcohol, colorless prisms melting at 219–220°[4] separated. An analysis was impossible for lack of material.

Higher Boiling Fractions.—Fraction V and the residue separated a small quantity of crystals, melting at 197–

Two Derivatives of 9,10-Dimethylanthracene

BY KEIITI SISIDO AND TYÛZÔ ISIDA

In view of the fact that 9,10-dimethylanthracene[1] often cited in the literature erroneously as 9,10-dimethyl-9,10-dihydroanthracene since the discovery of this compound,[2] we have undertaken to obtain the real 9,10-dimethyl-9,10-dihydroanthracene.

9,10-Dimethylanthracene was reduced with sodium and the desired new compound was obtained. It was found that 9,10-dimethyl-9,10-dihydroanthracene on treatment with aluminum chloride is converted to 9,10-dimethylanthracene.

The acetylation of anthracene[3] gives 9-, 1- and 2-acetylanthracenes, and the treatment of 9-acetylanthracene with aluminum chloride rearranges it into 1- and 2-acetyl compounds. Nenitzescu[4] acetylated 9,10-dihydroanthracene and obtained 9-acetyl-9,10-dihydroanthracene.

Acetylation of 9,10-dimethylanthracene in the presence of aluminum chloride gave 2-acetyl-9,10-dimethylanthracene. It was shown from this experiment that the acyl group can enter also directly into the 2-position of the anthracene nucleus, and that *meso*-acylanthracene is not always necessary as an intermediate.

In the Friedel–Crafts reaction of 1,2,3,4-tetramethylnaphthalene the substitution takes place only at the β-position of the nucleus.[5] This fact is probably due to the steric hindrance caused by the methyl groups at the 1- and 4-positions. The acetylation which takes place exclusively at the 2-position of 9,10-dimethylanthracene may be attributed to the same steric factor, inasmuch as the free benzene ring in 9,10-dimethylanthracene as well as in 1,2,3,4-tetramethylnaphthalene is attached to a tetra-substituted nucleus.

During this experiment we have experienced a slight skin-eruption, presumably caused by the acetyl compound. This fact may be of interest as compared with the similar poisoning effect of benzanthrone in view of the chemical constitution.

Experimental[6]

9,10-Dimethyl-9,10-dihydroanthracene.—Into a boiling suspension of 0.62 g. of 9,10-dimethylanthracene in 6 g. of ethyl alcohol was added 2.5 g. of metallic sodium in small portions. On addition of sodium the yellow crystals disappeared and a colorless solution resulted, which, however, turned reddish brown due perhaps to the action of sodium alcoholate. After two and a half hours of boiling, the solution was decolorized with active carbon. On cooling a small quantity of colorless crystals separated out. The solution was added with water in order to precipitate the desired reaction product. On repeated recrystallizations of the material from alcohol and from glacial acetic acid colorless, rectangular or square leaflet crystals of m. p. 130° resulted, yield 0.2 g. The product is very soluble in ether, benzene, carbon disulfide, moderately soluble in alcohol and glacial acetic acid. The product gives no picrate and its solution does not show a fluorescence.

Anal. Calcd. for $C_{16}H_{16}$: C, 92.26; H, 7.74. Found: C, 92.45; H, 7.92.

When the crystals were mixed with aluminum chloride in the presence or absence of benzene and after thirty minutes of standing poured into water, characteristic yellow crystals separated. A benzene solution of this material exhibits a beautiful violet fluorescence and on addition of picric acid gave dark violet-brown needles, thus proving the formation of 9,10-dimethylanthracene.

2-Acetyl-9,10-dimethylanthracene.—When a mixture of 7.0 g. of 9,10-dimethylanthracene, 150 cc. of carbon disulfide, 2.7 g. of acetyl chloride and 4.5 g. of aluminum chloride was stirred for four hours at room temperature, the reaction did not take place to any appreciable extent. But as soon as the temperature was elevated to 45° the reaction ensued. The progress of the reaction was traced by the liberation of hydrogen chloride. After an additional two hours at 45° the reaction product was poured into iced water acidified with hydrochloric acid, and treated in the usual way. There was obtained a brown solid which on repeated recrystallizations from alcohol using active carbon gave fine yellow crystals of m. p. 164.5°. The product developed blue coloration in concentrated sulfuric acid, yield 6.5 g.

Anal. Calcd. for $C_{18}H_{16}O$: C, 87.28; H, 6.45; mol. wt., 248. Found: C, 87.08; H, 6.45; mol. wt., 243.

A solution of 1.0 g. of the substance in glacial acetic acid was oxidized with 3.0 g. of chromic acid in the usual way and the product was recrystallized from glacial acetic acid. There was obtained an anthraquinonecarboxylic acid of m. p. 277–280°. The mother liquor yielded the same substance. As the isomers of the acid have nearly the same melting points, for the identification we have methylated the material by the E. Fischer method. An ester of m. p. 165–166.5° resulted, which, when admixed with an authentic sample of methyl ester of anthraquinone-2-carboxylic acid, did not depress the melting point.

NEW COMPOUNDS

Di-(*p*-anisyl)-methylcarbinol

Although 1,1-di-(*p*-anisyl)-ethylene has been made from di-*p*-anisyl ketone and methylmagnesium bromide,[1,2] the corresponding tertiary alcohol, di-(*p*-anisyl)-methylcarbinol, was not isolated because the intermediate Grignard addition compound was hydrolyzed in acid solution. The alcohol has now been made by modification of the Grignard reaction.

In a dry 500-ml. 3-necked flask fitted with a stirrer, nitrogen inlet, reflux condenser and dropping funnel was placed 50 ml. of 1.2 *N* (0.058 mole) methylmagnesium bromide. To this solution was added dropwise during

---

[2] Bergmann and Bondi, *Ber.*, **64B**, 1455 (1931).

twenty minutes 12.5 g. (0.048 mole) of di-*p*-anisyl ketone (m. p. 140–142°) dissolved in 125 ml. of dry, warm thiophene-free benzene. After fifteen minutes of stirring at room temperature, a qualitative test for the Grignard reagent[3] was made to be certain that an excess had been used. Otherwise the product is difficult to purify because of the ketone present. The mixture was hydrolyzed by pouring it into 200 g. of ice and water containing 10 g. of ammonium chloride. The benzene–ether layer was separated and washed successively with 100-ml. portions of water, 2% sodium carbonate solution, and water. The solvent was removed under reduced pressure at 60° to give 10 g., 83% of the calculated yield melting 80–83°. Crystallization from 95% ethanol made alkaline to phenolphthalein with aqueous sodium hydroxide raised the melting point to 82–83.5°. To avoid dehydration the alcoholic solution was not heated above 60°.

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.80; H, 6.94; mol. wt., 258. Found: C, 74.90; H, 6.74; mol. wt. (cryoscopic in benzene), 265.

One gram of this compound was oxidized by refluxing one hour in a solution of 10 ml. of glacial acetic acid, 2 drops of concentrated sulfuric acid, and 1.8 g. of chromic acid. The yield of ketone was 0.7 g., melting 141–142°. A mixed melting point with authentic di-*p*-anisyl ketone showed no depression.

Di-(*p*-anisyl)-methylcarbinol is very readily dehydrated to 1,1-di-(*p*-anisyl)-ethylene. A sample of the pure compound standing on the shelf spontaneously formed the ethylene in less than two months, whereas diphenylmethylcarbinol and di-(*p*-chlorophenyl)-methylcarbinol are stable under the same conditions. Thus, it is important in this synthesis to avoid elevated temperatures and even traces of acid.

4-Benzyl-2,3-isopropylidene-D-mannosan<1,5>β<1,6> and 2-Benzyl-3,4-isopropylidene-D-galactosan<1,5>β<1,6>

4-Benzyl-2,3-isopropylidene-D-mannosan<1,5>β<1,6>.—Two and one-half grams of 2,3-isopropylidene-D-mannosan<1,5>β<1,6>[1] was dissolved in 60 ml. of liquid ammonia in a three-necked flask (fitted with a mercury-sealed stirrer, a gas inlet tube and an outlet protected by a soda lime tube) cooled in a Dry Ice–acetone cooling bath. Three grams of sodium in small pieces was added in one portion and solution was completed by gentle stirring; the blue color imparted to the solution disappeared in a few minutes. Following the addition of 2.3 ml. (about 1.6 molecular equivalents) of benzyl chloride the flask was raised from the bath and the ammonia allowed to boil off slowly while standing at room temperature; dry air was then passed through the flask for two hours and the residue, which was easily scraped from the flask, was dried overnight in an evacuated desiccator. The reaction product was washed well with water and recrystallized from 5 parts of alcohol, forming large elongated plates which melted at 99–100° and rotated $[\alpha]^{20}D$ −13.0° in chloroform (*c*, 0.83). It is soluble in acetone, chloroform, pyridine and warm alcohol and nearly insoluble in water and petroleum ether.

Anal. Calcd. for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90. Found: C, 65.86; H, 7.07.

2-Benzyl-3,4-isopropylidene-D-galactosan<1,5>β<1,6>.—The procedure used for the benzylation of 3,4-isopropylidene-D-mannosan<1,5>β<1,6> was applied to 2.5 g. of 3,4-isopropylidene-D-galactosan<1,5>β<1,6> prepared by the pyrolysis of lactose.[2] The product remaining after removal of the ammonia was somewhat sticky and it was extracted with one 10-ml. and three 5-ml. portions of chloroform; the extract was evaporated and gave a mass of long fine needles which was stirred with 10 ml. of alcohol, cooled and filtered. The yield was 3.2 g. (89%). The compound was recrystallized from three parts of alcohol in the form of needles which melted at 84–85° and rotated $[\alpha]^{20}D$ −81.9° in chloroform (*c*, 0.85). The benzyl ether is soluble in acetone, ethyl acetate, ether, pyridine and warm alcohol and nearly insoluble in water and petroleum ether.

Anal. Calcd. for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90. Found: C, 65.86; H, 7.05.

2,6-Di-*tt*-octyl-4-methylphenol[1]

A mixture of 214 g. (2 moles) of *p*-cresol and an equal volume of diisobutylene was placed in an ice-bath and stirred for three hours during which were added additional diisobutylene to make a total of 896 g. (8 moles) and 21 g. of 45% boron trifluoride in ether as catalyst. The mixture then was let stand at 40–50° for fifteen hours. Catalyst was removed by agitation of the reaction mixture with 350 g. of 30% aqueous sodium hydroxide. Distillation through a column packed with Raschig rings (6 theor. plates) yielded a small amount of diisobutylene at atmospheric pressure, and then, at 10 mm., fractions containing approximately 581 g. of tetraisobutylene and 283 g. 2-*tt*-octyl-4-methylphenol[2] (b. p. 143–144° (10 mm.); $n^{27}D$ 1.5105 (super-cooled); m. p. 47.0–47.8°, from petroleum ether). The viscous residue was distilled without fractionation to give 61 g. (9% yield) of crude 2,6-di-*tt*-octyl-4-methylphenol, a highly viscous yellow liquid, b.p. 168–195° (5 mm.) and $n^{27}D$ 1.5036, which slowly crystallized. Recrystallized twice from alcohol, the long needles had m. p. 51.6–52.2° and b. p. 188° (10 mm.).

Anal. Calcd. for $C_{23}H_{40}O$: C, 83.07; H, 12.13; mol. wt., 332.55. Found: C, 82.81, 82.54; H, 12.24, 12.02; mol. wt. (micro-Rast), 338.

(1) The work reported was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Rochester.

(2) This compound has been prepared by Johnson, *J. Chem. Soc.*, 1009 (1946). Dr. Johnson has pointed out in a private communication that the material obtained by him is undoubtedly the *trans* form, whereas the sample obtained by us by catalytic reduction must be the *cis* form.

(3) *Cf.* Campbell and O'Connor, THIS JOURNAL, **61**, 2897 (1939).

(4) This compound was prepared at Northwestern University by Professor C. D. Hurd and Dr. Otis Fancher, to whom we wish to express our appreciation. It was obtained by the action of chloromethyl methyl ether on the acetylenic Grignard (Lespieau, *Ann. chim.*, [8] **27**, 172 (1912); Dupont, *ibid.*, [8] **30**, 492 (1913)).

sure. The calculated amount of hydrogen was taken up in a few minutes, with the evolution of appreciable amounts of heat. The catalyst was removed by filtration, the batches were combined, and distilled through a column until the b. p. reached 70°. Some low-boiling petroleum ether was added, causing separation of a lower layer, which was removed, and the solution dried. The solvent was removed and the residue distilled, which yielded the following fractions:

I	II	III
3.4 g.	b. p. 100–136°	$n^{20}\mathrm{D}$ 1.4213
29.0	136–141°	1.4220
16.0	141–146°	1.4240

The analytical sample had the properties: b. p. 138–138.5°; $n^{20}\mathrm{D}$ 1.4201; d^{26}_{20} 0.8958.

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.03; H, 10.42. Found: C, 62.00; H, 10.39.

1,4-Dimethoxybutane has $n^{15}\mathrm{D}$ 1.4031[5]; Johnson[2] reports $n^{20}\mathrm{D}$ 1.4220 for (*trans*) 1,4-dimethoxy-2-butene. The percentage composition calculated by this author for this compound (C, 63.2; H, 8.8) is somewhat in error.

1,4-Dimethoxy-3-chloro-2-butanol.—A 0.68 molar solution of hypochlorous acid was prepared by passing chlorine into a solution of 95 g. of sodium bicarbonate in 1140 cc. of water.[6] One hundred-cc. portions of this solution were added with stirring to 72.9 g. of 1,4-dimethoxy-2-butene while cooling with ice, a total of 1080 cc. (theoretical 930 cc.) of the hypochlorous acid solution being added. After the addition was complete, the solution was stirred for one-half hour in the ice-bath, then for three and one-half hours at room temperature, and allowed to stand overnight. At this point, a potassium iodide test showed practically no oxidizing power in the solution, and it was saturated with sodium chloride, extracted three times with ether and the residue from the ether extract distilled. A total of 69.0 g. was collected as product in several fractions, b. p. 92–98.5° (8 mm.) most of it boiling at 96–98.5°; the analytical sample had the following properties: b. p. 97–97.5° (8 mm.), $n^{21}\mathrm{D}$ 1.4542.

Anal. Calcd. for $C_6H_{13}ClO_3$: C, 42.74; H, 7.77. Found: C, 42.32; H, 7.41.

COMMUNICATIONS TO THE EDITOR

THE CRYSTAL STRUCTURES OF AMMONIUM AND POTASSIUM MOLYBDOTELLURATES

Sir:

A structural study is now being made in this Laboratory of heteropoly ions of the general type $[XMo_6O_{24}]^{-n}$, in which the charge *n* depends on the metalloid X. The investigation is centered on the salts ammonium and potassium molybdotellurate, $(NH_4)_6TeMo_6O_{24}\cdot 7H_2O$ and $K_6TeMo_6O_{24}\cdot 7H_2O$, which have been described morphologically by Donnay and Mélon[1] as orthorhombic, homeomorphous and probably isostructural. A preliminary X-ray lattice study was reported by the writer to the Crystallographic Society in March 1947.[2] A more complete diffraction study since then has shown that the two salts are not isostructural, but possess entirely different and unrelated (though similar) symmetries. The final unit cell and space group data are as follows:

$(NH_4)_6TeMo_6O_{24}\cdot 7H_2O$, orthorhombic *mmm*; a_0 = 14.62 Å., b_0 = 14.91, c_0 = 14.26; space group *Pnaa* = C_{2h}^{10}; 4 formulas (as above) per cell, density calcd. 2.82, found (Donnay and Mélon) 2.78.

$K_6TeMo_6O_{24}\cdot 7H_2O$, orthorhombic *mmm*; a_0 = 14.30 Å., b_0 = 14.95, c_0 = 14.26; space group *Pbca* = C_{2h}^{15}; 4 formulas per cell, density calcd. 3.15, found (Donnay and Mélon) 3.05.

The structure problem was attacked by the preparation of Patterson maps for the ammonium salt projected on the three pinacoid faces, using diffraction intensities visually estimated from Weissenberg photographs. These maps showed sharp peaks revealing the positions of the tellurium and molybdenum atoms. Although these maps were greatly simplified by the presence of the heavy tellurium atom at a symmetry center, an ambiguity still remained which allowed the possibility of three different models. This ambiguity is represented by an indeterminacy of sign of the parameters of one of the three kinds of molybdenum atoms in the structure. Calculation of the structure factors for a certain class of reflections in each of the series (*hk*0), (0*kl*) and (*h*0*l*) which is sensitive to this change of sign, shows that a reasonable check of observed and calculated intensities is obtained with only one of the three possible models. The correct parameters for the tellurium and molybdenum atoms in the ammonium cryatals, and probably also the potassium crystals (with *x* and *z* interchanged), are

	x	*y*	*z*
Te	0	0	0
Mo_{I}	0	0.228	0
Mo_{II}	0.113	0.121	−0.168
Mo_{III}	0.113	−0.121	−0.168

The model accepted here is one originally proposed hypothetically by Anderson.[3] In it, the molybdenum atoms lie in a hexagon about the tellurium atom at the center (Te–Mo and Mo–Mo distances 3.42 Å.); the oxygen atoms lie close-

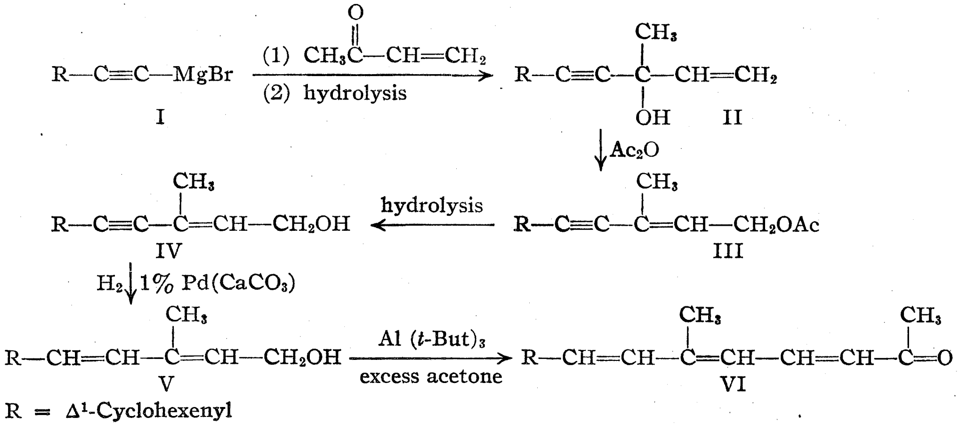
THE SYNTHESIS OF 1-[CYCLOHEXEN-1'-YL]-3-METHYL-1,3,5-OCTATRIEN-7-ONE (C_{15} KETONE)[1]

Sir:

Using the new approach to vitamin A synthesis,[2] we wish to report an alternative route which makes possible the synthesis of vitamin A and its analogs. The C_{15} ketone (VI) was thus synthesized by the following series of reactions:



The carbinol (II) was obtained in yields of 45–50%; b. p. 45–48° (10^{-4} mm.); n^{25}_D 1.5135; d^{25}_4 0.964; $\lambda_{max.}$ (alcohol), 231 mμ, log $\epsilon_{mol.}$ 4.36.

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.8; H, 9.13; A. H. (Zer.), 1.0; unsaturation, 4.0 ⌈. Found: C, 81.23, 81.60; H, 9.20, 8.99; A. H. (Zer.). 0.99; unsaturation, 4.08 ⌈.

When the carbinol (II) was refluxed with acetic anhydride, the acetate (III) was obtained in 58–60% yields; b. p. 69–70° (10^{-4} mm.); n^{25}_D 1.5267; d^{25}_4 0.9938; $\lambda_{max.}$ (alcohol), 266.5 mμ, log $\epsilon_{mol.}$ 4.33.

Anal. Calcd. for $C_{12}H_{18}O$: C, 77.2; H, 8.33; unsaturation, 4.0 ⌈; saponification equivalent, 218. Found: C, 77.03; H, 8.51; unsaturation, 4.21 ⌈; saponification equivalent, 216.

The carbinol (IV) was obtained in good yields by the saponification in nitrogen of the acetate (III); b. p. 61–64° (10^{-4} mm.); n^{25}_D 1.5530; d^{25}_4 0.983; $\lambda_{max.}$ (alcohol), 266.5 mμ, log $\epsilon_{mol.}$ 4.22.

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.80; H, 9.13; A. H. (Zer.), 1.0; unsaturation, 4.0 ⌈. Found: C, 81.51; H, 9.14; A. H. (Zer.), 0.9; unsaturation, 4.19 ⌈.

The carbinol (V) was obtained either by selective hydrogenation of (IV) or of (II) followed by allylic rearrangement. It boiled at 55–57° (10^{-4}–10^{-5} mm.); n^{25}_D 1.5268; d^{25}_4 0.961; $\lambda_{max.}$ (alcohol), 267 mμ, log $\epsilon_{mol.}$ 4.30.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.80; H, 10.18; A. H. (Zer.), 1.0; unsaturation, 3.0 ⌈. Found: C, 80.78; H, 10.48; A. H. (Zer.), 0.95; unsaturation, 3.16 ⌈.

The C_{15} ketone (crude) was obtained by the method previously described[2] in 90% yield; n^{25}_D 1.5765; A. H. (Zer.), 0.6. The mixture of the ketone and its aldol precursor was further dehydrated in toluene either with iodine or with *p*-toluenesulfonic acid; b. p. 75–85° (10^{-4} mm.); n^{25}_D 1.5960; $\lambda_{max.}$ (alcohol), 333 mμ; log $\epsilon_{mol.}$ 4.28.

Anal. Calcd. for $C_{15}H_{20}O$: C, 83.30; H, 9.31; unsaturation, 4.0 ⌈. Found: C, 83.38; H, 9.27; unsaturation, 4.0 ⌈.

The C_{15} ketone formed a light yellow semicarbazone which discolors on standing in air; m. p. 162–164° (dec.).

All of the compounds (II to V inclusive) were also prepared with the methyl group in position two of the ring by Tome[3] and those with methyl groups in both two and six positions of the cyclohexene ring by other members of our group.

A GENERAL THERMODYNAMIC THEORY OF ION EXCHANGE PROCESSES

Sir:

The specific volume of a strong (sulfonic) acid resin measured in water with the following cations in the exchange position is: H^+, 1.283; Na^+, 1.655; K^+, 1.434; Cs^+, 1.388; Mg^{++}, 1.665; Ca^{++}, 1.585; Ba^{++}, 1.453; Ag^+, 1.283. When an alkali metal resin is equilibrated with solutions of the same alkali ion, the specific volume decreases with increasing concentration, and usually becomes less than the pure water-equilibrated volume of the next heavier member of this group.[1]

These and other data, in conjunction with a simple mechanical model and classical physicochemical methods, provide a basis upon which exchange phenomena may be interpreted. The resin is an osmotic system in which the fixed, non-diffusible (anionic) groups act as though restricted by a semipermeable membrane separating the inner pore volume (V_i) from the external solution. V_i varies with the swelling pressures and the elasticity of the resin structure. V_i and total resin volume (V) can be determined by pycnometric[1] and other methods.[2]

Dry resins swell in water chiefly because of hydration of the fixed and counter ions and the osmotic pressure due to the latter. If a salt of the counter ion is added to the external water, Donnan effects virtually exclude it from the internal volume; a counter osmotic pressure is established with consequent reduction in swelling. The dependence of swelling upon the (calculable) counter osmotic pressure provides access to the $p-V$ relation; other methods may also be applicable.[3]

Consider the exchange process

$$\mathrm{A_i^+ + B_0^+ = A_0^+ + B_i^+}$$

where neither A^+ nor B^+ forms a weakly-dissociated compound with the fixed anion. The virtual osmotic work for $\mathrm{A_i^+} \rightarrow \mathrm{A_0^+}$ is $\delta n\ RT \ln a_{\mathrm{A_i^+}}/a_{\mathrm{A_0^+}}$, and the virtual pV work is $\delta n p \overline{V}_{\mathrm{A_i^+}}$. $\overline{V}_{\mathrm{A_i^+}}$ may be determined experimentally.

The expressions for $\mathrm{B_0^+} \rightarrow \mathrm{B_i^+}$ are similar, and, as $\delta w = 0$

$$RT \ln \left(\frac{a_{\mathrm{A^+}}}{a_{\mathrm{B^+}}}\right)_{\mathrm{i}} \left(\frac{a_{\mathrm{B^+}}}{a_{\mathrm{A^+}}}\right)_0 = p(\overline{V}_{\mathrm{B^+}} - \overline{V}_{\mathrm{A^+}})_{\mathrm{i}}$$

where p is of course the swelling pressure. The separation factor $K_{\mathrm{D}} = a_{\mathrm{A_i^+}}a_{\mathrm{B_0^+}}/a_{\mathrm{B_i^+}}a_{\mathrm{A_0^+}}$ is then unity for $\overline{V}_{\mathrm{B_i^+}} = \overline{V}_{\mathrm{A_i^+}}$. This is the case for K^+ and NH_4^+. K_{D} is not a constant because p and the $\overline{V}$'s are not constants; the latter depend strongly upon $a_{\mathrm{A_i^+}}/a_{\mathrm{B_i^+}}$ in a manner determined by the ionic diameters.

If the fixed group is weakly acidic (—COOH) or a weakly dissociated ion-pair is formed (—SO_3Ag), the corresponding dissociation constants must be introduced into the expression above; volume change terms of the form $(\overline{V}_{\mathrm{A^+}} + \overline{V}_{\mathrm{R^-}} - \overline{V}_{\mathrm{AR}})_{\mathrm{i}}$ occur and the expression becomes too complex for development within the limits of this communication. The dissociation constant becomes a function of swelling pressure. This complication appears in the alkaline earths; the swelling of Mg^{++}, Ca^{++} and Ba^{++} resins is directly proportional to the solubility of the benzene sulfonates.

These concepts form the basis of a general theory of exchange processes, applicable also to cationic resins and non-aqueous systems,[4] which permits predictions of K_{D} from measurable physical quantities.

RECEIVED DECEMBER 19, 1947

ON THE DYNAMIC STATE OF ANTIBODIES

Sir:

Experiments with N^{15} labeled amino acids carried out by Heidelberger, *et al.*,[1] have led these authors to the conclusion that normal serum proteins, as well as immune globulins, incorporate dietary amino acids during immunization. However, no exchanges were stated to occur with injected antibody though the authors found an excess of N^{15} in these substances which was about two to four times as high as their experimental error, and about one-fourth to one-eighth of their value for the active antibodies.

We have repeated these experiments using C^{14} leucine in the following manner:

A rabbit was actively immunized against *p*-azophenylarsonic acid-ovalbumin until the serum had a high titer of the corresponding antibodies. Ten days after the last injection (day 1) an injection of 10 cc. of concentrated rabbit pneumococcus antiserum (Type I) was given intravenously, followed by a similar injection on day 2. On the same day, an injection of 30 cc. of a 1% leucine solution was given intraperitoneally. The leucine contained C^{14} in the carboxyl group and had an activity of about 0.06 microcurie per milligram.[2] Similar injections of leucine were given on the three following days, 1.15 g. of leucine being injected in all.

Samples of serum were taken on days 5, 9 and 16. The antibodies were precipitated with the corresponding antigens, washed with saline (3x), distilled water (1x), alcohol and ether (2x), dried and analyzed for C^{14}. The results are given in the

[2] The C^{14} used in this investigation was supplied by the Monsanto Chemical Co. and obtained on allocation from the U.S. Atomic Energy Commission. This work was supported by a grant from the Rockefeller Foundation.

table. The numbers indicate counts per 10 mg. of substance per minute, after subtraction of the back-ground rate of 10 counts. The error was less than 1 count per minute.

	R-Azo-ovalbumin	Pneumococcus I	Serum proteins
First bleeding (day 5)	11	12	59
Second bleeding (day 9)	18	8	53
Third bleeding (day 16)	26	no antibody isolated (amount too small)	39

As a control on the purity of the precipitates, two experiments were carried out in which a small amount of pneumococcus I antiserum was added to radioactive serum containing no pneumococcus antibodies. After thorough mixing and standing for one hour in the refrigerator, the corresponding polysaccharide was added to precipitate the antibodies. The precipitate was worked up in the same way as the others but contained no C^{14} (less than 0.1 count per minute per mg.).

The order of magnitude of the radioactivity found in the passive antiserum was essentially the same as that found by Heidelberger and Schoenheimer, *viz.*, about one-fifth to one-sixth of the serum proteins. Our results are in line with theirs, though we think it very probable that an exchange takes place with the injected or passive transfer antibody.

A detailed paper on this subject will be published later.

NEW BOOKS

Elsevier's Encyclopaedia of Organic Chemistry. Volume 13, **Tricyclic Compounds.** Series III, **Carboisocyclic Condensed Compounds.** E. JOSEPHY AND F. RADT, EDITORS. Elsevier Publishing Company, Inc., 215 4th Avenue, New York 3, N. Y., 1946. xx + 1265 pages; 17.5 × 26 cm. Subscription Price, $78.00; Serial Price, $91.00; Single Volume Price, $104. Volume 14, **Tetracyclic and Higher-Cyclic Compounds.** Series III, **Carboisocyclic Condensed Compounds.** New York, 1940. xx + 711 pages; 17.5 × 26 cm. Subscription Price, $45.00; Serial Price, $52.50; Single Volume Price $60.00.

Elsevier is a monumental new encyclopedia of organic compounds comparable to Beilstein but written in English. The work was undertaken in Amsterdam in 1937 under the editorship of Drs. Edith Josephy and F. Radt, both formerly of the Beilstein staff. Volume 14, Tetracyclic and Higher-Cyclic Compounds, which includes sterols, sex hormones, triterpenes, and carcinogenic hydrocarbons, was selected as the first volume to be published because of the current interest in these fields. This volume was completed in 1940 but could not be published until 1946 because of the war. Volume 13, which includes anthracene, phenanthrene, the resin acids, dicyclopentadiene, trycyclene, also bears the publication date 1946 and has just become available. Further volumes are scheduled for publication at intervals of about six months. The whole range of organic compounds is to be covered in a total of twenty volumes in thirty-eight parts. The production plan provides for completion of the work by 1963.

Elsevier is no English-language version of Beilstein; it is a thoroughly excellent competitive compendium with a character all its own. The most substantial difference in the scope of the two works is that Beilstein covers the patent literature whereas Elsevier does not; the absence of references to patents in the new work is a shortcoming in some fields but of little consequence in others. Elsevier shares with Beilstein a high quality of accuracy, reliability and thoroughness. It contains more and better formulas and numerous summarizing reaction charts; it is printed on good paper in easily readable type; and the whole scheme of publication of the new compendium represents a certain advance over the classical German documentation of organic chemistry. It is my opinion, however, that the one work supplements, rather than supplants, the other. What the user of either work most urgently requires is data and references of the most recent possible date. Immeasurable research time can be saved by any combination of reference works that will expedite literature searches. Since Beilstein and Elsevier operate on different publication schedules such that new volumes of each will cover recent literature in alternate fields, the combination of the two is bound to afford a better general coverage than either alone. For this reason alone, if for no other, Elsevier can be recommended as a worthwhile investment for the library of any active center of research already equipped with Beilstein.

The avowed ultimate goal of the Elsevier publication is to include complete references to the literature until four years prior to publication. The recently published Volume 13 bears evidence that this high standard of attainment may eventually be realized. This volume, published as of 1946 under the difficult circumstances of the post-war period, covers the whole literature through 1936 and includes most or all key references concerning the structure of compounds through 1941 or 1942. This high speed of documentation is achieved in part by use of an ingenious scheme for the citation of references; each item of information in the text is followed by a parenthetical citation of the year of publication and the name of the first author. The full references are then listed by years at the end of short sections. One advantage of the scheme is that additional references of any date can be entered at the last minute without disturbance of any sequence of reference numbers. Another is the avoidance of the frequent repetition of reference citations (*cf.* Beilstein). Another is that the reader can see from a glance at the list of references for a given section the date to which the literature survey has been carried.

The data cited in Elsevier were almost all taken directly from the original papers. A total of 229 journals were consulted in the composition of Volume 14. In the case of a few papers from obscure journals both the *Chemisches Zentralblatt* and *Chemical Abstracts* were consulted.

The system of arrangement employed in Elsevier is a simple and rational one based upon structure; closely related compounds are placed together, and derivatives are described along with the parent compounds. The reader is further assisted in rapidly finding specific compounds by excellent subject and formula indexes in each volume. The subject indexes have the valuable feature of including a number of summarizing entries that list groups of compounds of similar structural and functional types: "Carcinogenic compounds," "Vitamins and provitamins," "Azido compounds." The editors showed wisdom in deliberately refraining from introducing new systems of nomenclature; the names recorded are those chosen by the investigators who built the science. Elsevier is thus a chemist's book, and it will be used and liked by those who build the science of the future. In my opinion, the contrasting disregard of chemists' preferences as expressed in established usage detracts enormously from the usefulness and lasting influence of *Chemical Abstracts*.

My wife and I have made considerable use of the section on sterols in Volume 14 and have found it excellent. The highly confused early literature has been untangled with care and skill. Good judgment has been exercised in the discussions of structures that are still controversial and in the selection of best values of physical constants. The data cited include physiological actions, specific rotations for different wave lengths and in different solvents, absorption maxima (unfortunately without specification of the solvent), axis ratios of crystals, magnetic susceptibilities. Although the sterol section is very complete, we noticed the omission of Δ^2-cholestene ("neocholestene"), discovered by Mauthner in 1909. We are sorry that Elsevier accepted Rosenheim and King's proposed names coprostene, coprostenone, and coprostenol for compounds obtained from cholesterol and more appropriately called Δ^4-cholestene, cholestenone, and Δ^4-cholestenol-3. We regret that the editors did not venture to cross the border of rigid classification and include D vitamins and the tachysterols along with ergosterol and 7-dehydrocholesterol and all the many other products of irradiation and isomerization. These are very minor points; we heartily endorse this splendid new Encyclopedia.

Louis F. Fieser

A Survey of Anti-Malarial Drugs 1941–1945. Edited by Frederick Y. Wiselogle. Subsidized by the Office of Scientific Research and Development on Recommendation by the Committee on Medical Research. J. W. Edwards, Ann Arbor, Mich. 1946. Two volumes (the second in two parts). 1921 + xi pages. 22 × 28 cm. Price, $30.00 the set.

In the Survey is presented an historical summary of the evolution of the organization developed under National Research Council auspices with funds from the Office of Scientific Research and Development for the all-out attack on the problem of the prevention and cure of malaria through chemotherapeutic means. Detailed data on the antimalarial activity of close to 15,000 substances which were examined for their response to experimental avian malarias are given. Further, pharmacological data are given on what appeared to be the more promising substances and extensive clinical data are recorded on those drugs which warranted clinical trial in man. The work is divided nominally into two volumes, the second volume appearing in two parts, making a total of three actual volumes.

In the first volume are recorded an outline of the organizational scheme whereby the whole vast undertaking was coördinated—a structure which by its flexibility and adaptability to changing emphasis may well serve as a model for future organizations; a critical and detailed discussion of the methods used in the pharmacological aspects of the problem, some of which represent for the first time a logical and rational approach to this and similar problems; and an equally detailed and rational discussion of the methods used in the clinical evaluation of the drugs which furnishes, at least as far as this reviewer is aware, one of the finest examples so far produced of the development of methods for comparison of drugs under carefully controlled and standardized conditions. Incorporated into the two latter sections are critical discussions of hypotheses of the mode of action of certain chemical classes of drugs and of the biology of the various malaria infections. For the reader interested in securing an over-all picture of the relationsip between chemical structure and antimalarial action, the summarizing tables dealing with chemical series of potential interest, which are incorporated in the discussion of the pharmacological aspects of the work, will be very useful.

The second volume (two parts) is devoted in its entirety to a tabulation of the results of the tests on all the compounds examined. The chemical classification used is novel, but after a moderate amount of study, presents no insurmountable difficulties in application. Presentation of the structural formula for every compound to which a definite structure can be assigned leaves no room for confusion regarding identity of the substances listed. One could wish that the mass of compounds listed in Volume II could have been arranged more in accordance with detailed structural variations. However, this is partially compensated for by the summarizing tables of Volume I. Of particular value is the discarding of the previously used and meaningless method of reporting antimalarial activity and toxicity as a therapeutic index and substitution therefor of absolute values in terms of selected standard substances such as quinine, sulfadiazine, etc. Also to be commended is the convention of reporting such data in exact mathematical equivalents referred to the standards rather than the use of such symbols as $^+$, $^{+++}$ or $\pm$. Of great value are the fine indices of which there are three: subject, molecular formula and Survey Number.

No details of the synthetic chemistry involved in the preparation of the drugs are given. Inclusion of this information would result in a work of inordinate size. By an arrangement whereby the authors of papers dealing with the large bulk of the synthetic chemistry list the drugs by Survey Number in their communications, sufficient cross referencing should be available to enable this gap to be conveniently filled from the chemists' point of view.

The work is clearly reproduced by the photo offset process and remarkably free from errors. It will prove of great value not only for one interested in the narrow field of the chemotherapy of malaria, but, by virtue of the mass of pure toxicity data alone as well as of the analytical methods described, to all who are interested in chemotherapy in general.

Robert C. Elderfield

Advances in Enzymology. Vol. V. 1945. Edited by F. F. Nord, Fordham University, New York, N. Y., and C. H. Werkman, Iowa State College, Ames, Iowa. vii + 268 pp. Illustrated. 15.5 × 23.5 cm. Price $5.50. Vol. VI. 1946. Edited by F. F. Nord. x + 563 pp. Illustrated. 15.5 × 23.5 cm. Price $6.50. Vol. VII. 1947. Edited by F. F. Nord. xi + 665 pp. Illustrated. 16 × 23.5 cm. Price $8.75. Interscience Publishers, Inc., 215 Fourth Ave., New York 3, N. Y.

The three most recent annual volumes of this valuable series continue the high standards set in the earlier volumes. When it is realized that these reviews were prepared while the writers were still under the stress of war conditions or were exposed to the almost equally disturbing events of the period immediately after the cessation of hostilities, the thoroughness and scientific detachment with which the topics have been discussed is the more surprising.

No adequate account of the contents of these volumes is possible in the space available. The reviewer must therefore content himself with reference to those chapters which were found to be most stimulating and informing. In Volume V, N. W. Pirie's thoroughly critical account of certain plant viruses is especially useful for its point of view. H. Blaschko's review of the amino acid decarboxylases of mammalian tissue together with that of E. F. Gale on the amino acid decarboxylases of bacteria in Volume VI summarize present day knowledge of this group of enzymes effectively. Gale's chapter is unusual inasmuch as so large a part of the material discussed derives from the work of his own laboratory. E. Stotz has given a clear account of pyruvate metabolism and F. Schlenk of the enzymatic reactions in which nicotinamide and related substances are involved in Volume V; V. A. Engelhardt has dealt with the adenosinetriphosphatase properties of myosin and F. Lipmann with acetyl phosphate in Volume VI. F. H. Johnson has discussed bacterial luminescence in Volume VII. These papers are all strictly within the field of enzymology.

However, the editor obviously interprets the extent of this field in the broadest terms and several of the reviews deal with topics that many would regard as straightforward biochemistry. For example, K. C. D. Hickman and P. L. Harris have discussed the biochemical interrelationships of tocopherol in Volume VI in a paper that is by far the clearest and most interesting account of this complex and difficult subject that has come to the reviewer's attention. Volume VII contains accounts of asymmetric synthesis by P. D. Ritchie, of hemoproteins by H. Theorell, and of the chemistry of tetrapyrroles by S. Granick and H. Gilder. However, G. Hevesy's outstanding review of the application of radioactive indicators in biochemical problems does indeed deal with reactions strictly within the field of enzymology.

Several of the reviews are concerned with topics allied with technology. In Volume VI, W. G. Frankenburg has discussed the chemical changes that take place in tobacco leaves during the process of curing, and W. F. Geddes the significance of the amylases of wheat in milling and baking. In Volume VII, F. M. Hildebrandt gives a review of industrial fermentation research in recent years.

On the whole the volumes under review are almost essential equipment for the present day biochemical laboratory. They are a mine of authoritative information. However, there is another side of the picture. Publishing costs of books are high and the marked advance in price and increase in size of the volumes means that an increasingly serious load is thrown upon the individual who feels that he must maintain his subscription to the series. To be sure, scientific journals have also increased their price, but not in the ratio of \$5.50 to \$8.75. The publishers would do well, therefore, to make every effort to diminish the cost of these volumes in the future, even if sacrifices in the length of the articles or in style of publication must be made.
