That a cyclic diester is an intermediate in this reaction has likewise been postulated by Price and co-workers[3] who further pointed out that if ring formation is the rate-controlling factor then so-called *cis* glycols would be expected to oxidize faster than the corresponding *trans* isomers. This follows since the requisite double inversion which must necessarily occur in cyclic ester formation does not change the relative positions in space of the *cis* and *trans* hydroxyl pairs.

Criegee[2] had previously shown this to be so in compounds in which the space relationships of the adjacent hydroxyl groups were determined and rigidly maintained by the cyclic nature of the compounds. Price and co-workers[3] extended the work to the open chain compounds, ethylene glycol and pinacol, and showed that the hydroxyl groups are on the average more proximal in acidic than in basic medium probably because of association with a proton at a lower *p*H. Furthermore, this difference in space relationship was readily detectable by the difference in rate of oxidation by periodate.

Thus previous work has shown that periodate oxidation is a valuable tool for the determination of configuration of glycols when the configuration depends either on a cyclic structure or on the *p*H of the medium. It was postulated, therefore, that this reagent would be valuable, likewise, in indicating the proximity of the hydroxyl groups in the diastereoisomeric open chain glycol pairs. That lead tetraacetate was an adequate reagent for this purpose had previously been reported by Hilditch and Jasperson[4a] and Dorée and Pepper[4b] who had shown respectively that the low-melting forms of 9,10-dihydroxystearic acid and 13,14-dihydroxybehenic acid are oxidized more rapidly than the high-melting forms.

In the case of alicyclic glycols the so-called *cis* and *trans* relationship arises from a combination of the repulsive effects of the hydroxyl groups and of the groups attached to the hydroxyl-bearing carbon atoms. In such instances it is interesting to note that free rotation is probably reduced to what may be regarded as a sort of oscillation within a restricted area.

Accordingly, periodate oxidation was applied to each of the forms of the 9,10-dihydroxystearic acids and the 1,9,10-trihydroxyoctadecanes in the hope that there would be a detectable difference in the rate of oxidation which in turn would provide additional evidence for the configuration of these compounds.

King[5] had previously oxidized with periodate both forms of the 9,10-dihydroxystearic acids in order to obtain the expected scission products without, however, noting a difference in the rates of oxidation. In the present investigation it was observed that low-melting 9,10-dihydroxystearic acid (95°) consumed periodate at a much more rapid rate than did the high-melting form (132°) when the oxidations were carried out in aqueous media in the presence of an emulsifying agent consisting of sodium β-alkylaminopropionate in which the alkyl moiety was derived from soybean oil fatty acids. This is indicated in Table I.

TABLE I

OXIDATION OF THE 9,10-DIHYDROXYSTEARIC ACIDS IN AQUEOUS MEDIA AT 24°

Time, min.	Moles of acid oxidized	
	Low-melting form	High-melting form
5	0.29	..
15	.60	..
30	.91	0.02
45	.94	..
60	1.04	.10
90	1.05	.30
105	..	.42
120	1.03	.54
180	..	.74
240	..	.89
300	..	.95

Since there was a possibility that the results might have been influenced by a difference in the solubilities of the two forms, the oxidations were carried out in the homogeneous medium provided by 75 volume per cent. aqueous ethanol. Although homogeneity greatly accelerated the reaction rates, a very marked difference in behavior was still demonstrated by the two forms.

Similarly the low melting form of 1,9,10-trihydroxyoctadecane was oxidized at a more rapid rate

10	.9	.63	.87	.61
15	...	.74	.96	.80

From the scission products of the low melting form of 1,9,10-trihydroxyoctadecane, pelargonic aldehyde was isolated as the 2,4-dinitrophenylhydrazone, indicating that the desired reaction had taken place.

The structural feature responsible for these results also comes into play when one determines which form is capable of yielding an acidic cyclic complex with boric acid by the classical procedure. Boëseken and Couvert[6] had shown that *cis* glycols of rigid systems form a complex possessing an acidic hydrogen atom which is readily demonstrable by conductivity measurements.

This technique was shown to be applicable to diastereoisomeric open chain glycols by Lees and co-workers[7] and by Knowlton and co-workers[8] who showed that the *dl* form of 2,3-butanediol formed a borate complex whereas the *meso* form did not. With the 9,10-dihydroxystearic acids conductivity measurements in absolute ethanol indicated that the low melting form was amenable to complex formation with boric acid since the specific conductivity increased with increasing concentration of the acid. On the other hand, successive increase of the concentration of the high melting form had no effect on the specific conductivity of the borate mixture. The data are presented in Table III.

TABLE III

SPECIFIC CONDUCTIVITY MEASUREMENTS FOR THE 9,10-DIHYDROXYSTEARIC ACIDS AT 25° IN ABSOLUTE ETHANOL

Low-melting form		High-melting form	
Moles of acid/liter of 1 *N* H_3BO_3	Specific conductivity	Moles of acid/liter of 1 *N* H_3BO_3	Specific conductivity
0	8.37×10^{-5}	0	8.37×10^{-5}
0.0106	1.58×10^{-4}	0.0112	1.04×10^{-4}
.0269	1.88×10^{-4}	.0275	1.03×10^{-4}
.0446	2.09×10^{-4}	.0510	1.02×10^{-4}
.0936	2.97×10^{-4}	.0989[a]	1.04×10^{-4}

[a] This was a supersaturated solution which started to crystallize as the reading was taken.

All of these data, then, indicate that the vicinal hydroxyl groups in the low-melting forms of 9,10-dihydroxystearic acid and 1,9,10-trihydroxyoctadecane possess a closer spatial relationship than those in the high-melting form. Accordingly it follows that the normal hydroxylation products of oleic acid and oleyl alcohol (*cis* double bond) are the high-melting forms of 9,10-dihydroxystearic acid and 1,9,10-trihydroxyoctadecane, whereas the normal hydroxylation products of elaidic acid and elaidyl alcohol (*trans* double bond) are the low-melting forms. These conclusions are in accord with those of Esafov,[9] King[10] and Wittcoff and Miller[11] but are at variance with those of Atherton and Hilditch.[12]

Acknowledgment.—The authors are indebted to Prof. Richard T. Arnold for several helpful discussions.

Experimental

Materials.

The low-melting form of 9,10-dihydroxystearic acid was prepared by the hydroxylation of U. S. P. oleic acid as described by Scanlan and Swern.[13] After numerous crystallizations from ethyl acetate it melted sharply at 94–95°.[14]

The high-melting form of 9,10-dihydroxystearic acid was prepared by the hydroxylation of U. S. P. oleic acid by action of permanganate as described by Lapworth and Mottram[15] save that considerably less water was used. Thus a solution of oleic acid (20 g.) and potassium hydroxide (10 g.) in water (3 l.) reacted at 0–5° with a solution (400 ml., 2%) of potassium permanganate. The product was isolated as indicated by the previous workers. During crystallization from ethyl acetate, however, an insoluble crystalline material separated. This was shown by melting point, neutral equivalent and elementary analysis to be one of the high melting forms of 9,10,12,13-tetrahydroxystearic (sativic) acid.[16] Thus from three runs there was obtained, in addition to 13 g. of 9,10-dihydroxystearic acid (m. p., 129–30°), 2.0 g. of sativic acid melting at 172–173°.

Anal. Calcd. for $C_{18}H_{36}O_6$: C, 62.07; H, 10.44; neut. eq., 348.5. Found: C, 61.89; H, 10.44; neut. eq., 345.

The low-melting form of 1,9,10-trihydroxyoctadecane was prepared according to the procedure of Scanlan and Swern,[13] employing commercial oleyl alcohol from which all of the C_{14} and C_{16} compounds had been removed by stripping through a Podbielniak column. The product was crystallized successively from absolute ethanol, ethyl acetate and isopropyl ether and melted at 75–76°.

The high-melting form of 1,9,10-trihydroxyoctadecane was prepared by hydroxylating with permanganate the half acid phthalate of oleyl alcohol and saponifying the resultant product as described by Collin and Hilditch.[17] Pure oleyl alcohol[18] was used and the crude hydroxylation

product was saponified by refluxing it (5.5 g.) with a solution of potassium hydroxide (3.0 g.) in ethanol (50 ml.) for two hours. The potassium phthalate was filtered from the cooled mixture, and the filtrate was made exactly neutral by addition of dilute hydrochloric acid. Evaporation to dryness *in vacuo* yielded a residue which was taken up in ethyl acetate and was filtered to remove inorganic salt. From the filtrate there resulted on standing 2.5 g. of product which, when crystallized from the same solvent, melted at 125–126°.

The Periodate Oxidation of the 9,10-Dihydroxystearic Acids in Aqueous Suspension.—All of the oxidations by periodate were performed at 24° using aqueous 0.05 *M* periodate (buffered, *p*H 4.2) prepared from trisodium paraperiodate and acetic acid.[19] The periodate oxidations of both forms of 9,10-dihydroxystearic acid were carried out in aqueous suspension in the presence of a known quantity of sodium β-alkylaminopropionate in which the alkyl moiety was derived from soybean oil fatty acids. The titrations of the aliquot portions of the reaction mixtures were carried out according to the method of Fleury and Lange[20] as modified by Grangaard, Gladding and Purves.[21] Corrections were made for blanks. The results of the periodate oxidation in aqueous suspension are given in Table I.

The Periodate Oxidation of the 9,10-Dihydroxystearic Acids and the 1,9,10-Trihydroxyoctadecanes in Ethanol–Water.—Since ethanol proved to be a suitable solvent for all of the glycols under investigation, the oxidations by periodate in homogeneous medium were carried out at 24° in the following manner: The compounds (0.0200 g.) were dissolved in absolute ethanol (15 ml.); a solution of periodate (0.05 *M*, 5 ml.) was added and the oxidations were permitted to continue for the periods of time indicated in Table II. The titrations were performed as previously described and corrections were made for blanks. Perfectly clear reaction mixtures resulted in all oxidations of this type. The results obtained are given in Table II.

Identification of Pelargonic Aldehyde among the Scission Products of 1,9,10-Trihydroxyoctadecane.—1,9,10-Trihydroxyoctadecane (5.0 g., m. p. 75–76°) was dissolved in absolute ethanol (100 ml.), and 0.5 *M* periodate (50 ml.) was added. After one hour at room temperature the reaction mixture was poured into water and was extracted with ether. From the ether solution there resulted an oil (4.8 g.) which was converted, during refrigeration, to a pasty solid. This crude product was dissolved in warm Skellysolve B. Cooling yielded a small amount of solid which was probably unreacted glycol. From the filtrate there was obtained an oil which was treated with 2,4-dinitrophenylhydrazine in the conventional manner. The crude dinitrophenylhydrazone first obtained melted at 91–96°. After three recrystallizations from ethanol the product melted at 104–5° (uncor., lit. 100°).[22]

Anal. Calcd. for $C_{15}H_{22}O_4N_4$: C, 55.9; H, 6.8; N, 17.4. Found: C, 55.8; H, 6.9; N, 17.7.

Conductivity of the Borate Complexes of the 9,10-Dihydroxystearic Acids.—The conductivity measurements were carried out in a one normal solution of boric acid in absolute ethanol with the aid of an alternating current, 1000 cycle, conductivity Wheatstone bridge. The results are contained in Table III.

Summary

The results of periodate oxidation have been used to show that the hydroxyl groups are more proximal in the low-melting forms of the 9,10-dihydroxystearic acids and the 1,9,10-trihydroxyoctadecanes than in the high-melting forms.

The low-melting form of 9,10-dihydroxystearic acid has been shown to form a cyclic, acidic complex with boric acid, whereas the high-melting form does not.

The Reaction of Amines with Phosphorus Pentasulfide; Thiophosphoric Amides

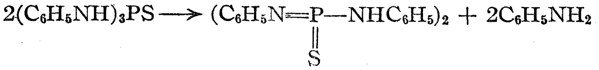
BY ALLEN C. BUCK,[1a] JOHN D. BARTLESON[1b] AND HERMAN P. LANKELMA

Previous investigations of products obtained by the action of amines on phosphorus pentasulfide have been limited to a single reaction. Knop[1c] observed that six moles of aniline and one mole of phosphorus pentasulfide heated at a temperature not exceeding 150° evolved hydrogen sulfide and gave a pungent smelling product in the form of monoclinic crystals which melted at 153°. Rudert[2] prepared the same product from aniline and thiophosphoryl chloride and showed it to be thiophosphoric trianilide, $(C_6H_5NH)_3PS$.

Knop's results were repeated in this Laboratory. A 50% yield of thiophosphoric trianilide melting at 153–154° was obtained. This product did not depress the melting point of thiophosphoric trianilide prepared from aniline and thiophosphoryl chloride. Although Knop regarded temperatures in excess of 150° to be detrimental, we obtained the maximum yield at a reaction temperature of 180°.

The anilide was not hydrolyzed upon refluxing with dilute acid or with aqueous or alcoholic potassium hydroxide, but was by heating with concentrated phosphoric acid at 130°, for two hours, and with glacial acetic acid for twenty hours.

When thiophosphoric trianilide was heated at 225° *in vacuo*, it lost aniline and formed dimeric thiophosphoric anil anilide:



$$2(C_6H_5NH)_3PS \longrightarrow (C_6H_5N{=}\underset{\underset{\displaystyle S}{\|}}{P}{-}NHC_6H_5)_2 + 2C_6H_5NH_2$$

Upon refluxing the anil anilide in aniline the reaction was reversed. This reaction will be discussed in a future paper.

[1a] Standard Oil Co. (Ohio) Fellow in Chemistry, Western Reserve University, 1946–1947. Present address: E. I. du Pont de Nemours and Co., Parlin, N. J.

[1b] Standard Oil Co., Cleveland, Ohio.

[1c] Knop, *Ber.*, **20**, 3352 (1887).

[2] Rudert, *ibid.*, **26**, 565 (1893).

The addition of four moles of aniline to one mole of phosphorus pentasulfide at 30° gave a copious evolution of hydrogen sulfide and rapidly formed thiophosphoric dianilide, $(C_6H_5NH)_2PSSH$. Thiophosphoric dianilide formed salts with silver, lead and mercury ions. These salts were insoluble in water and in organic solvents and could not be purified. The dianilide, unlike the trianilide, was immediately hydrolyzed by refluxing in water, dilute acids or bases.

Thiophosphoric dianilide was converted to thiophosphoric trianilide by refluxing in aniline. This reaction indicates that the formation of thiophosphoric trianilide from six moles of aniline and one mole of phosphorus pentasulfide involves the rapid formation of thiophosphoric dianilide followed by the slower formation of the trianilide at the higher reaction temperatures.

The reaction of two moles of aniline and one mole of phosphorus pentasulfide did not give a monoanilide, $C_6H_5NHPS(SH)_2$. Instead the dianilide and unreacted phosphorus pentasulfide were obtained.

The reaction of phosphorus pentasulfide was studied with a number of additional amines both aromatic and aliphatic.

With *p*-chloroaniline excellent yields of thiophosphoric tri-*p*-chloroanilide were obtained. With *o*-chloroaniline, however, no triamide could be obtained either from phosphorus pentasulfide or thiophosphoryl chloride. Excellent yields of the diamide were obtained using a 4:1 molar ratio of *o*-chloroaniline to phosphorus pentasulfide. The failure of the trianilide to form here may be ascribed to the much weaker basic character of the *o*-chloroaniline.

With 2-naphthylamine, the product obtained was phosphoric tri-2-naphthalide instead of thiophosphoric tri-2-naphthalide. It is probable that thiophosphoric tri-2-naphthalide was first formed but was hydrolyzed to the phosphoric 2-naphthalide in the purification process which included steam distillation. Rudert[2] also obtained phosphoric tri-2-naphthalide upon recrystallizing the reaction product of 2-naphthylamine and thiophosphoryl chloride from acetic acid.

With a high boiling aliphatic amine, benzylamine, 43% yields of tribenzyl thiophosphoric amide were obtained. Low boiling aliphatic amines, such as *n*-propyl amine, would not permit sufficiently high reaction temperatures at atmospheric pressure. However, in a sealed tube, low yields of tri-*n*-propyl thiophosphoric amide were obtained.

With a secondary amine, oily products which could not be purified were usually obtained. However, two crystalline secondary amine thiophosphoric triamides were obtained. Tetrahydroquinoline gave low yields of a crystalline triamide and piperidine gave a crystalline triamide by reaction with thiophosphoryl chloride according to the method of Michaelis.[3]

The secondary amine thiophosphoric triamides, exhibited stability to prolonged reflux in dilute acids, bases, and in glacial acetic acid.

Experimental

Materials.—The phosphorus pentasulfide was a commercial grade purified by extraction with carbon bisulfide using a Soxhlet extractor. The purified product melted at 273–277°. *Anal.* Calcd. for P_2S_5: P, 27.90; S, 72.09. Found: P, 27.64; S, 69.6. The amines were purified by distillation and where necessary, previously dried over potassium hydroxide. Tetrahydroquinoline was prepared from quinoline by the method of Hoffman and Koenigs[4] and purified by the method of Rupe, *et al.*[5]

Preparation of Thiophosphoric Triamides from Amine and Phosphorus Pentasulfide.—A mixture of phosphorus pentasulfide and amine, in a molar ratio of 1:6 with a small excess of amine, was heated in a three-neck round-bottom flask equipped with a stirrer and reflux condenser. The reaction was usually highly exothermic. After the initial reaction had subsided, the mixture was heated from two to four hours at a temperature of 180° to complete the reaction. (In the case of the volatile *n*-propylamine, the mixture was heated in a sealed tube.) The excess amine was removed by steam distillation or by treatment with dilute hydrochloric acid and the residual amide was purified by crystallization from alcohol. The yields and melting points of the products were:

Amide	Yield, %	M. p., °C.
Triphenyl	50	153–154
Tri-*p*-chlorophenyl	97	225–226
Tribenzyl	43	125–126
Tripropyl	10	73–74
Tri-tetrahydroquinolyl	15	190–192

Tri-*p*-chlorophenylthiophosphoricamide. *Anal.* Calcd. for $C_{18}H_{15}Cl_3N_3PS$: N, 9.49; P, 7.01; S, 7.2. Found: N, 9.24; P, 7.42; S 7.35.

Preparation of Thiophosphoric Diamides from Amine and Phosphorus Pentasulfide.—The amine was added dropwise to a mixture of phosphorus pentasulfide in 5 to 10 parts of toluene, with stirring. A small excess over 4 moles of amine to 1 mole of phosphorus pentasulfide was employed. The temperature was kept at 30° for two hours. The diamide separated as a white solid. It could be purified by dissolving in ice cold sodium hydroxide solution and extracting with ether to remove the amine. The diamide was then precipitated with dilute ice cold hydrochloric acid, washed with ether and carbon disulfide and dried.

Diphenylthiophosphoricamide, yield 47%, m. p. 161°–163°. *Anal.* Calcd. for $C_{12}H_{13}N_2PS_2$: N, 10.00; P, 11.07; S, 22.85. Found: N, 10.50; P, 10.90; S, 22.61. Di-*o*-chlorophenylthiophosphoric amide, yield 95%, m. p. 183–190°. It could not be recrystallized without decomposition.

Hydrolysis and Aminolysis of Thiophosphoric Diamides.—Thiophosphoric dianilide and *o*-chloroanilide, unlike the triamides were very sensitive to hydrolyses. Upon exposure to air, hydrolysis occurred slowly; rapid hydrolysis occurred upon boiling with water or treatment with aqueous acid or alkali.

The aminolysis of thiophosphoric dianilide was carried out with aniline, and of thiophosphoric di-*o*-chloroanilide with benzylamine. A mixture of 5.0 g. of thiophosphoric dianilide and 10 g. of aniline was heated at 180° for four hours. Three grams of thiophosphoric trianilide, melting point 150–153°, was obtained. It was identified by a mixed melting point.

Fifty grams of thiophosphoric di-*o*-chloroaniline was dissolved in 10.7 g. of benzylamine with cooling. The mixture was then heated to 180° for three hours. The crude product was washed with dilute hydrochloric acid to remove excess benzylamine and the residue recrystallized

---

(3) Michaelis, *Ann.*, **326**, 129–258 (1903).

(4) Hoffman and Koenigs, *Ber.*, **16**, 728 (1883).

(5) Rupe, Seiberth and Kussmaul, *Helv. Chim. Acta*, **3**, 75 (1920)

from alcohol. One and six-tenths grams of tribenzyl thiophosphoric amide, melting point 121–123°, was obtained. It was identified by a mixed melting point.

Thermal Decomposition of Thiophosphoric Triamides to Dimeric Thiophosphoric Acid Imide Amides.—Thiophosphoric trianilide and thiophosphoric tribenzylamide were converted to the imide amide. Twenty-three grams of thiophosphoric trianilide was heated at 215–225° for two hours under a vacuum of 30 mm. mercury. Six grams of aniline distilled over. The residual solid was recrystallized from alcohol and gave 10 g. of thiophosphoric anil anilide, m. p. 233–235°. This product did not depress the melting point of a sample of the material prepared by the method of Michaelis and Karstens.[6] The anil anilide was readily converted back to the triamide by heating with an excess of aniline at the boiling point for four hours.

Tribenzylthiophosphoric amide was converted to the imide amide by the same method, yield 70%, m. p. 197–199°. *Anal.* Calcd. for $C_{28}H_{30}N_4P_2S_2$: N, 10.22; P, 11.31; S, 11.68; mol. wt., 548 Found: N, 10.34; P, 11.01; S, 11.68; mol. wt., 560.

The Reaction of 2-Naphthylamine and Phosphorus Pentasulfide.—A mixture of 9.2 g. of phosphorus pentasulfide, 45 g. of 2-naphthylamine and 70 g. of diethylbenzene was heated for two hours at 185° with stirring. The diethylbenzene was removed by steam distillation and the excess amine by extraction with cold alcohol. The residue was recrystallized from alcohol and gave 7 g. of phosphoric tri-2-naphthalide, m. p. 168–170°. A mixed melting point with a sample of the material prepared from 2-naphthylamine and phosphorus oxychloride by the method of Rudert[2] gave no depression.

Summary

The reaction of six moles of a primary aliphatic or aromatic amine with one mole of phosphorus pentasulfide at 130–180° gave crystalline thiophosphoric triamides. Secondary amines usually gave oily products, piperidine and tetrahydroquinoline being exceptions.

The reaction of four moles of aniline with one mole of phosphorus pentasulfide at room temperature gave thiophosphoric dianilide. This dianilide appears to be an intermediate in the formation of the trianilide. The thiophosphoric triamides are very stable toward hydrolysis; the phosphorus sulfur linkage of thiophosphoric tri-2-naphthalide is an exception. The triamides of primary amines are hydrolyzed on prolonged heating with 85% phosphoric acid or glacial acetic acid.

Thiophosphoric diamides are very sensitive to hydrolysis.

The primary amine triamides upon heating to 225°, *in vacuo*, lose amine to form a dimeric imide amide. This reaction is easily reversible.

The preparation of thiophosphoric monoanilide from aniline and phosphorus pentasulfide was unsuccessful.

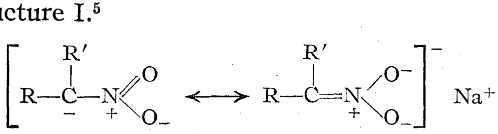
The Basis for the Reported Optical Activity of the Salts of Aliphatic Nitro Compounds: 2-Nitrobutane[1]

BY NATHAN KORNBLUM, JOHN T. PATTON[2] AND JOSEPH B. NORDMANN

The experimental basis for the report that 2-nitrobutane gives an active sodium salt[3] has been reëxamined in view of the recent finding that the optical activity attributed to the salts of 2-nitrooctane is really due to the presence of 2-octyl nitrate.[4] It has now been found that the 2-nitrobutane previously employed was contaminated with 2-butyl nitrate and that the activity ascribed to the sodium salt of 2-nitrobutane is due to this impurity.

Dextrorotatory-2-nitrobutane prepared according to the earlier workers[3] is only partially soluble in aqueous sodium hydroxide. The resulting aqueous alkaline solution, which contains the sodium salt of 2-nitrobutane, is devoid of activity whereas the insoluble portion is still *dextro*rotatory. Examination of the alkali insoluble material reveals that it is *d*-2-butyl nitrate $[\alpha]^{24}\text{D}$ +7.0°.

The "*d*-2-nitrobutane" was freed of *d*-2-butyl nitrate, and any other contaminants, by treatment with cold 96% sulfuric acid. Thus purified, *d*-2-nitrobutane has $[\alpha]^{20}\text{D}$ +7.2°, gives a negative test for nitrate esters, and is completely soluble in aqueous sodium hydroxide; the resulting solution is inactive. When sodium methoxide is used as the base the sodium salt is again devoid of activity and the 2-bromo-2-nitrobutane produced by brominating this salt is also inactive. These results, as well as the various other properties of the salts of aliphatic nitro compounds, lead to the conclusion that they possess the hybrid structure I.[5]



$$\left[R-\overset{R'}{\underset{-}{C}}-\overset{+}{N}\begin{smallmatrix}O\\O^-\end{smallmatrix}\longleftrightarrow R-\overset{R'}{C}=\overset{+}{N}\begin{smallmatrix}O^-\\O^-\end{smallmatrix}\right]^- Na^+$$

I

In addition to establishing I as the structure of the salts of aliphatic nitro compounds the present investigation corroborates the recent observation[4] that, contrary to the accepted view, the reaction of an alkyl halide with silver nitrite (The Victor

Meyer reaction) yields not only the anticipated nitroparaffin and alkyl nitrite but also a number of other products. As detailed in the experimental portion of this paper, the reaction of 2-iodobutane with silver nitrite gives 2-nitrobutane, 2-butyl nitrite, 2-butyl nitrate, 2-butanol and butanone.[6] Just as with 2-nitroöctane, the yield of pure 2-nitrobutane is very low, *ca.* 15%.

Experimental

Racemic 2-Iodobutane.—This compound was prepared according to Clarke.[7] It was rectified through a 12-inch modified Widmer column[8] fitted with a variable take-off head[8a]; yield 80–87%, b. p. 118°, n^{20}_D 1.4959, d^{20}_4 1.5962; literature values, b. p. 117–118°[9]; b. p. 118–119°; d^{20}_4 1.5952[10]; b. p. 121°, d^{20}_4 1.585, n^{19}_D 1.4945.[11]

Racemic "2-Nitrobutane."—Using 120 g. of racemic 2-iodobutane and following as closely as possible the directions of the previous investigators[3] 4 g. of "2-nitrobutane" was obtained; b. p. 30–31° (36 mm.); n^{20}_D 1.4042; lit. values,[3] b. p. 35–36° (17 mm.), n^{21}_D 1.4057. An authentic sample obtained from the Commercial Solvents Corporation had n^{20}_D 1.4040.

That the "2-nitrobutane" thus prepared is a mixture was demonstrated by shaking it with 10% aqueous sodium hydroxide; about 33% of the "2-nitrobutane" failed to dissolve even after prolonged shaking. This insoluble material was taken up in low boiling petroleum ether and dried over magnesium sulfate. The solvent was removed at atmospheric pressure leaving a colorless liquid, b. p. 121°, n^{20}_D 1.4016. Synthetic 2-butyl nitrate (see below) has b. p. 124°, n^{20}_D 1.4015. In contrast, 2-butyl nitrite (see below) has b. p. 68°, n^{20}_D 1.3710.

The aqueous alkali insoluble material gave a positive test for nitrates esters[12] and a negative test for nitrite esters.[13]

***d*-2-Butanol.**—Eastman Kodak Co. White Label 2-butanol was resolved according to Ingersoll.[14] The *d*-2-butanol distilled at 99°, n^{20}_D 1.3954, d^{20}_4 0.809, $[\alpha]^{25}_D$ +10.9° (no solvent); lit. values[15]: b. p. 99°, n^{20}_D 1.3954, d^{20}_4 0.808, $[\alpha]^{20}_D$ +13.87°.

***l*-2-Iodobutane.**—Following the procedure of Clarke,[7] 89 g. of *d*-2-butanol ($[\alpha]^{22}_D$ +10.9°) was treated with 138 g. of iodine and 24 g. of red phosphorus. The product was rectified[8a]; yield 199 g. (90%), b. p. 117.5–118°, n^{20}_D 1.4948, d^{20}_4 1.5959, M_D (calcd.) 33.47, M_D (found) 33.61; $[\alpha]^{24}_D$ −15.9° (no solvent); lit. values,[15] b. p. 117–118°, d^{17}_4 1.5970, $[\alpha]^{17}_D$ −31.98°.

Pure *d*-2-Nitrobutane.—One hundred and forty grams of *l*-2-iodobutane ($[\alpha]^{24}_D$ −15.9°) was treated with 175 g. of recrystallized silver nitrite[16] and 60 g. of freshly ignited quartz sand following, as closely as possible, the directions of the previous investigators.[3]

The silver nitrite and sand were placed in a 500 ml. round-bottom flask fitted with a condenser (the outlet of which led to a dry ice–acetone cooled trap), a tantalum Hershberg stirrer and a dropping funnel. The flask was submerged in an ice–salt mixture and the *l*-2-iodobutane was added dropwise over the course of one and one-half hours. Upon the addition of the first few ml. of iodide copious evolution of brown fumes was observed. When addition of the 2-iodobutane was complete the reaction mixture was allowed to come to room temperature and to stand overnight (*ca.* twelve hours). The flask was then heated at 90° for one hour and at the end of this period was fitted with a condenser set for downward distillation. Twenty-four grams of material distilled at atmospheric pressure when the reaction product was heated on a steam-bath (Fraction A). Further heating on the steam-bath under reduced pressure (60 mm.) gave an additional 38 g. of distillate (Fraction B). The Dry Ice trap contained 9 g. of a blue liquid, the color of which was discharged upon standing overnight at Dry Ice temperature.

Thirty-six grams of Fraction B, upon rectification[8a] at 188 mm., gave several fractions (Table I).

TABLE I

Fract.	B. p., °C.	Wt., g.	n^{20}_D
1	29	4.0	1.3762
2	30–51	1.0	1.3780
3	52–58	4.0	1.3891
4	60–61	5.0	1.3960
5	62–78	1.5	1.3970
6	79–80	6.0	1.4015
7	81–85	1.2	1.4029
8	86–87	10.5	1.4043
Dry Ice trap		1.4	1.3743

To 8 g. of Fraction 8 (Table I) was added 30 ml. of 96% sulfuric acid (precooled to 0°) at such a rate that the temperature did not rise above 3°. The solution was shaken for five minutes at 0° and then poured onto 50 g. of ice which was covered with 50 ml. of 30–60° petroleum ether. The aqueous layer was separated and extracted with fresh portions of petroleum ether. The extracts were combined, washed with water and dried over "Drierite." The solvent was removed at atmospheric pressure and the residue distilled under reduced pressure. The yield of pure 2-nitrobutane was 4.2 g., b. p. 60° at 70 mm., 137° at 760 mm. (Emich); n^{20}_D 1.4040, d^{20}_4 0.9627, M_D (calcd.) 26.21, M_D (found) 26.21, $[\alpha]^{20}_D$ +7.20° (no solvent); lit. values,[3] b. p. 35–36° at 17 mm., n^{21}_D 1.4057, d^{17}_4 0.9854, $[\alpha]^{22}_D$ +8.83°. An authentic sample of 2-nitrobutane obtained from Commercial Solvents Corporation was rectified and a middle cut taken; b. p. 140° (Emich), n^{20}_D 1.4040, d^{20}_4 0.9633.

Anal.[17] Calcd. for $C_4H_9NO_2$: C, 46.53; H, 8.79; N, 13.58. Found: C, 46.78, 46.87; H, 8.74, 8.69; N, 13.85, 13.90.

In contrast to "2-nitrobutane" prepared according to the earlier workers,[3] 2-nitrobutane thus purified is readily and completely soluble in aqueous alkali, gives a negative nitrate test,[12] and also gives a negative test for nitrite esters.[13]

Experiments with Pure *d*-2-Nitrobutane

(a) Racemization of *d*-2-Nitrobutane by the Action of Sodium Methoxide.—To a solution of 2 g. of *d*-2-nitrobutane ($[\alpha]^{20}_D$ +7.20°) in 5 ml. of absolute methanol was

---

(6) It should be pointed out that both instances in which products other than the nitro compound and alkyl nitrite were isolated involved secondary halides. It seems likely that the same result will be obtained with primary and tertiary halides; this point is being investigated.

(16) Mallinckrodt silver nitrite was purified as described previously[4] except that 60 g. of impure silver nitrite was used instead of 84 g. per four liters of water. From 300 g. of crude silver nitrite 250 g. of purified product was obtained.

(17) All analyses are microanalyses by Miss Theta Spoor of the University of Illinois unless otherwise stated.

added 15 ml. of 1.56 *N* methanolic sodium methoxide. The resulting solution was optically inactive $[\alpha]^{23}_{\mathrm{D}}$ 0.00 ($C = 10$).

(b) **Racemic 2-Bromo-2-nitrobutane from the Sodium Salt of *d*-2-Nitrobutane.**—The optically inactive methoxide solution obtained from *d*-2-nitrobutane (see preceding paragraph) was treated with an excess of bromine–water, care being taken to prevent the reaction mixture from becoming acidic. The alcoholic solution was then poured into water whereupon the brominated product separated as an oil. The mixture was then extracted with diethyl ether and the ether solution dried over "Drierite"; the resulting solution of crude 2-bromo-2-nitrobutane showed no optical activity, $[\alpha]^{24}_{\mathrm{D}}$ 0.00°; $l = 1$ dm. The ether was then removed by warming in an air stream, following which the residual oil was chromatographed on an aluminum oxide–Celite column using low boiling petroleum ether to develop the chromatogram. The solvent was removed and the residue chromatographed once again, this time on Darco; low boiling petroleum ether was used to develop the chromatogram. Most of the solvent was removed by blowing a stream of dry air over the solution at room temperature and the remainder by shaking at 30° in a vessel evacuated to 15 mm. The 3 g. (85% yield), of colorless product was still optically inactive, $[\alpha]^{24}_{\mathrm{D}}$ 0.00 (no solvent) $l = 1$ dm., n^{20}_{D} 1.4678, d^{20}_{4} 1.4927, M_{D} (calcd.) 34.05, M_{D} (found) 33.95.

Anal. Calcd. for $C_4H_8NO_2Br$: C, 26.37; H, 4.39; N, 7.69; Br, 43.90. Found: C, 26.25, 26.39; H, 4.41, 4.52; N, 7.69, 7.39; Br, 43.89, 43.67.

(c) **Racemization of *d*-2-Nitrobutane by the Action of Aqueous Sodium Hydroxide.**—Two-tenths gram of *d*-2-nitrobutane, ($[\alpha]^{20}_{\mathrm{D}}$ +7.20°) was shaken for ten minutes with 1 ml. of 20% aqueous sodium hydroxide. The mixture was then diluted with 1 ml. of water and shaken for an additional ten minutes. The *d*-2-nitrobutane had now dissolved completely and the resulting solution was devoid of optical activity ($C = 10$, $l = 1$ dm.).

(d) **Preparation of a Solid Derivative of 2-Nitrobutane. [2-(4-carboxyphenylazo)-2-nitrobutane].**—Immediately after neutralization, the aqueous alkaline solution of *d*-2-nitrobutane from the preceding section was coupled with diazotized *p*-aminobenzoic acid. The product was recrystallized from 85% ethanol, m. p. 128–128.7°; mixed m. p. undepressed; lit. values,[18] m. p. 128–129°.

Similar experiments were carried out with pure *l*-2-nitrobutane of $[\alpha]^{23}_{\mathrm{D}}$ −1.95°. In all instances the results agree with those obtained above but since the initial specific rotation is relatively low, the results are not as conclusive as those reported for the *dextro*rotatory isomer.

By-products of the Reaction between 2-Iodobutane and Silver Nitrite.—The reaction between 2-iodobutane and silver nitrite gives not only 2-nitrobutane and 2-butyl nitrite but also 2-butyl nitrate, 2-butanol and butanone. Their isolation from fractions A and B (see earlier section entitled "Pure-*d*-2-Nitrobutane") is described below.

(a) ***d*-2-Butyl Nitrate.**—Fraction 6 (Table I) was shaken by hand with 10 ml. of 20% aqueous sodium hydroxide for twenty minutes following which 10 ml. of water was added and the shaking continued for an additional twenty minutes; the organic phase was isolated and the treatment repeated. The organic layer was then washed with water and finally shaken with 10 ml. of 85% phosphoric acid for thirty minutes after which the mixture was allowed to stand until separation of the two layers was complete (*ca.* twelve hours.). The acid was drawn off and the organic layer was washed with water and dried over "Drierite." There was obtained 4 g. of colorless liquid, n^{20}_{D} 1.4016. Upon distillation at atmospheric pressure there was collected 3.7 g. of a colorless product, b. p. 124°, d^{20}_{4} 1.026, n^{20}_{D} 1.4016, M_{D} (calcd.) 28.80, M_{D} (found) 28.90, $[\alpha]^{24}_{\mathrm{D}}$ +7.02°, $l = 1$ dm. (no solvent); lit. values,[19] b. p. 124°, d^{0} 1.0382. Synthetic 2-butyl nitrate (see below) has b. p. 124°, d^{20}_{4} 1.029, n^{20}_{D} 1.4015.

The *d*-2-butyl nitrate thus isolated from the Victor Meyer reaction gave a positive nitrate ester test[12] and a negative nitrite test.[13]

Anal. Calcd. for $C_4H_9NO_3$: C, 40.33; H, 7.62; N, 11.77. Found: C, 40.46, 40.57; H, 7.64, 7.72; N, 11.72, 11.63.

(b) ***d*-2-Butyl Nitrite.**—Fraction A (24 g.) was dried over sodium sulfate and rectified at 200 mm. pressure using ice-water in the condenser.[8a] There was obtained 6.3 g. of *d*-2-butyl nitrite boiling at 30°. At atmospheric pressure the b. p. is 68° (Emich), d^{20}_{4} 0.8720, n^{20}_{D} 1.3710, M_{D} (calcd.) 27.01, M_{D} (found) 27.04, $[\alpha]^{24}_{\mathrm{D}}$ +0.44° (no solvent); lit. values[20] b. p. 68°, d^{0} 0.8981. Synthetic 2-butyl nitrite (see below) has b. p. 68° (Emich), d^{20}_{4} 0.8728, n^{20}_{D} 1.3710. The *d*-2-butyl nitrite thus isolated from the Victor Meyer reaction gives a positive test for nitrite esters.[13] The fact that this compound was a nitrite was further demonstrated by diazotizing *p*-toluidine with it and then coupling the diazonium salt with alkaline beta-naphthol according the procedure described for 2-octyl nitrite.[4] The crude azo compound after three recrystallizations from glacial acetic acid melted 132–132.7° and a mixed m. p. with an authentic sample showed no depression. The yield of pure azo compound was 40%. Under the same conditions 2-nitrobutane and 2-butyl nitrate did not diazotize *p*-toluidine.

(c) **2-Butanol.**—Two grams of Fraction 4, Table I (n^{20}_{D} 1.3960) was passed through a short column of aluminum oxide–Celite without the use of any solvent. The 1.1 g. of liquid thus obtained gave only a faint nitrite ester test[13] and had n^{20}_{D} 1.3967. This material was heated at reflux for five hours with 2.7 g. of phthalic anhydride and 3 g. of dry pyridine. No brown deposit was formed in the condenser nor was there any evolution of oxides of nitrogen as in the case when 2-butyl nitrite is subjected to the same treatment. At the end of this time the resulting solution was cooled to room temperature and poured into an excess of 37% hydrochloric acid. The oil which separated was taken up in benzene and the solution filtered. The solvent was removed and the remaining solid recrystallized from 60–90° petroleum ether. There was obtained 2.4 g. (67% yield) of 2-butyl hydrogen phthalate, m. p. 56–57°, $[\alpha]^{23}_{\mathrm{D}}$ 0.00, $l = 1$ dm. ($C = 20$); lit. values,[15] m. p. 56–57° (racemic), 46–47° (active). A mixed m. p. with racemic 2-butyl hydrogen phthalate showed no depression. The mother liquor was checked for optical activity, $[\alpha]^{23}_{\mathrm{D}}$ 0.00. It is interesting to note that whereas the 2-octanol produced in the Victor Meyer reaction between 2-bromoöctane and silver nitrite is optically active[4] the 2-butanol obtained here is completely racemic.

When 2-butyl nitrite is subjected to the phthalic anhydride–pyridine treatment 2-butyl hydrogen phthalate is formed; on the other hand 2-butyl nitrate does not give any phthalate ester.

(d) **Butanone.**—Fraction 1, Table I (n^{20}_{D} 1.3762) was passed through a silicic acid–Celite column. There was obtained, without the aid of a solvent, 1.8 g. of product, n^{20}_{D} 1.3785. This was treated with 1.5 g. of 2,4-dinitrophenylhydrazine.[21] A yellow, amorphous precipitate formed at once. It was filtered off while the solution was still hot. Upon cooling the filtrate, yellow needles of the 2,4-dinitrophenylhydrazone of butanone were deposited. After recrystallization from ethanol the derivative melted at 110–111° and showed no depression in a mixed m. p.; lit. value,[22] m. p. 111°. The yellow, amorphous material which came out of the hot solution does not melt below 200°. When 2-butyl nitrite was subjected to the same treatment only the amorphous material was obtained. With 2-butyl nitrate there was no evidence of any reaction.

Racemic 2-Butyl Nitrate.—A 500-ml. three-neck flask was fitted with a stirrer, condenser and dropping funnel and then immersed in a salt–ice mixture. In the flask was placed 190 g. of finely powdered silver nitrate and 137

[22] Ref. 21, p. 221.

g. of 2-bromobutane was added dropwise over a period of two hours. At the end of this time the reaction mixture was allowed to come to room temperature and then to stand for twelve hours. It was then heated at 60° until the organic layer gave a negative test for halogen. The flask was then fitted with a condenser set for downward distillation and heated to 80° at 60 mm. pressure; there was obtained 61 g. of distillate. This was shaken for one hour with 75 ml. of 85% phosphoric acid, and then allowed to stand in contact with the acid overnight. The acid layer was withdrawn, the organic layer was washed with water, dried over magnesium sulfate and then rectified.[8a] There was obtained 58 g. (49% yield) of 2-butyl nitrate boiling at 59° (80 mm.). At atmospheric pressure the nitrate boils at 124° (Emich), n^{20}_D 1.4015, d^{20}_4 1.029, M_D (calcd.) 28.80, M_D (found) 28.81, lit. value,[19] b. p. 124°, d^0 1.0382.

Anal.[23] Calcd. for $C_4H_9NO_3$: C, 40.33; H, 7.62. Found: C, 40.68, 40.34; H, 7.62, 7.79.

Racemic 2-Butyl Nitrite.—(a) Thirty-nine grams of racemic 2-butanol was treated with 38 g. of sodium nitrite and 15.5 ml. of 96% sulfuric acid according to the method of Noyes.[24] Upon rectification[8a] there was obtained 49 g. (83% yield) of a pale yellow liquid; b. p. 28° at 180 mm. At atmospheric pressure the nitrite ester boils at 68° (Emich), n^{20}_D 1.3710, d^{20}_4 0.8726, M_D (calcd.) 27.01, M_D (found) 27.02; lit. values,[20] b. p. 68°, d^0 0.8981.

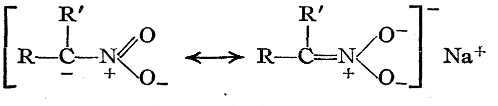
(b) Following the procedure described by Kornblum and Oliveto[25] 30 g. of racemic 2-butanol was treated with 40 g. of nitrosyl chloride. One modification was made, namely, the omission of the use of petroleum ether in working up the product; yield 21 g. (50%) boiling at 27° under 180 mm. pressure. At atmospheric pressure the nitrite boils at 68° (Emich); n^{20}_D 1.3710, d^{20}_4 0.8728.

Anal.[26] Calcd. for $C_4H_9NO_2$: N, 13.58. Found: N, 13.67, 13.70.

Summary

Contrary to an earlier report, optically active 2-nitrobutane does not give an active sodium salt upon treatment with sodium methoxide. Furthermore, 2-bromo-2-nitrobutane prepared from this salt is optically inactive.

It is concluded that the correct structure for the salts of aliphatic nitro compounds is



The action of silver nitrite on 2-iodobutane has been shown to form 2-nitrobutane, 2-butyl nitrate, 2-butyl nitrite, 2-butanol and butanone.

The Stereochemistry of Complex Inorganic Compounds. VIII. Configurations of Some Compounds as Revealed by Rotatory Dispersion Curves[1]

BY THOMAS D. O'BRIEN,[2] JAMES P. MCREYNOLDS[3] AND JOHN C. BAILAR, JR.

The determination of configuration of ions of the type $[M(AA)_2b_2]$ and $[M(AA)_2bc]$[4] by chemical means presents several difficult problems and no general method has yet been suggested. It is often stated that the *cis* compounds are more highly colored and more soluble than the *trans*, but there are so many exceptions to these rules that no reliance can be placed in them. Differences in reactivity of *cis* and *trans* isomers have been observed in several cases, but they are so scattered that generalization cannot be drawn from them. Finally, the fact that a compound is prepared from another of known structure is of no value in determining configuration because molecular rearrangements are common in such reactions.

Unless one or more of the coördinating groups is optically active, *trans* complexes are not resolvable, while those of the *cis* configuration are. Thus, it is definite that the optically active (violet) form of $[Co\ en_2\ Cl_2]^+$ (Ib) must have the *cis* configuration, while the inactive (green) form must be *trans* (Ia). If, on the other hand, the coördinating groups are optically active, both isomers of the complex will rotate the plane of polarized light, so that the presence of optical activity does not serve to distinguish one isomer from the other. As will be shown in this paper, however, the rotatory dispersion curves often give the desired information.

It has previously been pointed out[5] that the rotatory dispersion curves of resolved *cis*-dichloro-bis-ethylenediamine cobaltic chloride, $[Co\ en_2\ Cl_2]Cl$ (Ib) and the corresponding compound of *levo*-propylenediamine, $[Co(l\text{-}pn)_2Cl_2]Cl$, (IIb) are strikingly alike in general shape and in the positions of maxima, minima and points of zero rotation. The same is true of the carbonato complexes. Several investigators have shown that *cis* cobaltic complexes containing optically active diamines do not exist in all the possible stereo-

(2) Present address, Chemistry Department, University of Minnesota, Minneapolis, Minn.

(3) Died, June 19, 1943.

(4) The following abbreviations are used: AA = a group occupying two coördination positions; en = ethylenediamine; pn = propylenediamine; a, b and c = groups occupying one coördination position; Y = group occupying two coördination positions. The various compounds referred to are designated for convenience by Roman numerals, those of the ethylenediamine series being assigned odd numbers and those of the propylenediamine series, even numbers. For *trans* isomers, the Roman numeral is followed by the letter "a," for *cis* isomers, by "b."

(5) Bailar and McReynolds, THIS JOURNAL, **61**, 3199 (1939).

chemical forms but only in certain preferred configurations.[6] The optical activity is mainly due to the arrangement of the groups about the central atom, so the rotatory dispersion curves of complexes of similar configuration should have the same characteristics whether the coördinating base be active or not. Should the non-basic constituents be in the *trans* positions in the di-active-propylenediamine compounds, then one might expect their dispersion characteristics to be similar to those of active propylenediamine itself (Fig. 2). There is, of course, the possibility of having additional isomers due to the position of the methyl group in the active propylenediamine, *i. e.*, in *cis*-[Co(*l*-pn)$_2$Cl$_2$]$^+$ (IIb) the methyl groups could be adjacent to the plane containing the chlorine and cobalt or distant from it. Similar relations hold for the *trans* salt. However, it is assumed here that the contribution of the methyl groups in the different positions to the rotatory dispersion curve would be very small compared to the contribution of the central atom itself. It is also possible that both diastereoisomers [Co(*l*-pn)$_2$a$_2$]*d*$^+$ and [Co(*l*-pn)$_2$a$_2$]$_L$$^+$ (or [Co(*l*-pn)$_2$Y]^+_D and [Co(*l*-pn)$_2$Y]^+_L might form, although it is known that these are of different stabilities. Such a pair has been reported by Bailar and McReynolds for the carbonato-bis-propylenediamine cobaltic ion (XIV).[5] They found that the rotatory dispersion curves of the two differ widely. Even if the two *cis* diastereoisomers form in equal quantity, therfore, the dispersion curve of the mixture will not resemble the curve of the *trans* isomer.

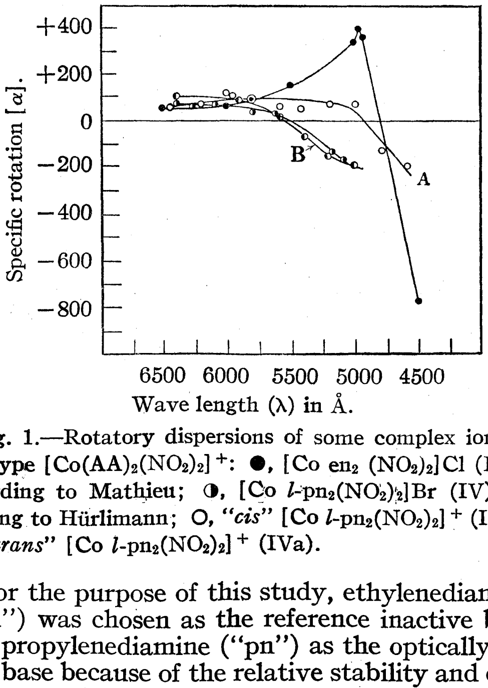

Fig. 1.—Rotatory dispersions of some complex ions of the type [Co(AA)$_2$(NO$_2$)$_2$]$^+$: ●, [Co en$_2$ (NO$_2$)$_2$]Cl (IIIb) according to Mathieu; ◑, [Co *l*-pn$_2$(NO$_2$)$_2$]Br (IV) according to Hürlimann; ○, "*cis*" [Co *l*-pn$_2$(NO$_2$)$_2$]$^+$ (IVb); ◐, "*trans*" [Co *l*-pn$_2$(NO$_2$)$_2$]$^+$ (IVa).

For the purpose of this study, ethylenediamine ("en") was chosen as the reference inactive base and propylenediamine ("pn") as the optically active base because of the relative stability and ease of preparation of most of their coördination compounds, and because Mathieu[7] has determined the rotatory dispersion curves of many diethylenediamine cobaltic complexes.

Hurlimann[6a] has reported the dispersion curve of dinitro-bis-*levo*-propylenediamine cobaltic bromide, [Co(*l*-pn)$_2$(NO$_2$)$_2$]Br (IV), which he obtained from the reaction of trinitro-triammine-cobalt and *levo*-propylenediamine. Hurlimann was of the opinion that his product was the pure *cis* isomer (IVb) and that none of the *trans* (IVa) form resulted from this reaction. This conclusion was based upon the fact that the compound gave a green color when heated with hydrochloric acid (a test which has been reported to distinguish the *cis* and *trans* isomers in both the ammonia and ethylenediamine series).[8] However, the dispersion curve which Hurlimann obtained (Fig. 1) shows no similarity to the one given by Mathieu for *cis*-dinitro-bis-ethylenediamine cobaltic ion (IIIb). We therefore studied Hurlimann's reaction further, and found that in addition to the product reported by him another material is formed in even larger amount. It gives a dispersion curve somewhat resembling that for *cis* [Co en$_2$(NO$_2$)$_2$]$^+$ (IIIb). The lack of greater similarity here may possibly be due to the fact that this was not the pure *cis* isomer. At least, this curve definitely differs from the curve of the *trans* isomer. The compound also gives the test which Hurlimann considered distinctive for the *cis* form. The *cis*-ethylenediamine compound is known to be slowly converted to the *trans* form on boiling in water. Our *levo*-propylenediamine complex which gave the "*cis*" rotatory dispersion curve was gradually converted by long boiling into a material which gave a curve resembling that reported by Hurlimann. As the curves show, the material which Hurlimann studied must have been largely the *trans* isomer. There are numerous examples in which *cis* compounds of the type [Ma$_4$b$_2$]$^+$ (when a and b are groups occupying one coördinate position) when heated in water are converted to the *trans* isomer. As the *cis* compound has only one form there is no possibility of getting a mixture of *cis* isomers. If A$_2$ groups (pn for example) are substituted for the a$_4$ ones, the same reaction occurs on heating in water. In addition, as no one has reported a mixture of *d* and *l* forms in which both were stable with respect to each other, it seems logical to assume that when a change occurs on refluxing the *cis* compound, it is the *trans* that is formed.

Again, it is possible that the two forms of the *levo*-propylenediamine compound might be diastereoisomers, [Co *l*-pn$_2$ (NO$_2$)$_2$]$_D$$^+$ and [Co *l*-pn$_2$(NO$_2$)$_2$]$_L$$^+$ (IVb). To test this point, each of the diastereoisomers of [Co *l*-pn$_2$ CO$_3$]$^+$ (XIVb)[5] was treated at room temperature with calcium nitrite. The curves for the two materials obtained were much alike, the product from the stable carbonato form apparently being all *trans*,

and that from the unstable form being predominately *trans*. It seems safe to say that the isomers of [Co *l*-$pn_2(NO_2)_2]^+$ (IV) which were obtained from trinitro-triamminecobalt were the stable *cis* form and the *trans* form.

The dispersion curve for chloro-ammino-bis-*dextro*-propylenediamine cobaltic chloride (VI) (Fig. 2) is quite smooth and regular, very similar to the curve for active propylenediamine itself, and very unlike the curve for the corresponding active ethylenediamine salt (Vb). Identical curves were obtained regardless of whether the material was prepared from the *cis* or from the *trans*-dichloro-bis-*dextro*-propylenediamine cobaltic chloride (II), and from their shape one concludes that the product has the *trans* configuration (VIa). The dichloro-bis-propylenediamine salt (II) evidently acts differently than the corresponding dichloro-bis-ethylenediamine salt (I), because the latter, whether *cis* or *trans*, always yields the *cis*-chloro-ammino salt (Vb) when treated with aqueous ammonia.

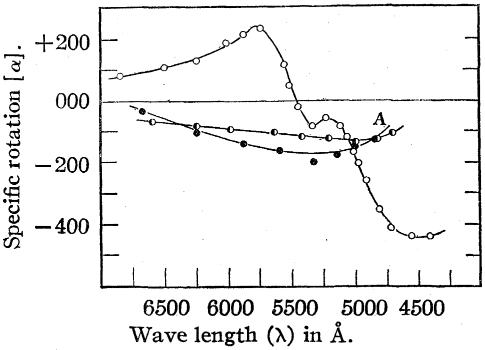

Fig. 2.—The rotatory dispersion of [Co $en_2(NH_3)Cl]Cl_2$, [Co *d*-$pn_2(NH_3)Cl]Cl_2$ and of propylenediamine: ○, [Co $en_2(NH_3)Cl]Cl_2$ (Vb) (Mathieu); ●, [Co *d*-pn_2 $(NH_3)Cl]Cl_2$ (VI) prepared from *cis*-[Co *d*-pn_2 $Cl_2]Cl$; ◐, *levo*-propylenediamine.

The configurations of the diammino and dithiocyanato complexes $[Co(AA)_2(NH_3)_2]^{+++}$ and $[Co(AA)_2(NCS)_2]^+$ can be related through the conversion of the latter to the former by the action of chlorine or perhydrol. These reagents destroy the thiocyanato group, eliminating the carbon and sulfur and leaving the nitrogen (as ammonia) coördinated to the cobalt. The fact that this takes place in acid solution shows that the nitrogen–cobalt bond is not broken during the reaction, and that the diammine must therefore have the same configuration as the dithiocyanato complex from which it is derived.

No rotatory dispersion curve for [Co en_2 $(NCS)_2]^+$ (IXb) was found in the literature, so a sample of the material was resolved and a curve prepared (Fig. 3). The rotations in all parts of the spectrum were low and the absorption high, so no great accuracy can be attached to the values given. However, they are sufficiently exact for our present purpose.

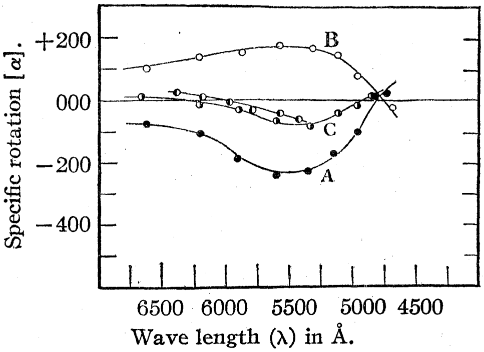

Fig. 3.—The rotatory dispersions of some complex ions of the type $[M(AA)_2(NCS)_2]^+$: ○, [Co *l*-$pn_2(NCS)_2]NCS$ (X) prepared from *cis*-[Co *l*-$pn_2Cl_2]Cl$; ●, [Co *d*-pn_2 $(NCS)_2]NCS$ (X) prepared from *trans*-[Co *d*-$pn_2Cl_2]Cl$; ◐, *cis*-[Co $en_2(NCS)_2]Cl$ (IX); ◑, [Cr *d*-$pn_2(NCS)_2]NCS$ (XVI).

The dithiocyanato-bis-propylenediamine cobalt compounds (X) used in this study were prepared by the reaction of potassium thiocyanate with [Co pn_2 $Cl_2]Cl$ (II).[9]

The products obtained from the *cis* and *trans* dichloro salts were evidently the same, as shown by the curves of Fig. 3. Here again, the rotations were low and absorptions high, so the values are not very exact. A comparison of the curves of Fig. 3, however, indicates that the propylenediamine complex (X) is quite different from the ethylenediamine compound (IXb) so must have the *trans* configuration.

Diammino-bis-*levo*-propylenediamine cobaltic chloride (VIII) was prepared by substitution of ammine groups for chlorine in *cis* and *trans* dichloro-bis-*levo*-propylenediamine cobaltic chloride (II) by allowing the salt to react with liquid ammonia at −35° and with ammonia gas at +80°, and by oxidation of the thiocyanato groups in [Co (*l*-pn)$_2$ $(NCS)_2]NCS$ (X) with chlorine gas.[9] The products of all procedures gave almost identical rotatory dispersion curves. Comparison of these curves with that obtained by Mathieu for *cis*-diammino-bis-ethylenediamine cobaltic chloride (Ib) (Fig. 4) shows marked differences, in that the curve for the ethylenediamine compound shows a sharp inflection at about 5200 Å. and crosses the zero axis at about 5100 Å., while the others are positive at all wave lengths. It was therefore concluded that all of the products of our reactions were of the *trans* form. Data are given in the Experimental Section for several different reactions, but to avoid crowding on the diagram, only the results of the reaction between [Co *l*-$pn_2Cl_2]Cl$ (II) and gaseous ammonia are shown in Fig. 4.

The sulfito salts in both series crystallize as hydrates, so might conceivably have the structure $[Co(AA)_2(SO_3)H_2O]Cl$, in which the sulfito group occupies but one coördination position, as it does,

---

[9] Werner and Dawes, *Ber.*, **40**, 791 (1907).

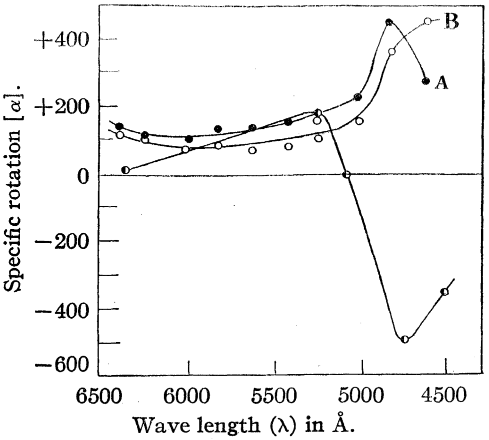

Fig. 4.—Rotatory dispersion curves of some complex ions of the type $[Co(AA)_2(NH_3)_2]^{+++}$: ●, [Co *l*-$pn_2(NH_3)_2]Cl_3$ (VIII) from *cis*-[Co *l*-$pn_2Cl_2]Cl$ and NH_3 gas; ○, [Co *l*-$pn_2(NH_3)_2]Cl_3$ (VIII) from *trans*-[Co *l*-$pn_2Cl_2]Cl$ and NH_3 gas; ◐, [Co $en_2(NH_3)_2]Cl_3$ (VII) according to Mathieu.

for example, in $NH_4[Co(NH_3)_4(SO_3)_2]$. Such a complex ion might have either the *cis* or *trans* configuration, and for a time we thought our propylenediamine complex to have the *trans* [Co $pn_2(SO_3)H_2O]^+$ structure because the dispersion curves (Fig. 5) differ markedly from the curves shown by other salts containing bidentate groups but resemble those of *trans* [Co *l*-pn_2 $X_2]^+$ salts. However, the discovery that the ethylenediamine compound is optically active proved that it must have the *cis* configuration; the striking similarity of the curves for the two series indicates that the propylenediamine compounds are also *cis*. Finally, the fact that the ethylenediamine sulfito compound can be dehydrated without change in color or loss of optical activity indicates that the water is not an integral part of the complex ion, which must, therefore, have the structure [Co en_2 $SO_3]^+$ (XI). On account of the great solubility of the corresponding propylenediamine salt, pure samples could not be obtained. The similarities between the members of the two series are so great, however, that there is little doubt that they have the same structure.

The physical properties of corresponding complex ions of cobalt and chromium are strikingly similar, as many investigators have observed. While we have not studied the reactions of chromic complexes in detail, the curves of Figs. 3 and 6 indicate that the rotatory dispersion curves of complex ions of the two elements are of the same general shape. Even though the points of inflection and points of zero rotation differ by several hundred Ångstrom units, the similarity of the curves is great enough to allow one to decide whether a complex ion of either metal is *cis* or *trans* if the configuration of an analogous complex of the other is known.

It is interesting to note that the thermal decomposition of tris-propylenediamine chromic thiocyanate leads to *cis*-dithiocyanato-bis-propylenediamine chromic thiocyanate. The corresponding reaction in the ethylenediamine series apparently yields the *trans* dithiocyanato compound.[10] This reaction is being investigated further.

Experimental

Rotatory Dispersion Curves.—The observed rotations were taken on a Schmidt–Haensch polarimeter with a prism monochromator and using a 1000-watt projection bulb as a light source. The wave lengths reported are not strictly monochromatic, but represent an average which covers about 100 Å. The polarimeter scale is graduated to 0.001°, although an accuracy of 0.01° was the best that could be obtained due to the high light adsorption by the colored solutions. Every time the wave length setting was changed the zero point of the instrument was checked, and it was found that there was some change due to the change in focus of the light source and to the different openings of the monochromator slit. The observed rotations are an average of at least five readings, and in some cases, where the light adsorption was high and the accuracy low, as many as ten readings were taken. A 1-dm. tube was used unless otherwise noted.

Dichloro-bis-ethylenediamine cobaltic chloride (I) was prepared by the usual method,[11] and the corresponding propylenediamine compound according to the directions given earlier [12]

***cis*-Dinitro-bis-*levo*-propylenediamine cobaltic nitrite (IVb)** was prepared from *levo*-propylenediamine and trinitro-triammine-cobalt as carried out by Watts.[13] The first fraction only was used. As has been pointed out in the discussion, this reaction leads to a mixture of *cis* and *trans* forms which can be separated by careful fractionation. The *trans* form was obtained in solution by refluxing the *cis* form in water for twenty-six hours. The *trans* form was also prepared by allowing the stable carbonato-bis-*levo*-propylenediamine complex (XIV) to stand in solution with a 10% excess of calcium nitrite for one week at room temperature. A mixture of *cis* and *trans* forms was obtained from a similar procedure using the unstable diastereoisomer of the carbonato compound.[5]

***cis*-Dinitro-bis-*levo*-propylenediamine Cobaltic Nitrite (IVb)**.—The readings were taken upon a solution containing 0.16 g. of the salt in 100 cc. of water in the regions of higher transmission and upon a solution of one-half this concentration for the regions of higher absorption. This solution was found to be stable over several days so that all the readings could be taken upon a single solution (readings taken with 0.16% are marked with an asterisk), Curve A, Fig. 1.

Wave length	Observed rotation	Specific rotation
6400*	+0.08	+ 50

(13) Watts, "Dissertation," Zurich, Switzerland, 1912.

A solution containing 0.16 g. per 100 cc. of the *cis* dinitro compound was refluxed in water for seven hours. The rotation was then taken at selected wave lengths.

Wave length	Observed rotation	Specific rotation
5400	+0.07	+ 45
5200	+ .04	+ 25
5000	− .14	− 88

The solution was then refluxed for another ten hours.

5400	+ .04	+ 25
5200	− .06	− 38
5000	− .16	−100

The solution was then refluxed for another nine hours (Curve B, Fig. 1).

Wave length	Observed rotation	Specific rotation
6400	+0.16	+100
5900	+ .13	+ 80
5800	+ .11	+ 70
5600	+ .03	+ 20
5400	− .05	− 30
5200	− .26	−160
5000	− .32	−200

Further refluxing gave no further change. This material is evidently the pure *trans* isomer (IVa).

Dinitro-bis-*levo*-propylenediamine cobaltic nitrite (IV), prepared from the stable diastereoisomer of carbonato-bis-*levo*-propylenediamine cobaltic carbonate (XIV), was used in a solution of 0.2% concentration. Readings were taken only in the range at which the values changed from positive to negative.

Wave length	Observed rotation	Specific rotation
5800	+0.14	+ 70
5600	+ .04	+ 20
5400	− .06	− 30
5200	− .33	−165

It will be noted that this series of readings checks well with those given above for the *trans* form (IVa).

Dinitro-bis-*levo*-propylenediamine cobaltic nitrite (IV) prepared from the unstable diastereoisomer of carbonato-bis-*levo*-propylenediamine cobaltic carbonate (XIV) was used in a solution of 0.3% concentration. It was found necessary to dilute this solution for the reading at 5200 Å.

Wave length	Observed rotation	Specific rotation
6000	+0.27	+90
5600	+ .15	+50
5400	+ .10	+30
5200 (0.15%)	− .09	−60

The dispersion characteristics of the solution indicate that this reaction leads to a mixture of *cis* and *trans* forms. From the shape of the curve at the point at which the sign of the rotation changes it would seem that more of the material is of the *trans* form than the *cis*.

Chloro-amino-bis-*dextro*-propylenediamine cobaltic chloride (VI) was prepared by the method of Watts.[13] This consisted of adding aqueous ammonia to *cis*-dichloro-bis-*dextro*-propylenediamine cobaltic chloride (IIb) until the resulting solution turned deep red. This was evaporated to dryness and the residue extracted with alcohol. The extract was then evaporated to dryness, and the resulting purple-red powder dried at 105° for two hours. The salt contains one molecule of water of hydration.

Anal. Calcd.: Cl, 30.58; N, 20.10. Found: Cl, 30.56; N, 20.09.

The rotatory dispersion curve was measured on a 0.05% solution (Curve A, Fig. 2). Due to the high adsorption at the lower wave lengths, reproducible readings could not be obtained below 4800 Å.

Wave length in Å.	Observed rotation	Specific rotation
6625	−0.02	− 40
6225	− .06	−120
5892	− .07	−140

Diammine-bis-*levo*-propylenediamine cobaltic chloride (VIII) was prepared from dithiocyanato-bis-*levo*-propylenediamine cobaltic thiocyanate (X) by oxidation with chlorine as reported by Werner and Dawes.[9] Further samples of diammino-bis-*levo*-propylenediamine cobaltic chloride (VIII) were prepared from *cis* and *trans* dichloro-bis-*levo*-propylenediamine (II) by allowing them to react with liquid ammonia at −33°. Samples were also prepared by passing ammonia gas over the dry *cis* and *trans* dichloro compounds at 80°. After recrystallization, the compound contains one molecule of water. *Anal.* Calcd. N, 23.01. Found for sample from *cis* dichloro and ammonia gas: N, 22.70; for sample from *trans* dichloro and liquid ammonia: N, 22.62.

The complete curves for the samples prepared from the

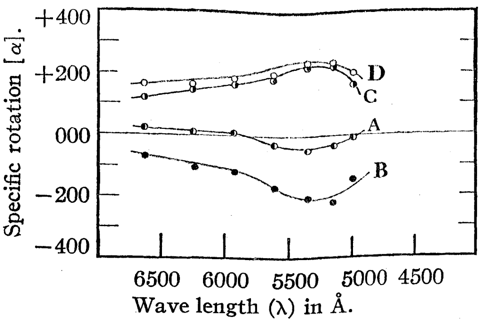

Fig. 5.—The rotatory dispersion of some complex ions of the type $[Co(AA)_2SO_3]^+$: ○, $[Co\ l\text{-}pn_2SO_3]^+$ (XII) prepared from *cis*-$[Co\ l\text{-}pn_2Cl_2]Cl$ and Na_2SO_3; ◑, $[Co\ l\text{-}pn_2SO_3]^+$ (XII) prepared from *trans*-$[Co\ l\text{-}pn_2Cl_2]Cl$ and Na_2SO_3; ●, $[Co\ d\text{-}pn_2SO_3]^+$ (XII) prepared from *trans*-$[Co\ d\text{-}pn_2Cl_2]Cl$ and Na_2SO_3; ◐, $[Co\ en_2SO_3]^+$ (XI) prepared from *levo-cis*-$[Co\ en_2Cl_2]Cl$ and Na_2SO_3.

dichloro compounds with dry ammonia at 80° were obtained. The other samples were examined only at intervals throughout the spectrum. The product of the reaction of dry ammonia upon the *cis* dichloro compound was run at a concentration of 0.1% at all wave lengths except those marked with an asterisk. The marked wave lengths were run at a concentration of 0.05% (Curve A, Fig. 4).

Wave length in Å.	Observed rotation	Specific rotation
6400	+0.13	+130
6200	+ .11	+110
6000	+ .10	+100

4800*	+ .19	+380
4600*	+ .23	+460

The product from the liquid ammonia and *trans* dichloro reaction was examined in a 0.1% solution. Only three wave lengths were used since the points fell well within the range of error for the curves already found.

Wave length, Å.	Observed rotation	Specific rotation
5800	+0.11	+110
5200	+ .20	+200
4800	+ .38	+380

The product of the liquid ammonia and *cis*-dichloro reaction was not isolated from the solution as it had been contaminated with sodium dithionate in an unsuccessful attempt to isolate the *trans* form as the dithionate. The concentration was approximately 0.1%. This solution was examined at only four wave lengths as the readings checked well with the curves already obtained.

Wave length, Å.	Observed rotation	Specific rotation
6400	+0.11	+110
5600	+ .12	+120
5200	+ .19	+190
4800	+ .45	+450

The product from the oxidation of the dithiocyanato complex was not isolated from solution since it was found that the solution was strongly acid and the compound decomposed on evaporation. The concentration used was approximately 0.16%. Only three wave lengths were examined since the points found fall close to the curves already obtained.

Wave length, Å.	Observed rotation	Specific rotation
6000	+0.15	+ 90
5400	+ .21	+130
4800	+ .60	+360

Sulfito-bis-ethylenediamine cobaltic chloride (XI) was prepared by the procedure of Werner and Pokrowska,[14] using optically active dichloro-bis-ethylenediamine cobaltic chloride (Ib). The material can be recrystallized from warm water and dried at 100° with only partial loss of optical activity. In order to get the largest readings possible, however, the material on which the dispersion curve was obtained was not isolated from the solution. Two hundred milligrams of optically active $[Co\ en_2Cl_2]Cl$(Ib) in 100 cc. of water was treated with 1 g. of sodium sulfite and the solution was diluted to 204 cc. Readings were taken as soon as the characteristic brown-yellow color of the sulfito salt appeared (Curve A, Fig. 5).

Wave length, Å.	Observed rotation	Specific rotation
6625	+0.04	+40
6225	+ .02	+20
5892	+ .02	+20
5615	− .02	−20
5360	− .04	−40
5160	− .02	−20
4985	− .01	−10

All attempts to isolate the sulfito propylenediamine salt (XII) in pure crystalline form proved fruitless, so the readings were made on a solution prepared by adding 1 g. (an eight-fold excess) of sodium sulfite to 200 mg. of *trans*-dichloro-bis-*dextro*-propylenediamine cobaltic chloride (II). This should yield 209 mg. of the sulfito complex, and it was on this assumption that the solution was diluted to 209 cc. to give a 0.1% solution (Curve B, Fig. 5).

5360	+ .22	+220
5160	+ .22	+220
4985	+ .17	+170

The following points were obtained from a 0.1% solution of sulfito-bis-*levo*-propylenediamine cobaltic ion (XII) made by the above procedure, with the exception that the *cis*-dichloro-bis-*levo*-propylenediamine cobaltic chloride (IIb) was used as a starting material rather than the *trans* (Curve D).

Wave length in Å.	Observed rotation	Specific rotation
6625	+0.16	+160
6225	+ .16	+160
5892	+ .18	+180
5615	+ .20	+200
5360	+ .24	+240
5160	+ .24	+240
4985	+ .20	+200

Dithiocyanato-bis-*dextro*-propylenediamine chromic thiocyanate (XVI) was prepared accordingly to the directions of Rollinson and Bailar.[14] Readings were taken on a 0.1% solution (Curve C, Fig. 3). At those wave lengths marked with an asterisk the solution had to be diluted with an equal volume of water because of high absorption.

Wave length in Å.	Observed rotation	Specific rotation
6625	+0.01	+10
6225	− .01	−10
5892	− .04	−40
5615	− .07	−70

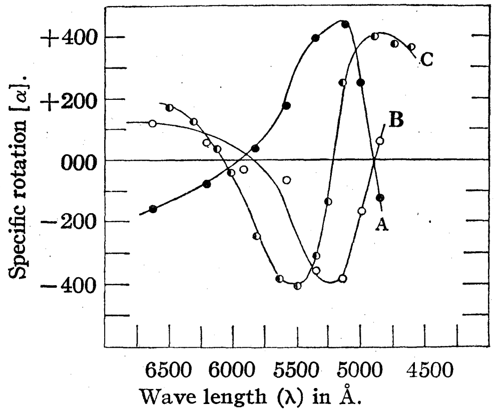

Fig. 6.—The rotatory dispersions of some complex ions of the type *cis*-$[M(AA)_2Cl_2]^+$: O, [Cr *l*-pn_2Cl_2]Cl (XVIII); ●, *levo*-[Cr en_2Cl_2]Cl (XVII); ◐, [Co *l*-pn_2Cl_2]Cl (II) (for data, see ref. 5).

Summary

Rotatory dispersion curves have been plotted for several ethylenediamine and propylenediamine cobaltic complexes of the types $[Co(AA)_2a_2]^+$ and $[Co(AA)_2Y]^+$. These can be used to distinguish between *cis* and *trans* isomers in the propylenediamine series.

It is shown that the reaction of $[Co(NH_3)_3(NO_2)_3]$ with propylenediamine leads to a mixture of *cis* and *trans* [Co $pn_2(NO_2)_2$]NO_2(IV). Either *cis* or *trans* [Co pn_2Cl_2]Cl(II), reacting with potassium thiocyanate, leads to *trans* [Co $pn_2(NCS)_2$]$^+$ (Xa). The reaction of either *cis* or *trans* [Co pn_2Cl_2]Cl (II) with aqueous ammonia yields *trans* [Co $pn_2(NH_3)Cl$]Cl_2 (VIa) and with anhydrous ammonia, *trans* [Co $pn_2(NH_3)_2$]Cl_3 (VIIIa). The reaction with aqueous ammonia is particularly interesting, as the corresponding reaction in the ethylenediamine series leads to the *cis* isomer (VIIb).

The reaction of sodium sulfite with *trans* [Co pn_2Cl_2]Cl (IIa) gives [Co pn_2SO_3]$^+$ (XII), in which the sulfite ion acts as a bidentate group.

The similarity between the rotatory dispersion curves shown by analogous complexes of cobalt and chromium is pointed out, with the suggestion that it may serve as a means of determining configurations.

The Sterochemistry of Complex Inorganic Compounds. IX. The Diastereoisomers of *dextro*-Tartrato-*bis*-ethylenediamine Cobaltic Ion

BY HANS B. JONASSEN, JOHN C. BAILAR, JR., AND E. H. HUFFMAN[1]

The stereochemistry of the octahedral complex ions offers many problems for which there is no counterpart in the better known stereochemistry of carbon. For example, the union of a metallic ion with three molecules of an optically active bidentate coördinating agent would be expected to lead to a large number of stereoisomeric complex ions.[2] The case of tris-propylenediamine cobaltic ion, $[\mathrm{Co\ pn_3}]^{+++}$[3] offers an interesting example. Considering optical activity only, the complex ion would be expected to exist in eight isomeric forms. Taking D and L to represent the signs of rotation of the complex as a whole (at the sodium D line) and *d* and *l* the signs of rotation of propylenediamine, these are D*lll*, D*lld*, D*ldd*, D*ddd*, L*lll*, L*lld*, L*ldd*, L*ddd*. (In addition, there might be several racemoids or partial racemoids.) Experiment has shown, however, that these combinations are not all of equal stability; in fact, only two of the isomeric ions are stable enough to be isolated. They are L*lll* and D*ddd*.[4]

A similar effect is observed if the complex contains only two optically active coördinating groups. It has been shown that such ions as *cis* $[\mathrm{Co\ pn_2\ Cl_2}]^+$ and *cis* $[\mathrm{Co\ cptdin_2\ Cl_2}]^+$ exist[6] in only two of the six possible forms—D*ll*$\mathrm{Cl_2}$ and L*dd*$\mathrm{Cl_2}$.[4b] If dichloro-bis-*levo*-propylenediamine cobaltic ion, $[\mathrm{Cl}\ l\text{-}\mathrm{pn_2\ Cl_2}]^+$, be treated with *dextro*-propylenediamine, the ion $[\mathrm{Co}\ l\text{-}\mathrm{pn_2}\ d\text{-}\mathrm{pn}]^{+++}$ apparently forms, but immediately rearranges to a mixture of the more stable L$[\mathrm{Co}\ l\text{-}\mathrm{pn_3}]^{+++}$ and D$[\mathrm{Co}\ d\text{-}\mathrm{pn_3}]^{+++}$.[4a,5]

These selective effects, while pronounced, are not absolute but only relative. Lifschitz[6] found evidence that cobalt and chromium tris-*dextro*-alanine exist in D*ddd* and L*ddd* forms. Bailar and McReynolds[7] have shown that the ion $[\mathrm{Co}\ l\text{-}\mathrm{pn_2\ CO_3}]^+$ exists in both D*ll* $\mathrm{CO_3}$ and L*ll* $\mathrm{CO_3}$ forms, but that the latter is unstable, rearranging to the former when warmed gently.

When only one molecule of the optically active base is present in the coördination sphere, there is some tendency toward the formation of preferred orientations, but not enough to completely fix the configurations. Thus, when Jaeger and Blumendal[4b] allowed racemic *trans*-cyclo-pentanediamine to react with $[\mathrm{Co\ en_2\ Cl_2}]^+$, they obtained a true racemic mixture of D$[\mathrm{Co\ en_2}\ l\text{-}\mathrm{cptdin}]^{+++}$ and L$[\mathrm{Co\ en_2}\ d\text{-}\mathrm{cptdin}]^{+++}$ without detecting any of the other two possible forms. When, however, they used *levo*-cyclopentanediamine, they observed that the base entered both the D and L forms of the complex, yielding D and L$[\mathrm{Co\ en_2}\ l\text{-}\mathrm{cptdin}]^{+++}$.[8]

This paper is concerned with another case in which the complex ion contains one optically active bidentate coördinating group—the tartrate ion. It has been found that *dextro* tartaric acid reacts readily with carbonato-*bis*-ethylenediamine cobaltic ion, $[\mathrm{Co\ en_2\ CO_3}]^+$ to give the two diastereoisomers D$[\mathrm{Co\ en_2}\ d\text{-}\mathrm{tart}]^+$ and L$[\mathrm{Co\ en_2}\ d\text{-}\mathrm{tart}]^+$, which differ strikingly in stability, reactivity and solubility.

The *dextro*-tartrato-bis-ethylenediamine cobaltic ion was prepared by the interaction of equivalent quantities of $[\mathrm{Co\ en_2\ CO_3}]\mathrm{Cl}$ or $[\mathrm{Co\ en_2\ CO_3}]\ \mathrm{Br}$ and *dextro*-tartaric acid. It makes no difference whether the carbonate salt is racemic or optically active; the final product is the same. Solutions of these substances react rapidly at room temperature with the evolution of carbon dioxide, but the primary product of the reaction is $[\mathrm{Co\ en_2\ (H_2O)_2}]^{+++}$. In order to insure complete replacement of the water molecules by tartrate, the solution must be evaporated to dryness and the residue heated on the steam-bath for several hours. The tartrato halides $[\mathrm{Co\ en_2}\ d\text{-}\mathrm{tart}]\ \mathrm{X}$ are extremely soluble, and form deep red glasses which cannot be crystallized.[9] *Anal.* of $[\mathrm{Co\ en_2}\ d\text{-}\mathrm{tart}]\mathrm{Br{\cdot}2H_2O}$, calcd.: N, 13.23; Br, 18.04. Found: N, 13.28; Br, 17.56. The rotation of a 0.1% solution at the sodium D line is about $-0.19°$.

On account of its high solubility, the mixture could not be completely fractionated into the D and L components. Partial fractionation was achieved, however, by dissolving the substance in water and reprecipitating about half of it by the addition of alcohol. The portion remaining in the filtrate was precipitated by addition of a large excess of ether. These fractions were again dissolved and reprecipitated. Repetitions of the process gave specific rotations as high as $+2°$ and as low as $-46°$.

Reaction of DL$[\mathrm{Co\ en_2}\ d\text{-}\mathrm{tart}]^+$ with Ethylenediamine.—A mixture of 20 g. of $[\mathrm{Co\ en}\ d\text{-}\mathrm{tart}]\mathrm{Br}$, 60 ml. of 56% ethylenediamine and 15 ml. of water was shaken at room temperature for definite time intervals. After each time interval, the solution was poured into 75 ml. of ice-cold ethyl alcohol, and the precipitate was removed by filtration. The filtrate was evaporated to 55 ml. in a current of air (to remove the alcohol), 10 ml. of ethylenediamine was added (to compensate for that lost by evaporation and reaction) and the mixture was returned to the shaker for another time interval. The precipitate was thrice dis-

solved in 15 ml. of water and reprecipitated by adding 15 ml. of methyl alcohol. This kept the unchanged tartrato salt in solution but precipitated the bright yellow tris-ethylenediamine salt. The filtrates were saved, and the complex in them was finally recovered by evaporation at room temperature to 50 ml. and addition of 150 ml. of a 2:1:1 mixture of methyl and ethyl alcohols and ether. The results are shown in Table I.

TABLE I

Time of shaking	Color of ppt.	Color of filtrate	α(obs.) 1-dm. tube	Yield, g.
10 min.	Pink	Red	+0.13 (0.1% soln.)	0.15
40 min.	Yellow	Red	+0.05 (0.5% soln.)	3.2
100 min.	Yellow	Red	+0.08 (0.5% soln.)	3.5
12 hours	....	Red	....	0.0

From the filtrate, after twelve hours of shaking, it was possible to recover 9 g. of $[\text{Co en}_2\ d\text{-tart}]\text{Br}$; 2 g. was also recovered from the filtrates obtained upon recrystallization of the precipitates. It is evident that the reaction proceeds rapidly for something over an hour, then stops completely.

A similar experiment was carried out at a higher temperature, the procedure differing only in that after each removal of tris-ethylenediamine salt the unchanged tartrato salt was completely precipitated by adding 100 ml. of a 2:1:1 mixture of methyl and ethyl alcohols and ether. This precipitate was then dissolved in twice its weight of water, and twice this volume of ethylenediamine was added. A small portion of the resulting solution was used each time for a determination of the rotation. The results are shown in Table II.

TABLE II

Time of shaking, hr.	Temp., °C.	Yield of $[\text{Co en}_3]^{+++}$ salt, g.	α observed ppt. (0.5%) 1-dm. tube	% purity of D$[\text{Co en}_3]^{+++}$	Filtr. (0.1%) 1-dm. tube

68	50	0.5	+ .25	70	− .40
82[a]	50	1.1	+ .01		− .45
106[a]	50	0.2	+ .02		− .06

[a] Two grams of activated charcoal was added in each of the last two time intervals. This greatly catalyzes the reaction, but the product is racemic. The filtrate from each of the last two filtrations was orange or brown (the color of $[\text{Co en}_3]^{+++}$), while the filtrates from the earlier shakings were a brilliant cherry red (as is $[\text{Co en}_2\ \text{tart}]^+$).

The fact that the $[\text{Co en}_3]^{+++}$ fractions all show positive rotations, while the material which has not reacted shows an increasing negative rotation, indicates that the original material is a mixture of two isomers rather than a single individual, D or L $[\text{Co en}_2\ d\text{-tart}]^+$.

The filtrate from the precipitate obtained after one-hundred six hours of shaking could not be precipitated by addition of 100 ml. of 2:1:1 mixture of methyl and ethyl alcohols and ether. The excess of ethylenediamine was therefore removed by bubbling gaseous hydrogen chloride through the ice cold solution until most of the ethylenediamine was precipitated as the hydrochloride and before the solution began to change to a purple color (indicative of the formation of $[\text{Co en}_2\ \text{Cl}_2]^+$). The ethylenediamine hydrochloride was filtered off, and the filtrate was evaporated in a stream of air. The residue was dried for four hours at 65°; yield about 3.5 g. The rotation was −0.06 for a 0.5% solution.

Similar results were obtained in several other runs although no exact duplications of the rotations were obtained. The tris-ethylenediamine salt obtained in the sixty-eight hours represents a little more than 12 g. of optically pure tris-ethylenediamine cobaltic bromide. Since 1.3 g. of almost inactive $[\text{Co en}_3]\text{Br}_3$ was recovered, as well as 3.5 g. of unchanged starting material, it is evident that an asymmetric synthesis has taken place.

In the best run, a 70% yield of *dextro*-$[\text{Co en}_3]^{+++}$ was obtained (out of a possible 100% for *dextro*- and *levo*-combined). Either the two isomers of $[\text{Co en}_2\ d\text{-tart}]^+$ are not present in equal amount or the less reactive is converted to the more reactive as the latter is used up by the reaction with ethylenediamine. The fact that the DL-$[\text{Co en}_2\ d\text{-tart}]^+$ mixture has a high negative rotation would suggest that the L isomer is somewhat more abundant and therefore more stable than the D. This leads to the conclusion that the D form is the more reactive and so is the one which reacts with ethylenediamine the more readily. Whether the difference in rate of reaction takes place in the formation of the tartrato complex or in its conversion to the *tris*-ethylenediamine salt, we have here a partially asymmetric synthesis of $[\text{Co en}_3]^{+++}$.

Reaction of DL-$[\text{Co en}_2\ d\text{-tart}]^+$ with Hydrochloric Acid.—A solution of ten grams of the tartrato salt in ten milliliters of water was treated with 10 ml. of concentrated hydrochloric acid. At given time intervals the mixture was poured into 50 ml. of ice cold methanol, which caused precipitation of the unchanged tartrato salt, but kept the violet colored *cis*-dichloro salt in solution. After filtration, the red precipitate was again treated with hydrochloric acid. The violet filtrate was treated with 75 ml. of concentrated nitric acid to precipitate the dichloro salt. This precipitate was filtered as quickly as possible, washed with ether and dried in a vacuum desiccator over potassium hydroxide for two weeks. This long drying is essential to remove the last traces of acid. Without it, the crystals turn green (*trans*-dichloro salt) when exposed to moist air. Table III shows the results of two runs. It will be observed that samples of the *cis*-dichloro salt obtained in the second run showed no optical activity. This is probably due to the fact that the acid was not entirely removed, and caused very rapid racemization. This *cis*-dichloro salt racemizes rapidly even under the best conditions, and the measurements of optical rotation must be made immediately. While the rotations of the *cis*-$[\text{Co en}_2\ \text{Cl}_2]\text{Cl}$ could never be duplicated, the increasing negative rotation of the unchanged tartrato salt was demonstrated repeatedly. Here again, the results show that $[\text{Co en}_2\ d\text{-tart}]^+$ is not a single individual, but is a mixture of two forms which differ greatly in reactivity.

Optical rotations were taken on 0.1% solutions at the sodium D line in a 1-dm. tube. *Anal.* Calcd. for $[\text{Co en}_2\ \text{Cl}_2]\text{Cl}$: Cl, 37.3. Found for sample B: first run, Cl, 37.21; second run, Cl, 37.45.

Reaction of DL-$[\text{Co en}_2\ d\text{-tart}]\text{Br}$ with Calcium Nitrite.—Four grams of the DL tartrato salt, in about 10 ml. of water, was mixed with 2.4 g. (100% excess) of calcium nitrite. Reaction was very slow, but over a period of several weeks calcium tartrate and a brown powder of $[\text{Co en}_2\ (\text{NO}_2)_2]\text{Br}$ gradually precipitated. This was recrystallized from water containing a little ammonium bromide. It was dextrorotatory; analysis showed 23.06% bromine; calcd., 22.77%. The reaction can be greatly accelerated by heating the mixture near the boiling point for five minutes and cooling immediately, or by heating to 50–60° for three hours. For the best sample prepared by the first of these techniques $[\alpha]_D$ was found to be +50°. Werner[10] reports $[\alpha]_D$ for $[\text{Co en}_2\ (\text{NO}_2)_2]\text{Br}$ to be +44°. For a typical sample prepared by the second technique, $[\alpha]_D$ was found to be +42°, and the percentage of bromine, 22.84.

In every case the filtrate still had the brilliant red color of the tartrato salt, and it was evident that much of this remained. When the reaction mixture was heated long enough to bring about complete reaction, the product was always racemic, probably because of the easy racemization

---

of [Co en_2 $(NO_2)_2$]$^+$. The best yield of optically active dinitro product that was ever obtained was 40%. It is apparently possible to convert one form of the [Co en_2 *d*-tart]Br to the dinitro salt without affecting the other form. When the reaction is allowed to proceed at room temperature, the precipitation of calcium tartrate goes on slowly but steadily until about half is precipitated; the reaction then stops unless the temperature is raised.

Summary

The presence of two or three optically active chelate groups in an octahedral complex tends to fix a definite configuration upon the complex ion as a whole, and in some cases the number of stereoisomers which can be isolated is limited to a small fraction of those theoretically possible. No such effect has been observed in complex ions containing only one asymmetric chelate group. It is now shown that while both the D and L forms of *dextro*-tartrato-*bis*-ethylenediamine cobaltic ion, [Co en_2 *d*-tart]$^+$, form when *dextro*-tartaric acid reacts with [Co en_2 CO_3]$^+$, they differ greatly in reactivity. When the mixture of the two is shaken with ethylenediamine at room temperature, part of the material reacts within two hours, giving *dextro*-[Co en_3]$^{+++}$. The remainder does not react even in twelve hours and can be recovered. At 50°, a 70% yield of *dextro*-[Co en_3]$^{+++}$ is obtained, and very little of the original material can be recovered. Evidently the less reactive form changes to the more reactive as the latter is used up. The reaction with hydrochloric acid seems to follow a similar course, and gives a large yield of *dextro*-rotatory *cis*-[Co en_2 Cl_2] Cl.

Reaction with calcium nitrite gives similar results; at room temperatures or slightly above, about half of the tartrato salt reacts, yielding *dextro*-[Co en_2 $(NO_2)_2$]$^+$. The remainder will not react at room temperatures. At higher temperatures the product is racemized.

These are evidently the first examples of asymmetric synthesis in the field of inorganic complex ions.

Hydrofluorination in the Presence of Boron Fluoride

BY ALBERT L. HENNE AND ROBERT C. ARNOLD

The addition of hydrogen fluoride to an olefinic hydrocarbon occurs with great ease[1]; addition also takes place easily with asymmetrically halogenated olefins such as $CH_2{=}CHX$, $RCH{=}CX_2$ or $RCX{=}CH_2$,[2] while the presence of the vinylic halogens on both sides of the double bond impedes or prevents it.[2] We have now observed that when the addition is carried out in the presence of small quantities of boron fluoride the reaction is greatly hastened, and even occurs where it had failed in the absence of boron fluoride.

Besides plain hydrofluorination, an alternation of HF additions and HX removals is observed, so that $RCH{=}CX_2$ gives not only RCH_2CX_2F, but also $RCH{=}CFX$, RCH_2CXF_2, $RCH{=}CF_2$ and RCH_2CF_3 in sequence. The presence of the boron fluoride increases the number of these steps and the extent to which they occur; the net effect is to increase the fluorine content of the final product.

The use of boron fluoride is particularly advantageous with heavily halogenated olefins, or with olefins bearing a CF_3 group which slows down the reactivity of their double bond. For more reactive olefins, boron fluoride may not be so desirable because it hastens resinification as well as addition; the economy of each case should be individually considered. The literature statement[1] that BF_3 is of no help should be restricted to non-halogenated olefins, where addition is so easy that it does not need any help.

Eleven different olefins were treated with hydrogen fluoride in the molar ratio of 1/2; when BF_3 was added, it was in the concentration shown in grams per mole of olefin in the table of experimental results.

The observed improvements can be explained by the formation of a coördinated complex $HF \rightarrow BF_3$, which enhances the percentage of ionic character of the H–F bond; this facilitates the separation of hydrogen as a proton, and makes it more available for addition to the more negative of the

doubly bonded carbons. In support of this interpretation is the opposite fact that hydrogen fluoride addition to alkynes is *slowed down* by an oxygenated solvent such as ether or acetone[3]; in this case, complex formation with the solvent involves hydrogen bonding to the unshared electrons of the oxygen atom and obstructs separation as a proton for the first stage of addition to the triple bond.

The **direction** of addition was always that expected from the ionic character of the olefin. The vinylic halides acted as if entirely in their resonating form  $:\overset{-}{C}H_2{-}\overset{H}{C}{=}X^{+}$, so that RR′C=CR″X lead exclusively to HRR′C=CR″XF. By induction, a CF_3 group attached to a doubly bonded carbon caused a polarization opposed to that created by a CH_3 group, so that the polarization of propene and trifluoropropene could be represented as $CH_3\underset{+}{C}H{=}\underset{-}{C}H_2$ and $CF_3\underset{+}{C}H{=}\underset{-}{C}H_2$, respectively.

The **ease** of addition was not determined solely by the extent of polarization of the double bond. $CH_2{=}CCl_2$ accepted hydrogen fluoride more readily than $CHCl{=}CHCl$ and $CCl_2{=}CF_2$ more than $CClF{=}CClF$; $CH_3CCl{=}CClH$ was more easily hydrofluorinated than $CF_3CH{=}CClF$, yet the latter compound should be much more polarized than the former due to the combination of the eletronegative character of the CF_3 group and the vinylic character of the $=CFCl$ group. It is proposed that the *absolute* electron density around the double bond should also be taken into account; if this is done, it is to be expected that all ethylenes bearing a CF_3 group should be slowed down by the electron drainage away from the double bond; in agreement, $HCCl{=}CCl_2$ was found more easily hydrofluorinated than $CF_3CCl{=}CCl_2$. This explanation would be similar to that used for the meta-directing effect of an electronegative group on a benzene ring, and its retarding influence.

Experimental Details

Reaction Equipment.—For relatively low pressure, an 800-ml. steel vessel fitted as previously described[4] was used; for the higher pressures prevailing with more boron fluoride, a 200 cc. Aminco bomb was used, with super-pressure fittings. Heating was done by immerging in a hot water-bath, or by strapping to the electrically heated mantle of a mechanical rocking devise.

Reagents.—Commercial grades.

---

(3) Henne and Plueddeman, THIS JOURNAL, **65**, 587 (1943).

(4) Henne and Flannagan, *ibid.*, **65**, 2362 (1943).

Loading Procedure.—As previously described.[5,6]

Metering of Boron Fluoride.—A steel cylinder of known capacity was connected to a commercial tank of boron fluoride; the gas was admitted and the pressure created was noted. Next, this loaded steel cylinder was connected to the reaction vessel and the amount of boron fluoride delivered was computed from the observed drop in pressure. For very small additions of boron fluoride, a stream of the gas was passed through weighed liquefied hydrogen fluoride cooled to −70°.

Treatment of Reaction Products.—Gaseous products were released through a washing train and collected in a Dry Ice cooled receiver. Liquids were poured on cracked ice, neutralized, steam distilled, dried and separated by fractional distillation. In the few cases where the olefin and its addition product boiled practically at the same temperature, the composition of the distillate was estimated from the index of refraction, but this procedure was avoided as much as possible by using efficient dephlegmators.

Summary

The addition of hydrogen fluoride to halogenated olefins is accelerated or made possible by using small amounts of boron fluoride as a catalyst. The action is attributed to the formation of a coördinate compound HF → BF_3, in which the H to F bond is weakened; this favors the supply of protons for the first step of the addition to the double bond. The direction and ease of addition are discussed. Eleven olefins have been tried and the results are tabulated.

Polyamide Resins from Dilinoleic Acid and Ethylenediamine. Molecular Weight–Viscosity Relationships[1a]

BY R. H. ANDERSON AND D. H. WHEELER

Introduction

In 1941, Bradley and Johnston[1b] isolated dilinoleic acid in a pure state as the methyl ester by fractional molecular distillation of the heat-polymerized methyl esters of the acids from dehydrated castor oil. They prepared polyesters of triethylene glycol with molecular weights of about 4300. Cowan and Wheeler[2] prepared polyesters with various glycols having molecular weights up to 20,000 to 30,000.

Polyamides have been prepared by Falkenburg, Teeter, Skell and Cowan[3] from various diamines and the residual polymeric fatty acids or esters (mixtures of dimer and trimers of linoleic and linolenic acids). The polyamide from ethylenediamine and these mixed polymeric fatty acids was proposed as a new synthetic coating material[4] under the name *Norelac*. The molecular weights of these resins were 3,000 to 5,000, determined by the method of end-groups. The same type of polyamide has been commercially prepared on a pilot plant scale,[5] and is apparently finding some use as a coating for heat-sealing and laminating paper.

No description has appeared of polyamides from pure dilinoleic acid and ethylenediamine. The present investigation describes the preparation and some properties of such linear polyamides having molecular weights from 2,000 to 15,000.

Viscosities were determined on solutions in 1:1 butanol-toluene solvent at concentrations from 0.2 to 9.8 g. per 100 cc. and intrinsic viscosities were calculated. The intrinsic viscosity was found to be related to molecular weight by the formula

$$[\eta] = KM^{a} \qquad (1)$$

Flory and Stickney[6] have pointed out the fact that a relationship such as equation (1) really relates to *viscosity* average (M_v) rather than *number* average (M_n) molecular weights of non-homogeneous polymers, and that M_v is greater than M_n, but less than M_w, the weight average molecular weight.

Now, the molecular weights, as determined by end-group titration in the present study, are actually *number* average molecular weights. The fact that the determined molecular weights and viscosities of these polyamides agree with equation (1) is interpreted to mean that these polymers, as prepared, have essentially a constant ratio of M_v to M_n. Flory[7] has shown on theoretical grounds that for bifunctional condensation polymers, M_w/M_n approaches 2 for higher polymers. Taylor[8] has shown that the ratio is very nearly 2 for 66-nylon polyamide, and that the value of M_v is close to that of M_w. The weight average can therefore be used interchangeably with M_v without introducing serious error.

When mixtures of condensation polyesters or polyamides are considered, the importance of considering a weight average rather than a number average in calculating viscosity is apparent. The viscosity in the molten state of a mixture of polyesters was shown by Flory[7] to agree with the M_w,

but not with the M_n, of the mixture. Similarly, the molecular weight of a mixture of polyamides calculated from its $[\eta]$ is shown in the present study to agree with a weighted average rather than the number average of the mixture.

Experimental

Dilinoleic acid was prepared from a commercial dehydrated castor oil of Z-3 Gardner viscosity by conversion to methyl esters, which were heated for twelve hours at 300° under nitrogen. Unpolymerized methyl esters were removed by ordinary vacuum distillation. The residue of dimer and trimer was fractionally distilled in an alembic flask similar to that used by Cowan, Falkenburg and Teeter.[9] The fractional distillation was repeated three times, taking a middle cut of about 80% on the second and third distillations. On the second and third distillations, the methyl dilinoleate distilled at 20 μ pressure with a vapor temperature of 225–235° and a pot temperature of 255–265°. The pure dimer fraction from the third distillation had a spread in refractive index of 10 units in the fourth place between the first and last small fraction. Continuation of the distillation until the pot temperature was 300° left about 1.2% of undistilled residue having a refractive index only slightly higher than the pure dimer. The pure ester showed the following analytical values: sapn. equiv. 295 (calcd. 294), iodine value 75.2 (calcd. 86.8), mol. wt. (ebul., acetone), 545, 571 (calcd. 588), density 0.943 (25°).

The ester was converted to acid in the usual manner. The acid showed: neutr. equiv., 285; sapn. equiv., 283 (calcd. 280.2). Aqueous ethylenediamine from Carbide and Carbon Co. was redistilled, b. p. 115.5–117.5°, and titrated with standard acid using methyl red indicator. It contained 67.5% ethylenediamine.

Preparations of the polyamides were carried out in a three-necked flask with stirrer, thermometer, dropping funnel and simple side arm take-off for distillate. Dilinoleic acid (70 to 100 g.) was heated to 120° and stirred under vacuum to remove dissolved gases, pure nitrogen was admitted and the calculated amount of ethylenediamine was added over a period of one-quarter hour at a temperature of 120–130°. After addition of the amine, the temperature was raised to 200° at a rate such that the vapor temperature never exceeded 100°. The mixture was then held at 200° for four hours (six hours for polymers no. 8 and 9) under nitrogen and for an additional hour at 200° under vacuum with a Dry Ice trap in the vacuum line to catch any amine. The resin was then cooled to 160°, and poured into containers under inert gas. Samples were stored under nitrogen when not in use.

The distillate plus trap material was titrated for amine lost, which was quite small, −0.1 to 0.2% of original amine.

Carboxylic end-groups were determined by titration of the resin in a 50–50 butanol–toluene mixture with 0.1 *N* alcoholic potassium hydroxide (phenolphthalein). Amine end-groups were determined by titration with freshly standardized 0.1 *N* alcoholic hydrochloric acid (brom cresol green). Average molecular weights were calculated from the combined acid and amine end-groups. The molecular weights as determined were in close agreement with those expected on the basis of the excess of acid used. A balance of the free acid and amine groups in the polymer against the amount of acid and amine used as starting materials showed less than 1% discrepancy in every case. This would indicate that not over 1% loss of acid groups occurred by decarboxylation, unless amine were lost in equivalent amounts. Some properties of the resins are given in Table I.

TABLE I

POLYAMIDES OF DILINOLEIC ACID AND ETHYLENEDIAMINE

Polymer	Acid no.[a]	Amine no.[a]	Mol. wt.[a]	Soft pt. °C.[b]	Viscosity[c]	Penetration[d]	Gel time[e]
1	51.00	0.00	2,200	94.6	A-3	31.4	1440
2	27.20	.00	4,125	111.0	A-1 to A	6.8	650
3	18.30	.00	6,130	112.5	A	4.1	513
4	16.20	.24	6,800	117.8	B	3.7	465

9	5.51	1.78	15,370	121.5	F	1.9	0

[a] Acid no. and amine no. equal milligrams of KOH equivalent to the acid and amine groups, respectively, in 1 g. of material, whence: Mol. Wt. = 2 × 56,100/acid no. + amine no. [b] Ball and ring. [c] Gardner bubble viscosity at 25° of a 35% solution in 1–1 (wt.) *n*-butanol–toluene solvent. [d] Tenths of a mm. with A.S.T.M. standard penetrometer needle, 200 g. load, thirty seconds at 25°. [e] Time in seconds for 0.03 inch film to gel in air on a hot-plate at 200°. Gelation is indicated by the drawing of a string upon touching with a pin point.

As shown by the data, with increasing molecular weight, the melting point increases rapidly at first and then levels off somewhat. Viscosity increases regularly and hardness increases (penetration decreases), whereas gel time decreases regularly with increased molecular weight. Gelation is caused by cross-linking induced by oxygen, since the resins are stable at this temperature in the absence of oxygen. The greater the chain length, the fewer cross-links should be necessary to cause gelation, and the shorter the gel time should be.

Solution viscosities of the polyamides were determined at concentrations ranging from 0.2 to 9.8 g. per 100 cc. of solution in 1–1 (wt.) *n*-butanol–toluene. The viscosities were determined in an Ostwald viscometer of 3.16 cc. volume, 9.5 cm. capillary with a diameter of 0.057 cm. Viscosities were calculated by the following equation which corrects for kinetic energy losses[10]

$$\eta = \rho C t - (\rho/8\pi l)(v/t) \qquad (2)$$

where C is a calibration constant, ρ is the density and t the time in seconds for efflux of volume v. The viscometer was calibrated with water (t = 82.4) using 0.00894 poise as the value for water at 25°. Most of the measurements were made in a constant temperature bath at 25°, controlled to ±0.02°. Several series were also run at 30°. The values for ηr at 30° were identical with those at 25° within experimental error. The solutions were quite stable, good checks being obtained on samples which had stood for a number of weeks. The solvent had a viscosity of 0.00973 poise at 25° ($t = 108.7$, $\rho = 0.832$).

The viscosity data for the polyamides (and for dimer acid) are shown in Fig. 1, where $\ln \eta r/c$ is plotted *vs.* concentration. Up to a concentration of 1.5% the values are constant within experimental error, with the values at higher concentrations for the polymers of higher molecular weights showing a progressive tendency to be lower than those obtained up to 1.5% concentration (accentuated in Fig. 1 by the change in scale beyond 2.0).

(10) E. C. Bingham, "Fluidity and Viscosity," McGraw-Hill Book Co., New York, N. Y., 1922, p. 17.

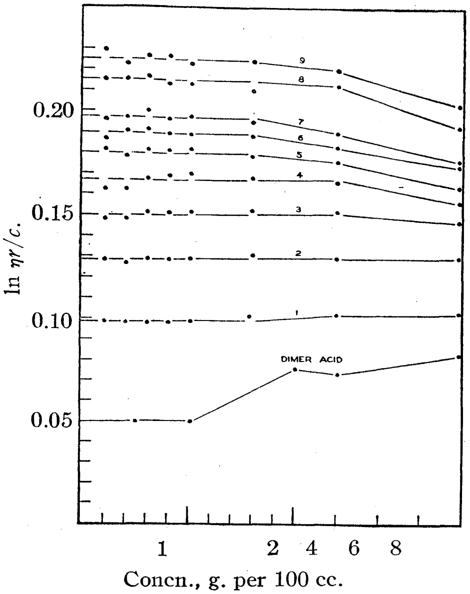

Fig. 1.—ln $\eta r/c$ *vs.* concentration.

The intercepts of the lines with the zero concentration axis, as determined from Fig. 1, are recorded in Table II as [η], with the corresponding molecular weights.

TABLE II

INTRINSIC VISCOSITIES AND MOLECULAR WEIGHTS OF POLYAMIDES

Polymer	Mol. wt.	[η]
1	2,200	0.0986
2	4,125	.129
3	6,130	.150
4	6,800	.167
5	8,220	.180
6	9,640	.190
7	10,000	.197
8	14,200	.215
9	15,370	.225

The relationship of molecular weight to intrinsic viscosity was best represented by a log–log plot of these values, as shown in Fig. 2. The largest deviation, that of no. 4, is 10% while the other samples were within 1 to 6% of the values for the line. The equations for the line in Fig. 2 are

$$[\eta] = 4.06 \times 10^{-3} M_n{}^{0.42} \qquad (3)$$

$$M_n = 5.50 \times 10^{5} [\eta]^{2.4} \qquad (4)$$

where K of equation 1 is seen to be 4.06×10^{-3} and a is 0.42. Taylor's values on 66 nylon in formic acid were 1.1×10^{-3} and 0.72, respectively.

Intrinsic viscosities of mixtures of high and low molecular weight polymers were determined in the same manner. Mixtures were made of the 2000 mol. wt. polymer with the 10,000 and 15,000 mol. wt. polymers. The mixtures had values for [η] which agreed fairly well with the weighted averages of [η] and with the [η] determined from the weighted number averages ("M_w") by means of Fig. 2, but did not agree with the [η] determined from the number average by Fig. 2. The results are shown in Table III.

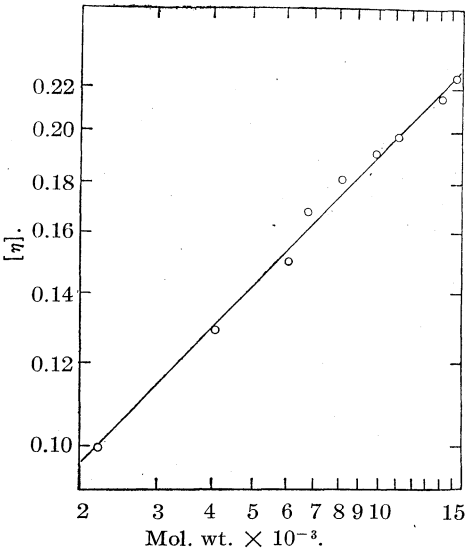

Fig. 2.—Molecular weight *vs.* intrinsic viscosity on log–log scale.

TABLE III

INTRINSIC VISCOSITIES OF MIXTURES OF POLYAMIDES

M. W. 2200 and 10,000

% of 2200	Obs.	Wtd.[a] av.	From "Mw"[b]	From Mn[c]
75	0.131	0.123	0.131	0.109
50	.156	.148	.153	.124
25	.182	.172	.172	.145
M. W. 2200 and 15,370				
50	0.163	0.162	0.179	0.125

[a] $[\eta]$ (weighted av.) = $[\eta]_1 w_1 + [\eta]_2 w_2$. [b] "$M_w$" (Mixt.) = $M_1 w_1 + M_2 w_2$. [c] M_n(Mixt.) = $1/(w_1/M_1 + w_2/M_2)$, where w_1 and w_2 refer to the weight fraction of polymers with determined molecular weights of M_1 and M_2, respectively.

It should be noted that the values for "M_w" referred to in Table III are really weighted number average values rather than true M_w values, since the molecular weights used are the determined number average values. However, the comparisons in Table III are valid if the determined M_n values of the components have a constant ratio to their M_w values, as is believed to be the case. Calculations based on an equation of Flory,[7] relating M_w to M_n for polyesters, indicate that M_w/M_n for the lowest polymer is about 1.86, while for the next higher polymer it is 1.93, with values more nearly approaching 2 for the higher polymers.

Discussion

All of the polyamides except no. 8 had acid end-groups almost exclusively (see Table I). The linear relationship of ln η_r to concentration, up to at least 1.5%, would indicate that association of acid end-groups is not an appreciable factor at these concentrations. Polymer 8, with a more nearly equal number of amino and acid end-groups, also shows no appreciable deviation of ln η_r in Fig. 1, and its general viscosity characteristics are similar to those of no. 9, which is of similar molecular weight, but which has a high ratio of acid to amino end-groups. The dimeric acid did show a slight increase in ln η_r/c with increasing concentration, and the polymer of lowest molecular weight, no. 1, also showed a slight similar increase of this value at concentrations above 1.5%, whereas the higher polymers often showed a slight decrease. These phenomena would indicate some association of acid end-groups at higher concentrations in the cases of polymers with a high concentration of acid end-groups.

Summary

1. Polyamides of dilinoleic acid and ethylenediamine have been prepared with molecular weights from 2,200 to about 15,000.

2. The relationship of molecular weight to intrinsic viscosity can be expressed by the equation

$$[\eta] = 4.06 \times 10^{-3} M^{0.42}$$

3. The nature of this relationship, and the results of a study of the viscosities of mixtures of polymers indicate that the number average molecular weights of the polymers, as prepared, bear a constant ratio to the viscosity and the weight average molecular weights.

4. Except at higher concentrations with polymers of high acid values, association of terminal end-groups is not very significant.

The Addition of Halogens to an Acetylenic Ketone

BY CHARLES L. BICKEL

Diaryl acetylenic ketones undergo many addition reactions; one of the simplest of these would appear to be the addition of the halogens. The halogenation of a diaryl acetylenic ketone has, however, been investigated in only one case—that of phenylbenzoylacetylene. Nef[1] obtained phenylbenzoylacetylene diiodide by the addition of iodine in ether solution. Later, Dufraisse[2] studied the addition of both bromine and iodine to phenylbenzoylacetylene and obtained phenylbenzoylacetylene dibromide, as well as the diiodide previously described by Nef.

Recent papers from this Laboratory describe the preparation of *o*-chlorophenylbenzoylacetylene,[3,4] a substance which can be obtained in excellent yield from simple starting materials. This acetylenic ketone crystallizes well from oily mixtures and can therefore be isolated more easily than the unsubstituted analogue. These facts suggested the present study of the action of the halogens on *o*-chlorophenylbenzoylacetylene.

Nef stated that an ethereal solution of phenylbenzoylacetylene easily absorbs iodine while Dufraisse stated only that an ethereal solution of the acetylene, treated with an ethereal solution of iodine, gives the iodine addition product. Neither author indicated that the reaction was sluggish. *o*-Chlorophenylbenzoylacetylene, on the other hand, gives no apparent reaction with iodine at room temperature. When a chloroform solution of iodine and the acetylene is heated, there is no evidence of reaction until the solvent has been completely evaporated. Further heating of the residual mixture of iodine and *o*-chlorophenylbenzoylacetylene gives a solid cake from which the iodine addition product can be isolated in good yield.

Although the melting point of phenylbenzoylacetylene diiodide has been variously reported,[1,2] there is no indication in the literature that the melting of this substance is attended by decomposition. *o*-Chlorophenylbenzoylacetylene diiodide, however, decomposes slowly at about 145° and rapidly at 172°, the temperature at which it appears to melt. The decomposition is a clean reaction, iodine and the original acetylenic ketone being the only products. In fact, the thermal decomposition of the diiodide provides the best method of analysis.

o-Chlorophenylbenzoylacetylene, like the unsubstituted analogue, reacts readily with bromine to give a dibromide, a substance which is stable at a temperature one hundred degrees above its melting point. The same dibromide is obtained by treating the diiodide with bromine.

In view of the successful addition of iodine and bromine to *o*-chlorophenylbenzoylacetylene, no difficulty was anticipated in the addition of chlorine. However, attempts to prepare the dichloride have so far met with no success. The acetylenic ketone is recovered unchanged when chlorine is bubbled through its chloroform solution, either at room temperature or at the boiling point of the solution, and even when a trace of iodine is added. When chlorine is bubbled through the molten acetylenic ketone, a red oil is obtained which has as yet given no solid products. Chlorine does not displace bromine from the di-

---

[3] Bickel, THIS JOURNAL, **69**, 73 (1947).

[4] Bickel, *ibid.*, **69**, 2134 (1947).

bromide, the dibromide being recovered unchanged.

When chlorine is bubbled into a chloroform solution of the diiodide, iodine is liberated and a single crystalline product is obtained. The analysis of this substance indicates that only one of the iodine atoms of the diiodide has been displaced. This product presumably has the structure A-CI=CCl-B or A-CCl=CI-B, where A is the *o*-chlorophenyl group and B is the benzoyl group. Prolonged treatment of the diiodide with chlorine at a higher temperature gives a mixture of substances. The analytical results indicate that one component of this mixture is a saturated compound formed by the addition of chlorine to the monochloride described above, which may be tentatively assigned the structure A-CICl—CCl$_2$-B or A-CCl$_2$—CICl-B.

The author is indebted to the Marine Biological Laboratory of Woods Hole, Mass., for the chemicals needed in preparing the starting materials used in this problem and also for the use of the facilities of the Marine Biological Laboratory.

Experimental

***o*-Chlorophenylbenzoylacetylene Diiodide.**—A suspension of 15 g. of *o*-chlorophenylbenzoylacetylene and 18.5 g. of iodine in 50 cc. of chloroform was heated until the solvent was completely removed. The residual solid cake was cooled, about 100 cc. of ether added and the solid cake pulverized, filtered and washed with ether. The ether solution, washed with sodium thiosulfate solution to remove excess iodine, gave 1.5 g. of the diiodide. The solid diiodide not dissolved by the ether weighed 26 g., a total yield of 89%.

o-Chlorophenylbenzoylacetylene diiodide is moderately soluble in chloroform and acetone, sparingly soluble in ether and very sparingly soluble in petroleum ether. It crystallizes as colorless needles from ether. When heated slowly, the diiodide begins to lose iodine at 140–145°; when heated rapidly, it appears to melt at about 172°. The diiodide was analyzed by heating a weighed sample in a platinum crucible at 160–170° until iodine was no longer liberated. The residue in the crucible solidified on cooling and melted at 94°, a mixed melting point proving it to be *o*-chlorophenylbenzoylacetylene.

Anal. Calcd. for $C_{15}H_9OClI_2$: $C_{15}H_9OCl$, 48.7; I, 51.3. Found: $C_{15}H_9OCl$, 49.0; I, 51.0.

***o*-Chlorophenylbenzoylacetylene Dibromide. A. By the Action of Bromine on *o*-Chlorophenylbenzoylacetylene.**—Bromine was added to a solution of 5 g. of *o*-chlorophenylbenzoylacetylene in 20 cc. of chloroform until the color of free bromine was apparent, considerable heat being liberated. The chloroform was then boiled off and the solid residue was taken up in about 100 cc. of ether. The ether solution gave 7.1 g. of the dibromide, a yield of 85%.

B. By the Action of Bromine on the Diiodide.—Six grams of bromine was added to a suspension of 8 g. of the diiodide in 30 cc. of chloroform. Evaporation of the chloroform gave a solid product which was taken up in ether. The ether solution, washed with sodium thiosulfate solution, gave 3.5 g. of the dibromide described above, a 54% yield. The residual orange-red oil has as yet given no solid products.

o-Chlorophenylbenzoylacetylene dibromide is readily soluble in chloroform, moderately soluble in ether and sparingly soluble in petroleum ether. It crystallizes as colorless prisms from ether and melts at 142°, with no sign of decomposition up to 250°.

Anal. Calcd. for $C_{15}H_9OClBr_2$: C, 44.9; H, 2.3. Found: C, 44.8; H, 2.5.

The Action of Chlorine on the Diiodide.—Dry chlorine was bubbled into a suspension of 5 g. of the diiodide in 25 cc. of chloroform at room temperature. The color of free iodine appeared immediately and the diiodide rapidly went into solution. After about one hour the delivery of gas was discontinued and the solvent evaporated. The product, which solidified on cooling, was dissolved in ether and the free iodine removed with sodium thiosulfate. The ether solution gave 2.5 g. of massive, colorless prisms melting at 125–126°.

Anal. Calcd. for $C_{15}H_9OCl_2I$: C, 44.7; H, 2.3. Found: C, 44.3, 44.5; H, 2.5, 2.5.

In a second experiment, dry chlorine was bubbled into a suspension of 10 g. of the diiodide in 50 cc. of chloroform, heated to the boiling point. After about two hours the solvent was evaporated, the flow of gas being maintained throughout. The product, after the removal of the iodine, was a mixture from which was obtained about 3 g. of colorless prisms, melting at 172.5° after repeated recrystallization from ether.

Anal. Calcd. for $C_{15}H_9OCl_4I$: C, 38.0; H, 1.9. Found: C, 38.5; H, 2.2.

Summary

Iodine and bromine give addition products with *o*-chlorophenylbenzoylacetylene, the diiodide losing iodine near its melting point and regenerating the acetylenic ketone.

Attempts to prepare the dichloride of *o*-chlorophenylbenzoylacetylene were unsuccessful. Two substances formed by the action of chlorine on the diiodide are reported.

The 1,3:5,7-Dibenzylidene and 1,3:5,7-Dimethylene Acetals of the D-, L- and D,L-Perseitols

BY ARTHUR T. NESS, RAYMOND M. HANN AND C. S. HUDSON

Dibenzylidene-D-perseitol[2] is of particular interest to the carbohydrate chemist because its original preparation and accurate analysis by Maquenne[3] led to the recognition that D-perseitol (I), discovered in the avocado by Avequin[4] in 1831 and long considered to be an isomer of mannitol, is indeed a heptitol. In the present article proofs are presented for the structure of dibenzylidene-D-perseitol and for that of a corresponding dimethylene-D-perseitol which we have prepared. The structures agree with those expected from perseitol as predicted by the generalizations[5] correlating the configuration of polyhydric alcohols with the structures of the benzylidene and methylene acetals derived from them.

D-Manno-D-*gala*-heptitol (D-Perseitol)

(I)

Maquenne[3] prepared dibenzylidene-D-perseitol by mixing benzaldehyde and a finely divided suspension of D-perseitol in aqueous-alcoholic solution which had been saturated with gaseous hydrochloric acid, and in his original description of the crystalline diacetal he stated that it softened at 215° but did not show a sharp melting point; in a later article[6] he recorded the softening point as 219° and this value is also given in his book on sugars.[7] Lobry de Bruyn and Alberda van Ekenstein[8] recorded a melting point of 230–235°. In our initial preparation of dibenzylidene-D-perseitol we dissolved the heptitol in 50% sulfuric acid and added benzaldehyde and alcohol; the diacetal which crystallized melted at the much lower temperature of 153–155°; it rotated $[\alpha]^{20}\mathrm{D}$ −58.2° in pyridine solution. Upon recrystallization from a pyridine–alcohol mixture the melting point of the compound increased progressively and after three recrystallizations it attained a maximum value of 280 ± 2°[9] but the substance still showed a rotation of −58.1° in pyridine. Next we prepared dibenzylidene-D-perseitol by Maquenne's procedure. In three experiments the products melted initially over ranges of 230–240°, 240–248° and 225–235°; after several recrystallizations from a pyridine–alcohol mixture the melting point reached the maximum value of 280 ± 2° and the specific rotation was −57.9°. The fact that recrystallization from pyridine–alcohol of dibenzylidene-D-perseitol, regardless of its method of preparation or its initial melting point, yields a final product melting at 280 ± 2° and rotating about −58° suggests that the products obtained initially by the different procedures of preparation may be mixtures of diastereomers in various proportions. Fischer[10] first called attention to the possibility of the occurrence of diastereomers in cyclic benzylidene acetals, due to different configurations of the acetal carbon atom of the benzylidene group, in his discussion of the formation of the labile and stable forms of what is now known to be 3,5-benzylidene-gluco-*gulo*-heptitol.[11] In the case of dibenzylidene-D-perseitol four diastereomers are theoretically possible. Whether the product melting in a range of 150–155° obtained by the sulfuric acid method and that melting at 280 ± 2° represent two relatively pure diastereomeric forms must await further evidence. As mentioned in the experimental part, these two products yield identical tribenzoyl-dibenzylidene-D-perseitols upon benzoylation in pyridine solution and identical trimethyl-dibenzylidene-D-perseitols upon methylation with thallous hydroxide and methyl iodide; it therefore seems evident that their isomerism is not due to different positions of the acetal linkages, but is to be ascribed to the stereoisomerism of the benzylidene groups. Ordinary crystalline dimorphism seems improbable.[11] An interconversion of the configurations present in the asymmetric carbon atoms of the benzylidene groups is possibly favored by the basic conditions attending the recrystallization, benzoylation and methylation.

Proof of the Structure of 1,3:5,7-Dibenzylidene-D-perseitol.—In initial tests to determine the structure of dibenzylidene-D-perseitol a solution of the diacetal (m. p. 280 ± 2°) in 2-methoxyethanol ("methyl cellosolve") was found to be fully resistant to oxidation by aqueous sodium

metaperiodate; this fact indicates that the structure of the compound does not include an α-glycol grouping. However, this limitation is by no means sufficient for establishing the structure since many conceivable structures conform with it. Additional evidence was sought through methylation studies. Attempts to methylate the dibenzylidene-D-perseitol melting at 153–155° with Purdie's reagents (silver oxide and methyl iodide) were unsuccessful, the diacetal being recovered almost quantitatively as the 280 ± 2° isomer by hot pyridine extraction of the silver oxide residues from the attempted methylation, but the methylation of the higher-melting isomer with Purdie's reagents gave nearly quantitative yields of a sirup showing the correct methoxyl content for a trimethyl-dibenzylidene-perseitol. Crystalline trimethyl-dibenzylidene-D-perseitol (m. p. 121–122°; $[\alpha]^{20}D$ $-43.5°$ in chloroform) was eventually obtained by methylation with thallous hydroxide and methyl iodide[12] of either the lower or higher melting dibenzylidene-D-perseitol. The hydrolysis of either the sirupy or the crystalline trimethyl-dibenzylidene-D-perseitol gave a crystalline trimethyl-D-perseitol (m. p. 120–121°; $[\alpha]^{20}D$ $+11.8°$ in water) which is not oxidized by sodium metaperiodate in aqueous solution. This evidence discloses the structure of the trimethyl derivative. Inspection of the formula of D-perseitol (I) shows that to fulfill the condition of absence of an α-glycol grouping in the trimethyl-D-perseitol, one methyl group must be at carbon atoms 1 or 2 and another at carbon atoms 6 or 7; of the four possible combinations of these positions, 1,6-, 1,7- and 2,7 are excluded because no combination of three methylated hydroxyl groups which includes such a pair can fulfill the condition that the trimethyl derivative be free of an α-glycol grouping; in the remaining 2,6-combination the third methyl group can be only at position 4 to exclude such a grouping, and therefore the compound is 2,4,6-trimethyl-D-perseitol. Accordingly, dibenzylidene-D-perseitol is a 1,3,5,7-diacetal and there can be little doubt that it is specifically 1,3:5,7-dibenzylidene-D-perseitol. The trimethyl ether of the diacetal is to be formulated as 2,4,6-trimethyl-1,3:-5,7-dibenzylidene-D-perseitol.

Proof of the Structure of 1,3:5,7-Dimethylene-D-perseitol.—The treatment of D-perseitol with aqueous formaldehyde solution and concentrated hydrochloric acid yielded a crystalline dimethylene-D-perseitol which melted at 251–253° and rotated $[\alpha]^{20}D$ $-19.3°$ in water. This dimethylene acetal was not oxidized by aqueous sodium metaperiodate, a result which shows that it possesses no α-glycol grouping. It formed a tritosyl ester which did not react when heated with sodium iodide in acetone solution at 100° for two hours, an indication by the Oldham–Rutherford rule that tosyl groups are not attached at carbon atoms 1 or 7, which accordingly must be involved in the acetal linkages. Proof that the hydroxyl groups in the diacetal are secondary and at positions 2, 4 and 6 follows from the fact that methylation of the dimethylene-D-perseitol with thallous hydroxide and methyl iodide gave a crystalline trimethyl-dimethylene-D-perseitol (m. p. 140–141°; $[\alpha]^{20}D$ $-6.2°$ in water) which was identical with the product resulting from the methylenation of authentic 2,4,6-trimethyl-D-perseitol (obtained through the benzylidene series as described) with aqueous formaldehyde solution and concentrated hydrochloric acid. Accordingly, the acetal linkages in the dimethylene perseitol must be at positions 1, 3, 5 and 7 and there can be little doubt that the substance is specifically 1,3:5,7-dimethylene-D-perseitol. Its tritosyl derivative is to be formulated as 2,4,6-tritosyl-1,3:5,7-dimethylene-D-perseitol and its methyl ether as 2,4,-6-trimethyl-1,3:5,7-dimethylene-D-perseitol.

Does the 1,3:5,7-diacetal structure that is present in the dibenzylidene- and dimethylene-D-perseitols conform with the previously mentioned generalizations regarding cyclic acetal structures of polyhydric alcohols?[5] An inspection of the formula of perseitol (I) shows according to the generalizations that the only pair of secondary hydroxyl groups favored to enter into methylene or benzylidene acetal formation consists of those at positions 3 and 6, which are *gamma* in position and *trans* in configuration. This combination was regarded as favorable to the formation of an acetal of the dioxepane seven-atom ring type when the generalizations were proposed because such an acetal was a prominent feature in the mannitol series. Later, it was also found in the closely similar L-rhamnitol (6-desoxy-L-mannitol) series.[13] Subsequent studies in the iditol[14] and talitol[15] series and the present one in the perseitol series fail to disclose the presence of such a dioxepane acetal although the configurations in each case seem favorable for its occurrence. However, in the iditol, talitol and perseitol configurations there are favorable positions for one or more dioxane six-atom ring acetals which conflict with the dioxepane ring acetal. Thus in perseitol the 1,3-acetal obviously competes with a 3,6-acetal. There is no such competition in the mannitol and rhamnitol series. We would accordingly extend the original generalizations by stating that formation of the dioxepane ring may not occur if competing dioxane-ring acetals are indicated by favorable positions in the configuration. It is readily evident that such competition will always occur in the case of any heptitol.

Using some L-perseitol which had been made by the reduction of D-gala-L-*manno*-heptose, we have prepared the enantiomorphous 1,3:5,7-dibenzylidene-L-perseitol and 1,3:5,7-dimethylene-L-perseitol, following the procedures already described. The L-perseitol behaved precisely like its enantio-

morph and it was especially noted that the indications of lability in the dibenzylidene acetal were duplicated.

A 1,3:5,7-dibenzylidene-D,L-perseitol melting at 271–272° was obtained by one recrystallization of a mixture of equal amounts of the higher-melting (280°) D- and L- forms from pyridine–alcohol solution. In an effort to obtain a D,L-compound from the low-melting (153–155°) D- and L- forms, cold solutions of equal amounts of them in 2-methoxyethanol were mixed and concentrated to crystallization at room temperature by an air current. The product melted at 235–237° and two recrystallizations from the same solvent raised the melting point to 271–272° which did not change on further recrystallization. The optical-crystallographic measurements which Mr. George L. Keenan reports (see Table I) show that the crystals of 1,3:5,7-dibenzylidene-D,L-perseitol (m. p. 271°) represent a true racemate having indices of refraction that are different from those of the crystals of its components.

An aqueous solution of equal amounts of the enantiomorphous dimethylene-perseitols deposited crystals of a dimethylene-D,L-perseitol hemihydrate melting at 236–237° and showing no detectable rotation in aqueous solution. The fact that it is a hydrate indicates that the crystals are a true racemate because the component enantiomorphs crystallize in anhydrous condition. The measurements of Mr. Keenan (see Table I) verify the true racemic character.

We thank Mr. Charles A. Kinser and Mrs. Betty Mount for the microchemical analyses and Mr. George L. Keenan for the optical-crystallographic measurements.

Experimental

1,3:5,7-Dibenzylidene-D-perseitol and Some of its Derivatives

1,3:5,7-Dibenzylidene-D-perseitol.—(A) To a solution of 5.0 g. of D-perseitol in 25 ml. of 50% sulfuric acid 25 ml. of benzaldehyde and 25 ml. of ethanol were added; needle-like crystals appeared in the clear solution in a few minutes. After three hours at 25° the magma was thinned with 100 ml. of ethanol, filtered and the precipitate washed with water and alcohol. The product (8.2 g., 89%) melted at 153–155° and there was no change in its weight or melting point upon digesting it with 200 ml. of hot water for two hours. It was insoluble in usual organic solvents except pyridine and 2-methoxyethanol. Its $[\alpha]^{20}\mathrm{D}$ value in pyridine (*c*, 0.5) was −58.2°. In four repetitions products were obtained which melted at 152–154°, 153–155°, 151–154° and 150–152°.

Anal. Calcd. for $C_{21}H_{24}O_7$: C, 64.94; H, 6.23. Found: C, 64.74; H, 6.29.

The dibenzylidene-D-perseitol (m. p. 153–155°) was recrystallized by solution in 15 parts of pyridine and the addition of 40 parts of alcohol. The melting point of the once-recrystallized product was 268 ±2°; after a second recrystallization it melted at 277 ±2° and after a third it reached a maximum value of 280 ±2°. Its $[\alpha]^{20}\mathrm{D}$ value was then −58.1° in pyridine (*c*, 0.9), and its analysis showed that there had been no change in its elementary composition.

(B) The dibenzylidene-D-perseitol was prepared by the procedure of Maquenne.[3] A slurry of suspended D-perseitol, prepared by adding 5 ml. of ethanol to a solution of 2.5 g. of the heptitol in 5 ml. of hot water, was cooled to 0° and saturated with dry hydrochloric acid gas; 5 ml. of benzaldehyde was added and the mixture agitated until solution was complete. Small needles soon separated and the magma which formed on allowing the reaction mixture to stand at 25° for three hours was thinned with 100 ml. of ethanol and the crystalline product was separated by filtration, washed with water and alcohol and dried. The yield was 3.9 g. (83%). The compound, which melted at 230–240°, was recrystallized by solution in 12 parts of pyridine and the addition of 20 parts of alcohol and it formed small needles which melted at 280 ±2° and rotated −57.9° in pyridine (*c*, 0.9). A mixed melting point determination with the dibenzylidene-D-perseitol (m. p. 280 ±2°) prepared by the pyridine–alcohol recrystallization of dibenzylidene-D-perseitol (m. p. 153–155°) showed no depression. A second preparation of the dibenzylidene-D-perseitol by Maquenne's method gave a yield of 97% of a product which melted at 240–248°. A quantitative yield of diacetal showing a melting point of 225–235° was deposited from a homogeneous solution of 2.0 g. of D-perseitol, 10 ml. of concentrated hydrochloric acid, 5 ml. of benzaldehyde and 5 ml. of ethanol which was allowed to stand at 5° for four hours. The melting point of these products was raised to 280 ±2° by recrystallization from pyridine–alcohol mixtures.

Stability of 1,3:5,7-Dibenzylidene-D-perseitol against Oxidation by Sodium Metaperiodate.—To a solution of 0.1086 g. of 1,3:5,7-dibenzylidene-D-perseitol (m. p. 280 ±2°) in 90 ml. of 2-methoxyethanol 3.0 ml. (5.73 molecular equivalents) of aqueous 0.534 *M* sodium metaperiodate solution was added and the volume was adjusted to 100 ml. at 25° with 2-methoxyethanol. Analysis of 10-ml. aliquots at the expiration of one, six and forty-eight hours showed that no oxidant had been consumed, indicating that dibenzylidene-D-perseitol has no pair of contiguous hydroxyl groups in its structure.

2,4,6-Tribenzoyl-1,3:5,7-dibenzylidene-D-perseitol.—To an ice-cold solution of 2.0 g. of 1,3:5,7-dibenzylidene-D-perseitol (m. p. 280 ±2°) in 20 ml. of pyridine, 3.0 ml. (50% excess) of benzoyl chloride was added dropwise. The reaction mixture was allowed to stand three days at room temperature (22–25°) and then poured into 500 g. of crushed ice. The gummy precipitate which formed was washed with water and upon trituration with 50 ml. of ethanol it yielded 3.2 g. (90%) of a crystalline product which melted at 181–182°. The compound was recrystallized from 100 parts of ethanol as long prismatic rods which melted at 181–182° and showed an $[\alpha]^{20}\mathrm{D}$ value +76.8° in chloroform (*c*, 0.85). It is soluble in pyridine, acetone, benzene and hot ethanol and nearly insoluble in water, cold ethanol and methanol, and hexane. Benzoylation of the dibenzylidene-perseitol (m. p. 153–155°) under the same conditions gave the same tribenzoate in a yield of 90%. This result is in agreement with the conclusion that these two dibenzylidene-D-perseitols are not ring-position isomers.

Anal. Calcd. for $C_{42}H_{36}O_{10}$: C, 71.99; H, 5.18; C_6H_5CO, 45.0. Found: C, 71.95; H, 5.19; C_6H_5CO, 44.7.

2,4,6-Trimethyl-1,3:5,7-dibenzylidene-D-perseitol.—Repeated attempts to obtain a trimethyl derivative of the 1,3:5,7-dibenzylidene-D-perseitol (m. p. 280 ±2°) by methylation of the diacetal with silver oxide and methyl iodide (Purdie's reagents) gave nearly quantitative yields of a stiff brown sirup which showed a methoxyl content of 21.82% (theory 21.63%). A crystalline 2,4,6-trimethyl-1,3:5,7-dibenzylidene-D-perseitol was obtained by the thallous hydroxide and methyl iodide procedure in the following manner. A suspension of 2.0 g. of 1,3:5,7-dibenzylidene-D-perseitol (m. p. 280 ±2°) in 20 ml. of acetone and 40 ml. (4.5 molecular equivalents) of 0.584 *N* thallous hydroxide solution was concentrated *in vacuo* to dryness and further dried by reconcentration with absolute alcohol. The dry residue was refluxed for eighteen hours with 40 ml. of methyl iodide and 10 g. of Drierite, the yellow precipitate was separated by filtration and washed with methyl iodide and the filtrate was evaporated to dryness; it yielded 2.0 g. of a solid melting at 110–130°. This product was dissolved in 20 ml. of acetone and following the addition of 36 ml. (4.0 molecular equivalents) of 0.584 *N* thallous hydroxide the reaction mixture was concentrated as before to a dry solid and refluxed for eighteen hours with 40 ml. of methyl iodide and 10 g. of Drierite; the solids were removed by filtration and the filtrate was concentrated and yielded 1.8 g. of a gummy solid. This product was dissolved in 20 ml. of acetone and the second step repeated as just described. The final filtrate was evaporated and it yielded 1.8 g. of a sirup which was dissolved in 5 parts of warm methanol; as the solution cooled it deposited 0.75 g. of prismatic crystals (m. p. 120–122°) and concentration of the mother liquor gave a further 0.25 g. (m. p. 112–120°) to make the total yield of product 1.0 g. (45%). The compound was recrystallized from 10 parts of methanol and yielded 0.8 g. of pure 2,4,6-trimethyl-1,3:5,7-dibenzylidene-D-perseitol as rosettes of prisms which melted at 121–122° and showed an $[\alpha]^{20}\mathrm{D}$ value −43.5° in chloroform (*c*, 0.62). It is readily soluble in acetone, chloroform, ether and benzene, moderately soluble in methanol and ethanol, and practically insoluble in water. Methylation of the dibenzylidene-D-perseitol (m. p. 153–155°) by this procedure gave a 45% yield of the same trimethyl derivative.

Anal. Calcd. for $C_{24}H_{30}O_7$: C, 66.96; H, 7.02; OCH_3, 21.6. Found: C, 66.91; H, 7.12; OCH_3, 21.7.

2,4,6-Trimethyl-D-perseitol.—(A) A solution of 5.0 g. of sirupy 2,4,6-trimethyl-1,3:5,7-dibenzylidene-D-perseitol in a mixture of 30 ml. of ethanol, 20 ml. of water and 2 ml. of concentrated hydrochloric acid was refluxed for six hours and after neutralization with sodium hydroxide the solution was concentrated *in vacuo* to dryness. The sirupy dark residue was extracted with 50 ml. of ethanol, the solution was warmed on the steam-bath with decolorizing carbon, filtered, and the yellow filtrate was concentrated *in vacuo* to dryness; it yielded 3.0 g. (quantitative) of a dark yellow viscous sirup. The sirup was dissolved in 50 ml. of hot acetone and as the solution cooled fine needles (1.0 g., m. p. 119–121°) formed; they were separated by filtration and the filtrate upon concentration to a small volume and dilution with 50 ml. of ether gave a further 1.0 g. of product (m. p. 114–119°) to make the total yield 2.0 g. (67%). The compound was recrystallized from 20 parts of acetone as small needles which melted at 120–121° and showed $[\alpha]^{20}\mathrm{D}$ values of +11.8° in water (*c*, 1.03) and +14.7° (*c*, 0.84) in ethanol. It is readily soluble in methanol and ethanol, moderately soluble in chloroform and acetone, and nearly insoluble in benzene, hexane, ether and isopentane. (B) A solution of 0.5 g. of 2,4,6-trimethyl-1,3:5,7-dibenzylidene-D-perseitol (m. p. 121–122°) in a mixture of 10 ml. of ethanol, 1.0 ml. of concentrated hydrochloric acid and 9 ml. of water was refluxed for six hours, neutralized with sodium hydroxide and concentrated *in vacuo*. The residue was extracted with 10 ml. of acetone, the filtered extract was concentrated to a volume of 3 ml., seeded and crystallization allowed to progress at 5° for eighteen hours; the yield of needles of 2,4,6-trimethyl-D-perseitol melting at 120–121° and rotating +11.8° in water (*c*, 0.42) was 0.17 g. (54%). The product did not depress the melting point of 2,4,6-trimethyl-D-perseitol prepared from sirupy 2,4,6-trimethyl-1,3:5,7-dibenzylidene-D-perseitol as just described under (A), but it did depress the melting point of 2,4,6-trimethyl-1,3:5,7-dibenzylidene-D-perseitol (m. p. 121–122°).

Anal. Calcd. for $C_{10}H_{22}O_7$: C, 47.23; H, 8.72; OCH_3, 36.6. Found: C, 46.97; H, 8.70; OCH_3, 36.5.

Stability of 2,4,6-Trimethyl-D-perseitol against Oxidation by Sodium Metaperiodate.—To a solution of 0.1031 g. of 2,4,6-trimethyl-D-perseitol in 30 ml. of water 5.0 ml. (5.92 molecular equivalents) of 0.480 *M* aqueous sodium metaperiodate was added and the volume adjusted to 50 ml. with water. The analysis of 5-ml. aliquots at the expiration of one, two, eighteen and forty-two hours showed no consumption of oxidant. This result indicates the absence of a contiguous pair of hydroxyl groups in trimethyl-D-perseitol, which limits its structure to that of 2,4,6-trimethyl-D-perseitol.

1,3:5,7-Dimethylene-D-perseitol and Some of its Derivatives

1,3:5,7-Dimethylene-D-perseitol.—A solution of 20.0 g. of D-perseitol in a mixture of 20 ml. of concentrated hydrochloric acid and 25 ml. of aqueous 37% formaldehyde solution was evaporated at 25° in a crystallizing dish placed in an evacuated desiccator containing small beakers holding concentrated sulfuric acid and pellets of sodium hydroxide. After five days, the damp solid was triturated with 25 ml. of absolute ethanol and the slurry was evaporated to dryness in the evacuated desiccator. The dry solid was transferred to a Büchner funnel with 100 ml. of cold ethanol, washed and dried. The yield of product, which melted at 230–240°, was 16.8 g. (76%). The compound was recrystallized from 15 parts of 50% ethanol and it formed long needles which melted at 251–253° and showed $[\alpha]^{20}\mathrm{D}$ −19.3° in water (*c*, 1.0). It is soluble in hot water and hot aqueous alcohols but nearly insoluble in chloroform, ether, benzene and cold methanol and ethanol.

Anal. Calcd. for $C_9H_{16}O_7$: C, 45.76; H, 6.83. Found: C, 45.79; H, 6.82.

Stability of 1,3:5,7-Dimethylene-D-perseitol against Oxidation by Sodium Metaperiodate.—To a solution of 0.2410 g. of 1,3:5,7-dimethylene-D-perseitol in 30 ml. of water, 7.10 ml. (4.0 molecular equivalents) of 0.575 *M* sodium metaperiodate solution were added and the volume was adjusted to 50 ml. with water. The analysis of 5-ml. aliquots at the expiration of one, two, eighteen, forty-two and one hundred fifteen hours indicated that no oxidant had been consumed.

Dibenzoyl- and Monobenzoyl-1,3:5,7-dimethylene-D-perseitol.—A solution of 1.5 g. of 1,3:5,7-dimethylene-D-perseitol in 37.5 ml. of pyridine was cooled to 0° and 2.7 ml. (3.6 molecular equivalents) of benzoyl chloride was added dropwise. After standing for forty-eight hours at 25° the reaction mixture was poured into 300 ml. of ice-cold water and the crystalline precipitate (2.4 g., m. p. 175–195°) which formed was recrystallized from 50 parts of ethanol and yielded 1.0 g. (36%) of pure dibenzoyl-1,3:5,7-dimethylene-D-perseitol as long lath-like crystals which melted at 212–214° and showed $[\alpha]^{20}\mathrm{D}$ −30.2° in acetone (*c*, 1.04) and −9.3° in chloroform (*c*, 0.86). The compound is soluble in acetone, chloroform, pyridine, benzene and hot ethanol and nearly insoluble in water, cold ethanol, hexane and ether.

Anal. Calcd. for $C_{23}H_{24}O_9$: C, 62.16; H, 5.44; C_6H_5CO, 47.3. Found: C, 62.19; H, 5.49; C_6H_5CO, 47.5.

The aqueous solution from which the 2.4 g. of reaction product had been separated by filtration was extracted with chloroform and the washed and dried extract was concentrated *in vacuo* to dryness. The crystalline residue was recrystallized from 30 parts of ethanol and gave 0.3 g. (21%) of pure monobenzoyl-1,3:5,7-dimethylene-D-perseitol in the form of small needles which melted at 217–219° and showed $[\alpha]^{20}\mathrm{D}$ +74.3° in acetone (*c*, 0.43) and +31.2° in chloroform (*c*, 0.21). The crystals are readily soluble in pyridine and hot ethanol, slightly soluble in acetone and chloroform and nearly insoluble in water, cold ethanol, benzene, hexane and ether.

Anal. Calcd. for $C_{16}H_{20}O_8$: C, 56.46; H, 5.92; C_6H_5CO, 30.9. Found: C, 56.51; H, 5.97; C_6H_5CO, 31.1.

2,4,6-Tribenzoyl-1,3:5,7-dimethylene-D-perseitol.—To a suspension of 1.5 g. of powdered 1,3:5,7-dimethylene-D-perseitol in 30 ml. of ice-cold pyridine, 4.5 ml. (6 molecular equivalents) of benzoyl chloride was added dropwise and the mixture was agitated gently on a shaking machine at 25° for forty-eight hours. The doughy product which precipitated upon pouring the mixture into ice-cold water was crystallized from 40 ml. of hot ethanol and gave two fractions (2.8 g. melting at 161–162° and 0.5 g. melting at 156–159°) of nearly pure tribenzoyldiacetal. The combined crystalline product (3.3 g., 95%) was recrystallized from 15 parts of ethanol and formed prisms which melted at 161–162° and showed $[\alpha]^{20}\text{D}$ +2.6° in acetone (*c*, 0.96) and +14.4° in chloroform (*c*, 1.0). The tribenzoate is readily soluble in acetone, chloroform, pyridine, benzene and ether and nearly insoluble in cold ethanol, water and hexane.

Anal. Calcd. for $C_{30}H_{28}O_{10}$: C, 65.68; H, 5.15; C_6H_5CO, 57.5. Found: C, 65.84; H, 5.22; C_6H_5CO, 57.3.

Ditosyl- and Monotosyl-1,3:5,7-dimethylene-D-perseitol.—Ice-cold solutions of 6.0 g. (3.7 molecular equivalents) of *p*-toluenesulfonyl chloride in 10 ml. of pyridine and 2.0 g. of 1,3:5,7-dimethylene-D-perseitol in 50 ml. of the same solvent were mixed and allowed to stand at 20–25° for two days. The gummy precipitate which formed on pouring the reaction mixture into 300 ml. of ice-cold water gradually crystallized and the crude product (3.0 g., 50%; m. p. 150–160°) was recrystallized from 40 parts of ethanol and yielded 2.5 g. of pure ditosyl-1,3:5,7-dimethylene-D-perseitol in the form of long lath-like crystals which melted at 164–165° and showed $[\alpha]^{20}\text{D}$ −2.5° in chloroform (*c*, 0.9) and −8.7° in acetone (*c*, 1.04). The substance is soluble in pyridine, acetone, benzene and chloroform and nearly insoluble in water, cold ethanol, ether and hexane.

Anal. Calcd. for $C_{23}H_{28}O_{11}S_2$: C, 50.72; H, 5.18; S, 11.77. Found: C, 50.72; H, 5.23; S, 11.69.

The mother liquor from which the 3.0 g. of ditosyl-1,3:5,7-dimethylene-D-perseitol had been separated was extracted with 250 ml. of chloroform and the washed and dried extract was concentrated *in vacuo* to dryness. The crystalline residue was twice recrystallized from 10 parts of alcohol and yielded 0.5 g. of pure monotosyl-1,3:5,7-dimethylene-D-perseitol as elongated six-sided plates which melted at 174–175° (decomposition); a chloroform solution (*c*, 0.22) of the compound failed to show optical activity, but in acetone solution (*c*, 0.88) a rotation $[\alpha]^{20}\text{D}$ +9.2° was observed. The substance is soluble in acetone, pyridine and hot ethanol, slightly soluble in chloroform and nearly insoluble in water, benzene, hexane and ether.

Anal. Calcd. for $C_{16}H_{22}O_9S$: C, 49.22; H, 5.68; S, 8.21. Found: C, 49.40; H, 5.81; S, 8.10.

2,4,6-Tritosyl-1,3:5,7-dimethylene-D-perseitol.—A solution of 2.0 g. of 1,3:5,7-dimethylene-D-perseitol and 10.0 g. (six molecular equivalents) of *p*-toluenesulfonyl chloride in 30 ml. of pyridine was allowed to stand in the dark at 20–25° for eight weeks and then poured into 800 ml. of ice and water. The product (6.2 g., quantitative; m. p. 160–165°) was recrystallized from 80 parts of ethanol and gave 5.1 g. of pure 2,4,6-tritosyl-1,3:5,7-dimethylene-D-perseitol which melted at 172–173° and rotated $[\alpha]^{20}\text{D}$ −4.7° in chloroform (*c*, 0.86) and −5.9° in acetone (*c*, 0.85). The compound is soluble in chloroform, acetone and pyridine and nearly insoluble in water and cold alcohols. The tritosyl derivative did not react with sodium iodide in acetone solution upon heating at 100° for two hours, a result which indicates that tosyl groups are not attached through primary hydroxyl groups.

Anal. Calcd. for $C_{30}H_{34}O_{13}S_3$: C, 51.56; H, 4.90; S, 13.76. Found: C, 51.47; H, 4.91; S, 13.69

2,4,6-Trimethyl-1,3:5,7-dimethylene-D-perseitol by the Methylation of 1,3:5,7-Dimethylene-D-perseitol.—A solution of 4.0 g. of 1,3:5,7-dimethylene-D-perseitol in 110 ml. (3.8 molecular equivalents) of 0.584 *N* aqueous thallous hydroxide[11] was concentrated *in vacuo* to dryness, with the inlet tube carrying a soda lime tube to exclude carbon dioxide, and the residue was dried through concentration *in vacuo* by two evaporations with absolute ethanol. The gray powdery product was refluxed for twenty hours with 10.0 g. of Drierite and 80 ml. of methyl iodide, the solids were separated by filtration and the filtrate was evaporated to dryness; it yielded 3.0 g. of crystalline material melting at 140–170°. This substance was dissolved in 90 ml. of 0.584 *N* thallous hydroxide and the solution concentrated *in vacuo* to dryness as previously described, the crystalline residue was refluxed for twenty-two hours with 10 g. of Drierite and 60 ml. of methyl iodide, the mixture was filtered and the filtrate was evaporated to dryness; it yielded 3.0 g. of product melting at 132–134°. After one more methylation in the same manner there was obtained 2.8 g. of product melting at 138–139°, which was recrystallized from 10 parts of absolute ethanol and yielded 2.1 g. (45%) of pure 2,4,6-trimethyl-1,3:5,7-dimethylene-D-perseitol as needles melting at 140–141° and rotating $[\alpha]^{20}\text{D}$ −6.2° in water (*c*, 0.83). A mixed melting point with the compound prepared by the methylenation of 2,4,6-trimethyl-D-perseitol with aqueous 37% formaldehyde solution and concentrated hydrochloric acid, as described in the following paragraph, showed no depression.

2,4,6-Trimethyl-1,3:5,7-dimethylene-D-perseitol by the Methylenation of 2,4,6-Trimethyl-D-perseitol.—A solution of 1.0 g. of 2,4,6-trimethyl-D-perseitol in a mixture of 2.5 ml. of concentrated hydrochloric acid and 2.5 ml. of aqueous 37% formaldehyde solution was allowed to evaporate to dryness in an evacuated desiccator containing small beakers of concentrated sulfuric acid and pellets of sodium hydroxide; after five days the dry solid (1.0 g., 90%; m. p. 138–142°) which resulted was crystallized from 20 parts of ether and yielded 0.8 g. (70%) of pure 2,4,6-trimethyl-1,3:5,7-dimethylene-D-perseitol melting at 140–141° and rotating $[\alpha]^{20}\text{D}$ −6.0° in water (*c*, 0.81). The compound is readily soluble in chloroform, acetone, benzene and water, sparingly soluble in ether and nearly insoluble in hexane.

Anal. Calcd. for $C_{12}H_{22}O_7$: C, 51.79; H, 7.97; OCH_3, 33.4. Found: C, 51.81; H, 8.00; OCH_3, 33.5.

Acetals of the L- and D,L-Perseitols

1,3:5,7-Dibenzylidene-L-perseitol.—About seven grams of crystalline L-perseitol was prepared by the reduction of D-gala-L-*manno*-heptose. From one gram of it the 1,3:5,7-dibenzylidene-L-perseitol was prepared as has been described in the case of the D-form, using sulfuric acid as the catalyst. The crystals melted at 153–155° and rotated +57.7° in pyridine. They were then recrystallized by refluxing with fifteen parts of pyridine fifteen minutes and adding thirty parts of ethanol to the hot solution; the product then melted at 280 ± 2° and rotated +57.6° in pyridine. Both enantiomorphs thus show the same behavior, namely, a labile form passing on recrystallization to a stable form.

1,3:5,7-Dibenzylidene-D,L-perseitol.—A mixture of equal amounts of the D- and L-enantiomorphs, each of which melted at 280 ± 2°, was dissolved in ten parts of hot pyridine and crystallized by the addition of 25 parts of ethanol. The fine needle-like crystals appear to be a true racemate according to Mr. Keenan's measurements of their indices of refraction (see table) and this conclusion is supported by our observation that they are much less soluble in pyridine than are those of the components. The racemate melts at 271–272°, a lower temperature than the 280° value shown by its components. The same racemate was likewise prepared from equal amounts of the labile forms of the enantiomorphs (m. p. 153–155°) by dissolving them in one thousand parts of 2-methoxyethanol without heating, followed by evaporation of the solvent at 27° by an air current. The crystalline residue melted at 235–237°; one recrystallization of it from hot 2-methoxyethanol raised this value to 267–268°, and a second increased it to 271–272°. Further recrystallization from either 2-methoxyethanol or the pyridine–ethanol mixture caused no change.

1,3:5,7-Dimethylene-L-perseitol.—The substance was prepared essentially as has been described for its enantiomorph. The recrystallized product melted at 252–254° and showed $[\alpha]^{20}\text{D}$ +19.0° in water (*c*, 1.01). Like its enantiomorph it was not oxidized by sodium metaperiodate.

1,3:5,7-Dimethylene-D,L-perseitol.—A solution of equal amounts of the enantiomorphs in fifty parts of hot 80% ethanol deposited fine needle-like crystals which melted at 236–237° and showed no rotation in aqueous solution. The substance is a hemihydrate which becomes anhydrous when heated at 120° *in vacuo* for some hours. The hemihydrate crystals obviously represent a true racemate. The anhydrous material also melts at 236–237°; apparently the water of crystallization leaves the hemihydrate before the substance melts.

Anal. Calcd. for $C_9H_{16}O_7 \cdot {}^1/_2H_2O$: C, 44.08; H, 6.99; H_2O, 3.67. Found: C, 43.90; H, 7.08; H_2O, 3.59.

Calcd. for $C_9H_{16}O_7$ (anhydrous): C, 45.76; H, 6.83. Found: C, 45.91; H, 6.83.

The racemic character of 1,3:5,7-dibenzylidene- and 1,3:5,7-dimethylene-D,L-perseitols was verified by determination of their optical-crystallographic properties by Mr. George L. Keenan. The data for the compounds and their component optically active forms are compiled in Table I.

TABLE I

OPTICAL-CRYSTALLOGRAPHIC PROPERTIES OF THE 1,3:5,7-DIBENZYLIDENE- AND 1,3:5,7-DIMETHYLENE PERSEITOLS

	Dibenzylidene perseitol		Dimethylene perseitol

Summary

Proof is presented that dibenzylidene-D-perseitol (dibenzylidene-D-manno-D-*gala*-heptitol) is the 1,3:5,7-dibenzylidene diacetal. Neither it nor the trimethyl-D-perseitol which is obtained by its methylation and hydrolysis is oxidized by sodium periodate and the absence of α-glycol groupings in this related pair of compounds limits the structure of the diacetal to that of 1,3:5,7-dibenzylidene-D-perseitol and that of the derived trimethyl-heptitol to 2,4,6-trimethyl-D-perseitol.

The condensation of D-perseitol with formaldehyde yields a diacetal which must be 1,3:5,7-dimethylene-D-perseitol since its trimethyl derivative is identical with the compound formed by methylenation of 2,4,6-trimethyl-D-perseitol.

The enantiomorphous 1,3:5,7-dibenzylidene- and 1,3:5,7-dimethylene-L-perseitols have been prepared from D-gala-L-*manno*-heptitol and they combine with the D-forms to form true racemate crystals.

The Cleavage of Tetraacetyl-β-D-thioglucosides with Bromine in Acetic Acid[1]

BY WILLIAM A. BONNER

Several years ago it was shown[2] that phenyl tetraacylglucosides were brominated quantitatively when treated with excess bromine in glacial acetic acid. That bromination occurred at the *para* position was shown by hydrolysis of the glucoside and isolation of the brominated aglucone, *p*-bromophenol. In this respect the phenyl glycosides, which are cyclic acetals, resemble true phenyl alkyl ethers such as anisole.

It seemed desirable to extend this reaction to the phenyl polyacylthioglycosides, and to determine whether these undergo similar *para*-bromination. Such was anticipated, since aromatic thioethers are known[3] to undergo nuclear halogenation with readiness. In addition, adducts of bromine to the sulfur atom of the thioglycoside were considered likely, since halogens have been shown[4] to add readily to organic sulfides to form what are presumably halo sulfonium halides.

When phenyl tetraacetyl-β-D-thioglucoside in glacial acetic acid was treated with about thirteen equivalents of bromine and permitted to stand at room temperature for several hours, a white, crystalline material was isolated. On recrystallization pure α-D-glucose pentaacetate was obtained. The crude reaction product was not pure α-D-glucose pentaacetate, however, since its specific rotation (88.5 to 91.7°, depending upon reaction conditions) and its melting point (98–103°) were somewhat below those for the pure substance. The presence of small quantities of the β-anomer may explain these low values, as well as the presence of other impurities. The crude material, however, was substantially α-D-glucose pentaacetate, since this was obtained in reasonable purity on one or two recrystallizations. Based on pentaacetate the yield of crude product varied between 75 and 81%, depending upon reaction conditions.

This striking and unexpected reaction which involves cleavage of the acylated thioglucoside and replacement of the sulfur moiety with acetoxy was found to be quite general with respect to the thioaglucone. Both benzyl tetraacetyl-β-D-thioglucoside and ethyl tetraacetyl-β-D-thioglucoside produced α-D-glucose pentaacetate in comparable

---

yields under similar conditions. Thus an aryl, an aralkyl, and an alkyl tetraacetyl-β-D-thioglucoside all showed identical behavior under the influence of bromine in acetic acid.

That bromine alone was responsible for the cleavage was shown by isolation of pure starting material in substantial yield when bromine was omitted from the reaction mixture, or when bromide ion (*i. e.*, lithium bromide) was substituted for bromine. Similarly, both hydrogen bromide and bromoacetic acid, other possible constituents of the reaction mixture, were found incapable of producing cleavage. Experiments designed to elucidate the mechanism of this unexpected cleavage of thioglucosides with bromine are currently in progress.

Under certain conditions bromine was found to have a labilizing effect on the acetyl functions of phenyl tetraacetyl-β-D-thioglucoside. Thus when the cleavage with bromine was attempted in methanol rather than acetic acid, the aqueous layer obtained during processing was dextro-rotatory, while the ether layer yielded only a small quantity of thin oil having a negligible rotation. Apparently bromine in methanol resulted in complete deacetylation. Similarly, when propionic acid was employed as solvent in the reaction, a sirup was isolated from which only minute quantities of indistinct crystalline materials were obtained. It is here probable that bromine engendered a partial replacement of the acetyl functions with propionyl, resulting in a substantially sirupy product. The deacetylating power of bromine in methanol was further demonstrated with α-D-glucose pentaacetate. When this substance was treated with bromine in methanol, permitted to stand several hours, and extracted with ether, optical activity was found in the aqueous layer while the ether layer was inactive. Similarly, when α-D-glucose pentaacetate was treated with bromine in propionic acid a sirup resulted, $[\alpha]^{25}\mathrm{D}$ 51.4°. Since the rotation of this product is fairly close to that of equilibrated sirupy D-glucose pentapropionate,[5] it seems probable that bromine not only caused replacement of acetyl with propionyl, but also brought about anomerization. Although it is indicated that bromine may labilize acetyl groups in acetic acid medium, the medium seems to prevent extensive deacetylation, transacylation or anomerization from occurring. Thus bromine in acetic acid is without action on α-D-glucose pentaacetate. These effects of bromine on acylated carbohydrate derivatives are under more extensive study at the present time.

Experimental Part

Phenyl Tetraacetyl-β-D-thioglucoside and Bromine in Acetic Acid.—Phenyl tetraacetyl-β-D-thioglucoside (1.00 g.) was dissolved in glacial acetic acid (20 ml.) and bromine (1.5 ml., 12.8 equivalents) added. The mixture stood at room temperature for about three hours and was then poured into water (100 ml.). The cloudy red suspension was extracted twice with 60-ml. portions of ether. The ether extract was washed once with water, then with sodium bisulfite solution to remove free bromine, again twice with water, then with saturated sodium bicarbonate solution until gas evolution ceased, and again with water. After drying over anhydrous sodium sulfate and decanting, the solvent was distilled to yield 0.67 g. (75.5%) of a clear glass which crystallized spontaneously. After three recrystallizations from 2-propanol this material melted at 111.5°. It was shown to be α-D-glucose pentaacetate by mixed melting point with an authentic sample (m. p. 112–112.5°), 111–111.5°, and specific rotation $[\alpha]^{25}\mathrm{D}$ 102.8° ($CHCl_3$; *c*, 4.047). The latter value is in agreement with $[\alpha]^{20}\mathrm{D}$ 101.6° reported by Hudson and Dale.[6]

In a second experiment phenyl tetraacetyl-β-D-thioglucoside (1.00 g.) in acetic acid (10 ml.) was treated with bromine (1.5 ml.) and permitted to stand for about twenty-three hours. The reaction mixture was processed essentially as above to yield 0.72 g. (81.3%) of crude, solid product. This crude material showed $[\alpha]^{25}\mathrm{D}$ 88.5° ($CHCl_3$; *c*, 2.535).

In a third experiment the thioglucoside (1.00 g.) in acetic acid (20 ml.) was treated with bromine (1.5 ml.) and allowed to stand for four hours. The crude product, a white solid, weighed 0.68 g. (76.8%). It melted from 98–103° with preliminary softening from 90°, and showed $[\alpha]^{25}\mathrm{D}$ 91.7° ($CHCl_3$; *c*, 1.887).

Benzyl Tetraacetyl-β-D-thioglucoside and Bromine in Acetic Acid.—Benzyl tetraacetyl-β-D-thioglucoside (0.50 g., m. p. 97.5–98°, prepared by the method of Schneider, Sepp and Stiehler[7]) was dissolved in glacial acetic acid (10 ml.), and bromine (0.75 ml.) added. The mixture stood at room temperature for three and one-half hours, was poured into 50 ml. of water, and the product isolated and purified as before. On removal of the ether there resulted 0.48 g. (110%) of thick sirup which crystallized rapidly. After two recrystallizations from a mixture of 2-propanol and water there remained 0.13 g. (30%) of pure α-D-glucose pentaacetate, m. p. 111–111.5°; mixed m. p. with an authentic sample, 110–111°; $[\alpha]^{25}\mathrm{D}$ 102.2° ($CHCl_3$; *c*, 0.920). A second crop (0.05 g.) was obtained from the mother liquors on standing overnight, m. p. 112°.

Ethyl Tetraacetyl-β-D-thioglucoside and Bromine in Acetic Acid.—Ethyl tetraacetyl-β-D-thioglucoside[7] (0.50 g.; m. p. 76.5–77.5°), acetic acid (10 ml.) and bromine (0.88 ml.) were mixed and permitted to stand for four hours. On processing in the usual fashion there resulted 0.46 g. (92%) of crude α-D-glucose pentaacetate. After two recrystallizations from dilute 2-propanol the material melted at 109.5–111°, and showed no melting point depression (110–111°) when mixed with an authentic sample.

Phenyl Tetraacetyl-β-D-thioglucoside and Bromine in Methanol.—Phenyl tetraacetyl-β-D-thioglucoside (1.5 g.) was placed in methanol (30 ml.) in which it was insoluble. On adding bromine (2.2 ml.) the thioglucoside dissolved immediately, and the solution stood for four hours. It was poured into dilute sodium bisulfite solution to decolorize, resulting in a completely clear solution in contrast to the cloudy suspensions previously obtained. The aqueous mixture was extracted twice with ether, and the extract washed as before. Distillation of the solvent resulted in 0.52 g. of a clear, malodorous oil which would not crystallize. This showed a minute rotation, $[\alpha]^{25}\mathrm{D}$ 2.5° ($CHCl_3$; *c*, 4.040), compared with that of the previous crude products. The clear, aqueous layer remaining after the above ether extraction was found to be dextro-rotatory.

Phenyl Tetraacetyl-β-D-thioglucoside and Bromine in Propionic Acid.—The above experiment was duplicated using propionic acid (30 ml.) in place of methanol. There resulted 1.12 g. of amber sirup after customary processing. This product showed qualitative tests for sulfur and bromine. On standing it underwent partial crystallization. A seed was removed, and the remainder dissolved in 2-propanol (8 ml.). The solution was cooled, seeded and placed at 0°. Ten milligrams of solid, m. p. 88–91°, was

(6) Hudson and Dale, *ibid.*, **37**, 1264 (1915).

(7) Schneider, Sepp and Stiehler, *Ber.*, **51**, 224 (1918).

isolated. The mother liquors were evaporated in an air stream to yield a solid. This was slurried with 2-propanol and filtered, giving a small quantity of crystals, m. p. 147–152°. The filtrate was kept at 0° for several weeks, resulting in *ca.* five milligrams of solid, m. p. 120–140°. No attempt was made to purify or identify these products, a complex mixture apparently having been obtained.

Phenyl Tetraacetyl-β-D-thioglucoside in Acetic Acid.—To be certain that bromine was essential for the cleavage reaction to take place, this constituent was omitted from one reaction mixture. The thioglucoside (1.00 g.) was dissolved in acetic acid (20 ml.) and the solution permitted to stand at room temperature for seventeen hours. The mixture was poured into water and the product isolated exactly as previously described. There resulted 1.01 g. of pure starting material, m. p. 117.5–118°; mixed m. p. 117–117.5°.

Phenyl Tetraacetyl-β-D-thioglucoside and Lithium Bromide in Acetic Acid.—To see if bromide ion was in any way responsible for the cleavage, lithium bromide was employed instead of bromine in one experiment. The thioglucoside (1.00 g.) was dissolved in acetic acid (5 ml.), and lithium bromide (0.59 g., 3 equivalents) was dissolved in acetic acid (4 ml.). The two solutions, cooled to room temperature, were mixed and diluted to 10 ml. Absence of reaction was observed by polarimetric observation, no mutarotation being noted during twenty-four hours. The mixture was poured into water and processed as usual, except that the bisulfite wash was omitted. There was recovered 0.95 g. (95%) of starting material, m. p. 117–117.5°, mixed m. p. 116.5–117.5°.

Phenyl Tetraacetyl-β-D-thioglucoside and Hydrogen Bromide in Acetic Acid.—The thioglucoside (0.61 g.) was dissolved in acetic acid and 32% hydrogen bromide in acetic acid (1.75 g., 5 equivalents of hydrogen bromide) added. The mixture was diluted to 100 ml. and observed polarimetrically. No mutarotation was noted during one hundred and eleven minutes. The mixture was poured into water, extracted with ether, and the product isolated as above. There resulted 0.55 g. (90%) of starting material, m. p. 117–118°, mixed m. p. 117–118°, $[\alpha]^{25}\text{D}$ −17.0° ($CHCl_3$; *c*, 1.587). Thus hydrogen bromide does not enter into the reaction mechanism in any direct manner. It is interesting to note that hydrogen bromide was also completely without action on phenyl tetraacetyl-β-D-glucoside under the same conditions, the starting material being recovered quantitatively.

Phenyl Tetraacetyl-β-D-thioglucoside, Bromoacetic and Acetic Acids.—Bromoacetic acid (1.58 g., 5 equivalents) was dissolved in acetic acid and diluted to 10 ml. Phenyl tetraacetyl-β-D-thioglucoside (1.00 g.) was added and the solution placed in a polarimeter tube. No mutarotation was observed during the course of over two hours. The solution was poured into water and treated as above. There was recovered 0.99 g. (99%) of starting material, m. p. 117–118°; mixed m. p. 117–118°. Thus bromoacetic acid, a constituent which might conceivably arise as a by-product in the cleavage reaction, is in no way responsible for the cleavage.

α-D-Glucose Pentaacetate and Bromine in Methanol.—α-D-Glucose pentaacetate (1.00 g.) was placed in methanol (10 ml.), in which it remained essentially undissolved. Bromine (1.5 ml.) was added to the mixture, causing rapid solution. The solution stood for two hours and was poured into 50 ml. of water. The clear, red solution was decolorized by the addition of sufficient sodium bisulfite, then extracted twice with 30-ml. portions of ether. The aqueous layer was strongly dextro-rotatory (0.34°), while the first ether extract was essentially void of rotation (0.02°), indicating that bromine in methanol had brought about deacetylation of the glucose pentaacetate.

α-D-Glucose Pentaacetate and Bromine in Propionic Acid.—α-D-Glucose pentaacetate (1.00 g.) in propionic acid (20 ml.) was treated with bromine (1.5 ml.) and permitted to stand at room temperature for six hours. The mixture was poured into water (75 ml.), decolorized with sufficient solid sodium bisulfite, extracted with ether, and processed as before. There resulted 1.01 g. of lachrymatory amber sirup as the crude product, $[\alpha]^{25}\text{D}$ 51.4° ($CHCl_3$; *c*, 2.397).

To see if bromine was essential for transacylation, this constituent was omitted from the above mixture. α-D-Glucose pentaacetate (1.00 g.) was dissolved in propionic acid (20 ml.) and the mixture treated as above except that the sodium bisulfite treatment was eliminated. The crude product was a white solid weighing 0.98 g. After one recrystallization from 2-propanol the substance had m. p. 112–112.5° and showed no melting point depression when mixed with starting material.

α-D-Glucose Pentaacetate and Bromine in Acetic Acid.—α-D-Glucose pentaacetate (1.00 g.) was dissolved in acetic acid (20 ml.) and bromine (1.5 ml.) was added. After standing for eighteen hours at room temperature the mixture was poured into water and the product isolated in the usual fashion. The crude product weighed 0.74 g., melted at 110–111.5°, showed no mixed melting point depression (111–112°) with starting material, and had $[\alpha]^{25}\text{D}$ 100.0° ($CHCl_3$; *c*, 4.006).

Summary

On treatment of phenyl, benzyl or ethyl tetraacetyl-β-D-thioglucosides with about thirteen equivalents of bromine in acetic acid, α-D-glucose pentaacetate is formed in good yield. This reaction, involving cleavage of the thiophenyl moiety and replacement with acetoxy, has been shown to be due to bromine alone, and to no other possible constituent of the reaction mixture. In addition, bromine seems capable of labilizing the acetyl functions of several acetylated carbohydrate derivatives, producing deacetylation when methanol is employed as solvent, and transacylation when propionic acid is employed as solvent.

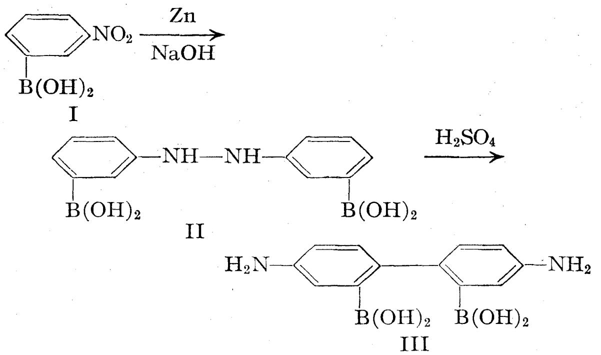
The Synthesis of Benzidine-2,2'-diboronic Acid

BY H. R. SNYDER, CLAY WEAVER[1] AND STANLEY M. PARMERTER[2]

Previous attempts[3] to prepare a biphenyldiboronic acid by the coupling of two molecules of a diazotized aminobenzeneboronic acid in the presence of cuprous hydroxide failed because of the removal of the boronic acid function by the reducing reagent. A synthesis of 4,4'-diaminobiphenyl-2,2'-diboronic acid (III) now has been realized by the application of the benzidine rearrangement to *m*-hydrazobenzeneboronic acid (II).



The alkaline reduction of *m*-nitrobenzeneboronic acid proceeded smoothly and a good yield of the crude hydrazo compound (II) was obtained. Removal of the boronic acid groups by heating the silver salt[4] with water gave azobenzene. Evidently the hydrazine linkage was oxidized to the azo group by the reagent (silver nitrate in the presence of ammonia). Since the reduction product (II) was nearly colorless it could not have contained an azo linkage.

The treatment of the hydrazo compound with acids, under the various conditions which have been employed to effect the benzidine rearrangement, brought about extensive decomposition of the substance. However, when the reaction was effected at temperatures of 50–60° with rather dilute hydrochloric or sulfuric acid (10–20%), the benzidine (III) was formed in sufficient quantity to permit its isolation in yields of 15–20%. The product (III) was amphoteric, and the boron content was very near the theoretical value. The substance (III) gave a good test (diazotization and coupling) for the primary aromatic amino group. When the acetyl derivative of III, prepared by treatment with acetic anhydride in water solution, was subjected to the procedure for the removal of the boronic acid group by hydrolysis of the silver salt diacetylbenzidine was formed. Similarly, treatment of the dibenzal derivative of III with silver nitrate in the presence of ammonia gave the dibenzal derivative of benzidine.

Experimental

***m*-Nitrobenzeneboronic Acid.**—The method of Seaman and Johnson[4] was used on a six-fold scale without detrimental effect upon the yield (65–70%).

***m*-Hydrazobenzeneboronic Acid (II).**—A solution of 15 g. of *m*-nitrobenzeneboronic acid, 20 g. of sodium hydroxide and 15 ml. of alcohol was heated with stirring to gentle reflux. After the solution had refluxed for twenty minutes the heating was discontinued and small portions of zinc were added at such a rate that gentle ebullition was maintained. The first portions of zinc were extremely small, as the initial reaction was quite vigorous. After 23 g. of zinc had been added the color of the solution faded to a light yellow. Near the end of the addition external heating was necessary to keep the solution refluxing. The solid material removed from the hot mixture by filtration under nitrogen was washed with 35 ml. of hot water, and the combined filtrate and washings were cooled and poured slowly with stirring into 18 ml. of cold concentrated hydrochloric acid. The resulting solution was made acid to litmus with 20% acetic acid and allowed to stand in an ice-bath for two hours. The crude *m*-hydrazobenzeneboronic acid was collected on a filter under nitrogen, and ordinarily it was used immediately in subsequent reactions without drying. The weight of the air-dried product corresponded to a yield of 91%.

The *m*-hydrazobenzeneboronic acid could be recrystallized from dilute ethanol. A sample so recrystallized and dried in the air was titrated with 0.1 *N* sodium hydroxide in a dilute ethanol solution with the aid of a *p*H meter. The neutralization equivalent so found was 137 (calcd., 135.9). This sample had no definite melting point; it softened at about 60° and charred at higher temperatures. A sample dried *in vacuo* over phosphorus pentoxide apparently was converted to the anhydride; it did not melt instantly on a Parr melting point bar at temperatures up to 350°, although it charred slowly at temperatures above 250°. This sample was analyzed.

Anal. Calcd. for $C_{12}H_{10}N_2B_2O_2$: N, 11.9. Found: N, 11.5.

Removal of the Boronic Acid Groups.—Application of the procedure of Seaman and Johnson resulted in the formation of a red crystalline solid, m. p. 66–68°, which was identified as azobenzene by a mixed melting point determination.

Benzidine-2,2'-diboronic Acid.—Of a variety of procedures tested in the rearrangement of the hydrazo compound (II) the following[5] gave the best and most consistent results. The crude, moist hydrazo compound from 15 g. of *m*-nitrobenzeneboronic acid was transferred to a flask containing 125 ml. of 10% sulfuric acid through which nitrogen had been bubbled for about an hour to remove dissolved oxygen. Without interruption of the flow of nitrogen the mixture was warmed for three hours in an oil-bath at 60°. The mixture was then filtered and the filtrate was cooled in an ice-bath while it was brought almost to the neutral point by the cautious addition of concentrated ammonium hydroxide. A brown precipitate formed during this process. If too much ammonia was added a white precipitate began to appear; when this occurred dilute sulfuric acid was added to redissolve the white material. The brown precipitate was removed by filtration and the benzidine was precipitated by the addition of ammonium hydroxide to the filtrate.

(3) Snyder and Weaver, THIS JOURNAL, **70**, 232 (1948).

(4) Seaman and Johnson, *ibid.* **53**, 711 (1931).

(5) The authors are indebted to Dr. Seymour L. Meisel, who carried out this preparation many times, for some of the details recorded here.

For the preparation of the benzidine dihydrochloride the suspension of the benzidine was stored in a refrigerator for two days before it was collected on a filter. The solid was dried to constant weight in a vacuum desiccator and was then extracted with small portions (about 20 ml.) of boiling absolute ethanol until the amount of undissolved solid appeared to undergo no further decrease. The combined ethanol extracts were diluted with twice the volume of anhydrous ether and dry hydrogen chloride was passed into the solution until precipitation of the hydrochloride was complete. The solid was collected and the mother liquor was tested by further dilution with ether; if more solid separated it was combined with the first crop and the second mother liquor was tested in the same way. The total yield of the dihydrochloride so obtained was 3.1 g. (19.3% based on the nitro compound I). The salt had no definite melting point, but decomposed slowly at temperatures above 300°.

Anal. Calcd. for $C_{12}H_{16}O_4B_2N_2Cl_2$: N, 8.15; B, 6.28. Found: N, 8.27; B, 5.85.

For the isolation of the benzidine directly from the rearrangement mixture the crude diamine was filtered immediately after the precipitation with ammonium hydroxide and the filtrate was stored for two days in a stoppered flask. The solid collected in the filtration was extracted with 100 ml. of 30% ethanol and the extract was allowed to cool. Both the dilute ethanol extract and the ammoniacal mother liquor deposited light brown crystals; the two crops were collected and decolorized in 150 ml. of hot 30% ethanol. This solution on cooling deposited 1.6 g. (13%) of the benzidine as short flesh-colored needles melting at 232–234°. The substance was insoluble in water, aqueous ammonia and ether, but soluble in dilute sodium hydroxide dilute acids, ethanol and glacial acetic acid. A sample dried in the air had the composition of a hemihydrate.

Anal. Calcd. for $C_{12}H_{15}O_{4.5}N_2B_2$: C, 51.25; H, 5.38; B, 7.70. Found: C, 51.01; H, 5.64; B, 7.75.

The combustion analyses on samples dried *in vacuo* over phosphorus pentoxide were erratic with respect to carbon and the combustion residues obviously contained carbon; the hydrogen and nitrogen values on such samples indicated that they consisted of the di-anhydride.

Anal. Calcd. for $C_{12}H_{10}O_2N_2B_2$: H, 4.27; N, 11.88. Found: H, 4.45; N, 11.51.

Removal of the Boronic Acid Groups from Derivatives of the Benzidine (III). (a) Diacetylbenzidine.—A solution of 1.36 g. of the diamine in 25 ml. of water containing 0.83 ml. of concentrated hydrochloric acid was treated with 1.16 ml. of acetic anhydride and then warmed to 50°. A solution of 0.82 g. of sodium acetate in 5 ml. of water was added, and the mixture was cooled in an ice-bath. A solid weighing 1.13 g. was collected which was soluble in dilute sodium hydroxide but insoluble in water and acids. A portion of the material was recrystallized from a large volume of 50% ethanol. The analytical data indicated that part of the material had lost boronic acid groups during the reaction.

Anal. Calcd. for $C_{16}H_{18}N_2O_6B_2$: C, 54.0; H, 5.1; B, 6.1. Found: C, 57.4; H, 5.4; B, 4.5.

A sample of about 0.5 g. of the crude acetyl derivative was suspended in 30 ml. of 50% ethanol and treated with 10 ml. of 10% aqueous silver nitrate and 6 drops of concentrated aqueous ammonia. The resulting mixture, which contained a brown precipitate, was refluxed for fifteen minutes and filtered hot. The filtrate deposited a white powder which melted at 329–331°, alone or mixed with authentic diacetylbenzidine.

(b) Dibenzalbenzidine.—To a warm solution of 0.5 g. of the benzidine in 70 ml. of 95% ethanol was added 1 ml. of benzaldehyde. The solution soon began to deposit fine crystals, which were collected after four hours. The yellow product melted at 141–143° and weighed 0.8 g. (97%). The substance could be recrystallized from benzene, but the product so obtained had no definite melting point; the material probably suffered the loss of water from the boronic acid groups during the heating with benzene. About 0.2 g. of the freshly prepared benzal derivative was suspended in 50 ml. of water and treated with six drops of aqueous ammonia; dilute aqueous silver nitrate was added until no further precipitation occurred and the brown solid was separated. The solid was added to 25 ml. of water and the mixture was boiled gently for fifteen minutes. The cooled mixture was filtered and the solid was extracted with 20 ml. of hot benzene. The yellow plates which separated when the benzene solution was cooled melted at 232–234°; the substance did not contain boron, and the melting point was not changed by mixture with authentic dibenzalbenzidine.

Summary

m-Hydrazobenzeneboronic acid can be prepared in good yield by the reduction of *m*-nitrobenzeneboronic acid with zinc in the presence of alkali. Rearrangement of the hydrazo compound by acids leads to complex mixtures, but under certain conditions benzidine-2,2′-diboronic acid is produced and can be isolated in yields of about 20%.

The Synthesis of Azo Boronic Acids. II. Dyes from Tetrazotized Benzidine-2,2′-diboronic Acid

BY H. R. SNYDER AND SEYMOUR L. MEISEL[1]

The speculations of Kruger[2] and Zahl and others[3–6] on the possible development of an irradiation therapy based on the nuclear disintegration process (equation 1) occurring when the boron isotope of atomic weight 10 captures a slow neutron have provoked an interest in the synthesis of boron-containing dyes having structures similar to those of Trypan Blue and Evans Blue. Such substances might be expected to concentrate in certain tissues, which might then be irradiated with slow neutrons with the result that the energetic nuclear disintegration would be localized. Recent studies[7] on the localization of derivatives of Trypan Blue and Evans Blue containing radioactive bromine indicate that the relative concentra-

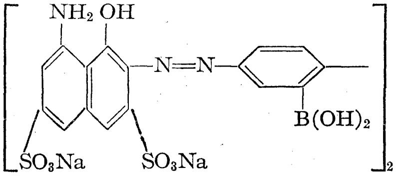
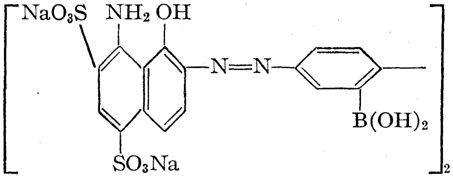
tion of the dyes in tumors is by no means as favorable as would be required for therapeutic application. Nevertheless, the possibility remains that a more selective action might be characteristic of the proposed boron-containing dyes, and in any event they should be of value in the study of the general effects of the nuclear disintegration of boron occurring within living tissues.

The dye (I) obtained by coupling benzidine-2,2′-diboronic acid[8] with 1-amino-8-naphthol-3,6-disulfonic acid (H acid) presumably has a structure differing from that of Trypan Blue only in the presence of the two boronic acid groups in the 2 and 2′ positions of the benzidine unit instead of methyl groups in the 3 and 3′ positions. The structure of the dye was not proved, but the linkage of the azo groups at the 7 positions of the 8-naphthol residues may be assumed by analogy to other dyes prepared by coupling with H-acid under comparable conditions.[9] No displacement of boron occurred during the coupling and purification of the product (I). Since the localization of Trypan Blue depends on the fact that it forms colloidal dispersions rather than true aqueous solutions, a qualitative dialysis experiment was carried out with the dye (I); it was found to diffuse only very slowly through a membrane which was readily permeable to phenolphthalein.



I



II

The analog (II) of Evans Blue was prepared by coupling the same benzidine with 1-amino-8-naphthol-2,4-disulfonic acid (Chicago acid). This substance also contained nearly the theoretical amount of boron and it also diffused very slowly through a collodion membrane. Dyes of the expected composition likewise resulted from the coupling of the benzidinediboronic acid with β-naphthol and with acetoacetanilide. Dyes were obtained by coupling of the benzidine with 2-naphthol-3,6-disulfonic acid (R acid), 1-naphthol-4-sulfonic acid (NW acid) and β-naphthylamine, but no satisfactory analytical samples of the products have been obtained.

Dyes of higher boron content and of higher molecular weight should be available by coupling diazotized aminobenzeneboronic acids into the 2 position of I. This possibility is being tested.

Experimental

Tetrazotization of Benzidine-2,2′-diboronic Acid.—A solution of 1 g. of benzidine-2,2′-diboronic acid[8] (or 1.27 g. of the dihydrochloride) in 30 ml. of 3*N* hydrochloric acid was cooled in an ice-bath. About 8 ml. of a solution of 0.52 g. of sodium nitrite in 10 ml. of water was added in small portions with good stirring, and the solution then was tested with starch–iodide paper; if the test was negative further small portions of the nitrite solution were added until a positive test resulted. The mixture was kept cold for one-half hour during which time the positive reaction to starch–iodide was maintained by further additions of small portions of the nitrite solution, if necessary. The excess of nitrous acid then was removed by the addition of very small amounts of the benzidinediboronic acid, and the resulting solution was used immediately in a coupling reaction.

Coupling with H Acid.—The technical H acid was purified as follows: A solution of 100 g. of the technical material in 500 ml. of hot water was filtered, decolorized with 15 g. of charcoal and salted out by the addition of about 70 g. of sodium chloride to the filtrate. The material so obtained was recrystallized from the minimum volume of boiling water, and the purified material was dried in a vacuum oven at 110°.

The cold tetrazonium solution from 1 g. of the benzidinediboronic acid was added over a period of one-half hour to a cold, stirred solution of 2.36 g. of purified H acid and 5 g. of sodium carbonate in 35 ml. of 5% aqueous sodium hydroxide. The resulting mixture was cooled and stirred for two hours, after which time it was warmed to 85° and filtered. The filtrate was stirred at 85° for fifteen minutes and then treated with 35 g. of hydrated sodium acetate, added in five portions. After fifteen minutes the heating bath was removed and the stirred mixture was allowed to come to room temperature. The precipitated dye was collected, dissolved in 50 ml. of hot water and again salted out as before with 30 g. of the hydrated sodium acetate. The product so obtained was extracted ten times with portions of about 15 ml. of boiling ethanol, each extract being removed by filtration. After four to seven extractions the residual dye gave a negative test for sodium acetate.[10] The purified dye weighed 1.5 g. It was a very dark purple powder which did not melt or decompose at temperatures up to 340°. Analytical samples, dried over phosphorus pentoxide at about 95° and at 5 mm. pressure, had the composition of the trihydrate. The boron content was determined by the sodium peroxide fusion method.[11]

Anal. Calcd. for $C_{32}H_{28}O_{21}N_6B_2S_4Na_4$: C, 35.79; H, 2.61; B, 2.02. Found: C, 35.64; H, 2.89; B, 1.88.

For the dialysis test enough of the dye was added to 75 ml. of water to produce an intense purple solution and a few drops of phenolphthalein indicator solution was added. The solution was placed in a collodion bag suspended in 200 ml. of water. After one day the water remained entirely colorless, and portions of it gave the phenolphthalein color when made alkaline. Even after a week the water in the outer compartment had assumed only a very faint color.

Coupling with Chicago Acid.—Technical Chicago acid was purified in the same way as the H acid. In an experiment in which the tetrazotization, coupling and isolation of the product were carried out exactly as described above for the coupling with H acid the yield of the dye II was only 0.6 g. It appeared that the lower yield resulted from lower efficiency in the salting-out process. Other experiments in which ammonium bromide was used for the

salting-out (with subsequent extraction of the product with methanol for the removal of ammonium bromide) gave about the same yield. The dye II was a very dark purple powder which did not melt or decompose at temperatures up to 340°. It rapidly imparted a purple color to water, but was insoluble in the organic solvents that were tested. Analytical samples, dried at about 95° at 5 mm., had the composition of the trihydrate. In a dialysis experiment it behaved exactly as did I.

Anal. Calcd. for $C_{32}H_{28}O_{21}N_6B_2S_4Na_4$: C, 35.79; H, 2.61; B, 2.02: Found: C, 35.76; H, 2.89; B, 1.77.

Coupling with β-Naphthol.[12]—The tetrazonium solution prepared, as described above, from 0.5 g. of benzidine-2,2′-diboronic acid was added with stirring to a cold solution of 0.54 g. of β-naphthol and 5 g. of sodium carbonate in 18 ml. of 5% aqueous sodium hydroxide. The mixture was stirred in the ice-bath for two hours and then added with stirring to 30 ml. of 5% hydrochloric acid. The mixture was diluted with 25 ml. of ethanol and filtered hot. The red solid was dissolved in the minimum amount of Cellosolve (less than 5 ml.) and the solution was diluted with 5 ml. of ethanol and filtered hot. Water was added to the filtrate until the precipitation of the dye was complete, and the mixture was boiled to coagulate the solid. The solid was collected and dried at 95° at 5 mm. About 0.2 g. of a bright red powder, easily soluble in Cellosolve, less soluble in ethanol and insoluble in water, was obtained; it decomposed at about 240°.

Anal. Calcd. for $C_{32}H_{24}O_6N_4B_2$: C, 66.01; H, 4.13; N, 9.63. Found: C, 65.99; H, 4.21; N, 9.75.

Coupling with Acetoacetanilide.—The coupling procedure was a modification of that described by Linstead and Wang.[13] The tetrazonium solution prepared from 0.64 g. of the benzidine dihydrochloride was added over a period of fifteen minutes to a stirred mixture of 0.64 g. of acetoacetanilide, 1 g. of sodium acetate and 50 ml. of 1% aqueous sodium hydroxide. The resulting mixture was stirred in an ice-bath overnight. The solid was separated by filtration and recrystallized three times from dilute ethanol. The bright yellow solid contained boron. It was insoluble in water or aqueous sodium carbonate, but soluble in 5% aqueous sodium hydroxide. It decomposed sharply at 174–175° to give a black residue which melted at 270–280°.

Anal. Calcd. for $C_{32}H_{30}N_6O_8B_2$: C, 59.29; H, 4.63; N, 12.97. Found: C, 58.87; H, 4.70; N, 12.96.

Summary

Analogs of Trypan Blue and Evans Blue have been prepared by the coupling of tetrazotized benzidine-2,2′-diboronic acid with 1-amino-8-naphthol-3,6-disulfonic acid (H acid) and with 1-amino-naphthol-5,7-disulfonic acid (Chicago acid), respectively. The dyes so obtained have the expected boron contents. Boron–containing dyes also have been prepared by coupling the benzidinediboronic acid with β-naphthol and with acetoacetanilide.

The Preparation of Synthetic Estrogens. I. The Synthesis of Diethylstilbestrol through the Pinacol–Pinacolone Compounds

BY KEIITI SISIDO AND HITOSI NOZAKI

Wessely[1] and others[2] have described synthetic approaches to the estrogenic diethylstilbestrol involving the use of the pinacol–pinacolone and retropinacolone rearrangements. We have carried out further investigations on this approach and have been able to improve several of the steps involved. The synthesis is outlined in the flow sheet.

Model experiments on the reduction of acetophenone and *p*-methoxyacetophenone to the pinacols using the method of Newman[3] gave the pinacols as a stereoisomeric mixture in 73 and 80% yields, respectively. With *p*-methoxypropiophenone (I) the yield of crystalline pinacol (II) was considerably lower, but after rearrangement of the crude pinacol the pinacolone (III) was obtained in 54% yield from the propiophenone (I). After reduction to carbinol (IV) and rearrangement with dilute sulfuric acid, only a small amount of crystalline product was obtained. However, heating the oily mixture with iodine in chloroform[1] effected isomerization and permitted the isolation of the dimethyl ether of diethylstilbestrol (V) in about 14% over-all yield from *p*-methoxypropiophenone (I). By further development of these procedures the yields can probably be improved.

By similar procedures starting with acetophenone we have prepared 2,3-diphenyl-2-butene in 30% over-all yield and 2,3-dianisyl-2-butene from *p*-methoxyacetophenone in 32% over-all yield.

According to a Swedish patent,[4] not accessible to us yet, diethylstilbestrol is said to be obtained from *p*-hydroxypropiophenone in an almost identical way. We have noticed in our model experiments with *p*-hydroxyacetophenone as well as with *p*-acetoxyacetophenone that the existence of free hydroxyl or acetoxyl groups hinders the smooth reaction of the pinacolic reduction.

Experimental[5]

(I) Pinacolic Reduction

2,3-Diphenyl-2,3-butanediol.—To a solution of 30 g. of acetophenone in 300 cc. of absolute alcohol and 200 cc. of dry, thiophene-free benzene were added 12 g. of alu-

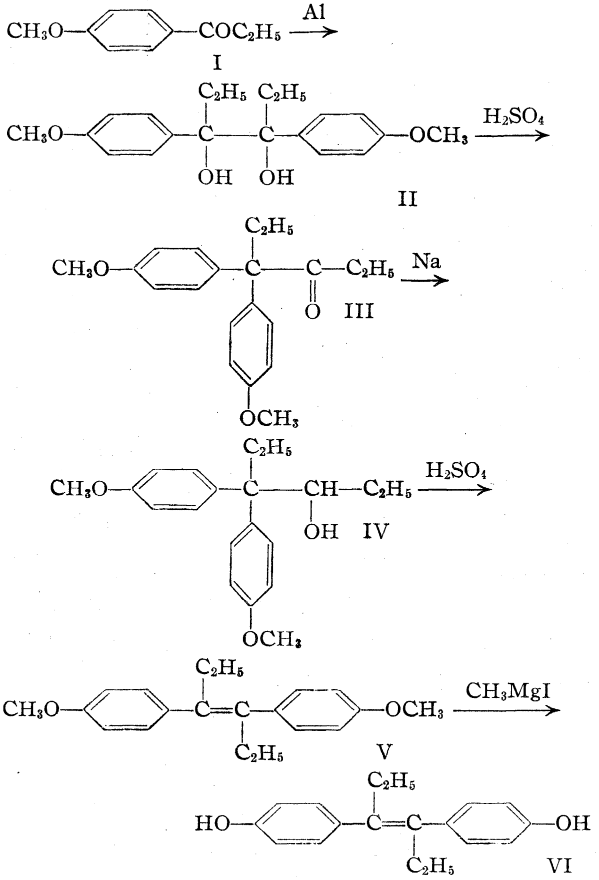
[5] Microanalyses by Miss Yasuko Meizyô of our Laboratory.



minum foil and 0.5 g. of mercuric chloride. On slight heating, a violent reaction ensued and the contents began to boil. When the reaction had subsided somewhat, the mixture was heated on a water-bath. After six hours of refluxing, the reaction product was poured over crushed ice acidified with hydrochloric acid. The top layer was separated and the bottom one extracted with benzene. The two benzene layers were combined, washed with a sodium chloride solution and dried. When the solvent was distilled off, the residue crystallized on cooling; there was obtained 22 g. of crude pinacol melting at 85–107°, which on recrystallizations from benzene–ligroin melted at 122°.

2,3-Dianisyl-2,3-butanediol.[6]—Forty grams of *p*-methoxyacetophenone[7] was subjected to the pinacolic reduction as above and the crude pinacol, m. p. 145–152°, was obtained with a yield of 32.5 g. Repeated recrystallizations from ethyl acetate gave colorless prisms melting at 159–160°. The same diol prepared by Price and Mueller[6] melted at 168–169°.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.50; H, 7.33. Found: C, 71.19; H, 7.66.

3,4-Dianisyl-3,4-hexanediol[1] (II).—Ten grams of *p*-methoxypropiophenone (I) was reduced in the same manner as mentioned above. As this pinacol is not easily soluble in cold benzene, the reaction product was added with 100 cc. of water and refluxed on a water-bath during an hour with stirring. The benzene layer was separated and the bottom one extracted with hot benzene. The combined benzene solution was washed with warm water and distilled without drying. The residue was crystallized from ligroin, yield 4 g., m. p. 186–190°. On repeated recrystallizations from ethyl acetate, the product formed colorless small prisms, m. p. 192–194°.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.70; H. 7.93. Found: C, 72.31; H, 8.38.

(II) Pinacolone Rearrangement

2,2-Diphenyl-3-butanone.—To a solution of 100 cc. of concentrated sulfuric acid in 100 cc. of water was added 22 g. of 2,3-diphenyl-2,3-butanediol. The mixture was refluxed for one and a half hours under stirring, poured into iced water and extracted with ether. When the extract was distilled under reduced pressure after removing the solvent, there was obtained 13 g. of ketone, m. p. 40°, which value accorded with that of the literature.

When 30 g. of acetophenone was subjected to the pinacolic reduction, and the crude product was immediately, without separating the pinacol, treated with dilute sulfuric acid, 15 g. of the ketone, m. p. 40°, was obtained.

2,2-Dianisyl-3-butanone.[6]—Thirty-two grams of crude 2,3-dianisyl-2,3-butanediol was treated in the same manner as above, and the product was recrystallized from ethyl acetate–petroleum ether; yield was 25 g., m. p. 69–70°.

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09. Found: C, 76.07; H, 7.09.

3,3-Dianisyl-4-hexanone (III).—From 4 g. of crude crystalline 3,4-dianisyl-3,4-hexanediol 2.3 g. of the ketone in yellowish viscous oil, b. p. 215–225° at 3 mm. was obtained.

Anal. Calcd. for $C_{20}H_{24}O_3$: C, 76.89; H, 7.74. Found: C, 77.25; H, 7.79.

For the preparation of this ketone, it is rather profitable to treat the crude product of the pinacolic reduction, without separating the crystals of the pinacol. Thus, from 21 g. of *p*-methoxypropiophenone 11.3 g. of the ketonic oil, b. p. 224–228° at 6 mm., was obtained.

Attempts to prepare a crystalline semicarbazone or oxime of this pinacolone were unsuccessful.

(III) Reduction and Retropinacolone Rearrangement

2,3-Diphenyl-2-butene.—A mixture of 50 cc. of xylene and 10 g. of metallic sodium was heated to 140° and 10 g. of crude 2,2-diphenyl-3-butanone was added. Under violent stirring, 110 cc. of absolute alcohol was run in at such a rate that the boiling of the mixture was uniform. To the reaction product isolated in the usual way a mixture of 50 cc. of concentrated sulfuric acid and 50 cc. of water was added. After one and a half hours of heating on a boiling water-bath the content was poured over crushed ice and extracted with ether. When the product was recrystallized from alcohol, there was obtained 5.6 g. of colorless prisms, m. p. 104° in accord with the literature.

2,3-Dianisyl-2-butene.[8]—From 13 g. of 2,2-dianisyl-3-butanone, 6 g. of the product, m. p. 126–128°, was obtained.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51. Found: C, 80.37; H, 7.88.

3,4-Dianisyl-3-hexene (V).—When 10 g. of oily 3,3-dianisyl-4-hexanone (IV) was reduced and the product was dehydrated as above, 1.3 g. of the crude crystals was obtained. The mother liquor was distilled *in vacuo*, and the fraction, boiling at 182–190° at 5 mm., weighing 6.5 g., was treated with 0.7 g. of iodine in 150 cc. of chloroform.[1] When this iodine treatment was repeated, there was obtained in total 2.8 g. of the hexene derivative. Recrystallization from petroleum ether gave colorless plates, m. p. 123–124°.

Anal. Calcd. for $C_{20}H_{24}O_2$: C, 81.08; H, 8.01. Found: C, 80.69; H, 7.83.

(IV) Demethylation[9]

2,3-bis-(*p*-Hydroxyphenyl)-2-butene.[8]—To the Grignard reagent from 2 g. of magnesium and 12 g. of methyl

3,4-bis-(*p*-Hydroxyphenyl)-3-hexene (VI).—Demethylation of 2.0 g. of crude 3,4-dianisyl-3-hexene (V) gave 0.8 g. of pure diethylstilbestrol, m. p. 167–169°.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51. Found: C, 80.92; H, 7.07.

Summary

1. The Newman method of pinacolic reduction was applied to acetophenone, *p*-methoxyacetophenone and *p*-methoxypropiophenone. There were obtained excellent yields of the corresponding pinacols.

2. 2,3-Diphenyl-2-butene, 2,3-bis-(*p*-hydroxyphenyl)-2-butene and 3,4-bis-(*p*-hydroxyphenyl)-3-hexene were synthesized from these pinacols, improving the previous procedures.

The Preparation of Synthetic Estrogens. II. The Synthesis of Hexestrol and its Homologs

BY KEIITI SISIDO AND HITOSI NOZAKI

One of the most important synthetic routes to hexestrol and related compounds involves the condensation of two molecules of *p*-α-bromopropylanisole (or the chloro derivative) with elimination of halogen. Magnesium, sodium, a Grignard reagent in the presence of cobaltous chloride, and other reagents have been used to effect the condensation.[1] All of these require the use of anhydrous conditions. According to Quelet[2] the α-halogenoalkylanisoles are more stable in the presence of moisture and accordingly a method which would not require the absence of water might have some advantages.

It is of interest that metallic iron powder is capable to act as a dehalogenating agent in the presence of water. Ogata, Turuta and Oda[3] have treated benzyl chloride, benzal chloride as well as benzo trichloride with iron powder in a large amount of hot water and obtained bibenzyl, stilbene and μ,μ′-dichlorostilbene, respectively. Model experiments on this condensation of α-chloroethylbenzene as well as of *p*-(α-chloroethyl)-anisole gave 2,3-diphenylbutane and 2,3-dianisylbutane, respectively, in 5–15% yields. With anethole hydrochloride[4] or hydrobromide the yield of the *meso* form of 3,4-dianisylhexane was 10 or 15%, respectively. It is to be pointed out that the recovered anethole was not subtracted in this calculation, as its purity was not determined. Demethylation of this product by heating with a Grignard reagent[5] gave hexestrol in good yield and in very pure state.

Although the yields realized from the present modification are not always superior to others, this method is believed to possess some merits in the simplicity and in the easy treatment, etc. The possibility of improving the yield by the use of very fine powder of iron or reduced iron in this condensation has been opened for a further research, which is now under way in our Laboratory.

Bretschneider and others[6] have prepared a metamer of hexestrol, 2,3-bis-(*p*-hydroxy-*o*-tolyl)-butane, and discovered that its estrogenic potency is of the same order as that of diethylstilbestrol or hexestrol. We have now prepared the same compound by means of our method from the hydrochloride of *p*-vinyl-*m*-methylanisole synthesized from *m*-cresol methyl ether.[7]

Experimental[8]

2,3-Diphenylbutane.—To a suspension of 12 g. of ordinary iron powder in 140 cc. of water heated at 95–98° was added with stirring 30 g. of α-chlorothylbenzene during ten minutes. The mixture was stirred for an additional three hours at the same temperature. The reaction product was extracted with benzene and the extract was fractionated. At 145–155° and 13 mm. came over 9.3 g. of colorless oil which solidified slowly. Repeated recrystallizations from alcohol yielded 3.6 g. of *meso*-2,3-diphenylbutane, m. p. and mixed m. p. 125.5°.

2,3-Dianisylbutane.—Dry hydrogen chloride was passed into a solution of 10 g. of *p*-vinylanisole containing about 10% of *o*-isomer[2,7] in 45 cc. of ligroin cooled in ice–salt mixture. The reaction solution was washed with ice-cooled water and subjected immediately to the condensation process. To a suspension of 4.2 g. of iron powder in 50 cc. of water the ligroin solution of the chloroethylanisole was added slowly with stirring at 85°. This required about thirty minutes, during which time the ligroin was removed from the vessel through a downward condenser. In the course of this, the ligroin solution contained in the dropping funnel was cooled with several pieces of crushed ice added directly in order to prevent the decomposition of the

chloro compound and to supply the water escaped together with the ligroin. The reaction mixture was heated now under an upward condenser for additional three hours at 95–98° and extracted with benzene. Fractional distillation of the product gave 4.3 g. of semi-solid mass boiling at 185–205° and 10 mm. This was recrystallized from methanol–ligroin and colorless prisms melting at 132.5–133.5° resulted. Mixtures of the product with a known sample of 2,3-dianisylbutane, which we had prepared[9] from 2,3-dianisyl-1,3-butadiene, melted without depression. As 2,3-dianisylbutane described by Dodds, *et al.*,[10] is said to have the m. p. 87–88°, our substance seems to be an isomeric compound, probably of the *meso* form.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20. Found: C, 79.87; H, 8.46.

2,3-bis-(*p*-Methoxy-*o*-tolyl)-butane.—A solution of 10 g. of *p*-vinyl-*m*-methylanisole[7] in 50 cc. of ligroin was saturated with dry hydrogen chloride at -18 to $-10°$ and treated with 5 g. of iron powder in 60 cc. of water as above. After recrystallization from alcohol 1.6 g. or 16% yield of pure colorless plates of the m. p. 142° was obtained.

Anal. Calcd. for $C_{20}H_{26}O_2$: C, 80.50; H, 8.78. Found: C, 80.91; H, 8.79.

The demethylation of the product with methylmagnesium iodide[5] yielded a free phenolic substance of m. p. 188–189° and the acetylation of the latter compound gave colorless plates of diacetate melting at 164°.

Anal. Calcd. for $C_{22}H_{26}O_4$: C, 74.55; H, 7.40. Found: C, 74.67; H, 7.56.

The melting points and other properties of these substances were found to be in accord with those reported by the Hungarian investigators.[6]

3,4-Dianisylhexane.—Twenty-five grams of anethole dissolved in 110 cc. of ligroin was saturated with dry hydrogen chloride. Upon working up the product with 15 g. of iron powder in 150 cc. of water as above, 8 g. of a distillate at 180–210° and 4 mm. was obtained. The first fraction of this vacuum distillation consisted of about 12 g. of anethole which could be employed in the next batch. The product crystallized out from methanol–ligroin and recrystallizations from petroleum ether gave 2.4 g. of colorless plates, m. p. 144°, in accord with the m. p. of the *meso* compound reported in the literature.

When the same procedure was repeated with hydrogen bromide instead of the chloride, the yield of 3.8 g. was obtained.

Anal. Calcd. for $C_{20}H_{26}O_2$: C, 80.50; H, 8.78. Found: C, 80.12; H, 8.51.

3,4-bis-(*p*-Hydroxyphenyl)-hexane (Hexestrol).—Demethylation of 3,4-dianisylhexane with a Grignard reagent yielded colorless plates, m. p. 186°, which value agreed with that of the literature.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20. Found: C, 79.70; H, 8.32.

On acetylation the diacetate was obtained, m. p. 140–141°.

Acknowledgment.—In preparing these reports I and II we are indebted to the Editorial Board of This Journal for the courtesy of checking the literature references since 1941 (except those of Japan) which we are not able to obtain even now in our city.

Summary

Hexestrol and 2,3-bis-(*p*-hydroxy-*o*-tolyl)-butane were prepared by the condensation of hydrochlorides (or hydrobromide) of anethole and *p*-vinyl-*m*-methylanisole, respectively, by the action of metallic iron powder in a water suspension followed by the demethylation.

X-Ray Diffraction Study of Some Synthetic Rubbers at Low Temperatures

By E. E. Hanson and G. Halverson

The use of the powerful X-ray diffraction method for the study of high polymers had its inception in 1925 with the experiments of Katz[1] on natural rubber. He observed that the X-ray diffraction pattern of stretched rubber consisted of a broad halo with a superposed set of discrete spots characteristic of crystallites oriented in the direction of stretching. Hauser and Rosbaud[2] observed that the diffraction pattern of frozen unstretched rubber consisted of sharp concentric rings characteristic of a randomly oriented polycrystalline material. From such X-ray data have been determined the unit cell of the rubber crystallite,[3–7] the arrangement and the shape of the molecular segments in the unit cell and the size and shape of the rubber crystallites.[8,9] In addition, the X-ray diffraction method has yielded important information regarding the structures of a host of other polymers,[10] particularly those of the plastics and fibers, most of which give well developed fiber diagrams. Examples of synthetic rubber polymers which crystallize upon stretching are neoprene,[11] polyisobutylene,[12] and thiokol.[13] However, it is unfortunate that the majority of the synthetic rubber polymers give only an amorphous halo and therefore the X-ray diffraction method can give correspondingly little information regarding the structures of these polymers.

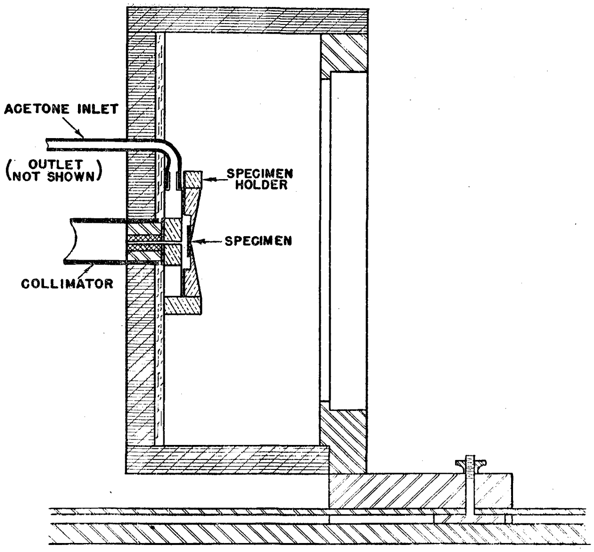

Fig. 1.—Low temperature X-ray camera.

The work to be discussed was an attempt to cause whatever regularity was present in some "non-crystalline" synthetic rubber polymers to show up in the X-ray diffraction experiment. The raw polymers were used because they can be elongated to a greater extent than the vulcanizates and because the cross-linking of molecular chains by vulcanization probably interferes with crystallization. Since the thermal motions of the molecular segments tend to prevent the relatively weak intermolecular forces from forming aggregates, the temperature of the polymer was reduced as much as possible prior to stretching. G. von Susich[14] found that the fibering of natural rubber upon stretching depended upon temperature, the amorphous fraction being favored by raising the temperature. Hauser and Mark[3] suggested freezing stretched natural rubber. In order to prevent relaxation of the elongated specimen during X-ray exposure, the specimen was frozen in an alcohol–Dry Ice bath immediately after stretching and the specimen was maintained at a temperature of −65 to −70° during the X-ray exposure. Essentially the same technique had been used in 1928 by Hock and Barth[15] in their study of polydimethylbutadiene, but their data did not permit calculations of the Bragg spacings of the diffraction lines.

The following steps were used in the manipulation of the specimens. 1. Cool the specimen to a temperature at which it may still be readily elongated. 2. Quickly stretch the sample to as high an elongation as possible. 3. Immediately freeze it at a temperature of −70° in an alcohol–Dry Ice bath, and 4. Obtain the X-ray exposure at a temperature of −65 to −70° in a special camera.

At the temperature of −65°, all of the polymers except emulsion polymerized butadiene were stiff enough to remain in their extended condition without clamping. To determine the elongation of the specimen, the length at −70° was measured, the specimen was allowed to warm up to room temperature, and the length of the relaxed sample was again measured. Conceivably, a small amount of permanent set was present in the relaxed state, and so the percentage of elongation recorded in the present data may be somewhat low.

Apparatus

A General Electric X-ray diffraction unit was used with either a copper target or a molybdenum target tube. The copper radiation was filtered by nickel foil, and the molybdenum radiation was filtered with a commercial zirconium oxide filter.

A sketch of the low temperature camera is shown in Fig. 1.

A box was made from 0.25-inch bakelite plates. One side was clamped firmly to the post supporting the collimating pinhole assembly. The film holder and the other four sides were mounted separately on a post which could be moved along the track. The five sides of the box were constructed to telescope over the sixth side (clamped to collimator assembly). Thus the specimen-to-film distance could be varied at will from 0 to 15 cm. The specimen holder consisted of a copper block with a recess cut away to receive a removable copper disc to which the specimen was clamped. The copper block was constructed with a 0.25-inch square channel, through which chilled acetone was pumped. The acetone circulating and cooling system is shown in Fig. 2. It consists of an automobile fuel pump, which was run continuously, a copper coil immersed in a Dry Ice–acetone-bath, a manually controlled needle valve for rough adjustment of the flow through the tubing by-passing the cooling coil, a second needle valve which was driven by a reversible motor controlled by a Micromax controller–recorder, and in the line a bimetallic spiral thermostat which acted as a limit switch. In this study, the automatic controls were not used because the specimen tempera-

ture was kept as low as possible. The specimen temperature was measured with a thermocouple clamped in the copper block close to the path of the X-ray beam.

Results

The following polymers were studied: emulsion and sodium polymerized butadiene, emulsion polymerized 75/25 butadiene–styrene copolymer, emulsion and sodium polymerized isoprene and emulsion polymerized dimethylbutadiene. Morris and Jordon[16] found that a tread-type vulcanizate of GR-S produced weak maxima on the equator of the X-ray diagram. Hock and Barth[15] observed a crystallization of polydimethylbutadiene when the raw polymer was stretched at a low temperature, but their patterns were incomplete and no spacings were given. Evidence for the crystallization of polydimethylbutadiene was also found by Katz and van Campen.[17] They observed that the X-ray pattern of a stretched sample of an especially prepared methyl rubber vulcanizate contained a single pair of equatorial spots (d = 4.3 Å.) and two elongated arcs on the meridian (d = 3.2 and 2.3 A., respectively). No evidence has been found in the literature[18,19] to indicate that any of the other polymers listed above show any ordering in the stretched condition.[20]

Polybutadiene-emulsion Polymerized.—Figure 3 is an X-ray diffraction pattern of emulsion polymerized butadiene elongated 500% at a temperature of −70°. The very intense equatorial arcs occur at a Bragg distance of 4.06 Å. and the second pair of weak equatorial arcs at 2.33 Å. On the meridian two very weak arcs are observed at 2.26 and 1.16 Å., respectively. The two arcs were interpreted as second and fourth order reflections, respectively. The arc at 2.26 Å. could possibly be due to two unresolved spots near the meridianal axis. The limiting values for the spacings of hyperbolic layer lines that can be drawn through the arc are 4.58 and 4.8 Å. The arc at 1.16 Å. lies close to the axis and the corresponding layer line of fourth order gave an identity period of 4.8 Å. which agrees with the largest calculated value derived from the 2.26 Å. arc. Since the planar zig-zag *trans* chain has an identity period of 5.05 Å., this constitutes evidence for the *trans* structure of polybutadiene in accordance with the statements of Meyer[21] and of Mark.[22]

The equatorial spacings are interpreted as the distances between the extended molecules. Now, the equatorial spot corresponding to the larger intermolecular distance is by far the more intense of the two. The degree of this difference is indicated in Figure 4 which is an X-ray pattern taken under similar conditions but with a shorter exposure time and a greater specimen to film distance. The second equatorial arcs and the meridianal arcs would be too weak to be registered by this exposure. Therefore, it seems likely that the extended frozen polymer is composed of an appreciable percentage of amorphous material and a larger percentage of molecules which are divided into two categories of ordering: 1. By far the most numerous of the ordered molecules are lined up in the direction of stretching without forming a three-dimensional lattice. Fuller and Baker[23] refer to this type of ordering as mesomorphic. The very intense equatorial spots are due to scattering from these molecules. 2. The weak equatorial arc at 2.33 Å. and possibly another obscured by the 4.06 Å. intense arc, and the two weak meridianal arcs are due to relatively few crystallites formed of chain segments composed of all 1,4-addition butadiene presumably in the *trans* form.

X-Ray diffraction photographs were also obtained for specimens at zero elongation. At room temperature, the Bragg spacing for the point of maximum intensity of the single amorphous halo was 4.58 Å., which agrees well with Katz[24] value of 4.6 Å. for liquid butadiene. The X-ray diffraction pattern of the unstretched polymer obtained at minus 70° is shown in Fig. 5. Besides the amorphous halo, a sharper ring occurs at a distance of 4.01 Å. which agrees fairly well with the spacing observed for the most intense of the equatorial spots for the stretched specimen. (The ring survived on extraction of the specimen.) It is apparent, therefore, that at the lower temperature there are groupings of parallel molecular segments reminiscent of the smectic state in certain liquids.[21] The amorphous halo has shifted to a lower value, 4.31 Å., as would be expected from the positive coefficient of linear expansion of the polymer.

Polybutadiene—Sodium Polymerized.—A. Saffer and B. L. Johnson[25] using the perbenzoic acid addition method have determined the percentages of 1,4 groups occurring in the polymers referred to in this paper.

They found that the sodium polymer of butadiene contained 40% of 1,4 units as compared with 75% of 1,4 units for the emulsion polymer. Since side groups presumably occur at random along the chain, it is to be expected that the sodium polymer would exhibit much less ordering than the emulsion polymer. That this is true may be seen from Fig. 6 which is the X-ray diagram of the sodium

polymer elongated 470% at —40°. A slight amount of alignment of molecules is observed from the pair of very weak and very extended equatorial arcs. The equatorial arcs occur at a Bragg spacing of 5.85 Å. as contrasted to the main equatorial spacing of 4.06 Å. for the emulsion polymer. The larger interchain distance for the sodium polymer would be expected from the larger amount of side groups present.

The Bragg spacing of the maximum intensity in the halo obtained from the unstretched polymer at room temperature was 5.92 Å. which is considerably higher than the value of 4.6 Å. given by Katz for the liquid monomer. This discrepancy is presumably due to the larger percentage of side groups present in the polymer.

Butadiene–Styrene Copolymer.—Figure 7 is the X-ray pattern of GR-S elongated 600% at minus 50°. The arc at the equator and the arc on the meridian appear at the same distances as for emulsion polymerized butadiene. The inference is, therefore, that polybutadiene crystallites occur in GR-S. Whether the molecules participating in the formation of these crystallites also contain styrene units outside of the crystallites is a question. No other evidence of regularity was found in the polymer.

It was found that milling the polymer tended to destroy the fiber pattern. A milling time of twelve minutes reduced the X-ray pattern to only the amorphous halo with only a slight enhancement at the equator. This may indicate that essentially pure chains of polybutadiene occur in the copolymer and that the milling process disperses them so thoroughly in the copolymer that they can no longer become associated in ordered aggregates.

Polyisoprene.—An additional factor promoting disorder in the polymer chains has been added in the case of polyisoprene, namely, the possibility of heterogeneous mixtures of head-to-head and head-to-tail additions of the monomer units. There is also the possibility of 3,4 addition. Therefore, it would be expected that these polymers would show less ordering than polybutadiene.

Figure 8 is the X-ray diffraction pattern of emulsion polymerized isoprene stretched 580% at −55°. The only sign of ordering is the weak pair of extended arcs appearing at 4.86 Å.

Figure 9 is the diffraction pattern of the sodium polymer stretched 600% at +10°. Here, too, only a weak equatorial arc appears at 6.53 Å.

The emulsion polymer contains 90% of 1,4 units and the sodium polymer 45% of 1,4 units. The inter-chain distances, therefore, increase with increasing percentages of side groups.

The room temperature X-ray patterns of the unstretched sodium and emulsion polymers consist of halos occurring at 5.95 and at 5.10 Å., respectively. The value given by Katz for the liquid isoprene halo is 4.9 Å. The agreement between the values for the monomer and for the polymer, therefore, is seen to be improved by a higher proportion of 1,4 additions in the polymer.

Polydimethylbutadiene (Emulsion).—Since polydimethylbutadiene is constructed of structurally symmetrical monomer units, the only hindrances to its regularity of structure are the presence of side groups and the possibility of mixtures of *cis* and *trans* forms. The emulsion polymer is known to be composed of about 85% 1,4 addition units. Therefore, it should exhibit a regularity of structure comparable with that of emulsion polymerized butadiene.

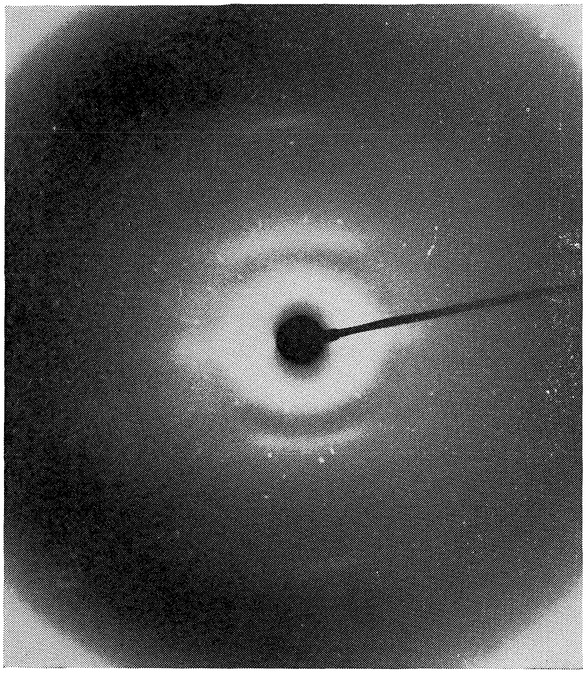
Figure 10 is the X-ray pattern for emulsion polydimethylbutadiene stretched 670% at 0°. A single strong arc is present at 5.3 Å. on the equator and three weak arcs on the meridian at 3.30, 2.24 and 1.17 Å. The 1.17 Å. arc is extremely weak and is not reproducible on a photographic print. Katz and van Campen's[17] values of 2.3 and 3.2 Å. for meridianal arcs correspond quite well with the above values, but their value of 4.3 Å. for the equatorial spot is in disagreement. Our value of 5.3 Å. for the equatorial spot agrees well with their value of 5.4 Å. for the amorphous halo.

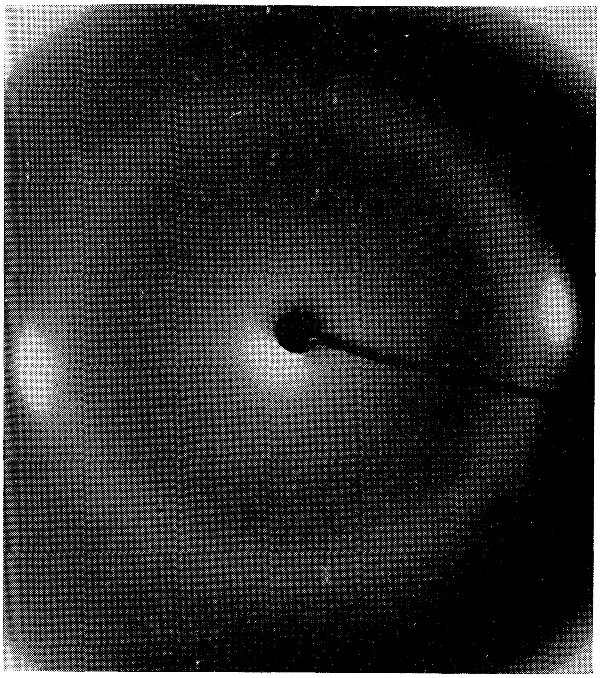
It was found that when the polymer was kept at 0° for one hundred and forty-four hours and elongated 650% the equatorial spot at 5.3 Å. was partially resolved into two spots at 4.8 and 5.8 Å. and a third extremely weak arc appeared on the equator at 3.9 Å. The same pattern could also be obtained after three or more cycles of retraction and elongation at 0° without prolonged storage at this temperature.

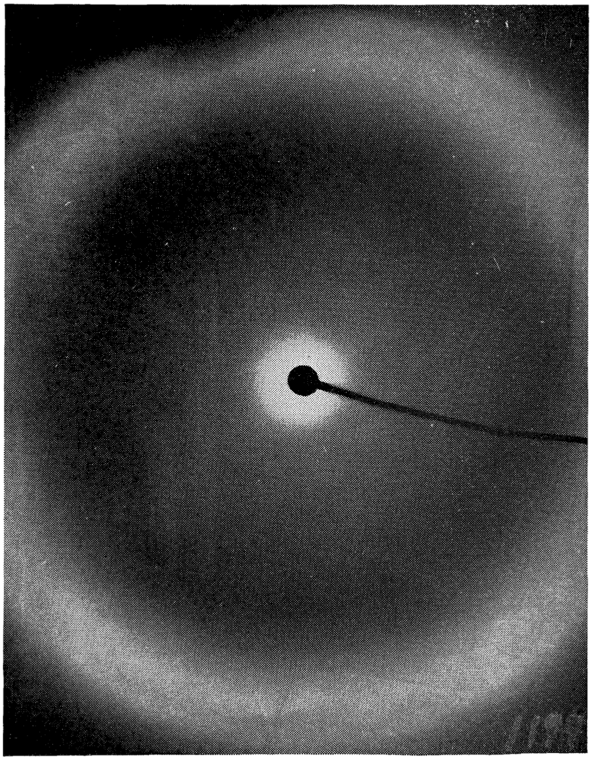
A tentative interpretation may be made of the meridianal arcs in terms of the identity period of the molecule. If the arcs occurring at the Bragg spacings of 3.30, 2.24 and 1.17 Å. are interpreted as reflections of order 2, 3 and 6, respectively, and if the possible layer-line hyperbolae are drawn through the arcs, the possible identity periods are 6.75 to 8.16, 6.72 to 8.26 and 7.38 to 9.0 Å., respectively. Therefore the values which are common to all three arcs lie between 8.16 and 7.38 Å. This would correspond to a *cis* structure for the polymer.

Since the equatorial spots are very intense, we can draw the same conclusions as we did for emulsion polybutadiene. A relatively small number of crystallites of 1,4 addition, polydimethylbutadiene, probably with a *cis* structure, exist together with a relatively large number of molecules containing side groups and which are lined up in the direction of stretch, but exhibit no other characteristics of regularity. In addition there is quite a large amount of the polymer which is amorphous in character.

The maximum in the halo obtained from the unstretched polymer at room temperature corresponds to a Bragg spacing of 5.76 Å. The value given by Katz for the liquid monomer is 5.3 Å.







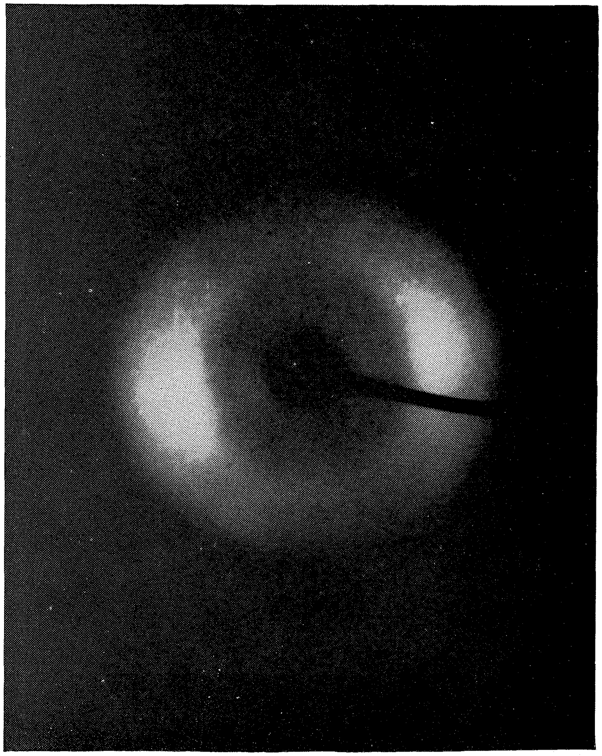


Fig. 3 (*top left*).—Emulsion polybutadiene stretched 500% at −70°. Fig. 4 (*top right*).—Emulsion polybutadiene stretched 600% at −30°. Fig. 5 (*bottom left*).—Emulsion polybutadiene—0% elongation, −70°. Fig. 6 (*bottom right*).—Sodium polybutadiene stretched 470% at −40°.

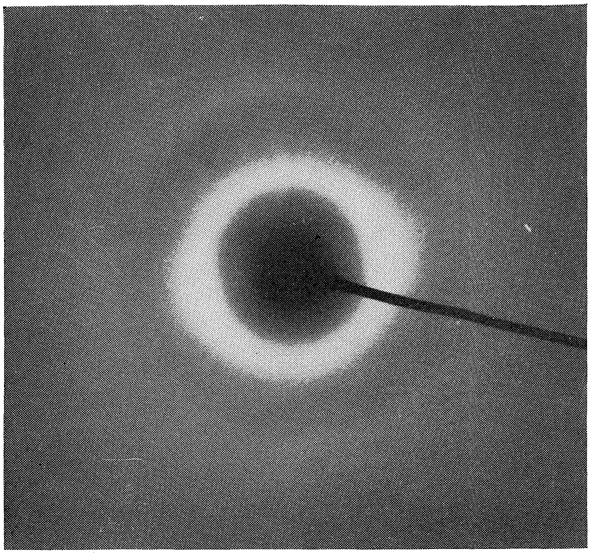

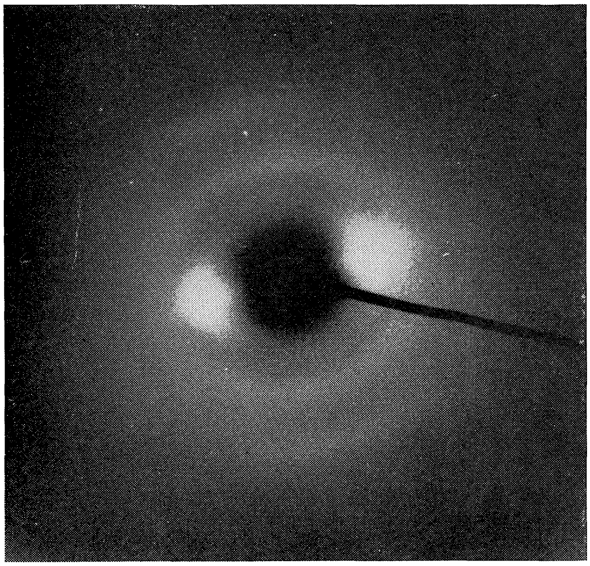

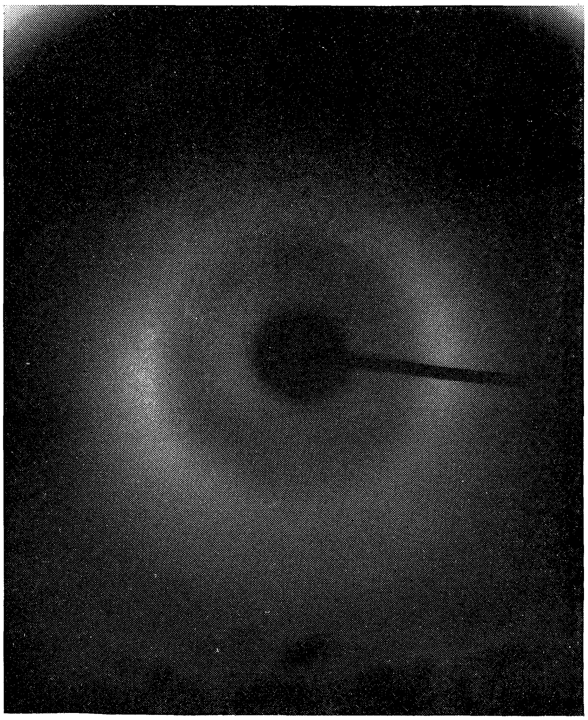

Fig. 7 (*top left*).—GR-S stretched 600% at −50°. Fig. 8 (*top right*).—Emulsion polyisoprene stretched 550% at −55°. Fig. 9 (*bottom right*).—Sodium polyisoprene—600% elongation and 10°. Fig. 10 (*center left*).—Emulsion polydimethylbutadiene—extended 670% at 0.0°. Fig. 11 (*bottom left*).—Emulsion polydimethylbutadiene, elongated 650% at 0°. Stored at 0° for one hundred and forty-four hours.

The difference is probably due to the presence of the side groups in the polymer.

Discussion

The above X-ray diagrams were not necessarily obtained under the most ideal conditions. Long, Singer and Davey[26] have shown that there is a lag in the fibering of rubber after stretching. Since the specimens were elongated by hand, it is not likely that the optimum conditions for fibering prevailed. The effects of temperature and of time will also need to be studied more thoroughly than we could in this preliminary report. However, the results obtained with the technique indicate that it has value in the study of "non-crystalline" high polymers.

The observation was made that the Bragg spacing of the halo obtained from the relaxed specimen at room temperature depended upon the quantity of side groups in the molecules. Similarly, the spacings of the equatorial arc for the stretched specimens increased with increasing percentages of side groups. These values are tabulated in Table I. It may be possible to develop a method for calculating the percentages of side groups present in the polymer from such X-ray data.

TABLE I

CORRELATION OF SIDE GROUPS WITH INTERMOLECULAR SPACING

Polymer	1,4-addition, %	Amorphous halo, Å. Polymer	Amorphous halo, Å. Monomer	Principal equatorial arc, Å.
Emulsion–butadiene	75	4.6	4.6	4.06
Sodium–butadiene	40	5.9		5.85
Emulsion–isoprene	90	5.1	4.9	4.86
Sodium–isoprene	45	6.6		6.53
Emulsion–dimethylbutadiene	85	5.7	5.3	5.30

It is not the purpose of this paper to discuss the correlation of physical properties and structures. However, it was observed that emulsion polybutadiene retained its rubber-like extensibility down to −70°, but that sodium polybutadiene was rigid at −70° and barely extensible at −60°. This constitutes evidence that increasing the side groups (and probably branching) would seem to raise the brittle point temperature. It would seem, from comparisons of the brittle points of rubber (*cis* structure), and balata (*trans* structure), that the *cis* structure should have the better cold properties. However, emulsion polybutadiene with a probable *trans* configuration has the lowest brittle point of all the rubbers.

Acknowledgments.—It is a pleasure to thank the Synthetic Rubber Group, especially Dr. R. L. Bebb, for supplying us with polymers, Dr. M. J. Brock for having the samples extracted, and Drs. B. L. Johnson, A. Saffer, F. W. Stavely and J. W. Liska for discussions of the problem.

Summary

A certain amount of ordering has been found in the "noncrystalline" synthetic rubbers which were studied by the use of the technique of cooling the raw polymer before it is elongated and freezing it immediately after stretching to prevent relaxation. Polybutadiene and polydimethylbutadiene whose monomer units were structurally symmetrical displayed the greatest degree of ordering. The presence of a high percentage of 1,2 units in sodium polymerized butadiene destroyed almost all of the ordering observed in the emulsion polymer. GR-S and emulsion polybutadiene showed the presence of small amounts of crystallites presumably of 1,4 addition polybutadiene, probably the *trans* form. Polydimethylbutadiene showed the presence of crystallites presumably of 1,4 addition in the *cis* form. The intermolecular distance between the extended chains increased with increasing amounts of side groups. The departure of the Bragg angle spacing of the amorphous halo from the corresponding quantity for the liquid monomer increased with increasing amounts of side groups.

The Quantum Yield of Oxidation of Hevea Rubber and GR-S

By E. J. Hart and M. S. Matheson

I. Introduction

Little previous quantitative work has been reported on the photoöxidation of rubber even though the light aging of rubber products is a serious technological problem. Recently Bateman[1] reported the relative photoöxidation rates of highly purified rubber after fixed oxygen uptake as a function of wave length. The results show a rapid drop in quantum efficiency as the wave length increases above 3000 Å. The considerable amount of qualitative work on the effects of light on rubber, particularly in the presence of air, also show that shorter wave lengths cause more serious oxidation than the longer wave lengths. For example, Raybaud[2] found light below 4000 Å. more effective in deteriorating raw rubber than longer wave lengths, while Yamazaki[3] reports a similar result for vulcanized rubber. According to Asano[4] in the presence of oxygen an insoluble product is formed in raw rubber below 2250 Å. Above this wave length, extending to about 3130 Å., a transparent oxidized rubber resulted.

Quantum yields have been measured for the initial oxidation of rubber following the absorption by the rubber of monochromatic light over the wave length range 2537 to 17,400 Å. Purified Hevea rubber and GR-S (styrene–butadiene copolymer) were investigated.

II. Experimental Details

The quantum yields of oxygen consumption at room temperature (∼25°) were obtained by irradiating thin rubber films with monochromatic light. The oxygen absorbed by the rubber was determined by a differential method and compared with the measured amount of absorbed light.

Apparatus for Ultraviolet and Visible.—The light source was either an Hanovia 85-watt H-3 or 100-watt H-4 mercury arc, operated from a stabilized voltage supply. A fused silica jacket was cemented in place of the original glass envelope of the mercury arc for experiments at 3130 and 2537 Å. It was found that filling the silica jacket with nitrogen prolonged the arc life.

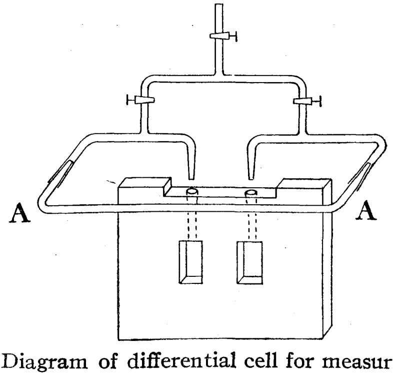

Fig. 1.—Diagram of differential cell for measuring photooxidation rates.

The various mercury lines were isolated by a Gaertner L-234 HT quartz monochromator (F/4 at 2000 Å). However, in one experiment (#15) the light from a portion of an Hanovia SC-2537 tube was focused directly on the rubber film by a quartz lens. This lamp supplies about 90% pure 2537 radiation. The impurity in this light is largely ineffective visible light and so the absorbed intensity was corrected for that fraction of the radiation passed by Pyrex.

The cell of Fig. 1 was placed directly behind the exit slit of the monochromator. This cell consists essentially of an aluminum block with two identical 1 × 2 cm. rectangular holes cut through it. The cavities were closed front and rear with Corning #791 glass windows, sealed with 0.1 mm. polyisobutylene gaskets coated with Apiezon Grease M. The absorption of oxygen by a rubber sample in one side of the cell was followed by the motion of a droplet of Amoil S in a calibrated capillary ($\sim 10^{-3}$ cc./cm.) connecting the two cavities. Barium oxide in each side absorbed any carbon dioxide or water present initially or produced during irradiation.

To measure light intensities an RCA-935 phototube in a Model 510 Electronic Photometer of the Photovolt Corp. was used. Ground quartz screens in front of the photocell diffused the incident light so that uniform response over a 1 × 2 cm. area of the ground quartz was obtained. The Photometer was calibrated against a Gaertner silver-bismuth thermopile L-234 VTBS using the monochromator and H-3 arc. This thermopile had previously been standardized against three National Bureau of Standards lamps. The photometer was corrected for non-linear response by means of an approximate point source and applying the inverse square law as the distance of the photocell from the light source was varied.

To check the photocell calibration, the photocell, H-3 arc and monochromator were used to measure the quantum yield of decomposition in an unstirred uranyl oxalate solution (0.005 M $UO_2C_2O_4$ and 0.025 M $H_2C_2O_4$). We obtained a quantum yield of 0.45 at 3660 Å. while Leighton and Forbes[5] report 0.46 in unstirred solutions of 0.01 M UO_2SO_4 plus 0.05 M $H_2C_2O_4$. According to Forbes and Heidt[6] these two actinometer solutions should give the same quantum yield.

Materials and Preparation of Films.—Deproteinized rubber[7] was prepared by an alkaline hydrolysis method. One liter of triple-creamed Hevea latex (63.3% solids) was diluted with two liters of aqueous 6% sodium hydroxide and heated and stirred eight hours per day at 70°. At night the alkaline latex was allowed to cream and the lower liquid drawn off and replaced with 4% aqueous sodium hydroxide. Ten successive heating and creaming cycles were carried out under oxygen-free nitrogen. The use of carefully purified nitrogen is necessary to avoid oxidation or degradation. After the final creaming, the latex was poured into 60 liters of distilled water and coagulated by adding one liter of 5% acetic acid with continuous stirring. The coagulum was sheeted in a calender between heavy canvas to 0.015″. Acetone extraction under nitrogen for ten days followed by five days of alcohol extraction completed the purification process. The

purified rubber of osmotic mol. wt. 500,000–1,000,000 analyzed 0.01% nitrogen and 0.03% ash. The high molecular weight indicates little, if any, degradation occurred during purification. The rubber was stored in an evacuated desiccator containing freshly cut sodium.

The fractionation[8] of 20 g. of deproteinized rubber was carried out on a 2.4% solution of rubber in benzene. To this solution methanol was slowly added with stirring until a cloudy precipitate just appeared at room temperature. The first fraction precipitated at a methanol concentration of 17.25 weight per cent. of total solvent. The solution was heated to 45° to redissolve the precipitate and then the solution flask was placed in a thermostat at 30° overnight. The next morning if a fraction of suitable magnitude had settled in the lower layer, the upper layer was carefully decanted. (Otherwise a small amount of benzene or methanol as necessary was added, the precipitate dissolved by warming and the flask returned to the thermostat.) The lower layer was dried by evacuation in a desiccator and the solid rubber fraction obtained was stored *in vacuo* as described above. Additional methanol was added to the decanted upper layer and the fractionation cycle repeated. Redistilled reagent grade methanol and benzene were used, and except during decantation or solvent addition the rubber solution was kept in the dark under nitrogen. In this way the deproteinized rubber was separated into the five fractions of Table I.

TABLE I

YIELDS OF FRACTIONATED RUBBER

Fraction	Wt. of fraction, g.	
I	2.453	Tough
II	8.365	Medium
III	3.642	Soft
IV	2.048	Soft
V	1.820	Very soft

Fraction II resembled the whole rubber, whereas I was practically insoluble and V was yellow and tacky, possibly containing an oxidized fraction. Fraction V was contained in the solution decanted from IV and probably was degraded during the solvent removal. Solvent was removed from fractions I to IV by pumping in evacuated desiccators, while a stream of commercial nitrogen was used to evaporate solvent from Fraction V.

Films of deproteinized rubber were laid down on glass plates by evaporating 5% *n*-hexane solutions under a slow stream of purified nitrogen. The films were stored *in vacuo* in the presence of sodium until used. Fresh films were prepared every two or three weeks.

Antioxidant-free GR-S (75 parts butadiene–25 parts styrene by weight) was prepared by emulsion polymerization by the Naugatuck Chemical Company, using 0.05 part of hydroquinone as shortstop. The polymer was extracted first with cold acetone and then with cold absolute alcohol under nitrogen. GR-S films were deposited from benzene solution on cellophane covered glass plates, since the films could not be removed without tearing or distortion if they were deposited directly on glass.

Linde tank oxygen passed through Dehydrite and Ascarite was used in all photoöxidation experiments.

Procedure.—A polymer film cut to about 3 × 18 mm. was pressed upon a cell window, which was then attached to the rear of one cell cavity. During handling this 3 × 18 mm. section came in contact only with clean glass. Film thicknesses (0.4 to 2.0 mm.) were calculated from the length, width, weight and density of the film. The cell was evacuated and filled with dry oxygen to one atmosphere pressure. The initial dark rate was generally so small it could be taken as zero. During irradiation the light intensity before and behind the cell was determined. Oxygen consumption was followed during and after irradiation.

Complete details of all photoöxidation experiments appear in Table II.

Infrared Experiments.—A 1000-watt tungsten filament projection lamp was substituted for the mercury arc described above. The monochromator slit widths corresponded to a range of 0.11μ at 1.74μ and of 0.08μ at 1.0μ. For infrared work, the light in front of the cell but not behind it was measured with the calibrated thermopile. At the end of an experiment the rear window was detached and the film transmission determined.

Calculations.—Quantum yields were calculated in the same manner as those for the actinometer, except that a correction was made for the light reflected at the back of the front window of the cell and at the front surface of the rubber film. The refractive index of rubber from L. A. Wood[9] enabled the latter correction to be made.

The oxygen consumption was never followed beyond a pressure decrease of 1–2%; so the pressure was assumed to be constant at 1 atmosphere in converting volumes of absorbed oxygen to molecules absorbed.

Absorption Spectra.—The absorption spectrum of the purified rubber was photographed on a Baird 3 meter grating spectrograph, using a quartz hydrogen discharge tube as a source of continuous radiation. Optical densities were measured with an ARL–Dietert densitometer and the plates were calibrated by varying the exposure with a rotating sector. Solid films of the purified whole rubber were deposited on thin quartz plates by slow evaporation of rubber–benzene solutions. Film thickness was calculated from the weight and area of the rubber. The absorptions of three of the rubber fractions (II, III and IV) were also determined in chloroform solution. The results are shown in Fig. 2 expressed as the molecular extinction coefficient per double bond.

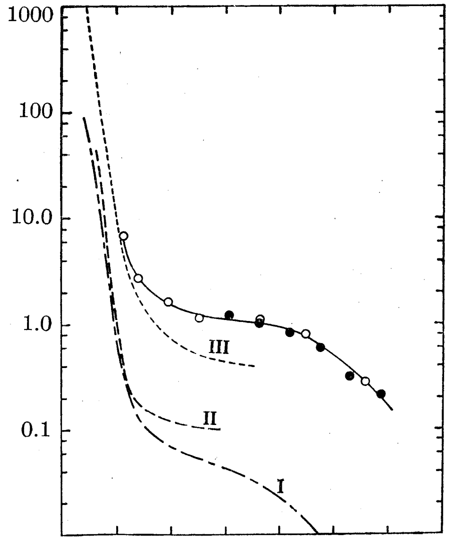

Fig. 2.—The ultraviolet absorption spectra of rubber and related olefins: I, trimethylethylene, ref. 17; II, 2,6-dimethyloctadiene-2,6, ref. 13; III, purified rubber (in cyclohexane + 10% ethyl alcohol) ref. 13; ●, purified rubber fractions II, III and IV (in chloroform)—this paper; ○, purified rubber films—this paper. $K = (1/Cl)\log_{10}(I_0/I)$ = molecular extinction coefficient, where C = moles of $>C=C<$/liter; l = centimeters depth; I_0 = incident light intensity; I = transmitted light intensity.

III. Results

Characteristic oxygen absorption curves as a function of time of irradiation of rubber are given in Fig. 3 for wave lengths 2537, 3130, 3660, and 4358 Å. In every case the intensity of monochromatic light incident on the rubber was kept constant within ±3%. It will be noted that an initial linear absorption occurs at 3130, 3660, and 4358 Å., whereas the absorption at 2537 Å. appears to be sharply autocatalytic from the beginning of irradiation. After about sixty minutes the rate increases autocatalytically at 3130 Å., but the rates remain constant at 3660 and 4358 Å. throughout the periods of observation. As far as the light rates at 2537 and 3130 Å. were followed they continue to increase with time of irradiation.

Fig. 4 in comparison with Fig. 3 shows that in GR-S the initial rates are lower than for rubber at 2537, 3130 and 3660 A. Further, the rates increase with time of irradiation at all these wave lengths, although at 2537 Å. the rate eventually begins to fall off again.

Diffusion of oxygen into the rubber is a factor affecting the rate of oxidation. In rubber at 3130, 3660 and 4358 Å., constant rates of oxygen absorption were apparently attained within a few minutes. However, at 2537 Å. the observed rate increases continually from the onset of irradia-

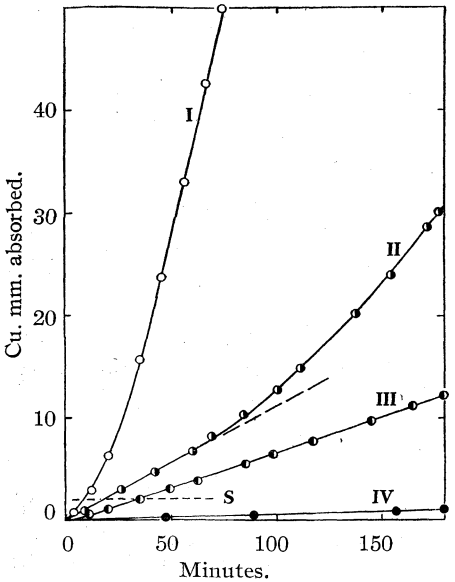

Fig. 3.—Photoöxidation of purified hevea rubber: I, Run 16 at 2537 Å. film 0.51 mm. thick; II, Run 2 at 3130 Å. film 0.48 mm. thick; III, Run 6 at 3660 Å. film 1.08 mm. thick; IV, Run 9 at 4358 Å. film 1.34 mm. thick; *S* = solubility of oxygen at 1 atmosphere pressure in 0.03 cc. of rubber (0.03 cc. = volume of irradiated rubber film 1.0 mm. thick).

tion, and the question arises whether this is due mostly to true autocatalytic effects or to a time lag in attaining a steady state.

No exact calculation has been made of the time lag required for the diffusion of oxygen into the rubber to attain, for example, 90% of a rate of oxygen consumption equal to that initially measured at 2537 Å. However, the following calculations on experiment 16 have been made:

0.0153 cc.	volume of irradiated rubber
0.00107 cc.	oxygen dissolved in irradiated rubber initially
0.000237 cc.	oxygen absorbed per minute according to initial measurement
0.000054 cc.	oxygen would diffuse into rubber per minute if diffusion occurred only through front irradiated area due to a linear concentration gradient down to zero concentration at the rear of the film.

The rate of diffusion and solubility of oxygen are calculated from the data of Barrer.[10] Comparison of the second and third figures shows that in 4.5 minutes as much oxygen flows into the rubber as was originally dissolved in the irradiated volume. This suggests that the rate of diffusion should approach the rate of reaction within a few minutes after irradiation is begun. Thus, the increasing rate may be attributed chiefly to autocatalytic effects and we will assume that at 2537 Å. also the measured rate corresponds closely to the actual rate of reaction at least in the initial stages of irradiation. Since about half the rubber film surface (including edges) which is in contact with oxygen is irradiated, it is apparent that at least half of the measured oxygen inflow must occur through the irradiated area. Comparing half of 0.000237 (the measured O_2 absorption rate) with 0.000054 (rate of O_2 absorption for linear concentration gradient) it appears that there is a high concentration gradient at the irradiated surface and that the gradient decreases in magnitude toward the rear of the sample.

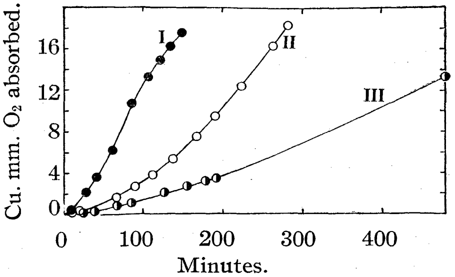

Fig. 4.—Photoöxidation of purified GR-S: I, Run 14 at 2537 Å. film 0.43 mm. thick; II, Run 12 at 3130 Å. film 0.91 mm. thick; III, Run 11 at 3660 Å. film 0.80 mm. thick.

In GR-S the observed rates in the ultraviolet always increased with time. However, since at each wave length the rate of oxygen absorption was considerably less than for rubber, it is likely that the effect of diffusion is less important in the photoöxidation of GR-S.

The quantum yields of oxidation for the measured reaction at various wave lengths of light are summarized in Table III and Fig. 5.

TABLE III

INITIAL AND THREE-HOUR QUANTUM YIELDS FOR DEPROTEINIZED RUBBER AND GR-S

λ (Å.)	Average initial yields		Average three-hour yields	
	Rubber	GR-S	Rubber	GR-S
2537	0.66	0.29	2.65[a]	0.31
3130	.51	.05	1.66	.16
3660	.17	.016	0.17	.016
4358	.02	...	.02	....
10000	..	...	.002[b]	.004[b]
17400	..	...	.001[b]	....

[a] After 1 hour. [b] Upper limits.

From Table III and Fig. 5 the following conclusions can be drawn: (a) All initial quantum yields are of the order of 1.0 or less, (b) initial and three hour quantum yields are lower for GR-S than for rubber, (c) quantum yields for rubber and GR-S decrease with increasing wave length. The initial quantum efficiency drops rapidly above 3660 Å. for rubber, and in the range above 2800 Å. for GR-S, (d) initial efficiencies are lower than the later (three-hour) yields at 2537 and 3130 Å. for both polymers. Figure 4 also shows that there is actually a slight increase at 3660 Å. for GR-S over this time interval, although the given yield is averaged over the first three hours.

Photochemical reactions in rubber not involving

---

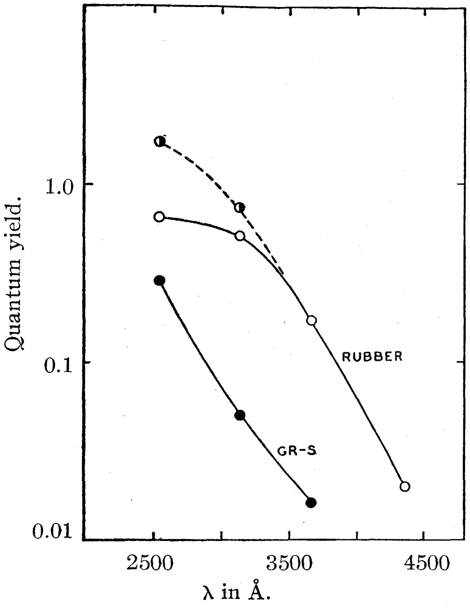

Fig. 5.—Initial quantum yields of photoöxidation as a function of wave length. The dotted line shows our best estimate of the upper limit for the quantum yields if they were measured in extremely thin films to eliminate diffusion effects.

oxygen have been studied by Bateman.[11] He measured the rates of gas formation from thoroughly degassed purified rubber when irradiated *in vacuo* in the wave length range 2300 to 4500 Å. An estimate of 4×10^{-4} was made for the quantum yield of non-condensable gas (mostly hydrogen) formation for the wave band 2300–3650. The largest relative yield reported at 2350–2850 Å. was about 2.5 times this so an upper limit of 10^{-3} may be set for the efficiency of non-condensable gas formation. From a typical experiment cited by Bateman (wave length not given), it can be calculated that the number of crosslinks formed is approximately equal to the molecules of non-condensable gas, while the number of double bonds disappearing may be as much as 100 times as large. Thus, the highest quantum yield of chemical change in rubber is not more than 0.1 in the absence of oxygen. If these calculations are permissible, chemical reactions of the rubber not involving oxygen account only in small part for the low quantum yields of oxidation.

The pale blue fluorescence excited in rubber by 3600 Å. light is visually very much weaker than the fluorescence of biacetyl. Since the strong fluorescence of biacetyl has a quantum yield of only 0.03,[12] it is concluded that fluorescence has a negligible effect in lowering the efficiency of the rubber–oxygen reaction.

The results discussed above on rubber have been obtained on unfractionated deproteinized rubber. In order to test the effects due to possible impurities in the rubber, a study was also made on the photoöxidation of Fractions II, III, and V described above under Experimental Details." The results obtained appear in Table IV.

Table IV

Quantum Yields of Oxidation of Fractions of Deproteinized Rubber at 3130 Å.

Fraction	Quantum yield Initial	Quantum yield 3-hour
II	0.24	1.095
III	.23	0.86
V	.12	0.09
Whole	.51	1.66

Fractions II and III comprise two-thirds of the whole rubber and their quantum yields are substantially the same as for the whole rubber. The somewhat lower values obtained for II and III may be partly due to diffusion effects as thicker films were used for II and III than for the whole rubber. In view of this agreement, it is concluded that the suspended and soluble impurities in the whole rubber do not greatly affect the results. The value of the quantum yield for Fraction V appears to be definitely lower than the values obtained for Fractions II and III. Fraction V shows about ten times the absorption of light as Fractions II and III which in turn are identical with the whole rubber. Fraction V therefore increased considerably in extinction coefficient during the fractionation process. The presence of these new chromophoric groups in the rubber may then be responsible for the lower quantum yield of Fraction V.

In Fig. 2 the extinction coefficient of our rubber appears to be twice that of Bateman and Koch's[13a] at 2537 Å.[13b] If their rubber corresponds to pure polyisoprene, then only half the light in our experiments is absorbed by polyisoprene. If no oxidation results from light absorbed by impurities, then the quantum yield for polyisoprene is double the measured value. If, on the other hand, the light absorbed by impurities causes considerable oxygen reaction, the initial quantum yield of pure polyisoprene may even be lower than found.

The course of the dark reaction following illumination is illustrated in Fig. 6. The dark reaction curve may be divided into three parts: a period of rapid rate decay when light is turned off, a period of apparently constant oxygen absorption, and finally a period when the dark rate begins to show the familiar autocatalysis of olefin oxidation. The initial decay could be due in part to oxidation chains of long life dying away. After irradiation was stopped, the dark rate dropped 60% in experiment 2, 75% in 16, and 50% in 12 in only five minutes and a steady state is achieved in sixty to one-hundred minutes. These results

[13b] Farmer, Koch and Sutton[23] give a curve for the absorption of the purified hexaisoprene, squalene, which corresponds very closely to that of our purified rubber in the region 2300–2900 Å.

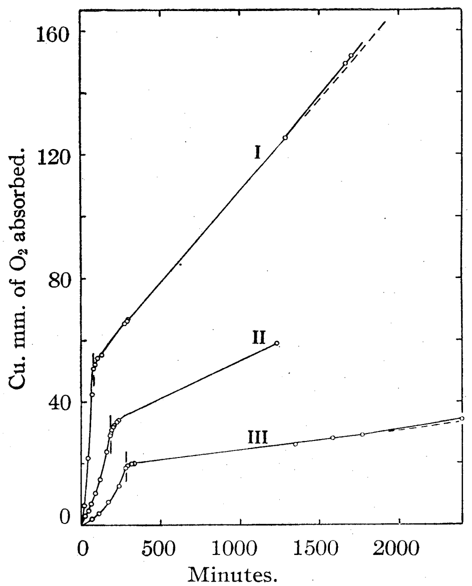

Fig. 6.—Absorption of oxygen by rubber and GR-S during and after irradiation: I, Run 16 rubber at 2537 Å.; II, Run 2 rubber at 3130 Å.; III, Run 12 GR-S at 3130 Å.; vertical lines indicate end of light exposure.

indicate that with the rubber strips used, the major portion of the change in the diffusion rate was achieved in only a few minutes. The steady dark rate after irradiation is 6–8% of the final rate in light, or much too small to account for the oxidation rate increases occurring during irradiation.

The steady dark rate is, as might be expected, approximately proportional to the amount of oxygen absorbed during illumination (Fig. 7). A similar dependence has been found for the dark rate following the chain reaction of later stages of photoöxidation.[1] It has also been found that the thermal rate of autoxidation in ethyl linoleate increases linearly with the extent of oxidation.[14] In Fig. 7, the steady thermal rate is plotted against the per cent. oxygen absorbed by the irradiated portion of the rubber at the end of illumination. This per cent. oxygen is an average value and does not take into account non-uniformity of absorbed light. Oxygen absorbed is greatest at the front surface of the sample, particularly if the extinction coefficient is high. GR-S at 2537 Å. deviates considerably and the reasons for this behavior are discussed later.

IV. Discussion of Results

Before proceeding to a discussion of the significance of these results, it is pertinent to consider the light absorption process. Carr and Walter[15] have shown that in addition to an intense absorption band (*circa* λ = 2000 Å.) unconjugated olefins possess a weak absorption tail extending to longer wave lengths. This long wave length band is shifted to the red by successive alkyl substitutions on the double bond. A simultaneous increase in intensity also occurs. The absorption band at 2000 Å. has been discussed by Mulliken[16] in terms of molecular orbitals, and has been assigned to an N → V transition involving the excitation of an "unsaturation" bonding electron of the double bond to the corresponding antibonding molecular orbital. Since this is a singlet–singlet transition, Snow and Allsopp[17] have suggested that the weak long wave absorption is the analogous singlet–triplet transition, the change in multiplicity thus accounting for the weakness of the absorption.

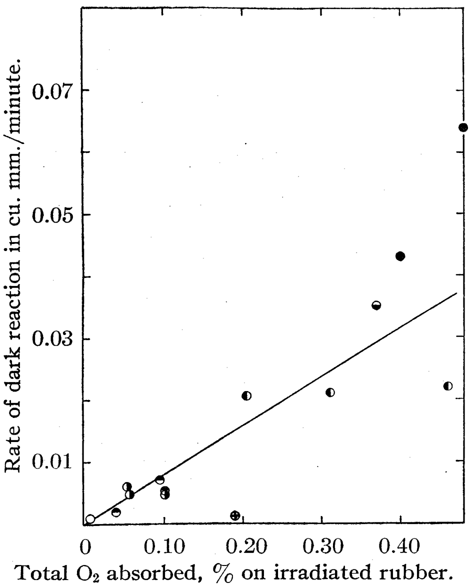

Fig. 7.—Dark reaction rates in rubber and GR-S as a function of the per cent. oxygen absorbed at the end of irradiation:

Rubber	Å.	GR-S

◑	3660	◒
◐	3130	◓
●	2537	⊕

Ultraviolet absorption curves are shown in Fig. 2 for trimethylethylene, 2,6-dimethyl-octadiene-2,6, and purified rubber corresponding, respectively, to one, two, and many isoprene units per molecule. Mulliken explains the red shifts of olefin spectra on alkyl substitution as due to hyperconjugation.[16,18] It is possible that the differences indicated in Fig. 2 between the spectra of mono-, di- and polyolefins are due to impurities, particularly in the case of rubber. If the differences are not due to impurities, these spectra indicate that, in addition to the alkyl substitution effect, there is an enhancement of absorp-

tion in the singlet–triplet region as the number of isoprene units per molecule increases.

All ultraviolet light absorbed in these photooxidation studies is in the long wave length band region. Therefore, we may tentatively conclude that in the photoöxidation of rubber in this spectral region an unsaturation electron of the double bond is lifted by the absorption of a photon to an antibonding level. Further, this electron is not localized but takes part in considerable hyperconjugation especially with the carbon–carbon bond midway between the double bonds.

Consideration of the absorption phenomenon leads to the question of the mechanism of attack by the oxygen molecule. Farmer[19] has shown that for unconjugated olefins photoöxidation leads at room temperature or lower to very high yields of a hydroperoxide on the carbon adjacent to the unchanged double bond. However, as he points out, this product is the result of a chain reaction and does not necessarily indicate that the initial attack occurs on the α-carbon atom. Farmer[20,21] considers the idea that the oxygen molecule in the initial step of the chain adds at the double bond. The radical resulting abstracts the hydrogen from the α-carbon of another olefin unit. However, Farmer, Koch and Sutton[22] in an earlier paper suggest that molecular oxygen may initiate reaction chains by detaching hydrogen atoms from the α-carbon, at least in 1:4-polyenes.

Farmer and Sundralingam[19b] irradiated a 1% rubber solution in cyclohexane at 12° with a mercury arc. The conditions involve high intensity light with the shortest effective wavelength at about 3130 Å. An induction period of less than one hour was reported and the least oxygen uptake recorded was 0.75%. All of our measurements were taken in the induction period of Farmer and Sundralingam's work and no photoöxidation was carried beyond 0.5% oxygen uptake. Thus, the work reported in this paper is concerned with the initiation of photoöxidation in purified rubber.

The initial quantum yield of 1.0 or less suggests that the primary reaction is not a chain process, but involves the addition of molecular oxygen to an isoprene unit to form a relatively stable intermediate. At 3660 and 4358 Å. where oxidation was carried to slight extents, the quantum yield remained constant during the entire period of irradiation and exhibited none of the autocatalytic character associated with the usual peroxidation of rubber. Thus, at these longer wave lengths the lack of chain character is especially apparent. At 3130 Å. the linear rate of oxidation gives way after about an hour to an autocatalytic effect, and at 2537 Å. the rate increases from the onset of irradiation.

The presence of inhibitors as the cause of low quantum yields is ruled out because of the purity of the rubber used. Furthermore, purification of the deproteinized rubber by fractionation did not appreciably change the quantum yield at 3130 Å. An alternative explanation which we favor is that the original stable intermediate, presumably a hydroperoxide, eventually attains such a concentration that a small but definite fraction of the light is absorbed by the hydroperoxide. This absorbed light decomposes the peroxide into radicals which initiate oxidation chains. This hypothesis is in agreement with linear rates at long wave lengths where a lesser extent of oxidation occurred and an increasing rate at shorter wave lengths where higher percentages of oxygen were absorbed. Further, such an effect could be expected to be more important at shorter wave lengths where peroxides absorb more strongly. In this connection, it was found that observed changes in light absorption during irradiation were small (about 1% or less) for all rubber samples except the fractionated rubbers. At 3130, 3660, and 4358 Å. a small decrease was always observed while in runs at 2537 Å. where the autocatalytic effect was most pronounced the light absorption during irradiation increased slightly.

It seems most probable that the oxygen molecule attacks the α carbon–hydrogen in the initial step to form a relatively stable hydroperoxide. If attack occurs at the double bond, a biradical would be formed which would probably initiate oxidation chains leading to high quantum yields, unless an intramolecular stabilizing reaction generally occurred. Farmer[21] suggests such a reaction leading to an allylic hydroperoxide by double bond displacement. With regard to the energetics of the initial reaction, Bolland and Gee[23] state that either double bond or α-methylene attack by oxygen is possible from thermochemical considerations. The possibility of energy transfer from the double bond to the α-methylene group is supported by the following ideas: (1) Heidt[24] has shown in the irradiation of *d*-glycosides that such transfers are possible, (2) the activated electron is not localized but takes part in hyperconjugation with the α-methylene group, and (3) Bateman[13] has shown that solid purified rubber irradiated *in vacuo* yields a gaseous product, mostly hydrogen, and that the reaction is probably due to dissociation of the α-carbon–hydrogen bond. Thus in the absence of oxygen of sufficient concentration, the photon energy occasionally splits off a hydrogen atom, while in the presence of oxygen a more frequent reaction occurs between the activated group and the molecule of oxygen.

The GR-S was prepared with added hydroquinone as a shortstop. Subsequent acetone and alcohol extractions may not have removed all traces of this inhibitor. It is possible that the presence of hydroquinone or of quinone derived therefrom could vitiate some of the conclusions to be drawn. However, at 2537 Å. calculations using the extinction coefficients of ethyl benzene and *p*-benzoquinone show that the absorption of the phenyl groups in GR-S is many orders of magnitude greater than that of the quinone which would be present even if all of the added hydroquinone were converted to benzoquinone. At 3660 and 3130 Å., one can only say that the highest amount possible of benzoquinone accounts for only a very small fraction of the observed absorption.

The low quantum yield of oxidation of GR-S as in rubber indicates that chains do not immediately follow the primary reaction with oxygen. The phenyl group is the effective absorbing group, and it seems likely that the photon energy is not so readily transferred from the benzene nucleus to the adjacent carbon–hydrogen grouping as from the double bond in rubber. Such an effect would explain the lower quantum yields of GR-S as compared with rubber. At all three ultraviolet wave lengths GR-S shows rates increasing with time of absorption which again may be due to photodecomposition of the peroxide first formed. Due to the high extinction coefficient of GR-S, a large proportion of the oxidation will occur near the front surface of the film and near this surface the per cent. oxygen added will be much higher than the average reported in Table II. Thus sufficient peroxides for autocatalysis may be quickly formed. The discrepancy of the dark reaction in GR-S at 2537 Å. in relation to total oxygen absorbed may be due to the formation of an oxygen-impermeable surface film or to the formation of phenolic type inhibitors during oxidation. Larsen, Thorpe and Armfield[25] have shown that alkyl substituted benzenes form inhibitors during thermal oxidation at 110°.

Summary

The initial quantum yields of photoöxidation for purified Hevea rubber have been measured for various mercury arc lines in the wave length region 2537–17,400 Å. All experiments were carried out at room temperature and at an oxygen pressure of one atmosphere. At the outset of irradiation all quantum yields of combined oxygen are less than unity, although the quantum efficiency rises above 1.0 at 2537 and 3130 Å. as photoöxidation proceeds. The low quantum yield suggests that in its initial stages (less than 0.1% oxygen combined on the rubber) photooxidation is not a chain reaction. It is postulated as the first step in rubber photoöxidation that the light activated rubber group reacts with oxygen to give a relatively stable intermediate which does not immediately dissociate to give a free radical reaction chain.

The quantum yields of photoöxidation of purified GR-S were also measured under the same conditions as used for rubber. At each wave length the quantum yield was lower than for rubber, indicating formation of a stable intermediate in the initial reaction also.

Studies of Retarders and Inhibitors in the Emulsion Polymerization of Styrene. I. Retarders[1a]

BY I. M. KOLTHOFF AND F. A. BOVEY

Typical retarders of polymerization processes are defined as substances which retard the polymerization throughout the entire reaction period, without giving rise to induction periods. On the other hand, ideal inhibitors are defined as substances which cause a well-defined induction period, after which polymerization starts with its normal rate. There are substances the behavior of which is intermediate between that of compounds in either of these two classes.

Inhibitors and retarders both exert their effect by reacting with free radicals to produce reaction products which are either slow in propagating chains (oxygen is an example of this type of inhibitor) or unreactive so far as further chain propagation is concerned. The rate of reaction of inhibitors with free radicals is much greater than that of retarders. Ideal inhibitors react with such a rate that all the free radicals produced in the system are made inactive. Thus a typical induction period is observed, during which the inhibitor is consumed by reaction with the free radicals.

A typical retarder reacts with free radicals with such a rate that only a fraction of the free radicals produced can initiate normal polymerization. In addition, the growing polymer chains can react with the retarder. Thus a retarder acts as a typical chain-breaker. If this concept is correct, a retarder should reduce the molecular weight of the polymer, although this effect may not be large when effective chain transfer agents are present.

[1a] This investigation was carried out under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the Government's synthetic rubber program.

Also, a fraction of the retarder added to the charge should be consumed during the polymerization and should be found in the polymer.

In the literature the terms "inhibitor" and "retarder" are often used synonymously. If added in large enough quantities, a retarder will virtually prevent the start of polymerization, and if added to a polymerizing mixture will virtually stop further reaction. Such an effect may be easily confused with the occurrence of an induction period. Actually, a large amount of a retarder does not give rise to a typical induction period, but causes the polymerization to be extremely slow at the beginning, and to remain slow throughout the entire reaction period. In this respect, it is of interest that much smaller quantities of an ideal inhibitor than of a typical retarder are required to shortstop a reaction. The shortstopping effect of a small amount of an inhibitor is only temporary, the length of the period of shortstopping increasing in proportion to the quantity of inhibitor initially present.

If the rate of reaction of a substance with free radicals is intermediate between that of an ideal inhibitor and a typical retarder, such a substance will give rise to an extremely small initial rate of polymerization, this rate increasing continually with time as more and more of the substance is consumed. In the presence of such a substance, the initial reaction-time curve approaches that found in the presence of an ideal inhibitor. After an ill-defined induction period, a retarded polymerization is observed, the retardation decreasing as the reaction progresses.

If the reaction product formed by reaction of an inhibitor with free radicals during the induction period acts as a retarder, a well-defined induction period is observed, followed by a retarded polymerization. Thus, such a substance combines the effect of an ideal inhibitor and a typical retarder. Similar behavior might be expected of a compound having functional groups characteristic of both an inhibitor and a retarder (*e. g.*, a nitroquinone).

In Fig. 1 are presented time–conversion curves typical of the effects we have described.

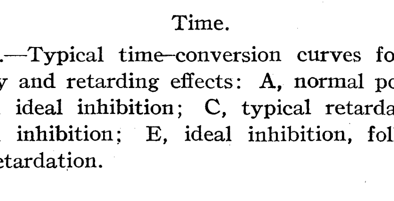

Fig. 1.—Typical time–conversion curves for various inhibitory and retarding effects: A, normal polymerization; B, ideal inhibition; C, typical retardation; D, non-ideal inhibition; E, ideal inhibition, followed by typical retardation.

No kinetic studies of the effect of retarders in emulsion polymerization are to be found in the literature. The present paper deals with the effect of retarders on the emulsion polymerization of styrene. In a subsequent paper, studies on the effect of inhibitors on the emulsion polymerization of styrene will be described.

Quite generally, the interpretation of the action of inhibitors and retarders in emulsion polymerization may be expected to be identical with that found in bulk or solution polymerizations. However, as far as the kinetics is concerned, interesting differences between bulk and solution polymerizations on the one hand and emulsion polymerization on the other may be expected under certain conditions. In emulsion polymerizations, we are dealing with typical heterogeneous systems. In order to act like a retarder, the substance must be at the locus of reaction. Thus, studies with retarders may give some insight into the locus of activation and of propagation. (See the "Discussion" section.)

Experimental Technique

Materials

***m*-Dinitrobenzene.**—A product with a melting point of 88.5–89.5° (lit. 90°) was used in part of this work. In the remainder, a sample recrystallized from ethanol (m. p. 90–91°) was employed.

3,5-Dinitrobenzoic Acid.—A product with a melting point of 201–202° uncor. (lit. 204°) was employed.

1,4-Pentadiene.—The 1,4-pentadiene used was supplied by Prof. C. S. Marvel of the University of Illinois.

Styrene.—Dow styrene with a purity of at least 99.5% was used. This material was distilled *in vacuo* just before use, although it may be safely stored for one or two days at 0 to 10°.

Water.—Conductivity water was used throughout.

Soap Flakes.—Commercial (S. F.) soap flakes (designated as S. F. flakes) supplied by Procter and Gamble were employed. This material is largely composed of the sodium salts of stearic, palmitic, and oleic acids, and contains only very small amounts of soaps of polyunsaturated fatty acids. The same lot of this material was used throughout this work.

Dodecylamine Hydrochloride.—Dodecylamine hydrochloride (designated as DDA·HCl) was prepared by neutralizing a solution of one mole of Armour dodecylamine dissolved in one liter of ethanol with concentrated hydrochloric acid, using methyl red indicator. Five hundred milliliters of ethyl ether was then added, and the hydrochloride was crystallized at about 0°, collected by suction filtration, washed with cold ether, and dried *in vacuo* for twelve hours at 25°.

Potassium Persulfate.—Reagent grade potassium persulfate was twice recrystallized from conductivity water, and the crystals dried *in vacuo* at room temperature.

Polymerization Technique.—The polymerizations were carried out in screw-cap bottles of 130-ml. capacity, sealed with pierced caps containing Buna-N self-sealing gaskets. The bottles were rotated end-over-end at about 35 r. p. m. in a thermostat and were sampled with hypodermic syringes in the same manner as described by Kolthoff and Dale.[1b] The 2-ml. samples thus obtained were expelled into weighed aluminum dishes containing 10.0 ml. of 0.02% aqueous hydroquinone solution, evaporated to dryness, and the residue dried for twenty–twenty-four hours at 80°. Per cent. conversion was calculated as previously described.[1b] The ingredients of the charge were added as described below.

(1b) I. M. Kolthoff and W. J. Dale, This Journal, **69**, 441 (1947).

Polymerization Recipe.—The following recipe, in which the amounts of several of the constituents were varied systematically, was used: styrene, 35.6 g. (39.3 ml. at 25°), designated as 100 parts; water, 65.7 ml., or 185 parts; emulsifier, 1.78 g. or 5 parts, based on the styrene. This quantity of emulsifier is designated as $1 - X$, and other quantities as fractions or multiples thereof. (Thus "$^1/_2 - X$" means 2.5 parts per 100 g. of styrene, or 0.89 g. per bottle.) When recipes containing dodecylamine hydrochloride were employed, the emulsifier was dissolved in water which had been flushed with nitrogen. No special effort was made to remove oxygen completely. Consequently, short and well-defined induction periods were observed, due to residual oxygen. In recipes with fatty-acid soap flakes, a given amount of oxygen causes a considerably larger induction period than in a dodecylamine hydrochloride recipe. To make the induction periods as short as possible, the dry soap flakes were brushed into the bottle while a current of nitrogen was passed into it, in the manner previously described.[1b] In both types of recipe, the styrene and aqueous persulfate solution were flushed with nitrogen while in the bottle. Potassium persulfate: 0.107 g. or 0.3 part, based on styrene. This quantity of persulfate is designated as $1 - X$ and other quantities as fractions or multiples thereof. The potassium persulfate was added as a solution in water. For $1 - X$ persulfate, 15.7 ml. of a 0.68% solution was added to each bottle. Retarders: the concentration of retarding substances is expressed as millimoles per 100 g. of styrene. The *m*-dinitrobenzene and 1,4-pentadiene were added as solutions in styrene. The 3,5-dinitrobenzoic acid was added as a water solution.

Experimental Results

Retardation by *m*-Dinitrobenzene.—Experiments were carried out with concentrations of *m*-dinitrobenzene varying between 0.052 and 0.830 millimole per 100 g. of styrene, employing both the DDA·HCl and soap flakes recipes. The conversion data obtained with the DDA·HCl recipe are plotted in Fig. 2, and the rates of conversion are presented in Table I. The results obtained with the soap flakes recipe are presented in Fig. 3 and Table II.

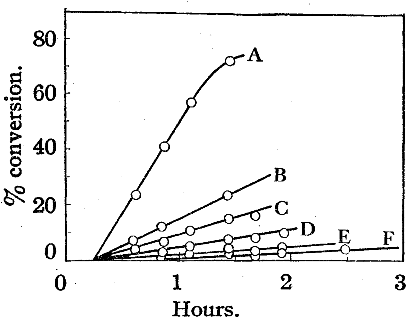

Fig. 2.—Effect of *m*-dinitrobenzene as retarder in emulsion polymerization of styrene: 1*X* dodecylamine hydrochloride, 1*X* persulfate, 50°, concentration of *m*-dinitrobenzene expressed in millimoles per 100 g. of styrene: A, 0.0; B, 0.052; C, 0.104; D, 0.208; E, 0.415; F, 0.830.

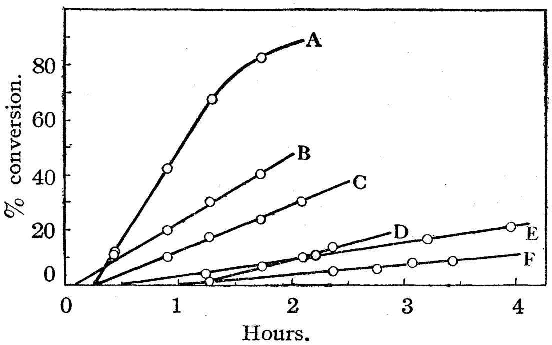

Fig. 3.—Effect of *m*-dinitrobenzene as retarder in emulsion polymerization of styrene: 1*X* S. F. flakes, 1*X* persulfate, 50°, concentration of *m*-dinitrobenzene expressed in millimoles per 100 g. of styrene: A, 0.0; B, 0.0520; C, 0.104; D, 0.208; E, 0.415; F, 0.830.

Since the smallest quantity of *m*-dinitrobenzene employed in the above experiments corresponds to only 0.0087% based on the styrene, it can be seen that *m*-dinitrobenzene is a very effective retarder. Its effectiveness is somewhat greater in the DDA·HCl recipe than in the S.F. flakes recipe. It produces no induction periods in either of the recipes, the small induction periods observed being caused by residual oxygen.

Effect of *m*-Dinitrobenzene on Molecular Weight of Polymer.—If *m*-dinitrobenzene exerts its effect in the soap micelle by terminating the growing polymer chains, the molecular weight of the polymer should be reduced. Accordingly, the experiments in Table II were repeated, the bottles being shortstopped with hydroquinone at times calculated to give approximately equal conversions in all cases. In addition, two more bottles were run, each containing 6.64 millimoles of *m*-dinitrobenzene per 100 g. styrene. These were shortstopped at 20% conversion (26 hr.) and 44% conversion (67.4 hr.). There appears in this case to be a considerable dependence of molecular weight on conversion.

The lattices obtained were coagulated with methanol and the polymer was dried *in vacuo* at 50°.

Intrinsic viscosities of 0.02% solutions in benzene were measured at 30°, using Ostwald pipets. The results obtained are summarized in Table III.

TABLE III

6.64	44.0	2.14

Effect of Large Concentrations of *m*-Dinitrobenzene at Varying Concentrations of Persulfate.—Polymerizations have been carried out in the presence of 0.415, 1.660, and 6.64 millimoles of *m*-dinitrobenzene per 100 g. of styrene, using different concentrations of persulfate. Figure 4 gives plots of the logarithm of the concentration of persulfate *versus* the logarithm of the observed rates of polymerization.

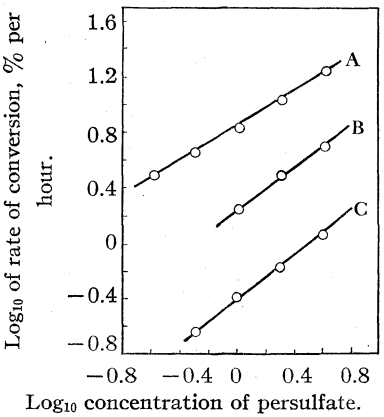

Fig. 4.—Log plots of rate of conversion *vs.* concentration of persulfate at three concentrations of *m*-dinitrobenzene, expressed in millimoles per 100 g. of styrene: A, 0.415; B, 1.66; C, 6.64.

The Disappearance of *m*-Dinitrobenzene during Polymerization.—If a retarder exerts its effect on the polymerization process by reacting with a fraction of the monomer and polymer radicals formed in the system, it appears that the retarder should become incorporated chemically into the polymer, and that the concentration of the free retarder in the reaction mixture should decrease during the polymerization. Experiments have been carried out to measure this decrease. The concentration of unconsumed *m*-dinitrobenzene was determined polarographically.

Curve A in Fig. 5 shows the reduction wave of 0.000880 *M* *m*-dinitrobenzene in 83% ethanol, the solution being 0.1 *N* in hydrochloric acid. It is seen that the reduction wave is composed of two waves, the first diffusion current being very poorly defined and not suitable for analytical purposes. On the other hand, the total diffusion current at potentials between −0.35 and −0.75 volt is well defined, and is suitable for analytical application. Assuming that the diffusion coefficient of *m*-dinitrobenzene is of the same order of magnitude as that of *p*-benzoquinone and benzaldehyde, it is found that the total diffusion current corresponds to a transfer of eight electrons per molecule. Since the height of the first wave is half that of the total wave, it may be concluded that *m*-dinitrobenzene is reduced at the dropping electrode in two steps, each corresponding to the reduction of the nitro group to a hydroxylamino group.

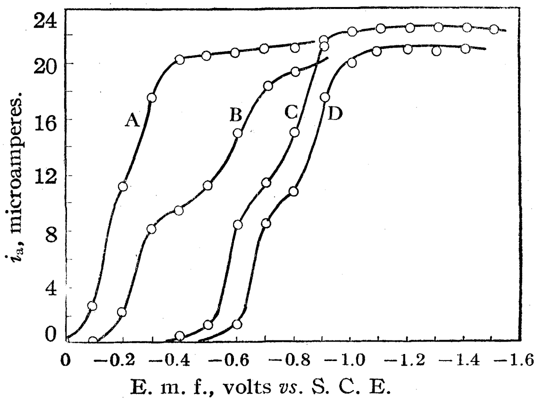

Fig. 5.—Polarographic reduction waves of 0.000880 *M* *m*-dinitrobenzene: A, in 83% ethanol, 0.1 *N* in HCl; B, same as A, but 1.5 ml. of styrene added to 25 ml. of solution in cell; C, in 90% ethanol, 0.1 *N* ammonium chloride plus ammonia, *p*H 8.5; D, same as C, but 1.5 ml. of styrene added to 25 ml. of solution in the cell.

From Curve B, it is seen that the presence of 6% styrene in the solution shifts the *m*-dinitrobenzene wave to more negative potentials, the first diffusion current becoming considerably more pronounced than in the absence of styrene. Unfortunately, the total diffusion current is no longer suitable for analytical purposes because of the appearance of the hydrogen wave.

By increasing the *p*H of the solution, the *m*-dinitrobenzene wave is displaced to more negative potentials. In Curve C is shown the wave of the nitro compound in 90% ethanol, the solution being 0.1 *M* in ammonium chloride, and containing enough ammonia to turn phenol red barely red (*p*H about 8.5). As is seen from Curves C and D the total diffusion current is now easily measurable, even though the presence of styrene shifts the wave to more negative potentials. The lowering of the diffusion current in Curve D is due entirely to dilution with styrene.

In preliminary work, about 20 g. of latex was coagulated in ethanol, and the *m*-dinitrobenzene determined. By adding known amounts of *m*-

dinitrobenzene to a 100% conversion polystyrene latex and coagulating in ethanol, it was found that a considerable amount of the *m*-dinitrobenzene was held in the coagulated polymer. Apparently the *m*-dinitrobenzene is soluble in polystyrene. After further investigation, the following procedure was adopted:

Approximately 25 g. of the latex was weighed into a 100-ml. beaker. In order to reduce the persulfate present, which interferes with the determination of the *m*-dinitrobenzene, 2.5 ml. of 6 *N* HCl and 5.0 ml. of a 5% aqueous solution of hydroxylamine hydrochloride were pipetted in. The contents of the beaker were heated to boiling to complete the reduction and allowed to cool. The polymer had now coagulated. Ammonia (about 3 *N*) was then added until phenol red turned red. The solution was decanted from the polymer through a coarse filter, the filtrate being caught in a 100-ml. volumetric flask. The polymer was washed in the beaker with alcohol and the washings were added to the filtrate. The polymer was extracted with 75 ml. of boiling 22:78 ethanol–benzene for three hours. It was established that by extracting with this solvent mixture, which swells the polymer considerably, 94% of a known quantity of *m*-dinitrobenzene added to a polystyrene latex could be recovered. To remove most of the benzene, the extracting liquid was boiled down on a steam-bath with frequent addition of ethanol. The ethanol solution was then added to the 100-ml. volumetric flask containing the filtrate, and the contents of the flask were diluted to volume with ethanol. This solution was then analyzed polarographically, using the diffusion current at −1.40 volt, and comparing to the current obtained with a known solution of *m*-dinitrobenzene in the same solvent.

This procedure was applied to a recipe containing 1*X* DDA·HCl, 1*X* persulfate, and 0.916 millimole of *m*-dinitrobenzene per 100 g. of styrene. After a reaction time of twenty-four hours, 33.5% conversion was obtained. This is a rate of about 1.4% per hour, or only about 2% of the normal rate in the absence of retarder. A control bottle containing no persulfate but the same quantities of the other ingredients was also run. No conversion occurred in this bottle.

m-Dinitrobenzene was determined after twenty-four hours in both bottles, two samples being taken from the bottle containing persulfate. The results obtained are summarized in Table IV.

TABLE IV

DISAPPEARANCE OF *m*-DINITROBENZENE DURING EMULSION POLYMERIZATION OF STYRENE, 1*X* DDA·HCl, 50°

Expt.	Concn. per sulfate	Conversion in 24 hours	Concn. *m*-dinitrobenzene, millimoles per 100 g. styrene initially present		Rate of *m*-dinitrobenzene disapp., millimoles/hour/liter of aqueous phase
			Initial	Final	
1	1*X*	33.5	0.916	0.609 0.590	0.069 0.073
2	0	0	.916	0.916	0.0

In the last column, the rate of disappearance (assumed to be linear over the twenty-four hour period) of the *m*-dinitrobenzene is expressed as millimoles per hour per liter of aqueous phase, in order to facilitate comparison with the rate of disappearance of *p*-benzoquinone (see "Discussion").

It should be noted that the quantity of *m*-dinitrobenzene that has disappeared, and which we assume to have become chemically bound into the polystyrene molecules, corresponds to a nitrogen content in the polymer of only about 0.026%. While this quantity is determinable by refined methods, the method employed in this investigation appears to be more sensitive and precise, although of course it does not directly indicate the fate of the *m*-dinitrobenzene.

Solubilization of *m*-Dinitrobenzene in Solutions of Emulsifiers.—In connection with the problem of the locus at which a retarder exerts its effect, the solubilization of *m*-dinitrobenzene in 0.14 *M* solutions of dodecylamine hydrochloride and soap flakes (corresponding approximately to "1*X*" in the standard recipe) was measured.

An excess (about 1 g.) of *m*-dinitrobenzene was added to 100 ml. of the emulsifier solution in a screw-cap polymerization bottle. The bottle was rotated for twenty-four hours at 50°, and then a 5.0-ml. sample was removed with a pipet (carrying a glass wool filter on the end), 2.5 ml. of 1 *M* ammonium acetate was added, and the solution diluted to 25 ml. with ethanol. The concentration of *m*-dinitrobenzene was determined polarographically. A blank, using 0.14 *M* ammonium chloride solution instead of DDA·HCl solution, was also run. The results are shown in Table V.

TABLE V

SOLUBILIZATION OF *m*-DINITROBENZENE IN G. PER 100 ML. OF SOLUTION IN 0.14 *M* SOLUTIONS OF DDA·HCl AND S. F. FLAKES

(0.14 *M* NH_4Cl)	0.14 *M* DDA·HCl	0.14 *M* S. F. Flakes
0.147	0.270	0.310
.140	.250	
	.250	

The results indicate conclusively that *m*-dinitrobenzene is solubilized in solutions of the two emulsifiers.

Combined Effect of Oxygen and *m*-Dinitrobenzene.—It has been established[2] that during the induction period caused by oxygen in the emulsion polymerization of styrene, the oxygen is consumed by copolymerizing with the styrene to produce a polymeric styrene peroxide. The rate of this copolymerization is only about 0.1% of that of the normal polymerization in the absence of oxygen. The polymer produced has an average chain length of about 40 styrene peroxide  $-(-\underset{C_6H_5}{\underset{|}{CH}}CH_2OO-)-$ units. It appeared that if this chain process were interrupted by an effective retarder, for example, *m*-dinitrobenzene, the rate of consumption of the oxygen would be decreased, and the induction period caused by a given quantity of oxygen would be prolonged.

An experiment was carried out using 1*X* S. F. flakes, 2*X* $K_2S_2O_8$ and three concentrations of *m*-

---

dinitrobenzene. In each bottle, 29 ml. of air and 101 ml. of liquid phase were present. The conversion curves obtained are shown in Fig. 6. It can be seen that the induction period caused by oxygen is not affected by the presence of *m*-dinitrobenzene.

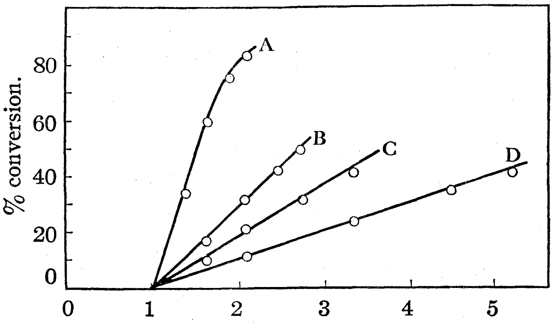

Fig. 6.—Effect of *m*-dinitrobenzene on induction period caused by 29 ml. of air per 101 ml. of charge in 1*X* S. F. flakes, 2*X* persulfate recipe, 50°; concentration of *m*-dinitrobenzene in millimoles per 100 g. of styrene: A, 0.0; B, 0.104; C, 0.208; D, 0.415.

Retardation by 1,4-Pentadiene.—This substance is an example of one type of retarder which may be encountered in commercial practice, since it is believed to occur as an impurity in technical butadiene. In addition, the structure —CH=CHCH$_2$CH=CH— which occurs in this compound also occurs in linoleic and linolenic acids. It is known from investigations carried out in this Laboratory that linoleic acid acts as an effective retarder when present as its sodium soap in commercial soap flakes. Linolenic acid has an even greater retarding effect. It was therefore of interest to compare equal molar quantities of 1,4-pentadiene and of a powerful retarder such as *m*-dinitrobenzene. In Table VI the rates of conversion with varying concentrations of 1,4-pentadiene are presented.

Table VI

Rates of Conversion with Varying Concentrations of 1,4-Pentadiene in Emulsion Polym. of Styrene at 50° 1*X* S. F. Flakes, 1*X* $K_2S_2O_8$

Concn. 1,4-pentadiene, millimoles per 100 g. styrene	Concn. 1,4-pentadiene, parts per 100 g. of styrene	Rate, %/hr.
0	0	78
0.415	0.028	74
0.830	.056	56
1.66	.113	43
3.32	.225	34

It is evident that 1,4-pentadiene is a much less effective retarder than *m*-dinitrobenzene.

3,5-Dinitrobenzoic Acid as Retarder.—If the locus at which a typical retarder, such as *m*-dinitrobenzene, exerts its effect is confined to the soap micelle and polymer particle, it appears that a compound having the structure of a retarder—for example, having two nitro groups in *meta* positions on a benzene ring—would be ineffective if it contained in addition a strongly polar functional group which confined it to the true water phase (*i. e.*, dissolved in water, but not in the micelles or in the polymer particles). Accordingly, 3,5-dinitrobenzoic acid, which has nitro groups meta to each other, was first tried in the alkaline recipe with S. F. flakes in order to compare its effect with that of *m*-dinitrobenzene. The acid is relatively strong ($K = 1.55 \times 10^{-3}$ at 25°), and at a *p*H of about 9, the concentration of free acid is vanishingly small.

In Figure 7 and Table VII are presented data for varying concentrations of 3,5-dinitrobenzoic acid in a 1*X* soap flakes, 1*X* persulfate recipe.

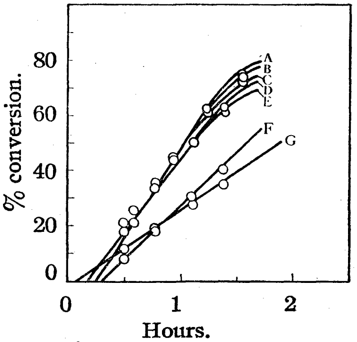

Fig. 7.—Effect of 3,5-dinitrobenzoic acid in emulsion polymerization of styrene: 1*X* S. F. flakes, 1*X* persulfate, 50°; concentration of retarder in millimoles per 100 g. of styrene: A, 0.0; B, 0.0415; C, 0.0830; D, 0.166; E, 0.332; F, 0.663; G, 1.33.

It will be observed that 3,5-dinitrobenzoic acid is very much less effective as a retarder in this recipe than an equal molar quantity of *m*-dinitrobenzene. Although the dinitrobenzoate is a very ineffective retarder, it was anticipated that the free acid would behave in a manner similar to that of *m*-dinitrobenzene, and that the retarding effect of the benzoate would increase with increasing hydrogen ion concentrations in the recipe. This was proved to be true. In Table VII are shown data obtained with a 1*X* DDA·HCl recipe in which the *p*H of the aqueous phase was made 3.3 (measured with the glass electrode) by adding acetic acid to a concentration of 0.3 *M* and sodium acetate to a concentration of about 0.03 *M*. The conversion curves are plotted in Fig. 8.

Table VII

Rates of Conversion with 3,5-Dinitrobenzoic Acid at Various *p*H's Compared to Effect of *m*-Dinitrobenzene at *p*H 9. Concn. Retarder in Millimoles per 100 G. of Styrene

Concn. of retarder → Retarder	*p*H	0	0.104	0.166	0.208	0.332	0.415	0.663	0.830	1.33
m-Dinitrobenzene	9.0	65	17	..	10	..	6.5	..	4	..
3,5-Dinitrobenzoic	9.0	65	..	58	..	58	...	40	..	30
acid	3.3	82	..	42	..	31	...	24	..	18
	1.0	66	..	21	..	11	...	4	..	1

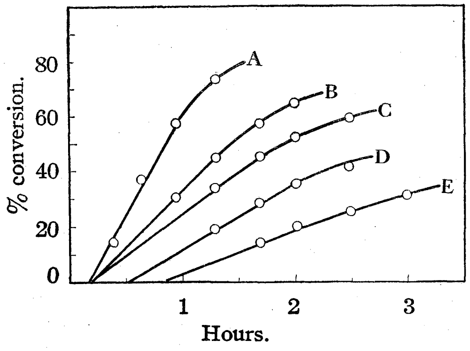

Fig. 8.—Effect of 3,5-dinitrobenzoic acid in emulsion polymerization of styrene: 1*X* S. F. flakes, 1*X* persulfate, sodium acetate–acetic acid buffer, *p*H 3.3, 50°; concentration of retarder in millimoles per 100 g. of styrene: A, 0.0; B, 0.166; C, 0.332; D, 0.663; E, 1.33.

This set of experiments was then carried out using the same recipe, except that instead of the sodium acetate–acetic acid buffer, the aqueous phase was made 0.1 *N* in hydrochloric acid, giving a measured *p*H of 1.0. The rates of conversion obtained under these conditions are also shown in Table VII, and plotted in Fig. 9.

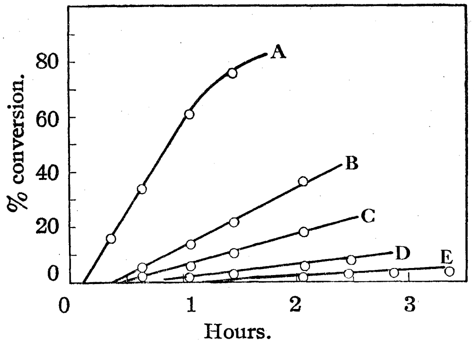

Fig. 9.—Effect of 3,5-dinitrobenzoic acid in emulsion polymerization of styrene: 1*X* dodecylamine hydrochloride, 1*X* persulfate, 0.1 *N* HCl; *p*H 1.0, 50°; concentration of retarder in millimoles per 100 g. of styrene: A, 0.0; B, 0.166; C, 0.332; D, 0.663; E, 1.33.

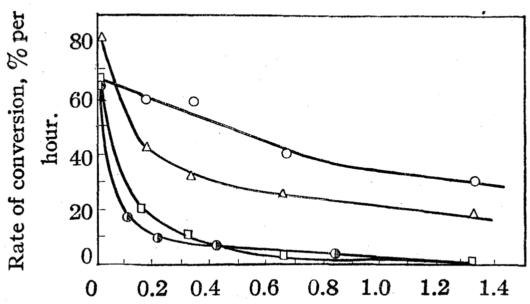
In Figure 10, the data of Table VII are plotted. It is evident from this plot that 3,5-dinitrobenzoic acid becomes equal in effectiveness to *m*-dinitrobenzene when the hydrogen ion concentration is high enough so that the acid is essentially un-ionized.

TABLE VIII

RATES OF CONVERSION AND INTRINSIC VISCOSITIES OF POLYSTYRENE IN PRESENCE OF 3,5-DINITROBENZOIC ACID; 1*X* $K_2S_2O_8$, 1*X* S. F. FLAKES, 0.03 *M* IN NaOH. CONCN. OF 3,5-DINITROBENZOIC ACID IN MILLIMOLES PER 100 G. OF STYRENE

Concn. of 3,5-dinitrobenzoic acid	Rate, %/hr.	η_i at 25°
0	67	13.2
1.33	46	12.0
2.65	47	12.5



Concentration of retarder, millimoles per 100 g. styrene.

Fig. 10.—Effect of 3,5-dinitrobenzoic acid at varying *p*H compared to effect of *m*-dinitrobenzene at *p*H 9: O, 3,5-dinitrobenzoic acid at *p*H 9.0; Δ, same at *p*H 3.3; □, same at *p*H 1.0; half-shaded circle, *m*-dinitrobenzene (*p*H 9).

Effect of 3,5-Dinitrobenzoate at High *p*H on Molecular Weight of Polymer.—An experiment was carried out with 1*X* $K_2S_2O_8$ and 1*X* S. F. flakes, using 1.33 and 2.65 millimoles of 3,5-dinitrobenzoic acid per 100 g. of styrene. The aqueous phase was made 0.03 *M* in NaOH. The rates of conversion and intrinsic viscosities of the polymers are shown in Table VIII.

It will be observed that, although considerable retardation is produced by these concentrations of 3,5-dinitrobenzoic acid at this high *p*H, the molecular weight of the polymer is practically unaffected.

Discussion

1. From the viewpoint of the locus of reaction, the retarding effects of 3,5-dinitrobenzoate and of 3,5-dinitrobenzoic acid are very instructive. At a *p*H of 10, all of the dinitrobenzoate may be considered to be present in ionic form, and in the "true" aqueous solution (not the soap micelles). As mentioned in previous papers,[1,2] evidence has been obtained in this Laboratory that persulfate exerts its activating effect mainly in the true aqueous phase. Therefore, at a *p*H of 10 the dinitrobenzoate reacts with a fraction of the radicals produced in the aqueous phase. However, it cannot interfere with the chain propagation reaction, which takes place in the soap micelles during the early stages of conversion and in the polymer particles in the later stages of conversion.[3]

On the other hand, at a *p*H of 1, the dinitrobenzoic acid may be considered to be entirely in the un-ionized form and to be in the styrene phase and solubilized with the styrene in the micelles. The retarding effect of the 3,5-dinitrobenzoic acid is now comparable to that of *m*-dinitrobenzene. At a *p*H of 1 these substances have no opportunity to react with the free radicals produced in the true aqueous phase, but act rather as chain-breakers at the locus of propagation.

The above interpretation is substantitated by the results obtained in the measurement of the

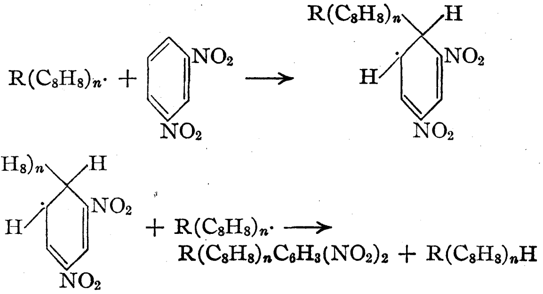
---

(3) W. D. Harkins, *J. Chem. Phys.*, **13**, 381 (1945); THIS JOURNAL, **69**, 1428 (1947).

intrinsic viscosities of the polymers. In the experimental part it has been shown that the polymer formed in the S. F. flakes recipe in the presence of dinitrobenzoate has practically the same intrinsic viscosity, and therefore molecular weight, as the polymer produced in the absence of this mild retarder. On the other hand, the molecular weight of the polymer formed is greatly reduced in the presence of *m*-dinitrobenzene in the same recipe (see Table III). It also has been shown that *m*-dinitrobenzene is solubilized in solutions of the two detergents used in this investigation. Hence this retarder should be present at the locus of the propagation reaction during the early stages of conversion. We also have shown that *m*-dinitrobenzene is soluble in the polystyrene particles. Therefore, it will also be present at the locus of the propagation reaction when the polymer particles become the locus of polymerization.

At higher concentrations of 3,5-dinitrobenzoate, some complex effects have been observed which are being studied further.

2. Following the suggestion of Price,[4] the reaction of the growing polymer chains with *m*-dinitrobenzene may be interpreted as follows



The adduct formed by addition of the radical to the aromatic ring is so much stabilized by resonance as to be unable to react further with monomer, although it can undergo disproportionation with another radical, as indicated.

The following kinetic scheme should be applicable to bulk polymerization and to emulsion polymerization in the presence of retarders. M represents monomer, C catalyst, R· a monomer or polymer radical, r the retarder, and Rr· the stabilized radical formed by addition of retarder to a monomer or polymer radical:

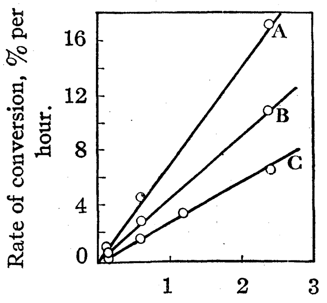


Fig. 11.—Reciprocal of *m*-dinitrobenzene concentration (millimoles per 100 g. styrene) *vs.* rate of polymerization at three concentrations of persulfate: A, 4*X*; B, 2*X*; C, 1*X*.

Initation: $M + C \longrightarrow R\cdot \qquad dR\cdot/dt = K_1(M)(C)$ (1)

Propagation: $R\cdot + M \twoheadrightarrow R\cdot$
$-dM/dt = K_2(M)(R\cdot)$ (2)

Normal termination: $2R\cdot \longrightarrow R_2$
$-dR\cdot/dt = K_3(R\cdot)^2$ (3)

Reaction with Retarder: $R\cdot + r \longrightarrow Rr\cdot$
$-dR\cdot/dt = K_4(R\cdot)(r)$ (4)

$Rr\cdot + R\cdot \longrightarrow Rr + RH$
$-dR\cdot/dt = K_5(R\cdot)(Rr\cdot)$ (5)

Where the concentration of (r) is very large, as with the three largest concentrations of *m*-dinitrobenzene, we may assume as a first approximation that termination of growing polymer chains occurs largely by (4) and (5) and that (3) may be neglected. We then have at the steady state

$$K_4(R\cdot)(r) + K_5(R\cdot)(Rr\cdot) = K_1(M)(C) \qquad (6)$$

$$-dM/dt = K_2(M)(R\cdot) = \frac{K_1K_2(M)^2(C)}{K_4(r) + K_5(Rr\cdot)} \qquad (7)$$

Also

$$K_4(R\cdot)(r) = K_5(R\cdot)(Rr\cdot), \text{ or} \qquad (8)$$
$$K_4(r) = K_5(Rr\cdot)$$

Thus instead of (7) we may write

$$-dM/dt = {}^1/_2\,\frac{K_1K_2(M)^2(C)}{K_4(r)}$$

In the presence of a separate styrene phase we find (M) constant, or

$$-dM/dt = K(C)/(r)$$

It has been well established[5] that in the normal emulsion polymerization of styrene without retarder and with persulfate as catalyst, the following relation holds

$$-dM/dt = K(C)^n$$

in which the value of *n* is 0.5. This relationship has also been repeatedly observed for bulk and solution polymerization with oil-soluble catalysts. From the slopes of the plots (Fig. 4) of the logarithm of the rate of conversion *vs.* the logarithm of the concentration of persulfate, in the presence of large concentrations of *m*-dinitrobenzene, the exponents *n* are found to be

Concn. *m*-dinitrobenzene	*n*
0.0	0.50
0.415	.63
1.660	.76
6.64	.83

As the concentration of retarder is increased the exponent *n* approaches a value of unity as predicted by the above kinetic expression. From the fact that a value of $n = 1$ is not reached, even when the rate of polymerization is less than 1% of the normal rate, it appears that even under these conditions, some normal recombination of polymer radicals (Step 3) occurs, or that the mecha-

nism of the normal emulsion polymerization reaction needs revision.

Using the data of Tables II and Fig. 4, it is also possible to test the prediction of expression (8) that at a given persulfate concentration the rate of polymerization should be proportional to the reciprocal of the concentration of retarder at large concentrations of retarder. It is seen from Fig. 11 that this is actually the case at three different persulfate concentrations.

3. Assuming the rate of disappearance of *m*-dinitrobenzene to be constant during polymerization, we find (see Table IV) that this rate is 0.071 millimole per hour per liter of aqueous phase. In a subsequent paper, dealing with the behavior of inhibitors, it will be shown that the rate of disappearance of the ideal inhibitor *p*-benzoquinone is 0.057 millimole per hour per liter of aqueous phase in the same recipe. There is evidence, which is not conclusive, that each molecule of *p*-benzoquinone reacts with two monomer free radicals, but that this substance does not copolymerize with the styrene to any appreciable extent under the conditions of our experiments. Since the rate of disappearance of *m*-dinitrobenzene is about the same as that of *p*-benzoquinone, it is evident that *m*-dinitrobenzene does not copolymerize with styrene, and that the adduct formed by addition of the growing polymer chain to the retarder molecule is incapable of reacting with monomer.

4. From the fact that the induction period caused by oxygen is not affected by the presence of *m*-dinitrobenzene, it is evident that this substance has no retarding effect on the copolymerization of oxygen with styrene. Apparently, *m*-dinitrobenzene cannot compete effectively with oxygen for monomer free radicals, nor with monomer for the peroxide free radicals formed by reaction of monomer radicals with oxygen.

Acknowledgment.—The authors acknowledge the assistance of Miss Julie M. Schott, who performed the experiments in which rates of polymerization were measured.

Summary

An experimental study has been made of the effect of retarders on the emulsion polymerization of styrene with potassium persulfate as catalyst. It is postulated that in the presence of large concentrations of a retarder, such as *m*-dinitrobenzene, the rate of polymerization should be given by

$$-\frac{\mathrm{dM}}{\mathrm{d}t} = K\frac{(\mathrm{C})^n}{(\mathrm{r})} \quad (n = 1)$$

where (C) = concentration of catalyst
(r) = concentration of retarder

The value $n = 1$ has been approached but not attained.

m-Dinitrobenzene is nearly equally effective as a retarder in alkaline and acid recipes. It acts as a chain-breaker and reduces the molecular weight of the polymer formed. From its rate of disappearance, it is concluded that it does not act as a comonomer, but that it reacts with growing polymer chains to produce adduct radicals incapable of further chain propagation.

3,5-Dinitrobenzoate is a very ineffective retarder at a *p*H of 10, but the free acid becomes equal in effectiveness to *m*-dinitrobenzene at a *p*H of 1. The behavior of water-soluble and oil-soluble retarders is explained on the basis of the loci of the activation and propagation reactions.

The Role of Bulk Cobalt Carbide in the Fischer–Tropsch Synthesis[1]

By Sol Weller,[2] L. J. E. Hofer[2] and R. B. Anderson[2]

The Fischer–Tropsch synthesis involves formation of hydrocarbons by the passage of carbon monoxide–hydrogen mixtures over metallic catalysts, usually cobalt or iron, at elevated temperatures. With cobalt catalysts, the equation for the reaction may be written approximately as

$$x\mathrm{CO} + 2x\mathrm{H_2} = (\mathrm{CH_2})_x + x\mathrm{H_2O}$$

The hypothesis that the synthesis proceeds through the intermediate formation of a metal carbide was first suggested by Fischer and Tropsch[3] in 1926. It has been popular ever since in the scientific and the technical literature[4]; patents have even been granted based on the idea that carbiding of catalysts before synthesis is desirable.[5]

The concept of metal carbide as a synthesis intermediate has heretofore been used rather loosely. Distinction has rarely been made between bulk carbide and some sort of "surface" carbide as a possible intermediate. Craxford and Rideal,[4] for example, have done some of the important work on the mechanism of the synthesis and speak of "surface" carbide; they give as evidence for the carbide theory, however, only examples indi-

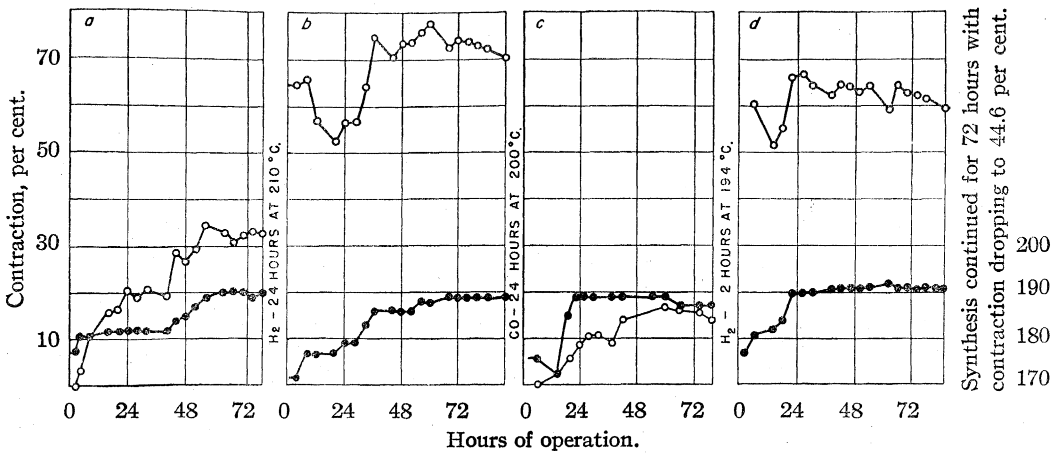

Fig. 1.—Apparent contraction ○ and temperature of operation ● *versus* time for test 73 with cobalt catalyst 108 B at atmospheric pressure. Catalyst was reduced in hydrogen at 360° and carbided with carbon monoxide at 200° for twenty-four hours prior to testing.

cating that bulk carbide accumulates in the catalyst under some conditions. The idea of "surface" carbide is a particularly elusive one, since it is very difficult to distinguish between a "surface" carbide and adsorbed carbon monoxide. The role of "surface" carbide as an intermediate in the synthesis will not be discussed here, but evidence will be presented which demonstrates that bulk carbide, in the case of cobalt catalysts, probably is neither an intermediate in the synthesis nor a catalytically active substrate for the synthesis.

Results and Discussion

Inhibition of Synthesis.—The presence of extensive amounts of carbide in cobalt catalysts severely inhibits the Fischer–Tropsch synthesis. In one experiment, for example, a cobalt–thoria–magnesia–kieselguhr (100:6:12:200) catalyst[6] was reduced with hydrogen at 400°, and carbided with carbon monoxide for twenty hours at 200°; the volume of carbon monoxide reacted was equivalent to 70% conversion of the cobalt to Co_2C. (Treatments of catalysts with hydrogen, carbon monoxide, and synthesis gas were carried out at atmospheric pressure.) Exposure of this carbided sample to circulating synthesis gas resulted in an over-all synthesis rate at 150° of 60–70 $\times 10^{-4}$ g. C/g. Co/hour. After removal of the carbide by hydrogenation at 150–194° and re-exposure of the sample to synthesis gas, a synthesis rate of 250–300 $\times 10^{-4}$ g. C/g. Co/hour was observed—an increase of 400%. The distribution of the synthesis products was about the same in both cases.

In another experiment, a sample of cobalt–thoria–kieselguhr (100:18:100) catalyst[7] was carbided in carbon monoxide at 210° to an extent equivalent to 110% Co_2C.[8] This sample was observed to have no appreciable activity in flowing synthesis gas, while a control sample, similarly reduced initially but not carbided, gave copious yields of oil and water. Partial hydrogenation of the carbided sample at 190°, with removal of 72% of the carbon which had been introduced, restored the activity to about one-half the normal value.

The loss of synthesis activity on carbiding can persist even when synthesis is continued for several days. This behavior is illustrated in Fig. 1. A sample of cobalt–thoria–kieselguhr catalyst[7] was carbided for 24 hours at 200° after initial reduction. On exposure to flowing synthesis gas at 182°, the carbided sample originally showed no catalytic activity, as measured by the fractional decrease in gas volume (contraction) as the gas passed through the converter (Fig. 1a). During operation for one day at 182°, the contraction rose to 20% but did not increase further during another eighteen hours of synthesis. Increasing the temperature to 190° increased the contraction only to 33%, even after a day. Subsequent hydrogenation of this sample at 210° and re-exposure to synthesis gas resulted in a (normal) contraction greater than 70% at 189° (Fig. 1b). Recarbiding the active catalyst for 24 hours at 200° again reduced the activity to the low value observed after the first carbiding (Fig. 1c) and rehydrogenation of the carbided sample again restored the normal activity (Fig. 1d).

This inhibitory effect of precarbiding before synthesis is not explainable as a poisoning due to free carbon deposited during the carbiding, since the effect is completely reversed by hydrogenation at temperatures where free carbon is not affected.[9] It is also known that carbiding of cobalt catalysts

results in the formation of not more than a monolayer of oxide or chemisorbed carbon monoxide[10]; since this is easily removed by hydrogen at 200° it might be expected to be removed by synthesis gas, and therefore to be not responsible for the inhibition. These experiments show, then, that bulk cobalt carbide is not a catalyst for the synthesis.

Bulk Carbide in Used Catalysts.—A second line of evidence which indicates that bulk cobalt carbide is not important in the synthesis is furnished by X-ray analysis of catalysts that have been used in the synthesis. It has previously been shown[11] that, on low-temperature carburization with carbon monoxide, reduced cobalt catalysts form a carbide, Co_2C, which has a characteristic X-ray diffraction pattern. This fact provides a means of identifying cobalt carbide in the catalyst. It has been observed by X-ray analysis that, if catalyst samples are partly carbided before synthesis and then used in synthesis, carbide is still present in the samples even after several days of synthesis. (In pure hydrogen, the carbide would have been completely removed as methane in several hours.) On the other hand, if the samples are used in the synthesis immediately after reduction (that is, no precarbiding), no carbide is found at the conclusion of the synthesis. In other words, bulk carbide apparently is not built up during steady-state synthesis in quantity sufficient to be detected by X-ray analysis, while carbide already present apparently is not removed at an appreciable rate during steady-state synthesis. Although quantitative determinations of the amount of carbide present under given conditions have yet to be made, the indication is that bulk carbide is neither formed nor destroyed as part of the synthesis process.

Cobalt in Used Catalysts.—The final evidence to be adduced in connection with the role of bulk carbide is also based on X-ray diffraction analysis. Cobalt in catalysts reduced at 400° is present primarily as face centered cubic cobalt.[11,12] There is a transition between face centered cubic cobalt and hexagonal close packed cobalt at about 400°.[13,14] The transition is very sluggish and there is an unusual type of disorder in the hexagonal structure near the transition point.[15] At the temperature of the Fischer–Tropsch synthesis on cobalt–thoria–kieselguhr catalysts (225° and below), the cubic cobalt is thermodynamically unstable with respect to the hexagonal close packed cobalt. Carbiding of the reduced sample containing cubic cobalt, followed by hydrogenation of the carbide so formed, both at 200°, always converts the cobalt to the low-temperature stable, hexagonal close packed form.[11] Now, all samples of cobalt catalysts (not precarbided) which have been examined after use in the synthesis have given a diffraction pattern identical with that of the freshly reduced catalyst. If any appreciable quantity of the cobalt had been through the cycle of carbiding and hydrogenation *at any time* during the synthesis, it would have appeared as close packed hexagonal cobalt rather than cubic.[16] Since this does not occur, it follows that, within the limits of the X-ray method, cobalt was not converted to bulk carbide and subsequently hydrogenated during the synthesis, that is, bulk carbide is not an intermediate in the synthesis.

Summary

Evidence is presented that for cobalt catalysts, bulk cobalt carbide is neither an intermediate in the Fischer–Tropsch synthesis nor a catalytically active substrate for the synthesis:

1. The presence of extensive amounts of carbide in cobalt catalysts severely inhibits the Fischer–Tropsch synthesis.
2. Used catalysts show no carbide by X-ray analysis, but samples carbided before synthesis show carbide to be present after synthesis.
3. The low-temperature unstable cubic cobalt produced by reduction of cobalt catalysts is not converted to hexagonal cobalt during the synthesis, although carbiding and subsequent hydrogenation of a reduced catalyst always results in this conversion.

[12] The expected 200 line in the powder pattern of the reduced cobalt is almost entirely absent as has been previously mentioned.[11] A detailed discussion of this unusual diffraction pattern will be published. However, the unusual diffraction pattern of the cubic cobalt does not affect the validity of the reasoning concerning the function of bulk carbide in the Fischer–Tropsch reaction.

[16] Because of difficulties inherent in X-ray diffraction analysis this statement is not strictly correct. If, for example, the carbiding-hydrogenation cycle occurs only in the outermost 10–20 atomic layers of cobalt particles, this phase change may not be detected by X-rays. Also X-ray diffraction analysis under any conditions will not detect less than 5% of a minor crystalline constituent so that if less than 5% of cobalt went through this cycle, the change would not be detected.

The Dielectric Properties of Solid and Liquid *cis*- and *trans*-Decahydronaphthalene

By Wm. F. Seyer and Gordon M. Barrow[1a]

The measurement of the dielectric constant of *cis*- and *trans*-decahydronaphthalene over a temperature range constitutes another addition to a series of measurements made on these substances. Hydrocarbons have in the pure state a low dielectric constant and have either zero or a very low value for the dipole moment. Hence very slight polarity is to be expected in these bicyclic hydrocarbons and this polarity is possible only when the molecules exhibit some lack of symmetry. One would, therefore, expect the symmetrical *trans* isomer to have no dipole whereas the unsymmetrical *cis* isomer might have a small permanent dipole moment.

In the present investigation it was decided to measure the dielectric constant over a temperature range for both liquid and solid. Any difference in behavior might then throw some light on the spatial structures of these two compounds. The problem of the dielectrics of non-polar substances in solid form has only recently been considered and the theory is therefore limited. Considerable theory has been developed for long-chain ketones which, being polar, show a pronounced change of polarization when they become fixed in a crystal lattice.[1b] Such changes in the dielectric constant of non-polar compounds have been found to be relatively small. Thus Müller noticed that the dielectric constant of a long-chain hydrocarbon increased at the freezing point by 2 to 6% for different experiments.[2] His work, however, was directed toward the measurement of polar compounds and he considered the changes for the hydrocarbon to be negligible. Much experimental work has been done on measuring the dielectric constant change in passing through the melting point region but little in the reverse direction. Recently R. Giullien[3] reported discontinuities in the dielectric constant–temperature relationships near the fusion point.

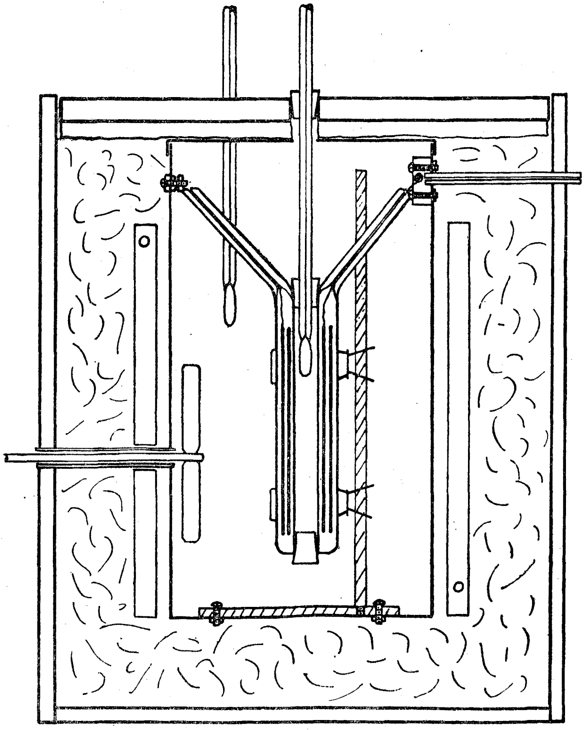

Fig. 1.—Test cell assembly.

The difficulties of measuring the dielectric constants with a cell suitable for both liquid and solid states is at once apparent. The dielectric constant change when the material in the cell crystallizes will depend somewhat upon the rate of crystallization, the type of crystals formed, the viscosity of the material, its latent heat and the temperature at which crystallization starts. All these factors will probably effect the nature of voids between the plates of the condenser. These voids will tend to lower the dielectric constant an indeterminate amount. As a result of these uncertainties it would be extremely difficult to obtain accurate values of the dielectric constant through the transition range from liquid to solid or the reverse. It should be possible, however, to get an indication of the nature of the change transpiring and a comparison of the behavior of the two isomers.

Procedure.—The dielectric constants were measured by using an electrical circuit designed by Alexander[4] and constructed here by Basil A. Dunell.[5] He, using a plate potential of 90 volts, had previously encountered troublesome drifts with the set-up which were, however, completely eliminated in the present case by raising the plate voltage to 160 volts. Also the open stainless steel cell used by him was replaced by one (Fig. 1) similar to that designed by Smyth[6] as evaporation losses were thus eliminated. Instead of three concentric cylinders as in the Smyth cell only two were used with an annular space of 0.09 cm. For shielding, the entire cell was placed in a grounded metal container. The cell held about 40 cc. of the test liquid.

Temperatures between room temperature and −40° were obtained by circulating acetone through the jacket and a copper coil immersed in a Dry Ice–acetone-bath. Temperatures below this and down to −60° were obtained by adding Dry Ice directly to the cell container.

Above room temperature, the temperature was measured by a calibrated mercury thermometer placed in the air-bath. This thermometer could not be placed in the

center of the cell because the mercury column would carry induced currents to the unshielded center plate. For measuring low temperatures a pentane thermometer was used. This was immersed in a liquid in the center cavity of the cell. Gasoline, being non-polar and having a low freezing point, was used as the liquid. This arrangement gave temperatures which at all times were very close to that of the liquid in the cell itself. With the mercury thermometer arrangement, however, considerable time was required for the liquid in the cell to come to the temperature indicated by the thermometer.

Materials.—The benzene used for calibrating the condenser was recrystallized "Merck thiophene-free benzene." Four crystallizations did not raise the freezing temperature, which remained constant over the entire freezing period. The freezing temperature as measured by a Leeds and Northrup platinum resistance thermometer was 5.38°. The sample was then taken as being pure.

The two isomers of decahydronaphthalene were samples taken from various lots of the material that had been prepared from time to time in this laboratory by methods previously described.[7] The *cis* form had freezing points lying between −43.15° and −43.24°, while that of the *trans* form lay between −30.64° and −30.80°. The cyclohexane was part of a sample specially prepared for spectroscopic work and had a freezing point of 6.5° and a refractive index of 1.4263 for the D line. All the hydrocarbons before use were dried by allowing them to stand for several days over metallic sodium.

Calibration of Cell.—The dielectric constant corresponding to the dial reading of the variable condenser was determined by observing the dial reading for resonance for benzene at a fixed temperature. The cell was filled with benzene and the two condensers (C_1 and C_2) were set so that the dial setting for circuit resonance was at the lower end of the dial for benzene at about 50°. With this setting the dielectric constants of both *cis*- and *trans*-decalin between 0° and 100° were in the dial range. The dial readings for benzene at other temperatures were also observed. From these results and from the known values of the dielectric constant of benzene a calibration curve could be drawn giving the dial readings in terms of the dielectric constant. Since the condenser had been found to vary linearly, the curve could be extrapolated to dial readings between 15 and 85.

The dielectric constants of benzene used in the calibration were taken from the results of Clay, Dekker and Hemelrijh[8] and were extrapolated to higher temperatures on the basis of the linear relation found by previous investigators.

Whenever it became necessary to change the setting of the condenser C_2 in order to measure dielectric constants in a different range, a known dielectric constant in the new range had to be measured and the calibration curve had to be shifted accordingly.

In order to find an unknown dielectric constant it was now only necessary to determine the dial reading for any fixed temperature. The dielectric constant could then be read off the calibration curve.

The maximum variation of the dial reading for successive runs at constant temperature was two dial divisions, corresponding to 0.003 dielectric constant unit. All the results, however, depend upon the benzene calibration and any error in this will produce a proportionate error in all the results. The relationships between the dial readings and the dielectric constants for benzene and those of the two bicyclic compounds were linear. Two methods of measuring the dielectric constants were used, one in which the temperature was kept constant to within 0.1°, and the other in which the temperature was allowed to rise or fall at a steady rate and dial readings were made over small temperature intervals. The values of the dielectric constant at various temperatures for *cis*- and *trans*-decahydronaphthalene were plotted and gave straight lines over the entire temperature range above their fusion points. The equations for these lines by the method of least squares was found to be for the *cis* compound: $\epsilon_{cis} = 2.238 - 0.00103T$ and for the *trans* compound $\epsilon_{trans} = 2.205 - 0.00101T$ where ϵ is the dielectric constant and T the absolute temperature.

Discussion of Results.—Careful attention was directed to the measurements of the dielectric property of the *cis* hydrocarbon in the neighborhood of 50°, since some of the other physical properties of this compound appeared to behave in an irregular manner at this temperature. None were observed in this case although Dunell[5] had observed a pronounced peak in the dielectric constant-temperature curve at this temperature. To test the behavior of this compound still further, a series of readings were made with the temperature slowly rising and falling over a temperature range from 40 to 90° with readings at intervals of 1°. The results when plotted showed decidedly linear relationships.

In measuring the dielectric constant at the liquid–solid transition point several difficulties were encountered. First, these difficulties were due to the fact that the cell and the circuit were designed specifically for the measurement of liquid dielectric constants at and above room temperatures. Since it was difficult to control the temperature in this region readings were taken with the temperature slowly falling or rising and no attempt was made to reach an equilibrium state. Second, the design of the cell made it rather difficult to add a seed crystal; hence, supercooling was another difficulty. Particularly was this so with the *cis*-isomer.

A third difficulty was fluttering and uncertainty due to the large changes in the dielectric constant at the freezing point. As mentioned previously, the circuit was constructed specially for the accurate measurement of small regular dielectric changes. This required a large capacity and a small L/R ratio resulting in considerable instability when abrupt dielectric constant changes were encountered.

Numerous runs for different samples of both the *cis* and *trans* hydrocarbons through the freezing and melting points were made. Typical runs are shown in Fig. 2. The configuration of the *trans*-decalin was remarkedly reproducible, largely perhaps due to the almost complete absence of supercooling. The maximum value of the dielectric constant for eight runs lay between 2.29 and 2.30. Much difficulty was encountered when working with the *cis*-decalin because of supercooling, and here it was always necessary to add a seed crystal to bring about the freezing process. Unlike the *trans*-decalin, only the general behavior and not the exact curves were reproducible.

What is striking in this case is the marked difference in shape of the two areas enclosed by the freezing and melting curves. This is most clearly seen in Fig. 3 where the curves drawn represent averaged values. In the case of *cis*-decalin the dielectric constant of the liquid just above the

---

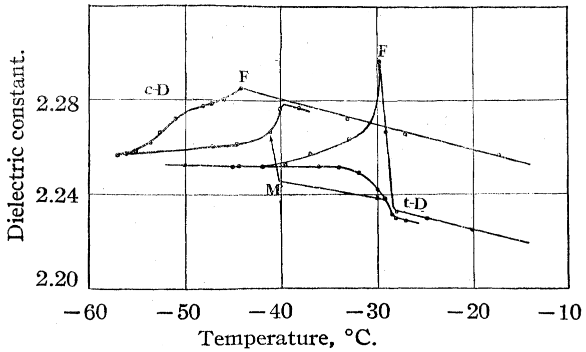

Fig. 2.—Typical run through freezing and melting points: *c*-D, *cis*-decalin; *t*-D, *trans*-decalin; M, melting point; F, freezing points.

freezing point is higher than that of the solid and the shape of the melting point curve is similar to that of many substances already examined, particularly glycerol. It is of course conceivable that if the freezing or melting processes were carried out infinitely slowly the area enclosed by the curves would vanish. In such a case freezing and melting would be a reversible process. It is obvious that the freezing process of the *trans*-decalin is quite different than that of the *cis*-isomer.

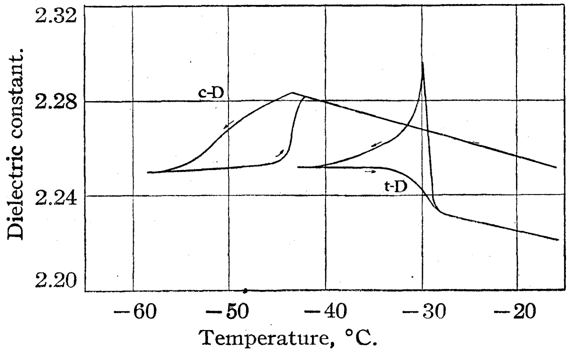

Fig. 3.—Averaged dielectric constant curves through freezing and melting points: *c*-D, *cis*-decalin; *t*-D, *trans*-decalin.

Here the dielectric constant of the liquid just above the freezing point is lower than that of the solid. During the freezing process the dielectric constant not only rises to meet that of the solid but rises considerably above it. Upon melting this path is not followed but the dielectric constant falls slowly to that of the liquid. As mentioned before, if little supercooling was allowed the curves were reproducible with considerable accuracy for the different runs. To investigate this matter further, the hydrocarbon cyclohexane was examined. Recent work on this compound indicates that at room temperatures this substance exists almost entirely in the *trans* state. The behavior of this compound is shown in Fig. 4 and its similarity to that of *trans*-decahydronaphthalene is noteworthy. In the case of cyclohexane the increase in the dielectric constant became so large during the freezing process that the reading was completely off the dial scale. Again, the dielectric constant of the liquid just above the freezing point is lower than that of the solid. Whether or not this sudden augmentation of the dielectric properties during the freezing or solidification process is characteristic of the *trans* state cannot be decided until further observations are made. However, in the case of these two compounds it must be assumed that some deepseated change in the geometrical structure of the molecule must take place, which would involve the loosening of some of the bonds during solidification. Figure 3 shows further that within the limits of experimental error the dielectric constant of solid *cis*- and *trans*-decahydronaphthalene is the same. This would lead one to suspect that the crystal structure of the two solids would be very similar. It would appear that in the *trans* system crystallization and melting are not, at least mechanically speaking, strictly reversible processes. Unlike the case of the *cis* isomer where crystallization and melting are merely the coagulation in an orderly manner and dispersion of the molecules, here some molecular change must precede crystallization.

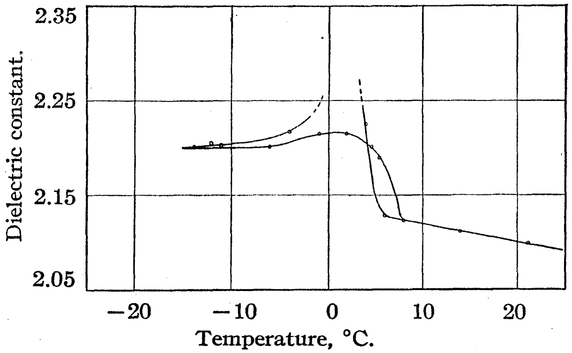

Fig. 4.—Dielectric constant of cyclohexane through freezing and melting points.

The molar polarizations (P) for *cis*- and *trans*-decahydronaphthalene have been calculated for a few temperatures up to 100° and are shown in Table I. The densities were those found previously in this laboratory.[9]

TABLE I

MOLAR POLARIZATION DATA FOR *cis*- AND *trans*-DECALIN

Temp., °C.	Density	Dielectric constant	*P*
	cis-Decalin		
20	0.897	2.219	44.4
50	.874	2.188	44.8
80	.852	2.156	45.1
100	.836	2.136	45.4
	trans-Decalin		
20	0.870	2.184	44.9
50	.848	2.150	45.2
80	.825	2.123	45.6
100	.810	2.103	45.8

---

[9] Seyer and Davenport, THIS JOURNAL, **63**, 2426 (1941).

The slightly larger value of P for the *trans*-isomer than for the *cis*-isomer is to be expected in view of the less compact structure of the former compound. At 20° this difference is close to 0.45. This is small but greater than the limits of error in the measurement of the dielectric constant. The polarizabilities (α) have been calculated in the usual manner and compared with those of benzene in Table II.

TABLE II

COMPARISON OF THE MOLAR POLARIZATIONS AND POLARIZABILITIES FROM RESULTS AT 20°

	P	α_{20}
Benzene	26.71	1.05×10^{-25}
cis-Decalin	44.4	1.75×10^{-25}
trans-Decalin	44.9	1.77×10^{-25}

Again it appears that the polarizability of the *trans*- is slightly greater than that of *cis*-isomer.

A comparison of the dielectric constants and the squares of the refractive index for the D line of sodium is made in Table III for benzene, cyclohexane and the two bicyclic hydrocarbons.

TABLE III

COMPARISON OF THE DIELECTRIC CONSTANT WITH THE SQUARE OF THE REFRACTIVE INDEX

	n_{20}	$(n_{20})^2$	ϵ_{20}	$\epsilon_{20} - n_{20}^2$
Benzene	1.50142	2.254	2.289	0.035
Cyclohexane	1.42635	2.033	2.052	.019
cis-Decalin	1.48113	2.194	2.219	.025
trans-Decalin	1.46968	2.160	2.184	.024

It is seen that even for the simple theory which is not directly applicable to liquids the agreement is quite satisfactory. All results indicate a zero or a very small dipole moment for both isomers.

Summary

1. The dielectric constant of *cis*-decalin has been measured at 3.5 megacycles and 20° and has been found to be 2.219±0.003. The temperature coefficient between the freezing point and 100° is 0.0010 per °C. No anomalous behavior in any of the samples tested was observed between −40 and 100°.

2. Under the same conditions, *trans*-decalin has been found to have the values 2.184±0.003. The temperature coefficient between the freezing point and 100° is also 0.0010 per °C. As in the *cis*-isomer no anomalous behavior was observed.

3. The dielectric constant has been measured through the freezing point and to the solid phase. A marked difference in the behavior of the two isomers was observed. Furthermore, the curves for heating and cooling for both the decahydronaphthalene isomers and cyclohexane are quite different. Both *trans*-decalin and cyclohexane show a pronounced and unexplained maximum at the freezing point.

4. The molar polarizations of *cis*- and *trans*-decalin have been calculated at a number of temperatures and the variation with temperature has been found to be the same as the variation of the polarization of liquid benzene with temperature. Furthermore, the squares of the refractive indices are in close agreement with the dielectric constants.

5. The molar polarization of the *trans*-isomer is slightly larger than that of the *cis*-isomer. This indicates a looser or less compact molecular structure for the *trans*-isomer.

The Electric Moments of Hydrogen Fluoride, Hydrogen Chloride and Hydrogen Bromide in Several Non-polar Solvents[1]

BY A. J. WEITH, JR.,[1a] MARCUS E. HOBBS AND PAUL M. GROSS

Introduction

The electric moments of hydrogen fluoride, hydrogen chloride and hydrogen bromide in dilute solutions of non-polar solvents are of particular interest since measurements[2] by Fairbrother on some of the hydrogen halides in a limited number of solvents indicated that hydrogen chloride, hydrogen bromide and hydrogen iodide all exhibit a positive solvent effect. Hydrogen fluoride was not measured by Fairbrother; in fact, only recently has a value for the electric moment for this molecule been reported[3] and this was for the gas state. The present measurements were undertaken to establish the magnitude of the solvent effect for these solutes in a more extended series of solvents, to determine the value of the electric moment of hydrogen fluoride in solution and finally to establish the effect of bonding of these acid molecules to acceptor solvent molecules by measuring the electric polarization of the solutes in solutions of dioxane. It was hoped that, because of the relative simplicity of the halides, the data obtained would be useful in future attempts toward elucidation of the origin and mode of action of the solvent effect in electric moment measurements and that some insight might be gained into

the process occurring when solutes combine with solvents to which proton transfer might occur.

Materials, Apparatus and Procedure

Solvents.—Benzene (Jones and Laughlin reagent grade) which was found to be thiophene free was stored over calcium chloride and then refluxed and finally distilled over sodium through a 2-meter Dufton column. The middle fraction, of essentially one-half the total volume, was collected directly in a transfer flask so the solvent could be transferred directly to the dielectric measuring system. The middle fraction boiling range never exceeded 0.02°. Recovered benzene from previous measurements occasionally was used. It was treated with solid sodium hydroxide to neutralize the acid, totally distilled and finally distilled as above over sodium. No differences in the constants of this benzene and that of a fresh sample were noted.

1,4-Dioxane (Carbide and Carbon Chemical Corp., C. P. Grade) was refluxed over solid sodium hydroxide for several hours, then totally distilled. This product was then refluxed and finally distilled over sodium, the middle fraction being collected directly in the transfer flask. The distillation was carried out only when the sodium showed and retained a bright metallic surface and, in addition, when there was no visible evidence of reaction of the sodium and dioxane. The b. p. range for the middle fraction used was generally 0.06° or less. Recovered solvent from previous measurements was used after being subjected to the same treatment as a fresh sample of dioxane.

n-Heptane (California Chemical Co.) in two-liter portions was shaken repeatedly with about 500 ml. of concentrated sulfuric acid until no further darkening of the sulfuric acid layer was observed. In general four portions of acid were required. The heptane was washed with dilute sodium hydroxide solution and distilled water and finally dried with fused calcium chloride. It was then refluxed and distilled over sodium wire and the middle fraction collected directly in the transfer flask. The middle fraction had a maximum b. p. range of 0.04°. Recovered samples of heptane were used in some runs.

Carbon tetrachloride (Eastman Kodak Co. best quality sulfur free) was purified according to the method suggested by Williams and Krchma.[4] The middle fraction distilled over fused calcium chloride was collected in the transfer flask. The fractions used had a b. p. range not exceeding 0.03°.

The actual boiling points of all samples of solvents were not recorded but samples of the same solvents have, on repeated tests in this laboratory, shown b. p. (cor.) falling within the range indicated: benzene, 80.06 to 80.08°; 1,4-dioxane, 101.25 to 101.45°; *n*-heptane, 98.47 to 98.52°; and carbon tetrachloride, 76.73 to 76.76°.

The average values of the dielectric constant for the solvents at 30.0° based[5] on benzene, $E = 2.263$, are 1,4-dioxane, 2.218; *n*-heptane, 1.906, and carbon tetrachloride, 2.216.

Solutes

Hydrogen flouride (anhydrous) obtained from E. I. du Pont de Nemours and Co., in steel tanks was represented as better than 99% pure. No attempt was made to effect further purification except that slow distillation at room temperatures through a monel metal trap was effected to reduce possible carry-over of liquid from the cylinder. Two cylinders were used during the course of the investigation and the results show no measurable differences. The hydrogen fluoride was distilled directly into the mixing chamber containing the solvent, all operations being carried out so as to exclude moisture.

Hydrogen chloride (anhydrous) was obtained from the Dow Chemical Co. in a steel tank. A typical analysis by them showed 98.2% hydrogen chloride, the chief impurity being nitrogen. This material was allowed to pass at atmospheric pressure through three conventional tube-packed traps maintained a few degrees above the liquefying temperature of the gas with Dry Ice–alcohol mixture. A fourth trap in the same cooling mixture consisted of ten feet of closely coiled 7-mm. o.d. tubing. At no time during the measurements was a visible deposit found in any of the traps.

Hydrogen bromide (anhydrous) obtained from the Dow Chemical Co. in a steel tank was stated to contain no known impurities other than bromine and water. The same trap system and cooling arrangement as for the hydrogen chloride was used on the hydrogen bromide since it was expected that both known impurities would be effectively removed by this method. Repeated measurements with both hydrogen chloride and hydrogen bromide showed no variations other than those that could be accounted for by the normal experimental error in the method used.

Water was used for one measurement in dioxane. It was purified by treatment with potassium permanganate and distilled from a silica still with the middle fraction being collected in a silica receiver.

Apparatus.—The heterodyne beat method of measuring capacity change has been used in this investigation. The oscillator circuits of a modified Hartley type were obtained commercially in the form of a beat frequency Clough–Brengle Audio Oscillator (No. 79-E). The variable oscillator circuit of the Clough–Brengle generator was altered by placing the measuring condenser and the compensating standard precision condenser in parallel with the capacitance in the variable oscillator circuit. With the two condensers at proper capacity, the original capacitance in the variable circuit was then reduced so that the over-all effect was that of the original capacitance. Variations in the capacity of the measuring condenser could then be compensated for and measured by the standard precision condenser, the reference point in all cases being that setting of the standard precision condenser that would give a zero beat frequency between the variable oscillator and the fixed oscillator. The "zero" beat was determined by the electron tube "eye" mounted in the front of the Clough–Brengle Oscillator. The two oscillating circuits in this equipment are very well decoupled so that there was no significant tendency for the two circuits to synchronize as they were tuned to the same frequency. High quality coaxial cable that was relatively insensitive to mechanical movement was used for all connections between the Clough–Brengle and the measuring and precision condensers, single contact microphone connectors being used for the actual connections. The standard precision condenser used was a 500 m.m.f. General Radio Company Precision Condenser, Type 222-B, with 2500 scale divisions. This capacitance was calibrated in arbitrary units which served as the unit for dielectric constant measurements.

It was obviously necessary to carry out all mixing and handling operations as well as the actual measurement in the absence of moisture. This was done by the construction of a completely enclosed measuring system which included a mixing chamber and a measuring condenser (see Figs. 1 and 2). The system was so constructed as to allow concentration and density samples to be withdrawn without contamination of the system. Movement of the solution from one vessel to another was effected by application of gas pressure at the proper point from a well dried (two liquid air traps) nitrogen source. All of the system that came in contact with the solution before or during a measurement was constructed either of monel, silver or nickel. Pure silver was used throughout for all welding. Connections between metal and glass portions were accomplished by means of ground glass–ground metal joints lubricated with graphite and sealed on the outside with De Khotinsky cement.

After much difficulty with the insulation problem a sample of polytetrafluoroethylene from the E. I. du Pont Company proved very satisfactory. No apparent deterioration occurred over a period of one and one half years of service.

The measuring condenser cell was constructed (see Fig. 2) of three concentric monel metal cylinders. The two inner cylinders were mounted integral with the top and

Mixing chamber.

Fig. 1.—Solution mixing chamber: A is the connection to the measuring condenser, B is the inlet tube for nitrogen, C is the inlet tube for the solute gases, D is the exit tube for the mixing chamber vapors, E is the inlet connection for the solvent, F is the inlet and exit tubes for nitrogen which flowed around the stirrer and G is the variable speed stirrer.

the outer one served as a container for the liquid and as support for the top. The top and bottom were formed from nickel plate. The bottom was "sweated" into proper place as determined by an undercut on the inside of the outside pipe. A gas-tight joint was made between the top and the outside pipe by means of compression of a polytetrafluoroethylene gasket. The middle cylinder was connected so that it could be placed either at high or ground potential by means of a switch on the top. This connection was insulated from the top by means of polytetrafluoroethylene. The middle cylinder was rigidly spaced and insulated from the innermost cylinder (which was always at ground potential) by four small pieces of polytetrafluoroethylene, two pieces being placed at each end of the cylinder assembly. The plastic pieces were put into place between the cylinders while the middle cylinder was sprung out of shape. On relieving the pressure on the middle cylinder, the plastic pieces were clamped quite securely between the two cylinders. Where necessary leads through the top were insulated by means of the polytetrafluoroethylene.

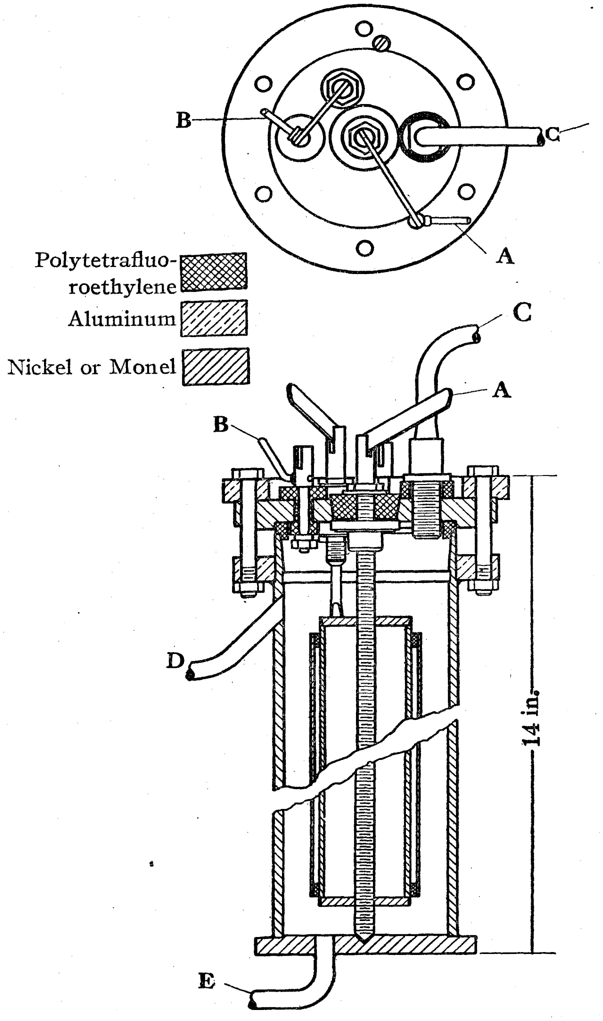

Fig. 2.—Dielectric measuring condenser: A is the ground potential lead, B is the high potential lead, C is the inlet tube for nitrogen, D is the liquid overflow constant level tube, and E is the connection tube to the mixing chamber.

The capacitance change in air when the middle cylinder was switched from ground to high potential was approximately 150 mmf. The condenser was calibrated by the use of air and benzene using Hartshorn and Oliver's value[5] for the dielectric constant of benzene. The liquid capacity of the cell was approximately 800 ml.

The density of the hydrogen fluoride solutions was determined by means of a monel metal pycnometer consisting of a tube equipped with a ground tapered plug at each end. A small hole in one of the ground plugs allowed the liquid to escape and was finally closed off after temperature equilibrium was established with a small tapered monel plug. This method of density determinations would, in general, be far from satisfactory if high precision were required, but in the hydrogen fluoride series the density term contributes less than 1% to the molar polarization so that the accuracy obtained was satisfactory.

The density determinations in the hydrogen chloride and hydrogen bromide series were determined in a conventional[6] glass pycnometer of 100-ml. capacity.

The density of all concentrations for several measurements was determined to test the consistency of the $\Delta d/f_2$ ratio, where f_2 is the solute mole fraction and Δd is the difference in density between the solution and solvent. The results showed that $\Delta d/f_2$ for these systems could be considered constant.[7] Thus, in most cases, only the density of the solvent and one or two of the solutions was determined, the other densities being calculated in turn from these. Several checks of the value of $\Delta d/f$ were made between runs of the same components. All measurements were carried out at 30.0°.

Actual measurements were carried out in the usual manner for solutions except that unusual precautions were taken to see that no air entered the measuring system during the course of a determination. The concentrations of the acids were determined from aliquots delivered directly from the measuring system into excess 0.1 *N* alkali. It was found that in the process of filling and emptying the measuring condenser some small striations of concentration occurred in the case of solvents where the solubility of the solute was low. Therefore, four samples were withdrawn for analysis from various levels of the measuring condenser and the average of these concentrations used as the concentration value in such cases. The average deviation of a series of measurements for such cases was generally less than 2% of the mean value. These uncertainties and other random ones caused the measurements for hydrogen fluoride in carbon tetrachloride and *n*-heptane to spread so much that the values of the electric moment are reported only to the tenths of an electric moment unit for these solvents.

Calculations and Data

The results recorded are the following: P_2 is the molar polarization of the solute calculated from an expanded form[8] of the usual Debye expression; R is the molar refraction; μ_D is the electric moment in debyes calculated from the average (or extrapolated) value of P_2; and μ^* is the external electric moment as calculated for infinite dilution from the Onsager[9] expression for this case, namely

$$(\mu^*)^2 = \frac{E_{12} - E_1}{N_2}\,\frac{3kT}{4\pi} \qquad (1)$$

where N_2 is the number of solute molecules/cc., E_1 is the dielectric constant of the solvent, and E_{12} is the dielectric constant of the solution. N_2 is given more explicitly by

$$N_2 = \frac{f_2 d_{12} N_A}{(1 - f_2)M_1 + f_2 M_2} \qquad (2)$$

The subscript 12 refers to the solution, 1 to the solvent, and 2 to the solute. M is the molecular weight, and N_A is Avogadro's number. The other terms of this expression have their usual meaning. In writing the above expression for $(\mu^*)^2$ the assumption has been made that there is no difference between the square of the refractive index of the solvent, n_1^2, and the dielectric constant of the solvent, E_1.

In the usual case of "so-called" non-polar solvents this assumption would be well taken, but it happens that for dioxane there is a rather large difference (*i. e.*, 0.23 at 30.0°) between the square of the refractive index n_1^2, for sodium light and the dielectric constant. It is recognized that the n_1 of Onsager's expression has reference to the value for the electron and atomic polarizability in a static field but this value is not available and rather than use a dubious extrapolation for n, it was felt that E_1 should be used.[10] μ_0 is the permanent electric moment as calculated from μ^* using the expression

$$\mu_0 = \frac{(2E_1 + n_2^2)}{E_1(n_2^2 + 2)}\,\mu^* \qquad (3)$$

There was some question as to the value of n_2^2 proper to the calculation. It is of course possible to calculate a value of n_2^2 from the molar refraction expression using a value of the density obtained from the density equation for the liquid state. For present purposes this expedient has been followed but it is recognized that the values obtained are truly approximate since the density functions used[11] have been extrapolated considerably beyond their indicated limits of validity.

Results

The results of the measurements at 30.0° are summarized in Table I, and detailed data for the halides are shown graphically in Figs. 3, 4 and 5.

TABLE I

Solute	R_D (cc.)	n_D^2	P_2 (cc.)	μ_D	Solvent	μ^*	μ_0
HF	2.1	1.329	(84)	2.0	CCl_4	2.8	2.2
			(99)	2.2	*n*-C_7H_{16}	2.8	2.3
			76.7	1.91	C_6H_6	2.63	2.04
			114.1	2.34	1–4$C_4H_2O_2$	3.32	2.60
HCl	7.1	1.577	29.8	1.06	CCl_4	1.48	1.12
			36.1	1.19	*n*-C_7H_{16}	1.55	1.23
			38.7	1.25	C_6H_6	1.62	1.22
			98.9	2.12	1–4$C_4H_8O_2$	2.92	2.21
HBr	10.0	1.566	27.8	0.93	CCl_4	1.23	0.93
			31.2	1.02	*n*-C_7H_{16}	1.27	1.00
			33.6	1.08	C_6H_6	1.43	1.08
			176	2.85	1–4$C_4H_2O_2$	4.05	3.07
H_2O	3.7	1.775	78.5	1.89	1–4$C_4H_2O_2$	2.64	1.96

Discussion

The results as summarized in Table I are recapitulated in Table II in terms of the difference between μ_D and the gas values as available in the literature[12]; *viz.* HF = 1.91D, HCl = 1.03D, HBr = 0.78D and H_2O = 1.84D.

TABLE II

	CCl_4	*n*-C_7H_{16}	C_6H_6	1,4-$C_4H_8O_2$
HF	0.1	0.3	0.00	0.43
HCl	.03	.16	.22	1.09
HBr	.15	.24	.30	2.07
H_2O				0.05

(7) If one takes $V_{12} = f_1V_1 + f_2V_2$ where V is the molar volume and 1 refers to solvent, 2 to solute and 12 to the solution, it can be readily shown that $\Delta d/f_2$ is given by $M_2(d_2 - d_1)d_1/(M_2d_1 + M_1d_2 (1 - f_2))$ where M is the molecular weight. Since generally $f_2 \ll 1$ it is consistent with the assumption of additive molar volumes that $\Delta d/f_2$ should be independent of f_2 as long as the solutions are sufficiently dilute.

The results in Table II show quite clearly the very significant positive solvent effect for the halides and in the case of dioxane the effect is so large that it may indicate "incipient" ionization.

We may infer that since the acid strength of H_2O is so much lower than the halides its bond moment is only slightly affected by the presumed coördination of the dioxane oxygen and hydrogen of the water. It may be remarked that in general the effects observed appear to be free from serious association effects since the graph of polarization against mole fraction as shown in Figs. 3, 4 and 5 shows trends only in a few cases, and in these the trend is not particularly large.

It should be noted in Table I that the lack of agreement between the μ_D values and corresponding μ_0 is not serious. This is rather important in that the same direction of solvent effect is shown by calculation using either the Debye of Onsager formulation. Furthermore, our data as are shown in Figs. 4 and 5 agree rather well with those of Fairbrother's, and the moment for hydrogen chloride in benzene of 1.25 debyes is to be compared with the value 1.21 debyes found in the same solvent by Mizushima,[13] *et al.*

In considering the results in more detail it appears that, if one excludes the dioxane solutions the observed solvent effects may be explained on the basis of the interaction of a polarizable dipolar molecule with a polarizable solvent. The generalized effect of solvents on the values of electric moments as determined in solution has been considered in some detail by Weigle,[14] Higasi[15] and Frank.[16] For the particular case of some diatomic molecules Fairbrother[17] has given what seems to be a rather specialized treatment which depends on the interaction of the solute in its totally ionic state with the surrounding solvent. From a rather general consideration of the solvent effect as originating from a polarizable solvent and the electric moments induced in it by the dipolar solute molecule the order of the maximum solvent effect to be expected can be shown to be about ±15 to 20% of the electric moment of the polar molecule. The sign of the effect is determined mainly by the geometry of the solute molecule and the location and direction of the electric moment within it.

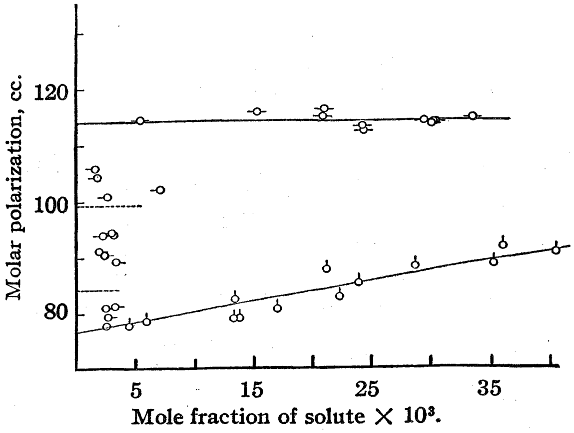

Fig. 3.—Hydrogen fluoride at 30° in: —O—, 1,4-dioxane; ȯ, benzene; -O, *n*-heptane; O-, carbon tetrachloride.

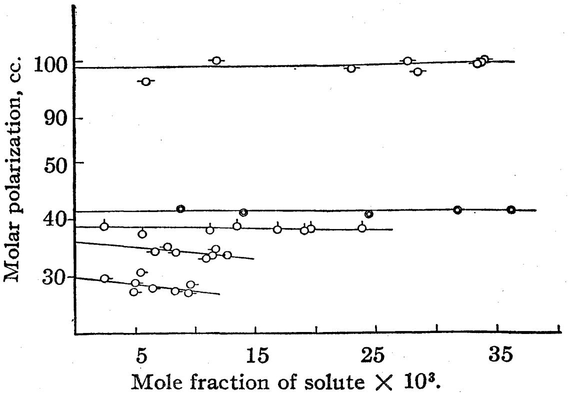

Fig. 4.—Hydrogen chloride in: -O-, 1,4-dioxane at 30°; -O, *n*-heptane at 30°; ȯ, benzene at 30°; O-, carbon tetrachloride at 30°; ◎, benzene (Fairbrother) at 20°.

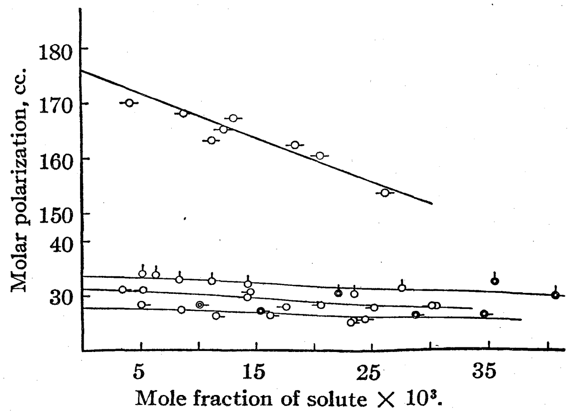

Fig. 5.—Hydrogen bromide in: -O-, 1,4-dioxane at 30°; ȯ, benzene at 30°; -O, *n*-heptane at 30°; O-, carbon tetrachloride at 30°; ◎, benzene (Fairbrother) at 20°; ◎-, carbon tetrachloride (Fairbrother) at 20°.

Review of the data of Table II in the light of this anticipated maximum solvent effect of the order of ±15 to 20% of μ_1 indicates that outside of the dioxane solutions the solvent effects observed can for the most part be accounted for by solute–solvent interactions of the type considered above. Hydrogen bromide in benzene appears to be somewhat high as is hydrogen fluoride in *n*-heptane. Hydrogen fluoride in benzene is anomalously low. As is well known hydrogen fluoride is very prone to associate, and in the case of hydrogen fluoride in *n*-heptane this may explain the apparently high though admittedly uncertain solvent

effect shown in Table II. In benzene the calculated molar polarization of hydrogen fluoride rises with increasing concentration. This suggests an increasing tendency toward an end to end type association of the hydrogen fluoride as the concentration increases. Buswell,[18] *et al.*, have by means of infrared absorption measurements concluded that dilute solutions (<0.002 mole fraction) of hydrogen fluoride in carbon tetrachloride show very little association of the hydrogen fluoride. Although our data on hydrogen fluoride in carbon tetrachloride are somewhat uncertain it does appear that end to end association in this solvent at the concentration used was not unduly serious. However, in the case of benzene considerably higher concentrations of hydrogen fluoride were reached than was the case with carbon tetrachloride, and if such end to end association did occur at the high concentrations the extrapolation of the polarization curve to the zero concentration axis might well give a value of $P_2{}^\infty$ which was lower than the actual value of the molar polarization of the single molecule of hydrogen fluoride in benzene. With the apparatus and technique used in the measurements values of molar polarization obtained for f_2 values less than 0.005 were for the solutes used too uncertain to warrant detailed investigation of the hydrogen fluoride–benzene system below this value of concentration.

As previously noted the solutions of the halides in dioxane exhibit, as may have been expected, a somewhat different order of solvent effect than was encountered with the other solvents. The oxygen of the ether linkage can presumably bind the hydrogen of the halides by means of a hydrogen bond and because all of these solutes are relatively strong acids in even mildly basic solvents one might expect a sensible change in the apparent ionic character of the solute molecules. Considerable infrared[19] and raman[20] spectroscopic work on these types of solutions has given evidence of a significant change in the hydrogen halide vibration characteristics when the halides form hydrogen bonds with oxygenated or other acceptor type solvents. For the case of the hydroxyl group, rather than the halides, Badger[21] has attempted to show a rather simple relation between the heat of formation of the hydrogen bond and the shift in frequency that occurs in the second harmonic of the OH stretching vibration. Gordy and Martin[22] have shown that for oxygenated solvents the maximum shift of the hydrogen chloride bond occurs in ether type solvents and that, in particular, dioxane causes the hydrogen chloride band that appears at 3.49 μ in benzene solution to shift to 4.05 μ in a 1.1 molar dioxane solution. The presumption is that both hydrogen fluoride and hydrogen bromide would, in dioxane solutions, show similar shifts of major magnitude in their characteristic frequency. To the knowledge of the authors no spectroscopic data is available for these two solutes in dioxane.

Gordy and Stanford[23] have observed a most interesting relation between the magnitude of band shifts for a particular solute in several solvents and the logarithm of the basicity constant[24] of the solvents. It is found that these two quantities are almost linearly related for about twenty observed cases, when the solutes used were D_2O and CH_3OD and the frequency shift observed was for the OD bond in these substances. One might infer that for a given basic solvent and several acids the relative shift for the acids might be in order of the increasing acid strength. In the case of water, hydrogen fluoride, hydrogen chloride and hydrogen bromide the dielectric evidence as will be noted later seems to show some parallelism of apparent shift in electric moment and the acid strength. Spectroscopic data on this series in dioxane is not at present available; therefore, the inference above regarding the frequency shifts cannot be checked.

The fact[22] that hydrogen chloride in dioxane shows absorption bands in a region that can be ascribed to the perturbed hydrogen chloride molecule is good evidence that the solute has not gone over into an ion-pair system in the dioxane. Gemant[25] has recently investigated by potentiometric methods hydrogen chloride in dioxane that was slightly diluted with water (solution of lowest dielectric constant, $E = 2.85$). In this investigation he calculated a dissociation constant, K, of 10^{-14} when $E = 2.85$. There is little reason to suppose that the conductivity or hydrogen ion concentration in these solutions was due to dioxane and hydrogen chloride since it would appear reasonably certain that water would be the ionizing agent as well as dissociating agent in a solution that consisted of a mixture of dioxane and water. The solvation by water of the negative chloride might aid materially in effecting actual dissociation of the hydrogen chloride; in anhydrous dioxane hydrogen chloride solution there would seem to be no reasonable method of achieving solvation effects of sufficient magnitude to energetically favor the existence of dissociated chloride ions in the solution.

The spectroscopic and potentiometric evidence may be taken to at least indicate the absence of serious amounts of ionization or dissociation in the hydrogen–dioxane solutions. This being the case one may tentatively conclude that the large solvent effect calculated for this solution has its origins in an incipient hydronium formation between the HCl and dioxane and that possibly this complex is

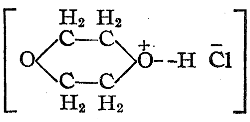
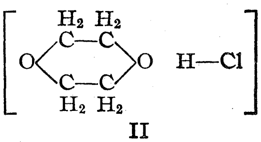
stabilized by both ionic and exchange forces. One may imagine exchange forces playing a significant part by considering that such structures as



I

make significant contributions to the ground state of the complex. It is presumed that in this case the most stable contributing structure would be



II

where this bond between the H and Cl is the HCl bond with its usual partial ionic character but in a slightly perturbed state because of the nearness[26] of the ether oxygen with its slightly negative charge. It does not seem unreasonable to suggest that in the case of hydrogen fluoride and dioxane one might expect, because of the great ionic character and bond energy of the HF bond and of the lower acid strength of this molecule, that this complex might partake more of the structure shown as II than that shown by I. Hydrogen bromide in dioxane might be expected to favor structure I even more than does hydrogen chloride. Water on which data was also obtained in dioxane might be expected to favor structure II practically altogether since the acid strength of this substance is very small compared to any of the hydrogen halides. It may be remarked that substances similar to water such as alcohols, weak hydroxy acids, etc., might also favor structure II, and as such one might anticipate only small effects on the apparent electric moment of such substances because of the complex formation. The latter statement is somewhat borne out by measurements made in dioxane on a number of weak organic acids[8,27] and by our data and those of Linton and Maass[28] on water.

In an effort to depict more clearly the relative effects of the complex formation in dioxane solution on the electric moment, data are presented in Table III in the form of calculated ionic character of the respective bonds, it being assumed[29] that the ionic character of the single bonds is given by μ/er where μ is the observed dipole moment in debyes, e is the electronic charge $\times 10^{10}$ *e. s. u.* and r is the internuclear separation in Å. The column under $\Delta\mu/er$ is carried only to the tenths place as the entire procedure of calculation is predicated on the approximation that r stays constant and that the ionicity of the bond is calculable from the measured value of the moment in dioxane solution. This method neglects normal solvent effects and many other recognizable but rather indeterminable compromising effects so that the values under the $\Delta\mu/er$ column should be regarded as indicative of rather than a quantitative measure of the effects involved. In spite of the necessarily approximate methods used, the data of Table III appear to bear out in some detail the arguments advanced in the previous paragraphs. In view of this it seems reasonable to suggest that the electric moment evidence points toward intermediate structures in hydronium formation and that such structures are probably not representable simply by dipole or charge interactions such as is usually considered to be the case for hydrogen bonds. More probably these structures are hybrids which have contributing structures which lie intermediate between true ion pairs and totally separated molecules.

TABLE III

		Gas		Dioxane		
	r	μ	μ/er	μ	μ/er	$\Delta\mu/er$
HF	0.92	1.91	0.43	2.34	0.53	0.1
HCl	1.28	1.03	.17	2.12	.35	.2
HBr	1.42	0.79	.12	2.85	.42	.3
HO(H_2O)	0.96	1.51	.33	1.55	.34	.0

Summary

The electric moments of hydrogen fluoride, hydrogen chloride and hydrogen bromide have been determined in several non-polar solvents. The moment values of the halides each show definite positive solvent effects in agreement with some previous work along these lines. The moment of hydrogen fluoride in solution has been determined for the first time and it may be concluded from the present measurements that the probable value of the electric moment of hydrogen fluoride is between 1.9 and 2.0 debyes. With these data values of the partial ionic character of the hydrogen fluoride bond can be closely approximated. The agreement of the benzene solution value of hydrogen fluoride with the gas value is regarded as coincidence.

The values of the electric moments of hydrogen halides in dioxane solution seem to point toward an incipient ionization of these solutes in this solvent. This concept is considered briefly.

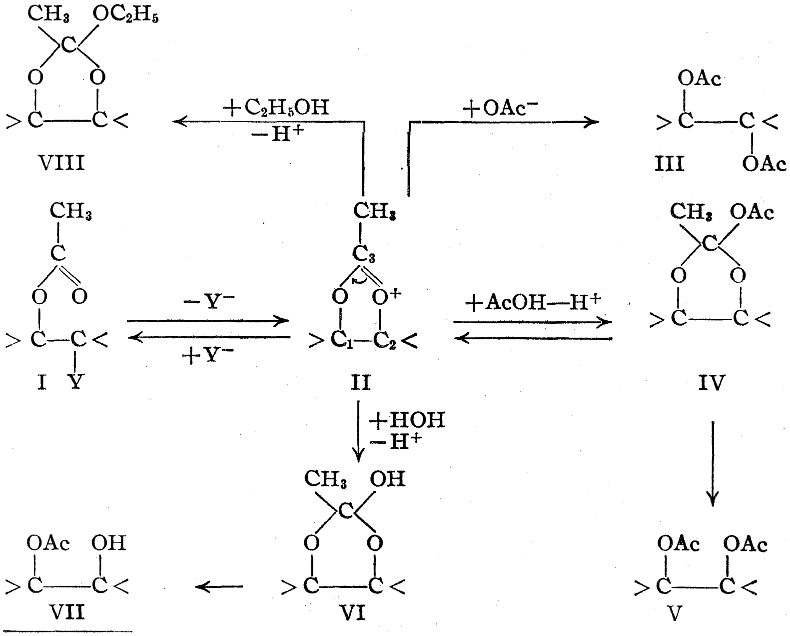
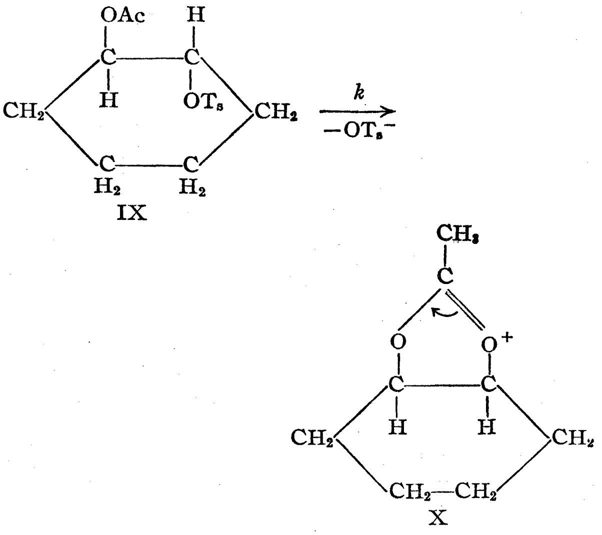
The Role of Neighboring Groups in Replacement Reactions. X.[1] Kinetics of Solvolysis of trans-2-Acetoxycyclohexyl *p*-Toluenesulfonate[2]

By S. Winstein, Carolyn Hanson and Ernest Grunwald

Of the groups encountered in previous work on the participation of neighboring groups in displacement reactions, the neighboring acetoxy[3–7] group has proved to be, in some respects, the most interesting. Thus, according to our interpretations of the results of previous experiments, the departure or extraction of a group Y such as bromide or toluenesulfonate from a molecule I such as 3-acetoxy-2-bromobutane, *trans*-2-acetoxycyclohexyl bromide or *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate gives rise to the cyclic intermediate II. This intermediate in anhydrous acetic acid containing acetate ion turns up as diacetate III with the familiar over-all steric result of retention of configuration.[3,5,7] In the absence of acetate ion in an acidic solution diacetate V with the inverted configuration is produced probably by way of the orthodiacetate IV. With water, intermediate II is thought to react to give orthomonoacetate VI which isomerizes to monoacetate VII, the over-all steric result being one of inversion.[4,5,7] With alcohol, intermediate II gives the analog of VI, the orthoester[6] VIII.





Since the participating acetoxy group is apt to be one of the most important ones to organic chemists, it seems desirable to understand its behavior as completely as possible. Toward this end we have studied the kinetics of the homogeneous solvolysis of *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate IX in acetic acid. This rate work, taken in conjunction with the previous work[3–7] on the nature of the product and the steric results, adds considerable precision to our interpretation of the mechanisms involved and shows up some remaining complications.

The solvolysis of the toluenesulfonate IX (ROT_s) was followed by titration of the toluenesulfonic acid which is seen to be generated according to equation 1.

$$ROSO_2C_6H_4CH_3 + AcOH \longrightarrow ROAc + HOSO_2C_6H_4CH_3 \quad (1)$$

The rates were measured in anhydrous acetic acid solvent, and also in solutions containing one or more of the added materials, water, acetic anhydride, potassium acetate, diphenylguanidine (DPG) and diphenylguanidinium *p*-toluenesulfonate (DPG·HOT_s).

In the presence of added water even in as low a concentration as 0.055 *M*, calculated first-order reaction rate constants were very steady. A typical run is shown in Table I, (ROT_s) representing the molarity of unreacted

ROT$_s$ and k the calculated first-order constant.

Without added water, but in the presence of potassium or diphenylguanidinium acetate, integrated first-order rate constants were quite satisfactory but tended to drop some 8 to 10% by the time the reaction was 70 to 80% complete. In the absence of added water or acetate salt, the kinetics were complicated, the rate constant decreasing markedly at first and then increasing again later in the run.

TABLE I

RATE OF SOLVOLYSIS OF 0.1 *M* *trans*-2-ACETOXYCYCLOHEXYL *p*-TOLUENESULFONATE AT 99.7 ± 0.10° IN AcOH 0.17 *M* IN H_2O

Time, min.	50(ROT$_s$)	$10^4 k$ (sec.$^{-1}$)
0.0	4.255	..

125.0	0.925	2.04
210.0	0.325	2.04
	Mean	2.03

In Table II are collected the data from the runs which yielded satisfactory first-order reaction rate constants. A number of comparisons are possible from this table which show the insensitivity of the rate constant to initial concentration of toluenesulfonate IX. The addition of water or acetate is seen to produce small increases in rate. A linear catalysis by water has been sometimes observed[8] in situations of this kind. In the present case, the catalysis may be linear, but the effect is so small that rigid linearity is obscured by normal experimental variations. The extrapolated rate constant for no added water or salt appears to be approximately 1.90×10^{-4} sec.$^{-1}$, 0.55 *M* water giving an increase in rate of 18%. At a concentration of 0.1 *M* diphenylguanidinium acetate, 0.55 *M* water increases the rate by 15%. For the acetolysis of α-phenylethyl chloride, Steigman and Hammett[8a] found the effect of water to be considerably larger.

[a] 0.10 *M* in *cis*-1,2-diacetoxycyclohexane. [b] Excess acetic anhydride. M. p. of solvent 16.32°. [c] Anhydrous ethanol as solvent.

The increase in rate due to addition of 0.1 *M* diphenylguanidine to the normal anhydrous solvent amounts to about 10%. The rates with potassium acetate in the presence of a slight excess of acetic anhydride in the solvent are in general a few per cent. lower, in part, at least, due to the removal of the residual trace of water from the glacial acetic acid.

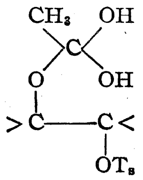
Following the previous interpretations,[3-7] the first order reaction rate constants in Table II represent the rate constant k of formation of the cyclic intermediate X (or II) and toluenesulfonate

---

(8) (a) Steigman and Hammett, THIS JOURNAL, **59**, 2536 (1937); (b) Farinacci and Hammett, *ibid.*, **59**, 2542 (1937).

ion from toluenesulfonate IX. The effects of water and acetate salt are then solvent and salt effects.

The small magnitude of the effect of water on the rate constant for solvolysis of the acetate-tosylate IX makes it very clear that water, which in the presence of acetate ion diverts the product to monoacetate VII and the steric result to inversion of configuration, does not accomplish these results in the rate-determining stage of the solvolysis. Were its action in the rate-determining step, then, judging by its efficiency, the reaction involving water when appreciable water concentrations are used would be much faster than the residual one. Thus, the presence of water would give rise to a large rate increase, unless, by some chance, toluenesulfonate IX and water combine quite completely to give a compound which is only moderately reactive. Conceivable examples of such compounds are a hydrogen-bond complex or the addition compound[4,5] XI (which may be criticized on other grounds).



XI

Actually, such compound formation would be reflected in abnormally small depressions of the freezing point of acetic acid by mixtures of toluenesulfonate IX and water. Pertinent freezing point measurements, summarized in Table III, speak against compound formation.

TABLE III

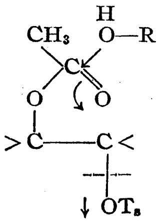
FREEZING POINTS OF ACETIC ACID SOLUTIONS OF WATER AND *trans*-2-ACETOXYCYCLOHEXYL *p*-TOLUENESULFONATE

(ROT_s), *M*	0.00	0.00	0.00	0.20	0.50	0.20
(H_2O), *M*	.00	.30	0.50	0.00	0.00	0.30
F. p. lowering, °C.	.00	.97	1.69	0.57	1.32	1.72

It can be seen that the depression of the freezing-point for the solution containing both the acetate-tosylate and water is even greater than the sum of the depressions for the appropriate concentrations of each solute alone, although this difference is not much greater than the experimental error. Thus no compound formation is indicated at the freezing point and is expected to be even less probable at the higher temperatures used in the rate experiments.

In the case of alcoholysis of the toluenesulfonate IX (which gives rise to orthoacetate VIII) again it is clear that no unique role is to be ascribed to the alcohol in the rate-determining step. The first-order rate constant for alcoholysis at 75° was steady and amounted to about two-thirds (Table II) of the value in glacial acetic acid. This is in line with the near equality of acetic acid and ethanol as solvents for solvolysis of halides.[9]

It becomes possible therefore to rule out for the present case such mechanisms as the one symbolized by XII which postulate a concerted attack by a water or alcohol molecule and simultaneous departure of the toluenesulfonate ion. This latter type of mechanism has been envisioned by Isbell[10] for orthoester formation from acetohalogen sugars. Similar mechanisms involving acetate ion instead of water are ruled out also by the data.



XII

The data for several runs with no added water or acetate salt (which gave the decreasing and then increasing first-order reaction rate constants) are summarized in Table IV. The first column lists *a*, the initial concentration of toluenesulfonate IX, and the second column indicates the concentration of added diphenylguanidinium *p*-toluenesulfonate (DPG·HOT_s) when it was used. From a plot of ln $(a - x)$ against time, *t*, *x* being the concentration of generated toluenesulfonic acid, fairly accurate values of the slope, d ln $(a - x)/dt$,

called k, could be measured at various points with the aid of a tangent meter. In Table V are shown the k values thus determined for one run. In the third and fourth columns of Table IV are listed the values of x and k at the minima. The last column gives the extrapolated initial value of k, k_0. It is seen that, within the accuracy of this kind of a procedure, the initial rate constants, k_0, were roughly those expected. The minimum rate constant, one-third to one-half the initial value, occurred at a value of x of about 0.01 M.

It is very clear that the complex behavior of the rate constant is due to generated toluenesulfonic acid. Toluenesulfonate ion by itself did not give a lowered rate by virtue of any ability to compete successfully with solvent or acetate ion for the intermediate X (or II). Thus the initial rate constant with added diphenylguanidinium *p*-toluenesulfonate (Table IV) was normal. Also, the substitution of DPG·HOTs for half of the diphenylguanidine in runs 21 and 22, Table II, gave essentially no rate lowering. On the other hand, runs with two moles of ester per mole of diphenylguanidine gave a quite normal rate constant initially which held up fairly well until the solution became acidic when it decreased very markedly and then increased again.

This phase of the subject has not been more completely investigated and requires more knowledge of the chemistry of orthoester intermediates. The indications from the rate work and the earlier work are that toluenesulfonate ion in acid acetic acid solution in the absence of water is able to divert some intermediate back to *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate IX (or I). The back reaction may involve orthodiacetate IV (which may not proceed to *cis*-diacetate V rapidly enough and thus accumulate), a proton and toluenesulfonate ion, perhaps by way of the cation X (or II) in equilibrium with orthodiacetate IV. In the presence of water no such complication is possible because of the very successful competition of water with acetic acid for coördination to carbon atom C_3 of the intermediate II, producing orthomonoacetate VI and subsequently monoacetate VII.

Experimental

Anhydrous Acetic Acid.—The water content of General Chemical Company reagent grade glacial acetic acid, m. p. 16.2° or higher, was estimated from its m. p., assuming water to be the impurity. Enough pure acetic anhydride was added to react with the water and the mixture was held under reflux for four hours. Distillation yielded, as a main fraction, acid, m. p. 16.55°. Virtually the same m. p. was obtained when the acid was dried with triacetyl borate.[11]

Solvent with excess acetic anhydride was prepared by refluxing 250 ml. of dry acid with 2.0 ml. pure acetic anhydride for three hours (m. p. 16.32°). For some of the runs, another solvent, 0.0459 M in acetic anhydride, was used.[12]

Diphenylguanidinium *p*-Toluenesulfonate.—To 150 ml. of dry ether was added 4.3 g. (0.0226 mole) of *p*-toluenesulfonic acid monohydrate. A small aqueous phase appeared which was separated and extracted with 50 ml. of ether. The combined ether solutions were slowly added with shaking to a solution of 4.9 g. (0.0232 mole) of diphenylguanidine in 150 ml. of dry ether. The mixture was kept in a refrigerator several hours. Then the crystals were filtered off, washed with cold ether and dried to yield 7.8 g. (0.0204 mole), 91% of material; m. p., after recrystallization from chloroform–benzene, 171.9–172.4°.

Anal.[13] Calcd. for $C_{20}H_{21}O_3N_3S$: C, 62.64; H, 5.52. Found: C, 62.61; H, 5.75.

***trans*-2-Acetoxycyclohexyl *p*-Toluenesulfonate.**—This material, m. p. 78°, was prepared as described previously.[5]

Titrations in Glacial Acetic Acid.—Approximately 0.05 N or 0.10 N perchloric acid in glacial acetic acid, prepared from 60% aqueous acid of known titer against aqueous standard sodium hydroxide, was used as standard acid. As standard base was employed either Eastman Kodak Co. diphenylguanidine, m. p. 147–148°, or standard sodium acetate prepared from pure sodium carbonate. As indicator was used either crystal violet[8a,14] or, in the later stage of the work, a brom phenol blue indicator solution.[12]

Procedure for Rate Measurements.—The reagents were weighed out and made up to volume in the proper acetic acid solvent at 20–23°, water being added from a graduated pipet in some cases. Concentrations are all given at room temperature. Approximately 6–7-ml. portions were sealed in tubes and immersed either in the vapor over boiling water in a 100° thermostat or an ordinary thermostat at 74.90 ± 0.05°. The exact temperature in the 100° thermostat was obtained from the barometric reading, but was always 99.70 ± 0.10. Time was counted from immersion of the tube to its removal and quenching in ice-water. After being cooled a tube was allowed to come to room temperature, then it was opened and a 5-ml. aliquot was pipetted out for titration with standard acid or base from a 5-ml. microburet. Time was called zero for the first tube after attainment of temperature, initial concentrations being adjusted from the titration data on this tube. In the experiments with added acetate ion titration of an unheated tube was used to check on the initial acetate ion concentration.

In the dry acetic acid solvent in the absence of acetate ion, the tubes tended to darken toward the end of a run. This made it impossible to obtain an infinity titre. With acetate ion present, titration after seventeen hours at 100° showed 99.9% of the theoretical consumption of base. Another series of experiments showed 99.6% after ten hours at 110°.

Titration of toluenesulfonic acid and diphenylguanidine solutions in glacial acetic acid showed that the former maintained its titre within 0.5% after two and one-half hours at 100°, and the latter within 0.4% after four hours at 100°.

Diphenylguanidinium *p*-toluenesulfonate, which was added in some of the rate runs, was shown not to liberate any detectable acid on heating two hours in acetic acid containing 0.0459 M acetic anhydride either in neutral solution or in solution 0.016 M in perchloric acid.

For the alcoholysis of the toluenesulfonate in absolute ethanol, the reaction was followed by titration of 5 ml. aliquot portions with 0.05 N standard aqueous base to the brom thymol blue end-point.

The potassium acetate used as a solute in some of the runs was carefully dried reagent-grade material.

Summary

The kinetics of acetolysis of *trans*-2-acetoxycycylohexyl *p*-toluenesulfonate are closely first-order in the presence of small concentrations of water or acetate ion. The evidence is that the

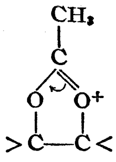
rate-determining step in the solvolysis is the formation of the ion II.



II

Water and acetate ion, which control the nature of the product and the steric result, do not exercise this control in the rate-determining step.

Similarly, for alcoholysis of *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate, II appears to be the intermediate, orthoester formation being accomplished at a later step than the rate-determining one.

The rate constants for acetolysis of the toluenesulfonate in acetic acid not containing water or acetate ion decrease seriously as acid develops and then increase again. The best interpretation of the downward drift is that *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate is regenerated by the action of acid and toluenesulfonate ion on an intermediate such as orthodiacetate.

LOS ANGELES, CALIFORNIA RECEIVED APRIL 3, 1947

[CONTRIBUTION FROM THE CHEMISTRY DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA, LOS ANGELES]

The Role of Neighboring Groups in Replacement Reactions. XI. Some Reactivities Involving Neighboring Groups[1]

BY S. WINSTEIN, E. GRUNWALD, R. E. BUCKLES AND C. HANSON

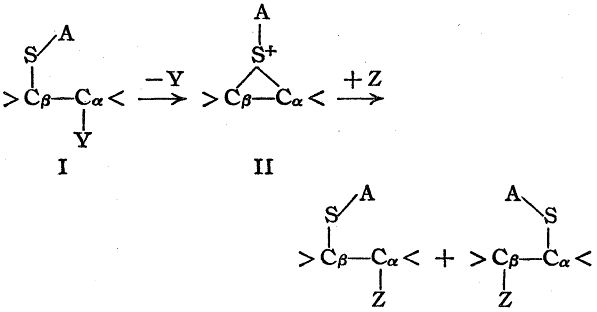
Participation of neighboring groups in displacement reactions has long been known with such groups as O^- (from OH) and NH_2, prior ring closure[2] to isolatable oxide or imine occurring on attempted displacement of halide in a halohydrin or aminohalide. In these cases the groups are those which also take part in known bimolecular displacements[3] symbolized in equations 1 and 2.

$$RO^- + R'X \longrightarrow ROR' + X^- \qquad (1)$$

$$RNH_2 + R'X \longrightarrow (RNH_2R')^+ + X^- \qquad (2)$$

While the so-called classical groups, O^-, NR_2 and SR have been mentioned in preceding articles of this series,[4] the main stress[5] has been on participation in nucleophilic displacement reactions by such neighboring groups as OAc, Br and OCH_3, which are not known to participate in external displacements. Actually there is no sharp division between the latter groups and the more classical ones.

Participation by a neighboring group S-A is symbolized[4a] below, Y and Z indicating the leaving and entering groups, respectively.



We have previously indicated there are questions of intimate mechanism with respect to both the closing and opening of the ring in II.[4a] Rate measurements are helpful in this connection, and in the present article and subsequent ones are reported reactivity measurements in some unimolecular-type[6] nucleophilic displacement reactions.

As is brought out in this paper and articles XII and XIII in the series, the rate measurements yield important formation concerning the nature of the rate-determining ionization step. Using a common set of symbols for all three papers, the ionization step may be[4a] either **A**, a one-stage ring closure to the cyclic intermediate II with Walden inversion (W.I.) at C_α or **B**, an ionization to the substituted carbonium ion III.[3,4a,7]

Two different criteria for distinguishing between the two rate-determining steps A and B have been employed in the work described in this paper. First, the effect on the rate of the disposition of the neighboring group *cis* or *trans* to the departing

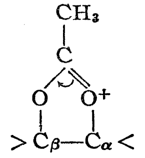
group has been investigated. Second, rates of substitution involving various neighboring halogens are reported, and the influence of a change in the halogen atom on the reactivity is observed.

In order to appraise the influence of the geometric position of the neighboring group on the substitution rate, the reactivities of cyclohexyl chloride and the *cis*- and *trans*-2-acetoxycyclohexyl chlorides toward silver acetate in glacial acetic acid have been compared. After a reaction period of thirty-two hours in acetic acid at 100–110°, cyclohexyl chloride was converted partly to cyclohexyl acetate and largely to cyclohexene. Under the same conditions, *trans*-2-acetoxycyclohexyl chloride reacted only incompletely in dry and slightly aqueous acetic acid to give 40–50% yields of materials of steric configurations identical with those reported before[4a,b] for the acetoxybromide and interpreted on the basis of the cyclic intermediate IV.



IV

Under the same conditions, *cis*-2-acetoxycyclohexyl chloride proved so unreactive that only unreacted starting material was recovered. Similarly only unreacted starting material was recovered when a reaction temperature some 20° higher was employed.

A more quantitative evaluation of the effect of a *cis*- and *trans*-acetoxy group is derived from the rates of first-order acetolysis of the cyclohexyl *p*-toluenesulfonates. The rate of acetolysis of trans-2-acetoxycyclohexyl *p*-toluenesulfonate is reported in a preceding paper,[4i] and we now add for comparison the rates for the cyclohexyl and *cis*-2-acetoxycyclohexyl esters.

In Tables I and II are given typical data obtained in the determination of the first-order rate constants k of acetolysis of the cyclohexyl and the *cis*-2-acetoxycyclohexyl esters. In Table III are collected first-order rate constants for the three compounds in anhydrous acetic acid with and without added 0.1 M diphenylguanidinium acetate. It is evident from the data in Table III that the specific rates remain quite unchanged, allowing for salt effects, upon the addition of 0.1 M acetate salt, indicating that the reactions are of the unimolecular type. On the basis of these data, the relative reactivities in anhydrous acetic acid at 99.7° are in the following sequence: unsubstituted, 1.00 > *trans*-2-OAc, 0.30 ≫ *cis*-2-OAc, 4.5 × 10^{-4}.

[a] Diphenylguanidinium acetate.

The relatively high reactivity of the *trans*-isomer, and the striking difference in reactivity between the *cis*- and *trans*-isomers are not readily explained on the basis of the carbonium ion mechanism B alone. It is clear from the available data on inductive effects, such as Branch and Calvin's inductive constants,[8] that the acetoxy group is strongly electron-removing. As a result, the reaction by way of a carbonium ion intermediate is expected to be considerably slower in the presence of a neighboring acetoxy group as is actually the case only with the *cis*-material. In order to correlate the observed reactivities, it is suggested

---

[8] Branch and Calvin, "The Theory of Organic Chemistry," Prentice-Hall, Inc., New York, N. Y., 1941, Chapter VI.

that the reaction of the *trans*-2-acetoxycyclohexyl ester proceeds by way of the one-stage ring-closure mechanism **A** which apparently involves a more favorable free-energy of activation than the carbonium ion mechanism **B**. On the other hand, the acetolysis of the *cis*-ester proceeds very probably by way of a carbonium ion mechanism because in the *cis*-position the neighboring acetoxy group cannot form a cyclic intermediate with inversion of configuration at C_α without essentially prohibitive strain.

Whereas the *cis*-2-acetoxycyclohexyl chloride was too inert to the action of silver acetate to allow isolation of the product, the acetolysis of *cis*-2-acetoxycyclohexyl *p*-toluenesulfonate proceeded rapidly enough so the stereochemistry of the displacement could be examined. The *cis*-toluenesulfonate yielded after a twenty-four hour reflux period in a potassium acetate solution in anhydrous acetic acid a diacetate which, on direct saponification and subsequent sublimation, gave rise to quite pure *trans*-glycol. Thus the steric result with the *cis*-compound is very predominant inversion of configuration in contrast to the very predominant retention of configuration in contrast to the very predominant retention of configuration observed[4e] under the same conditions with the *trans*-compound. Thus we have here another example of the tendency for production of *trans*-product from *cis*- and *trans*-2-substituted materials.[4a] The analogous action of an acetoxy group in the reactions of acetohalogen sugars with silver acetate has already been discussed.[4a]

The comparison of the effects of the various neighboring halogen atoms was based on semi-quantitative measurements of the rate of reaction of some alcohols with hydrobromic or hydrochloric acid. The reactions were followed by observing the rate of growth of the halide layer from a solution of the proper alcohol in the hydrobromic or hydrochloric acid and estimating the time for half-reaction. One set of reactivities deals with 2-butanol and the related bromohydrin and chlorohydrin, while another set is available for cyclohexanol and the related halohydrins. The pertinent data are summarized in Table IV. The rates of the unsubstituted and β-bromo and β-chloro-substituted alcohols were conveniently compared in fuming hydrobromic acid. The reactivity in the presence of neighboring iodine was so high that the less active concentrated hydrochloric and 48% hydrobromic acids were employed as reagents. Even though the half-life of cyclohexanol in 48% hydrobromic acid was 500 times that in the fuming acid, *trans*-2-iodocyclohexanol reacted so fast in the former solvent that the solution was cloudy before solution of the solid iodohydrin was complete. It is evident from the data in Table IV that a neighboring *trans*-iodine atom raises the reactivity of cyclohexanol almost to that of *t*-butyl alcohol.

TABLE IV

REACTIVITY OF VARIOUS ALCOHOLS TOWARD HALOGEN ACIDS

Compound	Solvent	Half-life *ca.* 20°	Rel. rate
Cyclohexanol	Fuming HBr	20 min.	1.0
Cyclohexanol	48% HBr	7 days	1.0
Cyclohexanol	Concd. HCl	12 days	1.0
trans-2-Chlorocyclohexanol	Fuming HBr	85 days	1.6×10^{-4}
trans-2-Bromocyclohexanol	Fuming HBr	4 hr.	0.08
trans-2-Iodocyclohexanol	48% HBr	*ca.* 15 min.	700
trans-2-Iodocyclohexanol	Concd. HCl	*ca.* 15 min.	1200
2-Butanol	Fuming HBr	75 min.	1.0
2-Butanol	48% HBr	76 hr.	...
threo-3-Bromo-2-butanol	Fuming HBr	3 hr.	0.4
Mixed 3-chloro-2-butanols	Fuming HBr	No halide layer in 25 days	3×10^{-4a}
t-Butyl alcohol	Concd. HCl	45 sec.	...

[a] Conservative estimate.

Again, the reactivities in Table IV are not compatible with the carbonium ion mechanism **B** alone. In the case of a rate-determining formation of a carbonium ion, the rates in the presence of a β-halogen atom are expected to be considerably slower than those of the unsubstituted alcohol due to the strong electron-removal by halogen which clearly opposes the formation of a positive charge on carbon. Moreover, from such physical evidence as ionization constants of aliphatic acids[8] and dipole moments of alkyl halides,[9] it would be reasonable to expect the retardation of the unimolecular rate to be not very far from equal for the various halogen atoms. The predicted rate sequence is therefore: unsubstituted $\gg$ I $\approx$ Br $\approx$ Cl. It is clear that the observed rates are not even in qualitative accord with this sequence, a neighboring iodine atom increasing reactivity by three powers of ten and a neighboring chlorine atom decreasing it by four powers of ten. In order to correlate the high reactivities in the presence of neighboring bromine and iodine, we suggest that we are here dealing with the one-stage mechanism of ring-formation, **A**. The sequence I $\gg$ Br is reasonable because iodine is generally a better nucleophilic agent than bromine. The data do not permit a definite decision regarding the substitution mechanism in the presence of neighboring chlorine although the sluggishness of the substitution suggests a carbonium ion intermediate, III. More evidence on this point is presented in succeeding papers.

It has been assumed in the preceding discussion that the reactions of the cyclohexanols and 2-butanols with halogen acids proceed by way of a unimolecular-type mechanism. This assumption is reasonable for the cyclohexanols since the alternate substitution process, bimolecular attack on carbon, has been shown to proceed only very slowly in the cyclohexyl system.[10] Moreover, the

(9) Wheland, "The Theory of Resonance," John Wiley and Sons, Inc., New York, N. Y., 1944, p. 123.

(10) *E. g.*, Bartlett and Rosen, THIS JOURNAL, **64**, 543 (1942).

stereochemistry of the replacement process in the presence of neighboring bromine[4d] rules out the possibility of considerable bimolecular reaction with inversion of configuration in the reaction of the bromohydrins. On the other hand, the reaction of 2-butanol may well proceed to a considerable extent by way of the bimolecular process C.

$$\text{(C)}\quad Br^- + ROH_2^+ \longrightarrow Br - R + OH_2$$

This fact is indicated by the rather high survival of optical activity together with the change in sign of rotation in the transformation.[11] In the analogous case of 2-octanol, we can estimate from the observed optical rotation data and data in the literature[11] a 57% survival of activity with predominant inversion in the reaction with fuming hydrobromic acid. As is clear from experiments described in the experimental section, racemization is of some importance during these transformations, so inversion would be even more prominent after proper correction.

Another indication that the reaction of 2-butanol may be largely bimolecular in type is the contrast in the reaction rates of cyclohexanol and 2-butanol in various halogen acids. While the reactivity of cyclohexanol is reduced to 1/500 by a change in reagent from fuming hydrobromic to 48% hydrobromic acid, the reactivity of 2-butanol is lowered only by a factor of 50. Moreover, while the rates of cyclohexanol in 48% hydrobromic and concentrated hydrochloric acid are quite comparable, solution of optically active 2-butanol in concentrated hydrochloric acid gives rise to no appreciable reaction and no change in optical activity after elapsed times comparable to the half-life in 48% hydrobromic acid. On the basis of these data it is probable that the relative rate of *threo*-3-bromo-2-butanol in a unimolecular-type displacement may well be above the figure 0.4 listed in Table IV.

Experimental

***cis*-2-Chlorocyclohexanol.**—This material was prepared by the method of Bartlett.[12] Careful distillation of the material after destruction of the *trans*-isomer with base yielded a solid product, b. p. 92.5–93.0° (27 mm.), m. p. 31.5°.

***cis*-1-Acetoxy-2-chlorocyclohexane.**—Acetylation of 20 g. of *cis*-chlorohydrin by the procedure used with the *trans*-bromohydrin[4a] gave rise to an 87% yield of acetate, b. p. 98.3–99.0° (12 mm.) n^{25}_D 1.4654.

Anal.[13,14] Calcd. for $C_8H_{13}O_2Cl$: C, 54.39; H, 7.42; Cl, 20.07. Found: C, 53.83; H, 7.41; Cl, 19.64.

***trans*-1-Acetoxy-2-chlorocyclohexane.**—*trans*-Chlorohydrin, prepared by the method of Coleman and Johnstone,[15] was acetylated by the procedure used with the *trans*-bromohydrin[4a] to yield material, b. p. 98.0–98.5° (12 mm.), n^{25}_D 1.4630.

Treatment of Cyclohexyl Halides with Silver Acetate.—Cyclohexyl chloride and the *cis*- and *trans*-2-acetoxycyclohexyl chlorides were treated with silver acetate in glacial acetic acid in the manner used previously with the analogous bromides.[4a,b] A bath temperature of 100–110° and a reaction time of thirty-two hours were employed.

From 17.7 grams (0.10 mole) of the *trans*-2-acetoxycyclohexyl chloride, using anhydrous acetic acid, was obtained on distillation at 12 mm.: 5.5 g., b. p. 98.5–100.0°, n^{25}_D 1.4609; 4.0 g., b. p. 100.0–117.4°; and 4.0 g., b. p. 117.4–118.8°, n^{25}_D 1.4482; the residue being 0.5 g. The saponification analysis procedure[4a] with the diacetate fraction (high-boiling) gave rise to a glycol, m. p. up to 95° (98–102° on mixing with *trans*-glycol), 103–103.5° after recrystallization from carbon tetrachloride.

Similarly from the treatment in acetic acid with an equivalent amount of water was obtained at 12 mm.: 5.5 g., b. p. 97.5–100.0°, n^{25}_D 1.4600; 4.0 g., b. p. 100.0–112.5°; 4.0 g., b. p. 112.5–115.0°, n^{25}_D 1.4568; residue 0.5 g. The high boiling fraction yielded largely *cis* glycol, m. p. up to 85° (m. p. lowered on mixing with *trans*-glycol), 97.0–97.5° after recrystallization from carbon tetrachloride.

Analogous treatment under anhydrous conditions of 17.7 g. (0.10 mole) of the *cis*-2-acetoxycyclohexyl chloride gave rise at 12 mm. to a 1.5 g. forerun up to 98.5°, 11.5 g., b. p. 98.5–100.0°, n^{25}_D 1.4651, and a 2 g. tarry residue from which diacetate could not be distilled. A similar run with a stoichiometric amount of water yielded at 12 mm. 2 g. of forerun, 11.5 g., b. p. 98.5–100.0°, n^{25}_D 1.4654, and a 0.5 g. residue. A run with xylene, b. p. 136–141°, as a solvent at the reflux temperature gave at 12 mm. 15 g., b. p. 97.5–100.5°, n^{25}_D 1.4674, and a 0.5 g. residue.

Treatment of 11.9 g. (0.10 mole) of cyclohexyl chloride, filtration, dilution with water and extraction with ether gave an ether extract of the product. This was washed with carbonate solution and dried over anhydrous potassium carbonate. Distillation gave rise to 2.5 g. (30%) of cyclohexene, b. p. 82°, and 2.1 g. (15%) of cyclohexyl acetate, b. p. 95–99° (67 mm.).

***cis*-2-Acetoxycyclohexanol.**—To a mixture of 59 g. (0.51 mole) of *cis*-1,2-cyclohexanediol (m. p. 98°), 51 g. (0.50 mole) of acetic anhydride and 10 ml. of ether was added 10 drops of concentrated sulfuric acid. Ten more drops of acid were added after a time. After the mixture had returned to room temperature it was shaken with calcium carbonate to neutralize the acid. Then it was filtered and distilled. From the distillate, 4 g. of solid glycol were filtered out. The remaining 62 g. of product, b. p. 114–115° (12 mm.) n^{25}_D 1.4618, saponification equivalent weight 149, 92 mole per cent. monoacetate, 8 mole per cent. diacetate, represented an 84% yield allowing for recovered glycol.

***cis*-2-Acetoxycyclohexyl *p*-Toluenesulfonate.**—This material was prepared analogously to the *trans*-isomer[4e,16] by treatment of the *cis*-1,2-cyclohexanediol monoacetate–diacetate mixture with *p*-toluenesulfonyl chloride in pyridine. Stirring the reaction mixture with water which was later acidified with sulfuric acid gave rise to an oil which was taken up in ligroin. Drying of the ligroin solution over anhydrous potassium carbonate and storage in the refrigerator gave rise to a 67% yield (on a 40 g. batch) of crude crystalline product, m. p. 76–77° after one recrystallization from aqueous methanol and 77–78° after another recrystallization.

Anal. Calcd. for $C_{15}H_{20}O_5S$: C, 57.67; H, 6.45. Found: C, 57.65; H, 6.53.

Cyclohexyl *p*-Toluenesulfonate.—This material was prepared in 46% yield by the general method of Gough, Hunter and Kenyon.[17] After recrystallization from petroleum ether the m. p. was 43.5–44.0° (reported[18] 44–45°).

Rate Measurements.—The procedure for the acetolysis measurements in anhydrous acetic acid was the same as

[16] Criegee and Stanger, *Ber.*, **69B**, 2753 (1936).

[17] Gough, Hunter and Kenyon, *J. Chem. Soc.*, 2052 (1926).

[18] Hückel, Neunhoeffer, Gercke and Frank, *Ann.*, **477**, 99 (1929).

described previously.[4i] Refluxing chlorobenzene was used as a thermostat liquid at 131°. The *cis*-2-acetoxycyclohexyl *p*-toluenesulfonate reacted very slowly and was followed to 5–6% reaction at 99.7 ± 0.10° and to 20% reaction at 131°. In the case of cyclohexyl *p*-toluenesulfonate the reaction was followed to 70–80% reaction.

Acetolysis of *cis*-2-Acetoxycyclohexyl *p*-Toluenesulfonate.—A 1.5 g. portion of *cis*-2-acetoxycyclohexyl *p*-toluenesulfonate was held under reflux twenty-four hours in 6 ml. of acetic acid containing a trace of acetic anhydride and a slight excess of potassium acetate. The neutralization of the reaction mixture, extraction of the ester product with ether, drying of the ether solution and evaporation of the ether yielded the ester product. Saponification of the ester, treatment of the reaction mixture with carbon dioxide, evaporation and then sublimation gave rise to 0.11 g. (20%) of glycol, m. p. 90–92°, 101–102.5° after recrystallization from carbon tetrachloride (103–104° on mixing with authentic *trans*-glycol). A blank saponification of *cis*-2-acetoxycyclohexyl *p*-toluenesulfonate followed by sublimation did not give glycol.

The yield of glycol (20%) was quite normal if one allows for the fact that, interpolating with the aid of the available rate constants in Table III, it is estimated that the extent of acetolysis of *cis*-2-acetoxycyclohexyl *p*-toluenesulfonate in twenty-four hours at *ca.* 120° is 35%.

***trans*-2-Iodocyclohexanol.**—To 100 ml. of 46% reagent-grade hydriodic acid (density 1.50) cooled in a salt–ice-bath was slowly added with effective stirring 49.2 g. (0.50 mole) of cyclohexene oxide. After approximately three fourths of the oxide had been added, solid precipitated. Stirring was continued for fifteen minutes after the addition of oxide was complete. Then the iodohydrin was filtered off and air-dried. The crude product obtained in nearly quantitative yield was dissolved in ether. The iodine color was discharged by the addition with vigorous shaking of small portions of solid sodium bisulfite. The ether solution was decanted and dried over anhydrous potassium carbonate. The ether was then removed at room temperature with the aid of the water pump, and 100 ml. of petroleum ether was added. Cooling gave crystalline product which was recrystallized from petroleum ether to yield 75 g. (66%) of air-dried material, m. p. 39–40°. Another recrystallization gave material, m. p. 39.9–40.4° (reported[19] m. p. 41.5–42.0°), which was slower to develop color on standing. The equivalent weight of the iodohydrin on treatment with base[12] was 226.3 (calculated 226.1).

Treatment of Alcohols and Halohydrins with Fuming Hydrobromic Acid.—This was usually carried out as previously described,[20] the reaction mixture being sealed at 0° and allowed to warm up to and remain at room temperature. The preparation of the samples of *threo*-3-bromo-2-butanol,[20] *trans*-2-bromocyclohexanol,[4a,d] and the mixed 3-chloro-2-butanols[21] needs no further description.

From the treatment of cyclohexanol, isolation of the product after 2 days gave rise to a 75% yield of cyclohexyl bromide, b. p. 69.5–69.8° (31 mm.), $n^{25}\mathrm{D}$ 1.4932.

From the treatment of a 17.5 ml. volume of partially resolved 2-butanol, b. p. 98.5–99.0° (745 mm.), $\alpha^{22.5}\mathrm{D}$ (1 dcm.) 1.20° was obtained after two days 24 g. of crude, 19.0 g. of distilled bromide, b. p. 89–91°, $n^{21.5}\mathrm{D}$ 1.4365, $\alpha^{23}\mathrm{D}$ (1 dcm.) −2.32°.

The bromide layer from the treatment of a 22.13 g. quantity of 2-butanol, prepared by mixing 11.15 g. of active 2-butanol, b. p. 99.0–99.3° (754 mm.), $\alpha^{24}\mathrm{D}$ (1 dcm.) 4.93°, with 10.98 g. *dl*-2-butanol, b. p. 98.8–99.0° (745 mm.), was removed three times so that three nearly equal portions of halide were obtained. The fractions, 12.4 g. 12.9 g. and 12.5 g., totaled 37.8 g. (92%) before distillation. Distillation of the portions gave materials boiling at 90.2–90.3° (750 mm.), $\alpha^{20}\mathrm{D}$ (1 dcm.) for the fractions, −5.33°, −5.12°, −4.45°, average −4.97°.

Partially active 2-bromobutane, $\alpha^{24}\mathrm{D}$ (1 dcm.), −5.03°, b. p. 90.3° (746 mm.), was sealed with fuming aqueous hydrobromic acid saturated at 0°. The mixture was kept on a shaker for seven hours and then left overnight. Isolation yielded bromide, b. p. 90.3° (746 mm.), $\alpha^{25}\mathrm{D}$ (1 dcm.) −4.26°.

Octanol-2 (14.5 g.), $\alpha^{22.5}\mathrm{D}$ (1 dcm.) −6.20°, was treated with fuming hydrobromic acid prepared from 100 g. of the 48% material. The octanol did not dissolve but with occasional shaking the reaction proceeded with shrinkage of the upper layer. This shrinkage appeared complete in about four hours. After two days the bromide was isolated to yield 19.5 g. crude, 15.5 g. of pure material, b. p. 77.8–78.5° (17 mm.), $n^{22}\mathrm{D}$ 1.4508, $\alpha^{23}\mathrm{D}$ (1 dcm.) 16.31°.

A solution of 7.75 g. of *trans*-2-chlorocyclohexanol in 54 g. of 48% hydrobromic acid was saturated with hydrogen bromide at 0°, sealed, shaken and observed at room temperature. The estimated weights of separated dihalide after 12, 17, 26, 40 and 102 days were 0.08, 0.3, 1.0, 1.6 and 5.8 g., respectively. After 139 days, the oil layer was removed with the aid of 15 ml. of petroleum ether, the extract was washed with carbonate solution and dried over magnesium sulfate. Distillation through a small Vigreux column yielded 4.0 g. of a colorless material, b. p. 66–69° (3.5–4.5 mm.), $n^{22.6}\mathrm{D}$ 1.5321, d_4^{23} 1.602. The equivalent weight on halogen analysis[22] of this material was 108.8. Analysis for chlorohydrin by treatment of a methanol solution with excess standard base and back-titration to the brom thymol blue end-point after four minutes showed only 0.3% chlorohydrin. The equivalent weight indicates the material was a 50–50 by weight mixture of cyclohexene bromochloride and dibromide, some exchange of bromide for chloride taking place in the reagent or product during the lengthy reaction period.

Treatment of Alcohols and Halohydrins with Concentrated Hydrochloric Acid or 48% Hydrobromic Acid.—The concentration of the cyclohexanols in each of the reagents was approximately 1 *M*.

Upon mixing 0.01 mole of *trans*-2-iodocyclohexanol with 10 ml. of concentrated hydrochloric acid or 48% hydrobromic acid at 0° the iodohydrin partly or largely dissolves and rapidly forms the insoluble liquid dihalide which wets and dissolves the remainder of the solid iodohydrin. The volume of the oily layer amounts to about 70% of the final volume after a period of about ten minutes with either halogen acid. The oily layer proved to be a mixture of dihalide and iodohydrin.

A 0.100 mole quantity of iodohydrin was shaken twenty-five minutes with 100 ml. of ice-cold concentrated hydrochloric acid. Then 25 ml. of carbon tetrachloride was added and the organic layer was separated, washed, dried and distilled at reduced pressure. There was obtained 20.5 g. (*ca.* 85%) of an iodochloride fraction b. p. 73–74° 2 mm.), $n^{24}\mathrm{D}$ 1.5674. Stephanov analysis[22] for halogen gave an equivalent weight of 154.3, corresponding to 55% by weight iodochloride.

A 10 ml. volume of *dl*-2-butanol was dissolved in 50 ml. of 48% hydrobromic acid at room temperature. The approximate volume of oil layer was 1.5 ml. after twenty-one hours, 6.0 ml. after six days and 7.5 ml. after twelve days.

Approximately 2 ml. of active 2-butanol, $\alpha^{24}\mathrm{D}$ (1 dcm.) 4.93°, was dissolved in approximately an equal volume of concentrated hydrochloric acid. The $\alpha\mathrm{D}$ (1 dcm.) remained at 2.21 ± 0.01° for twenty-three hours at the end of which time the solution was very slightly turbid. The reading after seventy-one hours was 2.17°.

Summary

In connection with participation of neighboring groups in nucleophilic displacements of the unimolecular type, rate measurements lead to an understanding of the rate-determining ionization step. This may be either a direct formation of the

III

Rates of acetolysis of cyclohexyl *p*-toluenesulfonates give the sequence: unsubstituted, 1.00 $>$ *trans*-2-OAc, 0.30 $\gg$ *cis*-2-OAc, 4.5×10^{-4}. Rates of reaction of the corresponding chlorides with silver acetate are qualitatively similar. Reactivities of 2-butanols and cyclohexanols toward hydrohalogen acids show that a neighboring *trans*-bromine atom gives a rate comparable to that of the unsubstituted material. A *trans*-iodine atom increases and a *trans*-chlorine atom decreases reactivity by factors of approximately 10^3 and 10^4, respectively.

These results are taken to indicate that with the *trans*-OAc, Br and I groups, the ionization is directly to II. On the other hand, with *trans*-Cl and *cis*-OAc, ionization is probably to III.

The product of acetolysis of *cis*-2-acetoxycyclohexyl *p*-toluenesulfonate is very predominantly *trans*.

The Role of Neighboring Groups in Replacement Reactions. XII. Rates of Acetolysis of 2-Substituted Cyclohexyl Benzenesulfonates[1]

BY S. WINSTEIN, ERNEST GRUNWALD AND L. L. INGRAHAM

In the present article are reported further rate measurements which give information on solvolysis rates involving a substantial series of neighboring groups in a cyclohexyl system. The reaction rate measured was that of acetolysis of a series of 2-substituted cyclohexyl *p*-bromobenzenesulfonates or *p*-toluenesulfonates symbolized by formulas VI and VII. These rate measurements serve to establish relative rates in the presence of various neighboring groups in a reaction of one charge-type and lend themselves better to a quantitative discussion than some reported in the previous paper.[2]

Results

Materials for Acetolysis.—For the most part, the materials for rate measurements (Table I) were prepared by conventional methods from the proper alcohol or glycol IV or V. The assignment of configuration (*trans* or *cis;* IV, VI *vs.* V, VII) to the various materials has been illustrated sufficiently in previous work[3] and is clear from the methods of preparation described in the experimental section.

The *trans*-2-iodocyclohexyl *p*-toluenesulfonate IX is very reactive and unstable and was difficult to obtain. All attempts at preparation by conventional methods from the cyclohexene iodohydrin IV (S-A = I) failed. A successful synthesis was achieved using the reaction of cyclohexene with silver *p*-toluenesulfonate and iodine in absolute ether. Under the special conditions used for this latter reaction (*e. g.*, absence of pyridine; no reactive solvent necessary in working up the reaction mixture) the product IX survived well enough to be isolated in reasonable yield. The reaction is formulated as proceeding through the iodonium ion VIII which reacts, in the absence of any better nucleophilic agent, with toluenesulfonate ion to yield *trans*-product IX. The material IX, thus prepared, gave a fair carbon–hydrogen analysis (Table I; this was not on the best sample). Also equivalent weight values which averaged within 1.5% of theory were obtained from: (a) titration of the iodine liberated on treatment with potassium iodide; (b) hydrolysis in aqueous acetone to iodohydrin followed by measurement of the quantity of alkali necessary to neutralize the acid and convert the iodohydrin to oxide; (c) the "infinity" titer in the actual acetolysis rate measurements.

slight excess of acetic anhydride, and also in some cases in two other stock solvents, one containing 0.025 M potassium acetate, and one 0.36 M in water. The reactions were followed by titrating at intervals for the arylsulfonic acid liberated during the acetolysis. The observed kinetics were nicely first-order in almost all cases, and the precision of the measurements was usually 2% or better except when the rate constants were below 10^{-7} sec.$^{-1}$. In the latter case, the reactions were so slow that initial rates were measured (to *ca.* 15% completion), and the precision attained was about 5%. In the case of the di-*p*-bromobenzenesulfonates, rate constants were evaluated on the assumption that two moles of acid are generated per mole of ester destroyed. With the β-halocyclohexyl esters, no serious difficulty was encountered due to displacement of the halogen atom. Thus, in the case of the iodine compound, the acid titer after 23 half-lives was only 0.7% greater than after 9 half-lives, while with the bromine analog the acid titer after ten half-lives was only 4–8% high. Table II lists the data for a run with *trans*-2-methoxycyclohexyl *p*-bromobenzenesulfonate, while a run with the unreactive di-*p*-bromobenzenesulfonate of *trans*-1,2-cyclohexanediol is illustrated in Table III. It is seen that in the two runs, which are typical of our measurements, a first-order rate constant $k = (1/t)\ \ln\ [a/(a - x)]$, where a is the initial concentration of ester and x is the concentration of sulfonic acid at time t, is satisfactorily constant. The slight upward drift during the runs, which was observed fairly consistently, is probably real and attributable to the salt effect of the liberated acid. In only three cases were the drifts in k outside of experimental error. The acetolysis rate of cyclohexyl *p*-bromobenzenesulfonate in dry acetic acid and in acetic acid 0.36 M in water increased during a kinetic run, and a typical set of data is presented in Table IV. A calculated first-order rate constant k decreased during the acetolysis of *trans*-2-acetoxycyclohexyl *p*-bromobenzenesulfonate in dry acetic acid, in qualitative agreement with the behaviour of the *p*-toluenesulfonate described previously,[4] and a typical set of kinetic data is given in Table V. It is seen that the drifts in either case are small. Initial rate constants were

estimated in these cases with satisfactory precision from a plot of *k vs.* extent of reaction by extrapolation to zero reaction. On the other hand the acetolysis of *cis*-2-acetoxycyclohexyl *p*-bromobenzenesulfonate in acetic acid 0.36 *M* in water was greatly catalysed by the liberated acid, and a precise estimate of the initial rate constant could not be obtained. The details of the observed kinetics are described in the experimental part.

Table VI contains a summary of the observed rate-constants and of the quantities of activation derivable from them. $\Delta\tilde{H}^{\ddagger}$ and $\Delta\tilde{S}^{\ddagger}$ symbolize the enthalpy and entropy of activation, and are calculated with the aid of equation 1.[5]

$$k = \frac{kT}{h} e^{-\Delta\tilde{H}^{\ddagger}/RT} e^{\Delta\tilde{S}^{\ddagger}/R} \qquad (1)$$

We estimate in general probable errors within 0.5 kcal. for $\Delta\tilde{H}^{\ddagger}$, and within 2 e. u. for $\Delta\tilde{S}^{\ddagger}$. The specific rates listed in the Table are averages of the observed values, except in the three cases discussed in the preceding paragraph where extrapolated initial rate-constants are given.

(6) Winstein and Grunwald, *ibid.*, **68**, 536 (1946).

Table VI gives an impression of the effects of solvent changes on the first-order acetolysis rate-constants. The change to the slightly aqueous solvent from the one containing a small amount of acetic anhydride raises the rate, as is to be expected,[7] by 26–39% in the case of the *trans*-Br, *trans*-OCH_3, *trans*-OAc, and unsubstituted compounds. For these compounds as well as for the *cis*-OAc compound, the change from the solvent containing 0.0459 *M* acetic anhydride to one 0.0088 *M* in acetic anhydride and 0.025 *M* in potassium acetate gives rise to increases in rate-constant of a similar magnitude. A portion of this effect is due to the decrease in acetic anhydride concentration.

Discussion

Nature of the Acetolysis.—Although the extent of the bimolecular and unimolecular reactions in alcoholysis and hydrolysis of secondary halides is still a matter of doubt,[8] our measured *k* values must be those for unimolecular ionization of the sulfonate group. Bimolecular reactions of cyclohexyl compounds, at least of halides,[9] are very slow. Moreover acetic acid is a poor nucleophilic agent and would be expected to coöperate only poorly in bimolecular displacement and elimination reactions which require an attack on carbon or hydrogen coincident with the departure of the sulfonate ion. Addition of acetate ion which would participate more readily in such bimolecular reactions, gives rise to no serious increase in observed rates.

It is assumed that the mode of cleavage of the sulfonate is the usual carbon–oxygen one (X) even in the slowest cases. Actually, there is evidence

$R-\!\!\mid\!\!-OSO_2C_6H_4X$

X

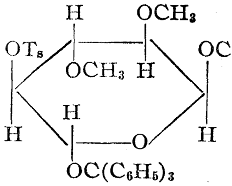
$R-\!\!\mid\!\!-OSO_2C_6H_5X$

XI

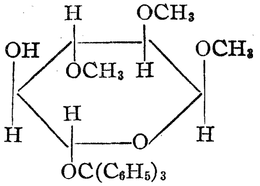
of long standing that sulfur–oxygen cleavage (XI) occurs in certain cases. Thus, in the case of phenyl *p*-toluenesulfonate, Lapworth[10a] reported and discussed the reaction with sodium ethylate, the rate-determining step of which must be a displacement on sulfur of phenolate ion by ethylate ion according to equation 2.

$$C_6H_5OSO_2C_6H_4CH_3 + C_2H_5O^- \longrightarrow C_6H_5O^- + C_2H_5OSO_2C_6H_4CH_3 \quad (2)$$

Lapworth's explanation was later supported by Phillips.[10b] This type of displacement must be responsible for some of the difficult displacements without inversion of a toluenesulfonate group from carbohydrate toluenesulfonates. An example of such a case is the hydrolysis without inversion of 4-*p*-tosyl-6-trityl-2,3-dimethyl-*α*-methylglucoside XII to XIII with the aid of sodium methoxide in benzene.[11]



XII



XIII

In dry acetic acid as a solvent, the sulfur–oxygen mode of cleavage of the sulfonate ester could depend only on an attack on sulfur by acetic acid to displace alkoxide ion or some type of ionization of the sulfur–oxygen bond, processes which would seem to be at least as favorable with phenyl esters as in our cases. Accordingly, the acetolysis of phenyl *p*-bromobenzenesulfonate was followed, no detectable reaction being observed in glacial acetic acid at 75° in three months. The rate constant was accordingly below 5×10^{-11} sec.$^{-1}$, the latter value representing an upper figure for the rate that could possibly be assigned to this other mode of cleavage of the sulfonate esters.

k/k_H Values.—The relative rates of acetolysis of the cyclohexyl benzenesulfonates are given in Table VI in the column headed k/k_H, k_H signifying the rate of acetolysis of the unsubstituted cyclohexyl ester. The effects of neighboring *trans*-halogen atoms are seen to be very similar in the present reaction to those observed previously[2] for the reaction of halohydrins with hydrohalogen acids. Again an iodine atom is rate-enhancing by a factor of *ca.* 10^3, while a chlorine atom is rate-retarding by *ca.* 10^4. The rate sequence for the halogens is $I \gg H \approx Br \gg Cl$ instead of $H \gg I \backsimeq Br \backsimeq Cl$ which would be expected for the carbonium ion mechanism **B**. Again the qualitative conclusion is that with neighboring iodine and bromine the ionization is very largely by mechanism **A**.

The contrast in behavior of the *cis*- and *trans*-di-*p*-bromobenzenesulfonates and the *cis*- and *trans*-2-acetoxycyclohexyl esters is striking. The two di-*p*-bromobenzenesulfonates react at nearly equal rates, k/k_H being less than 10^{-4}. On the other hand, as observed with the corresponding toluenesulfonates,[2] the *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate is very much more reactive than the *cis*-isomer, the factor between them being nearly 10^3. The data suggest that with the *trans*-2-OAc group, ionization is by step **A**, while with *cis*-2-OAc group, it is probably by step B. For the di-*p*-bromobenzenesulfonates with the very poorly nucleophilic neighboring *p*-bromobenzenesulfoxy group, a possible explanation of the equality in rates for *cis*- and *trans*-isomers is that ionization is by the carbonium ion mechanism B in both cases. The slow rate is consistent with the powerful electron-removing effect which can be expected from a benzenesulfoxy group. Also, the near equality in rates is not surprising in the mobile cyclohexane system although it would perhaps not be anticipated in a more rigid system.

[11] Oldham and Robertson, *ibid.*, 685 (1935).

k_Δ/k_c Values.—A more quantitative discussion based on the relative reactivities k/k_H begins with the recognition that the measured rate constants k must represent the sums of k_Δ and k_c, where k_Δ is the specific rate constant for the ionization **A** to yield the cyclic intermediate II, and k_c is the specific rate constant for ionization **B** to yield the open carbonium ion III. Thus the relative reactivities are given by equation 3. If k_c/k_H can be estimated, it becomes possible to estimate the relative

$$k/k_H = k_c/k_H + k_\Delta/k_H \qquad (3)$$

values of k_Δ and k_c, in other words the relative importance of steps **A** and **B**. The ratio of k_Δ to k_c is given by equation 4.

$$k_\Delta/k_c = [(k/k_H)/(k_c/k_H)] - 1 \qquad (4)$$

Judging by the behavior of the *cis*- and *trans*-di-*p*-bromobenzenesulfonates, it becomes possible to estimate k_c/k_H for the *trans*-2-acetoxycyclohexyl *p*-bromobenzenesulfonate as the figure observed for k/k_H with the *cis*-isomer. This estimate of k_c/k_H is listed in Table VII, together with the derived value of k_Δ/k_c equal to 2.33×10^3. The values of k/k_H in Table VII have been corrected to the uniform temperature 25°, and the other figures in the table refer to this temperature.

To estimate k_c/k_H for some of the other neighboring groups we have used an approach which has been used before in interpreting the effect of substituents on the strength of carboxylic acids and the rates of saponification of esters. This approach accounts for the effect of the substituent on electrostatic grounds. Kirkwood and Westheimer[12] have made important improvements in the method especially with regard to the calculation of an effective dielectric constant, $\mathbf{D_E}$, and Westheimer and co-workers[12] have made quite successful applications to the interpretation of both equilibria and rates.

The procedure is to calculate the extra work W involved in the generation of the C–O dipole of moment M_1, due to the partly ionized bromobenzenesulfoxy group in the transition state, against the dipole, moment M_2, due to the neighboring group. The interaction energy W (in kcal./mole) of two dipoles is given[13] by equation 5, where r is the length of the vector joining the centers of the dipoles, and ϵ, θ, and θ' are angles between M_1 and M_2, M_1 and r, and M_2 and r, respectively.

$$W = 1.439 \times 10^{13}\, M_1 M_2 \mathbf{D_E}^{-1} r^{-3}\, (\cos \epsilon - 3 \cos \theta \cos \theta') \qquad (5)$$

The assumed model for the transition state was simplified to involve a coplanar *trans* arrangement of the dipoles M_1 and M_2 and tetrahedral bond angles for carbon. The assumed value of M_1 was 4.6 D, one half of the moment, 9.2 D, calculated for complete ionization at the assumed[14] transition state distance of 1.93 Å. All other interatomic distances were derived from the covalent bond radii given by Pauling.[15] The point-dipoles were taken as situated at the midpoints of the respective bonds. The neighboring group dipole moment, M_2, was taken as 1.87 D for C–Cl, 1.78 D for C–Br, and 1.59 D for C–I.[12,16] A composite moment of 0.85 D was taken for the C–OCH$_3$ dipole, with the center of the dipole 0.72 Å. from the β-carbon atom.

For dipole–dipole interaction the effective dielectric constant $\mathbf{D_E}$ is close to the internal dielectric constant $\mathbf{D_i}$ as Westheimer has pointed out to us in private communications. For $\mathbf{D_i}$ Kirkwood and Westheimer have consistently used the value of 2.00. We have treated $\mathbf{D_E}$ as a disposable parameter, choosing a value which gives a calculated k_c/k_H equal to k/k_H in the case of chlorine. In the case of neighboring chlorine, the data previously[2] and now presented, and evidence included and discussed in the following article[17] indicate that the original ionization step is very predominantly by path **B** and thus that $k = k_c$. The relation between W and k_c/k_H is given by equation 6. The value of $\mathbf{D_E}$ determined in this way was

$$\ln (k_c/k_H) = W/RT \qquad (6)$$

1.23, a value which is quite reasonable, considering that we are requiring this adjusted value for $\mathbf{D_E}$ to compensate for the arbitrary choice of the other parameters. Values for $\mathbf{D_E}$ as low as 1.00[18] have sometimes been used in situations of this sort. On the whole, it is clear that the calculation along electrostatic lines accounts fairly quantitatively for the magnitude of the reduction in solvolysis rate due to a neighboring *trans*-chlorine atom.

Using the value 1.23 for $\mathbf{D_E}$, equations 5 and 6 have been applied to neighboring Br, I and OCH$_3$, the values of W and k_c/k_H being summarized in Table VII. The derived values of k_Δ/k_c are listed also. Although the treatment is admittedly crude and we comment in the following article[17] on a further complication, the values of k_Δ/k_c for neighboring bromine and iodine indicate, just as for *trans*-OAc, the very large predominance of ionization by process **A**, the fraction of this being k_Δ/k or $k_\Delta/(k_\Delta + k_c)$.

On the other hand, the case of *trans*-OCH$_3$ is in the nature of a borderline one, k_Δ/k_c being estimated at 4.3. From the nature of the treatment, when k_Δ/k_c is small as it is here, no accuracy can be claimed for the fraction of ionization proceeding by process **A**. For this case k_Δ and k_c are more comparable in magnitude and further work[17] will be required to more accurately estimate k_Δ/k.

TABLE VII

ACETOLYSIS RATES IN THE PRESENCE OF VARIOUS NEIGHBORING GROUPS

Neighboring group	k/k_H (25°)	W (Eq. 5) kcal./mole	k_c/k_H 25° (Eq. 6)	k_Δ/k_c 25° (Eq. 4)	L kcal./mole 25°
trans-Cl	0.94×10^{-4}	(5.50)	(0.94×10^{-4})	...	..
trans-Br	7.18×10^{-2}	5.09	1.87×10^{-4}	383	3.53
trans-I	1120	4.33	6.7×10^{-4}	1.7×10^{6}	8.49
trans-OCH_3	5.28×10^{-2}	2.73	1.00×10^{-2}	4.3	0.86
trans-OAc	0.305	..	1.31×10^{-4}	2.33×10^{3}	4.60

Driving Force Due to Participation.—It is useful to introduce a variable L which will be termed the driving force due to the participation of the neighboring group in the rate-determining process. The variable L is defined by equation 7, and the values for some of the neighboring groups are included in

$$L = RT \ln (k_\Delta/k_c) \qquad (7)$$

Table VII. These run from 0.86 kcal./mole in the case of *trans*-OCH_3 to 8.49 kcal./mole for *trans*-I, supplying a quantitative measure for the so-called driving force of neighboring groups.

The driving force L may be discussed in terms of the relative stabilities of the two envisaged cationic intermediates II and III. It is a necessary condition for the existence of a positive driving force due to participation of the neighboring group that the conversion of carbonium ion III to three-membered ring II be attended by a decrease in free energy. The observed driving-force represents that fraction of this decrease in free energy which is already applicable to the transition-states.

It is interesting to consider the relative contributions of enthalpy and entropy terms to the free energy effects associated with the various rate ratios discussed. Inspection of Table VI indicates that variations in k/k_H are due mainly to changes in $\Delta\tilde{H}^{\ddagger}$. Thus, the relative enthalpies of activation, $\Delta\tilde{H}^{\ddagger} - \Delta\tilde{H}^{\ddagger}_H$, vary from -5.3 to $+6.4$ kcal./mole corresponding to a rate-factor of *ca.* 10^8, while the relative entropies of activation, $\Delta\tilde{S}^{\ddagger} - \Delta\tilde{S}^{\ddagger}_H$ vary from -5.7 to $+3.0$ e. u., corresponding to a rate-factor of *ca.* 10^2. This indicates the greater importance, in general, of energy over entropy effects in consideration of k_c/k_H and k_Δ/k_c values. Although the differences in the entropies of activation are relatively small, the observed trend in $\Delta\tilde{S}^{\ddagger}$ for the halogens, with *trans*-I having the lowest value because it is involved in the most constrained transition-state configuration, is consistent with the general interpretations advanced.

Experimental

Carbinols and Glycols.—*trans*-1,2-Cyclohexanediol,[3c] m. p. 103°, *trans*-2-bromocyclohexanol,[3a,c] b. p. 72° (3 mm.), *trans*-2-methoxycyclohexanol,[3e] b. p. 68.9–70.2° (8 mm.), and *trans*-2-iodocyclohexanol,[2] m. p. 39–40° were prepared from cyclohexene oxide[3c] as previously described. *cis*-1,2-Cyclohexanediol, prepared by Criegee's method,[3d,19] was converted to the monoacetate, b. p. 112–114° (12 mm.) in the usual manner.[2]

trans-**2-Chlorocyclohexanol.**—This material, b. p. 78.7–79.8° (14 mm.), was prepared in 65% yield by reaction of 0.3 mole of cyclohexene oxide with 40 ml. of concentrated hydrochloric acid similarly to the preparation of the analogous bromohydrin.[3c]

Preparation of *p*-Bromobenzenesulfonates (Table I).—The equivalent amount of *p*-bromobenzenesulfonyl chloride was added in one portion to a solution, cooled to 0°, of 0.1 mole of carbinol or glycol in 100 ml. of anhydrous pyridine. The reaction mixture was shaken and left in the cold room, usually overnight. Then it was poured with vigorous stirring into 200 ml. of ice-cold 6 N hydrochloric acid. The product, either oily or crystalline, was taken up in carbon tetrachloride. The carbon tetrachloride solution was dried over potassium carbonate and placed in an evaporating dish. After evaporation of the solvent at room temperature, the residue was usually crystalline. In the case of *trans*-2-hydroxycyclohexyl *p*-bromobenzenesulfonate, the product was not soluble in carbon tetrachloride so it was directly filtered and dried. The materials were recrystallized from Skellysolve B (petroleum ether, b. p. 60–70°) or ethyl acetate–Skellysolve B. Methanol was sometimes used with the less reactive materials. Yields of products obtained were in the range of 45–89% except in the case of the di-*p*-bromobenzenesulfonates of *cis*- and *trans*-1,2-cyclohexanediol, where they were much lower.

Phenyl *p*-bromobenzenesulfonate, m. p. 116.6–117.1° (reported[20] 115.5°) was prepared by the above general procedure.

The cyclohexyl and *trans*-2-hydroxycyclohexyl *p*-bromobenzenesulfonates were the least stable of the bromobenzenesulfonates prepared and could not be kept long. The latter material showed an equivalent weight of 331.5 (calculated 335.2) on treatment for several minutes with methanolic base and back titration with acid as in the case of *trans*-2-chlorocyclohexanol.[21]

The treatment of *trans*-1,2-cyclohexanediol with 2 equivalents of *p*-bromobenzenesulfonyl chloride gave rise to a product contaminated with monoester which was destroyed with methanolic base before purification of the desired di-ester. In the case of the *cis*-1,2-cyclohexanediol, treatment with one equivalent of acid chloride gave rise to di-*p*-bromobenzenesulfonate as the isolated product just as in the case of the toluenesulfonate.[19]

trans-**2-Acetoxycyclohexyl *p*-Bromobenzenesulfonate.**—To a solution of 5 drops of concentrated sulfuric acid in 50 ml. of acetic anhydride cooled in an ice-bath was added 0.1 mole of *trans*-2-hydroxycyclohexyl *p*-bromobenzenesulfonate in approximately 8 portions and with vigorous shaking. There were added 5 drops more of sulfuric acid during the addition and 5 drops at the end. The mixture was shaken for one hour at room temperature, then treated with 300 ml. of water. The crude product obtained in nearly quantitative yield gave material, m. p. 97.4–97.9°, in 70–80% yield on recrystallization from ethyl acetate-Skellysolve B.

trans-**2-Iodocyclohexyl *p*-Toluenesulfonate.**—A mixture of 5 ml. of cyclohexene, 20 ml. of absolute ether, 5.8 g.

---

[19] Criegee and Stanger, *Ber.*, **69B**, 2753 (1936).

[20] Sekera, THIS JOURNAL, **55**, 421 (1933).

[21] Bartlett, *ibid.*, **57**, 224 (1935).

(0.021 mole) of silver toluenesulfonate[22] and 5.08 g. (0.020 mole) of resublimed iodine was shaken in a glass-stoppered flask for thirty minutes with occasional cooling in tap water. The silver iodide was removed on a filter and washed with two 10-ml. portions of a wash liquid containing 2 parts of absolute ether to 1 part of dry Skellysolve B. To the filtrate and washings was added dry Skellysolve B until no more precipitation of toluenesulfonic acid occurred. The mixture was filtered rapidly and the filtrate was cooled to Dry Ice temperature. An oil was obtained which crystallized as the mixture warmed up with shaking. Renewed cooling to Dry Ice temperature produced a crop of white crystals. Rapid filtration and washing with dry Skellysolve B with precautions against access of moisture gave rise to material, m. p. 51–52°, in yields of 20–50%. The material was quite unstable and a batch was prepared and used immediately for equivalent weight determinations and rate-runs.

A mixture of 2.0 g. of potassium iodide, 20 ml. of absolute acetone and 0.1376 g. of the iodocyclohexyl *p*-toluenesulfonate was left for two hours at room temperature. After acidification, 14.12 ml. of 0.0499 *N* thiosulfate was required for titration: equivalent weight 195.3, calcd. 190.1. A sample of the iodohydrin *p*-toluenesulfonate weighing 0.3570 g. was held in 100 ml. of 80% aqueous acetone at 35° for twenty-two hours. There was then added 39.15 ml. of 0.05063 *N* sodium hydroxide and the solution was left ten minutes. Back titration to the brom thymol blue end-point required 1.39 ml. of 0.0962 *N* acid. From these data the equivalent weight is 193.1, calcd. 190.1. From the rate runs, the iodocyclohexyl *p*-toluenesulfonate appeared to contain 1–2% by weight of toluenesulfonic acid.

The attempted preparation of the toluenesulfonate and also the bromobenzenesulfonate from cyclohexene iodohydrin by the ordinary method gave rise to an oil, from which was recovered a small amount of crude cyclohexene iodohydrin, m. p. 37°. An attempted preparation of the bromobenzenesulfonate in absolute ether using 1.2 molecular proportions of pyridine was unsuccessful with cyclohexene iodohydrin as well as with cyclohexanol. Reaction times of three to eighteen hours at 0° were employed, good recoveries of bromobenzenesulfonyl chloride being obtained.

Titrations.—Analyses were performed with approximately 0.05 *N* standard perchloric acid and/or sodium acetate in glacial acetic acid. The standard perchloric acid in acetic acid was prepared from 70% aqueous acid which was compared with Bureau of Standards potassium acid phthalate. The sodium acetate reagent was obtained by dissolving reagent grade sodium carbonate in glacial acetic acid and making the solution up to volume. Titrations were carried out with 5 ml. micro-burets.

The indicator which we empirically found to be advantageous was brom phenol blue (supplied by Paragon Testing Laboratories, Orange, New Jersey), used in the form of a saturated acetic acid solution (*ca.* 0.1%). The indicator is colorless in acidic acetic acid solution, dim yellow in neutral solution and brilliant yellow in basic solution, the strongest color change occurring at an acetate ion concentration approximately 10^{-6} to 10^{-5} *M*. It is most convenient to approach the end-point from the acid side, the accuracy being good with either perchloric, bromobenzenesulfonic or toluenesulfonic acid. Several checks on the titration procedure were carried out.

The standard sodium acetate and perchloric acid were many times compared. A complete summary of data obtained in a six months working period showed that the normality of perchloric acid based on the sodium acetate normality and the acid–base ratio agreed with the normality based on the weight of the standard perchloric acid within 0.0 ± 0.15%.

A slightly impure sample of cyclohexyl *p*-bromobenzenesulfonate was solvolyzed in methanol–water and also in acetic acid. The aqueous solution was titrated with base to the methyl orange end-point, the acetic acid solution with sodium acetate to the brom phenol blue end-point. The equivalent weight of the bromobenzenesulfonate was 324.0 in acetic acid, 324.4 in water–methanol.

A sample of *p*-toluenesulfonic acid monohydrate was titrated in aqueous solution to the phenolphthalein end-point, the equivalent weight being 192.4 ± 0.4. In acetic acid solution, the equivalent weight proved to be 191.7 ± 0.5.

For the titration of 5 ml. quantities of both toluenesulfonic and perchloric acids, variation in the concentration of acid from 0.05 *N* to 0.001 *N* gave rise to no systematic error in the volume of sodium acetate solution required. The precision of titration remained within the larger of the two errors, ±0.5% or ±0.004 ml.

Solvents. (Table VI).—The stock solvents were prepared from J. T. Baker reagent glacial acetic acid, pure acetic anhydride, and dried reagent grade potassium acetate. Concentrations of acetic anhydride were determined by Kilpi's anthranilic acid method.[23]

Rate Measurements.—Solutions, 0.03 to 0.05 *M*, of the compounds to be solvolyzed were made up at room temperature in a volumetric flask from a weighed portion of the material. In case of insufficient solubility at room temperature, solutions were made up gravimetrically. About 6-ml. portions of the solutions were sealed in ampoules and immersed in a suitable thermostat. At suitable times reaction was interrupted by removing an ampoule and immersing it in ice. The ampoule was then brought to room temperature and opened, a 5-ml. aliquot being removed for analysis. The time of the first analysis was called "zero time."

On complete acetolysis, the equivalent weight of cyclohexyl *p*-bromobenzenesulfonate was 320.8 (calcd. 319.2), of *trans*-2-acetoxycyclohexyl *p*-bromobenzenesulfonate 378.5 (calc. 377.3), and of *trans*-2-iodocyclohexyl *p*-toluene sulfonate 380.1 ± 4.0 (calc. 380.2).

With the *cis*-2-acetoxycyclohexyl *p*-bromobenzenesulfonate, the rate constant in solvent III at 75° climbed rapidly an effect which disappeared on addition of potassium acetate to the solvent. A plot of x against t gave, with the aid of a tangent meter, a rough estimate of the initial rate constant and a more accurate estimate of the instantaneous rate constant $k' = [(\mathrm{d}x/\mathrm{d}t)/(a-x)]$.

The variation of k' with x is given quite accurately by equation 8

$$10^3 k' = 27.76\, x^{1/2} - 0.23 \qquad (8)$$

obtained from the data by the method of least squares. This equation is based on the assumption of some preliminary rate-determining reaction of the acetoxybromobenzenesulfonate which is hydrogen ion-catalyzed, toluenesulfonic acid being treated simply as a weak acid. The experimental data as well as the values of k' calculated from equation 8 are summarized below.

$10^3 x$	$10^3 k'$ obsd.	calcd.
1.12	0.73	0.70
2.18	1.05	1.07
3.61	1.42	1.44
5.39	1.74	1.81
7.56	2.25	2.18
9.62	2.56	2.49
11.70	2.71	2.77

Summary

A series of 2-substituted cyclohexyl *p*-bromobenzenesulfonates and a toluenesulfonate have been prepared. A study of the acetolysis of these esters has given the relative rates of ionization of the alkyl–oxygen bond. These relative rates of solvolysis, k/k_H at 25° are in the sequence: *trans*-

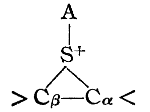
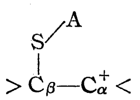
[23] Kilpi, *Suomen Kemistilehti*, **13B**, 19 (1940); *C. A.*, **35**, 2445 (1941).

I, 1120; *trans*-OAc, 0.305; *trans*-Br, 7.18×10^{-2}; *trans*-OCH_3, 5.28×10^{-2}; *cis*-OAc, 1.31×10^{-4}; *trans*-Cl, 0.94×10^{-4}; *cis*-$OSO_2C_6H_4Br$, 1.6×10^{-5}; *trans*-$OSO_2C_6H_4Br$, 1.4×10^{-5}. Variations in rate are largely due to variations in $\Delta H^{\ddagger}$.

The rate-determining ionization step appears to be largely a direct formation of the cycle II (rate constant k_Δ) in the case of neighboring *trans*-I, Br, and OAc and predominantly the formation of carbonium ion III (rate constant k_c) with neighboring *trans*-Cl and $OSO_2C_6H_4Br$ and *cis*-OAc and $OSO_2C_6H_4Br$.



II



III

Using k/k_H for neighboring Cl to determine an effective dielectric constant, the interaction energy between the C_β-SA and C_α-O dipoles in the transition state for formation of III has been calculated for neighboring I, Br and OCH_3. Thus estimates of k_c/k_H have been obtained and corresponding values of k_Δ/k_c have been calculated from the relation $k_\Delta/k_c = [(k/k_H)/(k_c/k_H)] - 1$.

The driving force L due to the *trans*-neighboring groups, defined as $RT \ln (k_\Delta/k_c)$, has the following values in kcal./mole at 25°: I, 8.49; OAc, 4.60; Br, 3.53; OCH_3, 0.86.

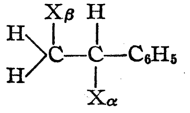
The Role of Neighboring Groups in Replacement Reactions. XIII.[1] General Theory of Neighboring Groups and Reactivity

BY S. WINSTEIN AND ERNEST GRUNWALD

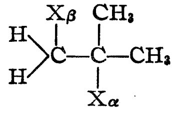
In the previous[2,3] rate work involving effects of neighboring groups, C_α and C_β were both secondary in the molecules (I)[2] whose ionization rates were measured. In considering further structural variations, it must be expected that the relative energies of the closed and open forms of the ionic intermediate,[2] II and III, respectively, will change with *alpha* and *beta* substitution. Thus there will be a change in L, the driving force,[3] which reflects that portion of the free energy difference between II and III which already appears in the transition states for ionization of I. In this paper, with the aid of relative reactivities here reported and others from the literature, we attempt to generalize the theory to cover the whole range of possible structures for the *alpha* and *beta* carbon atoms. Also, the discussion will logically lead to a consideration of the nucleophilic closure of small rings of the classical sort, most attention being given the ethylene oxide ring.

Rate Comparisons.—A group of the rate constants to be considered deals with solvolysis in alcohol or aqueous alcohol of some of the styrene dihalides IV and isobutylene dihalides V.



$H_2C(X_\beta)-CH(X_\alpha)-C_6H_5$

IV



$H_2C(X_\beta)-C(CH_3)(X_\alpha)-CH_3$

V

Although there were some difficulties in the determination of the desired solvolysis rates, it was possible to obtain rate constants reliably enough for the purpose. The rates were in some cases so slow that the measurements were complicated by reaction of hydrogen bromide, produced by solvolysis of a dibromide, with the ethanol solvent. This difficulty was met by determination of the initial rate of solvolysis. With olefin iodochlorides, the solvolysis was accompanied by a slight amount of iodine production but analyses for iodine showed this was not extensive enough to be very serious.

The first-order rate constants determined as described in a later section are summarized in Table I. It seems clear from our procedure in obtaining initial rate constants and from the chemistry of the materials IV and V and analogous ones that the rate constants relate to the solvolysis of the first and most reactive halogen atom, labelled *alpha* in IV and V. Thus styrene iodochloride is reported[4] to react with water to give iodohydrin and with silver nitrate to yield first its chlorine atom and next its iodine atom. Similarly, isobutylene iodochloride gives the β-iodo-*t*-butyl methyl ether[5] on refluxing with methanol. Analogous to the styrene derivatives are such materials as indene dibromide[6a] VI and 1-phenyl-1,2-dibromopropane[6b] VII.

The rate constants for solvolysis are interpreted as rates of unimolecular[7] solvolysis.[8] In

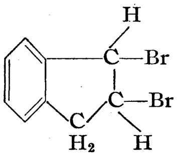
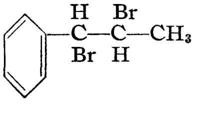
$HOCH_2CHClCH{=}CH_2$[e]	$CH_3CHClCH{=}CH_2$[f]	H_2O	18.0	7.3×10^{-3}	21, Table I

[a] Specific rate constant multiplied by a statistical factor of $^1/_2$. [b] Specific rate constant calculated from the data of Tischchenko[17] on the assumption that the solvolysis of the dichloride is slow compared to that of the daughter monochloride. [c] Extrapolated from data[13] at lower temperatures. [d] The specific rate in 5% acetone–95% water reported by Swain[20] was used. $E\ddagger$ was taken as 22.9 kcal./mole.[13] [e] Extrapolated from data[21] at higher temperatures. [f] $E\ddagger$ was taken as 23.5 kcal./mole.

the case of the very slow reactions (*e. g.*, in the case of styrene dibromide), there is the possibility that at least part of the solvolysis is bimolecular involving solvent. In this sense the values are upper limits. For styrene dibromide, the effect of added salt (sodium perchlorate) on the rate of alcoholysis was observed. This was quite high and to be anticipated[7] for a unimolecular solvolysis, much higher than for the alcoholysis (S_N2) of ethyl bromide as we report elsewhere.[9]



VI



VII

Comparison of the rate constants in Table I with the corresponding values k_H for α-phenylethyl bromide,[10] α-phenylethyl chloride,[11] *t*-butyl bromide[12] and *t*-butyl chloride[13] gives the relative rates k/k_H listed in the last column of Table I. Further pertinent rate comparisons are available from the literature and these are summarized in Table II.

The rate comparisons so far reported in Tables I and II and those for the cyclohexyl and 2-butyl systems reported in the two preceding papers[2,3] have been converted to values of k/k_H at 25° which are given in Table III for neighboring I, Br, Cl, OH or OCH_3 groups. Ratios have been calculated to 25° either with the help of activation energies when available, or otherwise, on the assumption that a rate difference between two similar substances is due to a difference in activation energy. For the cases on which information is available,[3] this is a fair approximation for the rough and small corrections being made. From Table II it is clear that the rate of solvolysis of $RCCl(CH_3)_2$ is very constant to variations in R from CH_3 to $(CH_3)_3C$. In deriving the values of k/k_H for Table III, the value of k for $CH_3CCl(CH_3)_2$ was used for k_H for materials of the type $RCCl(CH_3)_2$ and k for $CH_3CBr(CH_3)_2$ was used for k_H for materials of the type $RCBr(CH_3)_2$. The body of Table III is based on data with systems of the charge type actually represented by formulas I, II and III, that is, the departing group is $XC_6H_4SO_3^-$ or halide ion. The footnotes give the data in which the departing group is OH_2. In the Table, the nature of C_β and C_α is indicated by P,

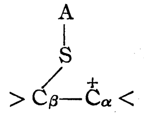
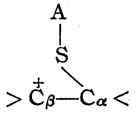
[a] Neighboring OH. [b] Neighboring OCH_3. [c] Calculated from the data of Suter and Zook in 2:3 dioxane–water[15] and the value of k/k_H for isobutylene dibromide in 80% ethanol. [d] The reported value refers to isobutylene dichloride. k/k_H for 2-methyl-1,2-dichlorobutane, 1.4×10^{-4}. [e] The corresponding values of k/k_H from reactions of cyclohexanols and 2-butanols with hydrobromic or hydrochloric acid are: cyclohexanols, *trans*-I, 1200 $\gg$ *trans*-Br, 0.08 $\gg$ *trans*-Cl, 1.6×10^{-4}; 2-butanols, *trans*-Br, 0.4.

S and T for *primary, secondary* or *tertiary*, respectively, or more specifically for the α-phenylalkyl or α-allyl types.

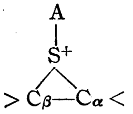
Qualitative Theory of the Effect of *alpha* and *beta* Substitution.—To understand the general reactivity situation it is necessary to refer to intermediates II and III. It is possible to predict the effect of *alpha* and *beta* substitution on the relative energies of II and III and therefore on the relative free energies of the corresponding transition states for the ionization of I. Intermediate II receives contributions[22] from such structures as VIII–X. Now the effect of *alpha* methyl or phenyl in stabilizing the carbonium ion III by hyperconjugation[23] or ordinary resonance is well understood.[7] The same substitution will also favor the contribution of structure VIII to intermediate II so that there will be less bond character between the neighboring group and C_α in II. This will decrease any superiority of II over III and decrease k_Δ relative to k_c. Thus, *alpha* methyl or phenyl groups will lower the driving force due to a neighboring group.



VIII



IX



X

The stability of structure IX and therefore its contribution to the stabilization of the hybrid intermediate II will depend on the structure of C_β, being greatest for *tertiary* and least for *primary*. Thus *beta* methyl groups will increase k_Δ relative to k_c and the driving force L will increase as C_β varies from *primary* to *tertiary*.

The same conclusions are reached in another way. There has long been a feeling that the transition in C–C bond type from ethylene to cyclopentane is gradual. Thus certain features of the ethylenic linkage remain in the cyclopropane ring. For example, there is spectroscopic evidence[24] of conjugation of the carbonyl group with a cyclopropane ring. Also, the dipole moment of cyclopropyl chloride[25] is intermediate between vinyl chloride and ethyl chloride. Another characteristic feature of the ethylenic linkage, stabilization by alkyl substitution, is expected to be retained in three-membered rings including the heterocyclic ring compounds of the type II.

On the basis that methyl substitution on a three-membered ring should give rise to what amounts to hyperconjugation energy,[23] it is clear that either an *alpha* or a *beta* methyl group will stabilize intermediate II and increase k_Δ. In the case of a *beta* methyl group this will result in a greater driving force L. In the case of an *alpha* methyl group, the hyperconjugative stabilization of an open carbonium ion III is expected to be greater than that of II, and k_c will increase more than k_Δ. The driving force L will consequently decrease even though the rate increases.

In discussing the effect of *alpha* substitution on k_Δ, we are in effect discussing the effect of substitution on an internal variety of a bimolecular displacement. Thus we are dealing with a phase of the general question of the factors involved in understanding concerted nucleophilic displacements on carbon. There have been some recent discussions[26,27] of some of these factors and we hope to contribute elsewhere on this general ques-

tion. In discussing k_Δ we have focused attention on only those considerations which are most important in the present connection. Some of these considerations are helpful in the general case, although the aspect of the stabilization of a small ring is unique with the present problem.

Neighboring Cl and OH. Structure and k_c/k_H.—Inspection of Table III reveals very constant values of k/k_H for neighboring chlorine and hydroxyl groups. For neighboring chlorine, the values however near 0.86×10^{-4}. This is very near the value of 0.94×10^{-4} calculated for k_c/k_H by the simplified electrostatic treatment previously[3] described. In this treatment one calculates, after some geometrical assumptions, the extra work involved in the generation of the transition state dipole due to the effect of the neighboring group dipole.

For neighboring hydroxyl the values of k/k_H hover near 6.5×10^{-3} while 1.07×10^{-2} is estimated (Table IV) as the value of k_c/k_H from the electrostatic treatment ($D_E = 1.23$) for a *trans*-chlorohydrin. As explained previously,[3] when k is of the order of magnitude expected for k_c, it is not possible to make any good estimate of the extent of operation of mechanism **A**. It is possible to conclude that k_c is at least comparable to k_Δ. Judging by the lack of any large effects of *beta* methyl groups, this last conclusion follows even when C_β is *tertiary* for neighboring hydroxyl with C_α *tertiary* and for neighboring chlorine with C_α *secondary* or *tertiary*. This kind of diagnosis on the basis of effects of *beta* substitution should prove to be very helpful.

TABLE IV

DEPENDENCE OF CALCULATED RELATIVE RATE k_c/k_H ON DEPARTING GROUP

N. group	Departing group	W^a (cal./mole)	k_c/k_H
trans-Br	$\bar{O}SO_2C_6H_4Br$	5090	1.87×10^{-4}
trans-Br	Br^-	5630	0.75×10^{-4}
trans-Br	Cl^-	5500	0.94×10^{-4}
trans-OH	Cl^-	2640	1.07×10^{-2}
trans-OH	$\bar{O}SO_2C_6H_4Br$	2510	1.45×10^{-2}

[a] D_E assumed equal to 2.23. Dipole moments and distances selected as in a previous paper.[3]

The constancy in the values of k/k_H (not far from k_c/k_H) for neighboring chlorine and hydroxyl is instructive in another way. It indicates how insensitive are the values of k_c/k_H to change in solvent, structure of C_α and C_β, and the nature of the departing group. This insensitivity is, to a considerable degree, expected on the basis of the electrostatic model previously[3] used in estimating k_c/k_H. As pointed out previously,[3] the effective dielectric constant D_E is very close to the internal one for dipole–dipole interactions. Thus the effects of change in external solvent and change in structure on D_E are very slight. Because of the geometry of the situation the effect of change in the departing group is also slight and this is shown in Table IV. In this Table, the calculated extra work W (see previous paper[3]) of ionization in the presence of neighboring groups Br or OH is summarized for departing Cl^-, Br^- or $BrC_6H_4SO_3^-$.

Actually, the value of k/k_H (essentially k_c/k_H) in the case of neighboring chlorine for the chlorohydrin–hydrobromic acid reaction is very nearly equal to the others, so it remains to be seen how gross may the changes in reaction type be with maintenance of essentially constant values of k_c/k_H.

Neighboring Br and I. Comparison with Qualitative Theory.—Turning to neighboring bromine and iodine in Table III, the values of k/k_H are far from constant as they would be if k were always substantially equal to k_c. For neighboring bromine k/k_H varies all the way from 1.6×10^{-4} to 7.2×10^{-2}. The calculated[3] values of k_c/k_H (Table IV) are 0.75×10^{-4} for departing Br^- and 1.87×10^{-4} for departing $\bar{O}SO_2C_6H_4Br$. Values of k_Δ/k_c are listed in Table III ranging from borderline values such as 1.1 to the value of 4.7×10^2.

For neighboring iodine the values of k/k_H vary over a thousandfold from 0.486 to the value 1120 reported previously[3] in the cyclohexyl system. Even the low value is much larger than the value of 6.7×10^{-4} anticipated for k_c/k_H from the electrostatic approach.[3] The corresponding values of k_Δ/k_c are given in Table III and are quite high (7.2×10^2 to 1.7×10^6).

For neighboring iodine there is further evidence that at least a substantial part of the rate-determining ionization is by mechanism **A**. First, for solvolysis of isobutylene iodochloride in 80% alcohol, $\Delta H^{\ddagger}$ is 21.8 kcal./mole and $\Delta S^{\ddagger}$ is -9.8 e. u./mole compared to values of 22.5 and -6.3, respectively, for *t*-butyl chloride.[13] The differences are in the same direction as in the case of the secondary system[3] previously reported, and smaller. Second, the change from a 48.61% aqueous dioxane solvent to 80% ethanol at 35° increases the solvolysis rate of *t*-butyl chloride by a factor of 19.7 and that of isobutylene iodochloride by a factor half as large, namely, 9.70. The lower sensitivity to solvent change for the latter compound is consistent with mechanism **A** by analogy with solvent effects in intermolecular cases. Thus the rate of bimolecular reaction of alkyl halides with neutral solvent has been shown to be less sensitive to a change to a more ionizing solvent than the rate of unimolecular solvolysis.[7]

The dependence of k/k_H on solvent in the presence of neighboring iodine indicates that k_Δ/k_H and thus k_Δ/k_c and L are not quite constant in different solvents. However, the drift with solvent is not extensive, judging by the case of iodine quoted above.

The values of k/k_H for neighboring bromine and iodine derived from the rough rates[2] of reaction of halohydrins with hydrohalogen acids (Table III) agree fairly well—as in the case of neighboring chlorine—with those derived from solvolysis rates of sulfonates. Thus values of k_Δ/k_c must also agree fairly well.

It is clear that the preceding theoretical considerations regarding the effect of *alpha* and *beta* substitution account qualitatively for the trends in k_Δ/k_c observed in Table III. *alpha*-Substitution definitely decreases k_Δ/k_c. For example the change from $\mathbf{S}_\beta\mathbf{S}_\alpha$ to $\mathbf{S}_\beta\mathbf{T}_\alpha$ with neighboring bromine changes k_Δ/k_c from 3.9×10^2 to 44. On the other hand *beta* substitution increases k_Δ/k_c. For example the change from $\mathbf{P}_\beta\mathbf{T}_\alpha$ to $\mathbf{S}_\beta\mathbf{T}_\alpha$ to $\mathbf{T}_\beta\mathbf{T}_\alpha$ with neighboring Br changes k_Δ/k_c from 1.1 to 44 to 4.7×10^2, respectively.

In classifying the systems as $\mathbf{S}_\beta\mathbf{S}_\alpha$, etc., we class methyl and other alkyl groups (as in cyclohexyl) together. Actually, closer inspection will probably show up significant differences. For example, the indications are that k_Δ/k_c is larger for 2-butyl[2] than for cyclohexyl (Table III).

With neighboring bromine and iodine, k_Δ/k_c is somewhat larger with the α-phenylethyl than the *t*-butyl halides. Even this detail is predicted by the qualitative considerations advanced. Judging that *alpha* substitution favors k_c more than k_Δ, and deducing that two methyl groups are slightly more than equivalent to a phenyl group from the slightly greater solvolysis rates of *t*-butyl[12,13] over α-phenylethyl halides,[10,11] one predicts the greater k_Δ/k_c for the α-phenylethyl type.

The striking variation of k/k_H with structure constitutes the most convincing single argument for the operation of both mechanisms **A** and **B** in ionization. We considered an alternative interpretation in which mechanism **B** was the sole one, the open carbonium ion always being formed in the rate-determining step. In this interpretation, deviations of k/k_H from the calculated values of k_c/k_H would be due to polarization of the neighboring group. The effect of *alpha* methyl or phenyl groups would be to diffuse the positive charge of C_α by hyperconjugation or resonance and thus decrease the polarization of the neighboring group and the corresponding gain in stability of the transition state. To explain the effect of *beta* methyl groups one could conceivably call on a steric effect such as is envisioned by Brown[28] and termed B-strain. Due to the postulated strain due to the alkyl groups on C_β, the relief afforded in spreading the $C–C_\beta–C$ angles could favor closer approach of the neighboring group to C_α with resultant increase in its polarization.

Examination of such an interpretation reveals some difficulties. First, a steric effect of *beta* methyl groups of the kind postulated appears to be too small in other phenomena to be of sufficient importance here. For example, in solvolysis of halides, steric strain might be expected to be rate-enhancing. In practice, rates of solvolysis[14] of $R_1R_2R_3CCl$ from $(CH_3)_3CCl$ to $(C_2H_5)_2CClCH(CH_3)_2$ are within a factor of 3. If strain were already serious with methyl groups, serious increases in rate would accompany change to the more substituted structures. Furthermore, the k/k_H values with a neighboring group such as Br drop too rapidly to practically the calculated value of k_c/k_H with addition of methyl to C_α and removal from C_β. Finally, such an interpretation does not predict the contrast between Cl on the one hand and Br and I on the other. With Cl, k/k_H is not sensitive to structure while with Br and I it is. However, estimates of the stabilization due to a dipole[29] at the center of the halogen atom induced by half a unit positive charge on C_α show that the effect is comparable in magnitude with all three halogens. Besides, the magnitude of the effect is far from sufficient to account for the large value of k/k_H with iodine. Even on the exaggerated basis of a half-charged C_α atom (not a transition state $C_\alpha–Y$ dipole), using usual distances and angles and halogen polarizabilities derived from atomic refractions one obtains values of the polarization energy in kcal./mole of: Cl, 1.8; Br, 2.3; I, 2.9. Distortion of the $C_\alpha–C_\beta–S$ angle (in I or III) from tetrahedral to 90°, for example, increases these values by only approximately 75 per cent., hardly enough to compensate for the work of bond-bending.

Thus on the basis of data so far available the interpretation on the basis of mechanisms **A** and **B** seems preferable. However, it is clear that the previous calculation of k_c/k_H based on neighboring Cl neglecting polarization and treating the effective dielectric constant $\mathbf{D_E}$ as an adjustable parameter actually is made on the simplifying assumption that polarization effects of the type mentioned in the transition state for formation of III are of comparable importance throughout. Thus there is still another reason[3] for lack of accuracy in k_c/k_H.

Closure of Other Small Rings.—The same theoretical considerations used above in discussing structure and reactivity are useful in interpreting the closure of classical small rings such as epoxide, imine and episulfide rings. In the case of epoxide ring closure, especially, there are available instructive data from the work of Smith[19] on the second-order rate constants k_2 for

TABLE V

RATE CONSTANTS FOR REACTION OF CHLOROHYDRINS WITH SODIUM HYDROXIDE

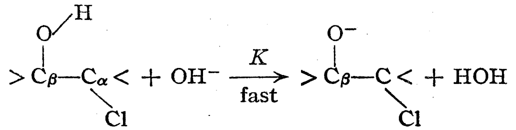
(29) Debye, "Polar Molecules," Dover Publications, New York, N. Y., 1945, p. 18.

reaction with sodium hydroxide of the series of methyl substituted ethylene chlorohydrins. These rate constants are listed in Table V.

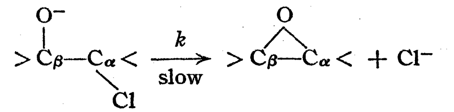
The mechanism we have suggested previously for the epoxide ring closure[22] involves the unimolecular conversion (specific rate constant k) of the chloroalcoholate ion to oxide (equations 4 and 5). The unimolecular rate constant k is given as a function of the measured second-order constant k_2 by equation 6, where K_A is the acidity constant of the chlorohydrin and K_W is the ion-product of

$$k_2 = kK = kK_A/K_W \qquad (6)$$

water. In order to estimate k, rough pK_A values for the chlorohydrins were calculated by the method of Branch and Calvin,[30a] using their inductive constants for Cl and CH_3 and a pK_A of 18.0 for ethanol.[30b] These estimated pK_A values are shown in Table V together with the derived values for k. The order of magnitude (5 to 10^5 sec.$^{-1}$) of the specific rate of conversion of chloroalcoholate ion to oxide is very large.



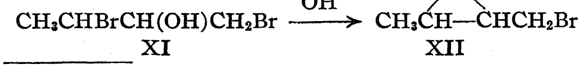
$$>\overset{\overset{H}{\diagup}O}{C_\beta}-\underset{\diagdown Cl}{C_\alpha}< + OH^- \xrightarrow[\text{fast}]{K} >\overset{O^-}{C_\beta}-\underset{\diagdown Cl}{C}< + HOH \qquad (4)$$



$$>\overset{O^-}{C_\beta}-\underset{\diagdown Cl}{C_\alpha}< \xrightarrow[\text{slow}]{k} >\overset{O}{\overbrace{C_\beta-C_\alpha}}< + Cl^- \qquad (5)$$

Primary and secondary halides ionize at rates no greater than 10^{-8} and 10^{-4} times, respectively, those of the corresponding tertiary halides.[7,26] Thus, from Smith's values[19] for the rate of hydrolysis of the tertiary halohydrins, values of the order of 5×10^{-13} and 5×10^{-9} sec.$^{-1}$, respectively, become upper limits for k_c of primary and secondary halohydrins. These estimates are exceeded by the values for k in Table V by factors of 10^{13} to 5×10^{15} in the case of the primary halohydrins and 7×10^9 to 3×10^{12} in the case of the secondary halohydrins. These factors are too large to ascribe to a simple electrostatic effect of the O^- charge, the ring closure being very predominantly a concerted one ($k = k_\Delta$).

The expected rate-enhancing effect of methyl substitution on either carbon atom of the halohydrin system is observed. While the primary propylene chlorohydrin is more reactive than the secondary, the latter is more reactive than ethylene chlorohydrin. The beneficial effect of alkyl substitution on oxide ring closure is further illustrated by the reported formation[31] of the most substituted oxide XII from the halohydrin XI which carries competing primary and secondary bromine atoms.



$$\underset{\text{XI}}{CH_3CHBrCH(OH)CH_2Br} \xrightarrow{OH^-} \underset{\text{XII}}{CH_3\overset{O}{\overbrace{CH-CH}}CH_2Br}$$

Other classical small ring closures show the rate-enhancing effect of an *alpha* methyl group. Thus in the case of ethylene imine formation in water at 25° relative reactivities[32] are $CH_3CHClCH_2NH_2$,4 > $CH_2ClCH_2NH_2$,1. On the other hand, for the closure of a 5-membered imine ring an *alpha* methyl group gives the unfavorable effect characteristic of external type bimolecular displacements.[32] The rate-enhancing effect of an *alpha* methyl group on β-lactone formation[33] is shown by the relative rates in water at 70°: $CH_3CHClCH_2CO_2^-$, 5 > $ClCH_2CH_2CO_2^-$, 1.

Inspection of the k values for the tertiary halohydrins in Table V reveals effects of methyl substitution which are formally correct for k_Δ. Actually, a calculation by the method of Kirkwood and Westheimer[34] of the extra electrostatic energy W due to the interaction of the negative charge on the O^- oxygen atom with the transition state C_α-Cl dipole (moment 5.42 D) gives values of k/k_{OH} (where k_{OH} is k_c for neutral halohydrin and k is from Table V) of the observed order of magnitude (Table VI). However, the factor of 10^2 introduced by two *beta* methyl groups is hard to account for electrostatically since the effective dielectric constant D_E is low and relatively constant. This gives calculated values of k/k_{OH} relatively constant to *beta* methyl substitution. On this account, the values of k of at least the *beta*-methyl substituted tertiary halohydrins are believed substantially equal to k_Δ.

TABLE VI

ELECTROSTATIC CALCULATION OF EFFECT W OF NEGATIVE CHARGE IN CHLOROALCOHOLATE ION

Compound	D_E[a]	W,[b] kcal./mole	k/k_{OH}, 18° C. calcd.	observed
$HOCH_2CCl(CH_3)_2$	2.70	10.85	1.4×10^8	2.3×10^7
$CH_3CH(OH)CCl(CH_3)_2$	2.60	11.28	2.9×10^8	4.7×10^8
$(CH_3)_2C(OH)CCl(CH_3)_2$	2.51	11.68	5.9×10^8	2.3×10^9

[a] Effective dielectric constant calculated from Kirkwood and Westheimer's equation 11 for a spherical molecule.[34a] Molecular radii calculated from Kopp's atomic volumes quoted by Leermakers and Weissberger.[35] Internal dielectric constant 2.00, external dielectric constant 78. [b] $W = (eM \cos \theta)/r^2D_E$. Symbols have usual meaning. Previous[3] conventions regarding tetrahedral bonds, bond distances, *trans*-arrangement of C–Cl and C–O^- bonds employed here. Transition-state C–Cl distance of 2.26 Å.

Semi-Quantitative Theory of the Effect of *alpha* and *beta* Substitution.—It is possible to extend the qualitative considerations with regard to *alpha* and *beta* methyl substitution to a semi-quantitative treatment for L and thus k_Δ/k_c, k/k_c and k/k_H. For any one neighboring group, leaving group and solvent, one can approximate

$\Delta F_c^{\ddagger}$, the free-energy of activation for mechanism **B**, by equation 7. L_c represents the free-

$$\Delta F_c^{\ddagger} = L_c - C_\alpha N_\alpha \qquad (7)$$

energy of activation for step **B** of the *beta*-substituted ethyl compound, N_α the number of *alpha* methyl groups, and C_α is a parameter that would have the value of *ca.* 5.5 kcal./mole from a tentative factor of *ca.* 10^4 per alpha methyl group in solvolysis rates.[7,26] Equation 7 assumes relative insensitivity to *beta* methyl groups of rates of ionization to open carbonium ions III. For solvolysis of $R_3CCCl(CH_3)_2$, Table II shows the lack of effect of *beta* methyl groups.

In approximating $\Delta F_\Delta^{\ddagger}$, the free-energy of activation of step **A**, equation 8 is used. L_Δ rep-

$$\Delta F_\Delta^{\ddagger} = L_\Delta - d_\alpha N_\alpha - d_\beta N_\beta \qquad (8)$$

resents the free-energy of activation for step **A** of the *beta*-substituted ethyl compound, N_β the number of β-methyl groups, and d_α and d_β are parameters. Equation 8 is based on the assumption that the stabilization by *alpha* and *beta* methyl groups of the transition-state leading to intermediate II is proportional to the number of *alpha* and *beta* methyl groups.

From equations 7 and 8, the variation of the driving force L with structure is readily derived. In principle d_α and d_β in equation 8 may vary with structure and neighboring group, depending on the extent of carbonium ion character of C_α. However, one single equation 9 fits the available experimental data quite well. In equation 9, L_0 is

$$L = 1.365 \log (k_\Delta / k_c) = L_0 - 2.27\ N_\alpha + 1.79\ N_\beta \quad (9)$$

$(L_c - L_\Delta)$ and is fairly insensitive to the nature of the solvent and leaving group. It varies mainly with the nature of the neighboring group and is termed the standard driving force of the neighboring group.

The values of L_0 for neighboring I, Br and OCH_3 are listed in Table VII. The value for OCH_3 stems from the one borderline value of k_Δ/k_c obtained in the cyclohexyl system.[3] In Table III, alongside the experimental values of k_Δ/k_c are given the values calculated from equation 9. It is clear that the crude energy treatment represented by equation 9 fits the data satisfactorily. Also listed in Table III are values of k_Δ/k_c calculated from equation 9 for structures where no direct determinations were possible.

According to equations 7, 8 and 9, d_β = 1.79 kcal. and $C_\alpha - d_\alpha$ = 2.27 kcal. Thus the hyperconjugative stabilization per methyl group in the transition-states is *ca.* 5.5 kcal. at C_α for step **B**, and *ca.* 3.2 kcal. at C_α and 1.8 kcal. at C_β for step **A**. The latter figure speaks for a stabilization energy per methyl group in the three-membered charged heterocyclic rings II in excess of the 2.5 kcal. hyperconjugation energy per methyl[23] in olefins. The sequence $C_\alpha > d_\alpha > d_\beta$ is reasonable because it is also the sequence of decreasing carbonium ion character of the corresponding carbon atoms.

The rates of oxide closure (k in Table V) afford a test of the validity of an equation of the type 8 over the entire range of structure of C_α and C_β. Equation 10 with the values of 1.45 for d_α and 1.67 for d_β fits the data in Table V with a mean de-

$$1.332 \log k = 0.94 + 1.45\ N_\alpha + 1.67\ N_\beta \qquad (10)$$

viation of 0.17 in log k.

Driving Force and Nucleophilic Character of Neighboring Groups.—Returning to the L_0 values in Table VII, we notice that we are in effect focusing attention on the relative abilities of the neighboring groups in nucleophilic attack on the adjacent carbon atom. Even for external substitutions, efficiency in nucleophilic attack on carbon is not well understood. In considering the activity of various nucleophilic agents, basicity is a fair guide as long as one remains with one attacking atom (*e. g.*, O in OH, CH_3COO, etc.). However, when one varies the nature of the attacking atom (*e. g.*, O, S), polarizability seems to be an important aspect. For internal substitution the problem is even more complicated because of such factors as strain. The values of L_0 for the neighboring groups represent one measure of nucleophilic character. To the values of L_0 derived from equation 9 and listed in Table VII are added rough minimum estimates of the driving force L for the neighboring groups SCH_2CH_2OH, NH_2 and O^- in the β-substituted ethyl chlorides in water at 25°. The estimated values of k/k_H for these compounds are also listed in Table VII, representing an alternative measure of nucleophilic character of the neighboring groups.

TABLE VII

VALUES OF STANDARD DRIVING FORCE L_0 AND k/k_H FOR VARIOUS NEIGHBORING GROUPS IN β-SUBSTITUTED ETHYL COMPOUNDS

Neighboring group	L_0	k/k_H
SCH_2CH_2OH	$13^{a,b}$	10^7
I	8.71	1.6×10^3
NH_2	$8^{a,c}$	10^4
O^-	$6^{a,d}$	10^{10}
Br	4.55	0.39
OH, OCH_3	1.34	0.1

[a] k_H for C_2H_5Cl in water at 25° estimated at 10^{-8} times value[20] for t-C_4H_9Cl or 3×10^{-10} sec.$^{-1}$ (upper limit). [b] k_c/k_H estimated at 10^{-2}. k_Δ from data of Bartlett and Swain.[36] [c] k_c/k_H estimated at 10^{-1}. k_Δ from Freundlich and Salomon.[32] [d] k_c/k_H estimated at 10^6. k_Δ from Table V.

Neighboring Groups in Primary Systems.—In considering the whole range of structure of compound I with a neighboring group, we expect the greatest driving forces L or highest values of k_Δ/k_c when C_α is primary as shown in Table III. Actually, it is only with some of the classical type neighboring groups such as O^-, NR_2 and SR that

---

(36) Bartlett and Swain, Report No. 4683, Division 9, N.D.R.C., O.S.R.D.

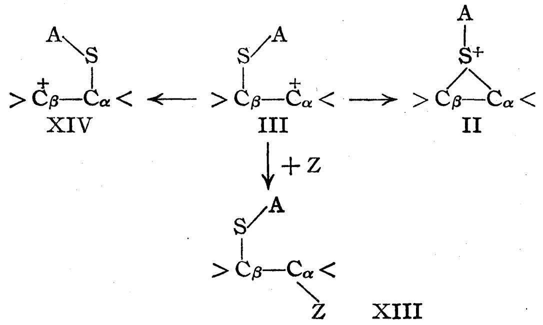
we have known rates which definitely indicate high values of k_Δ/k_c for primary compounds. With other neighboring groups such as Br, OCH_3, etc., we are in the process of collecting data on further structures, some with C_α primary. Because of the care which must be exercised in seeking unimolecular mechanisms with primary compounds, there is little of significance in the literature on these latter cases. Thus, for example, Bennett and Reynolds[37] found the reaction of ethylene chlorohydrin with hydrogen bromide in phenol proceeded at a rate negligible compared to that of ethanol. If the unimolecular type interpretation of Bennett and Reynolds were correct, the effect of the chlorine atom would be of direct interest here. However, it is very probable that the mechanism is bimolecular[9,26] ($R\overset{+}{O}H_2 + Br^-$) at least with ethanol.

Also of interest is the reaction of ethylene dihalides with silver salts. Ethylene dibromide has been reported[38] to react with alcoholic silver nitrate faster than ethyl bromide. However, Petrenko-Krichenko and Opotsky[39] report quantitative work to the contrary, and we have confirmed their findings by comparison of the relative rates of precipitate formation on treatment of pure samples of ethyl and ethylene bromides with alcoholic silver nitrate. From the data of Petrenko-Krichenko and Opotsky[39] on the reaction of halides with silver nitrate, it is clear that ethylene chloride is quite inert relative to ethyl chloride, ethylene bromide is roughly one-tenth as reactive as ethyl bromide and ethylene iodide is fully as reactive as ethyl iodide. While the effects of the neighboring Cl, Br, and I atoms are at least in the right order for participation, the reaction of halides with silver nitrate is too much complicated[40,41] by such things as higher order reactions and adsorption effects to justify any certain deductions and comparisons with values of k_Δ/k_c in Table III at the present time.

Rates, Stereochemistry and Products.—To control steric results of nucleophilic displacement reactions it is often necessary to assess the relative tendencies for bimolecular displacement with inversion or unimolecular type displacement which can lead to various steric results of which, perhaps, the most interesting is retention of configuration in the presence of a suitable neighboring group. For this purpose, a knowledge of the rates in reactions of the unimolecular type (as well as the bimolecular type) of the substituted compounds is essential, and toward this end the rate work so far reported is already useful.

Correlating the present work on rates of unimolecular solvolyses with the previous[42] work on the stereochemistry and products of such reactions, it becomes clear that most of the previous work has dealt with cases in which the rate-determining reaction step was the type **A**. Inversion of configuration in this step, followed by a second inversion in the conversion of cycle II to product, accounts for the clean-cut retentions of configuration.

For the situations where the rate work indicates the ionization is at least partly by mechanism **B**, there is little information on products and stereochemistry. In this sense, the rate work has helped to select crucial cases for stereochemical scrutiny. It is clear from the work of Lucas and Gould[43] that a neighboring chlorine atom gives rise to retention of configuration in the reaction of the 2-butene chlorohydrins with thionyl chloride. The conditions here are, of course, remote from those in the rate measurements. Also, it is evident that in the reactions of stilbene derivatives[42d] with silver acetate in acetic acid, a β-acetoxy group participates in the displacement reaction for at least one of the diastereomeric acetoxychlorides, whereas, apparently, a neighboring chlorine atom fails to participate in at least one of the diastereomeric dichlorides. In the cases where the rate-determining step is **B**, the rate constants refer to the rate of formation of open carbonium ion III and do not yield information on the reaction paths III follows. The ion III may close to II, it may coördinate with reagent or solvent Z to give product XIII, or it may rearrange either to new ion XIV or in other ways, to mention some of the possibilities. Also, the stereochemical results may be controlled by restriction of rotation around the C_β–C_α bond. Further chemical work is being carried on in these directions.



Experimental

Styrene Dibromide.[44]—This compound was prepared by addition of bromine to styrene. Recrystallization from alcohol gave material, m. p. 72.3–72.5°, reported variously[45] from 72° to 74–75°.

Styrene Iodochloride.—To a mixture of 13.6 g. (0.050 mole) of mercuric chloride, 10.4 g. (0.10 mole) of freshly distilled styrene and 200 ml. of absolute ether in a 1-liter round-bottom flask equipped with a reflux condenser, a mercury-sealed stirrer, and protected with a calcium chloride tube, was added with stirring 25.4 g. (0.10 mole) of iodine. Stirring was continued for one hour and then, because of illness, the reaction mixture was allowed to stand approximately a month.

The ethereal solution was decanted from the mercuric iodide and concentrated to a volume of 60 ml. with the aid of a water pump. The concentrated solution was washed rapidly with aqueous potassium iodide, then aqueous sodium bisulfite, finally water, and dried over potassium carbonate. Removal of the ether at reduced pressure and recrystallization of the residue from petroleum ether yielded 12.5 g. (47%) of product, m. p. 40.6° unimproved by further recrystallization. Ingle[4] reported m. p. 46° for the product of addition of iodine monochloride to styrene, but repetition of this preparation yielded material, m. p. 40°. After treatment of 0.1907 g. of material, m. p. 40.6°, in a stoppered Erlenmeyer flask overnight with a solution of 2 g. of sodium iodide in 25 ml. of absolute acetone, titration with thiosulfate required 28.49 ml. of 0.0499 *N* solution. Equivalent weight: 134.1 (calculated 133.3).

Isobutylene Dibromide.—Redistilled Eastman Kodak Co. material, b. p. 76.4–76.8° (74 mm.), $n^{19}\text{D}$ 1.5095 (reported[46] b. p. 147–148° (742 mm.), $n^{17}\text{D}$ 1.5103) was used for rate measurements.

Isobutylene Iodochloride.—Approximately a 20% excess of liquid isobutylene was distilled into a well-stirred mixture of 81.6 g. (0.300 mole) of mercuric chloride, 152 g. (0.600 mole) of iodine and 400 ml. of ether in a flask equipped with a dry-ice condenser and a mercury-sealed stirrer, and protected with a calcium chloride tube. Stirring was continued for one hour and then the mixture was left overnight. The ethereal solution was decanted, concentrated at reduced pressure and then washed rapidly with aqueous potassium iodide, aqueous sodium bisulfite and then water. It was dried over magnesium sulfate, then over potassium carbonate. The ether was removed at reduced pressure and the residue was distilled at 22.5 mm. through an 18″ glass spiral column to yield 88.3 g. (67%) of product, b. p. 55.5–56.2°, $n^{23}\text{D}$ 1.5237, $d^{23}{}_4$ 1.727, *MR*D 38.69 (calc. 38.34), equivalent weight for iodine chloride elimination as in the case of styrene iodochloride 109.4 (calc. 109.2). Istomin[5] reported $d^{15}{}_4$ 1.7502 for the product of addition of iodine chloride to isobutylene.

Solvents.—The absolute alcohol solvent contained less than 0.02% water by the paraffin oil test of Robertson.[47] Four volumes of alcohol were diluted with one volume of conductivity water at 25° to prepare 80% alcohol.

Aqueous dioxane was prepared by addition of 946 g. of conductivity water to 1000 g. of dioxane, b. p. 100.0° (747 mm.), purified according to the directions of Fieser.[48]

Rate Measurements.—The rates at 55° and 70°, and the rate of solvolysis of isobutylene dibromide at 25°, were measured by the sealed ampoule technique. The other measurements were carried out more conveniently by removing at intervals aliquots of the thermostated reaction mixture from a thin-walled glass-stoppered Erlenmeyer flask. Titrations were carried out on 5-ml. aliquots with 0.05 *N* sodium hydroxide from a 5-ml. microburet to the brom thymol blue end-point. Since in the partly aqueous solvents some halohydrin is produced during the solvolysis, a slightly acid green end-point color was used consistently, and titrations were performed rapidly with vigorous shaking in the cold, essentially by the method of Suter and Zook.[17] In all measurements except those in aqueous dioxane, aqueous base was found satisfactory. In the latter case, 0.05 *N* base in "50%" dioxane was used. The titrations were usually reproducible to within ±0.010 ml. of base, except in the earlier work on the dibromides where the probable titration error was *ca.* ±0.020 ml. of base.

In the case of the iodochlorides the concentration of halogen was estimated at intervals by rapid titration with 0.05 *N* aqueous thiosulfate. The amount of halogen was less than 1.5 and 7–12 mole % of the acid produced in the case of the isobutylene and styrene derivatives, respectively.

An approximate estimate of the specific rate of α-methylallyl chloride was obtained by a procedure similar to that used by Peters and Walker.[49] One to three drops of halide, b. p. 64.5–64.8° (752 mm.), $n^{20}\text{D}$ 1.4159, were added to 100 ml. of water containing two drops of brom thymol blue indicator and a known amount of sodium hydroxide. The time, *t*, until the indicator changed color was measured with a stop-watch, and the concentration of acid after at least ten periods of half-change was determined by titration. From these data, a first-order rate constant can be calculated.

Details on Rate Constants.—First-order rate constants, *k*, where $k = (1/t) \ln [a - x)]$, *a* being initial concentration in moles/liter of the organic halide, *t* the elapsed time, and *x* the concentration of generated acid or consumed base, were calculated.

In Table VIII are given data on a typical run on the alcoholysis of styrene dibromide. The first-order rate-constants are seen to drop during a run due to reaction of the liberated hydrogen bromide with the ethanol solvent.[9] The decrease in *k* is linear with time, and equation 11, obtained by the method of least squares, fits the data of this

$$k = 6.83 \times 10^{-4} - 0.0127 \times 10^{-4}\,t \qquad (11)$$

and a duplicate run with a mean deviation of 2.3%. Thus the empirical extrapolation gives an initial rate constant of 6.83×10^{-4} hr.$^{-1}$ or 1.90×10^{-7} sec.$^{-1}$. With added 0.1369 *M* sodium perchlorate there was no systematic decrease in the calculated first-order constants until the elapsed time was more than 122 hours. This was probably mainly due to the much lower rate of reaction of the generated hydrogen bromide with ethanol solvent[9] at this high ionic strength.

TABLE VIII

DATA FOR ETHANOLYSIS OF 0.1183 *M* STYRENE DIBROMIDE AT 54.95°

t, hours	*x* in ml. 0.0459 *N* NaOH per 9.96-ml. aliquot	$10^4 k$ (hr.$^{-1}$)
22.5	0.382	6.66
49.5	0.750	5.92
72.7	1.068	5.84
116.1	1.54	5.33
142.6	1.80	5.11
172.5	1.93	4.53
214.4	2.19	4.16
236.7	2.22	3.82

In the case of ethanolysis of *ca.* 0.10 *M* styrene iodochloride at 69.95°, first-order rate constants showed a tendency to climb, probably at least partly due to the greater effect of rising ionic strength than that of reaction of hydrogen chloride with solvent. This is illustrated in Table IX. Extrapolation to zero acid production for two such runs gave initial rate constants of 4.6×10^{-5} sec.$^{-1}$ and 5.2×10^{-5} sec.$^{-1}$.

For the determination of solvolysis constants in the aqueous ethanol or dioxane solvents, it was not necessary to extrapolate. The first-order rate constants were steady with a mean deviation of less than 3% to the following extents of reaction: 0.065 *M* isobutylene dibromide in 80% ethanol, *ca.* 10%; 0.085 *M* isobutylene iodochloride in 80% ethanol, *ca.* 13%; 0.033 *M* isobutylene iodochloride in the aqueous dioxane, *ca.* 20%; 0.007 *M* and 0.015 *M*

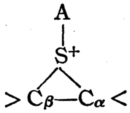
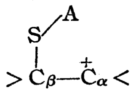
Summary

The rates of solvolysis (k) of styrene dibromide, styrene iodochloride, isobutylene dibromide and isobutylene iodochloride have been determined for comparison with reported rates (k_H) of the corresponding α-phenylethyl and *t*-butyl halides. The rates of solvolysis are also reported for *t*-butyl chloride in 48.61 wt. per cent. aqueous dioxane at 34.86° and for α-methylallyl chloride in water at 27.2°. The relative reactivities, k/k_H, here reported, together with others either previously reported or derived from rate data in the literature, cover the range of structure for both the *alpha* and *beta* carbon atoms (C_α and C_β) which may be *primary* (**P**), *secondary* (**S**), or *tertiary* (**T**)

With neighboring Cl in $\mathbf{S}_\beta\mathbf{S}_\alpha$, $\mathbf{P}_\beta\mathbf{T}_\alpha$, and $\mathbf{T}_\beta\mathbf{T}_\alpha$ systems and with neighboring OH in $\mathbf{P}_\beta\mathbf{T}_\alpha$, $\mathbf{S}_\beta\mathbf{T}_\alpha$, $\mathbf{T}_\beta\mathbf{T}_\alpha$ systems and in $HOCH_2CHClCH{=}CH_2$ values of k/k_H are quite constant. In these cases, the rate-determining ionization is predominantly the formation of the carbonium ion III (rate constant k_c) rather than the direct formation of cycle II (rate constant k_Δ) so that k/k_H is essentially k_c/k_H. The observed insensitivity of k_c/k_H to changes in structure, solvent and departing group is rather expected from the electrostatic treatment previously used in discussing the effect of neighboring groups.



II



III

For neighboring Br and I, k/k_H varies widely with structure. The values of k_Δ/k_c, obtained with the aid of estimates of k_c/k_H from the electrostatic treatment, range for I from 7.2×10^2 in the $\mathbf{P}_\beta\mathbf{T}_\alpha$ system to 1.7×10^6 in the $\mathbf{S}_\beta\mathbf{S}_\alpha$ system and for Br from 1.1 in the $\mathbf{P}_\beta\mathbf{T}_\alpha$ system to 4.7×10^2 in the $\mathbf{T}_\beta\mathbf{T}_\alpha$ system. These trends are exactly those predicted by a qualitative theory which recognizes that *alpha* substitution stabilizes II and, to a greater extent, III, and that *beta* substitution stabilizes II. Thus *beta* substitution increases k_Δ and k_Δ/k_c while *alpha* substitution increases both k_Δ and k_c and decreases k_Δ/k_c.

The qualitative theory explains the trends observed in rates of closure of the ethylene oxide ring from variously substituted ethylene chlorohydrins. Similarly, it is in accord with the favorable effect of *alpha* methyl substitution for closure of the ethylene imine and the β-lactone rings.

For neighboring Br, I and OCH_3 the data on the variation of the driving force L, defined as $RT \ln (k_\Delta/k_c)$, with the numbers, N_α and N_β, of *alpha* and *beta* methyl groups have been fit by the relation

$$L = L_0 - 2.27\ N_\alpha + 1.79\ N_\beta$$

L_0, the driving force in the $\mathbf{P}_\beta\mathbf{P}_\alpha$ system, is tabulated for I, Br, OCH_3, O^-, NH_2 and SCH_2CH_2OH neighboring groups.

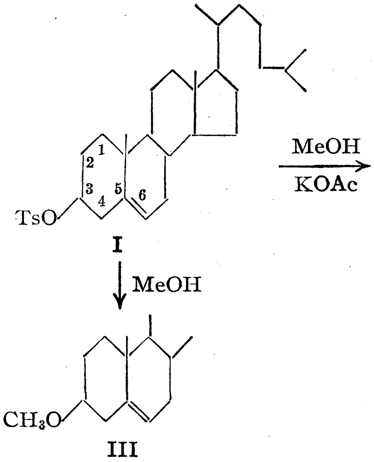
The Role of Neighboring Groups in Replacement Reactions. XIV. The 5,6-Double Bond in Cholesteryl *p*-Toluenesulfonate as a Neighboring Group

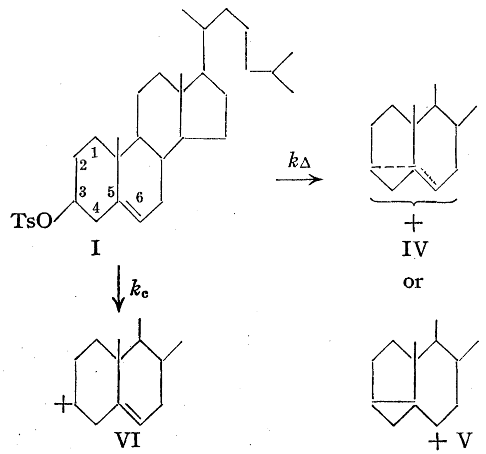
BY S. WINSTEIN AND ROWLAND ADAMS

Shoppee[1] has very recently pointed out the tendency toward a steric result of retention of configuration in nucleophilic displacements at C_3 in Δ^5-cholestene derivatives and similar systems. Also he has drawn an analogy which we also have been using between this phenomenon and our work, presented in previous papers of this series, on participation of such neighboring groups as bromine in nucleophilic displacement processes. We are prompted to report the results of a study of the kinetics of acetolysis of cholesteryl *p*-toluenesulfonate I which we carried out some time ago as part of an investigation which was unavoidably interrupted.



It is known[2] that cholesteryl *p*-toluenesulfonate I on treatment with potassium acetate in methanol gives rise to a material which is best represented as the *i*-ether[3] II. In the absence of potassium acetate in the methanol, normal ether III is produced. By the action of potassium acetate in acetic anhydride, I is converted to *i*-acetate.[3c,d] Cholesteryl chloride, similarly to the toluenesulfonate, also[4] gives rise to *i*-ether. The *i*-ethers are relatively unstable, for example being converted to normal acetate on treatment with potassium acetate in glacial acetic acid.[3a,b] From the properties of the *i*-ethers it is apparent that the action of the potassium acetate in the methanol where *i*-ether is formed from I is merely to buffer the solution so that high acidity is not developed.

The *i*-sterol rearrangement (I → II) represents a case of participation in a nucleophilic displacement reaction by a properly situated ethylenic linkage, a suitable example of which we had been seeking for study when we began the present investigation. The most likely general mechanism for this rearrangement would seem to involve either the hybrid carbonium ion IV or the rearranged carbonium ion V. The intermediate (IV or V) then reacts with nucleophilic agents more rapidly at C_6 than C_3.



With regard to the formation of the intermediate IV or V, the alternatives (with no regard for stereochemistry) are a direct formation by ionization of I or prior formation of unrearranged carbonium ion VI, which then is converted to intermediate V (as though an energy barrier existed between V and VI). The specific reaction rate constants for the two modes of rate-determining ionization are symbolized by k_Δ and k_c, the symbols used previously[5] for other neighboring groups.

The kinetics of acetolysis of cholesteryl *p*-toluenesulfonate I support the general mechanism outlined and point to the direct ionization to intermediate IV or V (rate constant k_Δ). The acetolysis of I in glacial acetic acid proved to be very cleanly first-order, the first-order rate constants k at 35.00 and 50.00° being summarized in Table I.

The catalytic effect of water and sodium acetate on the acetolysis is quite marked. However, these effects are definitely solvent and ionic

TABLE I

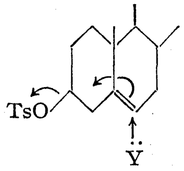
RATE CONSTANTS OF ACETOLYSIS k OF *ca.* 0.01 M CHOLESTERYL p-TOLUENESULFONATE IN GLACIAL ACETIC ACID

Other solute	Temp., °C.	$10^3 k$, min.$^{-1}$
....	50.00	7.9[a]
0.50 M H_2O	50.00	12.2
.0100 M KOAc	50.00	19.8
.0100 M NaOAc	50.00	20.0
.0200 M NaOAc	50.00	20.0
.0100 M $LiClO_4$	50.00	24.1
....	35.00	1.19[a]
....	50.00	0.111[b]

[a] $\Delta H^{\ddagger} = 24.4$ kcal./mole. [b] Cyclohexyl p-toluenesulfonate.

strength effects. Thus the effect of sodium acetate is not even as large as that of lithium perchlorate. Also raising the concentration of sodium acetate from 0.01 to 0.02 M gives no further increase in rate, which is not too surprising for ionic strength effects[6] in a solvent of as low a dielectric constant as that of acetic acid (*ca.* 6).

The fact that acetic acid is such a poor nucleophilic agent, that the rate is still nicely first order on addition of sodium acetate and that the effect of sodium acetate (the same at 0.01 and 0.02 M) is less even than that of lithium perchlorate indicates that the acetolysis represents a reaction of the unimolecular type and that concerted mechanisms of the type shown in VII are not important here.



VII

The rate of acetolysis of cholesteryl p-toluenesulfonate I is seen to be some 10^2 (depending on ionic strength) times as large as that for cyclohexyl p-toluenesulfonate[7] also determined at 50.00° for comparison (Table I). The latter compound represents at least one good choice of a model substance for comparison in order to estimate k_c. Now reactivities of ring compounds are not yet clearly understood so that other comparisons are desirable. Actually, there are other indications of enhanced reactivity due to the 5,6-ethylenic linkage. Thus, Stoll[8] compared cholesteryl p-toluenesulfonate I with cholestanyl and ergostanyl p-toluenesulfonates in ethanol (no added ethoxide) at 78° and from his first-order rate constants one calculates factors of the order of 40 in favor of the cholesteryl ester. In the solvent ethanol we had felt there was more reason to suspect mechanisms of the type VII. However, the rate constant of acetolysis of cholesteryl p-toluenesulfonate I extrapolated to 78° is 0.176 min.$^{-1}$, a value nearly equal to Stoll's value of 0.18–0.19 min.$^{-1}$ in ethanol. Since ethanol and glacial acetic acid give comparable[9] solvolysis rates in unimolecular solvolyses, the indications are against mechanism VII in alcohol also. Further, in the case of chlorides, rather than toluenesulfonates, there are qualitative indications of greater reactivity of the Δ^5-compounds and Shoppee[1] refers to these.

The evidence then is that the 5,6-ethylenic linkage exerts a driving force[5] in favor of ionization of I, the main ionization being directly to intermediate IV or V (rate constant k_Δ). Thus a pair of electrons in an ethylenic linkage may play a role analogous to that of neighboring groups discussed in previous articles. There are further indications of the ionization by the k_Δ process. Thus the $\Delta H^{\ddagger}$ of activation for cholesteryl p-toluenesulfonate is less than that for the cyclohexyl ester[5a] by some 2.6 kcal./mole. This kind of a decrease with an increase in rate effected by a neighboring group has been noticed before.[5]

Also, the acetolysis of cholesteryl p-toluenesulfonate is much more sensitive to addition of water and salts than is the case with the cyclohexyl esters. While further comparison with medium effects in the case of higher molecular weight saturated esters such as cholestanyl are needed, one is led to compare the present situation with the one prevailing in the case of solvolysis of alkyl halides studied by Hughes, Ingold and co-workers.[6] In the latter case, the increase in rate by salt climbs as one proceeds from t-butyl to benzhydryl, separation of charge in the transition state being larger in the latter example. It is possible that the cyclohexyl-cholesteryl trend is analogous, the transition state for ionization of cholesteryl p-toluenesulfonate having positive charge both on C_3 and C_6.

Just as a pair of electrons of the 5,6 double bond in I imparts reactivity in ionization at C_3, the pair of electrons in the 3-membered rings of i-compounds such as II apparently imparts high reactivity at C_6. One very likely mechanism for the reverse i-sterol rearrangement of type II to type I, which we are also investigating, involves ionization followed by competitive reactions at C_3 and C_6. On this basis, judging by the high reactivity of i-compounds[3], V is not the intermediate. If these suppositions prove to be correct, the mesomeric ion IV would be the common intermediate for forward and reverse rearrangements, no energy barrier existing between the limiting resonance structures V and VI.

The over-all steric result of the conversion of cholesteryl p-toluenesulfonate I or chloride to an i-compound (type II) and back to a normal compound is clearly quite clean-cut retention of configuration. Thus, i-ether II gives cholesteryl

chloride[3a,b] on treatment with hydrogen chloride in acetic acid and also is easily converted to cholesteryl acetate.[3a,b] This steric result is analogous to that involving other neighboring groups and is expected from the mechanism outlined for the formation of the *i*-compound and a reverse rearrangement which requires nucleophilic attack on C_3 to completely sever the C_3–C_5 bond.

Over-all retention of configuration with Δ^5-materials is very general and Shoppee[1] has summarized[10] the displacement reactions at C_3 in which 3-OH is converted to 3-Cl and 3-Cl to 3-OCOR. However, in these cases there is still need for further scrutiny to determine whether *i*-product is not the first predominant one, which quickly is rearranged to normal product.

Experimental

Materials.—Cholesteryl *p*-toluenesulfonate, m. p. 132–133°, was prepared in the usual manner.[3c] This material generated 98.5% of the theoretical amount of acid in acetolysis.

Lithium perchlorate trihydrate was prepared by treatment of Merck reagent grade lithium carbonate with perchloric acid. The reaction mixture, *p*H 4.5, was filtered, concentrated to a small volume and then allowed to cool slowly. The deposited crystals were pressed dry and dried in an oven at 140° for four hours. The hot liquid product was allowed to cool with stirring to yield a white crystalline solid, m. p. 93–94.5°.

The acetic acid solvent was prepared from Grasselli reagent grade acid and pure acetic anhydride, the residual concentration[5a] of the latter being 1×10^{-3} *M*.

Rate Measurements.—The titration procedures were those used previously.[5a] In case lithium perchlorate or sodium acetate (sodium carbonate was used) was added to the solvent, water was destroyed by treatment with the proper amount of acetic anhydride.

In the case of cyclohexyl *p*-toluenesulfonate,[7] m. p. 44–45°, sealed ampoules were used, concentrations being approximately 0.03 *M*. With the cholesteryl *p*-toluenesulfonate, concentrations approximately 0.01 *M* were used due to low solubility and low rate of solution. The toluenesulfonate was added to the solvent already at bath temperature and the mixture was shaken violently in a glass-stoppered flask until solution of the toluenesulfonate was nearly complete. Then the mixture was filtered rapidly into a volumetric flask already in the bath. In this way a homogeneous solution of the toluenesulfonate at bath temperature could be achieved in approximately five minutes. The initial concentration of the material was determined by titration of a sample of the reaction mixture after ten half-life periods.

Rates were followed to approximately 70% completion, the mean deviation of the individual first-order constants in one run being within 3% even for the rapid cases.

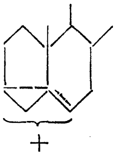
It is a pleasure to acknowledge helpful discussions with Drs. Byron Riegel of Northwestern University and Sam Siegel of the Illinois Institute of Technology.

Summary

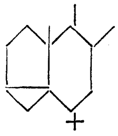
A study of the acetolysis of cholesteryl *p*-toluenesulfonate has shown that the first-order rate constant is *ca.* 10^2 (because of a corresponding decrease in $\Delta H^{\ddagger}$) times that for the cyclohexyl ester. Also the rate is quite sensitive to the addition of water, sodium or potassium acetate, or lithium perchlorate to the acetic acid solvent.

The poor nucleophilic character of acetic acid, the fact that the salt effect of sodium acetate in acetolysis is no greater than that of lithium perchlorate, and the near identity of acetolysis and alcoholysis rates of cholesteryl *p*-toluenesulfonate speak against a mechanism for the isosterol rearrangement involving nucleophilic attack at C_6 in the rate-determining step. Thus the isosterol rearrangement represents a case of participation by a pair of electrons of the 5,6-ethylenic linkage in a unimolecular type displacement reaction at C_3.

The relatively high rates of acetolysis and alcoholysis of cholesteryl *p*-toluenesulfonate and other qualitative indications of high reactivity of Δ^5-materials show that the double bond furnishes a substantial driving force. This speaks for the direct formation of intermediate IV or V in the ionization of the C_3-derivatives. It is highly possible that the reversed isosterol rearrangement (*i*-compounds to normal ones) normally proceeds through the same intermediate. On this basis, the high reactivity of *i*-compounds speaks for a driving force due to the pair of electrons in the 3-membered ring and thus intermediate IV is indicated.



IV



V

The over-all steric result of the conversion to an *i*-compound and back to a normal compound is analogous to the retention of configuration observed with other neighboring groups.

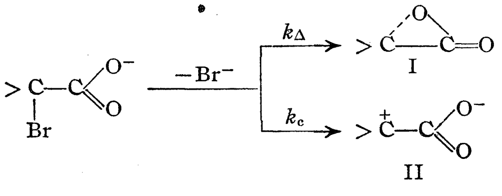
The Role of Neighboring Groups in Replacement Reactions. XV. Rates and Medium Effects in the Alcoholysis and Hydrolysis of α-Bromopropionate Ion. The Carboxylate Ion Group

BY ERNEST GRUNWALD AND S. WINSTEIN

Of the neighboring groups which participate in unimolecular type[1] nucleophilic displacements, one of the more important in organic chemistry is the α-carboxylate ion group. The recognition of retention of configuration as a possible over-all steric result of unimolecular reactions of materials of the type of α-bromopropionate ion has gone far toward clearing up a long-existing confusion attending the stereochemistry of displacement reactions of compounds containing various forms of the α-carboxyl group.[2]

Hughes and Ingold[2a] explained the effect of the carboxylate ion group as due to the presence of the negatively charged group in an alkyl cation, thus stabilizing the ion in a pyramidal configuration. We have since shown that the phenomenon of participation of neighboring groups such as OAc, Br, etc., in unimolecular displacement reactions is a general phenomenon, neutral groups being able to bring about retention of configuration. The action of the CO_2^- group is but one illustration of this general phenomenon, a charge being in principle unnecessary.

As in the case of other groups,[1,3] actual rates and other kinetic features of the unimolecular displacement reactions of α-halocarboxylate ions are of interest for the possible information afforded regarding the intimate mechanism of formation and the nature of the intermediate I, which has been termed an α-lactone[4] or a zwitterion.[2a] In principle, the rate determining ionization of the α-carboxylate ion may produce I directly with inversion of configuration (rate constant k_Δ) or it may yield first the more open zwitterion II (rate constant k_c). The first of these descriptions has been used previously.[4]



In connection with neutral neighboring groups, we have previously made some use of the variation of rate with changes in the solvolyzing medium (solvent or salt effects). The case of the CO_2^- group is one where salt effects might prove to be particularly helpful. For the intermolecular analogs of processes with the rate constants k_Δ and k_c, S_N2 and S_N1 type reactions of alkyl halides with a carboxylate ion, the sign of medium effects can be anticipated on the basis of the general theory[5] of solvent effects with which Hughes, Ingold and co-workers have had considerable success. For the S_N2 reaction, there is subdivision of charge in the transition state so that addition of inert salt or change to a more ionizing solvent will lead to a decrease in rate. In the S_N1 reaction, there is generation of charge in the transition state so the effect of solvent change will be opposite in sign. By analogy, k_c will increase with addition of inert salt or change to a more ionizing solvent. On the other hand, if there is enough involvement of the CO_2^- group with the carbon atom undergoing substitution in the transition state, k_Δ will decrease with such solvent change.

The most recent pertinent work on the solvolysis of α-bromopropionate ion is that of Cowdrey, Hughes and Ingold[6] and Chadwick and Pacsu.[7] With regard to salt effects, Cowdrey, Hughes and Ingold[6] report a large decrease in the first order rate on addition of 0.5 *M* sodium bromide in methanol solution. This they expect on the basis that "the rate-controlling stage is an ionization, in the transition state of which the anionic charge becomes divided between the carboxylate group and the bromine atom." This kind of salt effect would indicate that ionization occurs essentially by the process labelled k_Δ. On the other hand, in water Chadwick and Pacsu[7] report slight increases in first order rate with increase in ionic strength.

In this article are reported the results of a reinvestigation of the alcoholysis and hydrolysis of α-bromopropionate ion, special attention being given to salt effects.

In solvolysis, for example methanolysis, of α-bromopropionate ion, two reactions are prominent, the second order reaction with methoxide ion

$$CH_3O^- + CH_3CHBrCO_2^- \xrightarrow{k_2} CH_3CH(OCH_3)CO_2^- + Br^-$$

and the first order reaction by way of the so-called α-lactone or zwitterion III

either reaction path predominating, depending on conditions. At high concentrations of methoxide ion, κ_2, an apparent second-order reaction rate constant, is fairly constant, and at low concentrations of methoxide ion, κ_1, an apparent first-order reaction rate constant, is also quite constant. If one is interested in the first-order reaction rate constant in the low concentration region, a correction still needs to be made for the second-order contribution. Furthermore, if at low methoxide ion concentration the ionic strength is increased, κ_1 increases markedly, but so much of this is due to the increase in the second-order contribution that a careful analysis is necessary to decide whether increase in ionic strength increases or decreases κ_1.

Kinetic Part

For convenience the symbols we employ are summarized below:

t = time in seconds.
α_0 = concn. in moles/l. of α-bromopropionate ion at zero time.
α = concn. in moles/l. of α-bromopropionate ion at time t.
β_0 = concn. in moles/l. of methoxide or hydroxide ion at zero time.
β = concn. in moles/l. of methoxide or hydroxide ion at time t.
x = concn. in moles/l. of bromide ion from solvolyses at time t.
$\kappa_2 = \frac{1}{t(\alpha_0 - \beta_0)} \ln\left(\frac{\beta_0(\alpha_0 - x)}{\alpha_0(\beta_0 - x)}\right)$
$\kappa_1 = \frac{1}{t} \ln\left(\frac{\alpha_0}{\alpha_0 - x}\right)$
k_2 = specific reaction rate constant for the second-order reaction.
k_1 = specific reaction rate constant for the first-order reaction.
k' = depressed first order rate constant in presence of bromide ion.
μ = ionic strength in moles/l. at 64.04 ± 0.04°.
$\phi = x \Big/ \left(\frac{k_1}{k_2} + \beta_0\right)$
k_{Br} = specific reaction rate constant for reaction of intermediate with bromide ion.
k_s = specific reaction rate constant for reaction of intermediate with solvent (methanol or water).

Equation 1 is the differential equation applicable in the present case, both k_1 and k_2 being functions of ionic strength.

$$\mathrm{d}x/\mathrm{d}t = k_1\alpha + k_2\alpha\beta = k_1(\alpha_0 - x) + k_2(\alpha_0 - x)(\beta_0 - x) \quad (1)$$

Values of k_2 at various ionic strengths necessary in evaluating k_1 were derived as follows. A series of experiments with α_0 at *ca.* 0.03 M and β_0 at 0.25 M to 1.0 M (Table I) gave κ_2 values which were constant within experimental error in each run. Average values in each run, $\bar{\kappa}_2$, were corrected for first-order contribution according to equation 2 which chooses

$$k_2 = \bar{\kappa}_2 - k_1/(\beta_0 - \alpha_0/3) \quad (2)$$

$(\beta_0 - {}^1/_3\alpha_0)$ as a good working mean between β_0 and $\beta_0 - \alpha_0$, the extreme values to be considered here. Since $\beta_0 >> \alpha_0$ in these runs, the accuracy in this empirical procedure is good. In this correction, k_1 is at first an estimate based on data from largely first-order solvolyses. These first values of k_2 which were always within 4% of the final values enable one to obtain better values of k_1 (see below) and second approximations (which are sufficient) become possible for k_2. The data for the largely second-order runs in both methanol and water are summarized in Table I. In this table, as well as in all subsequent ones, rate-constants and concentrations have been corrected for solvent expansion.

The plot of log k_2 against $\mu^{1/2}$ gives a good straight line. Equation 3, obtained by least squares, fits runs 1 through 5 with a

$$\log k_2 = -4.568 + 1.308\mu^{1/2} \quad (3)$$

mean deviation of 0.006 in log k_2. For the runs 6 and 7 in water as a solvent one can write[8] equation 4

$$\log k_2 = -3.681 + 0.343\mu^{1/2} \quad (4)$$

The values of k_1 at different ionic strengths were based on runs with low methoxide or hydroxide ion concentrations, sodium perchlorate (or nitrate) being added. The solution of equation 1 is equation 5

$$\frac{1}{t}\left\{\ln\left[\frac{k_1 + k_2(\beta_0 - x)}{k_1 + k_2\beta_0}\right]\left(\frac{\alpha_0}{\alpha_0 - x}\right)\right\} = k_1 + k_2(\beta_0 - \alpha_0) \quad (5)$$

with which some investigators[7,9] have worked directly, although this is admittedly laborious. We found it much more convenient to evaluate an apparent first-order constant κ_1 and then, using ϕ as previously defined, equation 6 follows. The expansion of $-\ln(1 - \phi)$ in

$$\kappa_1 - k_1 = k_2(\beta_0 - \alpha_0) - \frac{1}{t}\ln(1 - \phi) \qquad (6)$$

$$\kappa_1 - k_1 = k_2(\beta_0 - \alpha_0) + \frac{1}{t}\left(\phi + \frac{\phi^2}{2} + \frac{\phi^3}{3} + \ldots\right) \qquad (7)$$

a series gives rise to equation 7 which is a convenient working equation since ϕ turns out to be of the order of 0.05, so that ϕ^3 is usually negligible and ϕ^2 and ϕ^3 can be obtained with the slide rule.

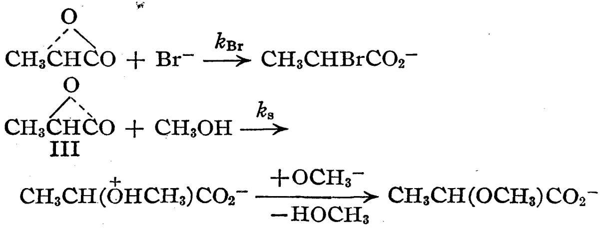
In the rate runs summarized in Table II a value of κ_1 was evaluated for each analytical point. Using κ_1, the known values of x, β_0 and α_0, the value of k_2 for the given ionic strength calculated from equation 3 or 4, and guessing a reasonable value for k_1, the right-hand side of equation 7 was easily evaluated and thus a first value for k_1 at any one analytical point was obtained. A second approximation (usually sufficient) was obtained by substituting this first approximation for k_1 into the right-hand side of equation 7. The values for k_1 at the different analytical points were averaged to give the values shown in Table II. In some cases separate rate constants are listed based on titration for both base and bromide ion and these are averaged for the final values.

Discussion

Inspection of Table II shows, in agreement with the report of Chadwick and Pacsu, that the first order reaction rate constant k_1 for solvolysis rises with ionic strength when sodium perchlorate is the added salt both in water and methanol. In water approximately a 6% increase is produced by a change in ionic strength from 0.06 to 1 M while the analogous figure is 17% in methanol. In water, Chadwick and Pacsu[7] recorded increases of 12 and 5% at 49.2° and 59.7°, respectively, on the addition of 0.95 M sodium nitrate to 0.2 N sodium bicarbonate solutions of the α-bromopropionate (*ca.* 0.04 M).

The observation of Cowdrey, Hughes and Ingold[6] with regard to the direction of the salt effect in methanol was due to the choice of the added salt, sodium bromide. The bromide ion competes very well for the intermediate III. This represents a type effect on which Hughes, Ingold and coworkers[5b] have since done considerable work but which they had not yet discovered at the time of the earlier work. In connection with the hydrolysis of bromomalonate ion Hughes and Taher[10] have reported a similar action of sodium bromide and mention the possibility that some of the effect is a "mass-law" effect.

The effect of bromide ion on the rate constant is very marked and may be treated according to the scheme



which depicts a competition between bromide ion and solvent molecules for the intermediate III, and neglects the competition by methoxide or hydroxide ion. According to this scheme, the first order rate constant k' evaluated by use of equation 7 (putting k' in place of k_1) is given by equation 8. This predicts, as is actually observed, that k' will be satisfactorily constant if the bromide concentration is essentially constant. The latter condition is fulfilled if the initial bromide concentration

$$k' = k_1 \frac{1}{1 + (k_{Br}/k_s)(Br^-)} \qquad (8)$$

---

[10] Hughes and Taher, *J. Chem. Soc.*, 956 (1940).

is large compared to that produced in the reaction. Comparison of the rate constant k' in the presence of sodium bromide with the rate constant k_1 at the corresponding ionic strength in the runs with sodium perchlorate allows one to estimate the ratio k_{Br}/k_S. These are shown in Table III, the values being close to constant at 2.9 in methanol and 0.76 in water.

The value of k_{Br}/k_S would not be expected to be absolutely independent of ionic strength. Actually our values show a slight downward drift with decrease in ionic strength but this is too slight to be sure it is not accidental, especially since we would have expected a reverse trend.

The success of equation 8 indicates that the rate constant for reaction of intermediate III with methoxide ion or hydroxide ion cannot be much greater than k_{Br}. In the course of a run, the methoxide or hydroxide ion concentration decreases markedly and, were these ions competing for intermediate III, bromide ion would show an increasing ability to compete for III and give a decreasing reaction rate constant as the reaction progresses. Instead, solutions containing high bromide ion and low base concentration produce acid in a good first-order fashion after allowance is made for second-order reaction with methoxide ion. The relative inactivity of the base ion for attack on the intermediate recalls the inactivity of hydroxide ion in the case of ethylene oxides.[11]

TABLE III

RELATIVE RATES OF REACTION OF INTERMEDIATE III WITH BROMIDE ION AND SOLVENT

Solvent	μ	(Br^-)	10^6k_1 (sec.$^{-1}$)	$10^5k'$ (sec.$^{-1}$)	k_{Br}/k_S	k_{Br}/k_S av.
CH_3OH	1	0.893	5.84	1.48	3.30	2.86 ± 0.22
CH_3OH	1	.865	5.84	1.72	2.77	
CH_3OH	0.5	.425	5.68	2.66	2.67

HOH	1	.986	13.25	7.48	0.78	0.76
HOH	0.5	.486	13.00	9.54	0.75	

Judging by the data obtained following the reactions for both bromide ion and base, either perchlorate ion shows negligible reaction with intermediate III or any ester product is unstable. Nitrate ion does react slightly with III (see experimental).

The information on k_{Br}/k_S adds information of a type which needs to be greatly expanded before the general phenomenon of participation is fully understood. These values for k_{Br}/k_S are listed in Table IV along with some related ones from similar situations. The value for the intermediate from bromomalonate ion is a rough one calculated from the data of Hughes and Taher.[10] The value for the intermediate from phenylbromoacetate ion is calculated from the data of Bulcraig and Dawson.[12] These workers report rate constants of hydrolysis of the 0.025 M neutral salt of 0.0238 (0.975 M $NaNO_3$) and 0.0250 (0.975 M $NaClO_4$) for an average of 0.0244, whereas the rate constant is 0.0184 for 0.975 M NaBr. The value for the stilbene bromonium ion is given by Bartlett and Tarbell[13] and the value for ethylene oxide is from the data of Bronsted, Kilpatrick and Kilpatrick.[11] More needs to be known regarding temperature coefficients of these values and, sometimes, effects of ionic strength before the figures are properly comparable.

The small positive salt effect in the unimolecular solvolysis of α-bromopropionate ion indicates generation of charge in the transition state for the rate-determining ionization of the bromide ion. Corresponding to the salt effect is the effect of solvent change, the solvolysis rate in water at 64° being approximately twice that in methanol. Thus the sign of the medium effects does not enable one to choose unambiguously between the two modes (rate constants k_Δ or k_c) of the rate-determining ionization. The intermediate III has very high ionic character[5b,14] to the new carbon–oxygen bond. Thus, even if it is produced in one stage (k_Δ), the transition state could have increased charge over the reagent α-bromopropionate ion. This possibility gains support from the observation that the effect of neutral salts and of solvent change in the case of β-lactone formation, which more surely proceeds by a concerted ring closure (k_Δ) in the examples available, is the same in sign as for α-bromopropionate ion. This is shown in Table V. On the other hand for the closure of the larger 6-membered ring from $CH_3CHBrCONHCH_2CO_2^-$ Chadwick and Pacsu[7] observed a salt effect of the sign anticipated for the intermolecular example.

TABLE IV

COMPETITION FOR INTERMEDIATES

Compound	T, °C.	Solvent	k_{Br}/k_S
 CH_3CHCOO	64	MeOH	2.9
 CH_3CHCOO	64	HOH	0.76
 $\overset{-}{O}_2CCHCOO$	100	HOH	2.7
 C_6H_5CHCOO	25	HOH	0.33
 $C_6H_5CH\overset{+}{Br}CHC_6H_5$	0	MeOH	1.21
 $H_2C\overset{+}{O}HCH_2$	20	HOH	37

In the case of the other neighboring groups it was useful to compare the unimolecular rate constant k with k_H, the rate constant of the unsubstituted material[3]. Estimated values of k_c/k_H made it possible to derive estimates of k_Δ/k_c. In the present case k_H is the specific rate of $CH_3CHBrCH_3$ if O_2^- is considered the neighboring group. With the charged neighboring group, the choice of solvent for the comparison k/k_H is difficult because a change to a more ionizing solvent affects the al-

kyl halide so much more than the α-halocarboxylate ion. Also k_c/k_H is hard to estimate since it may be considered to involve a large rate retardation due to two oxygen atoms which are ordinarily electron-attracting and the very large rate enhancement due to the negative charge of the O_2^- group.

TABLE V

RATES OF UNIMOLECULAR TYPE SOLVOLYSIS OF SOME BROMIDES

Compound	Solvent	Temp., °C.	k_1 (sec.$^{-1}$)	Ref.
$CO_2^-CHBrCH_2CO_2^-$	H_2O^a	25.8	4.65×10^{-5}	15

$CH_3CHBrCH_2CO_2^-$	$MeOH^c$	45.0	1.03×10^{-4}	16
$(CH_3)_2CBrCO_2^-$	H_2O^d	44.3	2.13×10^{-3}	18
$(CH_3)_2CBrCO_2^-$	MeOH	44.3	2.6×10^{-4}	16
$(CH_3)_2CBrCH_3$	$MeOH^e$	44.3	3.3×10^{-4}	
$CH_3CHBrCO_2^-$	MeOH	64.0	5.12×10^{-6}	Table II
$CH_3CHBrCH_3$	$MeOH^e$	64.0	5×10^{-8}	

[a] Interpolated between data at 25.00° and 37.39°. [b] Extrapolated from data at 25.0° and 38.0°. [c] At 0.2 M ionic strength, κ_1 has the following values[16]: $\beta = 0.129$ M, $10^4\ \kappa_1 = 2.70$; $\beta = 0.085$ M, $10^4\ \kappa_1 = 2.13$. Using $\kappa_1 = k_1 + k_2\beta$, $k_1 = 1.03 \times 10^{-4}$ sec.$^{-1}$; $k_2 = 1.30 \times 10^{-3}$ sec.$^{-1}$ M^{-1}. [d] Values of $10^4\ k_1$ (sec.$^{-1}$) at 25.0° and 35.0° are 1.21 ± 0.04 and 5.59 ± 0.08, respectively. These values were calculated from the data given by Simpson[18] on the hydrolysis of sodium α-bromoisobutyrate in initially neutral solution, assuming that the ratio of ionization constants of the α-bromo and α-hydroxy acid is 8.0 and using the equations developed by Bulcraig and Dawson.[12] Values of k_1 were satisfactorily constant up to 90% reaction at 25° and 70% reaction at 35°. [e] k_1 for *t*-butyl bromide at 25.0° is estimated at 3.53×10^{-5} sec.$^{-1}$ on the basis of solvolysis rates in alcohol-water mixtures[19] by a method to be published soon.[20] Taking $E^{\ddagger}$ as 22.0 kcal.,[19] k_1 is 3.3×10^{-4} sec.$^{-1}$ at 44.3° and 2.6×10^{-3} sec.$^{-1}$ at 64.0°. The ratio of specific rates of isopropyl and *t*-butyl bromide is tentatively taken[20] as 2×10^{-5}.

However, it is instructive to choose one solvent throughout and to contrast k/k_H for the α-bromopropionate ion with that for the α-bromoisobutyrate ion, $(CH_3)_2CBrCO_2^-$. Table V lists the necessary first order rate constants in methanol. It is seen that k/k_H for $CH_3CHBrCO_2^-$ is of the order of 10^2 or 10^3 while for $(CH_3)_2CBrCO_2^-$ it is 0.8. In the latter case, the carboxylate ion group is inferior to a methyl group. The data are consistent with a substantial driving force,[3a] $RT \ln (k_\Delta/k_c)$, due to the O_2^- group in α-bromopropionate ion and at least a much smaller one in the case of the more highly α-substituted α-bromoisobutyrate ion. This decrease in the driving force of a neighboring group with α-methyl substitution has been observed previously.[3a,b]

Consistent with a lowered interaction between the carboxylate ion group and the α-carbon atom in the transition state for ionization of α-bromoisobutyrate ion is the greater effect of solvent change than for α-bromopropionate ion. From the rate constants in Table V it is seen that the factor between water and methanol for α-bromoisobutyrate ion is approximately 8 whereas it is 2.4 for α-bromopropionate ion.

The extent of the superiority of the CO_2^- group over the CO_2R group for participation in unimolecular type displacement reactions is of some interest but not easy to judge. While k_c is high for the CO_2^- group and any positive driving force makes unimolecular reactions even easier to attain, k_c is very low in the case of the CO_2R group. Thus in the latter case even if k_Δ/k_c were appreciable, unimolecular reactions would be hard to attain. In the case of the reaction of ethyl α-bromopropionate with silver oxide in alcohol, one explanation[14] but, as pointed out, not necessarily the unique one, was that the reaction is unimolecular in type but that the carbethoxy group does not participate. It is probable that the reaction is not unimolecular in type and thus no information is afforded regarding participation of the carbethoxy group.

Experimental

Solvents.—Commercial synthetic methanol, dried by the method of Bjerrum and Zechmeister,[21] and containing less than 0.08% water from the miscibility temperature with cyclohexane,[22] was used in this work. Conductivity water was used as solvent in the aqueous runs.

α-Bromopropionic Acid.—Eastman Kodak Co. material was redistilled at reduced pressure. The samples used in the course of the work were: I, b. p. 99.0° (13 mm.), $n^{21.5}D$ 1.4747, equivalent wt. 152.8 ± 0.6 (calcd. 153.0), m. p. 24.2°; II, b. p. 98.5–98.8° (13.5 mm.), $n^{24}D$ 1.4737, equivalent wt. 152.8 ± 0.6, m. p. 25.3°.

Inorganic Salts.—Sodium nitrate and bromide were Baker and Adamson reagent grade or C. P. materials dried at 120° before use. Sodium perchlorate was prepared halide-free by careful neutralization of J. T. Baker C. P. 70% perchloric acid with C. P. sodium carbonate to the methyl orange endpoint. Concentration of the solution gave crystalline material which was washed with a little ether, and dried to constant weight over sulfuric acid *in vacuo*.

Rate Measurements.—Reaction mixtures were prepared by mixing weighed amounts of α-bromopropionic acid and added salts and measured volumes of aqueous sodium hydroxide or methanolic sodium methoxide (prepared by dissolving sodium in the absolute methanol) in a volumetric flask, the volume being made up at room temperature. As quickly as possible the initial titre of base was determined by titration of an aliquot with standard acid. Aliquot portions (20 ml.) of the reaction mixture were sealed off in tubes and placed in a thermostat at 64.04 ± 0.04° for suitable intervals. On removal from the thermostat, the tubes were chilled in ice and the contents were analyzed for base by adding an excess of standard halide-free nitric acid and back-titrating with standard halide-free base to the phenolphthalein endpoint. The neutral solution was analyzed for bromide ion by titration with standard silver nitrate with eosin or, sometimes, dichlorofluorescein as indicator. Control experiments showed that both titrations were reliable within ordinary experimental error. "Zero" time was called

the time of removal of the first tube after attainment of temperature.

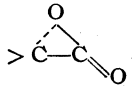
The "infinite" titer of bromide ion agreed well with the expected as indicated by the equivalent weights of the α-bromopropionic acid samples. The "infinite" titer of base was usually unreliable by a few per cent., probably due to reaction of the glass. Soft glass tubes were used in the experiments with methanolic solutions, and Pyrex tubes were employed for the aqueous runs.

In the runs with high base concentration, the reaction was followed chiefly by titration for bromide ion. With the low base concentrations, titration was carried out for both base and bromide ion except where bromide ion was added in large amounts initially. When added sodium perchlorate the rate constants based on the two titrations agreed closely (Table II). With added sodium nitrate, the rate constants from bromide titration were steady but those based on base titration were lower and drifted downward. In run 21 with 0.5 *M* added sodium nitrate, the base consumed during a run averaged 98.8 ± 0.7% of the bromide ion produced, while the analogous figure was 96.6 ± 1.5% for run 19 with *M* added sodium nitrate.

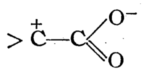
Summary

The hydrolysis and methanolysis of sodium α-bromopropionate in the presence of sodium hydroxide or methoxide was investigated in solutions of varying ionic strength at 64.04°. A kinetic analysis reveals that both the bimolecular and unimolecular specific reaction rate constants, k_2 and k_1, respectively, increase with ionic strength.

The variation of k_1 with change in solvent and ionic strength is discussed in terms of a rate-determining ionization either to the zwitterion II (specific rate k_c), or the α-lactone I (specific rate k_Δ). An unambiguous decision regarding the reaction mechanism is not possible from the salt and solvent effects alone.



I



II

However, the sign of these effects and related evidence, particularly the high reactivity of α-bromopropionate ion compared to isopropyl bromide and the contrast with α-bromoisobutyrate ion, are consistent with the rate-determining ionization symbolized by k_Δ.

The ratio of rate constants for reaction of the intermediate in the solvolysis of α-bromopropionate ion with bromide ion and solvent, k_{Br}/k_S, derived from measurements in solutions containing high bromide ion concentrations, is 2.9 in methanol and 0.76 in water.

The Correlation of Solvolysis Rates

BY ERNEST GRUNWALD AND S. WINSTEIN

One of the important mechanisms (**A**) for solvolysis[1,2] of alkyl halides involves more than one stage and is at present best formulated as involving a rate-determining ionization (equation 1) to a cationic intermediate. The rate constant k_1

$$RX \xrightarrow{k_1} R^+ + X^- \qquad (1)$$

depends on the so-called ionizing power of the solvent, and it is possible from such rates to arrange solvents in a relative order. For example substitution of the unimolecular type[3] proceeds slightly more rapidly in acetic acid than in absolute ethanol.[4] The rate is increased by addition of water to alcohol or partly aqueous acetone or dioxane.[1,2] Further, substitution is about as rapid in formic acid as in 50% aqueous ethanol.[5]

The question arises whether it is possible to assign to each solvent a definite number **Y** which is a quantitative measure of its ionizing power in determining k_1. In this article is reported a scheme for correlating unimolecular solvolysis rates with the aid of such a set of **Y** values and a simple functional relationship between k_1 and **Y**. Also, the theoretical implications of the method are discussed.

In addition to the solvolysis mechanism **A** there occurs solvolysis in neutral and acidic solvents by a process or processes (**B**, rate constant k_x) for which the nucleophilic character as well as the ionizing power of the solvent is important. The best understood concerted process is the so-called bimolecular substitution in which a solvent molecule plays a role such as that of a pyridine molecule in the Menshutkin reaction. One of the important problems for the proper understanding of such subjects as reactivity, stereochemistry of displacements and rearrangements[1b] is that of sorting out the fractions of solvolysis proceeding by mechanisms A and B.

The scheme for correlating solvolysis rates allows one to make deductions regarding the rate by process **A** and therefore the fraction of solvolysis by mechanism **A.** This application of the method is being actively pursued and the procedure is illustrated in the present article for isopropyl *p*-bromobenzenesulfonate.

A Quantitative Measure of Ionizing Power. The Y Function.—The specific solvolysis rates *k* for a number of halides which, the accumulation

[a] Data at 34.85°; $E^{\pm} = 26.43$ kcal./mole. [b] Data at 34.43°; $E^{\pm} = 25.97$ kcal./mole. [c] From data of Hughes.[6] [d] $k_2 = 3.61 \times 10^{-4}$ sec.$^{-1}$ M^{-1}.

of evidence indicates, react by the unimolecular-type mechanism **A**, are summarized in Table I together with the values of the corresponding Arrhenius activation energies, $E^{\pm}$, wherever available. The solvolysis rates for any one compound have been corrected to one temperature with the aid of available values of $E^{\pm}$ or else on the basis of reasonable estimates of $E^{\pm}$. The values of $E^{\pm}$ for any one compound are fairly insensitive to solvent change and all values of $E^{\pm}$ hover near 22 kcal (Table I). It is therefore possible to estimate $E^{\pm}$ with sufficient accuracy since the corrections made are small. Even an error of 2.0 kcal. in $E^{\pm}$ would cause an error of no more than 0.079 in log k for a 20° correction.

Supplementing the data in Table I are the solvolysis rates k we have measured for *t*-butyl chloride and α-methylneopentyl *p*-bromobenzenesulfonate, $(CH_3)_3CCH(OSO_2C_6H_4Br)CH_3$, in a num-

ber of solvents. These measurements are summarized in Table II.

Inspection reveals a simple quantitative relationship among the various solvolysis rate constants. Thus, when the values of log k for any one compound in a number of solvents are plotted against log k of some other compound in the same solvents a straight line is obtained. This linear relationship is illustrated for a number of compounds in Fig. 1.

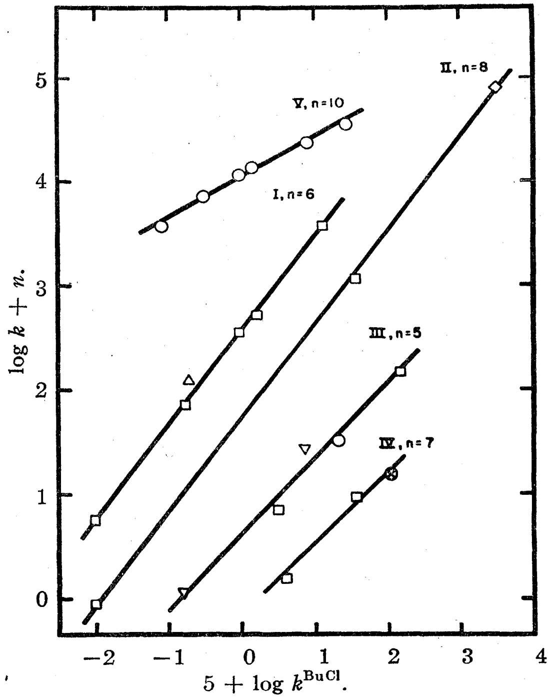

Fig. 1.—Plots of log k *vs.* log k^{BuCl}: I, *t*-butyl bromide 25.0°; II, α-methylallyl chloride, 25.0°; III, α-methylneopentyl *p*-bromobenzenesulfonate, 70.0°; IV and V, neopentyl bromide, 95.0°, and *n*-butyl bromide, 59.4°, both *vs.* *t*-butyl chloride, 25.0°; solvents: ◇, H_2O; □, EtOH–H_2O; ○, MeOH–H_2O; ▽, AcOH–Ac_2O; △, acetone–H_2O; ⊗, HCOOH.

The linear plots illustrated in Fig. 1 indicate that log k^{BuCl} (BuCl = *t*-butyl chloride) satisfies the requirements for a useful quantitative measure of ionizing power of a given solvent. However, log k^{BuCl} varies with temperature and is usually a negative entity of an inconvenient order of magnitude. It is convenient to define **Y** by equation 2, where k^{BuCl} and k_0^{BuCl} are the rate constants of

$$\mathrm{Y} = \log k^{\mathrm{BuCl}} - \log k_0^{\mathrm{BuCl}} \qquad (2)$$

t-butyl chloride at 25.0° in the given solvent and in "80%" ethanol, respectively. By virtue of this definition, **Y** is zero in "80%" ethanol, a solvent often employed and of intermediate reactivity, and **Y** varies from *ca.* +4 to −3 for the most common solvolyzing media. Although 25.0° is chosen as the reference temperature for computing values of **Y** it is clear from the near constancy of $E^{\ddagger}_{\mathrm{BuCl}}$ in various solvents that any other reference temperature would give an almost identical set of **Y** values.

The linear relationships illustrated in Fig. 1 combined with the defining equation 2 for **Y** lead to equation 3 for the variation of solvolysis rate constant k with solvent for these compounds. In

$$\log k = m\mathrm{Y} + \log k_0 \qquad (3)$$

this equation, m and log k_0 are parameters, although physically k_0 is the solvolysis rate constant in "80%" ethanol. Equation 3 is the basis of the quantitative scheme for correlating solvolysis rates.

In Table I are summarized values of **Y** for an extensive series of solvents. **Y** values for all solvents except the acetone–water mixtures were calculated from the available data for *t*-butyl chloride at 25.0° (Tables I, II). In order to obtain **Y** values in the latter solvent mixtures the parameters m and log k_0 were evaluated for *t*-butyl bromide and benzhydryl chloride from data at 25.0° in ethanol–water mixtures, and **Y** was calculated for various acetone–water mixtures with the aid of equation 3, using the available values of log k for these compounds. Two different sets of **Y** are obtained in this way, of which one (from *t*-butyl bromide) is used for aliphatic compounds while the other (from benzhydryl chloride) is used with α-phenylethyl chloride. Acetone–water mixtures were the only solvents where it was found necessary to use two different sets of **Y** in order to correlate all rates of unimolecular-type solvolysis scrutinized by the authors to date.

The functional relationship between **Y** and the composition of mixed solvents is apparently not

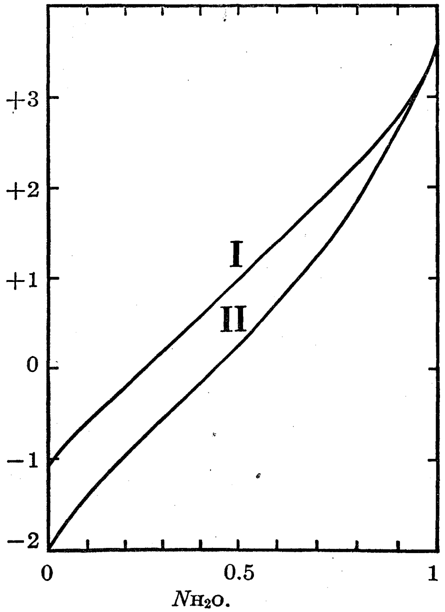

Fig. 2.—Plot of **Y** *vs.* mole fraction of water (N_{H_2O}) for: I, H_2O–MeOH; II, H_2O–EtOH.

simple. Plots of **Y** *vs.* weight % or volume % of water in aqueous ethanol and methanol have considerable curvature. The plot of **Y** *vs.* mole fraction of water, N_{H_2O}, is more nearly linear for these systems as illustrated in Fig. 2. The latter observation is useful for purposes of interpolation.

The parameters m and $\log k_0$ in equation 3 have been evaluated for a number of compounds by the method of least squares, using the values of k and **Y** in Tables I and II. The results are summarized in Table III together with the probable error of the fit,[15] r. The fit is satisfactory, particularly since the values of k often vary by 3 to 6 powers of ten, the mean value of r for the whole table being less than 0.05. The probable errors in m are of the order of 0.05 or less.

TABLE III

CORRELATION OF SOLVOLYSIS RATES IN VARIOUS SOLVENTS

No.	Compound	Temp., °C.	m	$\log k_0$	r
1	*t*-Butyl chloride	25.0	1.000	−5.034	...
2	*t*-Butyl bromide	25.0	0.917	−3.476	0.026
3	Neopentyl bromide	95.0	.712	−7.248	.059
4	α-Methylneopentyl *p*-bromobenzenesulfonate	70.0	.706	−2.837	.096
5	α-Methylallyl chloride	25.0	.894	−6.314	.052
6	Benzhydryl chloride	25.0	.757	−2.779	.004
7	α-Phenylethyl chloride[a]	50.0	1.195	−3.808	.072
8	*n*-Butyl bromide	59.4	0.392	−5.972	.026
		75.1	0.331	−5.419	.034

[a] The value of k for HOAc, 0.2 *M* KOAc (Table I), was not included since no value of **Y** is available at such high acetate concentration. From the above data $k = 1.74 \times 10^{-6}$ sec.$^{-1}$ at 0.025 *M* KOAc ($Y = -1.633$) in reasonable agreement with the value in Table I.

Equation 4 gives the variation of m with temperature T. This is slight since for most solvents the

$$2.303\ Y \frac{dm}{dT} = \frac{E^{\ddagger} - E_0^{\ddagger}}{RT^2} \qquad (4)$$

difference between the activation energy $E^{\ddagger}$ and the activation energy $E_0^{\ddagger}$ in "80%" ethanol is small for unimolecular-type solvolysis (Tables I, II).

Theoretical Interpretation. The Activity Postulate.—Application of the Brönsted theory to the variation of k_1 with solvent for unimolecular-type solvolysis leads to equation 5 where κ is the

$$k_1 = \kappa \frac{f_A}{f_A^{\ddagger}} \qquad (5)$$

specific rate in the standard state of unit activity and f_A and $f_A^{\ddagger}$ are the activity coefficients of reactant and transition-state. In the case of dilute solutions[16] of non-electrolytes it is useful to refer all activity coefficients to the gas phase so that equation 5 reduces to 6. In this equation H_A and $H_A^{\ddagger}$ are the Henry's law constants[16] of reactant

$$k_1 \kappa = (H_A/H_A^{\ddagger}) \qquad (6)$$

and transition-state.

Comparison of equations 6 and 3 leads to 7 which implies a linear relationship, 8, between

$$\log \frac{H_A}{H_A^{\ddagger}} = mY + \log \frac{k_0}{\kappa} \qquad (7)$$

$\log (H_A/H_A^{\ddagger})$ and $\log (H_B/H_B^{\ddagger})$ for any two com-

$$\log \frac{H_A}{H_A^{\ddagger}} = \frac{m_A}{m_B} \log \frac{H_B}{H^{\ddagger}} + \left(\frac{m_A}{m_B} \log \frac{\kappa_B}{k_{0B}} - \log \frac{\kappa_A}{k_{0A}}\right) \qquad (8)$$

pounds A and B solvolyzing by the unimolecular-type mechanism in a series of solvents. This deduction calls to mind the observation[17] that there exists an even simpler linear relationship, shown in equation 9, between $\log (f_B/f_{BH^+})$ for any two

$$\log \frac{f_B}{f_{BH^+}} = \log \frac{f_{B'}}{f_{B'H^+}} \qquad (9)$$

conjugate acid–base systems B and B′ in a series of solvents.

The success of equation 3 for correlating solvolysis rates of the unimolecular type may be due to the validity of a general relationship regarding ratios of activity coefficients. For systems undergoing similar changes of the type AZ → AZ′, BZ → BZ′, etc., the postulated general relationship may be expressed by equation 10, μ and β being parameters.

$$\log \frac{f_{AZ}}{f_{AZ'}} = \mu \log \frac{f_{BZ}}{f_{BZ'}} + \beta \qquad (10)$$

In the case of solvolysis by mechanism **A** the change AZ → AZ′ is from the dissolved halide or ester to the partly ionized and strongly solvated transition-state molecule. Equation 3 and thus 8 is successful for variations in the ionizing group to include chloride, bromide and bromobenzenesulfonate. Also, the change AZ → AZ′ is not restricted entirely to the A–Z bond. For example, resonance will diffuse any positive charge of the *alpha* carbon atom in the transition state to the *ortho* and *para* positions of an *alpha* phenyl group. Even in aliphatic cases the positive charge will be spread. Now evidently equations 3 and 8 hold for considerable variation in the R part of the solvolyzing molecule RX but further work is necessary to clearly outline the scope and limitations in this respect. The need for two sets of **Y** values for aqueous acetone mixtures is one of the limitations which has already appeared.

Solvolysis of *t*-Butyl Chloride.—The solvolysis rate of *t*-butyl chloride in a range of mixed aqueous solvents has previously been correlated by Olson and Halford[8] with the aid of the fugacity rate equation 11 where p_w and p_a are vapor

$$k = (k_w p_w + k_a p_a) H_{BuCl} \qquad (11)$$

pressures of water and alcohol, respectively. This equation, which empirically fits the rates but not

(17) Ref. 2, Chapter IX.

the products,[18] is based on assumed bimolecular reactions between halide and water or alcohol but it is set up according to an activity rate formulation, the respective terms not being divided by the activity coefficients of the corresponding transition states. Actually higher order[18] fugacity rate equations fit the rates at least as well as equation 11. Scrutinizing the data with our present approach, seeking generalizations regarding activity coefficients involved, we find that log k is a linear function of log H_{BuCl} for the range of solvents treated by Olson and Halford. Equation 12 fits

$$\log k^{\mathrm{BuCl}} = 1.232 \log H_{\mathrm{BuCl}} - 9.811 \qquad (12)$$

the data at 25.0° for all partly aqueous solvents (including also water and methanol) (Tables I, II, IV, ref. 8) with a probable error of 0.06. Thus, only two parameters are necessary.

The linear relation expressed in equation 12 indicates, according to equation 6, that a linear relation exists between log $H^{\pm}_{\mathrm{BuCl}}$ and log H_{BuCl} in the solvent range involved. This linear relation takes the form shown in equation 13.

$$\log H^{\pm}_{\mathrm{BuCl}} = -0.232 \log H_{\mathrm{BuCl}} + \text{Constant} \qquad (13)$$

TABLE IV

HENRY'S LAW CONSTANTS FOR *t*-BUTYL CHLORIDE AT 25.0°

Solvent	10^{-3} H_{BuCl}, mm.
HOH	5×10^3
EtOH	1.09 ± 0.09
HOAc, 0.025 *M* KOAc	1.23 ± 0.05
HOAc − Ac_2O, $N_{\mathrm{AcOH}} = 0.042$	0.786 ± 0.020

While there are indications that linear log–log relationships between the activity coefficients of non-electrolytes are fairly general,[19] the linear log–log relation expressed by equations 12 and 13 for *t*-butyl chloride and its solvolysis transition state breaks down when one proceeds to the more poorly ionizing solvents such as absolute alcohol or acetic acid–acetic anhydride combinations. The plot in Fig. 3 of log k^{BuCl} *vs.* log H_{BuCl} at 25.0° illustrates the linear relation for one range of solvents and the large departure for the slower solvents mentioned. Even with the departure from linearity the curve is smooth. However, a smooth curve is not necessarily to be expected and this feature may be fortuitous.

Further insight into the above-described situation is derived by reference again to equation 6. As shown in equation 14, (log H_{BuCl}–log k^{BuCl}) is a

$$\log H^{\pm}_{\mathrm{BuCl}} - \log \kappa = \log H_{\mathrm{BuCl}} - \log k^{\mathrm{BuCl}} \qquad (14)$$

measure of log $H^{\pm}_{\mathrm{BuCl}}$, and this quantity is plotted against log k^{BuCl} in Fig. 3. It can be seen that in the partly aqueous solvents where equation 12 holds the variation in k^{BuCl} is due largely to changes in H_{BuCl}. On the other hand, in the poorer ionizing media the variation in k^{BuCl} is due largely to changes in $H^{\pm}_{\mathrm{BuCl}}$.

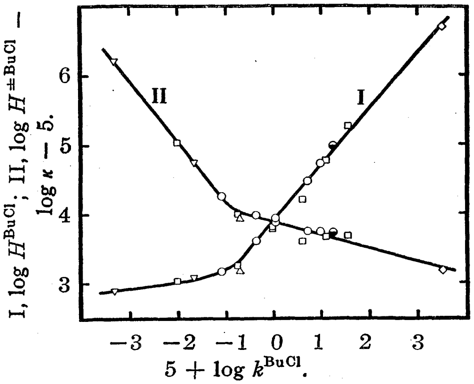

Fig. 3.—Plots of log H^{BuCl} and (log $H^{\pm\mathrm{BuCl}}$ − log κ) against log k^{BuCl}, 25.0°: □, H_2O–EtOH; ○, H_2O–MeOH; ◒, H_2O–dioxane; ▽, AcOH–Ac_2O; △, H_2O–acetone; ◇, H_2O.

Solvolysis of Isopropyl *p*-Bromobenzenesulfonate.—For the simple secondary alkyl compound, isopropyl *p*-bromobenzenesulfonate, without essentially prohibitive steric hindrance to nucleophilic attack on carbon such as evidently obtains in the case of pinacolyl *p*-bromobenzenesulfonate, the nucleophilic character of the solvent is very important. The first-order solvolysis rate constants k for isopropyl *p*-bromobenzenesulfonate are summarized in Table II and inspection reveals the contrast with the other compounds treated successfully by equation 3. For example, the rate constant in ethanol is much greater than in acetic acid although the **Y** value for acetic acid is the higher. This contrast is due to the fact that ionizing power and nucleophilic character of solvents do not go hand in hand. Instead of the rates in all solvents being manageable together it is now necessary to differentiate between basic solvents and others.

Quite a satisfactory understanding of the solvolysis rates of isopropyl *p*-bromobenzenesulfonate may be reached on the assumption that solvolysis proceeds by both mechanism types **A** and **B**, **B** being slight or negligible in the acidic type solvents such as acetic acid or its mixtures with acetic anhydride and serious in the more basic solvents.

In the acetic acid–acetic anhydride solvents the plot of log k for isopropyl *p*-bromobenzenesulfonate against log k' for pinacolyl *p*-bromobenzenesulfonate gives the least squares line shown in equation 15, the probable error[15] being 0.136. The

$$\log k = 1.204 \log k' + 0.031 \qquad (15)$$

straight line fit is not as satisfactory here as in the other cases, possibly because the acetolysis is not cleanly of the unimolecular type ($k = k_1$). It is not out of the question that acetic acid can func-

---

[18] (a) Bartlett, THIS JOURNAL, **61**, 1630 (1939); (b) Winstein, *ibid.*, **61**, 1635 (1939); (c) Bateman, Hughes, and Ingold, *ibid.*, **60**, 3080 (1938); (d) Bateman, Hughes and Ingold, *J. Chem. Soc.*, 881 (1938).

[19] Grunwald, Dissertation, University of California at Los Angeles, Calif., 1947, sections 6, 17.

tion in solvolysis by mechanism **B**. While the addition of $0.025M$ potassium acetate to glacial acetic acid gives no serious change in first-order rate constant the addition of $0.01M$ potassium acetate to the solvent rich in acetic anhydride produces a predominantly bimolecular reaction. However, the slope of the line represented by equation 15 is reasonable for solvolysis largely by mechanism **A**. The value of 1.204 combined with an m value of 0.706 for pinacolyl *p*-bromobenzenesulfonate (Table III) corresponds to 0.850 for m in the case of the isopropyl ester.

Assuming $k = k_1$ in the acidic solvents, equation 15 allows one to estimate k_1 in the nucleophilic alcoholic solvents. These estimates are listed in Table V along with k_x (*i. e.*, $k - k_1$) and the percentage of solvolysis by mechanism **A**, 100 k_1/k.

TABLE V

SOLVOLYSIS OF ISOPROPYL *p*-BROMOBENZENESULFONATE AT 70.0° IN NUCLEOPHILIC SOLVENTS

Solvent	10^4k sec.$^{-1}$	Calcd. 10^4k_1	Calcd. 10^4k_x	Calcd. $100k_1/k$
EtOH	2.64	0.108	2.53	4.1
MeOH	7.31	0.68	6.63	9.3
80% EtOH	17.0	3.86	13.1	22.7

It is interesting that k_x in the small range of comparably nucleophilic alcoholic solvents is fit by a linear equation of the same type as 3, equation 16 fitting the data in Table V with a probable

$$\log k_x = 0.360\,Y - 2.857 \qquad (16)$$

error of 0.046. In these solvents the rate of solvolysis by mechanism **B** seems to depend on the same properties of the solvent which control the rate of the **A** type, the slope m, however, being quite small.

It is an especially satisfactory feature of the assumed way of accounting for the solvolysis rates of isopropyl *p*-bromobenzenesulfonate that the slope in equation 16 is so small and so nearly equal to the one which is derivable for *n*-butyl bromide. There is reason to believe that the latter halide solvolyzes exclusively by mechanism **B** in alcoholic solvents, and Bird, Hughes and Ingold[20] have supplied rates of solvolysis in various aqueous ethanol and methanol solvents.[21] Using their data a plot of log k against log k^{BuCl} is linear as illustrated in Fig. 1 and equation 3 fits the data well as summarized in Table III. The values of m in aqueous methanol at 59.1° and aqueous ethanol at 75.1° are 0.392 and 0.331, respectively. In fact, values of m are also quite similar[22] for other primary halides apparently solvolyzing by mechanism **B**.

Experimental and Kinetic Part

Materials.—The *t*-butyl chloride was Eastman Kodak Co. "White Label" grade, b. p. 51.2° (752 mm.), n^{25}D 1.3820.

α-Methylneopentyl alcohol, b. p. 120.0–120.3° (754 mm.), was prepared by Miss Anita Suran from *t*-butyl magnesium chloride[23] and acetaldehyde.

α-Methylneopentyl *p*-bromobenzenesulfonate I and isopropyl *p*-bromobenzenesulfonate II were prepared in *ca.* 50% yield in 0.05 mole batches from the corresponding alcohols and *p*-bromobenzenesulfonyl chloride in pyridine by conventional methods.[24] I crystallized upon pouring the pyridine reaction mixture into ice-cold 6 *N* hydrochloric acid and was recrystallized several times from petroleum ether (b. p. 60–80°); m. p. 53.2–53.5; equivalent weight from quantitative solvolysis: calcd., 321.2; found, 323.2 (in acetic acid), 320.1 (in "80%" ethanol).

Anal. Calcd. for $C_{12}H_{17}O_3SBr$: C, 44.86; H, 5.34. Found: C, 44.99; H, 5.49.

II separated as an oil upon pouring the pyridine reaction mixture into 6 *N* hydrochloric acid. The oil was separated with the aid of *ca.* 40 ml. of carbon tetrachloride and the solution was dried over anhydrous potassium carbonate. After evaporation of the solvent at room temperature the viscous residue was induced to crystallize. The solid was purified by reprecipitation under petroleum ether (b. p. 60–80°); m. p. 32.3–34.1°. Equivalent weight from quantitative solvolysis: calcd. 279.2; found 282.1 (in acetic acid), 278.3 (in methanol). Analysis for carbon and hydrogen was unsuccessful because II decomposed rapidly on heating.

Solvents.—Synthetic methanol, containing less than 0.03% of water by the miscibility temperature with cyclohexane,[25] was used.

Ethanol was dried by the ethyl formate method[26] and contained less than 0.02% of water by Robertson's paraffin oil test.[26]

"80%" ethanol was prepared by adding 317.5 g. of conductivity water to 1000 g. of ethanol.

Acetic acid containing 0.0142 *M* (0.1%) acetic anhydride by Kilpi's anthranilic acid analysis[27] was prepared as described in a previous article.[3]

To 379.0 g. of Baker and Adamson "Reagent Grade" acetic anhydride, equivalent weight 51.20 ± 0.06 by hydrolysis and titration with standard aqueous base to the phenolphthalein endpoint (mole fraction of acetic acid 0.042), was added 80.6 g. of acetic acid containing 0.1 wt. % of acetic anhydride to give a solvent of equivalent weight 52.63 ± 0.06 (mole fraction of acetic acid 0.294).

In order to prepare solvents containing potassium acetate the Baker and Adamson "Reagent Grade" salt was dried to constant weight in a tared glass-stoppered flask at 110° *in vacuo* and dissolved in the desired weight of solvent.

Kinetic Measurements.—Rates were measured by the usual sealed ampoule technique. Titrations were made on 5-ml. aliquots from 5-ml. microburets. For the measurements in ethanol, methanol and "80%" ethanol, titration

---

[20] Bird, Hughes and Ingold, *J. Chem. Soc.*, 255 (1943).

[21] In the case of *n*-butyl bromide, the fugacity rate equation 11 has been found by Bird, Hughes and Ingold[20] to fit both rates and products. It must be noted that *H* may be expressed as the ratio of the vapor pressure of halide to either its mole fraction or its molarity. Olson and Halford[8] have used mole fraction as is also done in the present article, and Bird, Hughes and Ingold[20] have used molarity However, because of differences in molar volumes of various mixed solvents, if the use of molarity furnishes a fit for the product compositions, the use of mole fraction cannot furnish such a fit. A recalculation of the data of Bird, Hughes and Ingold, using mole fraction in evaluating *H*, shows that equation 11 will fit the rates but not the products.

for acid was carried out with 0.05 *N* sodium hydroxide using brom thymol blue as indicator. Titrations in glacial acetic acid and mixtures of acetic acid and acetic anhydride were performed as described previously[3,24] except that 0.05 *N* *p*-toluenesulfonic acid was substituted for perchloric acid in the solvents containing large amounts of acetic anhydride. Reactions were usually followed to *ca.* 75% completion. Reaction mixtures were prepared gravimetrically except for the rate-runs involving *t*-butyl chloride where initial concentrations were obtained from the "infinite" titer of acid and/or from Volhard titration for chloride ion. In order to avoid errors due to the volatility of *t*-butyl chloride, the vapor space above the reaction solutions in the ampoules was kept quite small.

The observed kinetics were first-order within the experimental error of 1–2% in *k* over the range of concentrations investigated except for the solvolysis of isopropyl *p*-bromobenzenesulfonate (RX) in 4.2 mole % acetic acid in acetic anhydride in the presence of potassium acetate. A representative set of experimental data is shown in Table VI. These data were fitted satisfactorily by equation 17 which assumes a simultaneous first-order solvolysis and second-order reaction with potassium acetate.

$$-\mathrm{d}\ln(\mathrm{RX})/\mathrm{d}t = k_1 + k_2(\mathrm{KOAc}) \qquad (17)$$

Using the data obtained during the latter part of the run where the potassium acetate has been neutralized, k_1 was calculated from the slope (obtained by the method of least squares) of the linear plot of log (RX) *vs.* time, *t*. The derivative, $-\mathrm{d}\ln(\mathrm{RX})/\mathrm{d}t$, was then obtained at various concentrations of potassium acetate from a large-scale plot of ln (RX) *vs.* *t* with the aid of a tangent meter. Substitution in equation 17 gave satisfactorily constant values for k_2. The average value of k_2 for this and a duplicate run was $(3.61 \pm 0.07) \times 10^{-4}$ sec.$^{-1}$ *M*.$^{-1}$

Equilibrium in the System *t*-Butyl Chloride, *t*-Butyl Acetate, Hydrogen Chloride.—In analogy with the report of Steigman and Hammett[14] for α-phenylethyl chloride, *t*-butyl chloride solvolyzes in initially neutral acetic acid to give an equilibrium mixture according to equation 18.

$$t\text{-BuCl} + \mathrm{HOAc} = t\text{-BuOAc} + \mathrm{HCl} \qquad (18)$$

The rate of establishment of equilibrium is considerably faster than the rate of solvolysis in the presence of potassium acetate. For example, at 40.0° *ca.* 97% of the equilibrium concentration of hydrogen chloride is produced from a solution of *t*-butyl chloride within 28 hours whereas the solvolysis in the presence of potassium acetate is only *ca.* 20% complete within the same period.

The pertinent equilibrium data are summarized in Table VII. The data were obtained by the sealed-ampoule technique described for the kinetic runs. The equilibrium titre of hydrogen chloride was constant within experimental error over a period of several days.

TABLE VII

EQUILIBRIUM IN THE SYSTEM *t*-BUTYL CHLORIDE, *t*-BUTYL ACETATE, HYDROGEN CHLORIDE

Initial *t*-BuCl $10^3 M$	*T*, °C.	(HCl) at equilibrium $10^3 M$	K^a
81.8	60.2	6.02 ± 0.2	2.1×10^3
158.3	60.2	$8.12 \pm .2$	2.3×10^3
81.8	40.0	$4.15 \pm .2$	4.5×10^3
158.3	40.0	$5.65 \pm .1$	4.8×10^3

[a] $K = (t\text{-BuCl})/(t\text{-BuOAc})(\mathrm{HCl})$.

Measurement of Henry's Law Constants.—Approximate Henry's law constants were determined as follows: A 500-ml. standard-taper round-bottom flask equipped with a graduated dropping funnel and an outlet tube leading by way of a T-joint to a manometer and an oil pump was placed in a thermostat and evacuated until the pressure was below 2 mm. A known volume of standard solution of *t*-butyl chloride in the appropriate solvent was introduced carefully from the dropping funnel and the increase in pressure read. Room temperature was maintained above that of the thermostat to avoid condensation of the vapors. A typical set of experimental data is given in Table VIII. In computing the mole fraction of *t*-butyl chloride, allowance was made for the materials in the known vapor space.

TABLE VIII

HENRY'S LAW CONSTANT OF *t*-BUTYL CHLORIDE IN ACETIC ACID CONTAINING 0.025 *M* POTASSIUM ACETATE, 25.0°

N_{BuCl}	*p*, mm.[a]	10^{-3} *H*, mm.
0.0000	16.0	..
.0338	53.6	1.13
.0359	59.1	1.22
.0293	52.3	1.26
.0137	33.5	1.29

[a] *p* = pressure increase due to the solution.

The Henry's law constant of *t*-butyl chloride in water was estimated from the vapor pressure and a rough determination of the solubility of the halide in water (*ca.* 3×10^{-3} *M*).

Summary

For compounds which appear to solvolyze by a rate determining ionization, plots of the logarithm of the first-order rate constant k in various solvents (either from the literature or here reported) against log k for t-butyl chloride are linear.

A set of values of the so-called ionizing power, **Y**, defined by the equation

$$\mathrm{Y} = \log k^{\mathrm{BuCl}} - \log k_0^{\mathrm{BuCl}}$$

(k^{BuCl} and $k_0{}^{\mathrm{BuCl}}$ being solvolysis rate-constants for t-butyl chloride at 25.0° in the given solvent and in 80% ethanol) has been set up for a number of solvents including water, methanol, ethanol, aqueous alcohols, formic acid and acetic acid. The solvolysis rate constants (varying sometimes by six orders of magnitude) are fitted by the equation

$$\log k = m\mathrm{Y} + \log k_0$$

with a mean probable error of less than 0.05 in the cases of t-butyl bromide, neopentyl bromide, α-methylneopentyl p-bromobenzenesulfonate, α-methylallyl chloride, α-phenylethyl chloride and benzhydryl chloride.

The observed linear relationships, interpreted on the basis of the Brönsted equation, lead to the equation

$$\log \frac{f_{\mathrm{A}}}{f^{\neq}_{\mathrm{A}}} = \frac{m_{\mathrm{A}}}{m_{\mathrm{B}}} \log \frac{f_{\mathrm{B}}}{f^{\neq}_{\mathrm{B}}} + \text{constant}$$

for the relationship among the pertinent activity coefficients (f_{A}, $f^{\neq}_{\mathrm{A}}$, *etc.*) for any two compounds A and B. It is postulated that linear logarithmic relationships among ratios of activity coefficients of this type may be quite general.

The solvolysis of t-butyl chloride is discussed in terms of the Brönsted equation. It is shown that, to a good approximation, log $f^{\neq}_{\mathrm{BuCl}}$ varies linearly with log f_{BuCl} in the partly aqueous solvents and that in these solvents the variation in k is due largely to changes in f_{BuCl}. On the other hand, in the more poorly ionizing solvents changes in k are attributable mainly to changes in $f^{\neq}_{\mathrm{BuCl}}$.

The reported method of correlating unimolecular type solvolysis rates is useful in elucidating the nature of the solvolysis of materials the rates of which depend markedly on the nucleophilic character of the solvent. For isopropyl p-bromobenzenesulfonate the rates of solvolysis in acetic acid and acetic acid–acetic anhydride mixtures furnish estimates of unimolecular solvolysis rates in ethanol, methanol and aqueous ethanol. The actual solvolysis rates are considerably larger in the latter solvents, the fractions of unimolecular solvolysis being low.

Hyperconjugation. II. The Competitive Bromination of Benzene and *t*-Butylbenzene

BY ERNST BERLINER AND FRANCES J. BONDHUS

When benzene and t-butylbenzene in an equimolecular mixture in 92% acetic acid are allowed to compete for an insufficient amount of bromine, the corresponding brominated hydrocarbons are formed in proportions which show that the ratio of the rates of bromination at 25° is about 115:1 in favor of t-butylbenzene. At 45° the ratio is about 72:1. Therefore the bromination of benzene requires a higher energy of activation than the bromination of t-butylbenzene.[1] Since under the same conditions toluene is brominated about four times faster than t-butylbenzene,[2,3] the rate of bromination of toluene appears to be about 465 times faster than that of benzene. Values for the individual rates of chlorination of toluene and benzene fix the ratio at about 345,[3,4] whereas in nitration with acetyl nitrate toluene reacts twenty-three times faster than benzene.[5]

The difference in the rates of bromination of toluene and t-butylbenzene was explained by no-bond resonance of the Baker–Nathan type,[2,3,6] which involves carbon–hydrogen bonds, but the much greater difference between t-butylbenzene and benzene clearly cannot be accounted for by such resonance, since no α-hydrogen atoms are available for conjugation.[7] On the other hand, it would be hard to see how the inductive effect, which, on the basis of the Baker–Nathan theory, should be operative in the absence of hydrogen atoms, could alone account for the great activation and strong *ortho–para* directive influence of the t-butyl group, particularly since inductive effects of alkyl groups are conceded to operate through a rather feeble relay mechanism. The definitions that make the Baker–Nathan type of resonance

---

[1] The bromination of different aromatic compounds is probably another case in which the differences in rate are primarily due to differences in the E term of the Arrhenius equation (Scheffer and Blanksma, *Rec. trav. chim.*, **45**, 522 (1928); Bradfield and Jones, *J. Chem. Soc.*, 1006 (1928)); *i. e.*, the relationship (log $k_1/k_2)_{T_1} = T_2/T_1$ (log $k_1/k_2)_{T_2}$ should hold. In the competitive bromination of toluene and t-butylbenzene the calculated ratio at 45° is 3.70 (found, 3.80); in the present bromination the agreement is less satisfactory (calculated ratio at 45°: 85.7, found: 71.5). This may be due to irregularities on account of the greater difference in rate.

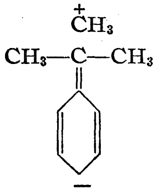
[7] Baker, *ibid.*, 1150 (1939).

dependent upon the number of hydrogen atoms available for conjugation are, however, not inherent in the quantum mechanical treatment of the problem.[8] According to this approach any three single bonds can take part in hyperconjugation, if they are linked to a carbon atom which is conjugated with a multiple link. It has been more or less assumed that the carbon–hydrogen bond is capable of contributing more to hyperconjugation than an equally situated carbon–carbon bond, an idea that is supported by a fairly large number of reaction rates and equilibrium constants that have been studied by Baker and his school.[9] Although this concept seems thus fairly well established experimentally, it has also been stated that "...every carbon–carbon single bond can act as hyperconjugation donor wherever this is needed, without appreciable cost."[10] In view of the unexpectedly large contrast in the rates of bromination of benzene and *t*-butylbenzene, the *t*-butyl group must be considered to release electrons and partake in resonance through the contributions of structures of the type



The order of electron release of alkyl groups by this mechanism is identical with the order of the inductive effect, *i. e.*, *t*-butyl > *i*-propyl > ethyl > methyl,[11] and the reverse of the order of the hyperconjugation effect involving hydrogen atoms only (Baker–Nathan effect).

Reinterpretation of the inductive effect of alkyl groups as a resonance effect allows all observed electron release by these groups to be treated from a common basis. This might seem particularly advantageous in that the origin of the inductive effect has always been obscure.[12] It does not, *a priori*, answer the vexing question: why should there be two differing orders of electron release by alkyl groups, *i. e.*, why does carbon–hydrogen hyperconjugation contribute more in some cases, whereas in others resonance of carbon–carbon links takes precedence?[13] Thus, in the bromination of alkylbenzenes hyperconjugation appears to be predominant in toluene, but it must still be appreciable in *t*-butylbenzene, where only carbon–carbon hyperconjugation is possible.

Measurements of physical constants, on the whole, seem to reveal increasing contributions from resonance with increasing number of carbon–carbon links available for hyperconjugation, whereas rates and equilibrium constants indicate a greater tendency for carbon–hydrogen hyperconjugation. It is true that in many of the reactions that have been studied the differences in rate or equilibrium constants are very small, and in the majority of the cases the sequence of the alkyl groups is far from clean or regular, but enough well spaced series have been obtained to establish the Baker–Nathan order for reactions and equilibria with a good deal of certainty, even though only as a trend.[14,15]

Table I summarizes some of the pertinent data referring to both physical constants and chemical reactions. The new figures for the resonance energies of alkylbenzenes deserve some comment. It is generally agreed that small differences in experimental resonance energies must not be relied upon too strongly, since the values are obtained as small differences of two large figures, both subject to experimental errors.[16] The heats of combustion, on which the present data are based, have been determined on extremely pure samples by one reliable group at the National Bureau of Standards.[17] If one is justified in using thermochemical data for the calculation of resonance energies, the present set of data is surely reliable. The alkylbenzenes thus show resonance energies that increase with the amount of branching, *i. e.*, they follow the order produced by hyperconjugation of carbon–carbon bonds (line 1).[18,19,19a] In lines 2 and 3 of Table I are listed the dipole moments and molecular exaltations of the alkylben-

[8] Mulliken, *J. Chem. Phys.*, **7**, 339, 356 (1939).

[9] See Baker and Hemming, *J. Chem. Soc.*, 191 (1942), for the preceding references.

[10] Mulliken, Rieke and Brown, THIS JOURNAL, **63**, 41 (1941).

[11] Resonance structures of the type R^+ —Ar place the alkylbenzenes in the same order.

[12] Ingold, *Chem. Rev.*, **15**, 225 (1934).

[13] The problem of the order of the "inductive" effect *versus* the order of the resonance effect has been treated by Baker and his co-workers in terms of the relative energy levels (ref. 7 and 9, and *Trans. Faraday Soc.*, **37**, 632 (1941)) by which numerical values are assigned to the two effects. According to the present presentation it would not seem justified to assign a zero value to the resonance effect of the *t*-butyl group.

[14] For a general survey see: Deasy, *Chem. Rev.*, **36**, 145 (1945).

[15] The rates of chlorination of different alkyl phenyl ethers (Jones, *J. Chem. Soc.*, 1831 (1935)), the relative directive influence of alkoxyl groups (Robinson and Smith, *ibid.*, 392 (1926), 2647 (1927)), and of alkyl benzoates (Zaki, *ibid.*, 983 (1928)), that have often been cited in support of the pure order of the inductive effect, can actually be accounted for by a Baker–Nathan order. Since conjugation between the alkyl groups and the benzene ring is not possible through the intervening oxygen atom the increase in electron density on the ring will ultimately depend on the partial ionic bond character of the alkyl–oxygen bond, which in turn will depend on the stability of the alkyl carbonium ion (or something approaching it); see footnote 18.

[16] Wheland, "The Theory of Resonance," John Wiley & Sons, Inc., New York, N. Y., 1944, p. 63.

[17] Prosen, Johnson and Rossini, *J. Research Natl. Bur. Standards*, **36**, 455 (1946). The resonance energies are calculated from Pauling's bond energy values, ref. 16, p. 75.

[18] The figures, *inter alia*, also suggest that any effect based on the order *t-butyl* > methyl cannot be entirely due to induction, but must be, at least in part, a resonance effect, because no stabilization is assumed to accompany the inductive effect. However, the inductive effect of *all* groups is due to partial ionic bond character, and is thus a resonance effect.

[19] F. J. Bondhus, Ph.D. Dissertation, 1947, Bryn Mawr College, Bryn Mawr, Pa.

[19a] It might be argued that the bond energy values are not accurate enough to warrant an interpretation of the small differences; it is felt, however, that the observed *relative order* is significant. The calculations of Wheland and Pinkston (*J. Chem. Phys.*, **12**, 69 (1944)) refer only to second order hyperconjugation.

TABLE I

		Hydrogen	Methyl	Ethyl	*i*-Propyl	*t*-Butyl

zenes, which parallel the resonance energies, except for the exaltation of *t*-butylbenzene, which shows a reversal. Exaltation data have been used by Mulliken,[8] and by Hurdis and Smyth[20] to detect the presence of hyperconjugation. Data on the absorption spectra are only available for some alkylcyclohexenes,[21] and these do not demonstrate any differences.[22] No differences are shown in the heats of hydrogenations of alkylolefins,[23] but any differences would be expected to be smaller in the olefins than in the alkylbenzenes. Attention is also directed to the increasing stability of the free radicals formed from *p*-alkylhexaphenylethanes (line 10). The remainder of Table I records reaction rates and one equilibrium constant that show the opposite order (*i. e.*, the Baker–Nathan order) of the effect of alkyl groups.

Resonance involving the carbon–carbon bond was used at an early date by Wheland to account for the stability of free radicals formed from secondary or tertiary dialkyltetraarylethanes,[24] and later by Lewis and Kasha for the phosphorescence of di-isopropyl ketone.[25] It has recently been employed to explain the decreasing dipole moments of branched aliphatic amines.[26] The very small difference in dipole moments of *i*-propyl and *t*-butyl chloride as compared with the larger difference between methyl and ethyl chloride has been discussed by Smyth,[27] and can similarly be explained by the postulation of structures of the type $^-CH_3(CH_3)_2C{=}Cl^+$. The decreasing strengths of aliphatic branched acids can be accounted for in a like manner, as can other data, whenever alkyl groups are situated next to an atom having unshared electrons available for the formation of another bond.[19]

Why two opposing orders, based on the same effect, should be operative is at present not obvious. Since the data indicate that carbon–carbon hyperconjugation contributes more to the ground state of the resting molecule than carbon–hydrogen hyperconjugation, one might be justified in looking for deviations from the order required by carbon–carbon hyperconjugation in the energy and configurational requirements of the transition state.[28] Of the factors that might conceivably influence the stability of the transition state and be responsible for the inverted order of electron release by alkyl groups, the following might be of importance. Hydrogen is more electropositive than carbon on the electronegativity scale,[29] and a resonance structure that places a negative charge on the more electronegative atom (carbon) should, on this basis, be favored over other possible structures.[30a] Such an effect should be influenced by the solvent and the extent of solvation, and might be of considerable importance in reactions such as these, which have been carried out in strongly polar solvents or in the presence of acids and bases. It is perhaps significant in this connection that, whereas toluene does not exchange its hydrogens in neutral medium,[28] a slow deuterium exchange is reported to take place in alkaline solution.[31] This does not

mean that hyperconjugation implies an ionization, as has been suggested[32] and repudiated,[28] but resonance will be an important factor leading to dissociation.[33] Carbon–hydrogen hyperconjugation should also be favored by the greater polarizability of the carbon–hydrogen bond, than that of the carbon–carbon bond,[34] a factor that should be important for the transition state of reactions depending on accession of electrons to the seat of reaction (Ingold's time-variable electromeric polarizability).[30b] The above factors might contribute to the Baker–Nathan order, but unlike the bond polarizabilities and electronegativities, the bond energy is smaller for the carbon–carbon bond than for the carbon–hydrogen bond.[35] If bond energies influence the stability of structures contributing to a resonance hybrid, then carbon–carbon hyperconjugation should represent an energetically preferred state. Since bond energies, however, refer to symmetrical cleavage of the bonds, it might seem plausible that reactions involving free radicals should show an order depending on carbon–carbon hyperconjugation. Such resonance would then account for the observed degree of dissociation of *p*-alkylhexaphenylethanes into free radicals,[36] and the stability of alkyldiaryl free radicals, which according to Conant increases with increasing amount of branching of the alkyl group.[37] That this increase in stability is a result of hyperconjugation is indicated by some calculations of Wheland.[24]

Experimental

Preparation of Materials

Benzene.—Thiophene-free benzene was distilled once from sodium through a 20-inch, electrically heated column filled with glass helices. The fraction boiling at 79.8° (755.7 mm.), m. p. 5.3–5.4°, d^{25}_{25} 0.8754, $n^{25}\mathrm{D}$ 1.4972, was collected and stored over sodium in an amber bottle for use in the competitive brominations.

***t*-Butylbenzene.**—*t*-Butylbenzene was prepared as previously described.[2] Material boiling at 165–166° (755 mm.), d^{25}_{25} 0.8645, $n^{25}\mathrm{D}$ 1.4898, was used in the competition reactions.

Glacial Acetic Acid.—J. T. Baker C.P. analyzed glacial acetic acid was used without further purification.

Bromine and Iodine.—C.P. products were used without further purification.

Bromobenzene and Bromo-*t*-butylbenzene.—Individual brominations of benzene and *t*-butylbenzene were conducted under conditions duplicating those used in the competition reactions. In the bromination of benzene no evidence of the formation of dibromobenzene was obtained. The product boiled at 155° (755 mm.), $n^{25}\mathrm{D}$ 1.5557. The pure bromo-*t*-butylbenzene obtained upon bromination of *t*-butylbenzene had the following physical constants: b. p. 226° (752.5 mm.), d^{25}_{25} 1.2493, $n^{25}\mathrm{D}$ 1.5309. These materials were prepared for use in analyzing the mixtures obtained from the competitive brominations.

Competitive Brominations

The competitive brominations of benzene and *t*-butylbenzene were conducted as described in Part I. Bromination of a homogeneous mixture of 0.5 mole of each hydrocarbon dissolved in 500 cc. of 92% aqueous acetic acid with 0.5 mole of bromine dissolved in 50 cc. of 92% aqueous acetic acid was carried out for twenty-four hours at 25 ±0.5° and for eight hours at 45 ±0.5° using one-half mole per cent. of iodine as a catalyst. The results of the individual runs are recorded in Table II.

TABLE II

Run	Moles bromobenzene formed	Moles bromo-*t*-butylbenzene formed	k_1/k_2
1 at 25°	0.0021	0.1919	114.9
2 at 25°	.0020	.1886	118.1
3 at 25°	.0020	.1832	113.9
			Av. 115.6
4 at 45°	.0034	.1927	71.4
5 at 45°	.0035	.1977	71.6
			Av. 71.5

Analysis of the reaction mixtures by the procedure employed in Part I was supplemented by an analytical determination of bromine. This seemed particularly desirable because the amount of bromobenzene in the *t*-butylbenzene fraction was very small, and refractive indices could not be used for its detection. The products of the reaction were separated into a bromobenzene–*t*-butylbenzene mixture and a *t*-butylbenzene–bromo-*t*-butylbenzene mixture by fractional distillation. Determination of the density of each fraction supplied directly the weight per cent. of brominated hydrocarbon in each, by comparison with weight per cent.–density curves derived from artificial mixtures of the desired components. Data from which the weight per cent.–density curve of bromo-benzene-*t*-butylbenzene mixtures was plotted are recorded in Table III.

TABLE III

DENSITIES OF BROMOBENZENE–*t*-BUTYLBENZENE MIXTURES

Weight per cent. bromobenzene	d^{25}_{25}
0	0.8645
2.75	.8747
3.61	.8781
4.41	.8812
4.95	.8834

The density–weight per cent. relationship of *t*-butylbenzene–bromo-*t*-butylbenzene mixtures is linear (per cent. bromo-*t*-butylbenzene $= 180.2D - 125.12$) in the range 98–100% bromo-*t*-butylbenzene, the range required for analysis of the high boiling fraction obtained from the competition reactions.

The bromine content of each fraction was determined by subjecting weighed samples to Wurtz type reactions and titrating the bromide ion formed by the Volhard method.[38] The latter determinations checked the density determinations of brominated hydrocarbons within 0.2%.

In a control run containing 0.33 g. (0.0021 mole) of bromobenzene 0.32 g. (0.0020 mole, 97%) was recovered. The agreement was considered satisfactory, and no corrections were applied to the final figures.

In a representative run a mixture of 39.06 g. (0.5 mole) of benzene, 67.11 g. (0.5 mole) of *t*-butylbenzene, 500 cc. of 92% aqueous acetic acid and 0.625 g. of iodine was

placed in a 1-liter, 3-necked, round-bottomed flask equipped with a reflux condenser, dropping funnel, and electrically driven glass stirrer and brought to constant temperature in a thermostat maintained at 25 ± 0.5°. One-half mole of bromine dissolved in 50 cc. of aqueous acetic acid was added to the solution through the dropping funnel, with constant stirring, over a period of one hour. Stirring at constant temperature was continued for twenty-three hours after completion of the addition of bromine. The reaction mixture was then poured into cold water and stirred with bisulfite to remove the unreacted bromine. The diluted mixture was divided into two portions. Each portion was extracted with two 200-cc. portions of ether. The ethereal extract was washed with aqueous sodium carbonate until all evolution of carbon dioxide had ceased. The alkaline washings were combined and extracted with 100 cc. of ether. The combined ethereal extracts were dried over anhydrous sodium carbonate for distillation. The ether and unreacted benzene were removed and discarded. Separation of the residue was effected by means of a twenty-inch electrically heated column filled with glass helices. The first fraction, containing bromobenzene and *t*-butylbenzene, distilled at 150–170°, d^{25}_{25} 0.8678, amount 37.4 g. The column was allowed to drain and was replaced by a small distillation outfit through which the entire residue, consisting of *t*-butylbenzene and bromo-*t*-butylbenzene, was distilled. This second fraction contained 41.2 g. of material, d^{25}_{25} 1.2453.

The density of the first fraction corresponds to 0.88% bromobenzene (0.0021 mole). The density of the second fraction corresponds to 99.28% bromo-*t*-butylbenzene (0.1919 mole).

A 4.3390 g. (5 cc.) sample of fraction I was dissolved in 40 cc. of ether and allowed to stand in contact with 1 g. of sodium wire overnight at room temperature. The sodium which had not reacted in twelve hours was destroyed with ethanol. The sodium bromide formed was extracted with water. The aqueous solution was diluted to 50 cc., of which 10-cc. portions were treated with 5 cc. of 0.1 *N* silver nitrate solution. The excess silver nitrate was titrated with 8.65 cc. of 0.0522 *N* potassium thiocyanate. This value corresponds to 0.0021 mole of bromobenzene in fraction I.

A 1.2453 g. (1-cc.) sample of fraction II was dissolved in 40 cc. of benzene and refluxed with 2 g. of sodium, cut into small pieces, for five hours. The aqueous extract of the sodium bromide formed was diluted to 100 cc.; 10-cc. portions were treated with 10 cc. of 0.1 *N* silver nitrate. The excess silver nitrate was titrated with 8.05 cc. of 0.0522 *N* potassium thiocyanate. The titration value corresponds to 0.1918 mole of bromo-*t*-butylbenzene in fraction II.

Applying the equation of Ingold, *et al.*,[5,39] $k_x/k_y = (\log x/x_0)/(\log y/y_0)$, where x and y represent the final concentrations of *t*-butylbenzene and benzene and x_0 and y_0 the initial concentrations, the ratio of velocities is 114.9/1.

Acknowledgment.—We gratefully acknowledge the assistance afforded by a grant from the Penrose Fund of the American Philosophical Society.

Summary

1. *t*-Butylbenzene is brominated about 115 times faster than benzene at 25°. This is explained by hyperconjugation involving carbon–carbon bonds.

2. It is pointed out that the so-called inductive effect of alkyl groups may be explained by hyperconjugation, and it is suggested that this may explain the entire effect. The factors that influence the operation of the effect are discussed.

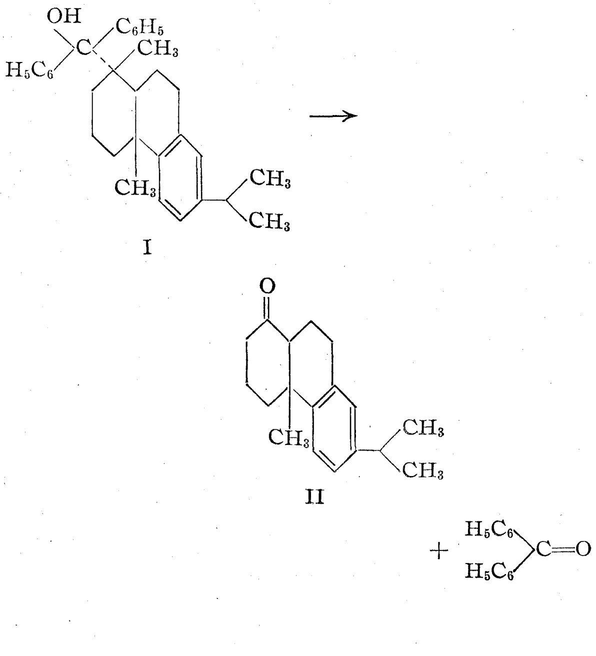
Studies on Resin Acids.[1] II. The Oxidation of Diphenyl-*t*-dehydroabietinol. A Postulated Mechanism

BY HAROLD H. ZEISS

The oxidation of tertiary alcohols is not a reaction generally employed in the laboratory principally because of product complexity and low yields. In the course of our study of the resin acids the previously reported tertiary resin alcohol, diphenyl-*t*-dehydroabietinol (I),[1] has been subjected to chromic acid oxidation in glacial acetic acid from which the cyclic ketone, 1-keto-12-methyl-7-isopropyl-1,2,3,4,9,10,11,12-octahydrophenanthrene (II), is obtained in yields as high as 67%, together with benzophenone. It is to be noted that this oxidation differs from the Barbier–Wieland type of oxidative degradation in that there cannot be a preceding dehydration of the carbinol to an olefin, since no hydrogen atoms are attached to the carbon atoms at which oxidation occurs.



Fifteen years ago Vocke[2] submitted the diphenyl carbinol of tetrahydroabietic acid to the

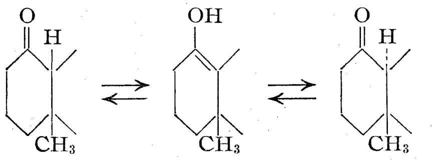
---

[1] Paper I, THIS JOURNAL, **69**, 302 (1947).

[2] Vocke, *Ann.*, **497**, 247 (1932).

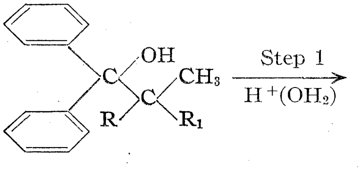
action of chromic acid at room temperature and with warming from which only benzophenone and benzoic acid were reported in the reaction mixture in addition to a considerable amount of unoxidized carbinol. At 50° diphenyl-*t*-dehydroabietinol is also largely unchanged by chromic acid and at 90° is oxidized to acidic material at the expense of the ketone (II). The optimum temperature for this oxidation has been found to be 80°, at which temperature the maximum yield of (II) is obtained with no unreacted carbinol (I) present and a minimum amount of acidic products, probably arising from ring cleavage.

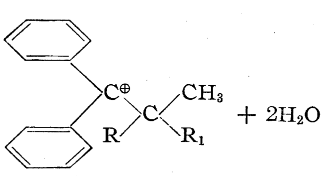
The cyclic ketone (II) is isolated, presumably, as a stereoisomeric mixture resulting from keto–enol tautomeric equilibrium. The ease of this tautomerism is adequately supported by Hückel,[3] who reported the facile conversion of *cis*-α-decalone to *trans*-α-decalone by simple distillation at atmospheric pressure. After purification through the sodium bisulfite addition product and through the use of Girard reagent T, the ketone (II) was obtained analytically pure as a pale yellow, viscous liquid from which the crystalline 2,4-dinitrophenylhydrazone derivative has been prepared. The sodium bisulfite addition product, combustion analyses and molecular refraction data leave little doubt that the structure of the cyclic ketone is as represented by (II). The identity of the benzophenone was established by mixed melting point determination and the 2,4-dinitrophenylhydrazone derivative.



As a gross approximation this reaction may be described as a dealcoholation (loss of methyl alcohol) followed by cleavage of the resulting double bond to form (II) and benzophenone. This of course is a highly oversimplified explanation but one which stipulates that any reasonable mechanism must account for the loss of the elements of methyl alcohol. One such mechanism is postulated solely as the basis of a working hypothesis.

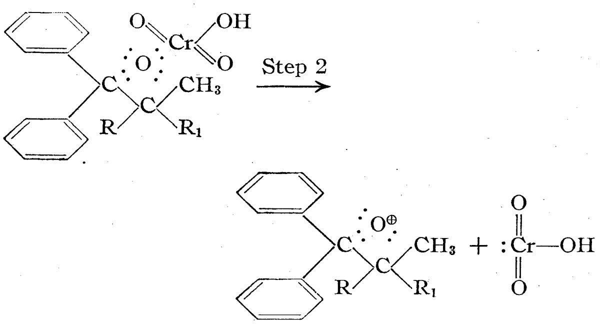
The first step is a proton transfer reaction to form a tertiary carbonium ion stabilized by resonance contributions from two phenyl groups (Step 1).



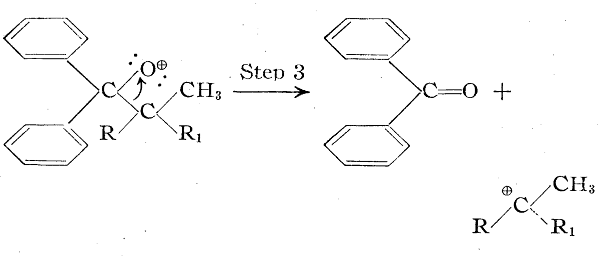


R = —CH$_2$
R$_1$ = —CH

The resultant center of low electron density is susceptible to nucleophilic attack by chromate ion to form a chromium complex which may then dissociate into two fragments (Step 2), the chromium atom now having a full share in the electron pair and the tertiary carbon fragment possessing a positively charged oxygen atom. The other alternative is a Wagner–Meerwein rearrangement leaving the electron deficient center on the carbon atom bearing the R and R$_1$ substituents. This latter possibility is unlikely to predominate because of the higher energy of the resulting carbonium ion.



In order to relieve the situation in which the oxygen atom is bearing a positive charge, the electron pair of the carbon–carbon bond must migrate (Step 3) since the phenyl-carbon bonds are unavailable.

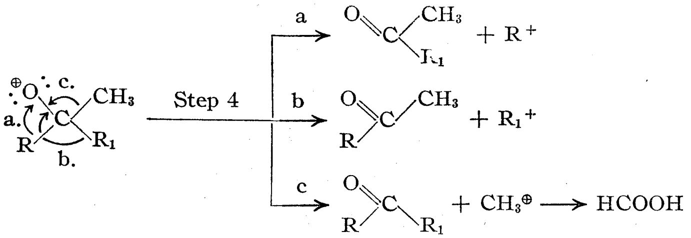


This shift releases the diphenylmethyl structure as benzophenone and leaves the positive charge on the carbon atom carrying the methyl group.

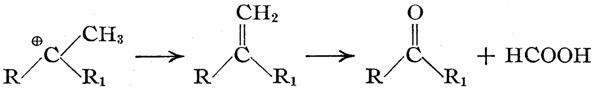
Repetition of chromate ion attack on the new carbonium ion and subsequent formation of positive oxygen leaves three possibilities open for electron shift. By Steps 4a or 4b the acidic byproducts are explained. Step 4c accounts for the formation of (II) but invites high speculation as to the formation of the very high energy methyl carbonium ion. Another explanation is one in which the carbonium ion rearranges to form the exocyclic double bond which immediately is

---

(3) Hückel, *Ann.*, **441**, 1 (1925).



cleaved by chromate ion to (II) and formaldehyde or formic acid. In this connection it is



interesting to note that Phillipov,[4] on oxidation of 1-methylcyclohexanol-1 with permanganate in aqueous solution, obtained cyclohexanone and formic acid on the one hand and acetic acid and glutaric acid on the other. The latter reaction was preponderant, however, under these conditions.

This oxidation is being further investigated as to the mechanism involved and its general application to tertiary alcohols as a class.

Experimental

1-Keto-12-methyl-7-isopropyl-1,2,3,4,9,10,11,12-octahydrophenanthrene (II): (a) **Oxidation at 90°.**—A solution of 42 g. of chromic trioxide in 30 ml. of water and 280 ml. of glacial acetic acid was added dropwise to a stirred solution of 33 g. of diphenyl-*t*-dehydroabietinol[5] in 300 ml. of glacial acetic acid at 90°. The addition extended over a period of one and one-half hours after which time heating and stirring were continued for three hours. The acetic acid was removed by distillation at the water pump and the remaining residue treated with sulfurous acid and dilute sulfuric acid on the steam-bath. The oily layer appearing on the surface of the cooled green solution was then extracted with ether. After washing the ethereal layer with water, the acidic material[6] was extracted with 1% sodium hydroxide. The ether layer was then washed free of alkali, dried over magnesium sulfate and the ether evaporated. The orange-red oil thus obtained gave two main fractions on fractional distillation: fraction 1, distilling at 140–150° (3 mm.) as a yellow fluid, and fraction 2, distilling at 220–230° (7 mm.) as an orange-red, viscous oil. Crystallization from methanol of fraction 1 gave large, transparent rods of benzophenone melting at 46.5–47.5°. Its 2,4-dinitrophenylhydrazone was prepared which gave a m. p. at 238–239°. A mixed m. p. of the crystals from fraction 1 with authentic benzophenone showed no depression. The yield of fraction 2, compound (II), was 9 g. (46%) and was identified as described under (b).

(b) **Oxidation at 80°.**—85 g. of diphenyl-*t*-dehydroabietinol was oxidized in exactly the same manner as in (a) with 103 g. of chromic trioxide with the one exception that the solution was maintained at 80 ± 0.5° during the oxidation. Fractional distillation of the neutral portion of the oxidation mixture gave 31.5 g. (63.5%) of crude ketone (II), boiling at 165–215° (1 mm.), and 16.2 g. (46%) of benzophenone.

The ketone was purified for analysis by the following methods: redistillation of the crude ketone, precipitation of the sodium bisulfite addition product in the cold (too unstable for characterization), regeneration and redistillation of (II), treatment with Girard reagent T, regeneration and final distillation of (II) as a pale yellow, viscous liquid at 208–212° (3 mm.[7]); $[\alpha]^{23}\text{D}$ 46° (4% in abs. alcohol); $[\eta]^{22}\text{D}$ 1.5572; d^{22} 1.0582.

Anal.[8] Calcd. for $C_{18}H_{24}O$: C, 84.38; H, 9.36. Found: C, 84.42, 84.54; H, 9.60, 9.41; M_R calcd., 77.65; found, 78.01.

The 2,4-dinitrophenylhydrazone of (II) was prepared in the usual manner which, after three recrystallizations from ethyl acetate, gave a sharp m. p. of 176.5–177°. A mixed m.p. with 2,4-dinitrophenylhydrazine showed a 12° depression.

Anal.[8] Calcd. for $C_{24}H_{28}N_4O_4$: N, 12.84. Found: N, 12.43, 12.32.

Acknowledgment.—The author is grateful to Dr. M. Frisch for experimental assistance in this work.

Summary

The oxidation of the tertiary alcohol, diphenyl-*t*-dehydroabietinol, to the cyclic ketone, 1-keto-12-methyl-7-isopropyl-1,2,3,4,9,10,11,12-octahydrophenanthrene, is described in which dehydration preliminary to oxidation cannot occur. A mechanism for the oxidation of this diphenyl carbinol has been postulated.

NOTES

Condensation Products from Acetaldehyde

By A. H. Andersen, R. M. Kitchen and C. H. Neufeld

Nord, *et al.*,[1] condensed acetaldehyde with magnesium aluminum alkoxide catalysts and isolated from the reaction product the monoacetate of 1,3-butanediol. No mention is made in their papers of the ethyl ester of β-hydroxybutyric acid which we have found to be present in the reaction mixture in approximately equimolecular proportion to the monoacetate of 1,3-butanediol. Similar proportions of the diol and the hydroxy acid have also been found in an oily by-product obtained in the commercial preparation of ethyl acetate from acetaldehyde.[2]

Experimental.—The procedure adopted for separating the constituents of the high-boiling oils was as follows:

(1) Acid hydrolysis with excess water and butanol: the mixture was heated in a flask provided with a packed distillation column. The overhead temperature was kept at the boiling point of the butyl acetate–butanol–water ternary azeotrope by adjusting the reflux ratio. The ester-containing top layer of the distillate was drawn off while the water layer was decanted back to the flask. This was continued until the temperature could no longer be kept below 90° by refluxing. The excess butanol was then removed in the same manner at a temperature of 92°.

(2) Neutralization and saponification: the saponification equivalent of the aqueous residue was determined, and just sufficient sodium hydroxide was added in 10% solution to neutralize the free acid and saponify the remaining esters. The mixture was boiled for an hour and cooled.

(3) Filtration to remove any resinous by-products.

(4) Vacuum distillation of filtrate: the excess water and the butanediol are removed leaving a fused residue of crude sodium β-hydroxybutyrate.

The glycol was purified by fractionation, b. p. 207°, $n^{20}\text{D}$ 1.441.

The sodium β-hydroxybutyrate was purified by recrystallization from butanol, m. p. 157–158°. It was identified by comparison with an authentic sample prepared through crotonic acid,[3] m. p. 157–158°; mixed m. p. 157–158°.

The butyl ester of β-hydroxybutyric acid was prepared from the sodium salt, hydrochloric acid and butanol, b. p. 103–104° (14 mm.).

The separation has also been carried out using potassium hydroxide. The potassium β-hydroxybutyrate melts at 148–149°. Care must be exercised since all the derivatives of β-hydroxybutyric acid so far examined by us are heat labile, dehydrating rather readily to the crotonates.

From our observations we conclude that termolecular condensation of acetaldehyde occurs under the influence of the coördination catalyst of Nord[1] and also to a much smaller extent under the influence of aluminum alkoxides. We believe that this reaction results from an initial aldolization followed by a condensation between the aldol and aldehyde molecules. This condensation can occur in either of two ways

$$CH_3CHO + CH_3CHOHCH_2CHO \longrightarrow CH_3CHOHCH_2CH_2OCOCH_3$$

Monoacetate of 1,3-butanediol (1)

$$CH_3CHO + CH_3CHOHCH_2CHO \longrightarrow CH_3CH_2OCOCH_2CHOHCH_3$$

Ethyl ester of β-hydroxybutyric acid (2)

Tischtschenko[4] mentions the formation of the ethyl ester of β-hydroxybutyric acid from acetaldehyde, and our observations confirm this and indicate that the ethyl ester is formed in similar quantities to the glycol ester.

The Addition of Dimethylamine to Benzoquinone

By Richard Baltzly and Emil Lorz

In the usual procedure for the preparation of *bis*-(dialkylamino)-quinones from benzoquinone two-thirds of the quinone is employed as an oxidizing agent so that, at best, only around 30% of the starting quinone can be isolated as the product.[1]

It has been found that re-oxidation of the intermediates can be accomplished by a stoichiometric amount of cupric salt or by a smaller quantity when the reaction mixture is stirred with oxygen. The latter procedure is preferable since the product crystallizes in virtually pure form from solution, uncontaminated by cuprous salts. The method was unsuccessful with methylamine, aniline and ammonia.

Procedure

A one-liter three-necked flask equipped with mercury-seal and stirrer was connected to a two-liter graduated cylinder having a levelling bulb and a stopcock for admission of oxygen. The system was flushed out with oxygen and a solution containing 20 g. (0.1 mole) of cupric acetate monohydrate and 27 g. (0.6 mole) of dimethylamine in 300 cc. of methanol was introduced. One-tenth mole (10.8 g.) of benzoquinone in 200 cc. of methanol was then added and the system was closed. The stirrer was started and the reaction was followed by the oxygen absorption which was initially about 120 cc. per minute. Considerable heat was evolved at the start of the reaction and the temperature was held near 25° by ice-water cooling. About five minutes after the beginning of the reaction, crimson platelets of *bis*-(dimethylamino)-benzoquinone became visible on the sides of the flask. After oxygen-absorption had ceased the flask was refrigerated overnight and the product was collected. This material melted at 171° (lit., 173°). A further crop of 2.5 g. was obtained by concentration of the filtrate (total yield, 93%).

bis-(Dimethylaminobenzoquinone is not itself oxidized

---

[1] (a) Mylius, *Ber.*, **18**, 463 (1885); (b) Kehrmann, *Ber.*, **23**, 897 (1890); (c) Anslow and Raistrick, *J. Chem. Soc.*, 1449 (1939).

under the above conditions but benzoquinone (and perhaps the intermediate quinones) can be. If the concentration of cupric ion is significantly diminished such oxidations take place and the yield is less. In the presence of 0.01 mole of cupric acetate the oxygen-absorption was about the same but the bisaminoquinone was then obtained in 72–76% yield.

Isolation of a Saponin from the Leaves of *Solidago canadensis* L.

BY R. C. BURRELL AND FORREST G. HOUSTON

In the course of the investigation of the chemical composition of several common weeds, leaves of *Solidago canadensis* L. were examined for the possible presence of a saponin. There are several reports of the recognition of both acid and neutral saponins in various other species of goldenrod,[1,2,3] but none of actual isolation.

Experimental

Method of Isolation.—Leaves of *Solidago canadensis* L. were gathered in late July, 1946, dried at room temperature, and ground to a fine powder. A 230-g. sample of this powder in a small cloth bag was exhaustively extracted, first with acetone, then with ether and finally twice with 95% ethyl alcohol. The combined alcoholic extracts were concentrated to a small volume (about 100 cc.) and 5 volumes of ether added with shaking. This produced a gummy, white precipitate. After decanting the ether, this precipitate was dissolved in the least possible amount of hot methanol. This solution, which had a light yellow color, was treated with acetone added from a large pipet while shaking the mixture vigorously. A flocculent white precipitate formed from which the liquid was decanted. The precipitate was once more dissolved in hot methanol and the acetone precipitation repeated. The final white flocculent precipitate was amorphous and very hygroscopic. It produced a stable creamy foam with water and stabilized an emulsion of kerosene in water. Fehling solution showed no reduction.

Preparation of the Sapogenin.—The moist saponin preparation was brought into solution in 50 cc. of 10% hydrochloric acid, 25 cc. of 95% ethyl alcohol added to reduce foaming and this solution refluxed for three hours. A grainy precipitate formed which consisted of microscopic, colorless needles. The supernatant liquid gave a positive Fehling reaction. The crystals were filtered off and brought into solution by refluxing with methanol. This solution was concentrated to about 50 cc. and on cooling some 500 mg. of colorless needles were isolated, representing a yield of 0.22% of the dried leaves.

Properties of the Sapogenin.—The crystals, which melted at 310–315° with decomposition, were slightly soluble in ethanol methanol, acetone, ether and ethyl acetate, insoluble in water, but dissolved easily in cold concentrated sulfuric acid, giving a faintly yellow colored solution which became deep red on warming or on the addition of a few drops of acetic anhydride, suggesting the behavior of a triterpene. The Rast method indicated a molecular weight of approximately 500.

Anal. Calcd. for $C_{30}H_{50}O_5$ (490.4): C, 73.41; H, 10.28. Found: C, 72.97; H, 10.02.

Insolubility in hot alkali and a neutral reaction in alcoholic solution indicates the absence of a carboxyl group. The acetate was prepared as flat rectangular crystals which melt at 182–183°. A search of the literature failed to reveal a compound approximating $C_{30}H_{50}O_5$ which possesses the above properties.

The Infrared Spectrum of Polyvinyl Alcohol

BY ELKAN R. BLOUT AND ROBERT KARPLUS

Despite two previously reported measurements on the infrared spectrum of polyvinyl alcohol[1,2] we should like to record some of our data, using carefully purified samples, because of their possible bearing on the details of the molecular structure of this material. The presence of chemical groups and arrangements other than those of the poly-1,3-glycol  $\left[\begin{array}{c}\text{—CH}_2\text{—CH—} \\ \quad\;\;| \\ \quad\;\;\text{OH}\end{array}\right]_n$ has been shown by chemical investigation. For example, terminal acetal,[3] keto or ketal[4] and 1,2-glycol groups[5] have been shown to be present in low percentage in the material known as polyvinyl alcohol.

The infrared spectra for the region 700–4000 cm.$^{-1}$ of carefully purified and dried films of polyvinyl alcohols of various degrees of polymerization are shown in Fig. 1. These spectra correspond in most salient features to those reported by Thompson and Torkington[2] except that there is no evidence of a band at 1650 cm.$^{-1}$. Other samples prepared so that water was not rigidly excluded at the time of measurement show a characteristic absorption band in this region. Another band typical of incompletely hydrolyzed polyvinyl alcohol is seen at 1710 cm.$^{-1}$ in Fig. 2, curve A. This figure also shows the effect of careful acid hydrolysis (removal of residual acetate groups) and drying on the spectrum in the region 1400–1800 cm.$^{-1}$.

It is difficult to correlate absorption bands definitely with molecular structure except through mathematical analysis. In the spectra shown in Fig. 1 the assignments of the bands above 1400 cm.$^{-1}$, *viz.*, 3350 cm.$^{-1}$ (O—H stretching), 2940 cm.$^{-1}$ (C—H stretching) and 1435 cm.$^{-1}$ (C—H bending) seem reasonable, based on analogy with the spectra of simple molecules and on the calculated characteristic frequency of various molecular groups.[6] In the region 1000 cm.$^{-1}$ to 1400 cm.$^{-1}$ five bands are observed at 1380, 1330, 1240 1135 and 1085 cm.$^{-1}$ which are probably associ-

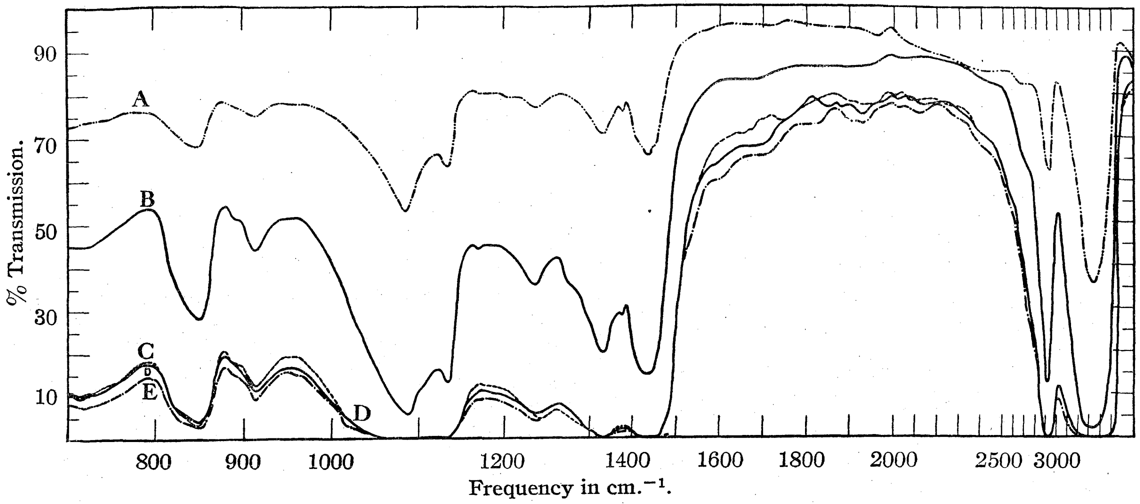

Fig. 1.—Polyvinyl alcohols after acid hydrolysis and drying: curve A, ··—··—··—, JRG-8200 (0.0002″ film); curve B, ————————, RH-391 (0.0003″ film); curve C, — — — — — — —, RH-393 (0.001″ film); curve D, ————————, RH-391 (0.001″ film); curve E, ·—·—·—·, RH-349 (0.001″ film).

ated with the motions of the substituent groups in the material, the last band arising from stretching of the C—O bond.[7] The absorption bands below 1000 cm.$^{-1}$ cannot be identified except as due to motions of the carbon skeleton. We find that the band at 1240 cm.$^{-1}$ is not removed by acid hydrolysis although a band at 1265 cm.$^{-1}$ in unpurified samples is removed simultaneously with the 1710 cm.$^{-1}$ band. This fact suggests that the 1240 cm.$^{-1}$ band is not associated with the acetate groups of polyvinyl alcohol, as has been previously pointed out.[2]

It is interesting to note that the band at 1380 cm.$^{-1}$, which is present even after repeated acid hydrolysis, is located in the region characteristic of the symmetrical deformation frequency of the C—CH_3 group.[6,8,9] This suggests the possibility that either the polymer contains methyl groups branching off the chain, or the chain ends are methyl groups or perhaps both.

Experimental

Materials.—The various polyvinyl alcohols were obtained as white powders.[7,10] Since they are prepared by the hydrolysis of polyvinyl acetate, further purification was undertaken to assure complete absence of residual acetate groups. This was accomplished by hydrolyzing 5% aqueous solutions with 0.02 *N* hydrochloric acid for twenty-four hours at 90° followed by precipitation and thorough washing with ethanol. The material so obtained was air-dried, then dissolved in water (approximately 15% solution) and cast into thin films (0.0002″–0.001″ thick) on glass plates at room temperature. To remove the

A Convenient Synthesis of Octahydropyrrocoline and 2-(γ-Hydroxypropyl)-piperidine

BY V. BOEKELHEIDE AND S. ROTHCHILD[1]

It has been found that octahydropyrrocoline, which has previously been prepared in poor yield by procedures involving three or more steps,[2] can be obtained readily in excellent yield by the direct hydrogenation of 2-(γ-hydroxypropyl)-pyridine[3] at 200° and 2500 lb. pressure with Raney nickel catalyst.

When the reduction was carried out at 125° instead of 200°, the product was not octahydropyrrocoline but rather 2-(γ-hydroxypropyl)-piperidine. The yield of 2-(γ-hydroxypropyl)-piperidine is practically quantitative and this is undoubtedly the best method for its preparation.[4] At temperatures intermediate between 125 and 200° the reduction gave mixtures of octahydropyrrocoline and 2-(γ-hydroxypropyl)-piperidine. Although it is probable that 2-(γ-hydroxypropyl)-piperidine is an intermediate in the formation of octahydropyrrocoline, 2-(γ-hydroxypropyl)-piperidine is not readily affected by heat and can be distilled repeatedly without change.

Experimental[5]

Octahydropyrrocoline.—A mixture of freshly distilled 2-(γ-hydroxypropyl)-pyridine (9.0 g., 0.066 mole), Raney nickel (2 g.), and absolute alcohol (10 cc.) was heated at 200° with shaking under an initial pressure of 2540 p. s. i. of hydrogen. At the end of one hour the drop in hydrogen pressure corresponded to that calculated. After removal of the catalyst by filtration, the oily product was distilled yielding 6.4 g. (78%) of a colorless oil; b. p. 71–72° at 32 mm.; $n^{21.2}$D 1.4702.

For purposes of identification, there were prepared the following derivatives: picrate, m. p. 228–9° (lit.,[2] m. p. 226°, 231–232°); gold chloride double salt, m. p. 188–192° (lit.,[2] m. p. 191–193°).

The methiodide of octahydropyrrocoline was formed in benzene and proved to be unstable in the presence of air. The amorphous solid, obtained from benzene, decomposed at 280–283° and was analyzed directly without further purification.

Anal. Calcd. for $C_9H_{18}NI$: C, 40.46; H, 6.79. Found: C, 40.00; H, 7.10.

2-(γ-Hydroxypropyl)-piperidine.—A mixture of freshly distilled 2-(γ-hydroxypropyl)-pyridine (14.0 g., 0.102 mole), Raney nickel (2 g.), and absolute alcohol (4 cc.) was heated at 125° with shaking under an initial pressure of 2500 p. s. i. of hydrogen. At the end of four hours the pressure drop corresponded to that calculated. After removal of the catalyst and solvent, the product was distilled yielding 12.5 g. (85%) of a colorless oil; b. p. 101–102° at 3 mm.; $n^{21.5}$D 1.4882.

For identification there was prepared the hydrochloride, m.p. 128–129° (lit.,[2b] m. p. 127–128°), and the mercuric chloride complex, m. p. 180–182° (lit.,[2a] m. p. 182–183°).

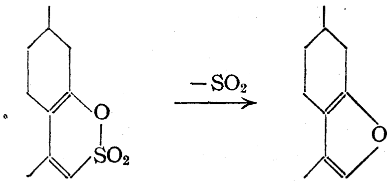
The Sulfonation of Mesityl Oxide

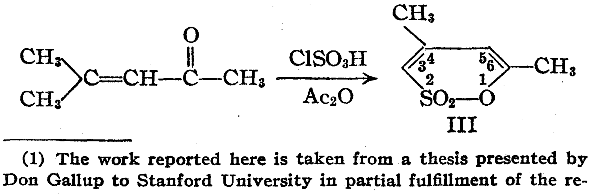
BY RICHARD H. EASTMAN AND DON GALLUP[1]

In seeking a convenient method for the synthesis of alkylated furans we have sought to extend to simple α,β-unsaturated ketones and aldehydes the observation of Treibs[2] that pulegone on treatment in acetic anhydride at ice temperature with concentrated sulfuric acid yields cyclopulegenol-sulfonic ester (I) from which menthofuran (II) is obtained in excellent yield on pyrolysis with zinc oxide at atmospheric pressure.



I II

We have attempted the sulfonation under varied conditions of concentration and temperature, using both sulfuric acid and chlorosulfonic acid, of crotonaldehyde, cyclohexylidenecyclohexanone, 3,4-dimethylhexene-3-on-2 and mesityl oxide. A clean-cut reaction was obtained only in the case of the sulfonation of mesityl oxide which on sulfonation with chlorosulfonic acid in acetic anhydride gave the cyclic sulfonic ester III in good yield. Pyrolysis of the cyclic sulfonic ester of mesityl oxide (III) at atmospheric pressure,



III

---

[1] The work reported here is taken from a thesis presented by Don Gallup to Stanford University in partial fulfillment of the requirements for the degree of Master of Science.

[2] W. Treibs, *Ber.*, **70B**, 85 (1937).

under reduced pressure and in an atmosphere of nitrogen did not effect the transformation analogous to I→II, but led rather to intractable tars.

Bromination of III with one mole of bromine resulted in a substitution product, formulated tentatively as the 5-bromo derivative of III. Treatment of III with an excess of bromine led to an unstable compound $C_6H_7O_3SBr_3$, formulated tentatively as the 5-bromo-3,4-dibromide of III.

Experimental

Mesityl Oxide Cyclic Sulfonic Ester (III).—Mesityl oxide (19.6 g.) was added to 41 g. acetic anhydride and the mixture was cooled to 0°. Chlorosulfonic acid (22.3 g.) was added dropwise while the temperature was kept at 0° with an ice–salt-bath. The mixture was stirred for one-half hour after the addition of the acid was complete, and then placed in the cold-room overnight. The reaction mixture was decomposed by pouring it into an equal volume of ice–water with vigorous stirring. The light-yellow precipitate which formed was separated and purified by crystallization from methanol to yield 13 g. (41%) of stout, colorless prisms of m. p.[3] 65–67°.

Anal. Calcd. for $C_6H_8O_3S$: C, 45.0; H, 5.03. Found: C, 45.1; H, 5.19.

After several weeks a sample of the compound suddenly decomposed with violence, the production of sulfur dioxide and a black tar.

Bromination of the Cyclic Sulfonic Ester of Mesityl Oxide.—A 5.0-g. sample of the ester (III) was dissolved in carbon tetrachloride (25 ml.) and bromine was added dropwise during ten minutes until the decolorization of it became slow. A precipitate formed rapidly and hydrogen bromide was evolved. A slight excess of bromine was removed with sodium thiosulfate solution and the solvent was removed by distillation. The crude product was crystallized from alcohol to give 3.0 g. of white, crystalline material of m. p. 75–76° (mixed with III, m. p. 46–47°).

Anal. Calcd. for $C_6H_7O_3SBr$: C, 30.1; H, 2.95. Found: C, 30.4; H, 3.36.

The substance is a powerful skin irritant and is formulated as the **5-bromo derivative** of the cyclic sulfonic ester of mesityl oxide (III).

A 5.0-g. sample of the cyclic sulfonic ester (III) was dissolved in 25 ml. of carbon tetrachloride and 10 g. of bromine was added rapidly. The mixture was allowed to stand for a day and the precipitate that formed was separated and washed thoroughly with methanol–water (1:1). The white crystalline product turned dark near its melting point and then melted with decomposition at 156–60°.

Anal. Calcd. for $C_6H_7O_3SBr_3$: C, 18.2; H, 1.88. Found: C, 18.3; H, 1.77.

This substance is formulated as the **5-bromo-3,4-dibromide** of the cyclic sulfonic ester (III).

The Reaction of *t*-Butylmagnesium Chloride with Ethyl Oxalate

By G. F. Hennion and Charles F. Raley

In connection with another problem we have recently had occasion to re-examine the reaction of *t*-butylmagnesium chloride with ethyl oxalate.[1] Our observations are not entirely in accord with the previous report which states that the reaction gives a mixture of products containing *t*-butylglycolic acid, ethyl *t*-butylglycolate, α-ethoxy-β,β-dimethylbutyric acid and smaller amounts of substances thought to be *t*-butyl neopentyl ketone and *sym*-di-*t*-butylglycol. *t*-Butylglycolic acid and its ethyl ester were obtained in the present study but the other products could not be found; instead, several other compounds were isolated.

We have carried out the reaction in three ways: addition of ethyl oxalate to the Grignard reagent (1:4); addition of the Grignard reagent to the ester (2:1); and simultaneous reaction of magnesium (2.5), *t*-butyl chloride (2.0), and ethyl oxalate (1.0). In each case there was considerable evolution of gas, evidently isobutylene, and after working up the products in the usual way complex mixtures were encountered. In view of the latter fact the reaction seems to have little preparative value.

Experimental

A. **Direct Addition.**—When 0.385 mole of ethyl oxalate was added dropwise to 1.54 moles of *t*-butylmagnesium chloride in anhydrous ether (previously filtered through glass wool), 0.7 mole of isobutylene was recovered by absorption in sulfuric acid. After hydrolysis of the reaction mixture with ice and hydrochloric acid in the usual way, extraction of the ether layer with sodium bicarbonate solution removed 18 g. of impure *t*-butylglycolic acid. The neutral components, after removal of the ether, were saponified and thus yielded an additional 10 g. of the acid. It was best purified by vacuum distillation (b. p. 110–117° at 4 mm.), followed by crystallization from water; m. p. 85–86°. Smaller amounts of other products were formed also; of these only hexamethylethane and diisobutylene were recognized.

B. **Reverse Addition.**—In this experiment, when 1.35 moles of filtered Grignard reagent was added to 0.676 mole of ester, the only acidic substance recovered was 2.5 g. of impure oxalic acid. There was obtained by distillation of the ether layer after hydrolysis, etc., 27 g. of ethyl *t*-butylglycolate and 30 g. of a substance whose analysis corresponds to $C_{12}H_{24}O_3$. There was good evidence that the latter compound is the previously unknown ethyl di-*t*-butylglycolate, $(t\text{-}C_4H_9)_2C(OH)COOC_2H_5$. In addition to these two compounds there was 26 g. of higher boiling material.

C. **Barbier Reaction.**—When this method was employed with 2.5 gram atoms of magnesium, 2.0 moles of *t*-butyl chloride and 1.0 mole of ethyl oxalate (the latter mixed and added slowly to the magnesium under ether), hydrolysis and removal of the ether left 137 g. of pale yellow oil. Distillation *in vacuo* through a helix-packed column yielded 38 g. of impure ethyl *t*-butylglycolate and 40 g. of ethyl di-*t*-butylglycolate. The remainder of the product was distilled at 2.5–3.0 mm. without the column and appeared to decompose somewhat in the process. The distillate (39 g.) deposited a crystalline solid; after removal and crystallization from aqueous alcohol it melted at 113–113.5°. The analytical data corresponded with the formula $C_{14}H_{28}O_2$. Despite the oxygen content this substance gave none of the tests specific for alcohols, carbonyl compounds, etc. It was tentatively decided that the compound is di-*t*-butylpivaloycarbinol, $(t\text{-}C_4H_9)_2C(OH)COC(CH_3)_3$. Decomposition by strong heating and the failure to respond to functional group reactions are consistent with this structure.

The physical properties and the analytical data for purified samples of the various products are summarized below.

***t*-Butylglycolic acid**: b. p. 118° at 9 mm.; m. p. 85–86°. Calcd. for $C_6H_{12}O_3$: C, 54.52; H, 9.15; neutral equiv.,

Some New 1,1,1-Trichloro-2,2-bis-(*p*-alkylphenyl)-ethanes

BY G. F. HENNION AND JOSEPH G. WALSH

The condensations of chloral hydrate with toluene,[1] two of the xylenes,[2] *t*-butylbenzene[3] and benzene itself[4] are known to yield crystalline derivatives structurally analogous to DDT. We have recently extended the reaction to several other alkylbenzenes to determine whether it may be used to prepare solid derivatives useful for identification purposes. Furthermore, an assortment of 1,1,1-trichloro-2,2-bis-(*p*-alkylphenyl)-ethanes (I) was desired to explore the possibility of preparing 4,4′-dialkyldiphenylacetylenes (III) from them by elimination of hydrogen chloride and chlorine.

$$\underset{\mathrm{I}}{(R-C_6H_4)_2CH-CCl_3} \xrightarrow{\mathrm{KOH}} \underset{\mathrm{II}}{(R-C_6H_4)_2C=CCl_2} \xrightarrow{2\mathrm{Na}}$$

$$\underset{\mathrm{III}}{R-C_6H_4-C\equiv C-C_6H_4-R}$$

The reactions of the alkylbenzenes with chloral hydrate were carried out in concentrated sulfuric acid (96.9%) in the ordinary manner. Toluene and *t*-butylbenzene gave solid products identical with those previously described.[1,3] Ethylbenzene, isopropylbenzene, *n*-butylbenzene, *s*-butylbenzene and 2-*s*-amylbenzene, however, yielded viscous oils which could not be induced to crystallize. The isolation and purification of these products proved somewhat troublesome because dilution of the crude reaction products with water gave emulsions, probably due to appreciable sulfonation as a side reaction. The emulsions were broken with ether and salt and the ethereal extracts finally distilled three times *in vacuo*. The physical constants, yields after the first distillation, and analyses for these compounds are given in Table I.

TABLE I

1,1,1-TRICHLORO-2,2-*bis*-(*p*-ALKYLPHENYL)-ETHANES

Alkyl group	B. p., °C.	Press., mm.	Yield, %	n^{25}_{D}	Chlorine, % Calcd.	Chlorine, % Found
Ethyl[a]	183	0.8	51	1.5780	31.2	31.1
Isopropyl	199	1.4	40	1.5672	28.8	28.5
n-Butyl	203	0.4	42	1.5611	26.8	25.6
s-Butyl	204	0.4	36	1.5597	26.8	25.7
2-*s*-Amyl	210	0.4	27	1.5515	25.0	24.2

[a] Wild, *Helv. Chim. Acta*, **29**, 497 (1946), reported the boiling point to be 180° at 0.2 mm. The refractive index was not given.

Each of the seven products (I) was treated with alcoholic potassium hydroxide to prepare the corresponding dichloroethylenes (II). Again the toluene and *t*-butylbenzene derivatives gave solids, as previously reported, while all the other yielded oils. In all cases the dichloroethylenes were insoluble in liquid ammonia and failed to react well with sodium in this medium. An ethereal solution of the di-*p*-tolyl compound, for example, decolorized only a fraction of the theoretical amount of sodium in liquid ammonia and yielded an insoluble, infusible, polymeric substance containing chlorine. All attempts to prepare acetylenes (III) in this manner failed.

Nitration of (*p*-Bromophenyl)-cyclopentane

BY RICHARD D. KLEENE

It was desired to prepare an acetamino derivative of (*p*-bromophenyl)-cyclopentane by the method of Ipatieff and Schmerling[1] for alkyl benzenes. The product obtained was free of halogen as described below.

(3,5-Diacetaminophenyl) - cyclopentane.—One gram of the bromo compound[2] was nitrated with 5 ml. of a mixture of one part of 70% nitric acid and one part of 98% sulfuric acid by volume. The red oil so obtained was dissolved in alcohol and reduced with tin and 36% hydrochloric acid. The amine was then acetylated with acetic anhydride and the resulting solid was recrystallized three times from dilute alcohol. Very fine hair-like needles were formed which melted at 233–234° (uncor.); yield 50%. Analysis showed the complete absence of bromine.

Anal. Calcd. for $C_{15}H_{20}O_2N_2$: C, 69.2; H, 7.70; N, 10.8. Found: C, 68.4; H, 7.57; N, 10.4.

A mixture of this new compound with (2,4-diacetaminophenyl)-cyclopentane[1] (m. p. 228°) melted at 220–225°. The two compounds also appeared dissimilar under the microscope. The removal of the bromine atom indicates that it is probably activated by both nitro groups. This reduces the possibility that the new compound is the 2,5- or the 2,6-diacetamino isomer.

---

[2] R. D. Kleene, *ibid.*, **62**, 2883 (1940).

The removal of halogens from aromatic compounds during the reduction of two activating nitro groups is a well-known phenomenon. Thus the reduction of 2,4-dibromo-3,5-dinitrotoluene with tin and hydrochloric acid gives 3,5-diaminotoluene.[3]

In contrast to the nitration with mixed acid as described above, nitration with 70% nitric acid alone according to the method of Mayes and Turner[4] led to a mixture of products from which a considerable amount of 1-nitro-4-bromobenzene was isolated. The other products were not identified.

The Acylation of Thiophene and Furan by Means of Boron Trifluoride[1]

BY HOWARD D. HARTOUGH AND ALVIN I. KOSAK[2]

The acetylation of thiophene and furan to form the respective 2-acyl derivatives has been effected previously by means of several catalysts.[3] This reaction has now been effected by means of catalytic amounts of boron trifluoride complexes in ether, methanol, and acetic acid. The yields were satisfactory (70%) with 0.03–0.075 mole of the catalyst per mole of acetic anhydride. When acetyl chloride was used instead of acetic anhydride the yield was poor. The analogous reaction with benzoyl chloride was effected in 22% yield.

Although the nucleus of 2-acetylthiophene is acetylated in the presence of zinc chloride, orthophosphoric acid and phosphorus pentoxide,[3] acetylation at the side chain of this ketone occurred in the presence of a molecular equivalent of boron trifluoride to form a triacetylthiophene in 17% yield; however, the product has not been identified. Acetylation at the side chain might have been anticipated from the work of Meerwein, Pannwitz and Vossen[4] and Hauser and Adams.[5]

With furan, acetic anhydride and a catalytic amount of boron trifluoride in methanol, 2-acetylfuran was obtained in 46% yield.

Boron Trifluoride Complexes.—The boron trifluoride etherate was used as received from the Eastman Kodak Co. The boron trifluoride methanol complex and the boron trifluoride acetic acid complex were prepared by saturating methanol and acetic acid with boron trifluoride gas at 100 p. s. i. pressure in a stirring autoclave.

2-Acetylthiophene.—To a mixture of 252 g. (3 moles) of thiophene and 107 g. (1 mole) of 95% acetic anhydride cooled to 10° by means of an ice-bath was added 4 g. of boron trifluoride–methanol complex (60% boron trifluoride). The temperature rose to 13° and when it finally subsided after five minutes to 5° the ice-bath was removed and the flask warmed to 50° for two hours. Two hundred milliliters of water was added, the mixture agitated for fifteen minutes, the lower organic layer drawn off, washed with 10% sodium carbonate solution until neutral, and distilled. Thiophene, 180 g., was recovered and 84 g. (70%) of 2-acetylthiophene, b. p. 87–88° (8 mm.),[6] $n^{20}_{\rm D}$ 1.5666, was obtained.

2-Benzoylthiophene.—To 126 g. (1.5 moles) of thiophene and 141 g. (1 mole) of benzoyl chloride was added 4 g. of boron trifluoride–acetic acid complex. No heat of reaction was noted and the mixture was heated at 90–95° for six hours. After cooling, the reaction mixture was washed with 10% sodium hydroxide solution until neutral. Distillation yielded thiophene, 42 g. (22%) of 2-benzoylthiophene, b. p. 146–147° (5 mm.), m. p. 56.5–57°,[7] after recrystallization from ASTM naphtha, and 21 g. of tarry residue.

"2-Triacetylthiophene."—To 42 g. (0.33 mole) of 2-acetylthiophene was added 107 g. (1 mole) of 95% acetic anhydride and 110 g. (0.84 mole) of boron trifluoride etherate. The temperature rose to 38° and after fifteen minutes the mixture was warmed on a steam-bath at 55° for thirty minutes. The hot mixture was poured slowly into one liter of water containing 120 g. of sodium acetate and shaken until the oily liquid crystallized. The crystals were filtered, washed with cold benzene, and purified by vacuum sublimation, yielding 12 g. (17%) of bright yellow crystals, m. p. 176–177°.[8]

Anal. Calcd. for $C_{10}H_{10}O_3S$: S, 15.31, Found: S, 14.92.

Oxidation with alkaline permanganate gave 2-thiophenecarboxylic acid, m. p. and mixed m. p. 127–128.5°.

2-Acetylfuran.—A procedure, analogous to that employed for to 2-acetylthiophene, was used but the temperature of the reaction mixture was maintained at 25° instead of 50° for two hours. Distillation yielded 53 g. (48%) of 2-acetylfuran, b. p. 89–90° (43 mm.),[9] m. p. 30–32°,[9] $n^{30}_{\rm D}$ 1.5015.

Acknowledgments.—The authors wish to thank Dr. D. E. Baderscher for advice and interest in this problem and Miss Loretta G. Conley who helped with a number of the laboratory experiments.

Derivatives of Diethylamino Compounds

BY NELSON J. LEONARD, FELICE MARY KRAFT AND VIVIAN WOLFMAN

In connection with studies in progress on reactions of aminoalcohols and aminoketones involving possible rearrangement, it was desirable to obtain readily identifiable derivatives of certain diethylamino compounds. The compounds of interest included amines, aminoethers, aminoalcohols and aminoketones, in all of which the amine function was tertiary. Derivatives have been formed with picric acid, picrolonic acid and ethyl iodide. Diethyl-*n*-propylamine has been obtained pure, as have β-ethoxyethyldiethylamine and γ-ethoxypropyldiethylamine. 2-Diethylamino-2-methyl-1-propanol has been prepared by a method similar to the previously unsuccessful diethylation of 2-amino-2-methyl-1-propanol[1] and the successful ethylation of 2-ethylamino-2-methyl-1-propanol.[2]

Experimental[3]

Diethyl-*n*-propylamine.—A mixture of 70 g. of *n*-propyl bromide, 32 g. of ethylene glycol and 61 g. of diethylamine was refluxed for forty hours. The amine was liberated with alkali and extracted with ether. After the ether solution was dried over potassium hydroxide the ether was removed, and 19 g. (27%) of diethyl-*n*-propylamine was distilled at 111.5–112.5° (750 mm.); n^{20}_{D} 1.4064; d^{20}_{4} 0.742.

Anal. Calcd. for $C_7H_{17}N$: C, 72.97; H, 14.88; N, 12.16; MR_D, 38.35. Found: C, 73.10; H, 15.01; N, 12.14; MR_D, 38.18.

The **ethiodide** melted at 262–263° (cor.) with decomposition (von Auwers and Mauss reported 255–256°[4]).

The **picrate** was prepared in and recrystallized from ether as long yellow needles, m. p. 82–84° (cor.).

Anal. Calcd. for $C_{13}H_{20}N_4O_7$: C, 45.34; H, 5.86; N, 16.27. Found: C, 45.41; H, 5.91; N, 16.14.

The **picrolonate** was prepared in ether and recrystallized from ethanol–ether as orange-yellow elongated prisms, m. p. 140–141° (cor.).

Anal. Calcd. for $C_{17}H_{25}N_5O_5$: C, 53.81; H, 6.64; N, 18.46. Found: C, 53.92; H, 6.69; N, 18.41.

Diethylisopropylamine Picrolonate.—Prepared from diethylisopropylamine[5] in ether, the picrolonate was recrystallized from absolute ethanol in leafy clusters of yellow prisms, m. p. 164–165.5° (cor.).

Diethylisopropylamine Ethiodide.—Formed by refluxing diethylisopropylamine in benzene with excess ethyl iodide, the microcrystalline ethiodide melted at 264–266° (cor.) with decomposition.

β-Ethoxyethyldiethylamine.—A mixture of a six to one molar proportion of diethylamine (50 g.) and β-ethoxyethyl bromide (16.7 g.) was heated under reflux for twenty-four hours. The product was isolated as in the method for diethyl-*n*-propylamine; b. p. 63–64° (25 mm.); n^{20}_{D} 1.4179.

Anal. Calcd. for $C_8H_{19}NO$: C, 66.15; H, 13.18; N, 9.64. Found: C, 65.81; H, 12.96; N, 9.64.

No picrate, picrylsulfonate, picrolonate, methiodide or mineral acid salt could be formed.

γ-Ethoxypropyldiethylamine.—Fifty grams of diethylamine and 19 g. of γ-ethoxypropyl bromide were heated under reflux and the product was isolated in the usual manner; b. p. 78–81° (25 mm.); n^{20}_{D} 1.4223.

Anal. Calcd. for $C_9H_{21}NO$: C, 67.87; H, 13.29; N, 8.80. Found: C, 68.01; H, 13.01; N, 8.84.

Prepared in and recrystallized from ethanol, the **picrolonate** melted with decomposition at 213–215° (uncor.).

Anal. Calcd. for $C_{19}H_{29}N_5O_6$: C, 53.89; H, 6.93. Found: C, 53.75; H, 6.92.

2-Diethylamino-2-methyl-1-propanol.—2-Diethylamino-2-methyl-1-propanol was prepared by a method similar to that of Olson and Whitacre and Bachman and Mayhew[2]; b. p. 82–83° (22 mm.); n^{20}_{D} 1.4421.

Anal. Calcd. for $C_8H_{19}NO$: N, 9.64. Found: N, 9.61.

The **picrolonate** was recrystallized from benzene containing a small amount of ethanol as elongated yellow prisms; m. p. 185.5–187° (uncor.) with decomposition.

Anal. Calcd. for $C_{18}H_{27}N_5O_6$: C, 52.80; H, 6.65. Found: C, 52.73; H, 6.67.

The **picrate** was recrystallized from ethanol–petroleum ether solution as yellow prisms; m. p. 156° (uncor.).

Anal. Calcd. for $C_{14}H_{22}N_4O_8$: C, 44.92; H, 5.92. Found: C, 45.00; H, 5.89.

Diethylaminoacetone Picrolonate.—Formed from diethylaminoacetone[6] in ether and recrystallized from ethanol, the picrolonate formed clusters of yellow prisms, m. p. 143–144° (cor.).

Anal. Calcd. for $C_{17}H_{23}N_5O_6$: C, 51.90; H, 5.89; N, 17.80. Found: C, 51.74; H, 6.11; N, 17.81.

5-Diethylamino-2-pentanone Picrolonate.—Prepared from Noval ketone in ether and recrystallized from ethanol–ether, the picrolonate formed stout yellow prisms, m. p. 105–107° (cor.).

Anal. Calcd. for $C_{19}H_{27}N_5O_6$: C, 54.14; H, 6.46; N, 16.62. Found: C, 54.32; H, 6.67; N, 16.67.

Conversion of Benzylamine to N-Substituted Thiobenzamides

BY FREEMAN H. MCMILLAN[1]

In a previous publication[2] the modified Willgerodt reaction[3] was applied to styrene in the presence of a series of amines and the yield of phenylacetic acid obtained by hydrolyzing the crude reaction mixture was measured. In some instances there was isolated from the crude reaction mixture a little of the pure thioamide for characterization and analysis. It has been found that the compound isolated and called N-benzylphenylthioacetamide was in reality N-benzylthiobenzamide. Since there was no doubt that it was phenylacetic acid which was obtained from the hydrolysis of the crude reaction mixture, the hydrolysis of pure N-benzylthiobenzamide was investigated. It was found that this thioamide was very slowly attacked by refluxing 50% (by weight) sulfuric acid (the conditions used for hydrolyzing the crude thioamides), thus explaining the absence of benzoic acid in the hydrolysate from the crude reaction mixture of styrene, sulfur and benzylamine. The identity of N-benzylthiobenzamide was established by hydrolysis with refluxing 65% (by weight) sulfuric acid followed by isolation of benzoic acid and benzylamine in the form of its picrate.

Since none of the other amines used to prepare thioamides reported in ref. 2 had the possibility of undergoing a reaction analogous to that which benzylamine underwent, there is no reasonable doubt as to their identity.

Although it is possible that the N-benzylthiobenzamide could have arisen through cleavage[4]

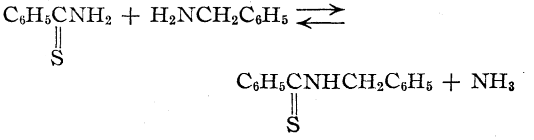
of styrene, such cleavage has not been observed with other amines, *e. g.*, morpholine, where the yield of phenylthioacetmorpholide is very good, and consequently this mode of formation is not considered probable. An alternative mode of formation is by oxidation (replacement of two hydrogens by sulfur) of part of the benzylamine used.[5]

It was found that by heating equimolecular portions of benzylamine and sulfur a 91% yield of N-benzylthiobenzamide was obtained. Wallach[6] reported that the reaction of benzylamine with sulfur in a sealed tube at 180° gave thiobenzamide. The discrepancy between our results and those of Wallach may be explained by the fact that ammonia was given off copiously from our reaction. Any reaction in which ammonia is one of the products would be favored in an open reaction vessel where the ammonia could escape and would be suppressed in a sealed tube where it would remain at the site of the reaction. Two such possible reactions which would lead to our product would be

$$C_6H_5CH_2NH_2 + H_2NCH_2C_6H_5 \rightleftarrows C_6H_5CH_2NHCH_2C_6H_5 + NH_3 \quad (1)$$



$$C_6H_5\underset{\underset{S}{\|}}{C}NH_2 + H_2NCH_2C_6H_5 \rightleftarrows C_6H_5\underset{\underset{S}{\|}}{C}NHCH_2C_6H_5 + NH_3$$

(2)

It was also found that heating an equimolecular mixture of benzylamine and morpholine with sulfur gives thiobenzmorpholide, presumably by the same route as the benzylamine–sulfur reaction.

Acknowledgment.—The author wishes to acknowledge the helpful criticisms of Dr. John A. King in the preparation of this manuscript.

Experimental[7,8]

Reaction of Benzylamine with Sulfur.—A mixture of benzylamine (21.4 g., 0.20 mole) and sulfur (8.0 g., 0.25 mole) was heated at reflux for forty-five minutes. Evolution of ammonia was noticed almost immediately after heating was begun. The cooled reaction mixture was treated with Skellysolve "C" (100 ml.) and then filtered. The solid material weighed 19.5 g. (91%) and melted at 81–83°. After crystallization from Skellysolve "C" (250 ml.) it melted at 84–85°.

Anal. Calcd. for $C_{14}H_{13}NS$: N, 6.16; S, 14.10. Found: N, 5.85; S, 14.10.

There was no depression in melting point when this compound was mixed with the material reported to be N-benzylphenylthioacetamide[2] but now known to be N-benzylthiobenzamide.

Hydrolysis of above Reaction Product.—The compound melting at 84–85° (2.0 g.) was refluxed for one hour with 65% (by weight) sulfuric acid (30 ml.). The hydrolysis mixture was cooled and extracted with two 30-ml. portions of ether. The combined ether extracts were extracted with 25 ml. of 10% sodium hydroxide solution and the caustic extract was acidified with dilute hydrochloric acid. The acidified solution was extracted with two 30-ml. portions of ether; the ether solution was dried over anhydrous sodium sulfate and the ether was removed under vacuum. The residue was crystallized from water giving white crystals (0.4 g.) melting at 120–121°, undepressed when mixed with an authentic sample of benzoic acid.

The hydrolysis mixture was made alkaline with 10% sodium hydroxide solution and then extracted with three 100-ml. portions of ether. The ether was dried over anhydrous potassium carbonate and the ether was removed under vacuum. The residue was treated with saturated alcoholic picric acid solution and gave a picrate which after crystallization from alcohol melted at 193–195°, undepressed when mixed with an authentic sample of benzylamine picrate.[9]

Reaction of Benzylamine, Morpholine and Sulfur.—A mixture of benzylamine (10.7 g., 0.10 mole), morpholine (8.7 g., 0.10 mole) and sulfur (6.4 g., 0.20 mole) was heated at 160° for one hour. The cooled reaction mixture was taken up in 150 ml. of boiling alcohol and then chilled. The solid that formed weighed 8.4 g. (40.6%) and melted at 137–138°, undepressed when mixed with an authentic sample of thiobenzmorpholide.[5]

Diffusion Coefficient of Nitroglycerin in Rocket Powder and in Cellulose Acetate[1]

BY S. S. PENNER[2] AND S. SHERMAN[3]

Double base rocket powders, consisting of approximately 60% nitrocellulose, 40% nitroglycerin and some minor components, constitute one type of widely used rocket propellant. These powders burn easily over their entire exposed surface. In order to restrict burning to a preferred direction and thereby lengthen the total burning time it is necessary to cover a portion of the powder surface with a strongly bonded inert material such as cellulose acetate. These wrappings of cellulose acetate, though initially almost noncombustible, lose their protective action in the course of time because of the diffusion of nitroglycerin into the cellulose acetate. By determining the nitroglycerin concentration as a function of the distance from the cellulose acetate–powder interface at a given time, it is possible to ascertain the average diffusion coefficient of nitroglycerin in cellulose acetate and in powder. Knowledge of the maximum allowable nitroglycerin concentration in the cellulose acetate permits calculation of maximum safe storage times at all temperatures for which diffusion coefficients are available.

A complete experimental study was not carried through. In view of the limited experimental

---

[1] This paper is based on OSRD report No. 4963 (PB report No. 50864) on the "Diffusion of Nitroglycerin in Wrapped Powder Grains." The diffusion study was carried out at the Allegany Ballistics Laboratory, Cumberland, Maryland, operated by the George Washington University under OSRD contract OEMsr-273. Analytical work was performed by J. J. Donovan and N. Marans.

[2] Present address: Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California.

[3] Present address: 413 Eckart Hall, University of Chicago, Chicago, Ill.

data available for calculation of the diffusion coefficient, an approximate treatment was employed which is strictly applicable only if the cellulose acetate and the powder have identical physical properties as regards the diffusion of nitroglycerin. The theoretical treatment of diffusion through a composite cylinder for the boundary values of interest in connection with the present study has been reported elsewhere.[4]

More extensive experimental investigations along the lines discussed in this report were carried out independently by B. H. Sage[5] and, at a later date, by J. J. Donovan.[5]

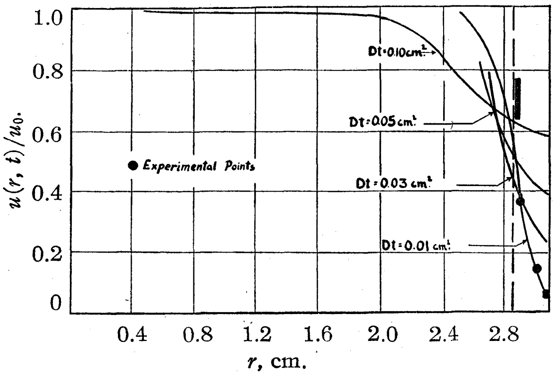

Fig. 1.—Comparison between experimental and calculated data.

Theoretical Treatment.—Consider an infinite cylinder of radius b surrounded by a cylindrical shell of thickness $c - b$. The initial concentration of diffusing material is U_0 in the cylinder and zero in the shell. From these data the boundary value problem may be formulated as follows[6]

$$\partial u/\partial t = \mathrm{D}[\partial^2 u/\partial r^2 + (1/r)(\partial u/\partial r)],\ 0 \leqslant r < c,\ t > 0 \quad (1)$$

$$u(r,0) = U_0,\ 0 \leqslant r < b \quad (2)$$

$$u(r,0) = 0,\ b < r < c \quad (3)$$

$$\partial u(c - 0,t)/\partial r = 0 \quad (4)$$

Here $u(r,t)$ represents the concentration of diffusing material at any point at any time, D is the coefficient of diffusion, r is the radial distance from the axis of the cylinder, and t represents the time. Condition (4) arises from the assumption that no nitroglycerin is lost through the outer boundary of the cellulose acetate wrapping. The general solution of the problem specified by equations (1) to (4) may be written as[7]

$$u(r,t)/U_0 = b^2/c^2 + (2b/c^2) \sum_{j=1}^{\infty} J_1(\lambda_j b) J_0(\lambda_j r) e^{-D\lambda_j^2 t}/\lambda_j [J_0(\lambda_j c)]^2 \quad (5)$$

where the positive eigen values λ_j satisfy the condition

$$J_1(\lambda_j c) = 0$$

and J_0 and J_1 represent, respectively, Bessel functions of order zero and order one of the first kind.

Calculation of Diffusion Coefficient.—The particular grain of wrapped powder for which analyses for nitroglycerin were available consisted of a long cylindrical powder stick 2.858 cm. in radius, wrapped with cellulose acetate 0.228 cm. thick. The powder grain was stored for a period of two months at an average temperature close to room temperature. At the end of this time it was sectioned and nitroglycerin analyses were carried out according to U. S. Army Specification R11B. The material to be analyzed is extracted with ether. The ether in the extract is then replaced by glacial acetic acid. Finally, the nitroglycerin is reduced with ferrous chloride and the concentration of ferric ion determined with titanous chloride.

By use of equation (5) it is possible to calculate the ratio $u(r,t)/U_0$ as a function of r for various values of the parameter Dt. The results of this calculation are represented in Fig. 1. Since the storage time was two months or 1440 hours, D in sq. cm. per hour is 1/1440 of the value of Dt for which theoretical and experimental results agree. Reference to Fig. 1 indicates that a satisfactory value for Dt is 0.01 sq. cm. so that D is 7×10^{-6} sq. cm. per hour.

The theoretical curve for $Dt = 0.01$ sq. cm. lies considerably below the experimental points closest to the cellulose acetate–powder interface. This discrepancy may probably be ascribed to contamination during sectioning of the sample closest to the interface with some powder, thereby causing abnormally large values of the nitroglycerin concentration and also impairing the reproducibility of the results.

The curves for different values of Dt show that the theoretical curve is quite sensitive to the value chosen for Dt. In view of the close agreement between experimental and calculated curves for $Dt = 0.01$ sq. cm., it follows that the calculated value for the average diffusion coefficient in powder and cellulose acetate is of the correct order of magnitude.

The boundary value problem specified by equations (1) to (4) may be simplified for the particular powder grain used for the present study. Thus, the composite cylinder may be approximated by a powder slab of thickness b in contact with a slab of cellulose acetate of thickness $c - b$. The composite slab treatment leads to the same value for Dt as the cylindrical treatment given here. Equally good results are obtained if the powder is considered to be a semi-infinite solid. However, it is not permissible to represent the relatively thin cellulose acetate coating by a semi-infinite solid.

N-β-Bromoethylaniline Hydrobromide

BY WILLIAM M. PEARLMAN

Although a product designated[1,2] as N-β-bromoethylaniline hydrobromide has been reported to be formed by converting N-phenylethanolamine into its hydrobromide at 100° with gaseous hydrobromic acid and then heating to 150–160°, no identification was made and no yields were given. In addition, the indicated procedures are cumbersome. It was found that the desired product could be obtained in 85% yield from β-hydroxyethylaniline and hydrobromic acid by a slight modification of the procedure of Cortese.[3]

Experimental

β-Hydroxyethylaniline (100 g.) was precooled to 0° and 310 ml. of precooled (0°) 48% hydrobromic acid was added dropwise with stirring and cooling. When all of the hydrobromic acid had been added the mixture was distilled with an efficient fractionating column until a constant boiling distillate was reached. The residue was cooled slightly, placed in a large, open dish in a vacuum desiccator and evacuated with a water jet overnight. The resulting slurry was filtered and the solid recrystallized from absolute ethanol. The yield of nearly colorless needles was 180 g. (85.5%), m. p. 136–139°. A sample recrystallized from benzene was colorless, m. p. 137–138°.

Oxidation–Reduction Potentials and Ionization Constants of the Reversible Series: Hexahydroxybenzene – Tetrahydroxyquinone – Rhodizonic Acid

BY PAUL W. PREISLER, LOUIS BERGER AND EDGAR S. HILL

Professor G. Schwarzenbach of the Universität at Zürich has recently called our attention to omission of reference in our publication[7] to the prior work and publication by Schwarzenbach and Suter[6] with the same substances. The oxidation–reduction potentials and ionization constants of this series of related compounds has been reported on several occasions.[1–7] It is regretted that there was no discussion of the work of Schwarzenbach and Suter[4,6] in our publications,[5,7] which oversight resulted from their being no abstract of the thesis of Suter[4] in *Chemical Abstracts* and no indication in the abstract[6a] of their joint publication[6] that they had worked with any compound of the rhodizonic acid series oxidation–reduction systems.

The two reports[6,7] differ mainly in the estimation of the ionization constants of rhodizonic acid. Our constants of $pK_1 = 4.1$ and $pK_2 = 4.5$ should be rejected in favor of those of Schwarzenbach and Suter, who found $pK_1 = 3.15$ and $pK_2 = 4.9$, since our values were estimated from the E_0'–pH curve of the rhodizonic acid–tetrahydroxyquinone system in a range where the curve is quite flat, while their values were determined by colorimetric and photometric methods.

Accepting their constants, 3.15 and 4.9, curves of $E_0' - p$H may be drawn which fit our experimentally determined points reasonably well. These changes do not affect the tetrahydroxyquinone–hexahydroxybenzene curve; the estimated ionization constant of tetrahydroxyquinone being unchanged at $pK_1 = 4.8$. Our E_0' values at $p\text{H} = 0$ become altered: for rhodizonic acid–tetrahydroxyquinone to $E_0' = +0.426$ volt (increase of +0.016) and for tetrahydroxyquinone–hexahydroxybenzene to $E_0' = +0.388$ volt (increase of +0.008).

These extrapolated values for $p\text{H} = 0$ and our measured potentials agree as well as may be expected for systems of this type with the potentials of Schwarzenbach and Suter. However, we experienced no difficulties in obtaining rapidly adjusting stable potentials in the entire pH range studied from 3.5 to 9.9. Therefore, where the slopes of our E_0'–pH curves are sufficiently well established, as for the tetrahydroxyquinone–hexahydroxybenzene system, we consider the ionization constants reported,[7] for tetrahydroxyquinone $pK_2 = 6.8$ and for hexahydroxybenzene $pK_1 = 9.0$, to be reliably estimated.

Freezing Point Depression of Sulfuric Acid by Siloxanes

BY FRASER P. PRICE

Since sulfuric acid is used as an equilibrating agent in the preparation of silicones,[1] it is of interest to investigate the kinds of particles produced when siloxanes are dissolved in this acid. It was hoped that such an investigation would shed some light on the mechanism of siloxane rearrangement.

The molal freezing point depressions and the van't Hoff "*i*" factors in approximately 100% sulfuric acid were determined by the method of Hammett and Deyrup.[2] The only departure from their method was that the weight of solvent

---

(1) Patnode and Wilcock, *ibid.*, **68**, 358 (1946).

(2) Hammett and Deyrup, *ibid.*, **55**, 1900 (1933).

was determined by weighing the freezing point tube containing the solute and acid at the end of the run and subtracting the weight of solute and tube.

The nomenclature used in this paper is a modification of that developed in this Laboratory for the simplified representation of polymethylpolysiloxane structures[3]: M = $(CH_3)_3Si$, D = $(CH_3)_2Si$, T = CH_3Si, Q = Si. The results of the study are given in Table I.

TABLE I

VAN'T HOFF "*i*" FACTORS FOR SEVERAL SILOXANES IN 100% SULFURIC ACID

	.0802	.066	2.053	4.27	4.28
$(DO)_4$	$.148 \times 10^{-3}$	.134	0.277	11.88[a]	
	$.487 \times 10^{-3}$	.134	0.965	12.60	
	1.01×10^{-3}	.134	1.951	12.58	12.59
$(MO)_3T$	8.59×10^{-3}	.092	0.425	8.20	
	21.0×10^{-3}	.092	1.035	8.25	
	39.0×10^{-3}	.092	1.874	8.23	8.23
$(MO)_4Q$	7.84×10^{-3}	.092	0.449	9.48	
	15.66×10^{-3}	.092	0.889	9.46	
	$26.6 \quad 10^{-3}$	.092	1.507	9.57	9.50

[a] This figure rejected as it is too far out of line.

Previous work with silyl sulfates[4] shows that only the normal sulfate is isolated when hexamethyldisiloxane is treated with sulfuric acid. However, the freezing point data for this siloxane indicate that the major reaction is

$$\text{MOM} + 3H_2SO_4 \longrightarrow 2MHSO_4 + H_3O^+ + HSO_4^- \quad (1)$$

which gives an "*i*" of 4. The slightly higher value observed is presumably due to the partial ionization of the $MHSO_4$. If the formation of the normal sulfate were the major reaction, then an "*i*" of only 3 would be observed or it would be necessary to assume that the reaction

$$M_2SO_4 \longrightarrow M^+ + MSO_4^-$$

went to completion in order to explain the observed value. Furthermore, it seems highly improbable that in this acid medium anything other than the acid sulfate could exist in appreciable quantity. It is more likely that the previous workers' results are due to the normal sulfate having a much higher solubility than the bisulfate in the extracting solvents. Hence, any small amount of sulfate that was formed would be removed and the equilibrium would shift to make up the deficiency.

The result obtained with the cyclic tetramer $(DO)_4$ is explained by the reaction

$$(DO)_4 + 12H_2SO_4 \longrightarrow 4D(HSO_4)_2 + 4H_3O^+ + 4HSO_4^- \quad (2)$$

The deviation from the integral value of 12 is probably due to ionization of the $D(HSO_4)_2$.

The deviations of the "*i*" factors from integers for both MOM and $(DO)_4$ are 0.28 and 0.59, respectively. However, when these deviations are made comparable by dividing by the number of silicon atoms, practically identical values are obtained. It then appears that the ionizations of $MHSO_4$ and $D(HSO_4)_2$ both proceed to about the same extent and that the replacement of methyl by bisulfate has little effect.

The two remaining siloxanes contain units capable of producing a three dimensional network Furthermore, these networks, if they form, will be quite insoluble in the acid. If these siloxanes reacted in a manner analogous to the two discussed above, the "*i*" factors should be 10 and 13 for $(MO)_3T$ and $(MO)_4Q$, respectively. Since the observed values are much lower, it is obvious that some type of polymerization must have occurred to remove T or Q units.

For the $(MO)_3T$ case the equations which most closely approximate the observed "*i*" value are

$$(MO)_3T + 6H_2SO_4 \longrightarrow 3MHSO_4 + \frac{1}{x}[T(HSO_4)O]_x + 2H_3O^+ + 2HSO_4^- \quad (3)$$

$$(MO)_3T + 7.5H_2SO_4 \longrightarrow 3MHSO_4 + 0.5[T(HSO_4)_2]_2O + 2.5H_3O^+ + 2.5HSO_4^- \quad (4)$$

Assuming that *x* in Equation 3 is large, these equations give values of "*i*" of 7 and 8.5 for Equations 3 and 4, respectively. It is, therefore, probable that both these reactions take place.

Consideration of the possible reactions for the $(MO)_4Q$ system leads to

$$(MO)_4Q + 7.5H_2SO_4 \longrightarrow 4MHSO_4 + \frac{.5}{x}[Q_2(HSO_4)_2O_3]x + \frac{5}{2}H_3O^+ + \frac{5}{2}HSO_4^- \quad (5)$$

$$(MO_4)Q + 9H_2SO_4 \longrightarrow 4MHSO_4 + \frac{1}{x}[Q(HSO_4)_2O]_x + 3H_3O^+ + 3HSO_4^- \quad (6)$$

with "*i*" factors of 9 and 10 for Equations 5 and 6, respectively. Whereas in the case of the $(MO)_3T$ the reaction lay between the cyclic polymer, $[T(HSO_4)O]_x$ and the dimer, $[T(HSO_4)_2]_2O$, here it lies between the three-dimensional gel and the cyclic polymer. In no case, however, does the number of HSO_4 radicals attached to silicon exceed two.

When freshly prepared polysiloxane hydrolysates are equilibrated with sulfuric acid, catalytic amounts, *ca.* 5%, of 95% acid are used. Hence, the conditions observed in the freezing point experiments are not exactly those prevailing during equilibration. In spite of these differences, in view of the non-integral values of "*i*" for MOM and $(DO)_4$ a probable active intermediate in the rearrangement is a positive siliconium ion which attacks the oxygen of the unreacted siloxane, forming a new Si–O bond and ejecting a new siliconium ion which repeats the process.

A Side Reaction of Acid Hydrazides in Qualitative Organic Analysis

By Louis Sattler and F. W. Zerban

In the course of the identification of small amounts of carbonyl derivatives obtained from heated fructose solutions which had been subsequently fermented with baker's yeast, *p*-nitrobenzhydrazide[1] and diphenylacethydrazide[2] were used.

With the *p*-nitrobenzhydrazide in 50% acetic acid, we obtained a small amount of a by-product of *s*-bis-(*p*-nitrobenzoyl)-hydrazine which crystallized in the form of yellow needles, and which on recrystallization from nitrobenzene melted at 288°.[3a] Previously reported melting points are 291°[3b] and 283°[3c].

Anal. Calcd. for $C_{14}H_{10}O_6N_4$: C, 50.91; H, 3.05. Found: C, 50.52; H, 3.21.

Similarly, diphenylacethydrazide in 60% ethanol plus 2 drops of glacial acetic acid[2b] yielded a white crystalline by-product of *s*-bis-(diphenylacetyl)-hydrazine. It was purified by recrystallization from a mixture of equal volumes of dioxane and 99% isopropyl alcohol. The pure crystals melted at 307°.

Anal. Calcd. for $C_{28}H_{24}O_2N_2$: C, 79.97; H, 5.75; N, 6.67. Found: C, 79.65; H, 5.60; N, 6.70.

Strain[4] has pointed out that while aqueous solutions of *m*-nitrobenzhydrazide are stable over long periods of time, strong acid solutions and elevated temperatures cause the formation of the symmetrical *bis*-hydrazine. It is evident that in addition to the normal reaction of acid hydrazides, a side reaction can also take place even in the absence of prolonged heating or strong acids. The ease with which these by-products are formed and isolated complicates the identification of expected derivatives. Consequently, due caution should be exercised in using hydrazides as derivatives of carbonyl compounds.

The authors express their thanks to Dr. Francine Schwartzkopf for the micro analyses.

4-Phenyl-*m*-dioxane

By Robert W. Shortridge

4-Phenyl-*m*-dioxane is produced in small amounts when styrene and formaldehyde react in acetic acid solution in the presence of a mineral acid catalyst such as sulfuric acid. The major product is 1-phenyl-1,3-diacetoxypropane, formed by the participation of the acetic acid in the reaction.

Prins,[1] in his original study of this reaction, erroneously formulated the products as derivatives of 2-phenyl-1,3-propanediol. Later, Fourneau, Benoit and Firmenich[2] proved their correct structure as derivatives of 1-phenyl-1,3-propanediol. Recently the structure of these compounds has been discussed by Emerson[3] on the basis of the results of the earlier workers.

It became necessary in the course of some research in this Laboratory to prepare moderate amounts of 4-phenyl-*m*-dioxane. To this end it was decided to study the reaction of Prins with a view to increasing the yield of the desired compound and the convenience of obtaining it.

An obvious change in the Prins procedure was to employ an inert mutual solvent in place of the acetic acid; such a change, of course, would eliminate entirely the formation of the undesired 1-phenyl-1,3-diacetoxypropane. It might be expected that the corresponding glycol would be formed under these changed conditions; this, however, proved not to be the case. When styrene and formaldehyde (in the form of trioxane) in a molar ratio of 1:2 were allowed to stand at room temperature in dioxane solution in the presence of sulfuric acid, a 78% yield of 4-phenyl-*m*-dioxane was obtained. There was no evidence of glycol formation and the remainder of the yield was accounted for by the production of polymers of styrene and of formaldehyde.

In a further step toward simplification the mutual solvent was eliminated completely and the reaction was run as a heterogeneous system, containing styrene, 37% aqueous formaldehyde and sulfuric acid. It was found necessary in this instance to work at reflux temperature. Carried out under these conditions the reaction yielded a maximum of 88% of 4-phenyl-*m*-dioxane. The sole identifiable by-products were polymers of styrene and of formaldehyde.

Since the completion of these studies, a patent[4] has issued claiming the preparation of a phenyl-*m*-dioxane in undisclosed yield by the reaction of styrene and 37% aqueous formaldehyde in the presence of hydrochloric acid and an inert hydrocarbon diluent. It is stated that only resinous products are obtained in the absence of the diluent. It appears, however, that under the conditions specified in the present paper the use of such a diluent is unnecessary.

Experimental

Reaction in Dioxane Solution.—A mixture of 220 g. of dioxane, 32 g. of 96% sulfuric acid, 30 g. of trioxane (du Pont) and 52 g. of styrene (Dow N-99) was allowed to stand at room temperature over a week-end. At the end of this time the reaction mixture was poured into 600 ml. of water and the organic layer was separated. The aqueous layer was extracted with three 50-ml. portions of benzene and the combined organic layer and extracts were washed with three portions of water and distilled. After removal of the benzene 64 g. (78%) of 4-phenyl-*m*-dioxane was obtained, b. p. 94–104° at 3 mm.

Reaction as a Heterogeneous System.—A mixture of 104 g. of styrene, 300 ml. of 37% aqueous formaldehyde and 16 g. of 96% sulfuric acid was refluxed and stirred overnight. The organic layer was washed successively

with dilute sodium carbonate solution, dilute sodium bisulfite solution and water. It was then dried by azeotropic distillation with 100 ml. of benzene. Further distillation yielded 144 g. (88%) of 4-phenyl-*m*-dioxane, b. p. 121–123° at 11 mm.

In several repetitions of the preceding preparation, the yields varied from 84 to 88%. The combined products were fractionated through a Vigreux column. A center cut from this distillation had these physical properties: b. p. 95° at 2 mm., $n^{25}{}_D$ 1.5288, d^{25} 1.101. Prins[1] reported b. p. 128–30° at 13 mm., $n^{18}{}_D$ 1.53063, $d^{18}{}_4$ 1.1111.

The Vapor Pressures of Solutions of Sodium and Potassium Bisulfates at 25°

BY R. H. STOKES

As part of a general study of the vapor pressure–concentration curves of a number of mono-sodium and mono-potassium salts of dibasic acids which is in progress in this Laboratory, isopiestic vapor pressure measurements have been made on sodium and potassium bisulfates. Owing to the relatively large second dissociation constant[1] of sulfuric acid (K_2 = 0.012 at 25°) these two salts have little in common with the others being investigated and are therefore reported separately.

Stock solutions of the two bisulfates were prepared by dissolving the calculated amount of the anhydrous normal sulfate in sulfuric acid which was previously analyzed by weight-titration against sodium carbonate. The resulting solutions were equilibrated (in platinum dishes) against sodium chloride as reference substance by the usual technique,[2] the molalities of pairs of solutions of equal vapor pressure being given in Table I. From these results and the standard values[3] for sodium chloride the vapor pressures at round concentrations were computed and are given in Table II in the form of $(p_0 - p)/mp_0$. A graph of this relative molal vapor pressure lowering against m shows a rapid rise below 1*M* as is to be expected in consequence of the increasing dissociation of the bisulfate ion with dilution. There seems, however, to be little justification for attempting a quantitative estimate of the amounts of the various ionic species present. The calculation of activity coefficients is also complicated by this dissociation which makes extrapolation to infinite dilution difficult. Consequently, though the data are of good accuracy (0.1–0.2%) no solute activity data derived from them are included in Table II.

Quinazolines. IV. Synthesis and Hydrolysis of 3-(4′-Quinazoyl)-4-quinazolone[1]

BY ARTHUR J. TOMISEK AND BERT E. CHRISTENSEN

In the attempts to prepare 4-cyanoquinazoline by fusion of 4-chloroquinazoline with either silver or cuprous cyanide[2] only small amounts of a fibrous material were isolated. This product appeared to be pure, and analysis suggested that it might be a diquinazolyl ether. Since 4-chloroquinazoline is easily hydrolyzed by traces of water, it is possible to account for diquinazolyl ether as resulting from the condensation of the 4-chloroquinazoline with small amounts of hydroxyquinazoline impurity.

There is no record in the literature of a diquinazolyl ether. Bogert and May attempted the syn-

---

thesis by refluxing sodium 4-quinazolonate with 4-chloroquinazoline in a benzene medium.[3] Attributing their failure to the insolubility of sodium 4-quinazolonate in benzene, the work was repeated in this laboratory using a dry dioxane solvent. This modified procedure gave a product which was found to be identical with that resulting from the cyanide fusions.

A diquinazolyl ether synthesized as above could have either of two possible structures: di-4-quinazolyl ether (I) or 3-(4′-quinazolyl)-4-quinazolone (II). Among the alkylquinazolyl ethers, O-ethers (I) or N-ethers[4] (II) are synthesized depending on which radical contains the halide and which the —ONa group (Fig. 1). When both radicals are quinazolyl, analogy to the alkylquinazolyl ethers fails to distinguish between the two possible isomers.

O-Ethers are very easily cleaved by acid in contrast to N-ethers which are stable.[3] The diquinazolyl ether prepared above reacted very readily with dilute hydrochloric acid to yield almost quantitatively a product ($C_{15}H_{13}N_3O$) which contained a quinazoline unit bound apparently to a degraded quinazoline nucleus. The failure to obtain 4-hydroxyquinazoline as the hydrolysis product, together with the fact that the two nuclei remain attached after hydrolysis, suggests an N-ether type of linkage. The stability of the ether toward boiling alcohol or water and to dry heat (m. p. 232° without decomposition or rearrangement) lends additional support to this point of view. The O-ethers are generally unstable under these conditions.[5]

II

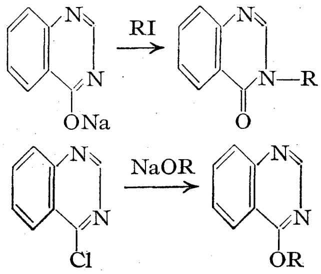

Fig. 1.

Experimental[6]

3-(4′-Quinazolyl)-4-quinazolone.—Twelve and seventenths grams of 4-hydroxyquinazoline was added to a solution containing 4.5 g. of potassium hydroxide (0.08 mole) in 75 ml. of absolute alcohol. The solvent was then removed on a steam-bath and the quinazolinate throughly dried under high vacuum. One hundred milliliters of dry dioxane and 14.6 g. of 4-chloroquinazoline (0.088 mole) were added to the pulverized residue and the mixture was refluxed for three days. Potassium chloride was removed by filtration while the reaction mixture was still hot. 3-(4′-Quinazolyl)-4-quinazolone separated from the liquors on cooling. Additional product was obtained by evaporating the mother liquors to dryness. The combined fractions were then triturated with dilute sodium hydroxide solution. The crude product (16.1 g., 74%), purified by charcoal treatment of a hot alcohol solution, yielded 14.1 g. (64%) of pure 3-(4′-quinazolyl)-4-quinazolone. The product recrystallized from alcohol as thin, wool-like fibers, m. p. 232.5°, was insoluble in water, soluble in both dioxane and hot benzene. It was stable to long boiling in water.

Anal. Calcd. for $C_{16}H_{10}N_4O$: C, 70.06; H, 3.68; N, 20.43: Found, C, 70.02; H, 3.85; N, 20.43.

Acid Hydrolysis Product of 3-(4′-Quinazolyl)-4-quinazolone.—The 3-(4′-quinazolone)-4-quinazolone (10.6 g.) was dissolved in hot dilute hydrochloric acid. In a few seconds the hydrochloride of the cleavage product precipitated. The mixture was cooled and filtered. The solid material and liquors were separately treated with excess sodium bicarbonate. The free base was then filtered, washed with water and dried. Combined fractions amounted to 9.3 g. (96%) of the crude product. After recrystallization from pyridine–water, fine, white, needle-like crystals melting at 244–225° were obtained.

Anal. Calcd. for $C_{15}H_{13}N_3O$; C, 71.69; H, 5.21; N, 16.72; mol. wt., 251. Found: C, 71.69; H, 5.23; N, 16.87; mol. wt.,[7] 255, 232, 257.

Investigation of the Oxidative Condensation of 2-Methoxy-4-nitrotoluene. The Use of Oxidative Catalysts

BY GINO R. TREVES

The oxidation of various substituted 4-nitrotoluenes to stilbenes was described by Green and Baddiley.[1] They also prepared 2,2′-dimethoxy-4,4′-dinitrostilbene by a two stage air oxidation of 2-methoxy-4-nitrotoluene. Recently Ashley and Harris[2] repeated the work of Green and Baddiley but were unable to obtain the stilbene. They report that the reaction ceased at the bibenzyl stage. When we carried out the reaction only minute quantities of condensation products were obtained. It was then decided to run the reaction with oxygen instead of air under more carefully controlled conditions.

The reaction mixture was shaken in the Adams shaker and the rate of oxygen consumption observed. The contact was continued for twenty-two hours and the product consisted of a mixture of the bibenzyl and the stilbene in 30% yield.

Compounds of high oxidation potential were tried in the hope that they would catalyze the reaction by functioning as hydrogen carriers. Results are shown in Fig. 1. Of special interest was the fact that cyclohexanol was almost as effective as cyclohexanone. This indicates that cyclo-

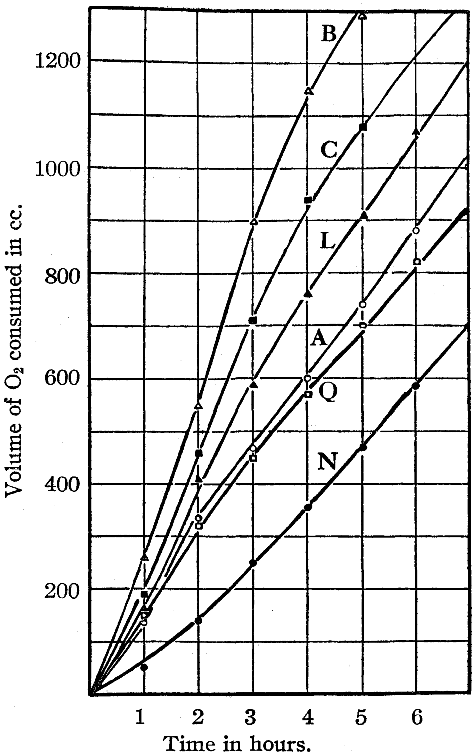

Fig. 1.—Effect of the addition of 0.001 M quantities of oxidation catalysts on the oxygen uptake in the oxidative condensation of 2-methoxy-4-nitrotoluene: ●, no catalyst, N; □, anthraquinone, Q; ○, acetone, A; ▲, cyclohexanol, L; ■, cyclohexanone, C; △, benzoquinone, B.

hexanol may be oxidized first to cyclohexanone which then acts as a catalyst. The total oxygen consumption was well above the expected theoretical amount. Therefore, oxygen was also used up in some side reaction.

Atmospheric oxygen as in the original method[1] was then tried in the presence of a catalyst and it proved to be effective. When benzoquinone was used and air bubbled through the reaction mixture for seven hours a 55% yield of the bibenzyl was obtained. When acetone was used and air bubbled through for twenty-two hours, 60% yield of a mixture of two parts of the bibenzyl and one part of the stilbene was obtained.

Experimental

Preparation of 2,2′-Dimethoxy-4,4′-dinitrobibenzyl.—Air is bubbled through a suspension of 10 g. of pure 2-methoxy-4-nitrotoluene in 200 ml. of 33% solution of methanolic potassium hydroxide containing one gram of benzoquinone for seven hours. The product is filtered, washed with dilute hydrochloric acid then with hot methanol and recrystallized from ethyl acetate, m. p. 179°; yield 5.5 g. On bromination it gives α,α'-dibromo-2,2′-dimethoxy-4,4′-dinitrobibenzyl, m. p. 247–249°.

Preparation of 2,2′-Dimethoxy-4,4′-dinitrobibenzyl and 2,2′-Dimethoxy-4,4′-dinitrostilbene.—Forty grams of 2-methoxy-4-nitrotoluene is placed in 800 ml. of 33% methanolic potassium hydroxide and 20 ml. of acetone. The mixture is well stirred and air is bubbled through at room temperature. After twenty-two hours the precipitate is filtered off. The mixture is then taken up in boiling ethyl acetate which dissolves the bibenzyl. The stilbene is filtered off and weighs 7.5 g. On cooling 16 g. of bibenzyl is collected from the ethyl acetate. The stilbene on bromination gives the same α,α'-dibromo-2,2′-dimethoxy-4,4′-dinitrobibenzyl as was obtained by brominating the bibenzyl.

Procedure Followed to Determine the Rate of Oxygen Consumption (see Fig. 1).—Ten grams of 2-methoxy-4-nitrotoluene and 0.001 M quantities of the different oxidation catalysts were placed in 200 ml. of 33% methanolic potassium hydroxide and shaken for twenty-two hours in the Adams shaker in the presence of oxygen at atmospheric pressure. The yield of mixture of the bibenzyl and the stilbene for all the catalysts tried varied between 30% and 38%. The mixture contained about equal quantities of the two substances.

STUDIES ON THE MECHANISM OF THE DEAMINATION OF DIAZONIUM SALTS WITH HYPOPHOSPHOROUS ACID

Sir:

In an attempt to introduce a deuterium atom into the *meta* position of nitrobenzene, a deamination reaction with hypophosphorous acid[1] was carried out. Thus, to a solution of diazotized *m*-nitroaniline containing 30% deuterium oxide was added a solution of hypophosphorous acid in water which contained 50% of deuterium oxide. Before use the hypophosphorous acid solution was allowed to stand at room temperature for twenty-four hours. Much to our surprise *the nitrobenzene which was obtained was found to contain no deuterium.* This was determined for us by Mrs. James L. Johnson and Dr. Foil A. Miller with an infrared spectrometer.[2] Similarly, aniline hydrochloride prepared from this sample of nitrobenzene was found to show no absorption in the region of the C–D stretching frequencies (2270 cm.$^{-1}$).

We are not yet in a position to comment on the mechanism of the reaction, but this result is par-

---

(2) The lower limit of the sensitivity of this method for the detection of deuterium in an aromatic ring has not yet been completely determined. From dilution experiments conducted with deuterobenzene in benzene, however, it appears that if 1–2% of the nitrobenzene molecules contained deuterium, it could be detected.

ticularly interesting in view of the fact that the work of Erlenmeyer, Schoenauer and Schwarzenbach[3] indicates that all three hydrogen atoms of hypophosphorus acid exchange rapidly with deuterium oxide. Apparently in the deamination reaction a hydrogen atom was extracted from another aromatic nucleus, since that is the only source of hydrogen which is not equilibrated with deuterium.

CAUSE OF EXPLOSIONS OCCASIONALLY OBSERVED DURING EVAPORATION OF SOLUTIONS OF ALUMINUM HYDRIDE AND RELATED COMPOUNDS

Sir:

In experiments involving dimethyl ether solutions of aluminum hydride, as well as of lithium and sodium aluminum hydrides, explosions have occasionally occurred. The details to be described have demonstrated that the explosions were caused by carbon dioxide present as an impurity in some samples of the ether.

Explosions have occurred toward the end of distillations undertaken to remove the solvent from dimethyl ether solutions of lithium aluminum hydride. That the explosions were due to an impurity more volatile than dimethyl ether was indicated by the facts (1) that later samples of the ether taken from a cylinder caused less violent explosions than the first few samples, and (2) ether taken from another cylinder at no time caused these explosions. These facts, as well as chemical tests to prove their absence, excluded aldehydes, alcohols or peroxide as the offending impurity. Considerable carbon dioxide was present in the cylinders whose contents led to explosions; its removal by fractionation *in vacuo* rendered the contents harmless. After carbon dioxide was reintroduced into the purified sample, the explosions recurred. It was then found that diethyl ether solutions of lithium aluminum hydride, which can ordinarily be safely evaporated, may also cause explosions if first treated with carbon dioxide in considerable amount.

Evaporation of dimethyl ether solutions of aluminum hydride and subsequent slow heating of the residue may result in a very rapid reaction in which, at slightly above 40°, relatively large quantities of gaseous material are suddenly released, but which is not accompanied by detonation, unless a large excess of aluminum chloride is present. But carbon dioxide-free ether leads to a residue which begins to decompose *slowly* above 70°, if aluminum chloride is not present in large amount; even in the presence of a large excess of the latter (2.5 moles/l.), the decomposition above 40° is sudden but without detonation. Other experiments have shown that aluminum chloride accelerates the decomposition of aluminum hydride.

On one occasion a violent explosion occurred when the residue resulting from evaporation of a dimethylcellosolve solution of aluminum hydride was warmed. The aluminum hydride was contaminated with aluminum chloride, which is known to decrease the stability of the former, and the dimethylcellosolve was impure. No explosion resulted when the experiment was repeated with purified materials.

Lithium aluminum hydride is considerably more stable than aluminum hydride. Approximately two hundred different reactions using the former reagent have been carried out in this Laboratory without untoward results although no precautions were taken to exclude carbon dioxide. We are, therefore, convinced that it may be used with perfect safety if the precautions suggested by the facts herein reported are followed. In other words, we recommend that in the reduction of organic compounds the normal procedure of hydrolyzing the initial reaction product before evaporation of the solvent be employed. If, as would rarely be the case, it is desired to evaporate the solvent before hydrolysis of the initially produced organic salts, the safety of the procedure should first be tested by use of a small sample.

CRYSTALLINITY OF HYDRO-CELLULOSES

Sir:

Hydrolytic methods are being used at present for evaluating the intramolecular structure of cellulose. It has been suggested in a paper to be published in THIS JOURNAL that such methods might possibly cause additional crystallization in the initial stages of hydrolysis. We have succeeded in obtaining data which indicate that such changes do occur. Consequently, it would seem necessary to reinterpret accessibility measurements based on hydrolysis rates in terms of two competing processes: hydrolysis and further crystallization.

The data in Table I were obtained on a beechwood pulp that had been digested in boiling 2.5 N hydrochloric acid–0.6 M ferric chloride solution constantly saturated with air.

TABLE I

Time treated, minutes	Percentage of samples destroyed	Specific vol. of bone-dry hydrocellulose, ml./g.	Percentage increase in crystallinity from Sp V. change, %
0	0	0.652	
10	4.8	.647	15
19	6.0	.646	18
28	39.0	.645	19

The specific volume was obtained from density, which was measured by flotation in carbon tetrachloride. The percentage increase in crystallinity was calculated using the values given by H. Mark[1] for the density of crystalline cellulose, 1.59 g./ml. (Sp V = 0.629). The density of amorphous cellulose was taken to be 1.50 g./ml. (Sp. V = 0.667) as estimated by P. H. Hermans.[2] The following relation was used to calculate the increase in crystallinity

$$\frac{\text{Sp. } V \text{ of untreated sample} - \text{Sp. } V \text{ of treated sample}}{\text{Difference in Sp. } V \text{ of amorphous and crystalline cellulose}}$$

A rayon of specific volume 0.653 showed a weight loss of 10% when treated with the reagent for five minutes. The specific volume of the treated sample was 0.647, indicating an increase of 16% in the crystallinity.

If the only process involved in the initial stages of this treatment is the attack and removal of the amorphous portion of the fiber, the density increase should predict a change of crystallinity of the same order of magnitude as the weight of material lost. However, the actual increase in density is much larger. This may indicate that with the rupture of a cellulose chain in an amorphous portion of the fiber a process of crystallization is initiated.

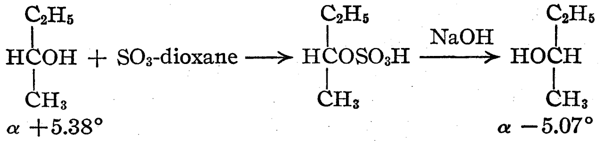
A NEW WALDEN INVERSION

Sir:

The following reaction sequence constitutes a new Walden inversion



$$\begin{array}{c}C_2H_5\\|\\HCOH\\|\\CH_3\end{array} + SO_3\text{-dioxane} \longrightarrow \begin{array}{c}C_2H_5\\|\\HCOSO_3H\\|\\CH_3\end{array} \xrightarrow{NaOH} \begin{array}{c}C_2H_5\\|\\HOCH\\|\\CH_3\end{array}$$

α +5.38° α −5.07°

The second step resembles the displacement of *p*-toluenesulfonate ion from secondary alkyl esters of the sulfonic acid by ethoxide or acetate ions, a reaction which has been shown to invert the configuration of the carbinol carbon.[1]

We previously[2] prepared (+)*s*-butylsulfuric acid by action of Suter's sulfur trioxide–dioxane reagent on (+)*s*-butyl alcohol and found that upon its acid hydrolysis a (+)alcohol was recovered whose rotation was 30% of that of the starting material. We had assumed that the racemization was confined to the hydrolytic step and that the formation of the alkylsulfuric acid proceeded with little if any racemization. This is now confirmed.

Since the action of chlorosulfonic acid and of sulfuric acid upon (+)alcohol gave (+)*s*-butylsulfuric acid, and since it was difficult to see how all these methods could involve breaking the carbon–oxygen bond of the alcohol, it was considered that the alkylsulfuric acid had the same configuration as the alcohol. If this is true, and its plausibility is increased by our finding that the sulfur trioxide–pyridine complex[3] also gives a (+)alkylsulfuric acid, then the saponification involves the displacement of a sulfate ion by a hydroxide ion with inversion of configuration. Since this reaction is one between two ions of like charge it is comparatively slow.

The alkylsulfuric acid was prepared by action of the sulfur trioxide–dioxane complex upon an alcohol of α +5.38. In one saponification, 8 g. of (+)sodium *s*-butylsulfate (from neutralizing the alkylsulfuric acid reaction mixture with sodium hydroxide, evaporating and extracting the sodium alkylsulfate with methanol) and 10 g. of sodium hydroxide were dissolved in 50 cc. of water. At 100° the reaction required two days for substantial completion. Alcohol was recovered in 54% yield with a rotation 6% below that of the starting alcohol and of opposite sign. About 8% of gas, apparently butylene, was evolved. A similar alcohol was obtained from the barium salt in a more concentrated potassium hydroxide solution, but several times as much butylene resulted.

Further investigation now under way at this laboratory should reveal the degree to which this reaction is common to secondary alcohols.

FORMYLFOLIC ACID, A FUNCTIONAL DERIVATIVE OF FOLIC ACID

Sir:

Previous studies from this Laboratory have indicated that a coenzyme containing *p*-aminobenzoic acid is involved in combining a single carbon unit into the pyrimidine ring of purines[1] and that folic acid functions in the biosynthesis of purines.[2] Seeking functional derivatives which could act as "carriers" of formate, we prepared *p*-aminobenzoylhistidine and condensed it with α,β-dibromopropionaldehyde and 2,4,5-triamino-6-hydroxypyrimidine to obtain pteroylhistidine. No pronounced activity was obtained with either of these histidine derivatives. The announcement of the structure of rhizopterin[3] which is *p*-[N-(2-amino-4-hydroxypyramido-[4,5-b]pyrazin-6-ylmethyl)-formamido]-benzoic acid gave a clue as

to how formate may be carried by a functional derivative of folic acid. Accordingly, formylfolic acid was prepared by heating 2 cc. of 98% formic acid and 0.5 cc. of acetic anhydride with 26 mg. of folic acid (pteroylglutamic acid) for one hour at 100°. The volatile reactants were removed *in vacuo*, and the light yellow product was precipitated from an alkaline solution by acetic acid. For analysis, a sample was hydrolyzed, and formic acid determined (Calcd.: 9.8%. Found.: 9.5%). The formylfolic acid was as effective as folic acid in stimulating the growth of *Streptococcus faecalis R* and *Lactobacillus casei*.

However, in an inhibition analysis with 7-methylfolic acid,[4] formylfolic acid was approximately thirty times as active as folic acid in preventing the toxicity of the inhibitor for *S. faecalis R;* the antibacterial index was 3,000 for formylfolic acid as compared with 100 for folic acid over a range of inhibitor concentrations from 10 to 100γ per 10 cc. In 10 cc. of medium,[2] a mixture of 0.3 γ of folic acid with 0.03 γ of formylfolic acid was no more effective than 0.03 γ of formylfolic acid alone in preventing the toxicity of the inhibitor. Synthetic rhizopterin[3] was two to three times as effective as folic acid in preventing the toxicity of the inhibitor. The toxicity of methylfolic acid was increased several fold by treating with 98% formic acid at 100° for two hours. For *L. casei* formylfolic acid was only slightly more effective than folic acid in preventing the toxicity of the inhibitor.

These results indicate that formylfolic acid is a functional derivative of folic acid and is competitively inhibited by methylfolic acid. The activity of rhizopterin indicates that it probably is converted directly to formylfolic acid.

These and other unpublished experiments offer additional evidence that the biochemical functions of *p*-aminobenzoic and folic acid derivatives involve the introduction of the single carbon unit into purines, pyrimidines and probably histidine.

The possibility of enhanced activity and decreased toxicity for formylfolic acid as compared with folic acid in treatment of pernicious anemia indicates the desirability for clinical testing.

CONCERNING THE STRUCTURE OF PHTHIOIC ACID

Sir:

Polgar and Robinson[1] have recently proposed, partly on the basis of the highly questionable degradative evidence of Wagner-Jauregg,[2] that phthioic acid,[3] isolated from tubercle bacillus, may be 3,13,19-trimethyltricosanoic acid. This acid was synthesized, but since it contains three asymmetric carbons the *dl*-mixture was of no value for comparison with the natural product. By use of the data which have now been collected concerning the optical rotation of fatty acids containing branching methyl groups, it is possible to estimate with some accuracy the maximum rotation to be expected of an acid such as 3,13,19-trimethyltricosanoic acid. Data of interest to this discussion appear in Table I.

TABLE I

Acid	$[\alpha]_D$	$[M]_D$
(+)-2-Methylhexacosanoic[4]	6.8°[a]	28°
(+)-2-Methyldodecanoic[4]	13.2°	28.3°
(+)-4-Methylhexanoic[5]	8.4°	11.0°
(+)-12-Methyltetradecanoic[6]	4.7°	11.4°
(+)-10-Methyloctadecanoic[7]	0.06°	0.2°
(+)-3-Methylhendecanoic[7]	5.0°	10.1°

[a] Taken in chloroform solution, remaining values obtained homogeneous.

As shown by the above data and elsewhere,[6] the molecular rotation remains reasonably constant for a given relationship of methyl group to the ends of the chain. Variables such as solvent and temperature have appreciable but not large effects in these compounds. For the case of 3,13,19-trimethyltricosanoic acid, it seems safe to assume that (a) the contribution of each asymmetric carbon to the rotation is unaffected by the presence of the other branching groups, (b) the contribution of carbon-19 is less than the rotation of the third or fourth acids listed in Table I, (c) the contribution of carbon-13 is similar to that of the fifth acid in Table I, (d) the contribution of carbon-3 is the same as the rotation of the sixth acid in Table I. It follows that the maximum molecular rotation for 3,13,19-trimethyltricosanoic acid should be approximately 22°, less than half the value of 49.7° observed for phthioic acid. Thus, it seems impossible that phthioic acid could have the structure suggested by Polgar and Robinson.

It is of interest that 2,3,21-trimethyltricosanoic acid has a calculated maximum molecular rotation of approximately 49.5° (ignoring any effect caused by the proximity of the 2- and 3-methyl groups), and all other trimethyltricosanoic acids would have a lower rotation. Thus, if phthioic acid is a long-chain acid with several branching methyl groups (evidence supporting this proposition seems doubtful), three of these groups are probably in the 2-, 3- and anteiso positions. Additional methyl groups between the 3- and anteiso positions should contribute little to the rotation.

THE EXCHANGE REACTION BETWEEN THE TWO OXIDATION STATES OF THALLIUM IN PERCHLORIC ACID SOLUTIONS

Sir:

We have studied the exchange reaction between thallous and thallic ions in aqueous perchloric acid and wish to make a preliminary report of the results. This reaction is of interest in that it involves transfer of two electrons between the reacting species and in that it is found to proceed at a slow and measurable rate, in contrast to the several other electron-transfer exchange reactions which have been reported to be fast.[1] Earlier studies of this reaction[2,3] were handicapped by the short half-life of the radioactive tracer used (ThC″, half-life 3.1 min.) and gave results which are difficult to interpret.

Using $Tl^{204,206}$ (half-life *ca.* 3 years), we have observed the exchange reaction and have investigated the dependence of the rate of exchange on the concentrations of thallous and thallic perchlorates, on the acid concentration, and on the temperature. The thallous perchlorate concentration was varied from 0.003 f. to 0.015 f., that of thallic perchlorate from 0.0006 f. to 0.003 f.

The method employed was to mix stock solutions of active thallic perchlorate and inactive thallous perchlorate in a stoppered flask immersed in a constant temperature bath, to withdraw samples at intervals, and to determine the distribution of activity between the two oxidation states of thallium. Thallous chromate was precipitated from the sample by the addition of a mixture containing chromate, cyanide, ethanol and excess ammonia. This method was found to give a reasonably clean separation, and not to induce a significant amount of exchange during precipitation.

The activity in the thallous fraction was found to vary with time in the simple exponential manner expected for an exchange reaction occurring at chemical equilibrium.[4,5] The rate of exchange was found to be proportional to the first power of the concentration of each reactant. The specific rate constant is 2.0 moles^{-1} liter hours^{-1} at 49.5° (perchloric acid 0.4 f.). The experimental activation energy is 12 kcal./mole. The addition of a neutral salt ($LiClO_4$ 0.6 f.) increased the rate, suggesting that ions of like sign participate in the exchange.

When the acid concentration was varied, the rate constant showed a maximum at about 1 f. ($k = 2.5$) and decreased to 0.9 at 3.9 f. This behavior doubtless results from the combined effects of ionic strength and hydrolysis of thallic ion.

We have also observed the exchange in 0.2 f. hydrochloric acid and find that the rate is markedly greater than in perchloric acid.

We are continuing these studies.

We are grateful to the Los Alamos Laboratory, in particular to Mr. J. W. Starner and Mr. E. L. Bentzen, for neutron irradiation of the thallium. We also are indebted to Dr. Norman Davidson for his interest and helpful advice.

EXCHANGE REACTION BETWEEN THALLIUM (I) AND THALLIUM (III) IONS IN PERCHLORIC AND NITRIC ACID SOLUTIONS

Sir:

We have measured the rate of the exchange reaction between thallium(I) and thallium(III) ions in aqueous solutions of perchloric and nitric acid and have found it to be slow and measurable. The data from earlier work[1,2] on this reaction are difficult to interpret because the short lived tracer, ThC″ (3.1 m.), limited the duration of the experiments.

Part of the $Tl^{204,206}$ (*ca.* 3.5 y) used as tracer in our experiments was prepared by the Tl(d, p) reaction in the Washington University cyclotron, the rest by the Tl(n,γ) reaction in the Oak Ridge pile. Our procedure was to mix acid solutions of thallium (I) perchlorate (nitrate) and active thallium (III) perchlorate (nitrate), remove aliquots at definite intervals of time, separate the two oxidation states, and assay and count the two fractions. Two methods of separation were used. (1) Thallium (III) hydroxide was precipitated with ammonium hydroxide; both fractions being subsequently weighed and counted as thallium (I) chromate. (2) Thallium (I) bromide was precipitated with sodium bromide solution, both fractions being weighed and counted as thallium (I) bromide.

A fast, incomplete, but reproducible exchange was induced at the time of separation. The induced exchange (exchange measured at zero time) could be varied from 45 to 70% for the hydroxide separation and from 8 to 13% for the bromide separation by adding the reagents in a different

(2) V. Majer, *ibid.*, **A179**, 51 (1937).

order or at different rates. However, the induced exchange was reproducible when conditions were held constant so we were able to correct for it using the equation

$$\% \text{ exchange} = \frac{\% \text{ exchange (measured)} - \% \text{ exchange (induced)}}{100 - \% \text{ exchange (induced)}} (100)$$

The corrected values (always three or more excluding the value at zero time) obeyed the exponential exchange law.[3,4] The half-times for the exchange rates are summarized in Table I. As expected the exchange rate is not dependent on the method of separation when proper account is taken of the induced exchange.

TABLE I

Tl(I)-Tl(III) EXCHANGE RATES

0.0244 f. Tl(I), 0.0244 f. Tl(III)

Acid	Temperature	Method of separation	Exchange, half-time hr.
1.0 f. HNO_3	*ca.* 25°C.	Bromide	2.5 ± 0.2
1.5 f. HNO_3	24.8 ± 0.2°	Bromide	1.8 ± 0.
1.5 f. HNO_3	24.8 ± 0.2°	Hydroxide	1.6 ± 0.2
1.5 f. $HClO_4$	24.8 ± 0.2°	Hydroxide	36 ± 4
1.5 f. $HClO_4$	24.8 ± 0.2°	Bromide	35 ± 4
1.5 f. $HClO_4$	24.8 ± 0.2°	Bromide	33 ± 4
2.5 f. $HClO_4$	24.8 ± 0.2°	Bromide	45 ± 4
3.5 f. $HClO_4$	24.8 ± 0.2°	Bromide	67 ± 5

We are extending this work to determine the effect of temperature, ionic strength, and concentrations of the reactants on the exchange rate.

THE STRUCTURE OF THE DECABORANE MOLECULE

Sir:

We are studying the structure of crystalline decaborane, $B_{10}H_{14}$, by single crystal X-ray diffraction methods. We have established the approximate positions of the ten boron atoms and four of the hydrogen atoms, and have assigned probable positions to the remaining ten hydrogen atoms. (Hydrogen atoms are well resolved in fourier sections.)

The $B_{10}H_{14}$ molecule has the symmetry C_{2v}–mm2. The bond distances are as follows (see figure): B_1–B_1', B_1–B_4, B_2–B_3, B_2–B_4, B_3–B_4, are all 1.74 ±0.04 kX; B_1–B_2 and B_4–B_4' are 1.96 ± 0.04 kX; B_4–H_4 is 1.34 ± 0.04 kX,[1] and all other B–H distances are assumed the same, except B_4–H_6 which is assumed to be 1.54 ± 0.04 kX. (B_4–B_4''' and B_4'–B_4'' are 2.76 ± 0.04 kX and are not bond distances.) Each hydrogen atom, except H_6 and H_6' is bound to a single boron atom; H_6 and H_6' are each bound to two boron atoms. Each boron atom has three boron neighbors at 1.74 ± 0.04 kX and one hydrogen neighbor at 1.34 ± 0.04 kX. In addition, B_4, B_4', B_4'' and B_4''' each has a boron neighbor at 1.96 ± 0.04 kX and another hydrogen neighbor at 1.54 ± 0.04 kX; B_1, B_1', B_2, B_2', each has two boron neighbors at 1.96 ± 0.04 kX; B_3 and B_3', each has another hydrogen neighbor at 1.34 ± 0.04 kX.

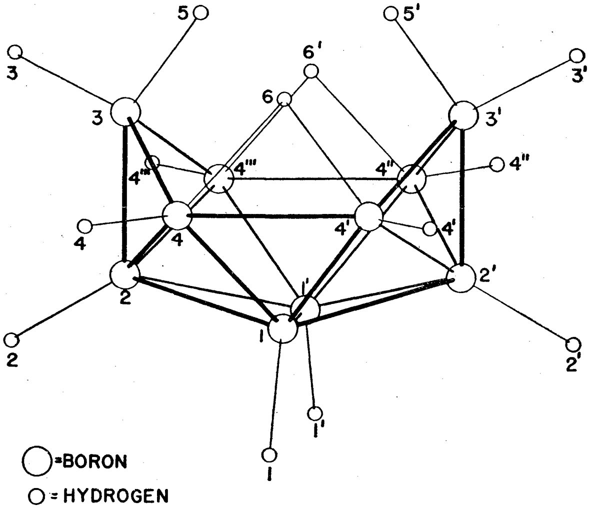

Fig. 1.

Each boron atom is bound to five or six other atoms, but the bonds are not all equivalent. Inasmuch as a bond distance of 1.96 kX has about half the "bond number"[2] of a bond distance of 1.74 kX, one can say that each boron forms five bonds of bond number 0.60. The corresponding radius, R(0.60) = 0.87 kX. Consequently, R(1) = 0.80 kX in agreement with Pauling.[2]

This structure for $B_{10}H_{14}$ gives excellent agreement with the observed X-ray diffraction intensities and also with the electron diffraction observations of S. Bauer.[3]

A detailed discussion of the determination of the structure of crystalline decaborane will be published soon.

(1) H_4, H_4', H_4'' and H_4''' were located on an electron density map; the positions of the other hydrogen atoms are assumed.

HETEROGENEITY OF CRYSTALLINE BETA-LACTOGLOBULIN

Sir:

That crystalline β-lactoglobulin is not a homogeneous protein was indicated by the solubility measurements of Grönwall[1] and by the electrophoretic results of Li.[2] Our experiments with

(1) Grönwall, *Compt. rend. trav. lab. Carlsberg*, **24**, no. 8–11, 185 (1942).

(2) Li, THIS JOURNAL, **68**, 2746 (1946).

this protein confirm these reports and indicate a relationship between the solubility of the protein and its composition as defined by the electrophoretic patterns obtained at *p*H 4.7.

β-Lactoglobulin was prepared by the method of Palmer[3] which involves the fractionation of milk whey with ammonium sulfate after the removal of casein with acid. The isolated β-lactoglobulin was recrystallized four times by dialyzing away the salt from sodium chloride solutions at the isoelectric point. Electrophoretic studies on a 1% solution of this material in acetate buffer of ionic strength 0.1, *p*H 4.8, showed the presence of a two component system. The same preparation was electrophoretically homogeneous on the alkaline side of the isoelectric point.

Fractionation experiments on the whey proteins from the filtrate after the partial removal of crystalline β-lactoglobulin gave crystalline fractions with a mobility comparable to that of the usual β-lactoglobulin at *p*H 8.3. Electrophoresis *p*H 4.8, however, indicated a variation in the concentration of the components in each of the fractions. These new crystalline fractions also varied from the standard preparation in that they showed a greater solubility in water and in dilute salt solutions.

Crystallization of the standard preparation by dialysis from an acetate buffer solution, varied with respect to *p*H, gave fractions with a partial separation of the components as indicated electrophoretically. Partial separation of β-lactoglobulin has also been obtained by fractionation with alcohol at low temperatures. The fractions obtained by alcohol have properties in agreement with the data reported in the table below for preparations obtained by the other methods. These results will be reported subsequently.

The solubility experiments were made as described by Grönwall.[1] In every case a suspension of the crystalline material containing 7.6 ± 0.1 mg. protein nitrogen per ml. was equilibrated for a twenty-four hour period. The protein nitrogen was then determined on the supernatant liquid after centrifugation. The table illustrates the variations in the electrophoretic components of a number of preparations at *p*H 4.8 and the solubility of these crystalline fractions at *p*H 5.2 ± 0.1.

Preparation	% Composition, $\mu \times 10^5$ 1.4–1.5	% Composition, $\mu \times 10^5$ 2.2–3.2	Solubility (mg. N/cc.) at 25° in H_2O	Solubility (mg. N/cc.) at 25° in 0.02 *M* NaCl

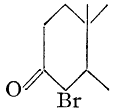
THE PREPARATION OF 3-KETO-Δ^4-STEROIDS

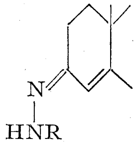
Sir:

For the introduction of a double bond at $C_4 : C_5$ in 3-ketosteroids hydrogen bromide has been eliminated from the 4-bromo derivative by treatment in boiling pyridine.[1] However, the yields have not been good. A new method for dehydrobromination has been found in which the reactivity of the bromine at C_4 is greatly increased through formation of a hydrazone at C_3. For a model compound, methyl 3,11-diketo-12-bromocholanate[2] was brominated to give methyl 3,11-diketo-4,12-dibromocholanate (I), m. p. 157.5–158.5°, $[\alpha]_D +13 \pm 2°$ (*c* 0.96 in chloroform). Calcd. for $C_{25}H_{36}O_4Br_2$: C, 53.58; H, 6.48; Br, 28.52. Found: C, 53.56; H, 6.69; Br, 28.5.

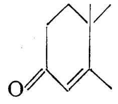
When 2,4-dinitrophenylhydrazine (1.2 equivalents) in the absence of molecular oxygen was added to an acetic acid solution of I which contained 5 equivalents of sodium acetate, a hydrazone was formed and hydrogen bromide was eliminated to give methyl 3,11-diketo-12-bromo-Δ^4-cholenate-3-(2,4-dinitrophenylhydrazone) (II). Hydrogen bromide also was eliminated quantitatively without the use of sodium acetate. Red needles, m. p. 238–239°; $\lambda_{max.}$ 387 mμ, log ε 4.48 (chloroform); yield, 82%. Calcd. for $C_{31}H_{39}O_7BrN_4$: C, 56.45; H, 5.96; Br, 12.12. Found: C, 56.21; H, 5.89; Br, 11.93.



I



II



III

The hydrazone (II) was converted into III by treatment in 20 cc. of chloroform, 30 cc. of pyruvic acid and 2.2 cc. of 2.3 *N* hydrogen bromide in acetic acid at 45°. After two and one-half hours the pyruvic acid 2,4-dinitrophenylhydrazone was removed with aqueous sodium bicarbonate, any C_{24}-carboxyl was esterified and III was separated in about 90% yield. The product was identical with a sample of III prepared by dehydrobromination of I in pyridine, m. p. 190–191°, $[\alpha]_D +29 \pm 2°$ (*c* 1.00 in chloroform); $\lambda_{max.}$ 238 mμ, log ε 4.22 (methanol). Calcd. for $C_{25}H_{35}O_4Br$: C,

A solution of hydrazone II is autoxidizable and should be protected from molecular oxygen with an inert gas. Before autoxidation of the unsaturated hydrazone was recognized dehydrobromination of the 4-bromo intermediates to give the adrenal hormones dehydrocorticosterone acetate (IV) and 17-hydroxydehydrocorticosterone acetate (V) was carried out. The yields of bromide ion, unsaturated hydrazone and IV were 96, 59 and 80% respectively. Slightly lower yields of V were obtained. The preparation of IV and V under more favorable conditions is planned as soon as the essential intermediate compounds again become available.

For the precursors of the adrenal hormones we are indebted to Merck and Co., Inc., Rahway, New Jersey.

VALENCE INDUCTIVITY

Sir:

Experiments conducted in this Laboratory on supported transition group oxides have led to what appears to be a new general principle in inorganic chemistry.

The effect was first observed in supported oxides of manganese. Thermal decomposition of manganous nitrate is well known to yield manganese dioxide. But if the manganous nitrate is first impregnated on high-area *gamma*-alumina, the oxidation state of the manganese becomes dependent on the concentration of the manganese. On an alumina with area of about 200 sq. m. per g., and with a manganese concentration less than 5%, all the manganese is in the +3 oxidation state. At higher concentrations the manganese reverts increasingly to the +4 state. The oxidation state is established both by direct titration, and by measurement of the magnetic moment.

This observation suggests that the manganese oxide tends to assume the crystal structure of the alumina, even to the extent of changing oxidation state in order to do so. It is well known that the *gamma* form of manganese(III) oxide is isomorphous with *gamma*-alumina.

Confirmation of this view is obtained by supporting the manganese on a high area (94 sq. m. per g.) rutile, which is isomorphous with pyrolusite. In this case the oxidation state of the manganese remains at +4, even at very low concentrations.

The experiments leading to the above results were performed by Marylinn Ellis and Kathryn Wethington. The effect described is strikingly shown by supported nickel in experiments performed by Fred N. Hill.

Magnesia is isomorphous with nickel(II) oxide. Supported nickel prepared by impregnation and ignition of high area magnesia is all in the +2 oxidation state. But dilute nickel oxide supported on high area alumina has the nickel in the +3 oxidation state. This state is established by direct quantitative uptake of hydrogen during reduction, and by magnetic measurements. It has proved possible to obtain up to 10% of nickel, all in the +3 state, by using multiple impregnation. This supported oxide is pale blue in color.

On the other hand, copper supported on alumina shows no tendency to assume the +3 state, nor does supported silver. It appears, therefore, that the effect is shown only when the supported positive ion may fairly readily assume a charge and radius similar to that of the positive ion in the support.

The effect illustrated for manganese and nickel may be described as a leading of the supported ion to take a different oxidation state than it would normally assume. Following a suggestion by Prof. Robert L. Burwell, Jr., we offer "valence inductivity" as a name for this effect. The general principle illustrated may be described as an induced change of valence brought about when a transition group ion is supported on a high area surface with which it may become isomorphous, and in which the ions may become isometric. The effect is somewhat related to the phenomenon of oriented overgrowth. It may be expected to aid in the understanding of several problems in catalysis and promoter action, and to be useful in the fields of mineralogy, crystallography, and coprecipitation.

EXCHANGE REACTION BETWEEN FERRIC AND FERROUS IONS IN PERCHLORIC ACID USING A DIFFUSION SEPARATION METHOD

Sir:

Equilibrium exchange was found to occur by Nahinsky in Professor Ruben's laboratory[1] when ferrous and tagged ferric ions mixed in perchloric acid solution were immediately separated by a chemical method. In a chemical separation of the ions, other ionic or molecular species formed through chemical change during the separation may exchange. For the perchlorate system, for example, ether–hydrochloric acid extraction of iron (III) leads to erroneous conclusions, because in 6 *M* hydrochloric acid ferrous and ferric iron exchange rapidly.[2] If separation is achieved by a physical method, without changing the environment of the ions, exchange incidental to chemical changes during separation may be avoided. Since catalytic effects of trace impurities and surfaces cannot be excluded, the results must still be interpreted cautiously.

---

(1) Nahinsky, Ph.D. Thesis, University of California, 1942.

(2) Seaborg, *Chem. Rev.*, **27**, 256 (1940).

We have investigated electronic exchange between ferric and ferrous ions in 3 M perchloric acid using radioferric ion[3] as indicator. The concentration ratio of ferric to ferrous ions (R_0) was consistently close to 0.25 and the total iron concentration was 0.023 M. Exchange was allowed to proceed for periods up to nine days. No measurable oxidation of ferrous to ferric ion by air occurred in this time. Hydrolysis of ferric ion was slight.[4]

Measurement of exchange was dependent on partially separating ferric and ferrous ions by their diffusion from the exchange mixture across a sintered glass membrane[5] into 3 M perchloric acid.

Ferric and ferrous ion concentrations were determined colorimetrically at 480 mμ employing the thiocyanate method.

In thirty-minute diffusion periods at 25° ratios (R) of around 0.54 were obtained for ferric to ferrous ion concentrations in the diffusate. The average separation factor ($S = R_0/R$) of about 0.47 indicates ferric ion diffuses relatively more rapidly than ferrous ion.

If the half time for exchange is much greater than the time required for diffusion separation, it is possible to derive the relation

$$F = \left(\frac{A}{a_0 W} - 1\right)\frac{R_0 + 1}{S - 1}$$

where the fraction of equilibrium exchange (F) is related to the radioactivity of the diffusate (A, in counts min.$^{-1}$), the specific activity of ferric ion (a_0, in counts min.$^{-1}$ mmol.$^{-1}$), and the millimoles of ferric ion in the diffusate (W) through the separation terms previously defined.

Initial results, subject to deviations of $\pm 5\%$ by virtue of the separation technique used, are: for thirty minutes, 2.2 and 3.8% of equilibrium exchange and for one case of poor separation, 9.6%; for two days, 8.7%; for five days, 13.9%; for seven days, 26.2%; and for nine days, 30.7%. These figures give a half time for exchange[6] of 18.5 ± 2.5 days.

We gratefully acknowledge the interest shown by Professor T. de Vries. Experimental results for ferric–ferrous ion exchange under other conditions will be the subject of a later communication.

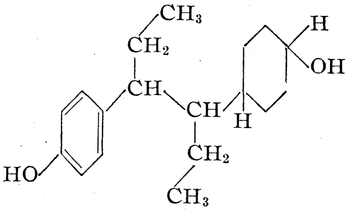
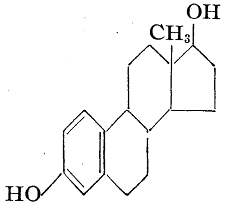
THE HEXAHYDRO DERIVATIVES OF *meso*-HEXESTROL

Sir:

After it was discovered that hexestrol is a highly potent estrogen, it became of considerable interest to prepare the hexahydro derivatives I since these bear a closer resemblance to the phenolic alcohol estradiol (II) than does the diphenol hexestrol itself. The activity of I would be of considerable significance in deciding whether the high physiological activities of hexestrol and diethylstilbestrol result from their superficial resemblance to the natural hormone II.



I



II

Our efforts to synthesize I (begun in 1940) have now proved successful, leading to the two stereoisomers corresponding in configuration at the bridge carbon atoms to *meso*-hexestrol. Recently Ungnade and Ludutsky [THIS JOURNAL, **69**, 2629 (1947)] reported the synthesis of the isomers of I related in configuration to the much less potent racemic hexestrol. In our synthesis hexestrol monomethyl ether was hydrogenated in the presence of copper chromium oxide catalyst at 240° and 425 atmospheres pressure, to obtain selective reduction of the phenolic ring. Demethylation of the mixture of methyl ethers by heating with methylmagnesium iodide at 170–190° gave a mixture of the phenolic alcohols I (soluble in Claisen alkali) in 40–50% yield. By recrystallization from dilute alcohol and benzene isomer A, m. p. 183–184° (cor.), was obtained. *Anal.* Calcd. for $C_{18}H_{28}O_2$: C, 78.2; H, 10.2. Found: C, 78.2; H, 9.9. The monobenzoate of A (Schotten–Baumann) melted at 68–69°. *Anal.* Calcd. for $C_{25}H_{32}O_3$: C, 78.9; H, 8.5. Found: C, 79.0; H, 8.6. Isomer B was obtained from the original filtrate and purified through the monobenzoate, m. p. 129.5–130° (cor.). *Anal.* Found: C, 79.0; H, 8.3. Saponification of the pure monobenzoate gave isomer B, which showed a variable melting point behavior. Recrystallization from benzene and from dilute methanol gave samples with the m. p. 133–134°; sublimation at 120° (0.01 mm.) resulted in material of m. p. 128–129.5°. When the 134° material was dried at 60° (0.1 mm.) the m. p. broadened to 134–141.5° (*Anal.* Found: C, 78.2; H, 10.0). Other samples melting as high as 143–145° were obtained. This behavior is indicative of polymorphism. Isomer B may be the same as the compound, m. p. 144–145°, obtained by Hoehn and Ungnade [THIS JOURNAL, **67**, 1617 (1945)] in low yield by hydrogenation of diethylstilbestrol.

Preliminary physiological assays carried out under the direction of Drs. R. K. Meyer and Elva Shipley Meyer of the Department of Zoology, indicate that both isomers are definitely weaker in estrogenic activity in rats than diethylstilbestrol. Further tests are in progress.

STREPTOMYCIN, VII. DEGRADATION OF O-TETRAMETHYLSTREPTAMINE TO D,L-DIMETHOXYSUCCINIC ACID

Sir:

N,N′-Diacetylstreptamine (1,3-diacetamido-2,4,5,6-tetrahydroxycyclohexane)[1] was converted with dimethyl sulfate and sodium hydroxide to O-tetramethyl-N,N′-diacetylstreptamine (m. p. > 300°; *Anal.* Calcd. for $C_{14}H_{26}O_6N_2$: C, 52.81; H, 8.23; N, 8.81; CH_3O, 39.07. Found: C, 52.99; H, 8.28; N, 8.67; CH_3O, 40.1), which on hydrolysis with hydrochloric acid afforded O-tetramethylstreptamine dihydrochloride (m. p. > 300°; *Anal.* Calcd. for $C_{10}H_{22}O_4N_2 \cdot 2HCl$: C, 39.09; H, 7.87; N, 9.12; Cl, 23.08. Found: C, 38.76; H, 7.71; N, 8.98; Cl, 23.4). The free base (m. p. 83–84°; *Anal.* Calcd. for $C_{10}H_{22}O_4N_2$: C, 51.26; H, 9.46; N, 11.96. Found: C, 51.18; H, 9.38; N, 11.71) was oxidized with neutral potassium permanganate at room temperature. The methyl ester mixture formed from the oxidation products with methanolic hydrogen chloride yielded on distillation several fractions which were treated separately with methanolic ammonia or methylamine. From the lower-boiling fractions there were obtained D,L-dimethoxysuccinic acid diamide (m. p. 266–268° (dec.)[2]; *Anal.* Calcd. for $C_6H_{12}O_4N_2$: C, 40.90; H, 6.87; N, 15.90; CH_3O, 35.2. Found: C, 41.14; H, 6.76; N, 16.19; CH_3O, 35.0) and D,L-dimethoxysuccinic acid di-N-methylamide (m. p. 188–189°; *Anal.* Calcd. for $C_8H_{16}O_4N_2$: C, 47.04; H, 7.90; N, 13.72; CH_3O, 30.4. Found: C, 47.46; H, 8.05; N, 13.96; CH_3O, 30.5). Synthetic specimens of these hitherto undescribed amides, prepared from D,L-tartaric acid, showed the same melting points, undepressed by admixture of the degradation products. The diamide[3] and di-N-methylamide[4] of *meso*-dimethoxysuccinic acid melted at 255–257° (dec.) and 210–210.5°, respectively. The *meso*-diamide strongly depressed the melting point of the diamides derived from streptamine and from D,L-tartaric acid.

If, as appears highly probable, streptamine and streptidine are *meso* compounds, it follows from the above results that the 5-hydroxyl group is oriented *trans* with respect to the 4- and 6-hydroxyl groups (*xylo*-configuration), a spatial arrangement also encountered at the corresponding positions in *meso*inositol. This would limit the number of possible *meso* forms for streptamine to four.

Furthermore, there was isolated from high-boiling ester fractions prior to amidation a compound $C_{10}H_{17}O_6N$ (m. p. 109–110°; *Anal.* Calcd C, 48.57; H, 6.93; N, 5.67; $4CH_3O$, 50.1. Found: C, 48.74; H, 6.87; N, 5.65; CH_3O, 49.2) which should be either the 2,6-lactam of a 2-amino-3,4,5-trimethoxyadipic acid-1-methyl ester, or the 3,6-lactam of a 3-amino-2,4,5-trimethoxyadipic-1-methyl ester.

NEW BOOKS

SMALL WONDER—The Story of Colloids. By GESSNER G. HAWLEY. Alfred A. Knopf, New York, N. Y., 1947. 220 pp. Price $3.50.

The author certainly deserves full credit for his courage and, as many parts prove, skill in attempting to explain "to those who have the curiosity but lack the time to study more erudite treatises" what the term "colloid" implies. In his preface he also states, however, that "there is such a thing as having an embarrassment of subject matter" and "it is easy to become bewildered and get lost in it all." That has happened, and it is unfortunate because the reader who takes many of the written words at their face value will not get a more general, but often a wrong, understanding of colloids. This refers specifically to the author's definition of colloids, the history of this branch of science, to the explanation of their electrical properties, to the discussion of how natural rubber is obtained, or synthetic rubber produced.

The discussion of the electron microscope is by far too extensive for a book of this type, so much the more since its use in attempting to pry deeper into the structure of lyophilic colloids is becoming more and more questionable. It would have been far more appropriate to explain to the reader the tremendous developments of ultramicroscopic techniques and what has been achieved by their use.

The author has made a few serious mistakes which must be corrected. Plate XV is a cut-away view of a Sharples *super*- and not ultracentrifuge. The statement that the first periodical given over exclusively to colloid chemistry is the "Journal of Colloid Science," which appeared for the first time in January, 1946, is incorrect; the Germans have had the periodicals "Kolloid Zeitschrift" and "Kolloidchemische Beihefte" since 1906, the French have had the "Revue Generale du Colloides" since 1923, and we in the United States have had the "Colloid Symposium Monographs," also since 1923. The fact that no credit was given to many of the most outstanding colloid chemists, like Freundlich, Weiser, Holmes, v. Weimarn, Duclaux and Houwink, only to mention a few, is unfortunate.

Despite these criticisms, the reviewer hopes that this book will accomplish its purpose: namely, to arouse more general interest in this world of dimensions which has been overlooked for too long. Then it will be up to us colloid chemists to keep the ball rolling.

ERNST A. HAUSER

Thermodynamics for Chemists. By SAMUEL GLASSTONE, formerly Research Associate of Princeton University, and Professor of Chemistry in the University of Oklahoma. D. Van Nostrand and Co., Inc., 250 Fourth Ave., New York, N. Y., 1947. viii + 522 pp. Illustrated. 15.5 × 23.5 cm. Price, $5.00.

This is a typical Glasstone book, a mosaic of pieces shaped and fitted together with skill. When the individual pieces can be made from adequate reviews the result is excellent, but when the best literature is out of date or highly specialized, it may not be so good.

The proof reading seems to have been very carefully done. The only typographical errors I found were omissions of the bar denoting a partial molal quantity in a few cases where the omissions are relatively harmless. There are more important errors which the instructor will need to correct if the students are to grasp the subject. Some of the more striking are:

"Energy is defined as *any property which can be produced from or converted into work*, including, of course, work itself" (p. 6).

The partial molal volume of a component of an ideal gas mixture is defined as RT divided by the partial pressure of that component, instead of by the total pressure (pp. 219, 261).

"The general conclusion to be drawn, therefore, is that *upon mixing two liquids which yield a system exhibiting positive deviations from Raoult's law there is an absorption of heat*" (p. 331).

The author has even succeeded in copying two errors from Lewis and Randall; there are not many more.

The limit at zero pressure of $d\alpha/dP$ [$\alpha = (RT/P) - V$ for a gas] is taken as zero. Figure 17 of Glasstone is not so unreal as the figure on page 195 of Lewis and Randall, but it is still misleading, as is the discussion on pages 253 and 255.

"TABLE XXXII. ACTIVITY COEFFICIENTS OF THALLOUS CHLORIDE IN PRESENCE OF VARIOUS ELECTROLYTES AT 25° C." is given as experimental evidence for the "ionic strength principle." The first three of the seven rows, which are the ones which show agreement, are in the range where there is neither added salt nor measurements. The fourth is only 25% above the solubility of pure thallous chloride.

There is more from Lewis and Randall which was good in 1923 but is not so good in 1947. For example, the chapters on electrolytes would be greatly improved if the author had made up his mind how much of the Debye theory he trusted, and had started with that. This would permit presentation of the limitations of the ionic strength principle, Brønsted's specific ion attraction theory and at least a qualitative discussion of the treatment of the higher terms in the expansion of the Boltzmann exponential.

The following topics might well have been included: pH and single ion activities with appropriate reservations; the Donnan equilibrium; the vapor pressure of a liquid in a capillary; and particularly, the effect of gravitational, centrifugal and electrical fields on thermodynamic properties and on concentrations.

In the preface the author claims three points of distinction which give a good indication of the character of the book.

(1) There are more than a hundred illustrative numerical problems solved in the text, and about three hundred and sixty exercises to be solved by the reader. These vary from drill in the relative magnitudes of various units to derivation of some of the general equations. They seem to be very well chosen, and should serve the author's purpose of making thermodynamics a live subject to the chemist.

(2) The theory of corresponding states as developed by American chemical engineers has been used "whenever feasible" under the name "generalized procedures." It is an excellent idea to present the method as an approximation which is valuable when specific data are lacking, but the emphasis here is much greater than the accuracy of the approximation warrants.

(3) The use of statistical methods is emphasized. The partition function is introduced early and often and its relation to the classical thermodynamic functions is clearly shown. This is one of the best features of the book.

The author does not tell the maturity of the reader for whom he wrote, but there are few chemists who cannot profit by this book.

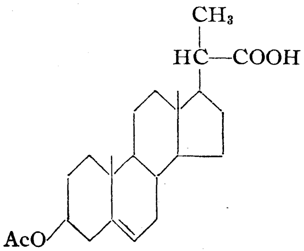
Sterols. IV. Δ^{20}-Pregnenes from *bisnor*-Steroid Acids

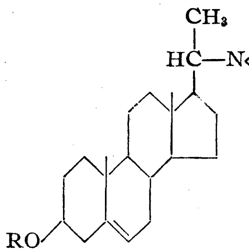
BY PERCY L. JULIAN, EDWIN W. MEYER AND HELEN C. PRINTY

Intensive studies in these Laboratories over the past few years have resulted in making 3-acetoxy-5-*bisnor*-cholenic acid a relatively cheap and useful raw material for the synthesis of most of the major steroid hormones. This communication presents one of the promising and convenient methods for degrading this acid to key intermediates in such a synthetic approach. The emphasis in this particular investigation centers upon the Δ^{20}-pregnenes prepared from 3-acetoxy-5-*bisnor*-cholenic acid and analogous steroid acids. The ease of preparation and the excellent yields encountered make the Δ^{20}-pregnenes focal points of interest in the general picture involving degradation and synthesis of physiologically active steroids.

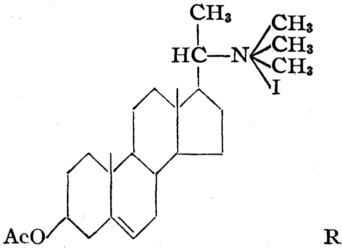
3-Acetoxy-5-*bisnor*-cholenic acid (I) was converted to 3-acetoxy-20-amino-5-pregnene (II) in practically quantitative yield *via* the acid chloride by the Curtius method.[1] Methylation of the 20-amine (II) with formic acid and formaldehyde[2] gave 3-acetoxy-20-dimethylamino-5-pregnene (III) and this compound reacted smoothly with methyl iodide to yield the desired quaternary halide (V). All steps to this point gave yields which were excellent. Decomposition of the ammonium iodide (V) by treatment with potassium hydroxide in ethylene glycol solution afforded 3-hydroxy-5,20-pregnadiene (VI) in only 65% yield, but the major portion of the remaining 35% was recovered as the 3-hydroxy-20-dimethylamine (IV). Thus this reaction, too, in the end, becomes nearly quantitative. Of the two competing reactions involved in the degradation of the quaternary base, namely, the loss of trimethylamine and the loss of methyl alcohol, the former predominates in this case sufficiently to make this procedure one of the cleanest of side-chain degradations. The decomposition of the halide (V) by silver oxide-pyrolysis gave a poorer yield of the pregnadiene (VI).



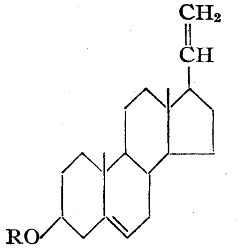
(I)



(II), R = Ac, R' = H
(III), R = Ac, R' = CH_3
(IV), R = H, R' = CH_3



(V)



(VI), R = H
(VII), R = Ac
(VIII), R = $C_7H_7SO_2$

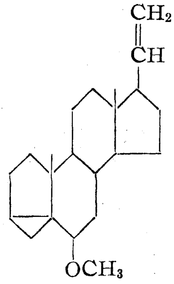
The structure of the pregnadiene (VI) was demonstrated by conversion into the *i*-ether (IX) followed by oxidation with potassium permanganate in pyridine and subsequent "rearrangement" and esterification with acidulated methanol to yield methyl 3-methoxy-5-*etio*-cholenate (X) identical with the compound prepared from 3-hydroxy-5-*etio*-cholenic acid. Oxidation of 3-hydroxy-5,20-pregnadiene (VI) offers the first authentic and clean-cut preparation of 3-keto-4,20-pregnadiene

---

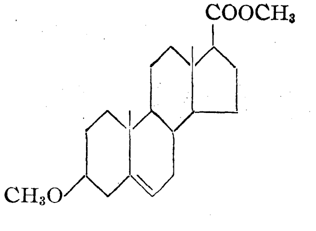
[1] Bochmühl, Ehrhart and Ruschig, U. S. Patent 2,108,646; Ruschig, *Med. u. Chem.*, **4**, 327 (1942) (*C. A.*, **38**, 4954 (1944)).

[2] Clarke, Gillespie and Weisshaus, THIS JOURNAL, **55**, 4571 (1933).

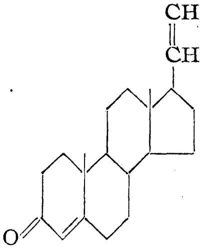
(XI). This material melted at 126.5° and gave a good yield of 3-keto-4-*etio*-cholenic acid (XII) upon mild treatment with ozone. The structure of the pregnadiene is, therefore, indisputably established.



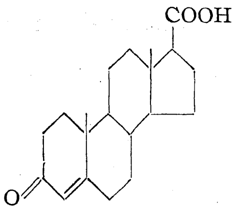
(IX)



(X)



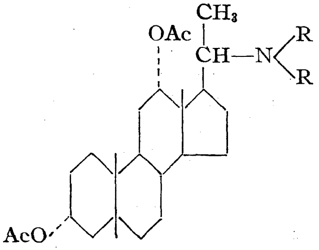
(XI)



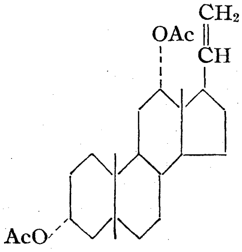
(XII)

Ruzicka and co-workers[3a] posed the possibility that their substance of melting point 132–133°, prepared by the reduction of 3,17-dihydroxy-17-ethynyl-5-androstene with sodium in ethanol–xylene, might have the structure of our pregnadiene (VI). These authors, however, in a later communication,[3b] presented satisfactory proof that their compound did not possess the first proposed structure but was instead the 3-hydroxy-5,17-pregnadiene.

The application of the above-described degradative scheme to 3(α),12(α)-diacetoxy-*bisnor*-cholanic acid afforded equally as facile a route to 3(α),12(α)-diacetoxy-20-pregnene (XV) *via* the aminopregnane derivatives (XIII) and (XIV). Oxidation of this pregnene gave a good yield of 3(α),12(α)-diacetoxy-*etio*-cholanic acid.



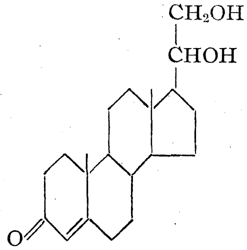
(XIII), R = H
(XIV), R = CH_3



(XV)

This preparation of *etio*-acids from *bisnor*-acids *via* the Δ^{20}-pregnenes constitutes, in our opinion, the most satisfactory route to *etio*-acids yet proposed. The preparation of 3-acetoxy-5-*etio*-cholenic acid by Steiger and Reichstein[4] gave, according to these investigators, only a 9.0% yield based upon 3-hydroxy-5-*bisnor*-cholenic acid. Hoehn and Mason[5] prepared 3(α),12(α)-dihydroxy-*etio*-cholanic acid in 14.5–17% yield by an improved procedure from 3(α),12(α)-dihydroxy-*bisnor*-cholanic acid. Our preparation gives a minimum yield of 33% of 3-keto-4-*etio*-cholenic acid based on the 3-acetoxy-5-*bisnor*-cholenic acid. Thus the Δ^{20}-pregnenes occupy a significant role in the classical route to the cortical hormones.

The Δ^{20}-pregnenes offer other interesting approaches to the typical ketol structure of the cortical hormones. The pregnadiene (XI) underwent hydroxylation with osmium tetroxide giving both of the expected diastereoisomeric 20,21-diols (XVI) which have been separated and characterized. One diol melted at 168°, $[\alpha]^{27}_D$ + 98°, and the other melted at 194°, $[\alpha]^{35}_D$ + 97°. The first of these agrees in its properties with the so-called "α-form" of the diol which Steiger and Reichstein[6] prepared from desoxycorticosterone. These workers, however, apparently did not have the β-modification in pure form as they give a melting point of 185° and indicate that they had too little material for analysis and complete characterization. These diols and their derivatives offer attractive routes to the cortical hormones[7] and we shall report more in detail later upon this phase of the investigation.



(XVI)

Experimental[8,9]

3-Acetoxy-20-amino-5-pregnene (II).—In a flask protected with a calcium chloride tube, a suspension of 50.0 g. of 3-acetoxy-5-*bisnor*-cholenic acid in 1000 ml. of anhydrous ether was treated with 29 ml. of freshly distilled thionyl chloride. After the addition of a few drops of 10% pyridine in benzene, the mixture was swirled occasionally. The acid dissolved within one-half hour. After two hours, the solvent was removed *in vacuo* with gentle warming. To remove the last traces of thionyl chloride, the residue was dissolved successively in several small portions of dry benzene and this solvent was removed *in vacuo*. The acid chloride remained as a white, crystalline cake.

(8) The carbon-hydrogen analyses were performed by Mr. C. W. Beazley of the Micro-Tech Laboratories, Skokie, Illinois.

(9) We are indebted to Miss Isabelle Ryden of this Laboratory for certain technical assistance.

The acid chloride was dissolved in 900 ml. of acetone and chilled in an ice-bath to 10°. A solution of 16.0 g. of sodium azide in 75 ml. of water was then added dropwise, with mechanical stirring, at such a rate that the temperature of the solution was maintained at 10–13°. After fifteen minutes of stirring, 1000 ml. of ice-cold water was added and the white crystalline azide was filtered. The moist cake which weighed 160 g. was added to a mixture of 1000 ml. of glacial acetic acid and 142 ml. of water. The mixture was warmed on a steam-bath with swirling. At about 38° nitrogen was evolved and the azide went into solution. After heating for one hour at 60–65°, the solution was steam distilled (about 2–3 l. of distillate). To the residual mixture, while still hot, a solution of 80 g. of sodium hydroxide in 300 ml. of water was added portionwise with good agitation. Upon cooling, the 3-acetoxy-20-amino-5-pregnene acetate formed needle-like crystals. The mass was filtered, washed with a small quantity of cold water and dried. The acetate weighed 51.7 g. (96%) and melted at 200–205° after softening slightly at about 185°. This material which contains a small quantity of sodium acetate is of sufficient purity for further experimentation.

A 5.0-g. sample of the acetate was dissolved in a small amount of methanol and treated with dilute sodium carbonate solution. After addition of ether, the ethereal solution was washed with water (it was necessary to add a small amount of methanol from time to time to solubilize the amine which is only moderately soluble in ether) and dried. The solid remaining after removal of ether was dissolved in hot methanol, filtered, and precipitated by the cautious addition of water. It was recrystallized several times from a concentrated methanol solution—white silky needles resulted, m. p. 116–120° (loss of solvent).

A convenient derivative for this amine was the benzal derivative, 3-hydroxy-20-benzaldimino-5-pregnene. For preparation, the 20-amine described above was hydrolyzed with 2% methanolic potassium hydroxide and this solution was treated with benzaldehyde. The benzal compound crystallized readily in the form of glistening plates. For analysis it was recrystallized from benzene–methanol, m. p. 191°.

Anal. Calcd. for $C_{28}H_{39}ON$: C, 82.90; H, 9.69. Found: C, 82.57; H, 9.31.

3-Acetoxy-20-dimethylamino-5-pregnene (III).—A solution of 20.5 g. of 3-acetoxy-20-amino-5-pregnene acetate in 17.8 g. of 90% formic acid and 13.2 g. of 35% aqueous formaldehyde was heated on a steam-bath under reflux for five hours. At the outset the evolution of carbon dioxide was vigorous but this subsided to a slow steady rate. The mixture was diluted with water and extracted with ether after the addition of dilute hydrochloric acid. The aqueous layer containing suspended insoluble hydrochloride was separated and combined with the water washings of the ethereal layer. The aqueous mixture was made alkaline with dilute sodium hydroxide and extracted well with ether. The ether solution was washed with water and dried. Upon removal of solvent, there remained 17.8 g. (92%) of a white, crystalline residue melting at 155–175°, which was sufficiently pure for the preparation of (V). For analysis, however, several recrystallizations from a small volume of ether gave glistening plates which melted at 184.5–187.5°; $[\alpha]^{34}D$ $-50 \pm 1°$ (77.2 mg. made up to 5 ml. with chloroform, α $-0.77°$, l, 1 dm.).

Anal. Calcd. for $C_{25}H_{41}NO_2$: C, 77.47; H, 10.66. Found: C, 77.65; H, 10.76.

3-Hydroxy-20-dimethylamino-5-pregnene (IV).—A 1.94-g. sample of the 3-acetoxy-amine was dissolved in a solution of 0.5 g. of potassium hydroxide in 50 ml. of methanol and 10 ml. of benzene. This solution was refluxed for three hours. It was then diluted with water and extracted with ether. The water-washed ether solution was concentrated to a crystalline mass which was recrystallized from ether–petroleum ether (b. p. 35–60°). The product, 1.7 g. of white prisms, melted at 162–171°. Recrystallization from ether gave material melting at 169–170°; $[\alpha]^{33}D$ $-54 \pm 2°$ (23.3 mg. made up to 5 ml. with chloroform, α $-0.25°$, l, 1 dm.).

Anal. Calcd. for $C_{23}H_{39}ON$: C, 79.94; H, 11.37. Found: C, 80.17; H, 11.08.

3-Acetoxy-5-*ternor*-cholenyltrimethylammonium Iodide (V).—Ten and four-tenths grams of the crude 3-acetoxy-dimethylamine was dissolved in 40 ml. of warm benzene, chilled and treated with 6 ml. of methyl iodide. The solution was refluxed for two hours. During this period a heavy crop of crystalline material separated. The mixture was slurried with ether, filtered, and the solid washed with ether. The mother liquor was concentrated to remove ether and was retreated with methyl iodide in the same fashion to obtain a second crop of material. The total yield of white, crystalline quaternary iodide amounted to 12.7 g. (89.2%), m. p. 255–265°, dec. Recrystallization from methanol gave plates which decomposed at 270°.

Anal. Calcd. for $C_{26}H_{44}O_2NI$: C, 58.97; H, 8.38. Found: C, 58.75; H, 8.23.

The ammonium iodide can be converted to the quaternary base, **3-hydroxy-5-*ternor*-cholenyltrimethylammonium hydroxide** by treatment with moist silver oxide. In one experiment, a solution of 1.0 g. of the iodide in 10 ml. of methanol was shaken with the moist silver oxide prepared from 1.0 g. of silver nitrate. After three hours the solution was filtered and the oxide washed with methanol. No attempt was made to isolate the base; however, it was converted directly to the picrate by the addition of 1.0 g. of picric acid in methanol to the methanolic solution of the base. After concentration the picrate was crystallized from methanol–ether; 0.8 g. of orange prisms melting at 188–194°. Recrystallization from methanol raised the melting point to 192–194.5°.

Anal. Calcd. for $C_{30}H_{44}O_8N_4$: C, 61.20; H, 7.54. Found: C, 60.92; H, 7.35.

3-Hydroxy-5,20-pregnadiene (VI).—A solution of 7.2 g. of 3-acetoxy-5-*ternor*-cholenyltrimethylammonium iodide in a mixture of 14.0 g. of potassium hydroxide, 15 ml. of water and 55 ml. of ethylene glycol was boiled, allowing the water vapor to escape until the solution reached a temperature of about 135°. Then heating was continued under reflux. Slowly oil globules separated and trimethylamine was liberated. After six hours the mixture was chilled, diluted with water and extracted with ether. The ether solution was washed with water, dried and treated with glacial acetic acid until a slight excess was present. The mixture was chilled and the white solid was separated by filtration and washed with ether (saved for amine recovery). The ether filtrate was then washed with dilute alkali, water and dried. Upon concentration there remained 2.8 g. (approximately 65% discounting water of crystallization) of a crystalline, white solid which lost water at 110–120° and melted 130–133°. Several recrystallizations from methanol gave colorless plates which frothed at 125–127° and melted 138–139.5°. Upon standing exposed to the atmosphere these crystals became opaque and slowly disintegrated; $[\alpha]^{27}D$ $-85 \pm 1°$ (46.0 mg. made up to 5 ml. with chloroform, α $-0.78°$, l, 1 dm.). For analysis the product was dried for five hours at 1 mm. over boiling chloroform.

Anal. Calcd. for $C_{21}H_{32}O$: C, 83.95; H, 10.72. Found: C, 83.64; H, 11.00.

The solid acetate, 3-hydroxy-5-*ternor*-cholenyldimethylammonium acetate, which was recovered from the reaction mixture weighed 1.4 g. Accounting for this material which may be re-used, the yield of the pregnadiene is 90%.

Upon titration of the pregnadiene in chloroform solution with a solution of bromine in chloroform, this substance absorbed the equivalent of two moles of bromine per mole of compound without liberation of hydrogen bromide. The first mole was absorbed more rapidly than the second but no sharp end-point existed between the two.

Treatment of the 3-hydroxy-pregnadiene with acetic acid–acetic anhydride at steam-bath temperature for one hour afforded **3-acetoxy-5,20-pregnadiene (VII)**. This material after two recrystallizations from methanol existed as white prisms which melted at 132.5–135°. $[\alpha]^{37}\text{D}$ $-76.8 \pm 1°$ (62.5 mg. made up to 5 ml. with chloroform, α $-0.96°$, l, 1 dm.).

Anal. Calcd. for $C_{23}H_{34}O_2$: C, 80.64; H, 10.01. Found: C, 80.53; H, 9.94.

3-Hydroxy-5,20-pregnadiene has also been prepared by conversion of the quaternary iodide to the ammonium hydroxide with moist silver oxide and subsequent pyrolysis of the quaternary base. In one experiment, 1.5 g. of the iodide was treated in 50 ml. of methanol with moist silver oxide prepared from 7.5 g. of silver nitrate. After twelve hours the oxide was separated and the pale yellow filtrate was concentrated *in vacuo*. The residue was pyrolyzed at 210° for fifteen minutes at 1 mm. It was then dissolved in ether, washed with dilute hydrochloric acid and water and dried. The gum which remained after removal of ether was crystallized from petroleum ether (b. p. 35–60°); 0.2 g. of white solid melting at 134° after losing solvent at 113–116°. Decomposition of the quaternary base was also effected by refluxing it in methanolic potassium hydroxide solution. This procedure was also effective in converting the quaternary iodide directly into the diene without employing moist silver oxide for the preparation of the intermediate base. However, the last two methods gave erratic results especially when applied to larger batches. Substitution of ethanol for methanol did not alter the situation.

3-*p*-Toluenesulfonoxy-5,20-pregnadiene (VIII).—A 5.8-g. sample of the 3-hydroxy-diene was dissolved in 13 ml. of pyridine. By warming on the steam-bath, 5.8 g. of *p*-toluenesulfonyl chloride was dissolved in this solution. The mixture was allowed to stand overnight, then diluted with water and extracted with ether. The ether solution was washed successively with dilute hydrochloric acid, water, dilute sodium carbonate solution. The residue remaining after removal of ether from the dried solution was crystallized from ether–petroleum ether (b. p. 35–60°). There resulted 7.4 g. (84%) of white solid which melted at 94–97°. After one crystallization from benzene–petroleum ether and another from petroleum ether, the colorless needles melted at 93.5–96°: $[\alpha]^{26}\text{D}$ $-65 \pm 1°$ (65.0 mg. made up to 5 ml. with chloroform, α $-0.84°$, l, 1 dm.).

Anal. Calcd. for $C_{28}H_{38}O_3S$: C, 73.96; H, 8.42. Found: C, 74.14; H, 8.39.

6-Methoxy-Δ^{20}-*i*-pregnadiene (IX).—A mixture of 5.2 g. of the *p*-toluenesulfonoxy derivative and 150 ml. of methanol containing 10 g. of freshly-fused potassium acetate was refluxed for two hours and allowed to stand overnight. It was then diluted to about 1.5 liters with water and extracted with ether. The extract was washed with water, dilute sodium carbonate solution, water and dried. Upon concentration (finally *in vacuo*) there remained 3.8 g. of a pale yellow sirup. This was dissolved in 50 ml. of petroleum ether (b. p. 35–60°) and treated with 10 g. of activated alumina (Aluminum Ore Company; grade F, −80 mesh). After shaking intermittently for fifteen minutes, the alumina was separated by filtration and washed with 150 ml. of petroleum ether. The filtrate was concentrated *in vacuo* to 3.2 g. (88.5%) of a colorless sirup: $[\alpha]^{27}\text{D}$ $+28.6 \pm 2°$ (43.7 mg. made up to 5 ml. with chloroform, α $+0.25$, l 1 dm.).

Anal. Calcd. for $C_{22}H_{34}O$: C, 84.01; H, 10.91. Found: C, 83.65; H, 10.72.

Methyl 3-Methoxy-5-*etio*-cholenate (X).—To a stirred solution of 2.5 g. of 6-methoxy-Δ^{20}-*i*-pregnadiene in 50 ml. of pyridine and 5 ml. of water, 5.0 g. of powdered potassium permanganate was added portionwise over a period of three hours. The manganese dioxide was filtered and washed with pyridine and water. The filtrate which remained clear upon dilution with water was acidified with dilute acetic acid and extracted with ether. The ether solution was washed with cold dilute sulfuric acid, with water and dried. The sirup which remained upon removal of ether was dissolved in 50 ml. of methanol. Fifteen drops of concd. sulfuric acid was added and the solution was refluxed for three and one-half hours. Water was added cautiously to the chilled solution until crystallization began. After completion of crystallization, the white solid was filtered, washed with aqueous methanol and dried. The solid, 1.5 g., melted at 115–128°. Several recrystallizations from a concentrated methanol solution gave 1.0 g. of white needles melting at 133–134°, $[\alpha]^{38}\text{D}$ $-23 \pm 2°$ (44.3 mg. made up to 5 ml. with chloroform, α, $-0.20°$, l, 1 dm.).

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.25; H, 9.90. Found: C, 76.10; H, 9.71.

The constitution of this *etio*-ester was proven by an independent synthesis. 3-Acetoxy-5-*etio*-cholenic acid was converted to the acid chloride with thionyl chloride in dry ether. The acid chloride when refluxed in methanol for a short period gave methyl 3-hydroxy-5-*etio*-cholenate (m. p. 175–178°). The 3-*p*-toluenesulfonoxy derivative (m. p. 155–157.5°) was prepared from this ester. The former upon refluxing in methanol yielded, as indicated by mixed m. p., the same compound as described above, namely, methyl 3-methoxy-5-*etio*-cholenate.

3-Keto-4,20-pregnadiene (XI).—Nine grams of 3-hydroxy-5,20-pregnadiene was dissolved in a mixture of 100 ml. of toluene and 54 ml. of cyclohexanone and then a few ml. of toluene was distilled in order to remove traces of moisture. After the addition of 9.2 g. of aluminum isopropoxide in 60 ml. of hot toluene, the solution was refluxed for one hour. The solution was then chilled, diluted with dilute hydrochloric acid and extracted with ether. The extract was washed with water, concentrated and then steam distilled. The residue was taken up in ether, washed with water, dilute sodium hydroxide solution and water. The pale yellow, crystalline residue remaining after the removal of ether from the dried solution was recrystallized from a concentrated methanol solution. The product, 7.3 g. (81.6%) of pale yellow prisms, melted at 120–125°. This material is soluble in ether, acetone, methanol, hexane and petroleum ether (b. p. 35–60°). After it was recrystallized several times from a concentrated methanol solution, the diene, practically colorless prisms, melted at 123.5–126.5°: $[\alpha]^{39}\text{D}$ $+106 \pm 1°$ (82.5 mg. made up to 5 ml. with chloroform, α $+1.75°$, l, 1 dm.).

Anal. Calcd. for $C_{21}H_{30}O$: C, 84.52; H, 10.12. Found: C, 84.56; H, 10.13.

3-Keto-4,20-pregnadiene formed a white, crystalline semicarbazone which melted at 243–244°, dec., after recrystallization from chloroform–methanol.

Anal. Calcd. for $C_{22}H_{33}ON_3$: C, 74.32; H, 9.37. Found: C, 74.13; H, 9.20.

3-Keto-4-*etio*-cholenic Acid (XII).—A solution of 2.0 g. of 3-keto-4,20-pregnadiene in 60 ml. of chloroform was ozonized (4.5% O_3 by volume at 0.5 l./min.) for ten minutes at ice-bath temperature. The solution was then steam distilled and the residual waxy solid dissolved in ether. The ether solution was washed with water and then extracted with cold dilute sodium hydroxide solution. Upon acidification of the alkaline solution with dilute hydrochloric acid, a white, crystalline solid separated. The solid was filtered, washed with water and dried; 1.2 g. (56.6%), m. p. 235–250°. After recrystallization from acetone–hexane and from acetone, the acid melted at 250–255°. This material showed no depression in melting point when mixed with an authentic sample of 3-keto-4-*etio*-cholenic acid prepared by the oxidation of 3-hydroxy-5-*etio*-cholenic acid. Reozonization of the neutral fraction yielded an additional quantity of *etio*-acid.

3(α),12(α)-Diacetoxy-20-aminopregnane (XIII).—A solution of 7.2 g. of 3(α),12(α)-diacetoxy-*bisnor*-cholanic acid in 20 ml. of dry benzene and 40 ml. of dry ether was treated with 4.2 ml. of freshly-distilled thionyl chloride. After standing at room temperature for one hour and forty minutes, the solvent was removed *in vacuo* with gentle warming. The last traces of thionyl chloride were removed by sweeping out, *in vacuo*, with several small portions of benzene. At this stage the acid chloride, which had begun to crystallize, was dissolved in 130 ml. of acetone. The solution was chilled in an ice–salt-bath to 0–5° and treated dropwise, with mechanical agitation, over a period of ten minutes with a solution of 2.3 g. of sodium azide in 10 ml. of water. Sodium chloride separated. After an additional twenty minutes of stirring, 200 ml. of cold water was dribbled in with continued stirring. The crystalline azide (a sample of this material melted at 86–90°, dec.) was then filtered, washed with cold water and suspended in 130 ml. of 80% acetic acid. This mixture was heated to 50–60° and held there for one hour. The azide dissolved rapidly and then decomposed with evolution of nitrogen. The solution was filtered, steam distilled for thirty minutes, filtered again and made alkaline with cold dilute sodium carbonate solution. The amine was extracted with ether and washed with water. Upon removal of solvent *in vacuo* from the dried solution there remained 6.2 g. (96.7%) of yellow amorphous material. Attempts to crystallize this material have not been overly successful. A small sample when crystallized from ether and ether–petroleum ether (b. p. 35–60°) melted at 207–209° but was not analytically pure.

The crude amine readily gave an acetamide upon treatment with acetic anhydride in acetic acid; 800 mg. with 4 ml. of acetic acid and 2 ml. of acetic anhydride gave 910 mg. of amide melting at 210–220°. After several recrystallizations from aqueous methanol, it melted at 220–221°.

Anal. Calcd. for $C_{27}H_{43}O_5N$: C, 70.24; H, 9.60. Found: C, 70.14; H, 9.44.

A sample of the crude azide upon warming with ethanol formed the urethan. After several recrystallizations from aqueous ethanol, it melted at 172–173°.

Anal. Calcd. for $C_{28}H_{45}O_6N$: C, 68.39; H, 922. Found: C, 68.23; H, 9.23.

3(α),12(α)-Diacetoxy-20-dimethylaminopregnane (XIV).—A mixture of 5.2 g. of the crude 20-aminopregnane, 6 ml. of 90% formic acid and 4 ml. of 35% aqueous formaldehyde was heated on the steam-bath under reflux for four hours. The orange liquid was poured into cold dilute sodium hydroxide solution and extracted with ether. The ether solution was washed with water, dried and concentrated *in vacuo*. There remained 5.5 g. (99%) of an orange glass. This material when crystallized from petroleum ether (b. p. 35–60°) gave 3.0 g. of white solid, m. p. 115–125° (cloudy). The residue (2.5 g.) in the mother liquor was also reserved for further processing. Several recrystallizations of the solid material from petroleum ether gave small, white needles melting at 134–137°.

Anal. Calcd. for $C_{27}H_{45}O_4N$: C, 72.45; H, 10.14. Found: C, 72.71; H, 10.52.

From one run there was isolated a small portion of material melting at 167–174°. Several recrystallizations from acetone gave fine, white needles melting at 184–187.5°. This material analyzed for an acetoxy-hydroxy-20-dimethylaminopregnane.

Anal. Calcd. for $C_{25}H_{43}O_3N$: C, 74.03; H, 10.68. Found: C, 73.90; H, 10.57.

3(α),12(α)-Diacetoxy-20-pregnene (XV).—A 2.2-g. sample of the crystalline 20-dimethylaminopregnane was dissolved in 20 ml. of benzene, treated with 5 ml. of methyl iodide and refluxed for two hours. The solution was diluted with ether, chilled, and the solid material separated. After washing with petroleum ether (b. p. 35–60°), the dry, pale yellow crystalline quaternary iodide was dissolved in a mixture of 6 ml. of water and 30 ml. of ethylene glycol containing 6 g. of potassium hydroxide. The mixture was refluxed (temperature of boiling solution about 135°) for seven and one-half hours, diluted with water and extracted with ether. The ether solution was then washed with water, dilute hydrochloric acid, water and dried. Concentration of the solution gave a pale yellow glass. This was dissolved in 10 ml. of acetic acid–3 ml. of acetic anhydride and treated with 1 ml. of 5 *N* perchloric acid[10] in acetic acid at ice-bath temperature and then allowed to stand for thirty minutes. Upon dilution with water, a white crystalline solid separated. This was filtered, washed with water and dried; 1.5 g. (75.7%), m. p. 162–175°. Several recrystallizations from methanol gave large needle-like prisms which melted at 184–185°.[11] $[\alpha]^{37}\text{D} + 102 \pm 2°$ (60.9 mg. made up to 5 ml. with chloroform, α 1.24°, *l*, 1 dm.).

Anal. Calcd. for $C_{25}H_{38}O_4$: C, 74.58; H, 9.52. Found: C, 74.63; H, 9.73.

The non-crystalline fraction (2.5 g.) of the diacetoxy-20-dimethylaminopregnane, when treated as described above gave 1.4 g. (62.2%) of crystalline material melting at 162–175°. Recrystallization from methanol raised the melting point to 184–185°.

3-Keto-20,21-dihydroxy-4-pregnene (XVI).—A solution of 1.1 g. of 3-keto-4,20-pregnadiene in 20 ml. of anhydrous ether was added to a solution of 1.0 g. of osmium tetroxide in a like amount of ether. After twenty-two hours at room temperature, the brown solid was separated and washed with ether–petroleum ether (b. p. 35–60°). It was then suspended in 75 ml. of 95% ethanol to which 8 g. of sodium sulfite in 40 ml. of water was added. The mixture was refluxed for four hours and, while hot, filtered to remove the black solid. After washing the solid with hot ethanol, the filtrate was concentrated *in vacuo* to about 20 ml. Upon addition of water, a white solid separated. This was chilled, filtered, washed with water and dried; 0.9 g., m. p. 170–175° after shrinking at 150°. Recrystallization from anhydrous ether gave 0.6 g. of white solid which melted at 176–183°. Four recrystallizations from acetone gave fine, colorless prisms melting at 192.5–194.5°; $[\alpha]^{35}\text{D} + 97 \pm 1°$ (47.3 mg. made up to 5 ml. with chloroform, $\alpha + 0.92°$, *l*, 1 dm.).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.87; H, 9.69. Found: C, 75.75; H, 9.85.

The residual material from the crystallization was chromatographed over 30 g. of activated alumina (Aluminum Ore Co. grade F, −80 mesh) in ether–methanol (9–1). The separation was not sharp, but an intermediate fraction eluted with ether–methanol (9–1) gave a small amount of white solid melting at 164–170° but softening at 140°. Several recrystallizations from acetone gave fine needles melting at 166–168°; $[\alpha]^{27}\text{D} + 98 \pm 1°$ (83.8 mg. made up to 5 ml. with chloroform, α, + 1.65°, *l*, 1 dm.). This material when mixed with a portion of the 192.5–194.5° material melted at 115°.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.87; H, 9.69. Found: C, 75.83; H, 9.87.

3(α),12(α)-Diacetoxy-*etio*-cholanic Acid.—A solution of 1.0 g. of 3(α),12(α)-diacetoxy-20-pregnene in 30 ml. of acetic acid was ozonized for thirty minutes (4.5–5% O_3 at 0.5 l./min.). The solution was then treated with zinc dust, warmed, filtered and steam distilled after the addition of a few ml. of 30% hydrogen peroxide. The residue was dissolved in ether and washed with water. The ether solution was then extracted with cold dilute sodium hydroxide solution. The neutral material remaining in the ether was retreated with ozone and worked for acidic material. Upon addition of dilute hydrochloric acid to the alkaline solution a solid separated. This was filtered, washed with water and dried. It was then acetylated in 8 ml. of acetic acid with 3 ml. of acetic anhydride employing 1 ml. of 5 *N* $HClO_4$ in acetic acid for catalyst.[10] The product was precipitated by addition of water and dried—0.7 g. (67%), m. p. 190–199°. After one recrystallization from ether–pentane the *etio*-acid melted at 195–199° (reported 196–198°[12]).

Summary

1. *bisnor*-Steroid acids have been degraded to Δ^{20}-pregnenes *via* the Curtius procedure to 20-

---

(11) This pregnene may be identical with the compound of m. p. 176–178.5° described by Brink, Clark and Wallis, *J. Biol. Chem.*, **162**, 695 (1946).

(12) Reichstein and von Arx, *Helv. Chim. Acta*, **23**, 747 (1940).

amino-derivatives, followed by Hofmann degradation.

2. Ozonization of 3-keto-4,20-pregnadiene constitutes a better route than any hitherto suggested to 3-keto-4-*etio*-cholenic acid. Likewise ozonization of 3(α),12(α)-diacetoxy-20-pregnene gave 3(α),12(α)-diacetoxy-*etio*-cholanic acid in good yield.

3. Hydroxylation of 3-keto-4,20-pregnadiene gave the isomeric 20,21-diols which have been separated and characterized.

4. This degradation of *bisnor*-acids facilitates the preparation of compounds containing the ketol structure of the cortical hormones.

Studies in the Quinoline Series. IX. The Mononitrophenyllepidylcarbinols and Related Compounds

BY R. STUART TIPSON AND ANNE FARLEY WALTON

In a recent communication,[1] methods were described for the preparation of the three mononitrophenylquinaldylcarbinols and certain of their derivatives. We now describe related work on the lepidyl isomers.

In an attempt to prepare *p*-nitrophenyllepidylcarbinol by Bulach's[2] method (used for the preparation, in good yield, of the corresponding quinaldyl compounds[1]) the yield was only 7% of the theoretical; this is in agreement with Eibner's work[3] showing that a methyl group at position 4 reacts less readily with aldehydes than one at position 2. However, on lengthening the reaction time to eight hours, and changing the method of isolating the product, the yields of the lepidylcarbinols were: *o*- and *p*-, 24%; *m*-, 19%. A lower yield of *m*-derivative had also been noted[1] in the quinaldyl series. The *o*- and *p*-derivatives were isolated directly; because of the greater solubility of the *m*-derivative, it was found more convenient to extract it as the hydrochloride and to reconvert the latter to the base.

When *two* moles of lepidine were used to one of aldehyde, the yield of *m*-carbinol (after eight hours at 120°) was increased to 24%, but for the *o*- and *p*- isomers there was no great improvement in yield of isolable product (presumably because these compounds were, to a somewhat greater extent, retained in solution in the excess lepidine, and the dissolved part could not be readily separated from it). Various attempts were made to increase the yield of *m*-derivative still further. It was found that heating the reaction mixture at 120° for twenty-four hours, or at 145° for eight hours, always gave a mixture of the carbinol and the corresponding *styryl* compound. Moreover, after cooling to room temperature, the reaction mixture was invariably found to be acid to litmus and it was concluded that this acid, presumably formed from the aldehyde during the reaction, had facilitated conversion of some of the carbinol to the styryl derivative. (The ability of acid to catalyze this dehydration has already been proved[1] for the corresponding quinaldyl carbinols.) It was therefore decided to add to the reaction mixture some substance which would neutralize acid as fast as it was formed. After examining the effect of a number of materials, anhydrous sodium carbonate was finally selected, and the reaction mixture was heated at 145° for twenty-four hours. At the end of this time, the reaction mixture was still alkaline to litmus, and *no* styryl derivative had formed, but the yield obtained (33%), though higher, was scarcely increased enough to warrant using this method.

Just as for the three quinaldyl isomers, we find the three nitrophenyllepidylcarbinols exhibit two melting points, depending on whether heated rapidly or slowly. On cooling until crystallized and remelting, the melting point is found to be lower in each case, presumably owing to partial conversion to the corresponding styryl derivative on heating. The carbinols were transformed to their monohydrochlorides which were isolated as colorless, crystalline substances showing no tendency to become dehydrated to the styryl derivatives during five months at room temperature, as evidenced by the recovery of pure carbinol on reconversion to the base. The acetyl derivatives of the three carbinol compounds were also prepared. Attempts to reduce each nitro carbinol to the corresponding amino derivative gave inconclusive results suggestive of formation of some β-hydroxylamino derivative[4]; we were unable to purify the products satisfactorily by fractional recrystallization.

It has been shown previously[5] that the reaction of *p*-dimethylaminobenzaldehyde with quinaldine gives rise to the corresponding styryl derivative *plus* *p*-dimethylaminobenzylidene diquinaldine (β-*p*-dimethylaminophenyl-α,γ-di-2-quinolylpropane) and that a preponderance of either product is obtainable by appropriate choice of the conditions. Similarly, on attempting to prepare the pure *styryl* derivatives by condensation of the appropriate nitrobenzaldehyde with lepidine in

[a] Loew (*Ber.*, **36**, 1666 (1903)) gave m. p. 162°. [b] Heymann and Koenigs (*Ber.*, **21**, 2167, 1424 (1888)) gave m. p. 131–132° and 135–136°; Kaslow and Stayner (THIS JOURNAL, **67**, 1716 (1945)) gave 130.5–131.5°. [c] Loew, ref. *a*, gave 221°.

the presence of an inorganic acid, it was found that the *dilepidine* derivatives are formed together with the nitrostyryl compounds. Indeed, the *m*- and *p*-nitrobenzylidene dilepidines could be isolated in good yield (77% and 63%, respectively, of the theoretical amount) by heating one mole of the appropriate aldehyde with two moles of lepidine in the presence of concentrated sulfuric acid for three hours at 165° (bath temperature). On the other hand, on treating lepidine with the *o*-aldehyde under the same conditions, a violent reaction ensued, resulting in extensive decomposition. At a reaction temperature of 100°, a mixture of the *o*-nitrostyryl-quinoline and its corresponding *carbinol* derivative was formed.

The three 4-(nitrostyryl) derivatives have now been isolated in pure form and are found to have melting points higher than those previously recorded in the literature. The *o*-nitrostyryl derivative was readily prepared pure since it was the *sole* product resulting either on boiling a solution of the pure carbinol compound in acetic anhydride,[2,6] or on boiling a solution of the *o*-aldehyde and lepidine in acetic anhydride.

The 4-(*m*-nitrostyryl)-quinoline could not be obtained as the *sole* product in any of the reactions attempted. On performing the reactions involving acetic anhydride (successfully used to prepare the pure *o*-styryl compound), the *m*-nitrostyryl derivative formed was contaminated with a higher melting, more insoluble compound (either the carbinol or dilepidine derivative, depending on the conditions). When propionic anhydride (b. p. 165–168°) was used instead of acetic anhydride, a mixture of the styryl and carbinol derivatives resulted. Again, on heating equimolecular proportions of aldehyde and lepidine in the presence of hydrochloric or sulfuric acids, a mixture of the styryl and dilepidine compounds was obtained. It was difficult to separate pure *m*-nitrostyryl compound from these more insoluble derivatives, but we succeeded in isolating it by fractional recrystallization of its mixture with the dilepidine compound.

On boiling pure *p*-nitrophenyllepidylcarbinol with acetic anhydride, the product consisted essentially of the styryl derivative plus a trace of *p*-nitrobenzaldehyde, which was detected by sublimation. This scission of *p*-nitrobenzaldehyde from the nitrophenyllepidylcarbinol molecule was presumably accompanied by formation of the corresponding amount of the dilepidine derivative. When lepidine was heated with *p*-nitrobenzaldehyde in the presence of hydrochloric acid, the styryl derivative was formed together with the dilepidine compound (which could not be removed by repeated crystallization), but the pure *p*-styryl compound was separable therefrom by conversion to the hydrochloride; the hydrochloride of the dilepidine derivative is fairly soluble in boiling water, whereas that of the *p*-nitrostyryl derivative is difficultly soluble.

Experimental

o- and p-Nitrophenyllepidylcarbinols.—The nitrobenzaldehyde (10.6 g., completely free from acid[1]) was treated with distilled lepidine (10 g.) at 120° (temperature of reaction mixture) during eight hours, and then allowed to stand overnight at room temperature. Chloroform (50 cc.) was now added to the partly crystalline mixture, the suspension cooled in ice during several hours, and filtered. The crystals were washed with two 10-cc. portions of chloroform and dried in the vacuum desiccator over phosphorus pentoxide.

A small second crop was obtained by extracting the chloroform filtrate with three 50-cc. portions of 5 *N* hydrochloric acid. The *aqueous* layer was separated from the chloroform layer (A), made alkaline to litmus with 8 *N* sodium hydroxide solution, and the lepidine plus product extracted with chloroform. The chloroform extract was washed, dried over anhydrous sodium sulfate, and evaporated to dryness. Heptane (50 cc.) was added to the resulting dark oil, and, on scratching and chilling, a second crop of crystals appeared. (The *chloroform* layer (A) was freed from acid by shaking with dilute sodium hydroxide solution, washed, dried, filtered and evaporated to dryness, giving unchanged aldehyde which could be used directly for another preparation.)

The crude product was recrystallized from a boiling mixture of ethanol and chloroform (see Table I); the hot solution was filtered and the filtrate cooled and kept overnight in the refrigerator. The *o*- and *p*-nitrophenyllepidylcarbinols were obtained as pale yellow crystals, fairly soluble in hot methanol, ethanol, chloroform, and acetone, and sparingly soluble in ether, benzene, and heptane. They were more soluble in methanol than in any of the other solvents mentioned. The *o*-compound was slightly more soluble than the *p*- in all these solvents.

---

(6) Wartanian, *Ber.*, **23**, 3644 (1890).

m-Nitrophenyllepidylcarbinol.—*m*-Nitrobenzaldehyde (10.6 g., free from acid) was heated, as in the previous section, but with *two* molar proportions of distilled lepidine (20 g.), and then kept overnight at room temperature. The resulting oil was washed into a flask with 50 cc. of chloroform and 5 *N* hydrochloric acid (50 cc.) was added, whereupon the fairly insoluble, colorless carbinol hydrochloride slowly separated out in the aqueous layer. The mixture was kept in an ice-bath for two hours, and the solid was then filtered off and washed successively with 5 *N* hydrochloric acid (25 cc.) and chloroform. The hydrochloride was now suspended in about 50 cc. of water, and 8 *N* sodium hydroxide solution was added until, after vigorous shaking, the suspension remained alkaline to litmus. The precipitated base was dissolved by extracting with chloroform, and the chloroform solution washed with water, dried over anhydrous sodium sulfate, filtered and evaporated to dryness. The yield of crude product was 24% of the theoretical. It was recrystallized from boiling ethanol (see Table I) and was obtained as colorless crystals. It was more soluble than the corresponding *o*- or *p*-compounds in all the solvents tested.

The yield was increased to 33% of the theoretical amount by heating 2 moles of lepidine plus 1 mole of the aldehyde and 0.5 mole of anhydrous sodium carbonate, with continuous stirring, during twenty-four hours at 145°.

Nitrophenyllepidylcarbinol Monohydrochlorides.—The base (2 g.) was dissolved in the minimum volume of cold chloroform and the calculated amount of concentrated hydrochloric acid (0.25 g.), dissolved in 10 cc. of absolute ethanol, was added rapidly to the solution, with stirring. A colorless precipitate of hydrochloride appeared slowly; after keeping the mixture overnight at room temperature, this was filtered off, washed successively with 10 cc. of ethanol and 10 cc. of chloroform, and dried.

All three hydrochlorides were obtained as colorless crystals which were stable at room temperature but started to decompose at about 200°. They were slightly soluble in water and sparingly soluble in absolute ethanol, the salt of the *m*-compound being more soluble than the hydrochlorides of either the *o*- or *p*-derivatives.

Anal. Calcd. for $C_{17}H_{14}N_2O_3 \cdot HCl$: N, 8.48. Found: (*o*-), N, 8.53; (*m*), N, 8.63; (*p*-), N, 8.51.

Samples of each were stored at room temperature for five months and then reconverted to the free base; there was no change in m. p. or analysis.

Acetylation of the Nitrophenyllepidylcarbinols.—The carbinols were acetylated as previously described[1] for the acetylation of *m*-nitrophenylquinaldylcarbinol; yield, quantitative.

o-Nitrophenyllepidylcarbinyl Acetate.—The crude compound was recrystallized from 10 volumes of hot absolute ethanol, the resulting crystals were dissolved in 3 volumes of chloroform, hexane (10 volumes) was added to faint opalescence, and the solution kept overnight in the refrigerator; colorless crystals; m. p. 103–105°.

Anal. Calcd. for $C_{19}H_{16}N_2O_4$: C, 67.83; H, 4.8; N, 8.34. Found: C, 68.19; H, 5.0; N, 8.16.

m-Nitrophenyllepidylcarbinyl Acetate.—The crude compound was first recrystallized from 9 volumes of methanol by adding 6.5 volumes of water. The resulting crystals were dried, extracted with 20 volumes of cold, dry ether, and the pure, colorless, acetyl derivative filtered off and dried; m. p. 95–97°.

Anal. Calcd. for $C_{19}H_{1}\ {}_{2}O_4$: C, 67.83; H, 4.8; N, 8.34. Found: C, 67.81, H, 4.8; N, 8.40.

p-Nitrophenyllepidylcarbinyl Acetate.—The crude compound was recrystallized from 7 volumes of boiling absolute ethanol; pale yellow crystals, m. p. 120–121.5°.

Anal. Calcd. for $C_{19}H_{16}N_2O_4$: C, 67.83; H, 4.8; N, 8.34. Found: C, 67.87; H, 5.0; N, 8.22.

m-Nitrobenzylidene Dilepidine.—A mixture of lepidine (10 g.), *m*-nitrobenzaldehyde (5.3 g.) and concentrated sulfuric acid (1.4 g.) was heated for three hours at 165° (glycerol bath) in a two-necked flask (thermometer). It was then cooled to room temperature and dilute sodium hydroxide solution added to the reaction mixture. After standing overnight at room temperature, the lumps of solid were readily broken up, the solid was transferred to a large beaker with water, 8 *N* sodium hydroxide was added until the solution was alkaline to litmus, and the mixture allowed to stand for about seven hours. The solid was then filtered off, washed with water until the washings were free from sulfate (barium hydroxide test), and dried; weight (cocoa-colored solid), 14.2 g.

The crude product was treated with 10 volumes of boiling absolute ethanol during one hour, the suspension cooled in ice, and the light-brown solid filtered off and dried. The weight of crude dilepidine compound was 11.2 g. (77%); m. p., 226–232° (shrinks at 220°).

The alcoholic mother liquor was evaporated to dryness (2.9 g.) and found to consist essentially of the styryl derivative.

Recrystallization of the crude dilepidine compound from boiling chloroform and absolute ethanol was unsatisfactory. One gram of material (partially purified thus) was treated with 75 cc. of water plus 2 cc. of concentrated hydrochloric acid. A trace of undissolved solid was filtered off and 8 *N* sodium hydroxide (about 3 cc.) was added to the filtrate until the solution was alkaline to litmus. The pure, colorless dilepidine compound which separated was filtered off and dried (0.8 g.); shrinks at 220°, followed by partial melting, and melts to brown liquid at 227–232°. This melt would not resolidify on cooling to room temperature.

Anal. Calcd. for $C_{27}H_{21}N_3O_2$: C, 77.29; H, 5.1; N, 10.03. Found: C, 77.24; H, 4.7; N, 9.89.

p-Nitrobenzylidene Dilepidine.—The procedure for preparing the *p*-dilepidine compound was initially similar to the one used for the corresponding *m*-compound but, after filtering it from the first alkaline solution, the cocoa-colored solid was suspended in water and enough 5 *N* hydrochloric acid was added to bring the solution to *p*H 1–3. The undissolved material was filtered off, suspended in dilute sodium hydroxide solution, the orange-colored product filtered off, washed with water and dried (13.3 g.).

The crude product was treated with a boiling mixture of absolute ethanol (10 volumes) and chloroform (15 volumes) during one hour, cooled to room temperature, and the undissolved solid was filtered off and dried; 6.1 g. of pink crystals. A second crop (3.2 g.) was obtained by allowing the mother liquor of this first crop to stand in the refrigerator for several days; total yield of crude product, 63%.

The mother liquor of the second crop was evaporated to dryness (4.1 g.) and found to be mainly composed of the styryl derivative.

The crude dilepidine compound (2 g.) was treated with 150 cc. of boiling 1% hydrochloric acid, the hot suspension filtered, and dilute sodium hydroxide added to the filtrate, giving colorless, free base; shrinks at 220°, followed by partial melting, and melts to a dark brown liquid at 237–240°.

Anal. Calcd. for $C_{27}H_{21}N_3O_2$: C, 77.29; H, 5.1; N, 10.03. Found: C, 77.25; H, 5.4; N, 10.15.

4-(o-Nitrostyryl)-quinoline.—A solution of pure *o*-nitrophenyllepidylcarbinol (2 g.) in 8 cc. of acetic anhydride was boiled under reflux for two hours, and the solution cooled and poured into 250 cc. of ice plus water, with stirring. The product was filtered off, washed with water until the washings were neutral to litmus, and dried; yield of crude product, 80% of the theoretical (increased to quantitative yield by working up the aqueous mother liquor). It was recrystallized from 15 volumes of boiling absolute ethanol plus 5 volumes of chloroform, giving bright yellow crystals having a silvery sheen.

4-(*o*-Nitrostyryl)-6-methoxyquinoline was prepared as for the 4-styryl derivative[7]; unchanged starting materials were removed by distillation[7] at 0.05 mm. The still residue was crystallized from absolute ethanol (m. p., 122–124°) and recrystallized from pyridine (10 volumes) plus water (10 volumes), giving bright yellow crystals, m. p., 128–129°.

---

[7] Campbell, Tipson, *et al.*, *J. Org. Chem.*, **11**, 803 (1946).

Anal. Calcd. for $C_{18}H_{14}N_2O_3$: C, 70.56; H, 4.6; N, 9.15. Found: C, 70.48; H, 4.5; N, 9.44.

4-(*m*-Nitrostyryl)-quinoline.—After repeated recrystallization, the styryl compound was finally obtained in pure form from a mixture with the corresponding dilepidine derivative.

Lepidine (5 g.), *m*-nitrobenzaldehyde (5.3 g.), and 3 cc. of concentrated hydrochloric acid were heated in a two-necked flask at 120° (inside temperature) during three hours. After cooling to room temperature, chloroform (50 cc.) was added and the mixture kept in an ice-bath for two hours. The solid was then filtered off, washed with 50 cc. of chloroform, the yellow-brown crystals suspended in water, and made alkaline to litmus with 8 *N* sodium hydroxide solution. The yellow solid was dissolved in chloroform, the solution washed with water, dried over anhydrous sodium sulfate, filtered, and the filtrate evaporated to dryness, giving 6.2 g. of yellow solid.

The crude product was dissolved in 15 volumes of boiling absolute ethanol plus 8 volumes of chloroform, filtered, and the filtrate kept in the refrigerator overnight. A small crop of cream-colored crystals which separated was filtered off and dried (0.7 g.); m. p. 220–230°. Microchemical analysis indicated that it was slightly impure dilepidine derivative. The mother liquor was kept in the refrigerator for a week, giving a second crop of cream-colored solid (0.5 g.); m. p. 217–231°.

The mother liquor of the second crop was evaporated to dryness (4.9 g.); m. p. 130–134°. It was recrystallized from 8 volumes of boiling absolute ethanol. The pure *m*-styryl compound separated on cooling, and was filtered off and dried (3.7 g.).

4-(*p*-Nitrostyryl)-quinoline.—When prepared as described for the *m*-styryl compound, in the presence of hydrochloric acid, the *p*-styryl derivative could not be separated from its impurity (probably the dilepidine compound) by repeated recrystallization. The most satisfactory method for obtaining the pure *p*-styryl compound when the impurity was the dilepidine derivative (*not* the carbinol compound) was by treatment with hydrochloric acid, as follows:

Impure *p*-styryl derivative (4 g.) was treated with 240 cc. of chloroform and a trace (0.1 g.) of insoluble material (which seemed to consist mainly of the more insoluble dilepidine derivative) filtered off. To the filtrate was added 100 cc. of 5% hydrochloric acid and the mixture swirled. The hydrochlorides which separated were filtered off, suspended in 150 cc. of 1% hydrochloric acid, the suspension boiled for a few minutes, filtered while hot, and the yellow solid washed with about 50 cc. of hot 1% hydrochloric acid. The solid hydrochloride was then suspended in dilute sodium hydroxide solution, the base extracted with chloroform, the chloroform solution washed with water, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness (2.5 g.). This material was now recrystallized by dissolving in 15 volumes of boiling absolute ethanol plus 25 volumes of chloroform. The solution was kept in the refrigerator overnight, and the crystals filtered off and dried (2.2 g.).

Summary

The three mononitrophenyllepidylcarbinols and their acetates and monohydrochlorides have been prepared and some of their properties are described. The corresponding styryl derivatives were isolated in pure form.

A method has been developed for the preparation of the *m*- and *p*-nitrobenzylidene dilepidines in good yield, and some of their properties are recorded.

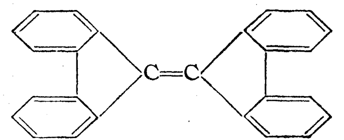
The Addition of Grignard Reagents to the Olefin, Bidiphenyleneethylene

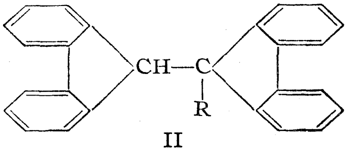
BY REYNOLD C. FUSON AND HERSCHEL D. PORTER[1]

Attempts to add Grignard reagents to olefins, involving a large number of hydrocarbons and a wide range of experimental conditions, have yielded only negative results.[2,3,4] Apparently successful attempts reported in some instances,[5,6] were subsequently found to have been misleading.[7]

The demonstration by Pinck and Hilbert[8] that bidiphenylethylene (I) as well as its tetrabromo derivative was capable of reacting additively with various carbonyl reagents suggested that this highly conjugated olefin might also combine with Grignard reagents. This idea was favored by the discovery of Ziegler and Schäfer[9] that phenyllithium condensed with bidiphenyleneethylene to give 1-phenyl-1,2-bidiphenyleneethane (II, R = C_6H_5).



I



II

In the present work it has been found that certain Grignard reagents will react with bidiphenyleneethylene to produce the corresponding substituted ethanes (II). It appeared that the best chance of success was to employ *t*-butyl or benzyl Grignard reagents, shown by Kharasch and Weinhouse[10] to be the most reactive.

When *t*-butylmagnesium chloride was allowed to react with bidiphenyleneethylene, 1-*t*-butylbidiphenyleneethane (II, R = C_4H_9) was produced in good yield. Similarly, benzylmagnesium chlo-

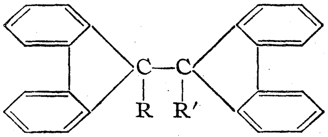
ride gave 1-benzylbidiphenyleneethane (II, R = $C_6H_5CH_2$). In one experiment with the benzyl reagent the chief product was 1,2-dibenzylbidiphenyleneethane (III, R = R′ = $C_6H_5CH_2$). It seemed likely that this product formed through benzylation of the primary adduct by excess benzyl chloride present in the solution of the Grignard reagent. In confirmation of this surmise, it was found that the dibenzyl derivative could be made in good yield by treating the olefin with benzylmagnesium chloride and then adding benzyl chloride to the resulting reaction mixture.

p-Chlorobenzylmagnesium chloride reacted in much the same way as the benzyl Grignard reagent. The structures assigned to the alkylated ethanes are indicated by analogy with the products obtained in other addition reactions of the olefin. They are given additional support by the following observations.



III

Treatment of the addition product from the olefin and benzylmagnesium chloride with *p*-chlorobenzyl chloride yielded 1-benzyl-2-*p*-chlorobenzylbidiphenyleneethane (III, R = $C_6H_5CH_2$, R′ = $ClC_6H_4CH_2$). The same derivative was formed by benzylation of the adduct from *p*-chlorobenzylmagnesium chloride and the olefin.

The bidiphenyleneethylene was prepared by the action of methanolic potassium hydroxide on 9-bromofluorene according to the directions of Thiele and Wanscheidt.[11] The bromofluorene was synthesized by a new method—treatment of fluorene with N-bromosuccinimide by the procedure of Ziegler, Späth, Schaaf, Schumann and Winkelmann.[12] The bromofluorene was made also by photochemical bromination of fluorene by the procedure of Sampey and Reid.[13] This method has the advantage of extreme simplicity and affords higher yields.

Attempts to condense less reactive Grignard reagents with bidiphenyleneethylene failed. Neither phenylmagnesium bromide nor methylmagnesium iodide proved to be capable of undergoing addition.

Inasmuch as Ziegler, Späth, Schaaf, Schumann and Winkelmann[12] have been able to add phenyllithium to benzalfluorene, it seemed possible that the Grignard reagent might react in a similar manner. Efforts to bring about condensation of this olefin with *t*-butylmagnesium chloride were, however, unsuccessful.

Experimental

9-Bromofluorene.—A solution of 99.6 g. of commercial fluorene (m. p. 108–111°) in 500 ml. of dry thiophene-free benzene was heated for four hours under reflux with an equimolar amount (106.8 g.) of N-bromosuccinimide, prepared (in 71% yield) by the directions of Ziegler, Späth, Schaaf, Schumann and Winkelmann.[12] The precipitate of succinimide which formed during this process was removed by filtration, the solvent distilled from the filtrate, and the residue taken up in 500 ml. of hot, high-boiling petroleum ether. Cooling caused long needle-like crystals of 9-bromofluorene to precipitate; yield 69 g., 47%; m. p. 103–104°.

The bromofluorene was also prepared, in approximately the yields reported, by the photochemical bromination of fluorene according to the directions of Sampey and Reid.[13]

Bidiphenyleneethylene.—The general directions of Thiele and Wanscheidt[11] were followed. A solution of 20 g. of 9-bromofluorene in 150 ml. of acetone was caused to react at room temperature with a solution of 10 g. of potassium hydroxide in 30 ml. of methanol. After one hour, 100 ml. of water was added, with vigorous stirring. The precipitate of bidiphenyleneethylene was collected by filtration and allowed to dry in the air overnight. The products of two such preparations were taken up in 50 ml. of boiling benzene, and precipitation was induced by the addition of 50 ml. of boiling alcohol; yield 64%; m. p. 188–190° (uncor.).

1-*t*-Butyl-1,2-bidiphenyleneethane.—A solution of *t*-butylmagnesium chloride, prepared from 9.25 g. of *t*-butyl chloride, 2.43 g. of magnesium and 130 ml. of absolute ether, was freed of magnesium by forcing it through a glass wool plug by means of nitrogen pressure. The *t*-butylmagnesium chloride was added to a solution of 3.28 g. of bidiphenyleneethylene in 100 ml. of a mixture of equal parts of dry benzene and absolute ether. After the material had been heated for eighteen hours under reflux in an atmosphere of nitrogen, with constant stirring, it was poured on an ice–hydrochloric acid mixture. The organic layer was separated and washed with very dilute hydrochloric acid. After the solvent had been removed by distillation, the residue was taken up in 15 ml. of boiling chloroform; precipitation was induced by the addition of 30 ml. of 95% ethanol; yield 2.63 g., or 68%. After the above purification procedure had been repeated ten times, the material was found to be analytically pure; m. p. 221–223° (cor.).

Anal. Calcd. for $C_{30}H_{26}$: C, 93.22; H, 6.78. Found: C, 93.24; H, 6.90.

1-Benzyl-1,2-bidiphenyleneethane.—A solution of benzylmagnesium chloride, prepared from 5.06 g. of benzyl chloride, 0.97 g. of magnesium and 100 ml. of absolute ether, was heated under reflux for one hour. Bidiphenyleneethylene (3.28 g.) was added in the form of small crystals. The solution was stirred overnight under gentle reflux, poured on an ice–hydrochloric acid mixture and processed as in the preceding experiment. A precipitate of 2.42 g. of light yellow needles melting at 223–231° (uncor.) was obtained; yield 57.6%. The sample for analysis did not reach a constant melting point until it had been subjected to twelve purifications in the manner described for the purification of 1-*t*-butyl-1,2-bidiphenyleneethane; m. p. 240–241° (cor.).

Anal. Calcd. for $C_{33}H_{24}$: C, 94.24; H, 5.75. Found: C, 94.25; H, 5.92.

1-*p*-Chlorobenzyl-1,2-bidiphenyleneethane.—A solution of *p*-chlorobenzylmagnesium chloride was prepared by the dropwise addition of 3.22 g. of *p*-chlorobenzyl chloride to 0.49 g. of magnesium in 50 ml. of absolute ether. After the solution was stirred under reflux for one hour, 3.28 g. of bidiphenyleneethylene was added in the form of small crystals. The solution was heated under reflux in an atmosphere of dry nitrogen for sixteen hours and worked up in the usual manner. Removal of the solvent produced a red oil which deposited yellow crystals when triturated with 100 ml. of low-boiling petroleum

ether. The compound was purified in the manner described for 1-*t*-butyl-1,2-bidiphenyleneethane; m. p. 234–235° (cor.); yield 12.5%.

Anal. Calcd. for $C_{33}H_{23}Cl$: C, 87.11; H, 5.10. Found: C, 86.97; H, 5.38.

1,2-Dibenzyl-1,2-bidiphenyleneethane.—A solution of benzylmagnesium chloride was formed by the addition of 0.67 g. of benzyl chloride to 0.14 g. of magnesium in 16 ml. of absolute ether. One gram of bidiphenyleneethylene was added immediately after the addition of the benzyl chloride was complete. The reaction mixture was diluted with 50 ml. of absolute ether, heated under reflux overnight and processed in the usual manner. The analytical sample was prepared by repeated recrystallization from a solvent composed of six parts of benzene and one part of toluene; m. p. 204–205° (cor.); yield 36%.

Anal. Calcd. for $C_{40}H_{30}$: C, 94.07; H, 5.93. Found: C, 93.80; H, 6.27.

A solution of benzylmagnesium chloride, prepared from 2.53 g. (0.02 mole) of benzyl chloride, 0.48 g. of magnesium and 50 ml. of absolute ether, was protected from the air by a stream of dry nitrogen and stirred for one hour to ensure completion of the reaction. A solution of 3.28 g. (0.01 mole) of bidiphenyleneethylene in 50 ml. of dry benzene and 30 ml. of absolute ether was then added. After the solution had been heated under reflux for four hours, 3 g. of benzyl chloride was added. The mixture was heated under reflux for fifteen hours and processed in the usual manner. The product was purified by dissolving in hot chloroform and reprecipitating by the addition of boiling alcohol. After two such operations the melting point was 196–198° (uncor.); a mixed melting point with the 1,2-dibenzyl-1,2-bidiphenyleneethane obtained previously was not depressed (196–198°).

1-Benzyl-2-*p*-chlorobenzyl-1,2-bidiphenyleneethane.—The benzylmagnesium chloride was prepared as in the preceding experiment and allowed to react with 3.28 g. of bidiphenyleneethylene dissolved in 100 ml. of a solvent composed of equal parts of dry benzene and absolute ether. After the solution had been heated under reflux for eighteen hours, 3.50 g. of *p*-chlorobenzyl chloride was added, and the reaction mixture was heated overnight under reflux, with mechanical stirring. The reaction mixture was poured on an ice–hydrochloric acid mixture, and the organic layer was washed with water. The reddish oil that remained, after removal of the solvent and trituration with low-boiling petroleum ether, deposited 1.69 g. of yellow, sandy crystals. Purification was accomplished by dissolving the compound in hot chloroform, and reprecipitating it by the addition of boiling alcohol. The analytical sample consisted of white needles and possessed a melting point of 203–205° (uncor.).

Anal. Calcd. for $C_{40}H_{29}Cl$: C, 88.13; H, 5.36. Found: C, 87.87; H, 5.66.

The addition product of *p*-chlorobenzylmagnesium chloride and bidiphenyleneethylene was prepared as in the preparation of 1-*p*-chlorobenzyl-1,2-bidiphenyleneethane. After the reaction mixture had been heated under reflux for eight hours, 2.78 g. of benzyl chloride was added, and the solution was heated under reflux overnight. The reaction mixture was poured on an ice–hydrochloric acid mixture; the organic layer was separated, washed with water and evaporated to dryness. The residual, red oil was triturated with a mixture of 8 ml. of benzene and 4 ml. of carbon tetrachloride in a bath of solid carbon dioxide; a precipitate of 0.37 g. (7%) was deposited. The material was purified as in the above experiment. Softening occurred at 195–199° and melting took place at 199–202°. A mixture with the product obtained in the preceding experiment softened at 196–199° and melted at 199–203°.

Attempted Reaction with Phenylmagnesium Bromide.—A solution of phenylmagnesium bromide, prepared from 3.14 g. of bromobenzene, was protected at all times from the air by an atmosphere of nitrogen. Bidiphenyleneethylene (3.2 g.) was added, and the solution was heated under reflux for twenty-five hours. It was then poured on an ice–hydrochloric acid mixture and worked up in the usual manner. A total of 2.84 g. (89%) of the original hydrocarbon was recovered.

Attempted Reaction with Methylmagnesium Iodide.—An ether solution, containing 0.02 mole of methylmagnesium iodide, was heated overnight under reflux with 3.28 g. (0.01 mole) of bidiphenyleneethylene. In addition to 2.53 g. (77%) of bidiphenyleneethylene recovered, a small amount of bidiphenyleneethane was obtained; m. p. 247–248° (cor.).

Anal. Calcd. for $C_{26}H_{18}$: C, 94.50; H, 5.49. Found: C, 94.45; H, 5.75.

Attempted Reaction of Grignard Reagents with Benzalfluorene.—The Grignard solution was prepared as described in the preparation of 1-*t*-butyl-1,2-bidiphenyleneethane. A solution of 2.55 g. of benzalfluorene, prepared in 70% yield according to the directions of Henle,[14] in 50 ml. of absolute ether was added, and the solution heated overnight under reflux in an atmosphere of nitrogen. A total of 2.11 g. (83%) of unchanged benzalfluorene was obtained.

In a similar experiment 5.10 g. (0.02 mole) of benzalfluorene was added to a solution of 0.04 mole of benzylmagnesium chloride, and the solution was heated under reflux for twenty-four hours. A total of 4.33 g. (84%) of unchanged benzalfluorene was recovered.

Summary

Grignard reagents have been found to react additively with the olefin, bidiphenyleneethylene. Reaction with *t*-butyl-, benzyl- or *p*-chlorobenzylmagnesium chlorides converts the olefin to the corresponding 1-alkylbidiphenyleneethane.

When the adduct obtained with benzylmagnesium chloride was treated with *p*-chlorobenzyl chloride, the product was 1-benzyl-2-chlorobenzylbidiphenyleneethane. The same compound was produced by the action of benzyl chloride on the adduct formed by *p*-chlorobenzylmagnesium chloride and the olefin. These facts show that the two points of attachment of the Grignard reagent are symmetrically situated.

Studies on the Reactions between Formaldehyde and Enediols.[1a] I

BY F. J. REITHEL AND E. S. WEST

Krishnamurthy[1b] showed that ascorbic acid reacted with formaldehyde as evidenced by a marked decrease in reducing power when titrated with 2,6-dichlorophenol-indophenol or iodine. Lugg[2] found that ascorbic acid reacted readily with formaldehyde at *p*H 3.5 but slowly at *p*H 1.5, that some reducing substances reacted readily at both *p*H values, and still others, among them a crude preparation of reductone, reacted with formaldehyde at neither *p*H value. A critical study of Lugg's work was made by Snow and Zilva,[3] who found that reductone did react with formaldehyde but more slowly. Mapson[4] has also published some observations.

The prime purpose of these investigators was to develop a method for determining ascorbic acid in foods and biological products which would be more accurate than the simple method of dye titration. In addition, both Lugg[2] and Snow and Zilva[3] attempted to discover the nature of the reaction between enediols and formaldehyde. Extensive data were obtained on reaction velocities and equilibrium constants were determined but the reaction products could not be isolated.

In 1937, one of the present authors[5] noted the fact that formaldehyde abolished the reducing power of ascorbic acid. A study of this phenomenon produced evidence that *l*-ascorbic acid, *d*-isoascorbic acid, *d*-gluco-ascorbic acid, α-hydroxytetronic acid, reductone, and dihydroxymaleic acid lost the ability to reduce 2,6-dichlorophenol-indophenol when they were treated with formaldehyde. Furthermore, it was found that under the proper conditions mixtures of ascorbic acids and formaldehyde and similar mixtures of α-hydroxytetronic acid and formaldehyde slowly evolved carbon dioxide.

Like Snow and Zilva[3] we attempted to isolate a reaction product from mixtures of *l*-ascorbic acid and formaldehyde but no crystalline product was ever obtained. The sirupy material formed on removal of excess formaldehyde and evaporation of such reaction mixtures was investigated by many of the standard methods of carbohydrate chemistry such as methylation, acetylation, tritylation, periodic acid oxidation and permanganate oxidation. An acetone derivative and a semicarbazide were obtained in crystalline form but in very small yield. We concluded that a complex mixture of compounds was formed.

The following is a study of the reactions between enediols and formaldehyde at *p*H 3.5–6.0, utilizing carbon dioxide production as a criterion of reaction.

Experimental

1. **Carbon Dioxide Formation by Ascorbic Acid–Formaldehyde Mixtures.**—Two-hundred fifty milligrams of ascorbic acid was dissolved in 25 ml. of carbon dioxide- and oxygen- free water and neutralized to *p*H 7.2 with sodium hydroxide. Two and five-tenths milliliters of 37% formaldehyde was added and the mixture introduced into a small flask with a side arm arranged so that any carbon dioxide produced could be swept into an absorbing spiral immersed in barium hydroxide by a stream of nitrogen (purified over hot copper). The mixture was allowed to react at 60° for four hours, then acidified: carbon dioxide found, 52.8 mg.; theoretical (assuming one mole of carbon dioxide per mole of ascorbic acid), 62.5 mg.

In an exactly similar experiment calcium hydroxide was used to bring the *p*H to 7.65. Reaction was allowed to proceed for four hours at 60°, then acidified to liberate carbon dioxide from the calcium carbonate precipitate; carbon dioxide found, 57.7 mg.

A third experiment was done using the same quantities and conditions except that no alkali was added. After five hours at 60°, 62.2 mg. of carbon dioxide was produced.

Other variables were checked and the following observations made. Never was there obtained more than one mole of carbon dioxide per mole of ascorbic acid. The reaction proceeded somewhat more rapidly in alkaline than in acid solution. The reaction was slower at 30° than at 60° but the rate was appreciable. In blank experiments where no formaldehyde was added no carbon dioxide was obtained from ascorbic acid.

Several experiments were conducted to determine the effect of formaldehyde on the optical rotation of ascorbic acid. We found, as did Snow and Zilva, that the phenomenon was not simple. If the reaction mixture was allowed to remain in polariscope tubes for several days it was observed, upon opening them, that a considerable pressure of carbon dioxide had developed.

Following are the data from a typical experiment. One gram of ascorbic acid was dissolved in 19% formaldehyde and made up exactly to 50 ml.

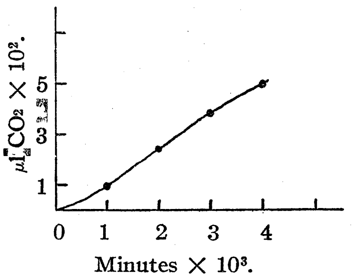

Fig. 1.—85 mg. of ascorbic acid in 10 ml. of 5.54% formaldehyde (0.0483 *M* ascorbic and 1.85 *M* formaldehyde), 40°, *p*H 3.5.

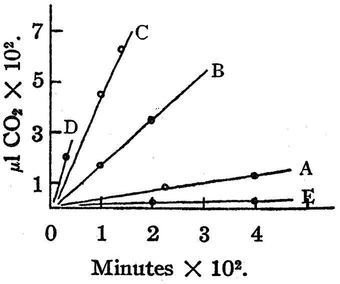

Fig. 2.—(A) 87.1 mg. of ascorbic acid in 10 ml. of formaldehyde (5% in 0.1 *M* phthalate buffer), *p*H 4.0; (B) 85.4 mg. of ascorbic acid in 10 ml. of formaldehyde (5% in 0.1 *M* phthalate buffer), *p*H 5.0; (C) 17 mg. of ascorbic acid in 2 ml. of formaldehyde (5.3% in *M* acetate buffer), *p*H 5.4; (D) 17 mg. of ascorbic acid in 2 ml. of formaldehyde (5% in 0.2 *M* phosphate buffer), *p*H 6.0; (E) portion of curve in Fig. 1 for comparison. All experiments carried out at 40°.

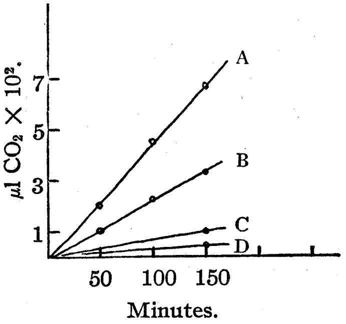

Fig. 3.—(A) 17 mg. of ascorbic acid in 2 ml. of formaldehyde (5.3% in *M* acetate buffer, *p*H 5.4), 0.0484 *M* ascorbic; (B) same except 0.0242 *M* ascorbic; (C) same except 0.0086 *M* ascorbic; (D) same except 0.0048 *M* ascorbic; all experiments carried out at 40°.

the following experiments the liberation of carbon dioxide from ascorbic acid–formaldehyde mixtures was followed in the Warburg manometric apparatus. All solutions were saturated with carbon dioxide before use and equilibrated with carbon dioxide while in the manometer flasks. The total volume of the reaction mixture was 2.0 ml. In most of the experiments the ascorbic acid was made up in buffer and tipped into the formaldehyde in the body of the Warburg flask after equilibration. (Figs. 1–5.)

3. Liberation of Carbon Dioxide from Mixtures of α-Hydroxytetronic Acid and Formaldehyde.—α-Hydroxy tetronic acid,  $\overbrace{CH_2—COH{=}COH—CO}^{O}$, was prepared by the method of Micheel and Jung.[6] (Fig. 6.)

4. The Effect of Formaldehyde on the Acidity of Solutions of Enediols.—A solution of 0.1000 *M* ascorbic acid in 37% formaldehyde was allowed to stand at 23° until it no longer reduced 2,6-dichlorophenolindophenol. As measured with a Beckmann *p*H meter this solution had a *p*H of 5.11. Five milliliters of this solution plus 2.50 ml. of 0.1000 *N* sodium hydroxide had a *p*H of 7.23. This corresponds to the *pK*. Our ascorbic acid (0.1000 *M* in water) had a *pK* of 4.08.

A similar experiment with reductone indicated a *pK* of 7.7 in 37% formaldehyde and 5.03 in water.

Two hundred and fifty milligrams of ascorbic acid was dissolved in 25 ml. of distilled water and 25 ml. of 37% formaldehyde added. The mixture was allowed to react in an atmosphere of nitrogen at 50°. At the beginning the *p*H was 4.4, at the end of eighteen hours the *p*H was 4.63.

Discussion

The foregoing data indicate that more than one reaction can occur in mixtures of formaldehyde and enediols. It is likely that Snow and Zilva were able to obtain reaction rates and equilibrium constants for an apparent single "condensation" reaction between enediols and formaldehyde because they worked with enediol concentrations of about 0.5 *M* and near room temperature. Under such conditions the liberation of carbon dioxide is very slow.

The hypothesis of Snow and Zilva that formaldehyde adds to carbons three and six of the ascorbic acid molecule is based on two lines of evidence. First, carbon number three was assumed to be involved because the *p*H of ascorbic acid solutions rose as reaction with formaldehyde progressed. This is confirmed by our data. Second, they found that six-substituted derivatives of ascorbic acid reacted at a different rate than ascorbic acid.

It would appear likely that such a reaction would lead to a product which is essentially neutral. Thus as reaction proceeds the *p*H should rise and sodium hydroxide titration values should decrease. However, Snow and Zilva found sodium hydroxide titration values to remain essentially the same throughout the course of reaction. They claim that this is due to reversal of the reaction by alkali. Krishnamurthy's data show that more ascorbic acid reacts at *p*H 6.0 than at 3.5 and our data show a marked acceleration of carbon dioxide liberation as the *p*H approaches 6.

Further we found that under our conditions little change in *p*H occurred during the course of carbon dioxide liberation. We interpret these findings as indicating that reaction with formaldehyde involves carbon number three and that the lactone ring breaks to free the potential carboxyl group. The carbon dioxide liberated probably arises from such a reaction product. That the lactone ring is involved is suggested by the fact that only those enediols possessing such a structure yield carbon dioxide when treated with formaldehyde.

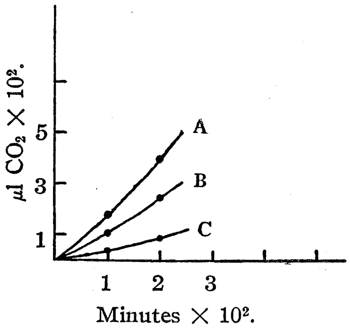

Fig. 4.—(A) 8.5 mg. of ascorbic acid in 2 ml. of formaldehyde (1.41 *M* in *M* acetate buffer, *p*H 5.4), 40° (B) same except 0.71 *M* formaldehyde; (C) same except 0.18 *M* formaldehyde.

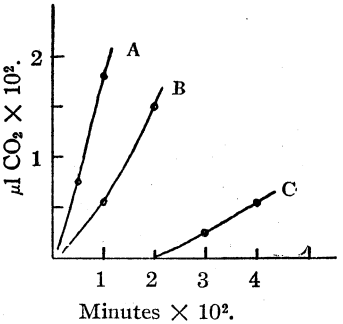

Fig. 5.—(A) 8.5 mg. of ascorbic acid in 2 ml. of formaldehyde (5.85% in *M* acetate buffer, *p*H 5.4), 40°; (B) same except 32°; (C) same except 25°.

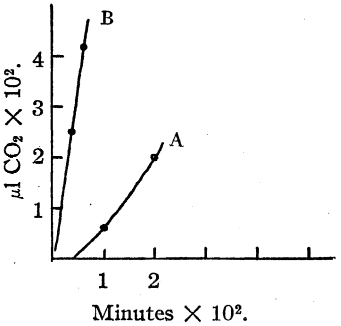

Fig. 6.—(A) 8.5 mg. of α-hydroxytetronic acid in 2 ml. of formaldehyde (5.85% in *M* acetate buffer, *p*H 5.4): 25.8° (B) same except 40°.

the phenomena described in this paper may lead to a quantitative method for determining ascorbic acid which is more specific than any yet devised.

Summary

1. It has been shown that ascorbic acid and α-hydroxytetronic acid react with formaldehyde and that under certain conditions one of the products of the reaction is carbon dioxide.

2. The rate of carbon dioxide formation in reaction mixtures of ascorbic acid and formaldehyde has been studied in relation to *p*H, temperature and concentration of reactants.

3. A similar study has been made on an α-hydroxytetronic acid–formaldehyde system.

4. The present work has been discussed in relation to previous studies which employed diminution of the reducing action of enediols as a criterion of reaction.

The Synthesis of 1-R-5-R'-5-Phenylhydantoins

BY LOREN M. LONG, C. A. MILLER AND H. D. TROUTMAN

The discovery by Putnam and Merritt[1] of the efficacy of Dilantin[2] in the treatment of epilepsy has resulted in the synthesis and subsequent testing of a large number of related compounds. The activity of many of these against electrically induced convulsions has been reported by Merritt and Putnam.[3] On examining this report one notes that the majority of the hydantoins which have been studied are those substituted in the 5-position only. It was logical, then, to extend the types of hydantoins studied to include those containing an N-substituent.

Since a search of the literature revealed that an appreciable number of 3,5-substituted hydantoins have been prepared,[4] it seemed that the synthesis of hydantoins substituted in the 1- and 5-positions offered a better opportunity of finding new and useful anticonvulsants. Indeed, in reference to 3-substituted hydantoins, a derivative of 5-ethyl-5-phenylhydantoin (nirvanol) has been introduced recently[5] as being effective in reducing the number of convulsions exhibited by epileptic patients. However, the use of this drug, 3-methyl-5-ethyl-5-phenylhydantoin, may result in rash formation similar to that caused by nirvanol.

Another possible advantage of compounds unsubstituted in the 3-position, as in structure (I), was thought to be the retention of dilute alkali solubility in contrast to the dilute alkali insolubility of compounds of structure (II). Thus, in many cases the sodium salts of cyclic ureides are preferred over the free compounds, *i. e.*, Dilantin[2] and phenobarbital.

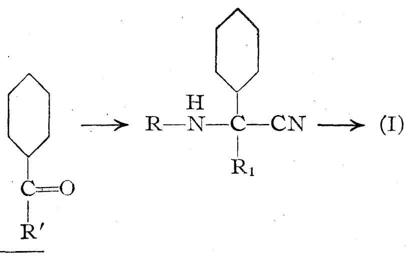
[a] Based on the amount of aldehyde or ketone employed. [b] The analytical data reported in this paper were determined by Arthur W. Spang. [c] Gabriel, *Ann.*, **350**, 124 (1906). [d] Swiss Patent 179,692. [e] German Patent 611,057; French Patent 769,667; Swiss Patent 169,509.

previously. The emphasis, however, has been on those representing 1-substituted nirvanol,[4] although an attempt was made to produce effective germicides by synthesizing 1,5-dihydroxyphenylhydantoins.[6]

Although the details of the procedure employed in the synthesis of the compounds listed in Table I were varied to improve yields, the general method was essentially the same throughout and may be represented by the following scheme.



This procedure is similar to that employed by other investigators[4,6] and is necessary since on alkylating 5,5-substituted hydantoins the first group entering the ring does so at the 3-position as in (II).

Since with primary amines benzaldehyde readily forms benzylidenimines which in turn react with hydrogen cyanide to form aminonitriles, such a procedure was utilized in preparing the 1-substituted-5-phenylhydantoins. It was found unnecessary to isolate any of the compounds intermediate between the imine and the hydantoin. In general the best method of synthesis consisted of mixing benzaldehyde with the appropriate amine. The resulting mixture was then added to cold 70–80% acetic acid containing about one-half of the required sodium or potassium cyanide. The remainder of the cyanide was then added and was followed shortly by the portion-wise addition of a slight excess of potassium cyanate. The resulting mixture, when treated with concentrated hydrochloric acid, gave yields of 35–70% of the expected hydantoin.

The procedure with ketones such as acetophenone and propiophenone was changed in that the ketone was first treated with liquid hydrogen cyanide. When the cyanohydrin thus formed reacted with an amine, water split out and the resulting aminonitrile was treated with potassium cyanate. In several reactions of this type results indicated that the presence of a strong mineral acid, either with or without acetic acid, offers some advantage over acetic acid alone.

The problem of preparing 1-alkyl derivatives of 5,5-diphenylhydantoin differs somewhat from that involved in either of the above types. Although it has been shown that diaryl ketones such as benzophenone, contrary to the findings of Bucherer and Lieb,[7] do in fact form hydantoins,[8] it is true that benzophenone exhibits very little tendency toward cyanohydrin formation with hydrogen cyanide.[9] In confirmation of this fact, all attempts to prepare aminonitriles from benzophenone itself ended in failure. However, this difficulty was overcome by treating dichlorodiphenylmethane with an amine as in the method used by Moore[10] in preparing benzophenone imine from dibromodiphenylmethane and ammonia. The substituted benzophenone imine thus produced reacted readily with hydrogen cyanide and the resulting amino-nitrile was converted to 1-alkyl-5,5-diphenylhydantoin by the use of cyanic acid.

Pharmacology.—The results of preliminary studies by Merritt and Putnam, part of which have been published,[3] and especially by Chen[11] of this Laboratory indicate that although many of the compounds in Table I exhibit anticonvulsant activity, the maximum inhibition of variously induced convulsions is attained with the 1-R-5-phenylhydantoins, where R represents a hydrocarbon radical of from two to four carbon atoms inclusive. Like other types of derivatives of 5,5-diphenylhydantoin,[3] the 1-alkyl-5,5-diphenylhydantoins have no inhibitory effect on electrically induced convulsions.

Experimental

1-Propyl-5-phenylhydantoin.—Two hundred and sixty-five grams (2.5 moles) of benzaldehyde was placed in a 1-liter flask fitted with a stirrer, a reflux condenser and a dropping funnel. The flask was cooled in a cold water-bath and 154 g. (2.6 moles) of *n*-propylamine (Sharples) was added with stirring. The addition, which was completed in twenty minutes, was made at such a rate as to cause the mixture to reach a temperature of 60°. Stirring was continued for one-half hour after the last of the amine had been added. The mixture was then cooled in an ice-bath.

One liter of 75% aqueous acetic acid was placed in an open 3-liter flask fitted with a stirrer and a thermometer and cooled to 0° in an ice-salt-bath. The acid was stirred slowly while 71 g. of sodium cyanide was added so that the temperature remained below 5°. The benzylidene–propylamine–water mixture was then added dropwise, keeping the temperature below 10°. The remainder of the sodium cyanide (70 g.) was added in 10-g. portions.

Stirring was continued, and when the aminonitrile solution had again cooled to 0°, a total of 212 g. of potassium cyanate was added over a period of one-half hour. The temperature increased to 5°. After one hour the slowly stirred mixture was heated to 70° for fifteen minutes on a steam-bath.

Concentrated hydrochloric acid (750 ml.) was added cautiously to the warm solution. After the acidified mixture had been heated on the steam-bath for an hour, it was diluted to 3 liters with cold water and thoroughly cooled in an ice-bath. The oily layer on top solidified slowly. The resulting mixture was filtered and the solid product washed with cold water and dried. Purification was accomplished by solution in 5% aqueous alkali, charcoaling and reprecipitation with Dry Ice. The final product was a white, crystalline solid weighing 337 g.

1-Allyl-5-phenylhydantoin.—Four hundred and twenty-four grams (4.0 moles) of benzaldehyde was mixed with 500 ml. of water in a 2-liter flask fitted with a stirrer, reflux condenser and a dropping funnel. The mixture was stirred and 234 g. (4.1 moles) of allylamine was added at a moderate rate. The temperature increased to about 65°. After refluxing for one-half hour, the mixture was cooled and extracted twice with 300-ml. portions of ether. The combined ether extracts were dried over magnesium sulfate, concentrated on a steam bath and the residue distilled at reduced pressure. The product, 517 g. or 89%, distilled at 96–99° (20 mm.).[12]

One hundred and forty-five grams (1.0 mole) of benzylidene allylamine was placed in a 500-ml. flask fitted with a stirrer, reflux condenser and a dropping funnel and cooled in an ice–salt mixture. While the imine was stirred slowly, 27 g. (1.0 mole) of liquid hydrogen cyanide was added dropwise. The resulting aminonitrile was allowed to warm up to room temperature.

The aminonitrile was dissolved in 350 ml. of 80% aqueous acetic acid cooled to 0°. To the cold solution was added in small portions with slow stirring 89 g. (1.1 mole) of potassium cyanate. The remainder of the process was carried out as in the preparation of 1-propyl-5-phenylhydantoin. The yield of white, crystalline product based on the benzylidene allylamine was 73%.

1-Methyl-5-methyl-5-phenylhydantoin.—One hundred and twenty grams (1.0 mole) of acetophenone was mixed with 29.7 g. (1.1 mole) of liquid hydrogen cyanide in a pressure bottle. A few drops of saturated sodium carbonate solution were added, and the bottle closed and allowed to stand at room temperature for twenty-four hours. The solution was then cooled and methylamine was passed in until one mole had been absorbed. On standing at 25° for twenty hours, an appreciable quantity of water separated.

The crude aminonitrile was added slowly to 1 liter of dilute hydrochloric acid cooled to 0°. A large part of the nitrile dissolved. The mixture was stirred slowly while 89 g. (1.1 mole) of potassium cyanate was added in small portions. After twenty minutes a white solid precipitated. The mixture was kept in the ice-bath for an additional hour. It was then heated on a steam-bath and 100 ml. of concentrated hydrochloric acid was added. After an hour the mixture was thoroughly cooled and filtered. The product was dissolved in an excess of 5% aqueous sodium hydroxide and the resulting mixture extracted twice with small portions of ether to remove unreacted ketone. The solution was then charcoaled, filtered and the product reprecipitated with Dry Ice. The purified product was a white crystalline solid.

1-Ethyl-5-diphenylhydantoin.—To a solution of 23.6 g. (0.1 mole) of benzophenone chloride[13] in 50 ml. of toluene

in a small metal bomb was added 22.5 g. (0.5 mole) of anhydrous ethylamine. The bomb was closed and heated to 100–105° for twenty hours. It was then cooled, opened and the contents filtered. The solid consisted of ethylamine hydrochloride (16.1 g.). The yellow filtrate was concentrated *in vacuo*. The cooled residue was mixed with 2.7 g. (0.1 mole) of liquid hydrogen cyanide. The solution became warm. It was cooled and mixed with 500 ml. of cold, dilute hydrochloric acid. Treatment with 8.9 g. (0.11 mole) of potassium cyanate and purification of the product as previously described in the preparation of 1-methyl-5-methyl-5-phenylhydantoin yielded a crystalline product.

1-β-Hydroxyethyl-5-phenylhydantoin.—Fifty-three grams (0.5 mole) of benzaldehyde and 14.9 g. (0.55 mole) of liquid hydrogen cyanide were mixed together in a small pressure bottle (ice-bath) and allowed to stand at 25° for two hours. The product was cooled and 30.5 g. (0.5 mole) of ethanolamine was added. Heat was evolved. The resulting mixture was cooled and added to a cold solution of 50 ml. of concentrated hydrochloric acid and 200 ml. of water. After the solution had cooled to 0°, 44.6 g. (0.55 mole) of potassium cyanate was added. Within a few minutes a yellow, semi-solid material precipitated. The mixture was left in the ice-bath for an hour before being heated on the steam-bath with an additional 100 ml. of concentrated hydrochloric acid. After the mixture was thoroughly chilled, it was filtered. The yellow solid was purified by dissolving in 800 ml. of boiling water, charcoaling and cooling to reprecipitate the product.

1-β-Bromoethyl-5-phenylhydantoin.—Twenty-two grams (0.1 mole) of 1-β-hydroxyethyl-5-phenylhydantoin was mixed with 50 ml. of dry chloroform and cooled in an ice-bath. Ten grams of phosphorus tribromide in 50 ml. of chloroform was added with stirring. After one-half hour the mixture was placed on a steam-bath and warmed for an hour. The resulting solution was poured with stirring into an excess of chipped ice. The solid product was filtered off and recrystallized from ethanol and water.

Summary

A series of 1-R-5-R′-5-phenylhydantoins, most of which are new compounds, has been prepared and tested for anticonvulsant activity.

Maximum activity is exhibited by those derivatives having a lower hydrocarbon group in the 1-position and only a phenyl group in the 5-position.

The Preparation of Some Substituted Quinoxalines

BY R. W. BOST AND E. E. TOWELL[1,2]

The reaction between aromatic ortho-diamines and alpha-diketones to form quinoxalines has been utilized to prepare a series of 2,3-disubstituted quinoxalines and 2,3-disubstituted-6-methoxyquinoxalines, with the purpose of studying their pharmacological properties.

The two diamines used were *o*-phenylenediamine and 3,4-diaminoanisole in the form of its hydrochloride, which was prepared in the laboratory from 4-amino-3-nitroanisole. The 4-amino-3-nitroanisole was prepared from commercial *p*-anisidine by the method of Reverdin,[3] with minor modifications. The diacetyl was obtained from the Forest Products Company. 3,5-Dicarboethoxycyclopentanedione-1,2 was prepared by the condensation of ethyl oxalate and ethyl glutarate in the presence of sodium ethoxide.[4] The following benzoins were prepared from the corresponding aldehydes by the "benzoin" condensation in the presence of alcoholic potassium cyanide: 4,4′-dimethoxybenzoin, *p*-dimethylaminobenzoin, 3,3′,4,4′-bis-(methylenedioxy)-benzoin, 2,2′,3,3′-tetramethoxybenzoin, 4-methoxy-3′,4′-methylenedioxybenzoin, and *p*-diethylaminobenzoin. *alpha*-Furoin and benzil were available in the laboratory. The following diketones were prepared by oxidation of the corresponding hydroxyketone with copper sulfate in pyridine[5]: 4,4′-dimethoxybenzil, *p*-dimethylaminobenzil, 3,3′,4,4′-bis-(methylenedioxy)-benzil, 2,2′,3,3′-tetramethoxybenzil[6]; 4-methoxy-3′,4′-methylenedioxybenzil, alpha-furil, and *p*-diethylaminobenzil (not obtained in crystalline form; alcoholic solution used to prepare the quinoxaline).

Attempts to prepare the quinoxaline from 2,3,2′-3′-tetramethoxybenzil and *o*-phenylenediamine were unsuccessful. An explanation of this anomalous behavior of an alpha-diketone toward an aromatic ortho-diamine has been offered by Schönberg and co-workers.[7]

Bennett and Willis[8] have shown that the methyl groups in 2,3-dimethylquinoxaline react with certain aromatic aldehydes in an excess of boiling acetic anhydride to form mono- and di-styrylquinoxalines. Attempts were made by us to bring about a similar reaction between 2,3-dimethylquinoxaline and formaldehyde, acetaldehyde and *n*-butyraldehyde, respectively, using the method of Bennett and Willis. Since no identifiable products could be isolated from the reaction mixtures, the experimental details are not given in this paper. An unsuccessful attempt was made to carry out a

Mannich[9] type reaction using 2,3-dimethylquinoxaline, methylamine hydrochloride and formaldehyde.

Experimental

3,4-Diaminoanisole.—This compound has been reported by Meldola and Eyre,[10] and has been prepared in the pure state by Bergeim,[11] *et al.*, by the reduction of 4-amino-3-nitroanisole with stannous chloride and hydrochloric acid. The free base has also been prepared by the reduction of 4-amino-3-nitroanisole with hydrogen and Raney nickel catalyst.[12] The authors prepared and used the compound in the form of its crude hydrochloride, since in this form it was less susceptible to oxidation by the air. In a typical run, 4-amino-3-nitroanisole (50.4 g., 0.30 mole) and fluid Raney nickel catalyst (8–9 cc.) were added to anhydrous ether (150 cc.) and reduced catalytically under pressure in the presence of hydrogen in the usual manner at an initial pressure of 1500 p. s. i. and an initial temperature of 30°. The reduction was complete within thirty to forty minutes. As soon as possible after opening the bomb, the straw-colored ether solution was poured rapidly through a glass-wool filter into chilled, anhydrous ether (1000 cc.), previously saturated with dry hydrogen chloride gas, and contained in a three-liter, three-necked, round-bottomed flask fitted with stirrer and gas trap. The diamine hydrochloride, pale purple in color, formed immediately, and the product from each run was allowed to remain in the flask until several runs had been made. The product was then filtered, washed with anhydrous ether, dried in air for two hours, and stored in the dark. One series of five runs gave 276 g. of the crude hydrochloride (87%). The product was used to prepare quinoxaline without further purification. A small sample reacted with benzoyl chloride in 20% sodium hydroxide solution to form the dibenzoyl derivative which, after recrystallization from glacial acetic acid, melted at 248–249°. Reported m. p. 251–252°.[10]

Benzoins.—The usual methods[13] of preparing benzoins, both simple and mixed, were employed, with certain modifications as to proportions of reagents used, time of reflux and standing, and method of isolating and purifying the product. In general, it was found that yields were improved by filtering off the first batch of product, returning the filtrate to the reaction vessel, adding a fresh portion of potassium cyanide solution and refluxing again. In some instances, this process was repeated more than once. The yields ranged from 25% for 4-methoxy-3′,4′-methylenedioxybenzoin to 74% for 3,3′,4,4′-bis-(methylenedioxy)-benzoin.

***p*-Diethylaminobenzoin.**—*p*-Diethylaminobenzaldehyde (53.1 g., 0.30 mole), freshly distilled benzaldehyde (41.8 g., 0.30 mole) and 150 cc. of 95% ethanol were warmed on the steam-bath until solution was complete. Potassium cyanide solution (5 g. in 100 cc. of water) was added, the whole refluxed for two hours, then allowed to stand overnight. A second portion of potassium cyanide solution (8 g. in 50 cc. of water) was added, the whole refluxed for three hours, and allowed to stand overnight. Chilling failed to produce crystallization, the reaction mixture persisting as two layers, the lower being dark orange-red in color. The mixture was steam-distilled until about five liters of distillate had come over. The residue was allowed to stand overnight, after which the aqueous layer was decanted, and the viscous orange-red lower layer taken up in 50 cc. of 95% ethanol. The solution was diluted with water (150 cc.), the resulting suspension warmed on the steam-bath, and 95% ethanol added gradually until the solution just became clear. The solution was boiled with Norite, filtered, and allowed to stand at room temperature for six hours whereupon 30.8 g. of lustrous golden-yellow flakes were obtained. After recrystallization twice from 95% ethanol, lustrous white flakes, m. p. 105–106°, were obtained.

Anal. Calcd. for $C_{18}H_{21}O_2N$: N, 4.94. Found: N, 4.97.

Benzils.—The oxidation of the benzoins to the corresponding benzils by copper sulfate in pyridine was found to give good yields (better than 60%) in nearly every case. The products were easily isolated and purified. An exception was the product from the oxidation of *p*-diethylaminobenzoin, which could be obtained only as a sticky yellow gum adhering to the walls of the vessel. This material was taken up in 95% ethanol, in which it was readily soluble, and the solution used to prepare the corresponding quinoxaline by reaction with *o*-phenylenediamine.

2,3,2′,3′-Tetramethoxybenzil.—This compound was obtained in an 84% yield when 2,3,2′,3′-tetramethoxybenzoin was oxidized by the above procedure. It consists of white needles, m. p. 140–142°. *Anal.* Calcd. for $C_{18}H_{18}O_6$: C, 65.44; H, 5.49. Found: C, 65.05: H, 5.29.

The 2,4-dinitrophenylhydrazone of this compound was prepared according to the method of Allen,[14] being obtained as brilliant orange crystals, m. p. 169–171° (uncor.), after three recrystallizations from a chloroform–methanol mixture.

Anal. Calcd. for $C_{24}H_{22}O_9N_4$: N, 10.99. Found: N, 11.11.

Quinoxalines.—The general procedure for preparing the 2,3-disubstituted quinoxalines was as follows[15]; equimolar portions (approx. 0.10 mole) of *o*-phenylenediamine and the benzil were refluxed for two to three hours in boiling glacial acetic acid (200–400 cc.), the reaction mixture allowed to cool, then poured, with vigorous stirring, into cold water (1000–2000 cc.). The resulting suspensions in most cases yielded precipitates on standing, or were broken with 20% sodium hydroxide solution. The products were recrystallized from ethanol, after treatment with Norite. The yields ranged from 85 to 99%. The 2,3-disubstituted-6-methoxyquinoxalines were prepared generally by the same procedure, except that the crude diamine hydrochloride was used instead of the free base. The yields ranged from 41 to 81%, it being found that the sooner the diamine hydrochloride was used after its preparation, the higher was the yield. The 2,3-dimethylquinoxalines were prepared in 10% acetic acid medium as given below.

2,3-Dimethyl-6-methoxyquinoxaline.—Crude 3,4-diaminoanisole hydrochloride (42.2 g., approx. 0.20 mole) was taken up in 10% acetic acid (300 cc.). Diacetyl (20 g., 0.23 mole) in 50 cc. of 10% acetic acid was added dropwise, with stirring, the mixture being heated on the steam-bath throughout the addition and for thirty minutes afterward. The dark-green mixture was allowed to cool to room temperature, diluted with water (750 cc.) and made alkaline to litmus with 20% sodium hydroxide solution. The brownish-black precipitate which formed was filtered, washed with water, taken up in dilute ethanol (1:1, 1000 cc.), boiled with Norite, then filtered. This operation was repeated four times, until the filtrate became pale straw-colored. Upon chilling, cream-colored crystals formed. Repeated recrystallization from dilute ethanol gave cream-colored crystals of constant m. p. 99–100° (uncor.).

Anal. Calcd. for $C_{11}H_{12}ON_2$: N, 14.89. Found: N, 14.81.

2,3-Dimethylquinoxaline Sulfate.—2,3-Dimethylquinoxaline (15.8 g., 0.10 mole), prepared according to the procedure given above, was taken up in anhydrous ether

[a] These compounds have not hitherto been reported. [b] Specific preparation given. [c] A sample of this quinoxaline with an authentic sample of piperil, m. p. 171.5°, gave a mixed m. p. 145–155°.

(400 cc.). Ten cubic centimeters of concentrated sulfuric acid (sp. gr. 1.84, 96–98% H_2SO_4) was added dropwise, with vigorous stirring. A voluminous pale yellow solid formed, and as the mass became too thick for efficient stirring, 100-cc. portions of dry ether were added at three successive intervals. The yellow solid was filtered and washed with dry ether. Two recrystallizations from absolute ethanol (300 cc.) gave 20 g. (78%) of pale green flakes, m. p. 151–152° (d.). The salt is readily soluble in water.

Anal. Calcd. for $C_{10}H_{10}N_2{\cdot}H_2SO_4$: neutral equivalent, 256.27. Found: neutral equivalent, 256.01.

2,3-bis-(*p*-Methoxyphenyl)-6-methoxyquinoxaline.—4,4′-Dimethoxybenzil (10 g., 0.04 mole) and crude 3,4-diaminosanisole hydrochloride (20 g., approx. 0.10 mole) were taken up in glacial acetic acid (300 cc.). The mixture was refluxed for two hours, allowed to stand overnight at room temperature, then refluxed again for two hours. After cooling, the mixture was poured, with vigorous stirring, into cold water (2500 cc.). The resulting light tan suspension was diluted with water (2500 cc.) and broken by the addition of 20% sodium hydroxide solution. The flocculent solid was filtered, washed with water, and recrystallized from 95% ethanol (300 cc.), after treatment with Norite. The cream-colored crystals weighed 7.6 g. after drying in air. A second crop (3.5 g.) was obtained by diluting the mother liquor to a volume of one liter with water and allowing to stand several hours. The combined yield of 11.1 g. was 81% of the theoretical, based on the 4,4′-dimethoxybenzil. Repeated recrystallization from 95% ethanol gave a product of constant m. p. 131–132° (uncor.).

Anal. Calcd. for $C_{23}H_{20}O_3N_2$: N, 7.52. Found: N, 7.43.

The 2,4-dinitrophenylhydrazone of 2,3-dimethoxybenzaldehyde was prepared, being obtained as brilliant red crystals, m. p. 218–219° (uncor.), after two recrystallizations from chloroform.

Anal. Calcd. for $C_{15}H_{14}O_6N_4$: N, 16.22. Found: N, 16.07.

Pharmacological Properties.—The pharmacological studies on these quinoxalines were carried out by the Wm. S. Merrell Co. of Cincinnati, Ohio, through the courtesy of Dr. Robert S. Shelton, to whom the authors are deeply grateful. The results will be reported elsewhere.

Acknowledgment.—The authors wish to express their appreciation to the Wm. S. Merrell Company through whose generous support this work was carried out.

Summary

1. A series of 2,3-disubstituted quinoxalines and 2,3-disubstituted-6-methoxyquinoxalines have been prepared.

2. A method for the preparation of 3,4-diaminoanisole hydrochloride in sizeable quantities has been developed.

3. The 2,4-dinitrophenylhydrazones of 2,3-dimethoxybenzaldehyde and 2,3,2′,3′-tetramethoxybenzil have been prepared.

The Molecular Weight of Lysozyme Determined by the X-Ray Diffraction Method

By K. J. Palmer, M. Ballantyne and J. A. Galvin

A method for growing single crystals of the several salts of lysozyme, including the chloride, bromide and iodide, has been described recently.[2,3] Since lysozyme has a comparatively small molecular weight (13,900) and forms chloride, bromide and iodide salts which can be crystallized, it appears probable that a comprehensive X-ray diffraction investigation of these salts may reveal some interesting information about the structure of a native protein molecule. With this end in view a coöperative investigation of the structure of the salts of lysozyme has been started by this Laboratory and the California Institute of Technology. The results of this joint endeavor will be published when available. The present paper is concerned with a preliminary account of the X-ray diffraction results obtained from air-dried lysozyme chloride crystals and the determination of the molecular weight of lysozyme.

Results and Discussion.—Two crystalline modifications of lysozyme chloride have been reported.[2] When the mother liquor has a *p*H between about 3.5 and 6, tetragonal, bipyramidal crystals appear,[2] whereas at a *p*H between about 7 and 11, needle-shaped orthorhombic crystals appear.[3] Both the tetragonal and orthorhombic crystals give rise to a large number of X-ray reflections when in the presence of their mother liquors. When air-dried, however, it has been possible to obtain a diffraction pattern from the tetragonal crystals only. Diffraction spots have been observed for *d* values down to about 5.7 kX from the air-dried tetragonal crystal as compared to 2.0 kX or less from the wet crystals. The fact that the air-dried tetragonal crystals give a diffraction pattern makes the X-ray method ideally suited for a determination of its molecular weight.

The tetragonal lysozyme chloride crystals used in this investigation were grown by the method of Alderton, Ward, and Fevold[2] at a *p*H of 4.5. Crystals suitable for X-ray diffraction analysis were obtained by allowing the crystals to grow on the side of an Erlenmeyer flask until they had attained a size of from 0.5 to 1.0 mm. on a side. The mother liquor was then decanted and the crystals allowed to dry. Many of the resulting crystals were transparent and had sharp edges and no apparent flaws. The crystals when air-dried are relatively hard and can be scraped from the wall of the flask without difficulty. Suitable crystals were mounted on the ends of thin glass fibers by means of clear shellac.

The optical and crystallographic properties of lysozyme chloride crystals grown at a *p*H of 4.5 have been determined.[4] This microscopic investigation showed that the crystals have positive uniaxial birefringence and appear to be tetragonal, tabular bipyramids of the first order. The tetragonal symmetry has been confirmed by taking several sets of 5° oscillation photographs 90° apart around the *c* axis. In all cases, these pairs of photographs appear to be identical.

Complete rotation and 5° oscillation photographs through a range of 90° have been taken around the [101], [110] and [001] axes. The unit cell size of the air-dried crystals has been determined from layer line measurements to be a = 71.1 kX and c = 31.3 kX. The volume of the unit cell is, therefore, $V = a^2c = 15.82 \times 10^4$ $(\text{kX})^3$. The approximately 1200 reflections have been indexed by using reciprocal lattice plots. The only systematic absences appear to be (h00) when $h \neq 2n$ and (0k0) when $k \neq 2n$. These latter restrictions are based on the appearance of only even orders through (14,0,0). No (00l) reflections have been observed from the air-dried crystals in spite of the fact that special care has been taken to observe them. When a tetragonal lysozyme chloride crystal is in the presence of its mother liquor, (00l) reflections are observed only when $l = 4n$. Since reflections are observed from the air-dried crystal only down to *d* values of about 5.7 kX, it is apparent that if the air-dried crystals, like the wet crystals, have a 4_1 or 4_3 screw axis, the first (00l) reflection that could appear (7.8 kX) would be expected to be weak because of the rapid falling off of intensity with angle. Since no conclusion can be drawn with regard to the *c* axis in the air-dried tetragonal crystal, the space groups compatible with the X-ray data are D_4^2—$P42_1$; D_4^4—$P4_12_1$; D_4^6—$P4_22_1$; D_4^8—$P4_32_1$; and D_{2d}^3—$P\bar{4}2_1m$. The space group D_{2d}^3—$P\bar{4}2_1m$ can be eliminated because lysozyme is optically active. None of these enantiomorphic space groups is in accord with the external holohedral appearance of the crystals.[4] This discrepancy is probably due to the fact that only the simple prism faces {101} appear. More complicated faces probably would reflect the non-holohedral symmetry.

Following the suggestion of McMeekin and Warner[5] the density of the lysozyme chloride crystals was determined with organic liquids by the suspension method. Since the relative humidity at the time the X-ray photographs were taken was approximately 40%, the crystals to be used for the density determination were first equilibrated in an atmosphere having this relative humidity.

A crystal was placed in a mixture of toluene and ethylene bromide and the composition of the liquid was quickly adjusted until the crystal remained suspended. A fresh crystal was then added to be sure that excessive dehydration of the original crystal had not occurred. In all cases where the time for adjusting the composition did not exceed a few minutes the second crystal appeared to have the same density as the original. A series of determinations of the density on several different air-dried crystals from two different preparations (both at *p*H 4.5) of tetragonal lysozyme chloride gave an average value of 1.312 ± 0.003 g./cc. at 27°. This value of the density must be corrected because all of the lysozyme chloride crystals have a small amount of sodium chloride associated with them. The sodium chloride results from the evaporation of the mother liquor adhering to the lysozyme chloride crystals after decanting. The major portion of the sodium chloride is probably encrusted on the external faces of the crystals as it can often be seen under the microscope.[4] That the sodium chloride is present as a separate phase is also shown by the fact that lysozyme chloride crystals give, on long exposure, a sodium chloride X-ray pattern.

To determine the correction to be applied to the observed densities, microchemical analyses for sodium and chloride were made[6] on the preparations from which the crystals were obtained for both the X-ray and density measurements. The averaged results, expressed as per cent. of air-dried weight, are shown in columns 1 and 2 of Table I.

TABLE I

ANALYTICAL DATA ON AIR-DRIED TETRAGONAL LYSOZYME CHLORIDE

Na, %	Cl, %	NaCl, %	Cl bound to lysozyme, %	Corrected density (27°C.)
0.50	3.15	1.27	2.38	1.305 g./cc.

The amount of sodium chloride was calculated by assuming that all of the sodium is present as sodium chloride. The result is given in Column 3 of Table I. Column 4 gives the amount of the remaining chloride which is presumably attached to the amino groups of lysozyme as the hydrochloride. On the assumption that the volumes of sodium chloride and lysozyme chloride are additive the observed density was corrected by the formula

$$\rho \text{ corr.} = \frac{m_0}{\dfrac{100}{\rho_2} - \dfrac{m_1}{\rho_1}}$$

where m and ρ are the per cent. by weight and density, respectively, and the subscripts 0, 1 and 2 refer to lysozyme chloride, sodium chloride, and the mixture, respectively. The corrected density is given in Column 5 of Table I.

Oncley[7] has determined approximate values for the molecular weight of lysozyme by osmotic pressure (17,500) and sedimentation–diffusion (14,000–17,000). Assuming a value of 16,000 for the molecular weight of lysozyme, the number of molecules in the unit cell can be calculated to be

$$N = \frac{(1.305)(15.82 \times 10^4)}{(1.65)\ (16{,}000)} = 7.8$$

It is evident, therefore, that there must be eight molecules in the unit cell.

The weight of a lysozyme chloride molecule in the air-dried crystal is then

$$M = \frac{(1.305)(15.82 \times 10^4)}{(1.65)(8)} = 15{,}680$$

This value is an upper limit for the molecular weight and must be corrected for both water of hydration and attached hydrochloric acid.

The weight of a lysozyme molecule, free of hydrochloric acid, can be obtained by reducing the value 15,680 by the amount of hydrochloric acid (2.45%) corresponding to the amount of chloride shown in column 4 of Table I. This leads to a value of 15,300 for the molecular weight of air-dried lysozyme.

The water content of the air-dried crystals was determined by placing weighed amounts of the crystalline material into a 105° vacuum oven for twenty-four hours and determining the loss of weight. Several runs made on different days gave a spread between 8.4% and 9.6% with an average value of 9%. With this value for the water content the molecular weight of dry lysozyme can be calculated to be 13,900.

It is difficult to estimate the probable error of this determination, but it seems reasonable to assume, in spite of the corrections made, that the probable error does not exceed 4% or about 560 molecular weight units.

The value 13,900 is slightly lower than the lower limit (14,000) given by Oncley[7] based on his sedimentation–diffusion measurements. His limits were, however, based on an assumed range of 0.70–0.75 for the partial specific volumes of lysozyme. In any case the lower limit is within the estimated probable error range of the X-ray determination. Oncley's osmotic pressure value of 17,500 is somewhat higher than the X-ray value. This discrepancy may be due to the fact that the membrane used by Oncley was not completely impermeable to lysozyme.

Acknowledgments.—The authors are indebted to H. L. Fevold and Gordon Alderton for their kindness in furnishing us with the lysozyme chloride crystals used in this investigation.

Summary

Five degree oscillation photographs have been taken of air-dried tetragonal lysozyme chloride. The only systematic absences appear to be (h00) when $h \neq 2n$ and (0k0) when $k \neq 2n$. No (00l) reflections appear. Possible space groups are D_4^2—$P42_1$; D_4^4—$P4_12_1$; D_4^6—$P4_22_1$; and D_4^8—$P4_32_1$.

---

[6] The authors are indebted to L. M. White of this Laboratory for the microchemical analyses.

[7] J. L. Oncley, private communication to H. L. Fevold.

The tetragonal unit cell of air-dried lysozyme chloride grown at a *p*H of 4.5 has dimensions of a = 71.1 kX and c = 31.3 kX. There are eight molecules in the unit cell. The density of the crystals was measured by suspension in a mixture of toluene and ethylene bromide. The observed density has been corrected for adhering sodium chloride (1.27%) to give 1.305 ± 0.003 g./cc. at 27°. The corrected density has been used to calculate the weight per molecule in the unit cell. This value was then corrected for moisture (9%) and hydrochloric acid bound to the amino groups (2.45%) to give a value for the molecular weight of dry, chloride-free, lysozyme of 13,900 ± 600.

Compound Formation between 2,6-Lutidine and Polyhalogenated Methanes

BY CALVIN A. VANDERWERF, ARTHUR W. DAVIDSON AND CARL I. MICHAELIS

In phase equilibrium studies recently reported from this laboratory,[1] evidence was obtained for the existence of eight addition compounds of pyridine with various polyhalogenated methanes. Because the structure of all of these compounds could not be explained in terms of a single consistent theory, the present investigation of the systems consisting of 2,6-lutidine with each of these same polyhalogenated methanes was undertaken in the hope that further light might be shed upon the process of addition compound formation in such systems. Selection of 2,6-lutidine was suggested by the following considerations: (1) because of its electronic structure, its nitrogen atom would be expected to exhibit a greater tendency than that of pyridine to act as an electron donor; (2) because of the proximity of the two substituent groups to the nitrogen atom, steric factors might be expected to interfere with the coördination of several lutidine molecules about a single molecule of polyhalogenated methane.

Experimental[2]

Purification of Materials.—The 2,6-lutidine, obtained from the Reilly Tar and Chemical Corporation, was purified by repeated recrystallization of the hydrochloride from concentrated hydrochloric acid. The base was regenerated by means of concentrated sodium hydroxide solution, and, after separation from the aqueous layer, was dried over sodium hydroxide pellets for ten days. Fractional distillation through a five-foot packed column gave pure 2,6-lutidine, b. p. 142.5° at 738 mm., f. p. (from cooling curve) −5.5°. The purified material was stored in a dark bottle and was guarded against contact with moisture and carbon dioxide.

The chloroform, bromoform and carbon tetrachloride were dried over drierite, then fractionally distilled through the column referred to above. The physical constants observed for the pure compounds are as follows: for chloroform, b. p. 60.7° at 745 mm., f. p. (from cooling curve) −62.1°; for bromoform, b. p. 148.2° at 740 mm., f. p. (from cooling curve) 8.3°; for carbon tetrachloride, b. p. 76.1° at 741 mm., f. p. (from cooling curve) −21.8°.

Eastman Kodak Co. iodoform and bromoform were recrystallized twice from ethanol; the former melted at 121.1°, the latter at 90.9°.

Apparatus and Procedure.—The freezing point cell used in the determination of the temperature–composition diagrams was similar to that described in a previous publication from this Laboratory,[3] except that the cell was constructed in two parts joined to each other by means of a ground glass joint. This design makes possible the easy removal of the stirrer. All cooling curves were recorded directly by means of a Brown Electronik Strip Chart potentiometer which had been calibrated at the m. p. of ice, the b. p. of ammonia, and the sublimation point of solid carbon dioxide. Each freezing point was determined at least twice. Data obtained by this method are believed to be correct, even for the steeper portions of the freezing point curves, to 1.5°.

Results

The experimental data are shown in tabular and graphical form below. Compositions, as indicated, are given in mole %.

likely that it is $2C_7H_9N{\cdot}CHI_3$. Extrapolation indicates that the melting point of the compound would be about 7.5°. The eutectic is 16.8 mole % iodoform, f. p. −19.4°.

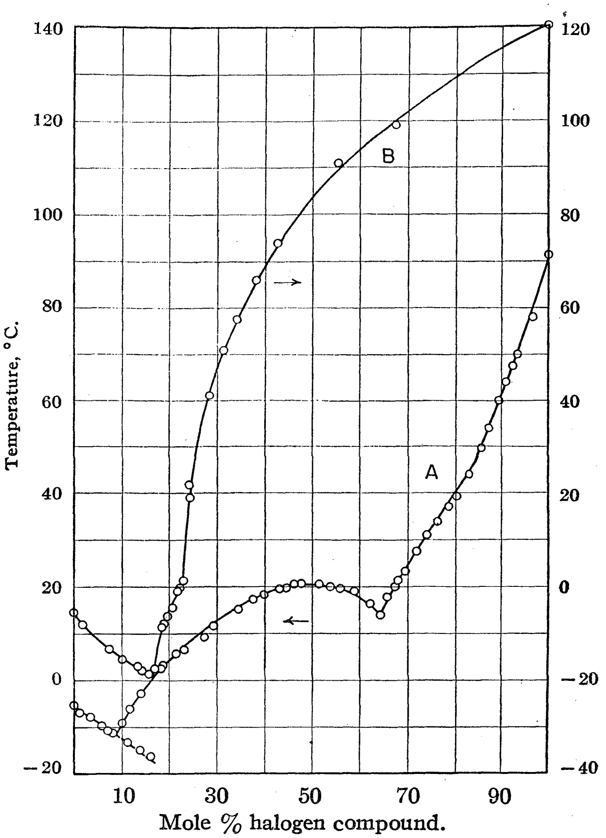

Fig. 2.—Curve A, system 2,6-lutidine–carbon tetrabromide (use temperature scale on left); curve B, system 2,6-lutidine–iodoform (use temperature scale on right).

D. As shown in Fig. 1, curve B, no compound formation occurs between 2,6-lutidine and carbon tetrachloride. The single eutectic is 70.4 mole % carbon tetrachloride, f. p. −57.0°. The distinct change in the slope of the curve at −46.5° results from the transition from the α- to the β-form of carbon tetrachloride.

E. As indicated in Fig. 2, curve A, 2,6-lutidine and carbon tetrabromide form a single stable compound, $C_7H_9N{\cdot}CBr_4$, which melts congruently at 20.7°. The eutectics are: (a) 8.3 mole % carbon tetrabromide, f. p. −11.3°, and (b) 64.5 mole % carbon tetrabromide, f. p. −11.3°, and (b) 64.5 mole % carbon tetrabromide, f. p. 13.9°. The change in the slope of the curve at 47° corresponds to the transition from the α- to the β-form of carbon tetrabromide at that temperature.

Discussion

In general, the number and complexity of the stable solid addition compounds between the polyhalogenated methanes and 2,6-lutidine is less than in the corresponding systems with pyridine, a fact which may probably be attributed to the steric factors effective in the 2,6-lutidine molecule. The fact that the compound of 2,6-lutidine with chloroform appears to be more stable than the corresponding compound of pyridine is noteworthy; in this case, the enhanced stability of the compound may be attributed to the greater tendency of the disubstituted base to act as an electron donor, resulting from the electron releasing effects of the two methyl groups.

Summary

1. Temperature–composition data are presented for systems consisting of 2,6-lutidine with each of several polyhalogenated methanes.

2. It has been shown that chloroform, bromoform and carbon tetrabromide each form a 1:1 addition compound with 2,6-lutidine, and that a 2:1 addition compound is formed in the system 2,6-lutidine–iodoform.

3. The behavior of 2,6-lutidine toward the polyhalogenated methanes is compared with that of pyridine in similar systems.

"Analytical Boundary" Method for the Determination of Transference Numbers

BY A. P. BRADY[1]

During the course of the investigation of solutions of colloidal electrolytes in this Laboratory, the need was felt for a fairly simple and rapid method for determining electrical mobilities to an accuracy of about 1%. It was desired to avoid the Hittorf method if possible, not only because of the time involved, but because of the difficulty in analyzing many of these solutions to an accuracy much better than 1%. The use of the moving boundary method with colloidal electrolytes usually involves a difficulty in the choice of a suitable following or "indicator" electrolyte for forming the boundary. The indicator must have a lower conductivity than the salt under investigation in the leading solution; further, the indicating ion must be slower than the leading ion in any possible mixture of the two solutions. The comparatively low conductivity of colloidal ions eliminates the use of simple electrolytes for indicators, and the possibility, or indeed probability, of interaction bars the use of another colloidal electrolyte. Hartley, *et al.*,[2,3] recognized this difficulty, and circumvented it in a study of certain cationic surface active agents by their "balanced boundary" method. Their method, although quite successful in this application, introduces a further complication in apparatus, since the boundary must be kept stationary by mechanical means. Moreover, because of the necessity of analysis *in situ*, the method is inapplicable in the many instances where multiple boundaries are formed.

The purpose of the present paper is to describe the theory and operation of a simpler cell in which, as in the "balanced boundary" method, the roles of the leading and indicating solutions are reversed. Experimental tests of the cell using simple electrolytes will be presented here, and applications to more complex systems given in the following paper.

The apparatus used is shown schematically in Fig. 1. The cell proper is a U tube divided into the two portions A and B by a sintered glass membrane (Pyrex medium grade). Compartment B contains the solution under investigation; the requirements for the solution in A will be referred to in more detail below. The electrode joined to compartment A is of the closed non-gassing type; that at the other leg of the U-tube may gas. The apparatus, called an "analytical boundary" cell for convenience, may be regarded as simply a means for combining the Hittorf and moving boundary methods. The procedure consists essentially of determining analytically the amount of the ion being studied in compartment A that has been transported electrically from compartment B through the boundary created by the membrane.

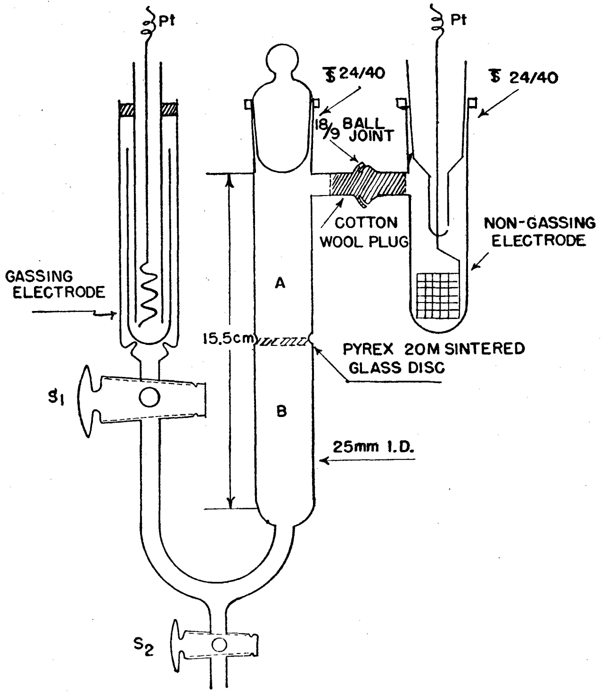

Fig. 1.—Analytical boundary apparatus: A, analytical compartment containing leading electrolyte; B, compartment containing solution under investigation; S_1, S_2, stopcocks.

The operation of the cell can most conveniently be examined from the standpoint of the moving boundary equations. Figure 2 is a diagrammatic representation of a moving boundary experiment. Originally AR and AS (at concentrations C_{AR} and C_{AS}, respectively) form a boundary at ab; after passage of current this boundary moves to cd. As a moving boundary experiment, the arrangement is designed to determine the transport number of S in AS. As an analytical boundary experiment, however, it will be used to determine that of R in AR.

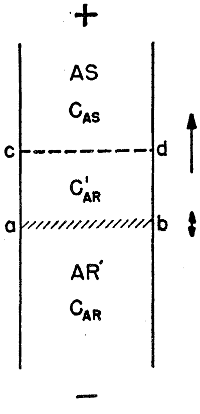

Fig. 2.—Moving boundary experiment.

After a quantity Q of electricity is passed through the solution, the volume V swept out by

[3] Drew and Hartley, *ibid.*, 653 (1934); Collie and Hartley, *ibid.*, 657 (1934).

the boundary cd is[4]

$$V = \frac{QT_{\mathrm{S}}}{FC_{\mathrm{AS}}} \tag{1}$$

where T_{S} denotes the transport number of S ion in AS. Equation (1) is the fundamental equation for determining the transport number of S by the moving boundary method. The concentration of AR behind the boundary is no longer the original C_{AR}, but an adjusted value, C'_{AR}, given by the Kohlrausch[5] conditions

$$\frac{T'_{\mathrm{R}}}{C'_{\mathrm{AR}}} = \frac{T_{\mathrm{S}}}{C_{\mathrm{AS}}} \tag{2}$$

where T'_{R} is the transport number of R at the indicator concentration, C'_{AR}. Substitution of equation (2) into equation (1) gives

$$C'_{\mathrm{AR}}V = Q\,T'_{\mathrm{R}}/F \tag{3}$$

Since in general $C'_{\mathrm{AR}} \neq C_{\mathrm{AR}}$, a slowly moving boundary will remain in the neighborhood of ab. Considering upward movement in Fig. 1 as positive, this boundary will sweep out a volume[4]

$$C' = \frac{Q(T_{\mathrm{R}} - T'_{\mathrm{R}})}{F(C_{\mathrm{AR}} - C'_{\mathrm{AR}})} \tag{4}$$

In the present instance, we are interested in the total quantity of R, M_{R}, that passes through the plane ab, since this is the quantity that will be determined. If the secondary boundary at ab is stationary or moves downward with time, evidently M_{R} is given by the left-hand side of equation (3); therefore

$$M_{\mathrm{R}} = QT'_{\mathrm{R}}/F \tag{5}$$

If, on the other hand, the secondary boundary moves upward with time, then $M_{\mathrm{R}} = C'_{\mathrm{AR}}V + (C_{\mathrm{AR}} - C'_{\mathrm{AR}})V'$, and from equations (3) and (4)

$$M_{\mathrm{R}} = QT_{\mathrm{R}}/F \tag{6}$$

Thus multiplying the amount of R passing through the plane ab by F/Q gives the transport number of the radical R at the initial or at the adjusted concentration, depending upon whether the secondary boundary moves upward or downward. In the applications to which this cell has so far been put there has been no ambiguity. If such a difficulty did arise, it would be necessary to determine the general shape of the T *vs.* C curve; by using a leading solution of known properties the value of C'_{AR} may be readily approximated from equation (2) and from equation (4) the decision made as to which concentration the observed transference number refers.

An experimental alternative that circumvents the above ambiguity and is convenient and easy to apply, especially in complex systems, is a radiotracer technique. In this method, the leading and unknown solutions are of identical composition, but the latter contains a radioactive isotope of the ion or ions under investigation. There are then no restrictions on the complexity of the system, and, since the "adjusted" concentration is automatically that of the original solution, no complications arise due to motions of secondary boundaries. This technique should find increasing applications as the larger supplies of radioactive elements from uranium piles become available.

The following comments concerning the analytical boundary cell are of importance. First of all, in the derivation of equations (5) and (6) for clarity the assumption was made that stable sharp boundaries are formed. This would require the fulfillment of definite conditions, namely, that the density increase from top to bottom of the cell and that the conductivity of C_{AS} be greater than that of C_{AR}. However, the above assumption is unnecessary since the equations may be derived in terms of the volume velocities past plane ab, and consequently the solution in compartment A does not have to satisfy such rigid requirements. For practical operation of the cell, however, it is necessary to insure that the material transported through the membrane will not be lost in the electrode compartment. Convectional instability is therefore to be avoided. Electrical stability is desirable but not necessary, although again, in order to minimize the possibility of losses the conductivity of the leading solution should not be much less than that of the unknown.

The radical R need not be a single species. However, if it is not, it will usually be necessary to neglect the motion of the secondary boundary, leading to the aforementioned uncertainty as to the exact concentration to which the transport number refers. The error so introduced is usually small. Again, the tracer method overcomes the difficulty.

It is obvious that the migration of foreign ions from either electrode to the neighborhood of the membrane will vitiate results. It is desirable, therefore, although not always necessary, to introduce a small amount of concentrated solution of the unknown around the gassing electrode; it will then be in a region of high conductivity and any hydrogen or hydroxide ion produced in the electrode will have less chance of getting over into compartment B. The baffle system at the gassing electrode is also an aid in this respect. The composition of the non-gassing electrode depends upon that of the leading solution in A and must be so chosen as to introduce no foreign ions into A by electrolytic migration.

Some of the early cells used by Hittorf[6] and by Steele[7] contained membranes. These were abandoned because such materials as fish bladder and gelatin obviously influenced results, either through electroendosmotic streaming or conductivity changes within the membrane. In the present apparatus endosmosis is prevented by the closed system above the membrane, and it is imperative that there be no leakage here. The pore diameter of the membrane is several microns, making the

[a] Radiotracer method; tagged with Br^{82}, see text. [b] Radiotracer method; tagged with Na^{22}.

existence of appreciable surface conductivity improbable. The possibility still exists, of course, but experiments with either uni-univalent electrolytes or solutions of surface active agents (to be presented in a following paper) give no indication of abnormal behavior.

As in the moving boundary method, a small correction in the observed values for the transport number must be made for volume changes above the original boundary during the course of electrolysis, in order to refer the movement to the water rather than the apparatus. The solutions reported here are sufficiently dilute for the correction to be within the experimental error, and it was consequently ignored.

Experimental

Materials.—Reagent grade chemicals were used throughout without further purification. The water used was de-ionized by ion exchange resins, and had a specific conductivity of 2 × 10^{-6} mho cm.$^{-1}$; this amounted in most cases to about 0.01% of that of the solution tested and never to more than 0.1%.

Radioactive sodium, Na^{22}, was obtained from a magnesium target which had been bombarded with deuterons in the University of California cyclotron. A chemical separation without sodium carrier was made by Mr. R. K. Madison of the Radioactivity Group of these Laboratories. Radiobromine, Br^{82}, was obtained with no carrier by the Szilard-Chalmers procedure(8) from C. P. ethyl bromide bombarded with neutrons from the Columbia University cyclotron. In preparing the tagged solutions, two aliquots of a stock solution were diluted to volume, in one case with a radioactive tracer solution and in the other with water.

Procedure.—The left-hand side of the U-tube, the region below the membrane, and the membrane itself are filled with the solution to be investigated. Compartment B may be rinsed by the use of stopcock S-2; stopcock S-1 is to prevent streaming through the membrane while compartment A is rinsed and filled with the leading solution.

The cell is placed in a thermostat and the desired voltage impressed across the electrodes from storage batteries. A milliammeter and voltmeter serve to check the approximate wattage; no extensive experiments have been made, but the apparatus works satisfactorily up to about 500 milliwatts. The current is read periodically with a Leeds and Northrup type K-2 potentiometer in terms of the voltage across a fixed series resistor. The duration of the experiment depends entirely upon the transference number of the ion under investigation; in the examples given in this paper a calculated movement of about a centimeter for the ion under investigation was found to be satisfactory—tripling this movement gave results several per cent. too low. With the arbitrary limit set on the wattage, this required thirty to ninety minutes, depending upon the concentration.

Analyses.—At the completion of a run the analytical compartment A was rinsed out, then the contents made up to a specified volume. Closing stopcock S-1 prevents streaming during this operation.

Silver and bromide ions were titrated conductometrically with potassium bromide and silver nitrate, respectively (precision *ca.* ±0.2%); the radioactive solutions were counted in a small glass jacketed Geiger counter tube(9) with a conventional amplifying and scaling circuit, and the total number of counts taken on a given sample was sufficient to make the probable counting error less than ±1%.

Results and Discussion

The results of a series of transport determinations in simple electrolytes using the analytical boundary method are given in Table I. The first example, potassium nitrate leading, silver nitrate following, from which T_{Ag^+} was determined, is a system forming a stable boundary. In the second example, potassium nitrate leading, potassium bromide following, from which T_{Br^-} was determined, the boundary is convectionally stable but unstable electrically.

The last three rows in Table I are examples of the radiotracer method. The second of these, in which Na^{22} is used to trace Na^+, is straightforward. In the first, Br^{82} is used to follow Cl^- in NaCl, this combination being adopted to test the general feasibility of using radiobromide to trace chloride ion. The radioisotopes Cl^{34} and Cl^{38} are of too short half life (thirty-three and thirty-seven minutes) for convenient use, and the long lived Cl^{36} (10^3 yr.) was not available to us. The observed migration of radiobromine was divided by the ratio of the equivalent conductivity of Br^- to that of Cl^- at infinite dilution to convert to chloride migration.

In Table II the analytical boundary results are compared with those obtained by the moving boundary(4) and the Hittorf(10) methods. The latter are older values and would be considerably improved by modern techniques, but only with a corresponding increase in manipulative and analytical difficulties. From the results in the table it

(10) Landolt-Börnstein, "Tabellen," HWII, p. 1109.

can be seen that although the listed analytical boundary results are only accurate to about 2%, they are as accurate as a reasonably careful Hittorf determination (taking the moving boundary values as correct), and certainly far less tedious and analytically exacting. The accuracy could be improved by a careful purification of materials and by more precise analytical procedures, but is shown to be sufficient for the purposes for which the cell was designed. The substances listed in Table I were run, of course, only for test purposes, since the moving boundary method gives more accurate results just as quickly. In a following paper (with D. J. Salley), an application to colloidal electrolytes will be presented. It is also obvious that the method is applicable to the study of proteins, dyes (where colorimetric analysis may readily be used), and complex systems such as solutions of acid polymerized trimethylol melamine.

Table II

Comparison of Analytical Boundary Results with Other Methods

Solution	Concn.	Cation transference no. Analytical boundary	Moving boundary	Hittorf[a]
$AgNO_3$	0.1	0.473	0.468	0.474
	.01	.469	.465	.474
KBr	.1	.481	.485	...
	.01	.471	.483	.496
NaCl	.05	.399	.390	.396
	.02	.396	.389	.396

[a] These values are at 18°; the temperature correction is small but should tend to *raise* them.

Acknowledgment is due to cyclotron groups at the University of California and at Columbia University for radiotracers. In addition the writer wishes to express his gratitude to Drs. J. K. Dixon and D. J. Salley for advice and criticism, and to thank the Directors of this Laboratory for permission to publish these results.

Summary

1. The design and operation of a cell of simple construction for measuring transference numbers, embodying a combination of the Hittorf and moving boundary techniques, is described. Because of the interchange of the usual roles of the leading and indicator solutions as compared to the moving boundary method, the method is suited for electrolytes containing a colloidal ion.

2. Analytical requirements are much less exacting than in the Hittorf method, permitting a wide choice of methods (*e. g.*, radioactivity counts, conductometric titrations, and colorimetry).

3. In complex systems where the moving boundary results would be difficult or impossible to interpret, radiotracer techniques may be readily applied. Because of the reduced analytical requirements ordinary counting methods may be used.

4. Tests of the cell using solutions of simple electrolytes, employing both analytical and radiotracer methods, indicate an accuracy equivalent to that obtained in reasonably careful determinations by the Hittorf method.

The Self-diffusion Coefficients and Transference Numbers of the Small Ions in Colloidal Electrolytes

By A. P. Brady[1a] and D. J. Salley

Introduction

The fraction of small ions associated kinetically with the large aggregates in aqueous solutions of colloidal electrolytes is of general interest for the better understanding of these solutions. The "fraction bound" has been estimated for various colloidal systems from measurement of the thermodynamic properties of the solution, as by freezing point depression[1] or dew point lowering,[2] from the conductivity plus the transference number,[3,4] from e. m. f. measurements,[5,6,7] and from membrane equilibrium.[8] In addition specific methods have been used, such as measuring the *p*H of hexanolamine caprylate solutions containing excess hexanolamine,[9] and the increase of conductivity of lauryl sulfonic acid solutions when potassium nitrate is added.[10] Another general method that suggests itself is self-diffusion, but insofar as the authors are aware it has not yet been applied to this problem.

Any value of the fraction bound derived from experimental data must, of necessity, result from a series of assumptions. Because of this, the values obtained from any one of the above methods may be quite uncertain. This paper compares, under consistent assumptions, the fraction bound as obtained by three methods: self-diffusion, conductivity plus transport, and freezing point lowering.

The experimental work comprised the determination for two cationic and two anionic agents of the self-diffusion constant and the transference number of the small ion, as well as the solution conductivities. The freezing point data used were taken from the literature.

A feature of the experiments was that radioactive isotopes were employed. In self-diffusion, isotopic tracers are of course required, and they are also of considerable aid in the rapid measurement of transference numbers in complex systems by the "analytical boundary" method described in the foregoing paper.[11] It is worthy of note that the tracer technique obviates errors which may arise if equilibria involving various micelle types are not fast compared to diffusion or electrical transport.

Experimental

Materials

Sodium 2-Ethylhexyl Sulfosuccinate (Aerosol OT).—Commercial "Aerosol OT 100%" (American Cyanamid Company) was used after vacuum drying at 110° for several hours.

Sodium Methyl Amyl Sulfosuccinate (Aerosol MA).—Dried commercial "Aerosol MA 100%" (American Cyanamid Company) was used. At low concentrations faintly hazy solutions were formed presumably because of the presence of a small amount (approximately 1%) of the corresponding maleic ester. Such solutions were cleared by passage through a bacteriological filter, in order to protect the membranes in the diffusion and transport cells. The filtration had no detectable effect upon the conductivity.

N-(Laurylcolaminoformylmethyl)-pyridinium Chloride (E-607).—Material supplied by the Emulsol Corporation was used directly.

Myristamidopropyldimethylbenzylammonium Chloride.—This is hereafter referred to as "Agent M," for purposes of abbreviation. A special preparation made at these Laboratories was employed. The only impurity detected (other than water) was 1.0% of the unbenzylated tertiary amine.

Radiotracers.—The anionic materials were tagged with either Na^{22} or Na^{24}. The former was obtained carrier free as described in the foregoing paper.[11] The latter was usually received as a solution of sodium chloride from Columbia University. In one series of runs, however, Aerosol OT solutions were bombarded directly with neutrons to produce the Na^{24}.

The chloride ion in the cationic agents was followed by Br^{82}, the latter being obtained carrier free from neutron-bombarded ethyl bromide. Radiobromine appears to serve well as a chloride tracer provided the results are corrected for its 3% higher mobility.[11]

Solutions.—The tagging of the various solutions was accomplished by adding the requisite amount of radioactive solution to one aliquot of a stock solution and an equal volume of water to another. The radioactive solutions used for tagging invariably contained extraneous electrolytes, and the amount present was estimated by conductivity or analysis. The specific activities were so high that the total amount of electrolyte introduced in the tagging operation was less than 0.1% of the final concentration. One exception to this is referred to below.

Procedure

Self-diffusion.—The cells used for self-diffusion were the sintered-glass membrane (Pyrex F) type similar to those described by McBain and Dawson.[12] To provide stirring, which is necessary because of lack of density gradients, each compartment contained a 1-cm. length of 1-cm. Pyrex tubing and the cells were rotated end-over-end at 3 r. p. m. A preliminary diffusion period of three to six hours was adopted to establish a steady state in the membrane, after which fresh solutions were substituted and diffusion allowed to proceed until 5 to 10% of the radioactivity had diffused. Determination of the cell constants was carried out with 0.1 *N* KCl, taking 1.595 sq. cm./day as the diffusion constant.[13] The diffusion results were calculated according to the usual logarithmic formula

$$KD = -\frac{1}{t}\log\left[1 - \frac{(1+F)C}{C_0}\right]$$

where K is the cell constant, D the diffusion constant, F the ratio of the volumes of the diffusate to diffusing compartments, t the duration of the experiment, C the concentration of the diffusate and C_0 the initial concentration of diffusing material. Concentration units cancel, so that radioactivity counts can be substituted directly.

Transference.—Transference numbers were determined by the "analytical boundary" method described in detail in the foregoing paper.[11] The present application involves the measurement of the amount of radioactivity transported electrically across the boundary created by the sintered glass membrane.

Conductivity.—A Leeds and Northrup 60-cycle bridge (Cat. no. 4866) and a dipping electrode were used. Results were good to about ±0.5%, no attempt being made to obtain highly precise data. Diffusion, transference, and conductivity experiments were made at 25 ± 0.01°.

Radioactivity Measurements.—This radioactive solutions were counted in a small glass-jacketed Geiger counter tube with a conventional amplifying and scaling circuit.[11] Sufficient counts were taken to make the probable counting error less than ±1%.

Results

Self-diffusion.—Self-diffusion results for sodium in Aerosol OT and in Aerosol MA, and for bromine in Agent M and in E-607 are given in Table I. Included are the data for the same ions in sodium chloride. The effect of micelle formation in lowering the rate of self-diffusion of the small ions is clearly evident from the data; this will be discussed quantitatively in a later section of this report.

TABLE I

SELF-DIFFUSION COEFFICIENTS OF SODIUM AND OF BROMIDE IONS

Substance	Tagging ion	Concentration *N*, mole/liter	Self-diffusion constant of tagging ion, *D*, sq. cm./day *a*	*b*	Av.

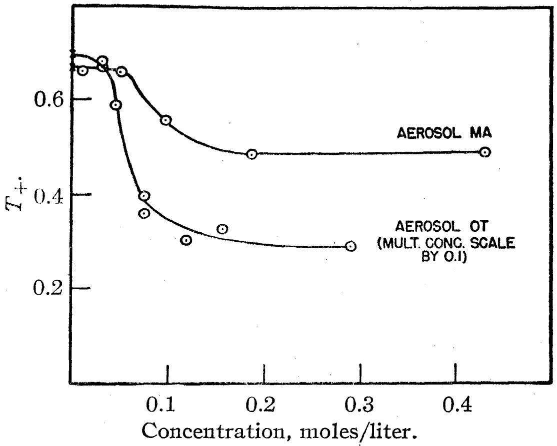

Fig. 1.—Cation transference numbers in Aerosol OT and in Aerosol MA solution.

Aerosol OT or sodium chloride, 1.20 sq. cm./day, is greater than the theoretical limiting value, 1.15 sq. cm./day. This probably arises because the method of calibration of the cells (diffusion of 0.1 *N* KCl into water) leads to density gradients, whereas no such gradients exist in this self-diffusion. Such differences may bring about a 5 to 10% change in the effective thickness of the membrane.[14] Since the self-diffusion will be employed entirely on a comparative basis, a calibration error of this sort will have no appreciable effect upon the conclusions drawn.

Conductivities.—The equivalent conductivities of the two Aerosols are included in Table II; these agree with the data of Haffner, Piccioni and Rosenblum[15] to within 1%. The critical concentrations appear to be about 0.005 *N* and 0.05 *N* for the OT and the MA, respectively. Extrapolation of the usual curves of conductivity *versus* square root of concentration leads to limiting conductivities of 72 and 75, which in turn give 22 and 25 as the limiting conductivities of the two Aerosol anions (using 50.1 for the Na ion).

Transference Numbers.—Table II also gives the mobilities and transference numbers at various concentrations. The specific conductivities are those of the tagged solution, which in most cases do not differ appreciably from those of the untagged. Special mention is required, however, for one series with Aerosol OT, where because of a miscalculation far too much tagging solution was added, and the extra electrolyte so introduced could not be neglected. About the only recourse under these circumstances is to assume that the extra electrolyte did not appreciably affect the mobility of the sodium ion, even though its transference number changed. The observed mobility and the conductivity of the untagged solution may then be employed in order to estimate the transference number in the absence of a foreign electrolyte. Because of the resulting uncertainty, however, a series was also run in which the Aerosol OT solutions were directly bombarded by neutrons to give Na^{24}; this procedure should introduce no foreign electrolyte. As is shown in Table II, results by both methods are in essential agreement.

Table II

Transference Numbers of Sodium and of Chloride Ions

Substance	Tagging ion	Concentration, *N*, mole/liter	Sp. cond. mho/cm. × 10^3	W, sq. cm./volt, sec. × 10^4	*T*	Λ^c
Aerosol MA	Na^{22}	0.0100	0.69	4.75	0.65	69
	Na^{22}	.0300	1.93	4.70	.68	64

[a] Activity produced directly by neutron bombardment of the solutions. [b] Excess electrolyte, see text. [c] Derived from measurements on the untagged solutions.

The transference numbers of Aerosols MA and OT are plotted against concentration in Fig. 1. There is a sharp change in transference number in the neighborhood of the critical concentration.

Calculation of the Fraction of Small Ions Bound to the Micelles.—In order to utilize the foregoing data for calculating the fraction of small ions bound, a general model for the association is necessary. We shall assume that below the critical concentration the long chain ions have a concentration equal to the stoichiometric concentration of the solution; above the critical, large aggregates are formed by these ions, including varying amounts of small ions. The free monomeric ions will be assumed to behave roughly as they would in a univalent salt solution at the same total concentration. This is in accord with earlier data of others[7,16] obtained on similar systems.

Since the aggregate is assumed large, as a first approximation the concentration of monomeric long chain ions may be taken to change little with total concentration above the critical, in the range considered in this paper. Actually, since more long chain ions than small ions are included in the micelle, mass law predicts that at concentrations above the critical the concentration of monomeric long chain ions will decrease with increasing

total concentration. However, calculation of the rate of decrease on a reasonable model indicates that, in the concentration region where the influence of the single long chain ions is important in the equations to be developed, the inaccuracy of the above simple assumption is small compared to other uncertainties.

In the following equations the colloidal electrolyte will be considered to be anion active; for a cation active agent the signs of the subscripts are simply interchanged. Because of lack of detailed knowledge concerning the colloidal particles, all species must, of necessity, be lumped together and thought of as an "average" micelle. This effectively assumes that the mobility of the average bound small ion is the same as that of the average aggregate, which is, of course, not necessarily true.

Self-diffusion.—Denoting the diffusion constant of the average micelle by D_m, that of the free cations by D_+^0, and the measured net diffusion constant of the cations by D_+

$$D_+ C = D_+^0 C_+^0 + D_m C_+^B \qquad (1)$$

where C, C_+^0 and C_+^B are the total, free cation, and bound cation concentrations, respectively. Noting that $C_+^B + C_+^0 = C$, equation (1) transforms to

$$C_+^B/C = \frac{D_+^0 - D_+}{D_+^0 - D_m} \qquad (2)$$

Transference.—Letting W be the mobility in sq. cm./volt second, with subscripts and superscripts having the same meaning as before, the flux of the positive and negative ions across one square centimeter at a field strength of one volt/cm. is given by

$$\begin{aligned} CW_+ &= C_+^0 W_+^0 - C_+^B W_m \\ CW_- &= C_-^0 W_-^0 + C_-^B W_m \end{aligned} \qquad (3)$$

Equations (3) may be combined with the well known equations $W_i = \Lambda_i/F$, $T_+ + T_- = 1$, and $T_i = \Lambda_i/\Lambda$ (where Λ is the observed equivalent conductivity) and the material balance $C = C_+^0 + C_+^B = C_-^0 + C_-^B$. It follows that

$$C_+^B/C = 1 - \frac{\Lambda - (C_-/C)(T_+\Lambda + \Lambda_-^0)}{\Lambda_+^0 + (1 - T_+)\Lambda - (C_-^0/C)\Lambda^0} \qquad (4)$$

where $\Lambda^0 = (\Lambda_+^0 + \Lambda_-^0)$ is the hypothetical conductivity the solution would have if there were no micelle formation. Now, according to the assumption made above for the model, $C_-^0 \cong C_c$ at concentrations above the critical; consequently in applying equation (4) in subsequent calculations, this approximation will be used. It may be noted that at concentrations far above the critical, where $C_c/C \ll 1$, the above equation reduces to that derived and discussed by Molliet, Collie and Hartley.[17]

Freezing Point Depression.—Since it is supposed that the micelles are of sufficient size so that their contribution to the freezing point depression is negligible, the osmotic coefficient, g (the ratio of the observed to the theoretical freezing point lowering), may be considered to be the sum of two terms, the first arising from the free long chain ions, the second from free small ions

$$g = \frac{C_-^0 + C_+^0}{2C}$$

Again using the approximation that $C_-^0 \cong C_c$, along with the equation for the material balance

$$C_+^B/C = 1 - 2g + C_c/C \qquad (5)$$

Calculations.—The non-experimental quantities in equations (2), (4) and (5) are D_+^0, D_m, Λ_+^0 and Λ^0. Accordingly, the model must be used for their estimation.

The self-diffusion constants for the sodium ions, D_+^0, may be taken directly from the experiments on sodium chloride recorded in Table I, except in the case of Aerosol MA, which was studied in a higher concentration range. Since Jehle[18] has found that the self-diffusion coefficient of Na^+ in NaCl in the concentration region 0.05–0.5 N is nearly constant and about 8% lower than at infinite dilution, D_+^0 may be taken as 1.10 sq. cm./day throughout the range studied for the Aerosol MA.

There is no very good way to estimate the self-diffusion coefficient of the micelles, D_m. It is hoped to measure this in the near future for the sulfosuccinates using radiosulfur. One logical assumption is that the micelles binding small ions are so large that their diffusion constant can be neglected. Another, which is that employed here, is to extend the observation of Hartley and Runnicles[19] that the diffusion coefficients of some cationic agents swamped with salt roughly correspond to those of spheres with a radius equal to the length of the molecule. This leads to a D_m of 0.16 and 0.14 sq. cm./day for the micelles of Aerosols MA and OT, respectively, corresponding to lengths of 13 Å. and 15 Å. Those for E-607 and Agent M will be taken as 0.073 and 0.070, corresponding to 29 and 30 Å.

The electrical conductivities of the free monomeric ions, Λ_+^0 and Λ_-^0, will, according to the model, vary with concentration in the same proportion as the conductivity of sodium chloride solutions.

No correction will be applied to D_+^0, D_m, Λ_+^0 or Λ_-^0 for the viscosity increase of the solution. Such a viscosity correction would not greatly influence results for Aerosol OT and the cationic agents, but if applied to the results for Aerosol MA the self-diffusion of the sodium ion not only falls out of line with the other salts but becomes unreasonably high at the higher concentrations. This lack

of influence of solution viscosity on the mobility of the small ions is in harmony with McBain's observations on the conductivity of solutions of colloidal electrolytes.[20]

The critical concentration for micelles is also needed for utilization of the equations for the fraction of small ions bound. Table III lists this quantity for the surface active agents considered here, as determined by transference (Fig. 1), conductivity (Table II and Ref. 16), freezing point,[21,22] and surface tension.[23] The present self-diffusion data are too meager to be useful in this connection.

TABLE III

CRITICAL CONCENTRATION OF THE SURFACE ACTIVE AGENTS

Substance	Critical concn., N	Method
Aerosol MA	0.055	*a, b, c*
Aerosol OT	.0035	*a, c, d*
	.0055	*b*
Agent M	.0009	*d*
E-607	.005	*c*

[a] Transference numbers. [b] Conductivity. [c] Freezing point lowering. [d] Surface tension.

Table IV gives a comparison of the application of equations (2), (4), and (5) in estimating the fraction of small ions bound to the micelle. The osmotic coefficients for the Aerosols were taken from McBain and Bolduan,[21] that for E-607 from McBain and Brady.[22] The data of the table show that there is fair concordance among the three methods of measurement up to concentrations three to four times greater than the critical. This lends support not only to the model, but to the general validity of the self-diffusion or the transport approach to systems where the freezing point method is not applicable. (An exception to the general agreement is the self-diffusion run at the lowest concentration of Aerosol MA; this value is included because nothing could be found wrong with the experiment, but it can be seen even in Table I that it falls out of line.)

TABLE IV

COMPARISON OF PERCENTAGE OF SMALL IONS BOUND AS CALCULATED FROM SELF-DIFFUSION, TRANSPORT, AND FREEZING POINT

Substance	Concn., N	% Small ion bound Self-diff.	Trans.	F. P.
Aerosol MA	0.050	22 (?)	0	0
	.096	17	12	14
	.186	25	37	39
	.430	50	30	55
Aerosol OT	.0029	0	0	0
	.0045	..	15	11
	.0074	..	22	19
	.0118	..	29	30
	.0289	36	35	52[a]
Agent M	.0194	75	65	..
E-607	.0617	69	54	70

[a] Calculated from an extrapolated value of g obtained from a generalized curve for this compound.[22]

The results of the calculation according to equation (2) are relatively insensitive to values chosen for the self-diffusion coefficient of the micelles, D_m, since under any reasonable assumption, D_m should be small compared with D_0^+. If, for instance, zero had been assumed instead of 0.16 for D_m, then at 0.430 N Aerosol MA, the calculated per cent. bound would be 47 rather than 50. Results from Equation (4) are still less sensitive to variations in Λ_0^-, the equivalent conductivity of the monomeric long chain ions.

At the higher concentrations, the agreement in the calculated "fraction bound" becomes less satisfactory, especially between freezing point and transport results (at still higher concentrations than those studied here it is known[4] that such disparity becomes even greater). The disagreement could arise from a true difference in this quantity when the three different measurements are involved; thus surface conductivity on lamellar micelles of high surface area would give a lower "fraction bound" for diffusional or electrical transport processes than that derived from osmotic measurements. Another cause for disagreement lies in the assumption of an "average" micelle, since the presence of some "ionic" micelles, proposed by McBain a number of years ago,[2] would lead to an apparently lower "fraction bound" from the transport than from the diffusion and freezing point methods.

The inclusion of small ions in the colloidal particle is a logical consequence of the electrostatic effects of aggregation. The juxtaposition of the like charges of the end groups at the water-micelle interface would disrupt the micelle unless a large number of small ions of opposite charge are drawn in to neutralize partially what would otherwise be an excessive electrostatic potential. In the interior of the lamellar micelles indicated by X-ray diffraction studies,[24] this effect will be even more pronounced, so that there should be virtually no osmotically active small ions arising from this region. Because of the masking effect of the small ions, osmotic data from freezing points consequently give no direct idea of the size of the micelle, except in that it is fairly large.

A further consideration of the question of bound ion, however, offers an opportunity for indirect comparison between certain colloidal electrolytes. The values for the fraction bound given in Table IV are based on total long chain ion, micellar plus monomeric. In order to determine the amount bound per mole of micellar ion, use can be made of the probability that in the range considered the concentration of monomeric long

chain ions changes little with total concentration above the critical. The desired quantity is then $\mathrm{d}C_+^{\mathrm{B}}/\mathrm{d}C$, the number of small ions bound per mole of colloidal electrolyte added to an infinite amount of solution. From equation (5)

$$\frac{\mathrm{d}C_+^{\mathrm{B}}}{\mathrm{d}C} = 1 - 2\,\frac{\mathrm{d}(gC)}{\mathrm{d}C} \qquad (6)$$

Figure 2 shows a plot of gC *vs.* C for Aerosols MA and OT, and, for comparison potassium laurate.[21,25] It can be seen that slightly above the critical concentration straight lines result, the slopes of which provide values for $\mathrm{d}(gC)/\mathrm{d}C$ in equation (6). The slopes for the Aerosol-type agents are about 0.16; hence, $\mathrm{d}C_+^{\mathrm{B}}/\mathrm{d}C = 0.68$, and consequently for each hundred moles of Aerosol added 68 moles of sodium are included in the micelles. For potassium laurate, on the other hand, $\mathrm{d}C_+^{\mathrm{B}}/\mathrm{d}C = 0.86$. Since nearly all of the potassium is included, this suggests much larger micelles for this substance, although possibly the structure of the micelles may also play a role. This general difference exists between the branched chain salts, to which class most of the efficient wetting agents belong, and the straight chain salts, among which are found the more efficient solubilizing and emulsifying agents.

Acknowledgment.—The authors wish to thank the cyclotron groups at Columbia University and the University of California for the supply of radiotracers. Also, we wish to express our indebtedness to Dr. J. K. Dixon for valuable advice and criticism, and to the Directors of these Laboratories for permission to publish these results.

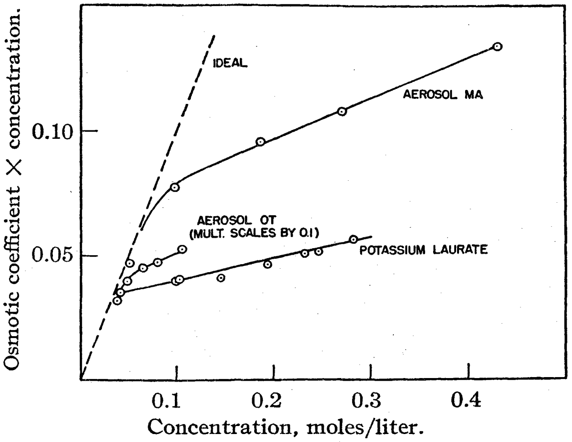

Fig. 2.—Osmotic coefficient times concentration *vs.* concentration for some colloidal electrolytes.

Summary

1. The transference numbers and self-diffusion coefficients for two anionic and two cationic surface active agents were determined using radiotracer techniques.

2. Utilizing the present results and freezing point data extant in the literature, the fraction of the small ions bound to the colloidal aggregates was calculated under consistent assumptions. The values calculated from the three types of measurements agreed well with one another up to several times the critical concentration for micelles. Possible causes for disagreement among the three types of measurements at higher concentrations were discussed.

3. The relationship of the extent of binding to the structure and size of the micelles was briefly considered.

Liquid Immiscibility in the System H_2O–Na_2O–SiO_2

BY O. F. TUTTLE[1] AND I. I. FRIEDMAN

Introduction

The dwindling supply of natural quartz for piezoelectric uses, together with the remarkable success attained in growing other crystals for a variety of uses, has stimulated interest on the part of the Armed Forces in the production of synthetic quartz. This work on phase equilibria in a portion of the ternary system H_2O–Na_2O–SiO_2 is a result of efforts to find a commercially feasible method for growing quartz crystals.

The data presented here are incomplete, but publication at this time seems advisable because of the theoretical and practical value of the information. Liquid immiscibility has been observed and investigated in the region $Na_2Si_2O_5$–SiO_2–H_2O. The 250, 300 and 350° isotherms have been worked out at the vapor pressures of the compositions investigated.

Preparation of Materials

All mixtures used in this work were made from a stock solution of sodium hydroxide and quartz or silica glass. The solution was prepared by saturating distilled water with reagent grade sodium hydroxide at 80°. The sodium carbonate precipitated was allowed to settle and the solution decanted through glass wool. The saturated solution was then diluted to approximately 20 *N* and stored in a wax-lined bottle. The composition was determined by titrating a weighed volume against a standard solution of sulfuric acid. The resulting solution contained 388 g. of sodium oxide per 1000 g. and had a specific gravity

---

[1] Present address: Geophysical Laboratory, Carnegie Institution of Washington, Washington, D. C.

of 1.566 at 25°. After one year, the composition was again determined by titrating with sulfuric acid and was found to be unchanged. A gravimetric check of the sodium oxide and silicon dioxide content gave a sodium oxide content of 386 ± 2 g. per 1000 g. and a silicon dioxide content of less than 0.1%.

Quartz oscillator plates of various sizes were used for all solubility experiments. The rate of solubility was determined using slabs of quartz cut and ground to uniform size. The variation in area of these blocks was less than 0.5%.

Clear silica glass rods were used for all other experiments. The rods were crushed in a diamond mortar and sieved. The material passing the 100 mesh, but not the 250 mesh screen was used after boiling in concentrated hydrochloric acid, washing and igniting at 800° in platinum crucibles. A 0.5 g. sample gave less than 0.0001 g. of residue on treatment with sulfuric acid and hydrogen fluoride.

Analytical Methods

The composition of the two immiscible liquids was determined by chemical analysis. The water content was determined in platinum crucibles by the loss of weight on ignition at bright red heat. As both liquid phases were readily soluble in water, the silicon dioxide was determined by precipitating with hydrochloric acid and igniting as silicon dioxide. It was found necessary to use two precipitations. Evaporation of the filtrate from the silicon dioxide precipitations gave the sodium oxide content as sodium chloride. The sodium chloride was heated to constant weight at 250°.

Experimental Methods

As the vapor pressures of the compositions investigated are of the order of magnitude of the vapor pressure of water at the temperatures employed (250, 300, 350°), it was necessary to use a container that was capable of withstanding considerable pressure. A bomb (Fig. 1) described by Morey and Ingerson[2] was found to be satisfactory. For part of the work it was found necessary to modify the seal slightly and to line the chamber by plating with gold (0.01 in.). The seal on the gold-plated bombs is illustrated in Fig. 2. The silver disc welded to the seat during the experiments, and on opening it was necessary to cut out the center of the disc, leaving a silver ring on the shoulder of the pressure chamber. In subsequent runs the silver continued to weld to the previous silver rings and it was necessary to dissolve the excess silver from the shoulder after 10 or 20 runs. The silver disc seal was also used in unlined bombs for much of the work, as it tended to prevent leaking during quenching.

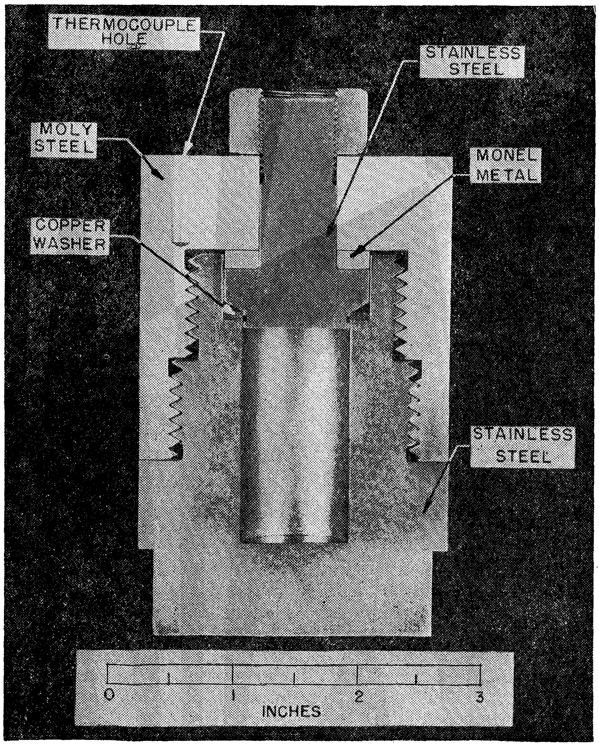

Fig. 1.—Cross-section of bomb used for this work.

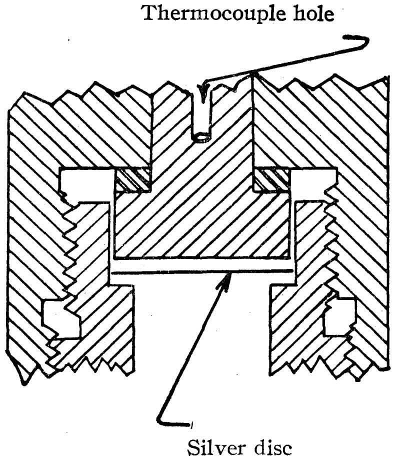

Fig. 2.—Cross-section of a portion of bomb showing construction when used with a silver disc as a seal.

The charges were stirred to hasten equilibrium by rocking the furnaces throughout the experiments (Fig. 3). The cylindrical resistance furnaces were oscillated 60° at 15 cycles per minute about an axis normal to the long axis of the bombs. Furnace temperatures were set manually by regulating the input voltages to the wire-wound heating element by means of a variac. Line voltage variations were kept to a minimum by a constant voltage transformer. It was possible to maintain temperatures at the thermocouple within ±2° by this method, but variations in the gradients between the thermocouple and charge in the different bombs used leads to an estimated uncertainty of ±5°. Temperatures were continually recorded by a Brown Electronik Strip Chart recorder using iron–constantan thermoelements.

Quartz Solubility Determinations.—The solubility of quartz in sodium hydroxide solution was used to establish the boundary of the quartz field. A weighed block of quartz was placed in an 18-cc. bomb together with 10 cc. of a sodium hydroxide solution of known composition, and the bomb was sealed. The bombs were then placed in the rocking furnaces at a predetermined temperature and allowed to attain equilibrium (thirty-six to one-hundred hours, depending upon temperature and composition), after which they were quickly removed and quenched under the cold water tap. The bomb and contents cooled to 100° within forty-five seconds and to room temperature in ninety seconds. The bombs were then opened and the quartz plate removed, washed and reweighed.

The composition of the solution in many of these runs passed through the stability field of sodium disilicate as the silica was being dissolved from the quartz plate; hence, if the length of run was insufficient to reach equilibrium, crystals of sodium disilicate were present on quenching.

Hydrothermal Quenching Method.—Equilibrium relations were studied by determining, at various constant

---

[2] G. W. Morey and Earl Ingerson, *Am. Mineral.*, **22**, 1121–1122 (1937).

temperatures, the presence or absence of crystalline and liquid phases on changing the composition of a series of sodium hydroxide–water solutions varying in composition from 1.5 to 38.8% sodium hydroxide, by adding different amounts of silica. A weighed amount of silica glass was placed in a bomb and 10 cc. of sodium hydroxide solution of known composition added. The bombs were heated, quenched, and examined as in the solubility determinations. All crystalline phases were examined and identified with a petrographic microscope.

The method can be illustrated by an example as follows: To 10 cc. of a solution containing 5.8% sodium oxide and 94.2% water at 300°

0.22 g. silica—one liquid, no crystalline phase
0.33 g. silica—one liquid plus disilicate crystals
1.35 g. silica—two liquids plus disilicate crystals
1.50 g. silica—two liquids no crystalline phase
1.90 g. silica—two liquids plus quartz crystals

Thus it can be seen that, by varying the amount of silica above and below that at which a new phase appears, the limits between which the phase appears can be fixed. These are, then, points on fusion or solubility surfaces of the phases in question.

One disadvantage of the method is that the pressures are not known and cannot be calculated with any reasonable degree of accuracy except in compositions approaching pure water. However, as there is only one pressure at which equilibrium between any of the phases can exist for a given temperature and composition, the results are useful without this information. The data represent what is usually called the condensed system, that is, the solid–liquid relations at the vapor pressure of the system.

Morey and Fenner[3] have discussed in considerable detail two sources of error in the hydrothermal quenching method as used in working out the system H_2O–K_2O–SiO_2. The first source of error described concerns the possibility that the composition of the quenched glass does not represent the composition of the liquid. This error is negligible in the present work because the composition of the liquid or liquids at the liquidus temperatures *is the composition placed in the bomb* with the exception of the amount lost to the vapor phase. This error would increase, then, as the density and amount of the vapor phase increased. Since the density of the vapor increases with pressure, it seems reasonable to assume that this factor would be greatest for compositions approaching water because the vapor pressure at constant temperature for the compositions investigated would be in all cases less than for water. The amount of vapor phase is greatest at the 300° isotherm since 10 cc. of liquid was placed in the 18 cc. bomb for all runs. For water, the amounts in the liquid and vapor phases would be

at 250° 9.85 g. in liquid, 0.12 g. in vapor
300° 9.77 g. in liquid, 0.20 g. in vapor
350° 9.89 g. in liquid, 0.08 g. in vapor

It thus appears to be a reasonable assumption that the greatest error that would arise would be less than 2% of the composition placed in the bomb.

The second source of error in the quenching technique is in the certainty that the quenched phases have not changed composition during the quench. This has been discussed by Morey and Fenner[4] in considerable detail and the possibility of error in this respect seems very remote.

A third error is in being certain that equilibrium conditions have been attained. This possibility was repeatedly checked by making successive runs with increasing time. Consistent results over a wide range of compositions at different temperatures add to the certainty that equilibrium was attained.

out to determine the equilibrium conditions for the 250, 300, and 350° isotherms. The three isothermal sections are shown graphically in Figs. 4, 5, and 6. Compositions investigated are shown by small circles.

Equilibrium relations can perhaps best be illustrated by discussing, in some detail, the 250 and 350° isothermal sections. (The 300° and 350° are essentially alike.)

At 250° (Fig. 4) the area investigated is divided into two principal regions by the complicated curve H_2O–A–B–C–D–E–F. All compositions to the left of the curve are unsaturated at 250°, and all mixtures to the right of the curve consist of two liquids or of one liquid and one or more crystalline phases. The composition of all liquids that can coexist with crystalline phases is represented by the curve itself with the exception of the portion A–B–C. Mixtures in the area A–C–B consist of two liquids whose compositions vary along A–B and C–B. All other mixtures are partly crystalline at 250°, with the exception of compositions along the SiO_2–Na_2O side of the diagram which are completely crystalline at 250°.

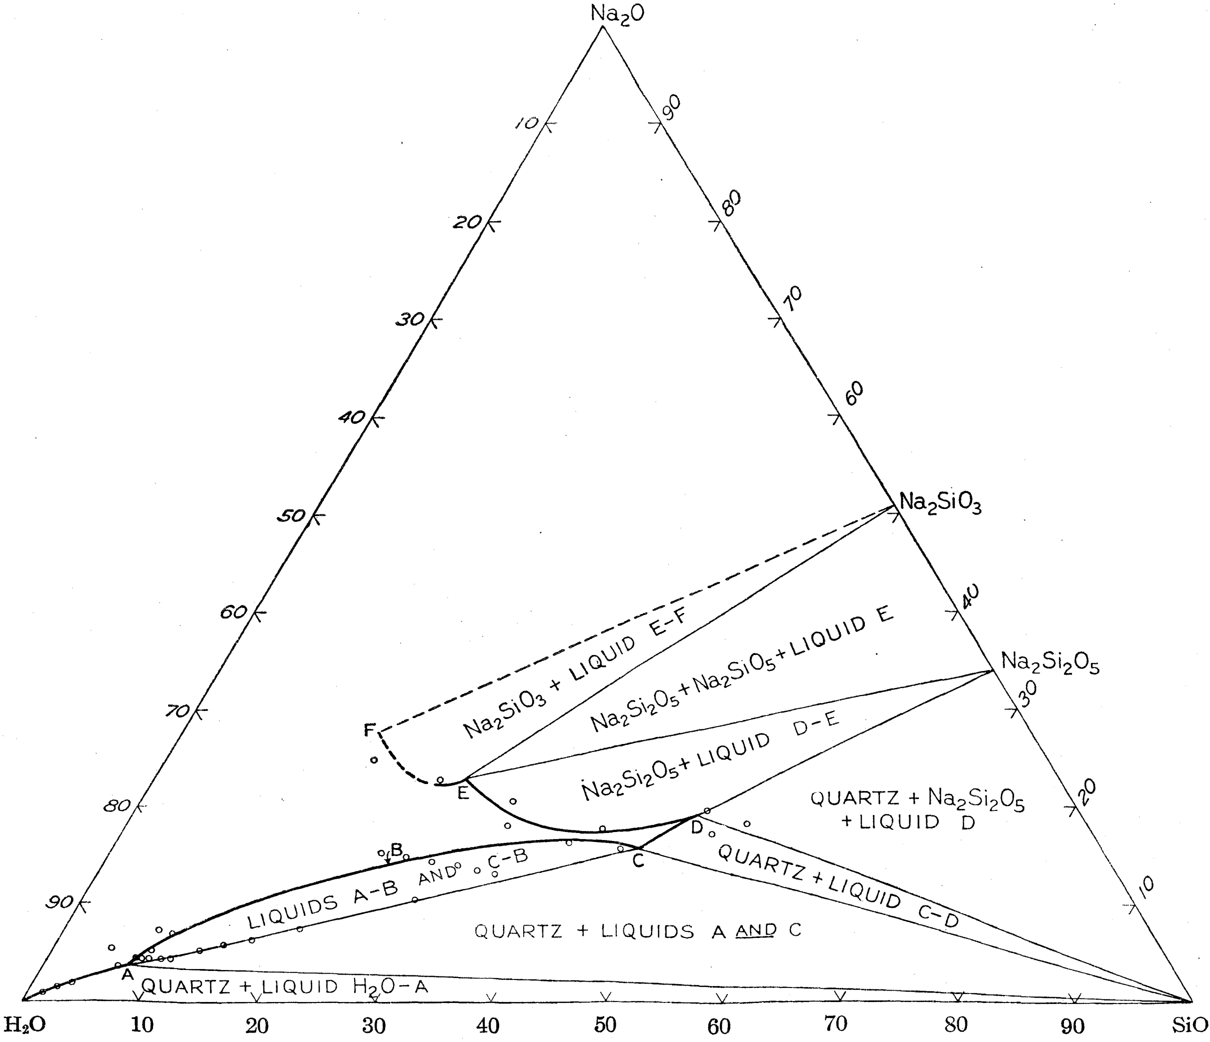

Fig. 4.—Polybaric saturation relations at 250° in the system H_2O–Na_2O–SiO_2.

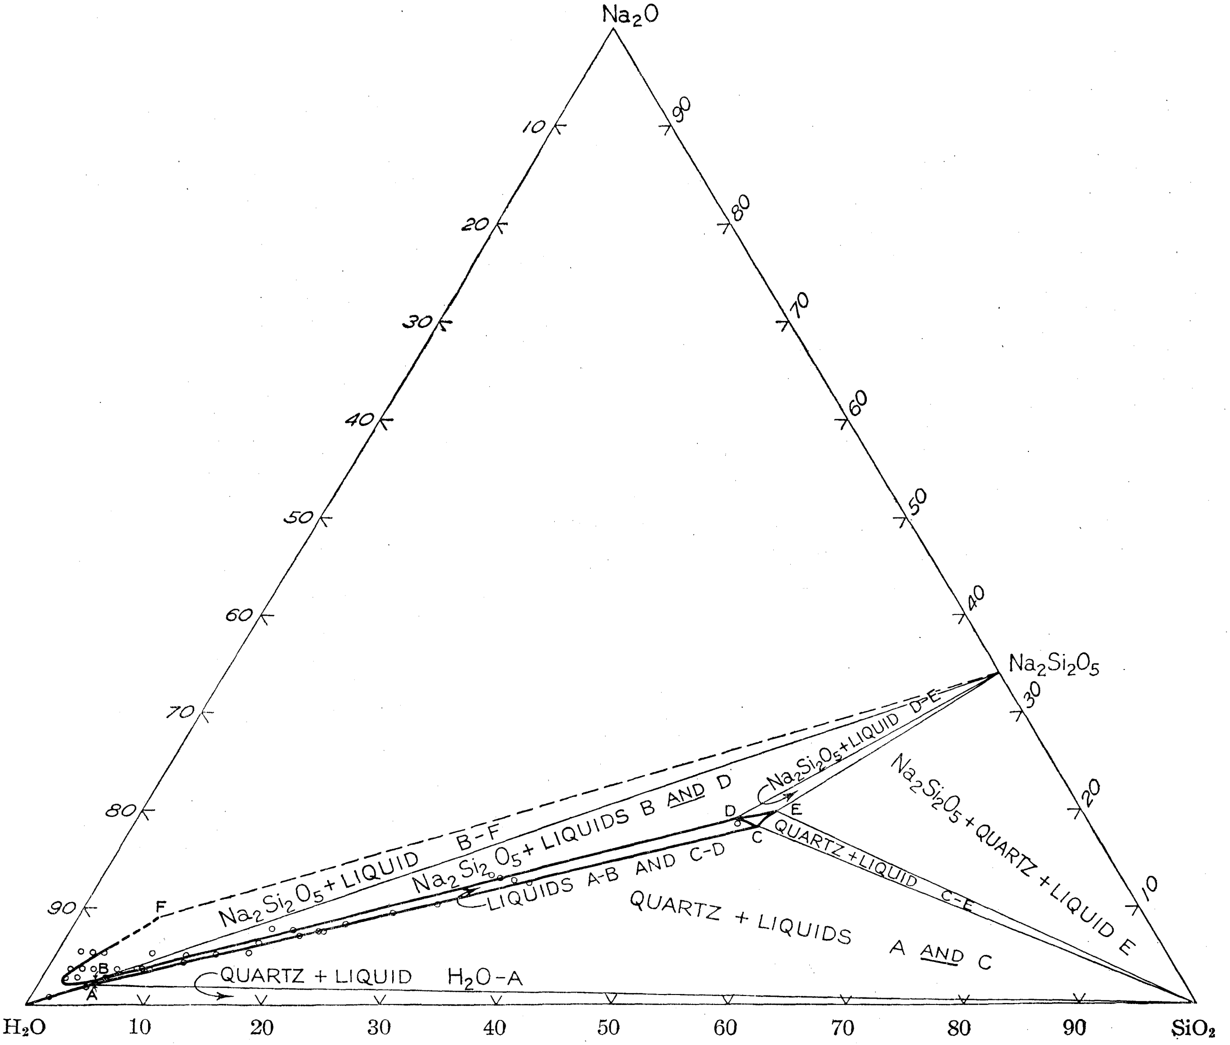

Fig. 5.—Polybaric saturation relations at 300° in the system H_2O–Na_2O–SiO_2.

All mixtures in the area H_2O–A–SiO_2 consist of one crystalline phase (quartz) and one liquid whose composition lies along the curve H_2O–A. Compositions in the triangle A–C–SiO_2 consist of quartz and two liquids A and C. The remainder of the diagram is largely self-explanatory and it seems unnecessary to describe each stability field separately.

The saturation relations at 350° are illustrated in Fig. 6. The relations here are similar to those at 250° with the exception that the $Na_2Si_2O_5$ stability field intersects the immiscible area. All mixtures, then, lying in the area A,B,D,C consist of two liquids A–B and C–D. Compositions in the triangle A–C–SiO_2 consist of quartz and two liquids A and C as at 250° and compositions in the triangle B–D–$Na_2Si_2O_5$ consist of $Na_2Si_2O_5$ crystals and two liquids B and D. The small area C–D–E represents a region consisting of one liquid only and was not realized experimentally; but from theoretical considerations such a relation appears necessary.

The Binary System $Na_2Si_2O_5$–H_2O.—A portion of this system has been studied by Morey and Ingerson.[5] They worked out the pressure–temperature relations at saturation from the melting point of $Na_2Si_2O_5$ (874°) down to 730° and 2000 lb./sq. in.[2] This portion of the system is apparently binary.

At 250° (Fig. 4) the system is binary in part, but where the $Na_2Si_2O_5$–H_2O join intersects the immiscible field, the two liquids formed do not lie on the join, hence the system is not binary from this point to A. From H_2O to point A, quartz crystallizes from $Na_2Si_2O_5$–H_2O mixtures and therefore this part of the system is not binary. There is some uncertainty as to whether or not the system is binary at 300 and 350° because the precision with which point B (Figs. 5 and 6) is located does not permit a decision as to whether $Na_2Si_2O_5$ will form two liquids or one. If two liquids are formed the system will not be binary, as the com-

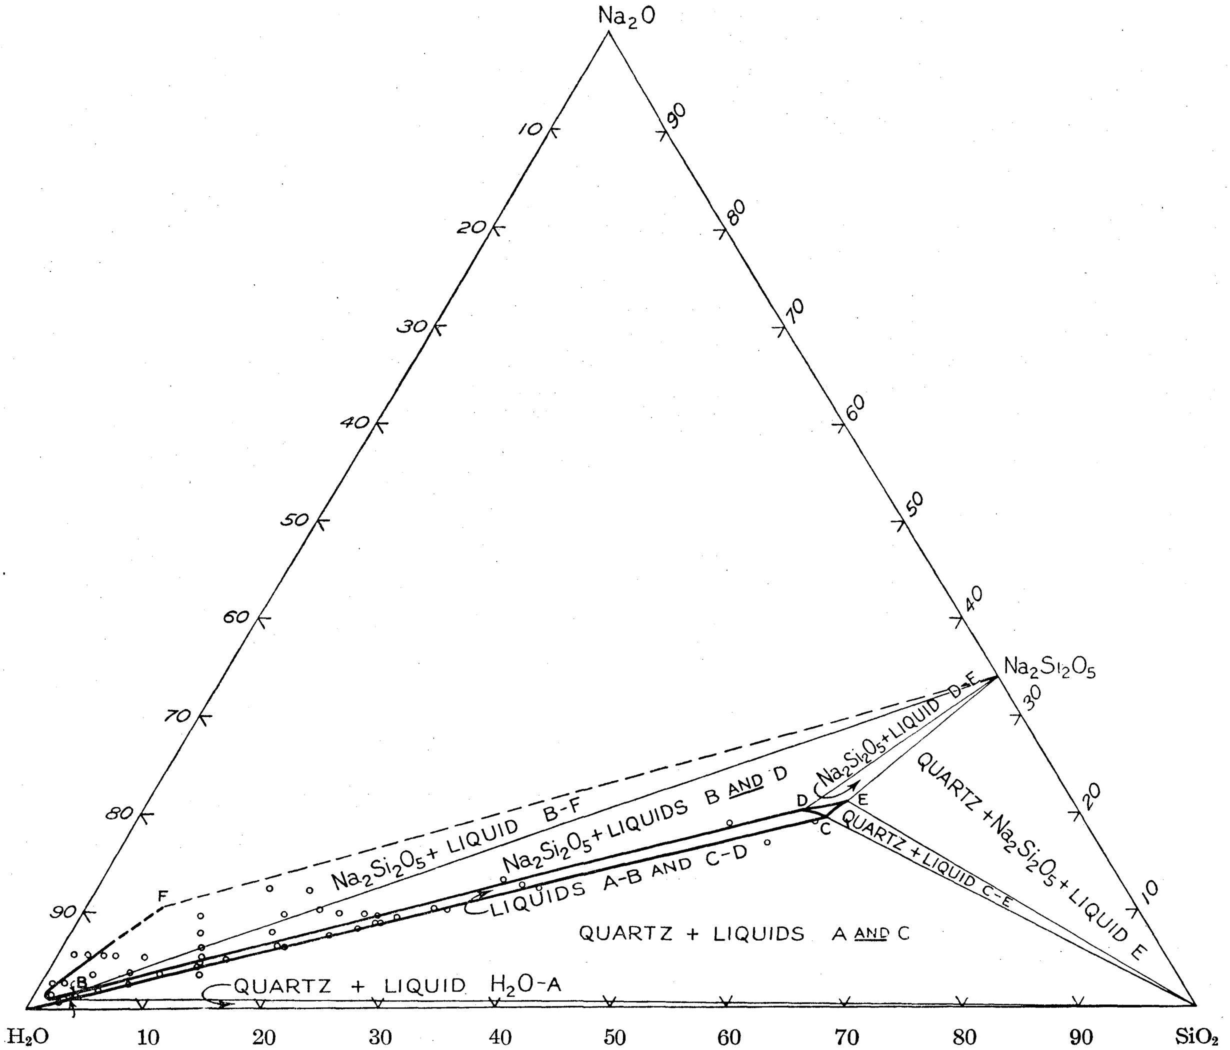

Fig. 6.—Polybaric saturation relations at 350° in the system H_2O–Na_2O–SiO_2.

position of the heavy liquid will not lie on the $Na_2Si_2O_5$–H_2O join. At 300° it is probable that the quartz field crosses the $Na_2Si_2O_5$–H_2O join at low $Na_2Si_2O_5$ concentrations, in which case this portion of the system will not be binary.

Liquid Immiscibility.—Many of the quartz solubility runs were characterized by the presence of a clear water-soluble glass together with a thin liquid upon quenching and opening. The amount of glass increased as the Na_2O concentration was increased. The glass was shown to be a liquid at the temperature of the experiment by quenching the bomb in different positions and observing that the glass always occupied the lowest point in the bomb.

The presence of a small amount of glass, which represented a liquid phase containing 30 to 40% H_2O, in a run whose total composition was 90% water, established the fact that two liquids must coexist at the temperature of the experiment. The question arises, is it possible that the glass represents a liquid phase and the thin liquid the vapor phase? A simple calculation shows that at 350°, for example, less than 1% of the volume of the 18-cc. bomb could be occupied by the vapor phase and the thin phase present on quenching may occupy as much as *8 or 9 cc. at room temperature*. It is obvious, then, that the thin phase represents a liquid phase at the temperature of the experiment plus a small amount of material that was in the vapor phase.

Character of the Heavy Phase.—Quartz solubility determinations at 250° yielded a glass whose composition is represented by point C (Fig. 4). This glass has a hardness of about 2.5 and is readily soluble in water. At 300° the glass had a composition shown by point C (Fig. 5) and is noticeably harder and less soluble than the 250° glass. The 350° glass is very brittle, has a hardness of approximately 5, and is slowly soluble in water (C, Fig. 6). As the composition of the heavy phase approached the critical point (B,

Fig. 4), the viscosity of the quenched material changed continuously from a glass at C to a liquid with the approximate consistency of SAE 20 lubricating oil.

Table II is a summary of analyses of the two phases, together with the original composition. The composition of the two immiscible liquids cannot be determined with great accuracy without elaborate equipment for sampling under the pressure–temperature conditions encountered. However, the heavy phase quenches readily to a glass which, with some caution, can be sampled with little or no contamination from the light phase, but the latter cannot be sampled nearly so accurately because of contamination from the condensed vapor phase and solution of some of the heavy phase.

TABLE II

Temp., °C.	Initial composition, %			Composition of light phase, %			Composition of heavy phase, %		
	SiO_2	Na_2O	H_2O	SiO_2	Na_2O	H_2O	SiO_2	Na_2O	H_2O
250	33.9	13.0	53.1	21.8	9.0	69.2	45.5	17.5	37.0
300	35.1	12.9	52.0	17.2	6.7	76.1	51.0	18.0	31.0
350	36.1	12.6	51.3	12.1	4.5	83.4	55.4	20.1	24.5

The analysis of the heavy phase was used in locating the boundary of the immiscible area on the high silica end of the region. The boundary of the immiscible area in the low silica region was defined by allowing the bombs to remain inverted in the furnace a few minutes prior to removal, and quenching in the inverted position for forty-five seconds, after which the bombs were turned right side up and opened. The heavy phase collects on the silver washer, and amounts as small as 0.05 g. of the glass can easily be detected.

The Immiscible Region.—In the three-dimensional temperature–composition prism the region of liquid immiscibility in a ternary system in which there is no solubility gap in the liquid phases of the binary systems has the shape of a spheroid when it is not intersected by the stability field of a crystalline phase. Theoretically, this spheroid may be cut off by the stability fields of crystalline phases in almost any manner. In most examples the lower portion of the spheroid is intersected by one or more stability fields of crystalline phases. The present system is unusual in that the upper portion of the spheroid is apparently cut off by stability fields of $Na_2Si_2O_5$ and quartz. Immiscibility has not been found in several runs at 200°, hence the lower consolute point on the immiscibility spheroid is probably between 200 and 250°. The upper extent of the immiscible region has not been reached.

Acknowledgment.—This work was undertaken on the basis of preliminary experiments done at the Geophysical Laboratory by Dr. G. W. Morey and O. F. Tuttle.

Summary

A portion of the system Na_2O–SiO_2–H_2O was investigated. Equilibrium relations were determined at 250, 300 and 350°. The system possesses liquid immiscibility with a lower consolute temperature between 200 and 250°. The immiscible region is intersected at 250° by the quartz stability field, and at 300 and 350° by the stability fields of quartz and $Na_2Si_2O_5$.

The Methanolysis of 3,4-Epoxy-1-butene

BY PAUL D. BARTLETT AND SIDNEY D. ROSS[1]

Introduction

Kadesch[2] reported that the allylic epoxide, 3,4-epoxy-1-butene, was attacked by methanol at the primary position in the presence of sodium methoxide and at the secondary position in the presence of sulfuric acid. In an attempt to prepare the resulting isomeric ether–alcohols we repeatedly obtained products from both acid and alkaline treatments yielding the same 3,5-dinitrobenzoate (m. p. 75.5–76°). Furthermore, the yield of this derivative was highest in the case of the acid-catalyzed methanolysis from which Kadesch reported only a 3,5-dinitrobenzoate melting at 107–109°. As a result of these discrepancies we have made a more careful study of the reaction than was at first intended, with the following conclusions: The product of the acid-catalyzed methanolysis is the primary alcohol 2-methoxy-3-buten-1-ol (II) as reported by Kadesch, although its 3,5-dinitrobenzoate melts at 75.5–76° and not at 107–109°. The alcohol is accompanied by a small amount of crotonaldehyde and by a larger amount of a dimolecular product, probably the 2-erythryl ether of 2-methoxy-3-buten-1-ol (VIII). The low-boiling product of the base-catalyzed methanolysis is a mixture of II and 1-methoxy-3-buten-2-ol (I) which could not be separated and from which only the 3,5-dinitrobenzoate of II could be crystallized. We obtained neither the dinitrobenzoate of I nor any compound resembling the dinitrobenzoate of Kadesch melting at 107–109°. Our results and their relation to the results of Kadesch are summarized in the flow sheet and in Table I.

Discussion of Results

Kadesch[2] has given an able discussion of the

mechanisms of the opening of the epoxide ring which might be expected under acidic and basic conditions. This author points out that the S_N1 mechanism, favored by acidic conditions, should involve cleavage of the allylic, secondary C-O bond rather than that of the non-allylic, primary C-O bond. Our results are in entire accord with this interpretation of the acidic mechanism although we, like Kadesch, have not carried out kinetic or quantitative studies of the reaction. With regard to the alkaline methanolysis, Kadesch cites previous reasons for believing that the mechanism of this reaction is of the S_N2 type, in view of which it was not surprising to find apparently exclusive opening of the expoxide ring at the primary position. The recent results of Chitwood and Freure[3] on the alcoholysis of propylene oxide provide further examples of the occurrence of attack by alkoxide ion exclusively at the primary position in a saturated epoxide. Our observation that the alkaline methanolysis of 3,4-epoxy-1-butene leads to a mixture of the primary and secondary methyl ethers raises the question: is the attack at the secondary position due to the appearance of the S_N1 mechanism even in alkaline solution, or does the allylic character of the secondary position make it susceptible to S_N2 attack in competition with the primary position?

An experiment for which we are indebted to Dr. Harry F. Herbrandson seems to settle this question in favor of the S_N2 mechanism in the case of both products of the alkaline cleavage. Methanolysis of the oxide by a concentration of sodium methoxide more than seven times that used previously by us led to essentially the same proportion of the isomers in the product. Had the attack on the primary position involved direct participation of the methoxide ion and the attack on the secondary position not, this experiment should have given seven times the ratio of I to II previously observed. It is, of course, well recognized that allylic character can enhance the reactivity of halides in direct bimolecular displacement reactions as well as in reactions of the S_N1 type.[4] This can be regarded as a lowering of the energy of the transition state through allylic resonance.

A factor limiting the interpretation of the relative amounts in which isomers are isolated in this reaction should perhaps be pointed out.[5] If our interpretation of the higher-boiling material is correct, the primary alcohol II is much more likely to be converted into such material than is the secondary alcohol I, and the ratio of (II)/(I) isolated will be smaller than the ratio of reactivities at carbon atoms 3 and 4 whenever higher-boiling products are also present.

Experimental Details

Methanolysis of 3,4-Epoxy-1-butene with 1 mole per cent. Sulfuric Acid.—To methanol (192.2 g. (6 moles) dried over magnesium methoxide, b. p. 64.6°, $n^{25}D$ 1.3279) and sulfuric acid (1.92 g. (0.02 mole) Merck reagent grade; sp. gr. 1.84) in a three-neck flask, fitted with a mechanical stirrer and reflux condenser and heated to reflux, was added over a ninety-minute period 120 g. (2 moles) of 3,4-epoxy-1-butene. This epoxide was obtained from the Columbia Chemical Division of the Pittsburgh Plate Glass Co. and redistilled through a Lecky-Ewell type column rated at sixty theoretical plates. The oxide had b.p. 67°, $n^{23}D$ 1.4151. Boiling was continued for two hours after the addition, ten grams of potassium carbonate was added and the mixture was stirred at room temperature for one-half hour. The total reaction mixture was then distilled through the column used in purifying the 3,4-epoxy-1-butene. The following fractions were obtained:

Fraction	Pressure, mm.	B. p., °C.	Wt., grams	$n^{25}D$
1	760	64.6	131	1.3280
2	55	to 65	1.5	1.3829
3	55	65–69	4.5	1.4250
4	55	69–71	10.5	1.4280
5	55	71	17.5	1.4280
6 (Trap)			6.5	1.3849
7	55	71	11.0	1.4280
8	55	69	42.5	1.4280
9	55	69	7.0	1.4278
Combined higher boiling fractions			59.5	

Fraction 1 above is recovered methanol, fractions 2, 3 and 6 are intermediate fractions and fractions 4, 5, 7, 8 and 9 are 2-methoxy-3-buten-1-ol, II. Fraction 7 was analyzed.

Anal. Calcd. for $C_5H_{10}O_2$: C, 58.68; H, 9.85. Found: C, 59.13; H, 9.99.

Detection of Crotonaldehyde.—A little of fraction 6 was treated with 2,4-dinitrophenylhydrazine in alcohol. A

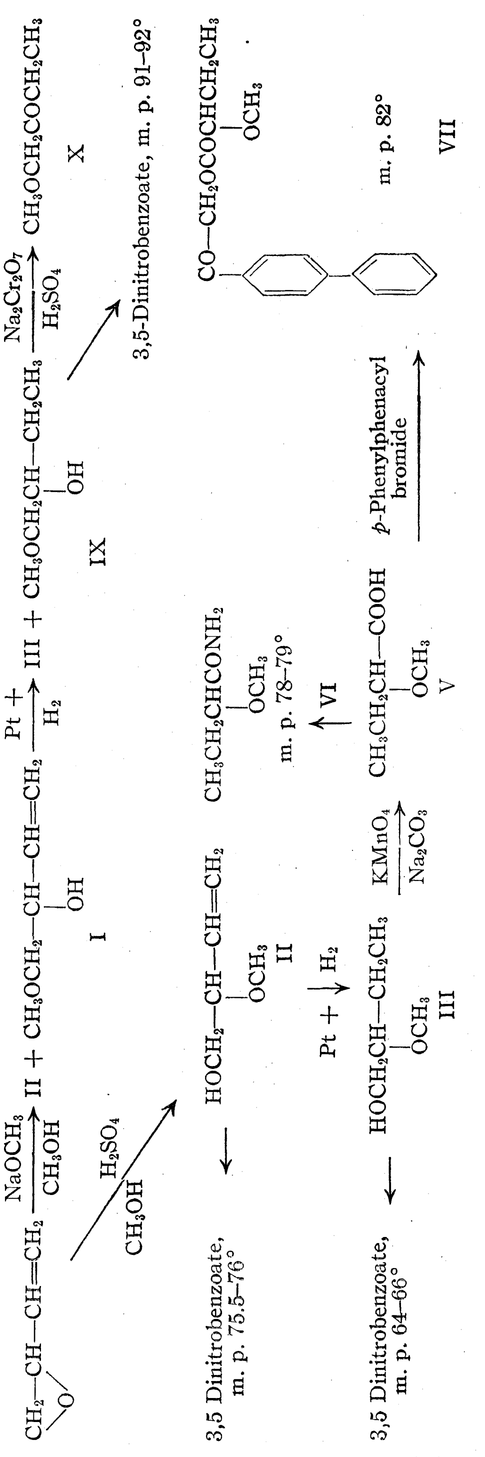
(4) For example, in the bimolecular reaction between chlorides and potassium iodide in acetone at 50°, allyl chloride is 79 times as reactive as *n*-butyl chloride (Conant, Kirner and Hussey, THIS JOURNAL, **47**, 488 (1925)).

(5) For this point we are indebted to Dr. X, a colleague of Referee 5.



drop of concentrated hydrochloric acid was added and the mixture was warmed on the steam-bath. On cooling the hydrazone crystallized. The melting point after crystallization from ethanol–acetic acid was 188–189°. The melting point of a mixture with an authentic sample of the 2,4-dinitrophenylhydrazone of crotonaldehyde showed no depression.

Preparation of the 3,5-Dinitrobenzoate of II.—Fractions 4, 7 and 9 were converted to the 3,5-dinitrobenzoate by heating 0.92 g. of 3,5-dinitrobenzoyl chloride with 0.31 g. of the alcohol in 10 cc. of benzene containing 0.40 g. of pyridine. All three fractions gave quantitative yields of crude ester. On recrystallization from alcohol–water they gave, respectively, 83.5, 89 and 78% yields of the pure ester melting at 75.5–76°.

Anal. Calcd. for $C_{12}H_{12}O_7N_2$: C, 48.65; H, 4.08. Found: C, 48.82; H, 3.95.

Methanolysis of 3,4-Epoxy-1-butene with 5 mole per cent. Sulfuric Acid.—A procedure similar to that in the 1 mole per cent. acid run gave 113.5 g. of recovered methanol, 22.5 g. of intermediate fraction, 62.5 g. of 2-methoxy-3-buten-1-ol, II and 68 g. of higher boiling material.

The High-Boiling Product, VIII.—Repeated fractionation of the combined higher boiling fractions from the two acid-catalyzed reactions above gave finally 15.0 g. of a viscous, colorless liquid boiling constantly at 112° at 23 mm. and having n^{25}_{D} 1.4520. The product shows one active hydrogen in the Grignard machine and has been assigned structure VIII.

Anal. Calcd. for $C_9H_{16}O_3$: C, 62.76; H, 9.37. Found: C, 63.27, 63.59; H, 9.47, 9.54.

Treatment of 2-methoxy-3-buten-1-ol, II (47 g., 0.46 mole), with 3,4-epoxy-1-butene (18 g., 0.3 mole) in the presence of a small pellet of sodium followed by warming for three and one-half hours on the steam-bath gave on distillation 22 g. of a colorless liquid having b. p. 113° at 21 mm. and n^{25}_{D} 1.4510. This product, too, shows one active hydrogen in the Grignard machine, but analogy with the base-catalyzed methanolysis of the oxide points to its being a mixture of isomers rather than a single substance.

Anal. Calcd. for $C_9H_{16}O_3$: C, 62.76; H, 9.37. Found: C, 63.31, 63.46; H, 9.68, 9.46.

Hydrogenation of 2-Methoxy-3-buten-1-ol, II.—2-Methoxy-3-buten-1-ol, II (30.6 g., 0.3 mole), in 100 cc. of absolute ethanol was hydrogenated over 0.2 g. of Adams catalyst. Hydrogen was rapidly taken up while the gage showed a drop in pressure of 25.5 lb. The catalyst was filtered off and the product was distilled giving 27 g. of 2-methoxy-1-butanol, III, which boiled at 60–63° at 25 mm. and had n^{25}_{D} 1.4130. A small portion, redistilled through a one-foot Vigreux column for analysis, had b. p. 147.2° and n^{25}_{D} 1.4138.

Anal. Calcd. for $C_5H_{12}O_2$: C, 57.61; H, 11.62. Found: C, 58.43; H, 11.91.

Preparation of the 3,5-dinitrobenzoate as previously described for II gave a quantitative yield of crude ester and a 66% yield of purified 3,5-dinitrobenzoate, m. p. 64–66°.

Anal. Calcd. for $C_{12}H_{14}O_7N_2$: C, 48.32; H, 4.73. Found: C, 48.66; H, 4.81.

Oxidation of 2-Methoxy-1-butanol, III.—2-Methoxy-1-butanol III (10 g., 0.96 mole), in 30 cc. of water containing 3 g. of sodium carbonate was placed in a three-neck flask fitted with a mechanical stirrer and cooled in an ice-bath. Potassium permanganate (19.8 g., 1.25 mole) in 600 cc. of water was added gradually with stirring. The mixture was stirred an additional six hours with cooling and finally left standing over-night at room temperature. The manganese dioxide was filtered off and the aqueous solution was concentrated *in vacuo* to a volume of 50 cc. It was then extracted continuously with ether. The ether extract was dried over magnesium sulfate and distilled yielding 1.5 g. of crude 2-methoxybutyric acid, V, b. p. 90–107° at 25 mm.

Preparation of 2-Methoxybutyramide, VI.—The acid, V, (0.5 g.) was refluxed with thionyl chloride for thirty minutes, the excess thionyl chloride was removed and 5 cc. of concentrated ammonia was added. The aqueous solution was extracted continuously with ether. The ether extract was dried and the ether was then removed yielding a viscous brown oil. The oil was extracted with boiling water. The aqueous extract was decolorized with Norite and the water was removed *in vacuo*. This gave the crude amide, VI, melting at 69–75°.[6] Several crystallizations from a mixture of benzene, petroleum ether and methanol

---

[6] Duvillier, *Ann. chim.*, [5] **17**, 548 (1879).

raised the melting point to 78–79°. On admixture with acetamide (m. p. 81° pure) the melting point was depressed to 40–65°. Mixing with propionamide (m. p. 79–80° pure) resulted in an oil.

Preparation of the *p*-Phenylphenacyl Ester, VII.—The acid V (0.5 g.), in 3 cc. of water was just neutralized with 10% sodium hydroxide. It was then made acid with a few more drops of V. Ethanol (8 cc.) and *p*-phenylphenacyl bromide (0.5 g.) were added, and the mixture was refluxed for one hour. This gave a crude product which after two crystallizations from methanol weighed 0.5 g. and melted at 82° alone and when mixed with a synthetic specimen made from 2-methoxybutyric acid obtained by the methanolysis of 2-bromobutyric acid.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45. Found: C, 72.81; H, 6.63.

Base-catalyzed Methanolysis of 3,4-Epoxy-1-butene.—To methanol (192.2 g., 6 moles, dried over magnesium methoxide, b. p. 64.6°, $n^{25}D$ 1.3279) and sodium (3.2 g., 0.14 mole) heated to reflux was added dropwise 3,4-epoxy-1-butene (120 g., 1.7 moles, b. p. 67°, $n^{25}D$ 1.4151). The mixture was heated under reflux for four hours after the addition and then left standing overnight. Seven cc. of acetic acid was added to decompose the sodium methoxide and the total reaction mixture was distilled in a Lecky–Ewell type still rated at sixty theoretical plates. The following fractions were obtained.

Fraction	Pressure, mm.	B. p., °C.	Wt., grams	$n^{25}D$
1	760	64.1	124.5	1.3280
2	55	50–70	6.5	1.4222
3	55	70–71	7.0	1.4261
4	55	70–71	9	1.4281
5	55	70–71	19	1.4290
6	55	71	7.0	1.4290
7	55	71	9.7	1.4291
8	55	71	6.5	1.4283
9	55	71	18.0	1.4265
Combined higher boiling fractions			47.9	

Fraction 1 above is recovered methanol, fractions 2 and 3 are intermediate fractions and fractions 3–8 contain mixtures of 3-methoxy-3-buten-1-ol, II, and 1-methoxy-3-buten-2-ol, I.

Preparation of the 3,5-Dinitrobenzoate of the Base-catalyzed-Product.—3,5-Dinitrobenzoates were prepared from fractions 4 and 8 as previously described for the acid-catalyzed product. Fraction 1 gave only an 11% yield of the ester (m. p. 73–75°) whereas fraction 8 gave a 39% yield of the same derivative. No other solid 3,5-dinitrobenzoate could be isolated from either reaction mixture.

Hydrogenation of the Base-catalyzed Product.—Fractions 3–8 of the base catalyzed product above were combined and 30.6 g. (0.3 mole) was hydrogenated over 0.2 g. of Adams catalyst in 100 cc. of ethanol. The hydrogen pressure dropped by 28 lb. On distillation the following fractions were obtained.

Fraction	Pressure, mm.	B. p., °C.	Wt., grams	$n^{25}D$
1	85	73–75	8.5	1.4106
2	85	75–76	6.0	1.4110
3	30	to 60°	1.5	1.4129
4	30	60–62.5	4.0	1.4135

Fraction 1 above gave a 78% yield of a 3,5-dinitrobenzoate melting at 91.5–92°. This is the 3,5-dinitrobenzoate of 1-methoxy-2-butanol, IX.

Anal. Calcd. for $C_{12}H_{14}O_7N_2$: C, 48.32; H, 4.73. Found: C, 48.39; H, 4.50.

Fraction 4 above gave a 44% yield of the 3,5-dinitrobenzoate of 2-methoxy-1-butanol, III, m. p. 64–66°, showing no depression on mixture with the previously obtained sample.

Oxidation of 1-Methoxy-2-butanol, IX.—To a stirred mixture of sodium dichromate monohydrate (15.8 g., 0.053 mole) and sulfuric acid (12.6 g., 0.129 mole) in 75.5 cc. of water was slowly added 1-methoxy-2-butanol, IX (fraction 1 above, 8 g., 0.077 mole). The reaction mixture was surrounded with an ice-bath and the temperature was not permitted to rise above 50° during the addition. The reaction mixture was permitted to come to room temperature and then steam distilled. The steam distillate was extracted continuously with ether. The ether extract was dried and distilled yielding 3 g. of 1-methoxy-2-butanone, X, b. p. 132–135°, $n^{25}D$ 1.4068 (reported, b. p. 133–133.6°, $n^{20}D$ 1.4063).[7]

The ketone gave a 2,4-dinitrophenylhydrazone which after several crystallizations from acetic acid melted at 193.2–194° (reported, 198–198.5°).[8]

Summary

The addition of methanol to 3,4-epoxy-1-butene in the presence of sulfuric acid produced predominantly 2-methoxy-3-buten-1-ol. Small amounts of crotonaldehyde and a higher boiling product resulting from the attack of 2-methoxy-3-buten-1-ol on 3,4-epoxy-1-butene were also obtained.

With sodium methoxide as catalyst the predominant product was 1-methoxy-3-buten-2-ol, but some 2-methoxy-3-buten-1-ol was also obtained.

The mechanisms of these reactions have been discussed.

Polarographic Studies on Aliphatic Polyene Aldehydes

BY MELVIN FIELDS AND ELKAN R. BLOUT

The polarographic behavior of polyene aldehydes is of interest in connection with other research in progress in this Laboratory.[1,2] Several investigators have studied the polarographic behavior of compounds containing one or two aliphatic carbon–carbon double bonds conjugated with a carbonyl group,[3,4,5] but polarographic data for the more highly unsaturated ketones or aldehydes have not been reported.

In this paper we are reporting the results of work on the behavior at the dropping mercury electrode of unsaturated aldehydes of the type I

$$CH_3—(CH{=}CH)_x—CHO \qquad \text{I}$$

where x equals 1, 2, 3, 4 and 5. We were particularly interested in determining the effect of increasing chain length on the number, relative heights and half-wave potentials of the polarographic waves. In addition, we have studied the effect of *p*H on the polarographic characteristics of each compound. We have also calculated from the Ilkovic equation the diffusion coefficients of these polyenic aldehydes.

Experimental

Preparation of Aliphatic Polyene Aldehydes.—These compounds were prepared and purified by the procedures described or referred to in a previous paper.[1] The samples used for the polarographic measurements were of the same purity as those used for spectral measurements.

Instrument and Cells.—Polarographic measurements were made using a simple manual apparatus similar to the one described by Lingane and Kolthoff.[6] The usual H-type polarographic cell with a saturated calomel reference electrode was used. At a pressure of 65.0 cm. the capillary had a drop time of 3.5 seconds and an *m*-value of 1.908 mg. of mercury per second measured on open circuit in 50% aqueous dioxane solution tenth molar in potassium chloride.

Buffers.—The compositions of the stock buffer solutions which were prepared are listed below; when diluted with an equal volume of water or of dioxane they covered the indicated *p*H values as determined by measurement with a glass electrode.[7]

Stock buffer	Components	*p*H Range of buffer dil. with H_2O	*p*H Range of buffer dil. with $C_4H_8O_2$
A	0.2 *M* NaOAc–HCl	1.2–3.2	1.1–4.4
B	0.2 *M* NaOAc–HOAc	3.9–5.8	5.3–7.2
C	0.2 *M* NaOH–NH_4Cl	8.6–10.5	8.4–10.4

Polarographic measurements on the polyene aldehydes were made in 50% aqueous dioxane solutions prepared by dilution of the stock buffer solutions with dioxane purified as previously described.[1] The *p*H values mentioned throughout the rest of this discussion refer to the solutions 50% in dioxane and are uncorrected for the non-aqueous solution error of the glass electrode.[8] For that reason they are nominal values only.

For comparison of the polarographic behavior of members of this series it was desirable to use solutions of approximately the same concentration of supporting electrolyte throughout. The solubility characteristics of this series of aldehydes led to the choice of the particular solvent and buffer solutions used. Since the higher members of the series, particularly 2,4,6,8,10-dodecapentaenal, are only slightly soluble even in 50% aqueous dioxane solution, it was necessary in some cases to employ a solution whose buffer capacity is less than that desirable for polarographic work. The complications which this factor introduces in the interpretation of some of our data will be discussed in the sequel.

Procedure.—Because the aliphatic polyene aldehydes are relatively unstable the stock solutions of the compounds in dioxane were not allowed to stand more than three hours before measurement. The solutions of the aldehydes in the appropriate buffers were deaerated in the usual manner for twenty to thirty minutes with nitrogen purified by passage through a tube filled with freshly-reduced copper filings maintained at 450–500°. All potentials were measured against a saturated calomel electrode (S. C. E.) and the values recorded in this paper have been corrected for the *iR* drops of the solutions. Diffusion currents were corrected for the residual current of the supporting electrolyte. Measurements were made at 25 ± 0.5°.

Results and Discussion

The characteristics of the polarographic curves of the unsaturated aldehydes in acid, essentially neutral, and basic solutions may be seen in Figs. 1 to 5. Each of the compounds studied shows at least one well-defined wave in the *p*H range of 1 to 11. In addition a second polarographic wave of approximately the same height as the first is observed for each compound over a more limited *p*H range. The initial appearance of the second wave occurs at progressively lower *p*H values as the number of double bonds is increased. Although the first wave of each substance is well defined over the *p*H range investigated, the second tends to become less distinct in the most alkaline solutions.

As can be seen from Table I the values of the ratio $i_d/Cm^{2/3}t^{1/6}$ of the first wave are essentially independent of *p*H for all the unsaturated aldehydes. Moreover, the average value of this ratio is, to a first approximation, unaffected by the number of carbon–carbon double bonds conjugated with the carbonyl group; the slight de-

crease in these ratios with increasing molecular weight probably arises from diminished diffusion coefficients rather than a change in the electron requirements of the waves. Furthermore, the near equivalence of the $i_d/Cm^{2/3}t^{1/6}$ ratios for the first and second waves of each compound except crotonaldehyde makes it probable that the *n*-values of the two waves are identical. The variations in the diffusion current for the first wave of crotonaldehyde are probably to be attributed to losses of varying quantities of this volatile compound during deaeration with nitrogen. Since the second wave of crotonaldehyde does not attain its limiting value before decomposition of the supporting electrolyte occurs, accurate measurement of its diffusion current and half-wave potential is difficult. The $i_d/Cm^{2/3}t^{1/6}$ ratios for 2,4-hexadienal are somewhat lower than might be expected from the values of the ratios for the higher members of the series; this may arise from the greater instability of this compound as compared with the more highly conjugated aldehydes.

In Fig. 6 we have plotted for the polyene alde-

$i_d/Cm^{2/3}t^{1/6}$	1.25	1.22	1.22	1.30 (0.94)	1.20 (1.08)	1.26 (1.14)	1.31 (1.14)	1.34 (1.38)	1.33 (1.36)	1.29 (1.25)	

[a] The values in parentheses refer to the second wave.

hydes the half-wave potentials of the first wave $(E_{\frac{1}{2}})_1$ and of the second wave $(E_{\frac{1}{2}})_2$ for several pH values as a function of the number of carbon–carbon double bonds. The addition of another C=C to an aliphatic polyene aldehyde with x double bonds causes a shift in $(E_{\frac{1}{2}})_1$ toward less negative potentials; that is, the ease of reduction increases with the number of double bonds conjugated with the carbonyl group. It is noted, however, that the increment per double bond decreases as the chain is lengthened.[9] Thus, while the $(E_{\frac{1}{2}})_1$ values for 2,4-hexadienal are on the average 0.23 volt more positive than those for crotonaldehyde, the $(E_{\frac{1}{2}})_1$ values for 2,4,6,8,10-dodecapentaenal are on the average only 0.07 volt more positive than those for 2,4,6,8-decatetraenal.

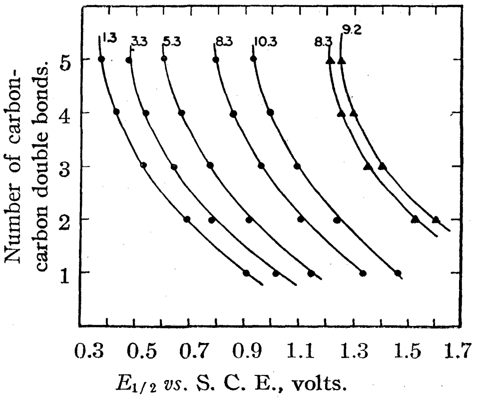

Fig. 6.—Half-wave potentials *vs.* number of carbon–carbon double bonds: —●—●—, first wave —▲—▲—, second wave. The number beside each curve refers to the pH at which measurements were made.

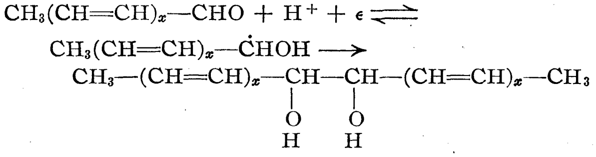
A plausible explanation for the direction of the shift of $(E_{\frac{1}{2}})_1$ with x can be given if we assume that in the reaction which produces the first polarographic wave the electrode-active species are the aldehyde (I) and the conjugate acid (II) of the radical-ion formed by a one-electron reduction of the parent substance.[10] The formation of the radical II may be followed by its dimerization to produce, perhaps, the unsaturated glycol III. Although dimerization of the initially-formed radicals makes the over-all electrode reaction an irreversible process, the step involving electron transfer may very well be a reversible one. The significance of the half-wave potentials for systems of this type is the same as for reversible ones.



$$CH_3(CH{=}CH)_x{-}CHO + H^+ + \epsilon \rightleftharpoons$$

---

(9) This effect is similar to that observed in the ultraviolet and infra-red spectra of these compounds where the shift in the position of at least one of the absorption maxima seems to become smaller as the length of the conjugated system is increased.[1,2]

(10) The bimolecular reductions of carbonyl compounds are well known. Familiar examples which may be mentioned are the electrolytic reduction of anisaldehyde to a mixture of the pinacols, hydroanisoin and iso-hydroanisoin,[a] the reduction of crotonaldehyde and cinnamaldehyde with zinc-copper couple to dipropenyl glycol[b] and hydrocinnamoin,[c] respectively, and the reduction of aromatic and unsaturated aldehydes with vanadous salts to the corresponding pinacols.[d] (*a*) Law, *J. Chem. Soc.*, **89**, 1512 (1906). (*b*) Young, Levanas and Jasaitis, THIS JOURNAL, **58**, 2274 (1936). (*c*) Kuhn and Winterstein, *Ber.*, **60**, 432 (1927). of the aldehyde and its related free radical on going from one member of the series to the next.

An aliphatic polyene aldehyde such as 2,4-hexadienal may be represented as a hybrid of the classical form, IV, and ionic forms such as V through VII.

On the other hand, the major contributing forms of the corresponding free radical, structures VIII-X, all contain the same number of the same kinds of bonds, do not involve charge separation and are probably of approximately equal energy. The resonance energy of the radical, therefore, is probably greater than that of its related aldehyde.

While the resonance energy of a polyene aldehyde as well as that of the corresponding radical would be expected to increase with the length of the conjugated system, each additional double bond should lead to a relatively greater stabilizaton of the radical than of the aldehyde. This factor would account for the direction of the shift. The decrease in the magnitude of the change in $(E_{\frac{1}{2}})_1$ per double bond noted for the higher members of the series can be correlated with the fact that as x is increased each additional double bond produces a proportionately smaller increase in the number of equivalent forms contributing to the structure of the aldehyde and the free radical and, thus, probably also a smaller change in the relative stabilities of the aldehyde and its reduction product.

For the five polyene aldehydes studied $(E_{\frac{1}{2}})_1$ is an approximately linear function of *p*H (Fig. 7); in each case a unit increase in *p*H shifts the half-wave potential to more negative values by 0.06 volt. In the measured *p*H range 6–8 two points on the crotonaldehyde curve and one on the hexadienal curve deviate markedly from the straight lines which fit all the remaining data. Although the buffer capacity of the *p*H 6 and especially the *p*H 7 supporting electrolytes are quite low, it appears unlikely that the deviations of the half-wave potentials of crotonaldehyde and hexadienal arise from this cause. No such pronounced deviations in this *p*H region are observed for the other (more stable) compounds which were studied at approximately the same concentrations and in solutions of the same compositions. For a thermodynamically reversible reaction such a dependence of $E_{\frac{1}{2}}$ would indicate that the reduction product differed from its oxidized form by one hydrogen atom. It is interesting to note that in the electrode reactions under consideration the variation of $(E_{\frac{1}{2}})_1$ with *p*H conforms closely to that anticipated for the reversible case.

The second half-wave potential, like the first, shifts toward less negative values as the number of double bonds is increased (Fig. 8). The increment of $(E_{\frac{1}{2}})_2$ for those members of the series which show a well-defined second wave decreases with increasing chain length in much the same manner as observed with $(E_{\frac{1}{2}})_1$.

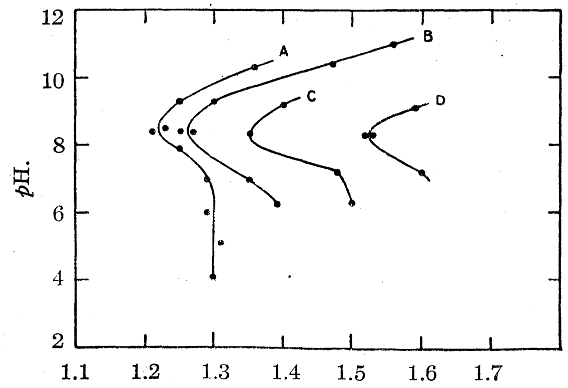

Fig. 8.—Half-wave potential of second wave *vs.* *p*H for: A, 2,4,6,8,10-dodecapentaenal; B, 2,4,6,8,-decatetraenal; C, 2,4,6-octatrienal; D, 2,4-hexadienal.

The second wave is well defined in most cases only in solutions more alkaline than *p*H 6; generally, in acid solutions this wave merges with or is obscured by that due to decomposition of the supporting electrolyte. For 2,4,6,8,10-dodecapentaenal a distinct second wave is obtained over the pH range of 4 to 10 and in acid solutions $(E_{1/2})_2$ seems to be independent of pH. In all the compounds studied the plot of $(E_{1/2})_2$ *vs.* pH shows a minimum in the region of pH 8. A possible explanation for this unusual behavior may be the low buffer capacity of some of the supporting electrolytes used. Further work on this point is now in progress.

Calculation of Diffusion Coefficients.—The diffusion coefficient, D, of a substance which undergoes oxidation or reduction at the dropping mercury electrode can be calculated from the Ilkovic equation[11] $i_d = 605nD^{1/2}Cm^{2/3}t^{1/6}$. We have calculated the diffusion coefficients of each of the five unsaturated aldehydes investigated using the average values of the diffusion currents for the first and second waves and assuming that each wave corresponds to a one-electron reduction. The values found are listed in Table II.

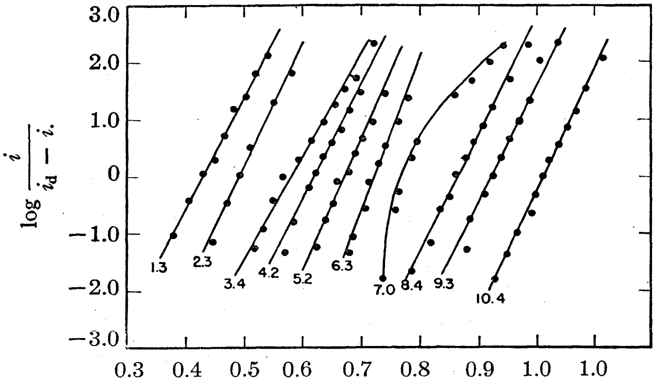

Fig. 9.—Plots of log $i/(i_d - i)$ *vs.* potential of the dropping mercury electrode for 2,4,6,8-decatetraenal. The number beside each curve refers to the pH at which measurements were made.

TABLE II

Compound	D (cm.² sec.⁻¹)
Crotonaldehyde	6.1×10^{-6}
2,4-Hexadienal	5.3×10^{-6}
2,4,6-Octatrienal	5.1×10^{-6}
2,4,6,8-Decatetraenal	4.3×10^{-6}
2,4,6,8,10-Dodecapentaenal	4.2×10^{-6}

In all cases the drop time used in these calculations was measured at the same potential as the diffusion current. The diffusion coefficient recorded above for crotonaldehyde is probably somewhat below the actual value because the loss of this rather volatile aldehyde during deaeration results in a decrease in the actual concentration of the material below the original value. This loss of aldehyde results in a lower diffusion current and hence a lower diffusion coefficient. All the higher aldehydes have sufficiently low vapor pressures so that the error from this source is probably negligible. The value of the diffusion coefficient of 2,4-hexadienal is probably low, possibly as a result of some decomposition of this relatively unstable compound during deaeration and measurement.

Reversibility of Electrode Reactions.—For a reversible reaction at a constant pH at 25° the potential of the dropping mercury electrode is related to the current at any point on the polarographic wave by the equation

$$E_{\text{d.e.}} = E_{1/2} - \frac{0.059}{n} \log \frac{i}{i_d - i}$$

If log $i/(i_d - i)$ is plotted as a function of $E_{\text{d.e.}}$, a straight line is obtained from the slope of which the number of electrons involved in the electrode reaction can be calculated. It is observed experimentally that many irreversible reactions obey the related equation

$$E_{\text{d.e.}} = E_{1/2} - \frac{0.059}{\alpha} \log \frac{i}{i_d - i}$$

and also yield linear plots of log $i/i_d - i)$ *vs.* $E_{\text{d.e.}}$ In these cases, α is not necessarily an integer and may even be less than 1. An exact interpretation of the polarographic waves obtained in such cases has not yet been presented.

We have plotted for the first polarographic wave of each of the five unsaturated aldehydes log $i/(i_d - i)$ as a function of $E_{\text{d.e.}}$ and have found approximately linear relationships at many of the pH values examined. The curves shown in Fig. 9 for 2,4,6,8-decatetraenal are typical of those obtained for the other members of the series. Table III lists the values calculated from the slopes of the straight lines mentioned above or from the slopes of the tangents to the curves at the half-wave potentials.

TABLE III

	Crotonaldehyde									
pH	1.3	2.3	3.1	4.2	5.2					
α	1.7	1.8	1.3	1.2	1.1					
	2,4-Hexadienal									
pH	1.3	2.1	3.1	4.3	5.2	8.3	9.1	10.4		
α	1.4	1.8	1.4	1.5	1.2	1.2	1.3	1.0		
	2,4,6-Octatrienal									
pH	1.3	2.4	3.3	4.1	5.2	6.3	8.3	9.2	10.4	
α	2.0	1.7	1.3	1.4	1.6	1.7	1.1	1.6	1.1	
	2,4,6,8-Decatetraenal									
pH	1.3	2.3	3.4	4.2	5.2	6.3	7.0	8.4	9.3	10.4
α	1.2	1.3	1.0	1.1	1.3	1.6	1.6	1.2	1.2	1.2
	2,4,6,8,10-Dodecapentaenal									
pH	1.3	2.3	3.1	4.1	5.1	6.0	7.0	8.4	9.3	10.3
α	1.4	0.9	0.9	0.8	1.1	1.1	1.2	1.2	1.2	1.0

The deviation from linearity of the curve for 2,4,6,8-decatetraenal at pH 7 quite probably arises from the low buffer capacity of this supporting electrolyte. Some of the high α-values may also be due to this cause or to a degree of irreversibility in the electrode reaction.

Although the relationship between $E_{\text{d.e.}}$ and

---

[11] Kolthoff and Lingane, "Polarography," Interscience Publishers, New York, N. Y., 1941, p. 30.

$\log i/(i_d - i)$ affords a convenient and reliable means of determining the n-values of reversible electrode reactions, other methods are generally used when dealing with irreversible reactions. The Ilkovic equation can be used to calculate the n-values of irreversible as well as reversible electrode reactions, but the paucity of diffusion coefficient data severely limits the usefulness of this procedure. Coulometric measurements afford the most reliable means of determining n- values in irreversible reactions.[12] Such measurements for the aliphatic polyene aldehydes will be reported in a later paper.

Acknowledgment.—We wish to express our appreciation to Mr. Marshall Kane, who assisted in the preparation and measurement of many of these compounds.

Summary

The polarographic behavior of aliphatic polyene aldehydes has been examined in buffered 50% dioxane solution over the *p*H range 1 to 11. The variations in half-wave potentials and the $i_d/Cm^{2/3}t^{1/6}$ ratios have been examined as functions of *p*H and the number of double bonds in the molecule.

The Isolation and Physical Properties of the Diisopropylbenzenes

BY F. W. MELPOLDER, J. E. WOODBRIDGE AND C. E. HEADINGTON

Introduction

The physical properties of the isomeric diisopropylbenzenes reported in the literature are fragmentary and the wide variations in these values indicate that only incomplete separations of the isomers have previously been accomplished.[1–7] Newton,[8] however, isolated meta and para diisopropylbenzene by distillation from a propylated benzene which apparently contained none of the ortho isomer. The physical properties reported by him for the two isomers are in substantial agreement with those found by the authors in the work to be described (Table I).

[a] Antoine equation, $\log_{10} P = A - B/(C + t)$, P = pressure, mm. t = boiling point, °C. [b] Calculated from data of Newton.

In this work the isolation of substantially pure ortho, meta, and para diisopropylbenzenes from benzene–propylene alkylate was accomplished by a combination of distillation, fractional crystallization, adsorption, sulfonation, and hydrolysis. Precise physical properties as well as ultraviolet, infrared and mass spectra are reported on each of the isomers.

Initial Separation.—The source of these compounds was a high boiling by-product fraction, b. p. 200–215°, produced by a commercial process for making cumene wherein benzene is alkylated with propylene over U. O. P. phosphoric acid catalyst. To roughly determine the distribution of the isomeric diisopropylbenzenes in the mixture a 700-cc. volume was fractionally distilled through a 100-plate Heligrid column into 5% cuts. Although the distillation curve (Fig. 1) exhibits only two boiling point flats, the refractive index curve indicates that at least two distinct compounds are present in fraction I, b. p. 203–204°, and one in fraction II, b. p. 210–211°. Inspection of the refractive indices and ultraviolet spectra indicated that the material present in fraction I contained a major amount of meta diisopropylbenzene and a minor concentration of the ortho isomer, while fraction II, comprising nearly half of the crude mixture, was largely para isomer. The next step was therefore to distil 15 liters of the charge stock into two fractions, one boiling at 203–204° and the other at 210–211°.

Separation of *o*- from *m*-Diisopropylbenzene.—It was found that repeated high efficiency distillations of the 203–204°, material resulted in only a partial separation of ortho and meta isomers. The best distillate fraction of ortho isomer froze to a viscous partially crystalline mass at −80° whereas the meta isomer fraction crystallized with some difficulty at −72°.

Since *m*-xylene was successfully purified by Mair, Termini, Willingham and Rossini[9] by the selective sul-

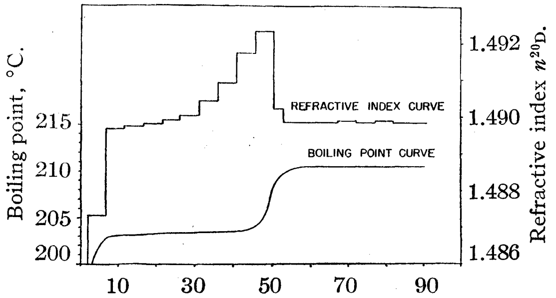

Fig. 1.—Distillation of the crude diisopropylbenzene mixture.

fonation and hydrolysis of a meta and para xylene mixture, the same technique was applied to this separation. A small quantity of ortho–meta-diisopropylbenzene mixture was sulfonated at room temperature with 105% H_2SO_4, the reaction reaching completion in about half an hour. The mixture was diluted with ice and then steam distilled at elevated temperatures. A small amount of unreacted hydrocarbon distilled over at 120°, but no appreciable hydrolysis occurred until a temperature of 135° was reached. At this point there was collected a large fraction of nearly pure meta as evidenced by the low refractive index, n^{20}D 1.4890, and high freezing point, −64°. As the temperature of the hydrolysis was raised the concentration of ortho in the distillate gradually increased to a maximum at 160°. A graph showing the progress of the hydrolysis (Fig. 2) is indicative of the sharpness of the separation of the ortho and meta isomers. In view of the separation obtained, 4 liters of 203–204° material were similarly treated. To further purify the meta isomer, the fraction which hydrolyzed at 135° was resulfonated and hydrolyzed. Similar treatment of the fractions which hydrolyzed at 160°, however, failed to enrich the ortho isomer.

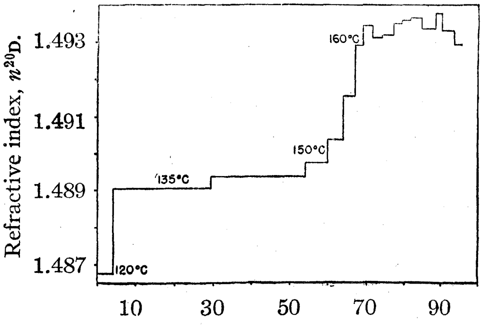

Fig. 2.—Hydrolysis of *o*–*m*-diisopropylbenzene sulfonic acids.

Isolation of *o*-Diisopropylbenzene.—The hydrolyzed ortho isomer fraction was washed with caustic solution and water and then distilled in a 100-plate column. A 150 cc. middle fraction, n^{20}D 1.4955, f. p. −60°, was collected. A time–temperature melting test[10] showed this fraction to be only about 90% pure.

A new technique for purification of compounds by silica gel adsorption was recently reported by Hirschler and Amon[11] wherein it is possible to adsorb preferentially small concentrations of impurities having adsorbabilities similar to that of the major component at higher concentrations. In accordance with this the 150-cc. distillate fraction was percolated several times through an 11-mm. i. d. column packed with fine silica gel as recommended by Mair.[12] The total length of column utilized was equivalent to about 30 feet. The first 17 cc. of percolate, n^{20}D 1.4960, f. p. −57°, was found to be 99.6% pure by the time–temperature melting test.

Isolation of *m*-Diisopropylbenzene.—After washing and drying, the meta isomer fraction was distilled in a 100-plate column at high reflux ratio. About 500 cc. of distillate was collected, n^{20}D 1.4888, f. p. −63°. A time–temperature melting test indicated that this material was also 99.6% pure.

Isolation of *p*-Diisopropylbenzene.—The fraction boiling at 210–211° was subjected to an 80-plate distillation. A volume of 3 liters of para isomer concentrate was collected which was estimated from a freezing test to be about 90% pure. A second distillation failed to increase the purity of this material. It formed large crystals from a non-viscous solution at approximately −20°, the symmetry of the para molecule accounting for the high freezing point.

Three liters of para isomer concentrate were therefore fractionally crystallized in four stages. Batches up to 500 cc. each were slowly crystallized with constant stirring in a partially evacuated Dewar type vessel immersed in a Dry Ice-bath. The slush was then transferred to a precooled basket centrifuge inside a large Dewar and the contents spun until the crystals were dry. By properly blending the crystalline and mother liquor fractions from the various stages more than half of the para isomer fraction was isolated as best crystals, f. p. −17°. The purity of the final product was found to be 99.8% by the melting point test.

Physical Properties.—Precise physical properties (Table I) were determined for each isomer by the following methods:

1. Purities were determined by the time–temperature freezing and melting point procedure described by Glasgow, Streiff and Rossini.[10] Since time–temperature freezing tests were found to be unsuitable due to the existence of non-equilibrium conditions between solid and liquid phases, purities were calculated from time–temperature melting curves.

A special melting point apparatus was constructed to accommodate the small quantity of pure ortho isomer fraction. A glass liner was placed in the conventional apparatus in order to reduce the required sample volume to 5 cc. A stirrer was then constructed from piano wire in spiral form, slightly larger in diameter than the platinum resistance thermometer. The accuracy of this apparatus was checked by comparing the melting point of a 50-cc. sample of meta isomer measured in the larger apparatus and a 5-cc. sample of the same material in the modified tube. The difference in melting point was 0.02° and no significant change was noted in the shape of the time–temperature curves.

2. Cryoscopic constants were determined by adding a known quantity of impurity to each pure isomer and measuring the corresponding melting point depression. *m*-Diisopropylbenzene was added to the ortho isomer, *m*-methylethylbenzene to the meta isomer, and *p*-methylethylbenzene to the para isomer.

3. To check the relative concentrations of the isomers in the original starting mixture the cryoscopic method of Streiff and Rossini[13] was employed. This was done by adding a measured amount of the crude diisopropylbenzene mixture to each isomer and finding the resultant melting point depression. These tests revealed that the 200 to 215° alkylate fraction contained 6% ortho, 36% meta and 42% para diisopropylbenzene.

4. Boiling points were determined in a Cottrell type ebulliometer and temperatures were measured to 0.002° with the same platinum resistance thermometer used in

the melting point tests. The pressure was regulated by a manostat system to ± 0.5 mm. Pressures were read on an open arm mercury manometer and corrected for barometric fluctuations. Boiling point measurements were made at the pressures 760, 300, 100 and 50 mm. and the data were fitted to the Antoine equation to permit calculation of boiling points at intermediate pressures.

5. Refractive indices were measured with a Bausch and Lomb precision refractometer at 20 and 25 ± 0.05°. A sodium lamp and filter provided the source of 5890 A. light. The accuracy of the refractive index values is believed to be ±0.0001.

6. Specific dispersions were determined with the Bausch and Lomb refractometer at 25° using the hydrogen 4860 and 6570 Å. lines.

7. Densities were measured at 20° in a 10-cc. pycnometer described by Lipkin, Davison, Harvey and Kurtz.[14] The temperature of the thermostat was automatically controlled by an electronic regulator at 20.00 ± 0.01°.

---

(14) M. R. Lipkin, J. A. Davison, W. T. Harvey and S. S. Kurtz, *Ind. Eng. Chem., Anal. Ed.*, **16**, 55 (1944).

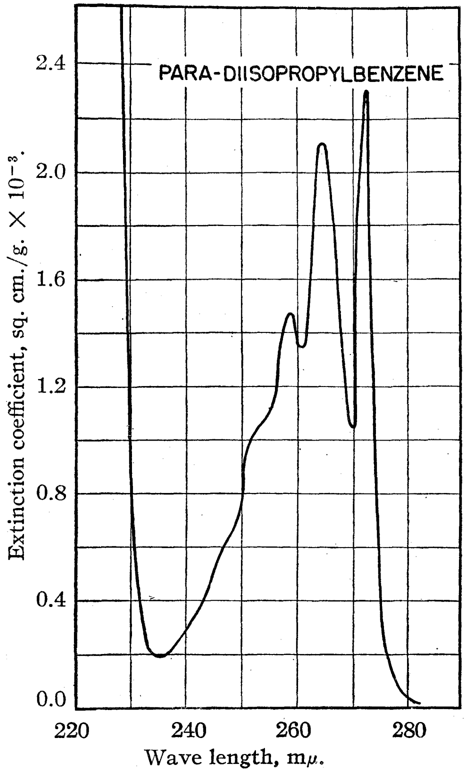

Fig. 5.—Ultraviolet spectrum of *p*-diisopropylbenzene.

The accuracy of these measurements by comparison with other pure compounds was better than ±0.0001 g./ml.

8. Molecular weights were determined for each isomer by observing the freezing point depression in benzene at several concentrations. Good agreement was found between the calculated molecular weights at different concentrations, indicating that the ideal solution laws apply.

9. Carbon–hydrogen ratios were found by the usual combustion method. Based on results of other known samples the accuracy is within ±0.5%.

10. A structure analysis of each isomer was made by oxidation of the side chains to the corresponding phthalic acids, and preparation of derivatives. Of particular interest was the resistance of the ortho isomer to oxidation. Both chromic acid and permanganate solution at 100° gave little conversion, but vapor phase oxidation over vanadium oxide catalyst at 350° gave a good yield of orthophthalic acid. The meta and para isomers were readily oxidized with chromic acid at 100°. The following derivatives were prepared; phthalanil from orthophthalic acid, dimethyl isophthalate from isophthalic acid, and dimethyl terephthalate from terephthalic acid. Melting points of these derivatives checked those appearing in the literature thereby verifying the structure of the isomers.

Absorption and Mass Spectra.—Ultraviolet absorption spectra of the isomers were obtained with a Beckman spectrophotometer. The curves showing the extinction coefficients, sq. cm./g., at various wave lengths are shown in Figs. 3, 4 and 5. The extinction coefficient k is defined as $k = E/cd$ where E = optical density, c = concentration g./cc. and d = cell length. It will be observed that distinctive and characteristic peaks appear at 264 and 272 mμ for the para isomer, but that the ortho and meta spectra are not readily distinguishable.

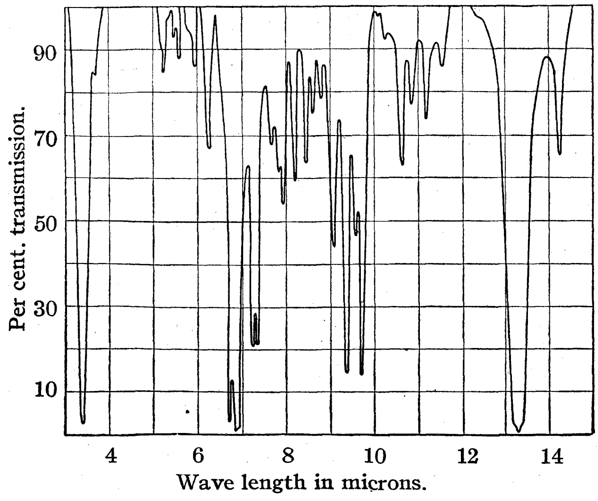

Fig. 6.—Infrared spectrum of *o*-diisopropylbenzene measured at 25°, 0.051 mm. cell length.

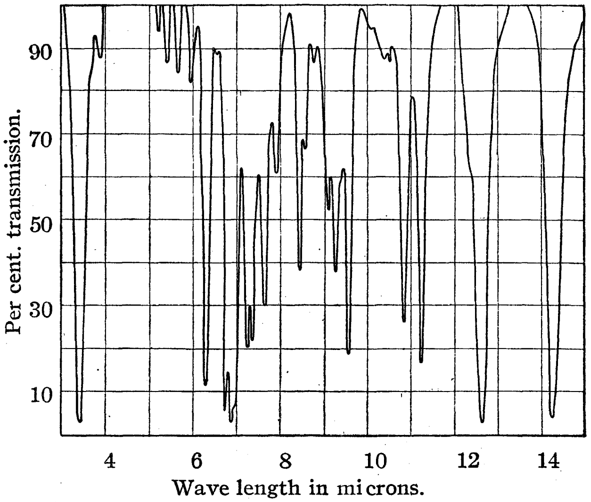

Fig. 7.—Infrared spectrum of *m*-diisopropylbenzene measured at 25°, 0.051 mm. cell length.

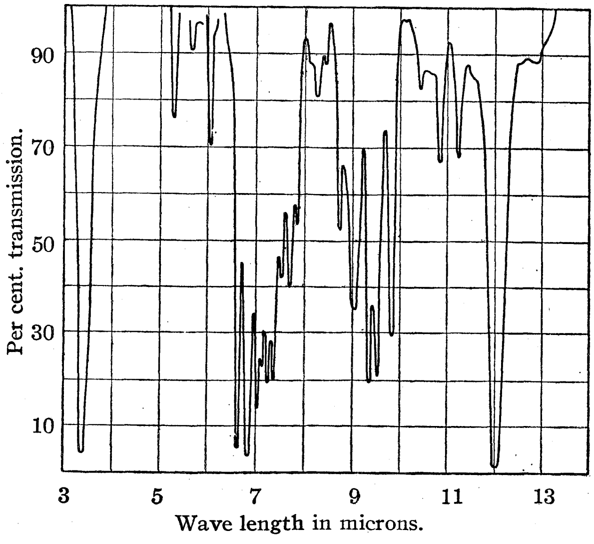

Fig. 8.—Infrared spectrum of *p*-diisopropylbenzene measured at 25°, 0.051 mm. cell length.

Infrared spectrograms of the isomers were determined on a Perkin-Elmer Infrared Spectrometer, Model 12A. These spectra (Figs. 6, 7, 8, and Table II) are seen to confirm the proof of structure by chemical means, the strong absorption bands characteristic of ortho occurring at 13.3 microns, of meta at 12.6 and 14.2 microns, and para at 12.0 microns. The isopropyl group is evident from the doublet in the region of 7.3 microns.

The mass spectra of the isomers, obtained on a Consolidated Engineering instrument, are shown in Table III. As would be expected no significant differences are seen in the mass spectra of the individual isomers.

Acknowledgment.—Acknowledgment is hereby made to Barton Zieber for the infrared spectra and to C. W. Warfield for much of the laboratory manipulation.

Summary

The isolation of the three isomeric diisopropylbenzenes from a high boiling propylene-benzene alkylate is described. The most important physical properties and the relative concentrations of the isomers in the alkylate are listed. Infrared, ultraviolet, and mass spectra also are given, the former confirming the chemical evidence of the structure of the compounds isolated.

The Thermodynamics of Metallo-protein Combinations. Copper with Bovine Serum Albumin

BY IRVING M. KLOTZ AND HENRY G. CURME

The importance of metal ion–protein complexes in biological systems has long been recognized, and numerous studies have been made of the extent of combination of such cations with proteins.[1,2,3] Unfortunately most of these investigations have utilized protein preparations of questionable homogeneity and have correlated their quantitative data in terms of equations which are essentially empirical in nature. With the recent availability of crystallized plasma proteins[4] it has seemed opportune to make a careful quantitative study of metal complexes with pure proteins and to treat the data obtained in terms of relations similar to those used in describing the multiple equilibria between proteins and organic anions.[5]

Experimental

Apparatus.—The extent of binding of cupric ions by bovine serum albumin was measured by the equilibrium dialysis technique described previously.[5] However, the apparatus was modified slightly so that a bead could be suspended by a glass thread within the bag containing the protein solution. With the bead to facilitate stirring within the bag and with a mechanical shaker to agitate the outside solution, the time for the attainment of equilibrium was reduced materially.

Time Required to Attain Equilibrium.—With the modified apparatus the dialysis tubes reached equilibrium in

less than six hours. This was true whether protein solution or buffer was inside the bag, as is illustrated by the data in Table I. For the work carried out at 25° this shaking method was used, therefore. For the studies at 0° the dialysis tubes were maintained in an ice-water-bath, with occasional shaking by hand, for a period of seventy-two hours. In both cases, temperatures were maintained within ±0.05°.

TABLE I

TIME REQUIRED TO ATTAIN EQUILIBRIUM

Time in hours	Free Cu^{++} in blank bag	Free Cu^{++} in protein bag
0	0.0048	0.0048
6	.00282	.00195
10	.00282	.00195
22	.00283	.00195

Analytical Methods.—Analyses for cupric-ion concentrations were made by one of two methods, depending on the concentration range under investigation. In solutions of 0.001 to 0.01 molar the triethanolamine method of Yoe and Barton[6] was used. Two ml. of a 25% solution of triethanolamine in water was added to 10 ml. of the cupric ion solutions in acetate buffer and the absorption of light at 6460 Å. was measured with a Beckman spectrophotometer. In the dilute region of cupric ion concentrations, *i. e.* below 0.001 molar, the absorption of ultraviolet light by the cupric ions themselves was used to determine the concentration of cations.

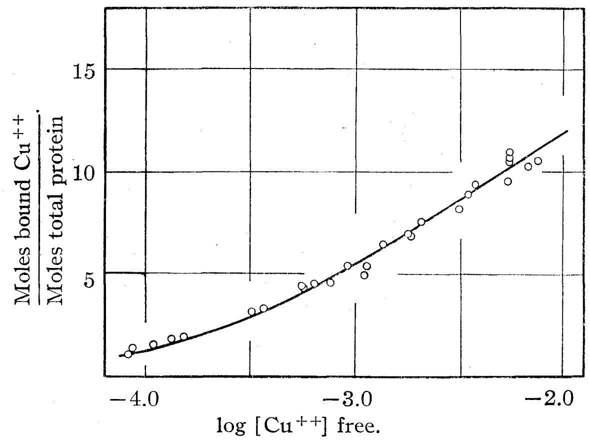

Fig. 1.—Binding of cupric ions by bovine serum albumin at 0°; *p*H of 4.83 at 25°.

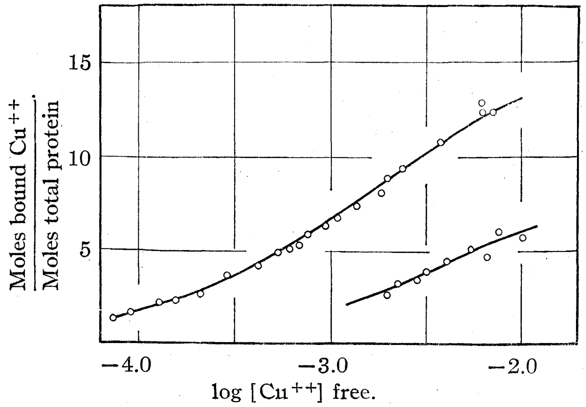

Fig. 2.—Binding of cupric ions by bovine serum albumin at 25°: upper curve at *p*H 4.83; lower curve at *p*H 4.00.

Materials.—Bovine serum albumin was Armour crystallized product. Corrections for water content were made by heating a small sample in an oven at 110° until constant weight was attained. Solutions of approximately 2% protein content were used. The copper salts employed were of analytical reagent grade and were used without further purification. Triethanolamine was an Eastman product.

The buffer solution used for the experiments near *p*H 5 was composed of 0.0357 molar acetic acid and 0.0643 molar sodium acetate. The same concentration of sodium acetate was used in the buffer of *p*H 4 but the acetic acid was increased to 0.2455 molar. The same concentration of acetate was used at both *p*H's in order to keep the ionic strengths equal in both solutions.

Results and Calculations

The extent of binding of cupric ions by bovine serum albumin has been calculated from the difference in the concentrations of free copper in a control tube containing buffer inside the bag and one containing protein. The details of such a calculation have been outlined previously.[5] The degree of binding has been represented in graphs of the average number of bound ions per molecule of protein versus the logarithm of the concentration of the free cupric ion, as is illustrated in Figs. 1 and 2. It is immediately evident, as has been observed previously for organic anions,[5] that the bovine albumin molecule is capable of binding many cupric ions even at relatively low concentrations of free copper.

Reversible Nature of the Binding.—Before considering the application of the laws of equilibirum to these observations it has seemed desirable to establish the reversible nature of the process under examination. To settle this point the experiment outlined in Table II was carried out. The dialysis bag was removed from a solution in which equilibrium had been attained between protein and free Cu^{++} at a final concentration of 9.18×10^{-4} *M*. This bag, containing an average of 6.30 bound ions per molecule of protein, was then placed in a solution of pure buffer and the bound copper allowed to dialyze out until a second equilibrium was established. From the volumes of the solutions used, and the concentration of free Cu^{++} at the end of the second equilibrium, it was possible to determine the average number of bound ions under the new conditions. This observed value, 4.39, is in excellent agreement with that of 4.60 which may be read from Fig. 2. The binding of Cu^{++} by bovine albumin thus seems to be a reversible process.

TABLE II

REVERSIBILITY OF BINDING

	First equilibrium	Second equilibrium
Free Cu^{++}, *M*	9.18×10^{-4}	4.98×10^{-4}
Number of bound ions per molecule of protein	6.30	4.39 (observed) 4.60 (from graph)

Method of Representation of the Data.—Under these circumstances it is permissible to

---

[6] J. H. Yoe and C. J. Barton, *Ind. Eng. Chem., Anal. Ed.*, **12**, 456 (1940).

represent the series of equilibria involved by equations of the form

$$\mathrm{PCu}_{i-1} + \mathrm{Cu}^{++} = \mathrm{PCu}_i \qquad (1)$$

where PCu_{i-1} and PCu_i represent protein–copper complexes with $i-1$ and i cupric ions, respectively. The number i may vary from 1 to n, the maximum number of bound cations. The moles of bound cation per mole of total protein, represented by r, would be obtained from the expression

$$r = \frac{\sum\limits_{i=1}^{n} i \left(\prod\limits_{j=1}^{i} k_j \right) (\mathrm{Cu}^{++})^i}{1 + \sum\limits_{i=1}^{n} \left(\prod\limits_{j=1}^{i} k_j \right) (\mathrm{Cu}^{++})^i} \qquad (2)$$

where the k's represent the equilibrium constants corresponding to each of the reactions of (1). Thus the calculation of the moles of bound ion per mole of total protein depends on a knowledge of these n equilibrium constants.

For the ideal situation, based on a model of a spherical protein molecule and assuming the absence of electrostatic interactions between successively bound ions, the equilibrium constants bear a simple relation to each other, given by the equation

$$k_i = \frac{n - (i - 1)}{i}\, k \qquad (3)$$

in which k is an intrinsic constant which depends on the nature of the protein and of the ion which is bound. When equation (3) is applicable, equation (2) may be simplified appreciably and the binding data may be correlated by the linear expression

$$\frac{1}{r} = \frac{1}{kn} \frac{1}{(\mathrm{Cu}^{++})} + \frac{1}{n} \qquad (4)$$

It has been shown previously[7] that the binding of calcium ions by casein may be represented adequately by an equation of the form of (4). For complexes between copper and bovine albumin, however, this linear expression has been found not to fit the observed data.

In similar circumstances in studies of the binding of organic anions by proteins,[5] deviations from the simple statistical relation have been attributed to electrostatic interactions between successively bound ions and have been accounted for quantitatively by assuming that they may be estimated from the equations of the simple Debye–Hückel theory. Thus successive equilibrium constants have been related to each other by the equation[5]

$$RT \ln (k_{i-1}/k_i) = RT \ln \left[\frac{n - (i - 2)}{n - (i - 1)} \frac{i}{i - 1} \right] + \frac{Nz^2e^2}{D} \left(\frac{1}{b} - \frac{\kappa}{1 + \kappa a} \right) \qquad (5)$$

with the second term representing the electrostatic factor. An attempt has been made to use this equation to correlate the data on copper complexes also. For this purpose, a value of 3 Å. was used for the radius of the aqueous cupric ion[8] and 30 Å. for the serum albumin molecule. With these parameters, values of $\Delta F_{\mathrm{elect.}}$, the second term in equation(5), were found to be 169 and 186 calories per mole at 0° and 25°, respectively, for free copper concentrations below about 0.001 molar.

Using such values for the electrostatic-interaction term, wide deviations were obtained between calculated and observed values of r. Excellent agreement between calculated and observed binding curves (Figs. 1 and 2) was obtained, however, when $\Delta F_{\mathrm{elect.}}$, was reduced arbitrarily to 60 calories/mole at both temperatures. The possible significance of this discrepancy between the theoretical and empirical values of $\Delta F_{\mathrm{elect.}}$ will be discussed shortly.

Using 60 calories/mole for $\Delta F_{\mathrm{elect.}}$ and 16 for n, one can calculate the free energy of formation of each protein-cation complex from its predecessor. These free energies, together with the entropies and enthalpies which may be derived therefrom by standard thermodynamic procedures, have been summarized in Table III. Strictly speaking these thermodynamic values refer only to solutions with copper concentrations not exceeding 0.001 molar. Above this concentration the cupric salts contribute appreciably to the ionic strength of the solution and hence change $\Delta F_{\mathrm{elect.}}$ slightly. For most purposes, however, the slight discrepancies may be neglected.

TABLE III

THERMODYNAMICS OF BINDING OF Cu^{++} BY BOVINE SERUM ALBUMIN

pH 4.83 at 25°; $\mathrm{PCu}_{i-1} + \mathrm{Cu}^{++} = \mathrm{PCu}_i$

	ΔF^0 at 0°, cal./mole	ΔF^0 at 25°, cal./mole	ΔS^0 cal./mole/ deg.	ΔH^0 cal./mole
1	−5179	−5908	29.2	2780
2	−4708	−5399	27.6	2840
3	−4391	−5058	26.7	2900
4	−4135	−4784	26.0	2960
5	−3910	−4544	25.4	3020
6	−3704	−4325	24.8	3080
7	−3509	−4117	24.3	3140
8	−3319	−3915	23.8	3200
9	−3131	−3715	23.4	3260
10	−2941	−3513	22.9	3320
11	−2746	−3305	22.4	3380
12	−2540	−3086	21.8	3440
13	−2315	−2846	21.2	3500
14	−2059	−2572	20.5	3560
15	−1742	−2231	19.6	3620
16	−1271	−1722	18.0	3680

These free energy quantities may be correlated also in the form of the equations

$$\text{At } 0°\text{:}\ \Delta F^0{}_i = -5179 + \sum_{j=2}^{j=i} RT \ln \frac{n - (j - 2)}{n - (j - 1)} \frac{j}{j - 1} + (i - 1)\phi_{\mathrm{elect.}} \qquad (6)$$

---

(7) I. M. Klotz, *Arch. Biochem.*, **9**, 109 (1946).

(8) J. Kielland, THIS JOURNAL, **59**, 1675 (1937).

$$\text{At } 25°: \Delta F^0_i = -5908 + \sum_{j=2}^{j=i} RT \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} + (i-1)\phi_{\text{elect.}} \quad (7)$$

where $\phi_{\text{elect.}}$ is taken as 60 calories/mole at each temperature. From these equations it is possible to deduce the following expressions for the entropy and enthalpy changes

$$\Delta S^0_i = 29.2 - \sum_{j=2}^{j=i} R \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} \quad (8)$$

$$\Delta H^0_i = 2780 + (i-1)\phi_{\text{elect.}} \quad (9)$$

It should be pointed out that in the general case the equations for ΔS^0_i and ΔH^0_i would also contain a term involving the factor $\partial\phi_{\text{elect.}}/\partial T$. However, in the present situation the data can be represented adequately with the same value of $\phi_{\text{elect.}}$ at both temperatures so the temperature coefficient of the electrostatic term vanishes.

Effect of *p*H on Binding.—Since the *p*H dependence of the binding ability reflects on the nature of the groups involved in the bond, a few experiments were carried out at a *p*H of 4.0. These data are compared in Fig. 2 with the corresponding results at *p*H 4.8 at the same temperature. It is immediately evident that the maximum number of binding groups has been decreased substantially in solutions of higher acidity.

Discussion

Thermodynamics of the Complex-formation.—Both the table and equations showing the dependence of ΔF^0 on i illustrate the general trend downward in stabilization energy as the number of bound ions increases. The equations (6) and (7), in addition, show explicitly the basic sources of this trend—the contributions of the statistical and electrostatic terms, respectively, to the free-energy change. In the same connection it is of interest to note that the expression for the entropy, equation (8), contains the statistical term and lacks the electrostatic one, whereas the expression for the enthalpy, equation (9), includes an electrostatic contribution but no statistical one. Thus if no electrostatic interactions were involved, the enthalpy change, ΔH^0_i, would be the same for each successive complex.

It is also of interest to note that it is $T\Delta S$ term which supplies the necessary energy to make ΔF negative in the binding process. Thus from Table III it is evident that with positive values for the heat of binding, complex-formation between albumin and cupric ions would not be favored, were it not for the relatively large values of ΔS. The magnitude of the entropy changes probably indicates that the transfer of a Cu^{++} ion from the solvent to the protein molecule is accompanied by the release of several "frozen" water molecules and acetate ions.

Magnitude of the Electrostatic Effect.—It has been mentioned above that a value of 60 calories has been used for $\phi_{\text{elect.}}$ rather than 186 calories as would be expected from available molecular parameters and the electrostatic portion of equation (5). The basis of this large discrepancy is not clear. One source might be the use of a spherical model for the protein molecule instead of an ellipsoidal one. To estimate the magnitude of this difference, a calculation has been made of the electrostatic charging energy (at infinite dilution) of an ellipsoid of revolution with a major axis[4] of 150 Å. and a minor axis of 38 Å., and the value obtained has been compared with that of a sphere with a diameter of 60 Å. Though both these models encompass the same volume, the charging energy of the ellipsoid is 84% that of the sphere. The use of an ellipsoidal model, therefore, would change $\phi_{\text{elect.}}$ in the correct direction. Nevertheless, the extent of the decrease is not nearly sufficient to account for the observed drop from 186 to 60, or down to almost 30% of the spherical value.

It should be mentioned, of course, that the use of the Debye–Hückel expression to obtain the electrostatic portion in equation (5) is not really justified from a molecular point of view, for the protein molecule has discrete charges distributed along its surface as well as in its interior. In the absence of detailed information on the distribution of these charges it would be difficult to derive any convenient expression for further approximation of the electrostatic effect. Nevertheless, in connection with calculations at higher copper concentrations, where the cupric ions make an appreciable contribution to the ionic strength, it has been found convenient to use the Debye–Hückel expression and to take account of its inadequacy by increasing the magnitude of the dielectric constant to 350. This is a procedure similar to that used by Kirkwood and Westheimer,[9] though we do not have a corresponding theoretical justification. Using this higher "effective" dielectric constant at higher copper concentrations (above 10^{-3} *M*) one finds good agreement between the observed and calculated values of the extent of binding. Nevertheless, this agreement cannot be used to validate the approach because the binding equations are not sufficiently sensitive to small changes in the electrostatic contribution.

Nature of the Cation–Protein Bond.—The decrease in extent of binding at *p*H 4.0 as compared to that observed at *p*H 4.8 (Fig. 2) indicates that anionic carboxylate groups on the protein molecule are involved in bond formation with the cation. Such behavior would be in line with the many observations of complex-formation between cupric ions and carboxylic acids, including amino acids,[10] where similar *p*H dependence has been found. That the cation–protein linkage is through the carboxyl group is indicated also by the absorption spectrum of cu-

---

[9] J. G. Kirkwood and F. H. Westheimer, *J. Chem. Phys.*, **6**, 506 (1938).

[10] H. Borsook and K. V. Thimann, *J. Biol. Chem.*, **98**, 671 (1932).

pric ions in albumin solutions (Fig. 3).[11] As has been pointed out by Borsook and Thimann,[10] in their work on amino acid complexes of copper, the absorption peak remains in the near infrared in complexes bound through the carboxylate substituent and moves toward shorter wave lengths when Cu–N bonds are formed. The absorption peak of cupric ions in the presence of protein is substantially in the same region as in copper chloride or copper sulfate solutions.

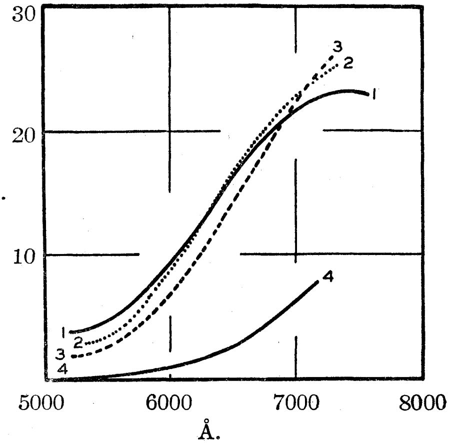

Fig. 3.—Absorption spectra of some copper complexes: 1, cupric ions with 2% bovine serum albumin at pH 4.23; 2, copper acetate in alcohol[10]; 3, cupric ions with glycine[10]; 4, cupric chloride pH 4.66.

Despite these indications of the importance of the carboxyl group in binding the cation, there is no agreement between the maximum number of bound copper ions (16) and the number of aspartyl (56) and glutamyl (80) residues in bovine serum albumin.[12] A similar lack of correspondence with the content of basic amino acids has been found in investigations of the binding of anions by bovine albumin.[5] It seems apparent once again that the primary focus of binding on the protein, the carboxyl group in Cu^{++} binding, must be in suitable juxtaposition with other substituents or residues before a stable complex can be formed.

Acknowledgment.—These investigations were carried out with the aid of a grant from the Office of Naval Research. The authors are indebted also to Professor George Scatchard of the Massachusetts Institute of Technology for several suggestions on improving the treatment of the data.

Summary

1. Measurements have been made of the binding of cupric ions by bovine serum albumin at a pH of 4.8 and at temperatures of 0° and 25°, respectively.

2. The results obtained have been correlated in terms of equations derived from statistical and electrostatic considerations. Free energies, entropies and enthalpies have been calculated for the multiple equilibria involved.

3. The decrease in binding with decrease in pH, as well as the character of the absorption spectrum of the copper–albumin complex, indicates the importance of carboxyl groups on the protein in the bond with the cation.

The Binding of Some Sulfonamides by Bovine Serum Albumin

BY IRVING M. KLOTZ AND F. MARIAN WALKER

Numerous studies have been made of the binding of sulfonamides by plasma.[1-3] From a pharmacological point of view it has been emphasized, particularly by Davis,[1] that the distribution of sulfonamides in various body fluids is strongly dependent on the extent of their binding by proteins. Similarly in connection with their chemotherapeutic properties, it has been pointed out that the antibacterial activity of these compounds parallels their adsorbability by plasma,[1] as well as by microörganisms.[4]

Davis[1] has demonstrated that it is the albumin fraction of plasma which is primarily responsible for the binding properties. Nevertheless, no investigations have been made of the formation of complexes between sulfonamides and crystallized serum albumin. Such a study with purified serum protein would be highly desirable, particularly since it would then be possible to apply a physicochemical analysis,[5] to the binding data and thereby to correlate the energy of binding with structural features in the drugs.

Experimental

Reagents.—Crystallized bovine serum albumin was obtained from Armour and Company. As in previous work,[5] corrections for water content were made by heating a

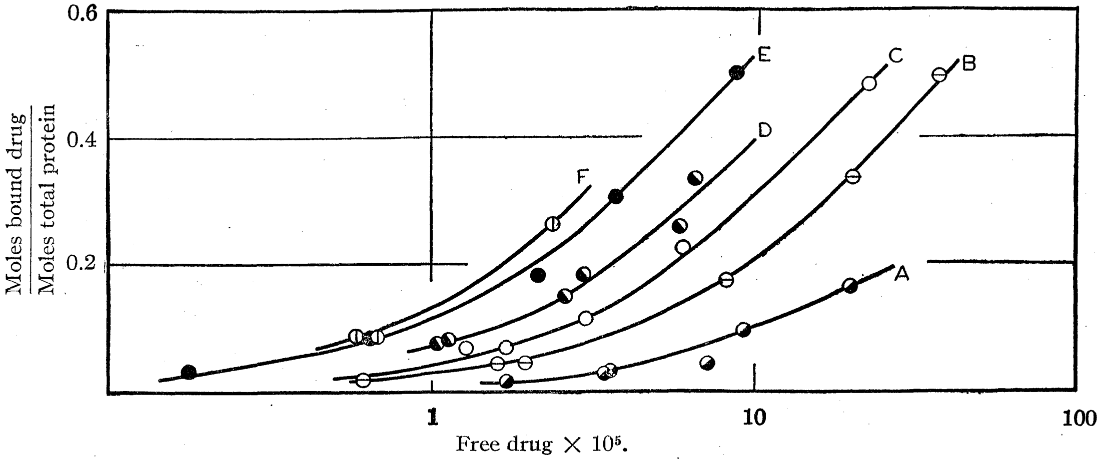

Fig. 1.—Binding of sulfonamides by bovine serum albumin in a phosphate buffer at *p*H 7.6 and 5°: A, sulfanilamide; B, sulfapyridine; C, N^1-acetylsulfanilamide; D, 5-sulfanilamido-3-methyl-isoxazole; E, 2-sulfanilamido-5-chloropyridine; F, N^1-benzoylsulfanilamide.

small sample in an oven at 110° until constant weight was attained.

Samples of the sulfonamides were kindly supplied by Drs. R. O. Roblin, Jr., and P. H. Bell of the American Cyanamid Company.

Dialysis Experiments.—The general procedure was the same as that described in earlier work.[5] Cellophane bags, prepared from commercial sausage casing, were filled with a measured amount of the protein solution of approximately 4% concentration. The bags were immersed in a solution of the sulfonamide and allowed seventy-two hours in a cold room (*ca.* 5°) for the attainment of equilibrium. For each sulfonamide concentration a control tube was also prepared which differed from the primary tube only in that the former contained buffer rather than a protein solution inside the bag.

Upon the attainment of equilibrium the sulfonamide concentrations *outside* the bags in the primary and control tubes, respectively, were analyzed. Though the compounds under investigation have no color, the absorption of ultraviolet light[6,7] may be used as an analytical method. These absorption measurements were made with a Beckman spectrophotometer using silica cells of 1 cm. thickness. The wave length of the maximum absorption of the compound was used in the analysis of the particular sulfonamide under investigation.

The calculation of the amount of bound sulfonamide per mole of total protein is essentially the same as in the example described in previous work.[5] In this investigation, however, the concentration of protein was much higher than in previous studies and hence the Donnan effect must be considered. An examination of the literature[8] reveals that the Donnan effect for serum, containing about 7% protein, would produce a ratio of monovalent anion concentrations outside and inside the bag, respectively, of about 1.02. Since the ratio is approximately proportional to the concentration of protein[8] the Donnan effect in the experiments described in this paper should produce a sulfonamide anion concentration outside the bag about 1% greater than inside.

This 1% Donnan correction on the anion concentrations would be completely negligible in the experiments with sulfanilamide and sulfapyridine, for only a small fraction of either of these compounds would be in the ionized form at the *p*H's used (7.6). For the other sulfonamides, the correction has been made though it is actually within experimental error.

In these experiments it was difficult to reproduce binding values to better than about 5%, perhaps because of very minute leakages from the bag containing the protein. While such leakages would not significantly affect the quantity of protein within the bag, it might introduce appreciable errors in the ultraviolet-absorption readings because bovine serum albumin has a strong peak in the neighborhood of those for the sulfonamides. Thus with a specific extinction coefficient, $E^{1\%}_{1\,\text{cm.}}$, of about 5 near 2800 Å.[9] the loss of as little as 0.004% protein from the liquid inside the bag (10 cc.) to that outside (20 cc.) would produce an increase in optical density of about 0.01 and hence an error of 1 to 5% in the readings (generally in the range of 0.2 to 0.8).

Results and Discussion

The binding data for six sulfonamides are summarized in Fig. 1. The method of presentation, average number of moles of bound drug per mole of total protein, *r*, *versus* the logarithm of the concentration of the free drug, log (A), is that most convenient for comparative studies of binding ability and for theoretical analysis in terms of the principles of mass action.

The equilibrium constants for the formation of the respective sulfonamide complexes may be calculated by methods previously described.[5] As is evident from Fig. 1, the average number of bound drug molecules per protein molecule does not exceed 1 over the region investigated. For purposes of comparison, then, it is sufficient to calculate k_1, the equilibrium constant for the formation of the first complex in each case. The statistical relation described previously (Equation (4) in reference (5))

$$k_i = \frac{n - (i - 1)}{i} k \qquad (1)$$

may be reduced to

$$k_1 = nk \qquad (2)$$

for the first equilibrium constant. Since the concentration of higher complexes must be small,

TABLE I

COMPLEX FORMATION AND RELATED PROPERTIES FOR SOME SULFONAMIDES

Compound	Formula	pK_a[10]	Per cent. in anionic state	Association[a] constant, k_1	ΔF_1^0 cal./mole
Sulfanilamide	$H_2N—C_6H_4—SO_2NH_2$	10.43	0.2	0.89×10^3	3740
Sulfapyridine		8.43	14	2.5×10^3	4320
N¹-Acetylsulfanilamide	$H_2N—C_6H_4—SO_2NHCOCH_3$	5.38	99	4.2×10^3	4600
5-Sulfanilamido-3-methyl isoxazole		4.2	100	7.8×10^3	4950
2-Sulfanilamido-5-chloropyridine		(7.15)[b]	80	13×10^3	5230
N¹-Benzoylsulfanilamide	$H_2N—C_6H_4—SO_2NHCOC_6H_5$	4.57	100	16×10^3	5350

[a] The buffer solution was at a pH of 7.6, and at a temperature of 5°. [b] The value for 2-sulfanilamido-5-bromopyridine has been used since data for the chloro compound are lacking.

electrostatic factors may be neglected, and the expression

$$\frac{1}{r} = \frac{1}{nk}\frac{1}{(A)} + \frac{1}{n} \qquad (3)$$

may be used as a reasonable approximation to the binding data. Thus from the slope of a graph of moles total protein per mole bound drug, $1/r$, *versus* the reciprocal of the concentration of free drug, $1/A$, one may evaluate the product nk for use in equation (2) in determining k_1. These slopes have been evaluated for the six drugs investigated and the equilibrium constants and free energy changes calculated for the association reaction

$$P + S = PS \qquad (4)$$

where P represents the protein molecule and S the sulfonamide. The results, together with acidity constants, pK_a's, taken from Bell and Roblin[10] have been assembled in Table I.

It is evident from these calculations that the binding energy increases with decreasing pK_a in the first three compounds in the table. This behavior is undoubtedly an expression of the increased concentration of anions as the pK_a decreases. That anions combine more strongly with proteins than do the corresponding non-ionized acids has been evident from other work.[11] That the sulfonamide ion is also the active species in bacteriostasis has been suggested previously.[12,13]

The difference in binding energy between sulfapyridine and 2-sulfanilamido-5-chloropyridine also seems attributable to the difference in anion concentration. If one takes into account the 5.7-fold higher anion concentration of the latter compound, it is evident that its binding energy should be approximately 960 calories (RT ln 5.7) higher than that of sulfapyridine. The observed difference in binding energy is 910 calories.

On the other hand in comparing the binding energies of N¹-acetylsulfanilamide and N¹-benzoylsulfanilamide, for which the anion concentrations in solutions of pH 7.6 are substantially identical, it is evident that another factor must enter. It seems likely that the additional stabilization energy of 750 calories for the albumin complex with benzoylsulfanilamide may be attributed to the stronger van der Waals forces which would be obtained with a phenyl group as compared to a methyl group. A similar effect has been noted by Gilbert[14] in studies of adsorption by wool where the phenyl group contributes about 1340 calories to the free energy change for the process, and the methyl group approximately 640 calories, a difference of 700 calories.

The relatively low binding energy for the isoxazole, as compared with the chloropyridine, for example, may be due to two factors. The van der Waals energy of the former is probably smaller because the number of atoms (excluding hydrogens) in it is fewer. Furthermore, the lower pK_a of the isoxazole would tend to reduce its ability to combine with the protein, if one adopts the Lewis generalized acidity concept discussed previously.[15] The loss in binding energy with decreasing pK_a in the sulfonamides seems to be small, however. If one corrects the binding energy of the chloropyridine to 100% anion concentration by adding RT ln (100/80) (130 calories), the difference between its ΔF_1^0 and that for the isoxazole is still only 400 calories for a change of 3 units in pK_a.

These investigations were supported by grants from the Lederle Laboratories Division of the American Cyanamid Company and from the Office of Naval Research.

Summary

Quantitative measurements have been made of the binding of sulfanilamide, sulfapyridine, N^1-acetylsulfanilamide, 5-sulfanilamido-3-methylisoxazole, 5-sulfanilamido-5-chloropyridine and N^1-benzoylsulfanilamide, respectively, by crystallized bovine serum albumin. Binding energies have been calculated and have been correlated with the structures of the compounds.

The Synthesis of Some Cyclopropane and Spirane Hydrocarbons[1]

BY R. W. SHORTRIDGE, R. A. CRAIG, K. W. GREENLEE, J. M. DERFER AND C. E. BOORD

This paper describes an extension of the Gustavson method[2,3,4] for the synthesis of cyclopropane and its derivatives. Three 1,1-dialkylcyclopropanes have been prepared; two of these compounds are new, and improved physical properties were determined for the third. The method has been applied to the preparation of spiranes containing a cyclopropane ring and provides an easy, straightforward way of producing this type of hydrocarbon in quantity and in a good state of purity. Cleavage of the cyclopropane ring by hydrogen has been investigated.

1,1-Dimethylcyclopropane has been produced from *sym*-dibromoneopentane most recently by Whitmore[5] and his co-workers. Isobutyraldehyde was condensed with formaldehyde in the presence of potassium hydroxide to obtain 2,2-dimethyl-1,3-propanediol which was converted to the corresponding dibromide by the action of phosphorus tribromide; the cyclization was accomplished with zinc in molten acetamide (Hass–McBee[6] procedure). In the present work the intermediates were synthesized by the same series of reactions, but the dibromide was cyclized by zinc in aqueous ethanol. The hydrocarbon was obtained in 96% yield (based on distilled dibromide), and it froze over a 0.4° range; physical properties were determined on a center fraction from the distillation of this product at about 10-plate efficiency.[7]

1,1-Diethylcyclopropane and 1-ethyl-1-butylcyclopropane were prepared by an analogous series of reactions. The yields from the dibromides were 92 and 94%, respectively; as in the case of 1,1-dimethylcyclopropane, the initial product was of high purity.[8] These two compounds have not been described previously.

TABLE I

		B. p., °C. (760 mm.)	F. p., °C.	d^{20}_4	n^{20}_D
1,1-Dimethyl cyclopropane	This work	20.63	−108.96	0.6589	1.3668
	Whitmore[5]	19.9	−108.4 to −107.3	....	....
1,1-Diethylcyclopropane		88.67	−105.91	.7318	1.4042
1-Ethyl-1-butylcyclopropane		140.41	−102.68	.7559	1.4183

Few spiranes have been synthesized. In all reported preparations where closure of the second ring was not the final step, the over-all yields have been no more than a few per cent. Recently spiropentane has been identified as a product from the reaction of pentaerythrityl tetrabromide with zinc[9,10] the yield being in the neighborhood of 25% based on the tetrabromide; this is the highest yield reported for any spirane. We have applied the Gustavson reaction to the preparation of spiro(2.5)octane and 4-methylspiro(2.5)octane. This work provides a general method for the preparation of spiranes containing a cyclopropane ring and is limited only by the availability of cyclic aldehydes which contain the desired configuration and which will undergo the methylol reaction to yield *gem*-dicarbinols. The yields are good.

Spiro(2.5)octane was prepared in the following way: 3-Cyclohexene-1-carboxaldehyde was prepared by condensing acrolein with butadiene (Diels–Alder). The adduct, an unsaturated alde-

[4] This reaction has been called the Freund reaction on occasion. However, reference to the original literature shows that although Freund (*Monatsh.*, **2**, 642 (1881)) was the first to make cyclopropane itself, he used an extension of the Wurtz reaction, and therefore had no claim to the method of ring closure which employs zinc in the presence of protonic solvent. This method was first reported by Gustavson[2] in 1887 by a paper entitled: "Concerning a New Method of Preparation of Trimethylene." Gustavson and Popper[4] extended this method to the preparation of substituted cyclopropanes.

hyde, reacted with formaldehyde to yield 4,4-bis-(hydroxymethyl)-1-cyclohexene which was hydrogenated catalytically to the corresponding saturated diol. Treatment of the diol with phosphorus tribromide gave 1,1-bis-(bromomethyl)-cyclohexane. Cyclization of the dibromide with zinc in ethanol produced spiro(2.5)octane in 91% yield. On distillation at about 25-plate efficiency, 71% of this material had a boiling range of 0.1° and a refractive index range of 0.0007; 51% had a constant boiling point and refractive index. The sample did not absorb bromine from carbon tetrachloride solution, and its time–temperature freezing curve showed it to be of high purity. Physical properties were determined on the constant index material.

4-Methylspiro(2.5)octane was made by the same series of reaction, starting with crotonaldehyde and butadiene. The yield of crude spirane was 89% from the dibromide; distillation at about ten-plate efficiency reduced this yield to 58% having a refractive index range of 0.0002. A good time–temperature freezing curve could not be obtained for this material, even after redistillation at about 25-plate efficiency and fractional crystallization. The physical properties listed were determined on the sample after recrystallization, and the material appeared to freeze over a range of about 5°. Since the ring closure reaction on di-primary halides gives high purity products consistently, it does not seem logical that in this case rearrangement occurred with the formation of an inseparable impurity; it is believed that the cryoscopic behavior can be attributed to a low heat of fusion for this spirane.

TABLE II

	B. p., °C. (760 mm.)	F. p., °C.	d^{20}_4	n^{20}_4
Spiro(2.5)octane	125.5	−86.2	0.8282	1.4476
4-Methylspiro(2.5)-octane	149.0	−53.6	.8386	1.4529

The stability of the cyclopropane ring is greatly affected by the nature and position of substituted groups. Willstätter and Bruce[11] found that cyclopropane, itself, is converted to propane at 80° by hydrogen over a nickel catalyst. Both Whitmore[12] and Fuson[13] state that alkyl-substituted cyclopropanes usually undergo ring opening more easily than does the parent substance. Studies on certain alkylcyclopropanes by other workers[14] indicate that temperatures of 150–170° are necessary to effect rupture of the ring.

In the present work hydrogenation studies have been carried out on three compounds containing the cyclopropane ring. No reaction occurred when an attempt was made to treat 1,1-diethylcyclopropane with hydrogen over platinum oxide catalyst at 60° and 40 p. s. i.; likewise, no reaction occurred when a palladium on calcium carbonate catalyst was used under these conditions. When the hydrocarbon was diluted with 60% of its volume of absolute ethanol, absorption of hydrogen did not occur even at 195° and 2400 p. s. i. over nickel on kieselguhr catalyst (Universal Oil Products). Successful hydrogenation of 1,1-diethylcyclopropane was accomplished in the absence of a solvent at 180° and 2000 p. s. i. over the nickel catalyst. Distillation of the hydrogenated product at about 10-plate efficiency gave 20% as headings and tailings (decomposition products and unchanged 1,1-diethylcyclopropane) and 80% of material (3° boiling range) which was identified as 3,3-dimethylpentane by inspection of the distillation curves (b. p. and $n^{20}\text{D}$). The boiling point range may be attributed to the presence of unchanged 1,1-diethylcyclopropane which boils only 2.5° higher than 3,3-dimethylpentane. No evidence was found for the presence of the other possible hydrogenation product, 3-ethylpentane.

Spiro(2.5)octane was hydrogenated successfully in the absence of a solvent over the nickel catalyst at 155° and 1900 p. s. i.; the theoretical amount of hydrogen was absorbed. Distillation of the hydrogenated product at about 25-plate efficiency gave 9% headings and tailings (decomposition products and unchanged spirane) and 91% of material (0.5° boiling range) which was identified as 1,1-dimethylcyclohexane on the basis of the physical properties of a heart cut (b. p. 119.65° (760 mm.), f. p. −34.02°, d^{20}_4 0.7809, $n^{20}\text{D}$ 1.4291). No evidence was found for the presence of the other possible hydrogenation product, ethylcyclohexane.

4-Methylspiro(2.5)octane was hydrogenated under the same conditions as spiro(2.5)octane. The single hydrogenation product found was tentatively identified as 1,1,2-trimethylcyclohexane, a new compound, and it had the following physical properties: b. p. 145.2° (760 mm.), f. p. −29.2°, d^{20}_4 0.7986, $n^{20}\text{D}$ 1.4385. A good freezing curve could not be obtained for this product, the general contour being the same as that for the original unhydrogenated spirane. 1,1,2-Trimethylcyclohexane, prepared at a later date[15] by a different method, and believed to be of good purity, had physical properties which agreed well with those of the product prepared by the hydrogenation of 4-methylspiro(2.5)octane. It exhibited the same peculiar cryoscopic behavior and was found to have a low heat of fusion and an unusually high freezing point depression on addition of *n*-heptane as impurity. This suggests that the original 4-methylspiro(2.5)octane was of good purity.

These studies indicate that when a *gem*-dialkylcyclopropane, or a spirane containing a cyclo-

propane ring, is hydrogenated under the conditions described above, rupture of the cyclopropane ring occurs almost exclusively at the bond opposite the *gem*-disubstituted carbon atom. Thus, hydrogenation under controlled conditions can provide an easy, reliable method for proving the structure of these types of compounds, and in some cases it may prove to be a good preparative reaction for synthesizing *gem*-dimethylcycloalkanes with rings containing more than three carbon atoms. Since ring cleavage requires rather severe conditions (especially in the presence of a solvent), it appears that alkylcyclopropanes can be produced from cyclopropylolefins by preferential hydrogenation of the carbon-carbon double bond.

Experimental

Preparation of 2,2-Dimethyl-1,3-propanediol.—This diol was prepared from isobutyraldehyde and formaldehyde by the procedure of Whitmore and his co-workers,[5] except that stirring of the reaction mixture was maintained during the dropwise addition of the alcohol solution of the reactants. Sodium hydroxide could be substituted for potassium hydroxide with little sacrifice in yield. After a twenty-four hour reflux period the reaction mixture was stripped of alcohol, and the residue was subjected to continuous ether extraction. After removal of the ether, the crude product was distilled from a Claisen flask at atmospheric pressure to obtain a 76% yield of the diol boiling at 176–205°. The bulk of the product was collected at about 200°; it melted at 130°.

Preparation of 1,3-Dibromo-2,2-dimethylpropane.—This compound was prepared from 2,2-dimethyl-1,3-propanediol and phosphorus tribromide by the procedure of Whitmore, *et al.*,[5] except for the following innovation. Phosphorus tribromide was added to the diol at 70°, the rate of addition being such as to maintain the temperature. The reaction is immediate under these conditions and is easily kept under complete control.[16] It was not necessary to stir the reaction mixture, although this is now believed to be advisable for large runs.

The steam distillate, after drying, was fractionated under reduced pressure at 5 to 10-plate efficiency. Based on diol, a 46% yield of good dibromide was obtained. It had the following physical properties: b. p. 68° (9 mm.), n^{20}_D 1.5050, d^{20}_4 1.6934.

Preparation of 1,1-Dimethylcyclopropane.—The method of cyclization was a modification of that of Gustavson.[2,3] In a 2-liter three-necked flask equipped with a dropping funnel, mercury-sealed stirrer and reflux condenser (connected to a trap surrounded by a Dry Ice–acetone-bath), were placed 900 ml. of 95% ethanol, 90 ml. of distilled water and 628 g. (9.6 moles) of zinc dust; it was necessary to maintain vigorous stirring at all times to prevent caking of the zinc. The mixture was brought to gentle reflux, and 562 g. (2.4 moles) of 1,3-dibromo-2,2-dimethylpropane was added dropwise at this temperature. Heating and stirring were continued for twenty-four hours after the last of the dibromide had been added; the bulk of the hydrocarbon collected in the trap during this period. The remaining 1,1-dimethylcyclopropane (along with some alcohol) was then distilled from the reaction flask and was collected in the trap. The crude product (162 g.) was washed with ice water and dried. The properties and purification of this material have already been described.

Preparation of 2,2-Diethyl-1,3-propanediol.—This compound was prepared from 2-ethylbutyraldehyde (Carbide and Carbon) by the same procedure as was used for the synthesis of 2,2-dimethyl-1,3-propanediol from isobutyraldehyde. Because of the lesser solubility of the resulting diol in water in this case, continuous ether extraction was unnecessary, and the crude product was merely extracted from the reaction mixture with ether. The ether was removed from the extract by distillation, and the residue was distilled from a Claisen flask to give a 91% yield of good product (b. p. 128–132° (12 mm.)). This material was fractionated at about 10-plate efficiency, and the following physical properties were determined on a center fraction: b.p. 131° (13 mm.), m. p. 61.0–61.6°. This compound has not been described previously. *Anal.* Calcd. for $C_7H_{16}O_2$: C, 63.6; H, 12.2. Found: C, 64.0; H, 12.2.

Preparation of 1,3-Dibromo-2,2-diethylpropane.—This dibromide was prepared from the corresponding diol in exactly the same way as 1,3-dibromo-2,2-dimethylpropane was prepared from 2,2-dimethyl-1,3-propanediol. The yield of steam distilled material was 40% (from diol) and was shown to be 90% pure by distillation under reduced pressure at 5 to 10-plate efficiency. The following physical properties were determined on a purified sample: b. p. 97° (10 mm.), m. p. 39.2–40.6°; this compound has not been described previously. *Anal.* Calcd. for $C_7H_{14}Br_2$: Br, 61.9. Found: Br, 62.1.

Preparation of 1,1-Diethylcyclopropane.—The ring closure reaction was carried out in the same way as in the preparation of 1,1-dimethylcyclopropane. Since the dibromide (1,3-dibromo-2,2-diethylpropane) was a solid, it was necessary to heat the dropping funnel in order to use the same technique. The 1,1-diethylcyclopropane was allowed to accumulate in the reaction flask; then the hydrocarbon was distilled from the reaction mixture through a 1.5 × 50 cm. Vigreux column until dilution of the fresh distillate with water did not cause a phase separation. The distillate was washed free of alcohol and was fractionated at about 10-plate efficiency; all of the material distilled at a constant temperature and had a constant refractive index; the total yield was 92% of theory (from dibromide). The physical properties of the distilled hydrocarbon are listed in Table I. This compound has not been described previously. *Anal.* Calcd. for C_7H_{14}: C, 85.6; H, 14.4. Found: C, 85.9; H, 14.2.

Preparation of 2-Ethyl-2-butyl-1,3-propanediol.—This diol was prepared from 2-ethylhexaldehyde (Carbide and Carbon) in the same way 2,2-diethyl-1,3-propanediol was prepared from 2-ethylbutyraldehyde. The crude product distilled at 151–152° (11 mm.) and was obtained in 70% yield. The material was redistilled at about 10-plate efficiency, and the following physical properties were determined on a center cut: b. p. 152° (10 mm.), m. p. 41.4–41.9°. This compound has not been described previously. *Anal.* Calcd. for $C_9H_{20}O_2$: C, 67.4; H, 12.6. Found: C, 67.6; H, 12.5.

Preparation of 1,3-Dibromo-2-ethyl-2-butylpropane.—This dibromide was prepared from the corresponding diol in exactly the same way as 1,3-dibromo-2,2-dimethylpropane was prepared from 2,2-dimethyl-1,3-propanediol. The yield of steam distilled material was 59% (from diol) and was shown to be 80% pure by distillation at about 10-plate efficiency. The following physical properties were determined on a purified sample: b. p. 133° (16 mm.), d^{20}_4 1.4400, n^{20}_D 1.5018. This compound has not been described previously. *Anal.* Calcd. for $C_9H_{18}Br_2$: Br, 55.9. Found: Br, 56.2.

Preparation of 1-Ethyl-1-butylcyclopropane.—1,3-Dibromo-2-ethyl-2-butylpropane was cyclized in the same way as was 1,3-dibromo-2,2-diethylpropane in the preparation of 1,1-diethylcyclopropane. The crude 1-ethyl-1-butylcyclopropane was fractionated at about 10-plate efficiency, and all of the material distilled at a constant temperature and had a constant refractive index. The yield from the dibromide was 94%. The physical constants of the distilled hydrocarbon are listed in Table I. This compound has not been described previously. *Anal.* Calcd. for C_9H_{18}: C, 85.6; H, 14.4. Found: C, 85.6; H, 14.4.

Preparation of 3-Cyclohexene-1-carboxaldehyde.—The procedure used was patterned after that described by Chayanov.[17] Butadiene (5 moles) was placed in a one-

---

[16] At lower temperatures an excess of phosphorus tribromide may accumulate, and a sudden uncontrollable reaction may occur.

[17] N. A. Chayanov, *J. Gen. Chem.* (*U. S. S. R.*), **8**, 460 (1938).

liter steel bomb (American Instrument Company type) which contained acrolein (5 moles) and 5 g. of hydroquinone, the bomb and contents having been cooled previously in a Dry Ice chest. The bomb was sealed, placed in a mechanical shaker, and heated as rapidly as possible to 130°. At this temperature reaction appeared to begin, and the temperature quickly rose to 185° without further external heating. After cooling, the crude adduct (543 g.) was distilled at reduced pressure (75 mm.) through a 122 cm. Vigreux column. A center cut with a refractive index range of 0.0004 and a boiling point range of 1.0° represented 74% of the theoretical yield. Physical properties were determined on a heart fraction (values in parentheses are those of Chayanov[17]): b. p. 164° (760 mm.) (163.5–164.5°), f. p. −96.1°, d^{20}_{4} 0.9709 (d^{19}_{4} 0.965), n^{20}_{D} 1.4725 (n^{19}_{D} 1.4725).

When the reaction was run on a larger scale, lower yields were obtained. This may be explained by the fact that rapid heating to reaction temperature is necessary to minimize the formation of by-products; further, the temperature rise from the heat of reaction is greater in larger batches and may cause undesirable side reactions.[18]

Preparation of 4,4-bis-(Hydroxymethyl)-1-cyclohexene.—This diol was prepared from 3-cyclohexene-1-carboxaldehyde by the same procedure as 2,2-dimethyl-1,3-propanediol was prepared from isobutyraldehyde. On evaporation of the ether from the extract a large crop of crystals separated; the uncrystallized residue was distilled to obtain the remainder of the diol (b. p. 128° (3 mm.)). The total yield of diol was 84% of theory (from aldehyde), and, after two crystallizations, it melted sharply at 92.0°. (literature value,[19] 92.5°).

Preparation of 1,1-bis-(Hydroxymethyl)-cyclohexane.—1,1-bis-(Hydroxymethyl)-3-cyclohexene was dissolved in methanol (40 g. per 100 ml.) and placed in a steel bomb with 9% by weight of Raney nickel catalyst. Absorption of hydrogen began at 45° and 1000 p. s. i. The catalyst was removed by filtration, and the solvent was removed by distillation; white crystals melting at 98.5° remained. No further purification was attempted.

Preparation of 1,1-bis-(Bromomethyl)-cyclohexane.—This dibromide was prepared from the corresponding diol in the same way as 1,3-dibromo-2,2-dimethylpropane was prepared from 2,2-dimethyl-1,3-propanediol. After a twelve-hour heating period at 140–150°, the reaction mixture was hydrolyzed and subjected to superheated (150°) steam distillation. The steam distillate was dried and fractionated at 5 to 10-plate efficiency under reduced pressure to obtain a 27% yield (from diol) of purified dibromide. Physical constants determined on a center cut were: b. p. 117° (6 mm.), d^{20}_{4} 1.6302, n^{20}_{D} 1.5390.

Preparation of Spiro(2.5)octane.—1,1-bis-(Bromomethyl)-cyclohexane was cyclized in the same way as was 1,3-dibromo-2,2-dimethylpropane in the preparation of 1,1-dimethylcyclopropane. The hydrocarbon was allowed to accumulate in the reaction mixture and was isolated by distillation from the reaction flask. The crude product (n^{20}_{D} 1.4660) was washed free of alcohol and was obtained in 91% yield from dibromide.

Preparation of 6-Methyl-3-cyclohexene-1-carboxaldehyde.—This compound was prepared from butadiene and crotonaldehyde. The crotonaldehyde was placed in a steel bomb and heated to 150°. The butadiene was placed in a small cylinder connected to the bomb by small bore steel tubing. Nitrogen (pressure 300 p. s. i.) was used to push the butadiene into the reaction bomb in liquid form, the rate of addition being regulated by a valve so that about 7 g. per minute were added. A 46% yield of the desired aldehyde was obtained after distillation at 5 to 10-plate efficiency under reduced pressure. Its physical properties were: b. p. 99° (64 mm.) or 117.8° (760 mm.), d^{20}_{4} 0.9500, n^{20}_{D} 1.4680.

Preparation of 4,4-bis-(Hydroxymethyl)-5-methylcyclohexene.—This compound was prepared from 6-methyl-3-cyclohexene-1-carboxaldehyde by the same procedure as 2,2-dimethyl-1,3-propanediol was prepared from isobutyraldehyde. Purification was attempted by reduced pressure distillation. The distillate (b. p. 134° (6 mm.)) contained substantial amounts of the cyclic aldehyde (from dissociation during distillation); a yield was not calculated. Some pure crystalline diol was separated and melted at 45°. (This value agrees well with that given by French and Gallagher.[19])

Preparation of 1,1-bis-(Hydroxymethyl)-2-methylcyclohexane.—The crude cyclohexenedicarbinol was hydrogenated at 45° in ethanol solution over 10% by weight of Raney nickel. Distillation of the hydrogenated material at low efficiency gave a 51% yield (from original aldehyde) of saturated diol (m. p. 77°.).

Preparation of 1,1-bis-(Bromoethyl)-2-methylcyclohexane.—This compound was prepared from the corresponding diol by the same procedure as 1,1-bis-(bromomethyl)-cyclohexane was prepared from 1,1-bis-(hydroxymethyl)-cyclohexane; the yield of purified dibromide was 28% (from diol), and it had the following physical properties: b. p. 115° (4 mm.), n^{20}_{D} 1.5380.

Preparation of 4-Methylspiro(2.5)octane.—1,1-bis-(Bromomethyl)-2-methylcyclohexane was cyclized in the same way as was 1,1-bis-(bromomethyl)-cyclohexane in the preparation of spiro(2.5)octane. An 89% yield of crude spirane was obtained.

Acknowledgment.—Sincere appreciation is expressed for the use of the equipment and materials of the American Petroleum Institute Research Project 45.

Summary

1. The synthesis of three *gem*-dialkylcyclopropanes is described; two of these are new compounds; improved physical properties were determined for the third.

2. Spiro(2.5)octane and 4-methylspiro(2.5)octane, both new compounds, have been synthesized in good yield by an extension of the Gustavson reaction. This method appears to be a general one for preparing spiranes containing a cyclopropane ring.

3. Hydrogenation of three of these compounds has been investigated to determine the point of rupture of the cyclopropane ring and the conditions necessary to effect it. Cleavage seems to occur exclusively at the bond opposite to the gem-disubstituted carbon atom. The stability of the cyclopropane ring toward catalytic hydrogenation is discussed.

COLUMBUS, OHIO RECEIVED JULY 7, 1947

(18) It has been observed both here and in other laboratories that in Diels–Alder reactions of this kind (especially when butadiene is involved) an extremely exothermic reaction may occur quite suddenly, thus raising the temperature and pressure to extreme values. This is supposedly due to self-polymerization of the diene and is catalyzed by peroxides; it can be checked by use of peroxide free dienes and/or addition of a strongly reducing substance such as hydroquinone. Other essential precautions are that the reactants should be thoroughly mixed, the reaction vessel (bomb) should not be filled to more than two-thirds of its capacity at room temperature, and the vessel should be connected directly to a blow-out assembly with a discharge line leading to the out-of-doors. Neglect of these precautions caused one bad accident in this Laboratory. The head was blown from a 3-liter bomb containing butadiene and crotonaldehyde; the ensuing gas explosion did much damage and burned one man seriously.

Sulfur-containing Amines. V. Local Anesthetics. I

BY R. O. CLINTON, U. J. SALVADOR, S. C. LASKOWSKI AND C. M. SUTER

In continuation of the investigation proceeding in these laboratories on the effect of sulfur-interrupted basic side chains on pharmacological activity[1] there have been prepared a number of local anesthetic type compounds derived from sulfur-containing amines. The majority of these compounds contain the *p*-aminobenzoyl nucleus, as in (I) or (II). As variants of this type, the *p*-amino group has been altered to a *p*-*n*-butylamino group (III), and the amide linkage has been changed from secondary to tertiary (IV). No compounds of these types have previously been described in the literature.

I, X = O, R = H III, X = NH, R = *n*-C_4H_9
II, X = NH, R = H IV, X = NC_2H_5, R = H

Although considerable work has been carried out on investigations of *p*-aminobenzoates, very few *p*-aminobenzamides are described in the literature. Wenker[2] described a short series of N-alkyl and N,N-dialkyl *p*-aminobenzamides, the higher homologs of which were strong surface anesthetics. Einhorn[3] has patented a series of N-(2-dialkylaminoethyl)-*p*-alkylaminobenzamides and ascribes to this series a high local anesthetic activity. Blicke, Parke and Jenner[4] prepared a number of N-(2-dialkylaminoethyl)- and N-(3-dialkylaminopropyl)-4-amino-1-naphthoamides, whose activity was less than that of the corresponding esters. The well known compound 2-butoxy-N-(2-diethylaminoethyl)-cinchoninamide hydrochloride (nupercaine) possesses a very high activity, but also a high toxicity. In general, it appears from statements in the literature that conversion of the ester linkage to the amide linkage in these local anesthetic types produces a moderate to large increase in activity, but the therapeutic index is not affected advantageously.

The favorable toxicity ratios obtained with therapeutically active compounds by inclusion of the thio linkage[5] in the basic side chain indicated that this desirable property might also be obtained in other series. In order to determine both the effect of sulfur on toxicity and the effect as a "weighting" atom in the basic side chain (*i. e.*, considered as equivalent to two methylene groups), the series was extended to include *p*-aminobenzamides containing basic side chains interrupted by oxygen, and in both types the number of methylene groups in the side chain was widely varied.

The basic side chains used in the present work were mostly prepared by methods previously reported.[1,6] However, the sulfur-interrupted basic side chains containing the —$SCH_2CH_2NH_2$ termination were most conveniently prepared by a modification of the method of Brighton and Reid,[7] involving reaction between a thiol and 2-bromoethylamine in the presence of a base. When solutions of equimolecular amounts of thiol and 2-bromoethylamine hydrobromide in methanol were treated with two equivalents of sodium methoxide at −10° to 0° there were obtained 70–90% yields of the desired amines.

Attempts to prepare the 2-(dialkylaminoalkylmercapto)-ethylamines through reaction of a dialkylaminoalkyl halide with 2-aminoethylisothiouronium bromide hydrobromide and a base, or through reaction of a dialkylaminoalkylisothiouronium chloride hydrochloride with 2-bromoethylamine hydrobromide and a base, resulted in considerably lower yields than were obtainable by the above described procedure.

This series of compounds has been tested for local anesthetic activity following subcutaneous administration around the external canthus of rabbits' eyes. The compounds showed varying degrees of activity; at present, however, the data are insufficient to classify them according to activity. A complete report will be published by Dr. T. J. Becker and Dr. F. P. Luduena of these Laboratories at a later date.

Experimental[8]

Isothiouronium Salts.—All of the isothiouronium salts used in the present work were prepared by refluxing equimolecular amounts of a dialkylaminoalkyl chloride

hydrochloride (or bromide hydrobromide) and thiourea in three to four volumes of ethanol for six to twenty-four hours.[9] The shorter time could be used with ethyl chlorides or bromides; the longer period is preferable with propyl chlorides and with higher dialkylaminoethyl chlorides. Usually the isothouronium salt partially crystallized during the reflux period. The reaction mixture was cooled, filtered and the filtrate concentrated to a small volume. The combined crops of crystalline material were then recrystallized to a constant melting point, usually from absolute ethanol–ethyl acetate. New isothiouronium salts are listed in Table I.

Thiols.—Two modifications were used in the preparation of the thiols. Examples of each method follow:

2-Dimethylaminoethanethiol.[10] **Method A.**—One mole of 2-dimethylaminoethylisothiouronium chloride hydrochloride (m. p. 182–183°; ref. 10 gives m. p. 181–182°) was dissolved in 350 ml. of warm water and treated with an aqueous solution of two moles of sodium hydroxide in 100 ml. of water. Upon working up by a method analogous to that previously described[9] there was obtained a 22% yield of colorless product, b. p. 142–146° at 750 mm. In this and similar cases of low molecular weight thiols the loss of product by ether co-distillation is very high.

Method B.—For the preparation of large amounts of 2-diethylaminoethanethiol[9] it was found more convenient to proceed as follows:

A mixture of 855 g. (5.00 moles) of 2-chlorotriethylamine hydrochloride, 380 g. (5.00 moles) of thiourea and 3000 ml. of water was refluxed for five hours. The cooled solution was treated with a solution of 408 g. (10.00 moles) of 97% sodium hydroxide in 1000 ml. of water, the mixture saturated with salt, and extracted with ether. The ethereal solution was dried over anhydrous potassium carbonate, filtered, and the ether distilled through an efficient column at atmospheric pressure. The residue was distilled *in vacuo*. There were thus obtained yields of 45–60% of theory of colorless product, b. p. 46–48° at 4 mm.

An additional method, namely, the conversion of the isothiouronium salts to thiols by means of alkoxides in alcohols, is at present being investigated. Preliminary results indicate that this reaction is complicated by the formation of by-products other than the desired thiols (*e. g.*, the corresponding dialkylaminoalkylmercaptoalkanes). These results will be made the subject of a later communication.

The new thiols prepared in the present work are listed and characterized in Table II.

2-(Dialkylaminoalkylmercapto)-ethylamines

2-(2-Diethylaminoethylmercapto)-ethylamine.—Method A.—In a one-liter three-neck flask, equipped with a mechanical Hershberg-type stirrer, internal thermometer and dropping funnel, was placed 102.5 g. of 2-bromoethylamine hydrobromide,[11] 66.5 g. of 2-diethylaminoethanethiol and 400 ml. of methanol. The mixture was cooled to −10° by means of an external ice–salt–Dry Ice bath and there was added during forty-five minutes, with stirring, a solution of 23.0 g. of sodium in 400 ml. of methanol. During the addition of the first half of the sodium methylate solution, no exothermic effect was noted; addition of the second half produced an exothermic reaction. The internal temperature was maintained at −10° throughout this addition. The cold bath was removed and stirring was continued for an additional two hours. The flask was equipped with a 24″ Claisen-Vigreux column and the methanol was distilled with stirring at atmospheric pressure. The semi-solid residue was triturated with several portions of ether, the combined ether triturates were concentrated by distillation, and the residual oil fractionated *in vacuo*. There was obtained 81 g. (92% yield) of colorless product, b. p. 92–94° at 1.1 mm., n^{20}_{D} 1.4912. The dithiocarbamate-alcoholate had m. p. 142–143° (d.).[6]

Method B.—Treatment of a mixture of 124 g. of 2-diethylaminoethylisothiouronium chloride hydrochloride[9] and 102.5 g. of 2-bromoethylamine hydrobromide in 400 ml. of absolute ethanol with a solution of 46.0 g. of sodium in 1000 ml. of absolute ethanol at −10°, under the general conditions outlined in Method A above, gave 47.0 g. (53%) of 2-(2-diethylaminoethylmercapto)-ethylamine. Variation of the temperature during the reaction (*e. g.*, between −15° and 5°) did not improve the yield; however, preparation of the thiol *in situ* by the addition of the equivalent amount of sodium ethylate to the isothiouronium salt at 25°, followed by the addition of 2-bromoethylamine hydrobromide and sodium ethylate at −10°, increased the yield to 84%.

Method C.—Treatment of an equimolecular mixture of 2-aminoethylisothiouronium bromide hydrobromide and 2-chlorotriethylamine hydrochloride in absolute ethanol with four equivalents of sodium ethylate at −10° gave an 18% yield of 2-(2-diethylaminoethylmercapto)-ethylamine. Temperature variation (*e. g.*, between −15° and 10°), or difference in mode of addition of the reaction components did not markedly improve the yield. In all cases substantial amounts of N^1,N^4-diethylpiperazinium diethochloride[12] were formed.

The new 2-(dialkylaminoalkylmercapto)-ethylamines prepared in the present work are given in Table II. All of these compounds were prepared by Method A at −10° in methanol. The yields given represent material boiling within a two degree range; the boiling points reported are those of the analytically pure samples. The thiols used in the preparation of these amines are described in References 1 and 6, in the text above, and in Table II. Characterizing derivatives are listed in Table II.

2-(2-Diethylaminoethylmercapto)-diethylamine.—2-Hydroxydiethylamine[13] was converted by 48% hydrobromic acid to **2-bromodiethylamine hydrobromide**, essentially by the general procedure of Cortese.[11] The compound was obtained in 79% yield, white prisms from absolute ethanol–ether, m. p. 200–203°.

Anal. Calcd. for $C_4H_{10}BrN \cdot HBr$: N, 6.01. Found: N, 5.87.

The bromoamine was condensed with 2-diethylaminoethanethiol in methanol at −10° as described in Method A above, to yield 83% of the desired product, b. p. 88.5° at 0.20 mm., n^{25}_{D} 1.4765.

Anal. Calcd. for $C_{10}H_{24}N_2S$: N, 13.58; S, 15.53. Found: N, 13.50; S, 15.80.

The **dipicrate** formed canary-yellow prisms from dilute ethanol, m. p. 127.0–128.5°.

Anal. Calcd. for $C_{22}H_{30}N_8O_{14}S$: S, 4.82. Found: S, 4.80.

2-(2-Diethylaminoethoxy)-ethylamine.—A mixture of 253.5 g. of 2-chloro-2′-phthalimidoethyl ether,[14] 219 g. of diethylamine and 1500 ml. of ethanol was refluxed for thirty hours, and then concentrated to dryness *in vacuo*. The residual paste was taken up in water and extracted with three 200 ml. portions of ether. Washing and evaporation of the ether gave 218 g. of crude **2-(2-phthalimidoethoxy)-triethylamine** as a mobile light brown oil. The **hydrochloride** formed white prisms from absolute ethanol–ethyl acetate, m. p. 141–142°.

Anal. Calcd. for $C_{16}H_{23}ClN_2O_3$: N, 8.57; Cl, 10.85. Found: N, 8.57; Cl, 10.93.

Cleavage of the phthalimido base with hydrazine hydrate in the usual manner[15] gave a 61% yield (based on 2-phthalimido-2′-chloroethyl ether) of colorless product, b. p. 78.0° at 4.00 mm., n^{25}_{D} 1.4430.

3-(2-Diethylaminoethoxy)-propylamine and 3-(3-diethylaminopropoxy)-propylamine were prepared by the method of Whitmore, *et al.*,[16] in comparable yields. The amines were characterized through the **dithiocarbamates**, m. p. 134.5–136.0° and 119–121.5°, respectively.

Anal. Calcd. for $C_{10}H_{22}N_2OS_2$: S, 25.55. Found: S, 25.74. Calcd. for $C_{11}H_{24}N_2OS_2$: S, 24.25. Found: S, 23.74

2-(2-Diethylaminoethylmercapto)-ethyl *p*-Nitrobenzoate.—To a cooled solution of 79.5 g. of *p*-nitrobenzoyl chloride in 300 ml. of dry benzene was added a cold solution of 75 g. of 2-(2-diethylaminoethylmercapto)-ethanol[6] in 200 ml. of dry benzene over a period of fifteen minutes with vigorous stirring and maintenance of the internal temperature below 5°. The mixture was then allowed to warm to room temperature, and treated with a slight excess of 35% sodium hydroxide solution with cooling. The benzene layer was separated and concentrated *in vacuo*, yielding 91.6 g. (66%) of crude product as a yellow mobile oil. The *picrate* crystallized in yellow needles from a large volume of ethanol, m.p. 154–155°.

Anal. Calcd. for $C_{21}H_{25}N_5O_{11}S$: S, 5.77. Found: S, 5.77.

3-(2-Diethylaminoethylmercapto)-propyl *p*-Nitrobenzoate.—The condensation of 3-(2-diethylaminoethyl-

1-(2-Dimethylaminoethylmercapto)-isopropyl *p*-Nitrobenzoate Hydrochloride.—This compound was obtained directly from the alcohol[1] and *p*-nitrobenzoyl chloride by the above method, small white prisms from absolute ethanol–ether, m. p. 133.7–135°.

Anal. Calcd. for $C_{14}H_{21}ClN_2O_4S$: S, 9.19. Found: S, 9.40.

***p*-Nitrobenzamides.**—The condensation of *p*-nitrobenzoyl chloride with the dialkylaminoalkylmercaptoalkylamines could be carried out in cold, dry benzene, as outlined above for the alcohols. The crude yields averaged 70–80%, but under these conditions decomposition and side-reactions were extensive, and the products were very difficult to purify. The following general method was found preferable:

To a solution of 37.8 g. of sodium bicarbonate in 240 ml. of water was added 52.8 g. of 2-(2-diethylaminoethylmercapto)-ethylamine. To the resulting mechanically stirred mixture was added dropwise during one hour a solution of 66.9 g. of *p*-nitrobenzoyl chloride in 600 ml. of dry chloroform at room temperature. The addition proceeded smoothly, without large exothermic effects or vigorous carbon dioxide evolution. After stirring for an additional hour the chloroform layer was separated and the water layer extracted with an additional 50 ml. of chloroform. After washing the combined chloroform layers successively with dilute sodium bicarbonate solution and with water, they were dried over Drierite and concentrated *in vacuo*. The pale yellow, mobile residue of **N-(2-(2-diethylaminoethylmercapto)-ethyl)-*p*-nitrobenzamide** weighed 91.2 g. (92% crude yield). The compound could not be obtained in crystalline form.

Attempts to distil the *p*-nitrobenzamide bases at pressures as low as 10^{-5} mm. failed, due to extensive decomposition at the boiling point. However, in certain cases the bases could be obtained crystalline after purification through a suitable derivative.

The *p*-nitrobenzamide bases prepared in the present work are described and characterized by derivatives in Table II.

2-(2-Diethylaminoethylmercapto)-ethyl *p*-Aminobenzoate.—The reduction of the nitro compound was carried out with reduced iron powder and hydrochloric acid in aqueous alcoholic solution, by a method analogous to that of West.[17] There was obtained a 92% yield of crude product as a pale yellow, mobile oil. The **phosphate hydrate** crystallized from ethanol in tiny white needles, m. p. 141–145°.

Anal. Calcd. for $C_{15}H_{27}N_2O_6PS \cdot H_2O$: N, 6.79. Found: 6.63.

By a similar reduction there was prepared **3-(2-diethylaminoethylmercapto)-propyl *p*-aminobenzoate** in 95% yield. The pale yellow mobile oil could not be induced to crystallize. The **picrate** formed golden yellow needles from ethanol, m. p. 125–126°.

Anal. Calcd. for $C_{22}H_{29}N_5O_9S$: S, 5.94. Found: S, 5.90.

1-(2-Dimethylaminoethylmercapto)-isopropyl *p*-aminobenzoate diphosphate formed white prisms from ethanol– m. p. 128–130°.

Anal. Calcd. for $C_{14}H_{28}N_2O_{10}P_2S$: N, 5.86; S, 6.70. Found: N, 5.88; S, 6.75.

***p*-Aminobenzamides.**—Reduction of the *p*-nitrobenzamide bases by means of reduced iron–hydrochloric acid gave crude yields of 40–50% of impure *p*-aminobenzamides. The yields and purity were substantially improved through the use of ferrous sulfate and ammonia for the reduction:

A three-liter beaker was mounted on a small electric hotplate and equipped with a Hershberg-type mechanical stirrer, an internal thermometer, and two 250-ml. dropping funnels. In one funnel was placed a solution of 42.5 g. of N-(2-(2-diethylaminoethylmercapto)-ethyl)-*p*-nitrobenzamide in 320 ml. of ethanol and in the second was placed a mixture of 135 ml. of concentrated ammonium hydroxide (28%) and 150 ml. of water. A solution of 255 g. of pure ferrous sulfate heptahydrate in 900 ml. of water was prepared in the beaker and heated to 80–85°. While the ferrous sulfate solution was stirred vigorously the contents of the dropping funnels were added dropwise during forty-five minutes, maintaining the ratio so that the mixture in the beaker always remained alkaline. The internal temperature was maintained at 80–85° during this addition, and for an additional one hour of stirring. The volume was maintained nearly constant by the occasional addition of alcohol. Filter-cel was then added to the hot mixture and the slurry was filtered, the filterpad being washed thoroughly with warm ethanol. The ethanol was distilled from the filtrate *in vacuo*, the aqueous residue was made strongly alkaline with concentrated aqueous ammonia, and extracted with ethyl acetate. After drying the combined extracts over Drierite the ethyl acetate was removed *in vacuo*, finally at 60° and 0.05 mm. There was thus obtained 29.5 g. (76%) of **N-(2-(2-diethylaminoethylmercapto)-ethyl)-*p*-aminobenzamide**. Crystallization from ethyl acetate–Skellysolve B gave pure material with but little loss.

The *p*-aminobenzamide bases could not be distilled without decomposition at pressures as low as 10^{-5} mm. The above procedure gave analytically pure material in most cases, however. A number of attempts were made to catalytically reduce the sulfur-containing nitro-bases, using a variety of catalysts and conditions. In all cases catalyst poisoning was rapid and reduction failed. Catalytic reduction of the non-sulfur-containing nitro-bases proceeded readily with Raney nickel or platinum.

The *p*-aminobenzamides prepared in the present work are described, and characterized by derivatives, in Table II.

N-(2-(2-Diethylaminoethylmercapto)-ethyl) *p*-*n*-Butylaminobenzamide.[18]—A mixture of 59.0 g. of N-(2-(2-diethylaminoethylmercapto)-ethyl)-*p*-aminobenzamide, 52.2 g. of pure zinc dust (4 mole proportion), 49.2 ml. of glacial acetic acid (4.10 mole proportion) and 200 ml. of dry benzene was stirred and heated under reflux. To this mixture was added dropwise during thirty minutes a solution of 17.4 g. (1.21 mole proportion) of *n*-butyraldehyde in 20 ml. of dry benzene. After stirring under reflux for an additional one hour the mixture was filtered hot and the filter cake was washed thoroughly with hot benzene. The filtrate (two layers) was made strongly basic to litmus with 35% sodium hydroxide solution, the benzene layer was separated, and the aqueous layer was extracted with two further portions of benzene. The combined benzene extracts were dried over Drierite, decolorized with Darco G-60, and concentrated *in vacuo*, finally at 60° and 0.05 mm. for three hours. The product was a viscous, pale yellow oil.

West, *J. Chem., Soc.*, **127**, 494 (1925).

(18) This procedure is an adaptation of the general method of German Patent 491,856 (*Frdl.*, **16**, 356 (1927)).

Summary

There has been described the preparation of a series of dialkylaminoalkylmercaptoalkyl *p*-aminobenzoates and N-(dialkylaminoalkylmercaptoalkyl)-*p*-aminobenzamides, and several of their oxygen analogs. Preliminary pharmacological data indicate a high local anesthetic activity coupled with low toxicity for certain of these compounds.

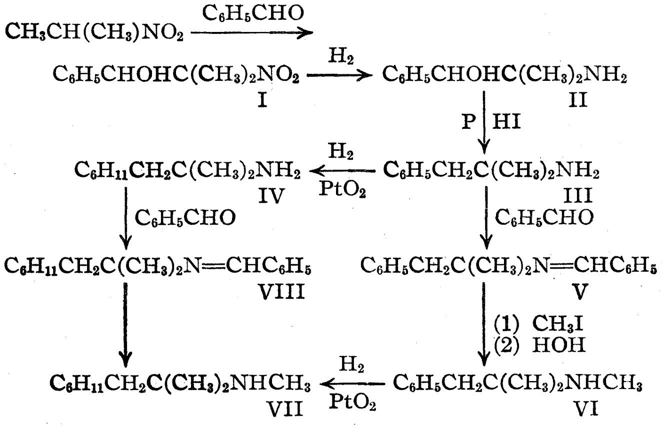
Preparation of α,α-Dimethyl- and N,α,α-Trimethyl-β-cyclohexylethylamine

BY BERNARD L. ZENITZ,[1a] ELIZABETH B. MACKS[1b] AND MAURICE L. MOORE[1c]

Since it was found that the series of β-cyclohexylalkylamines previously reported[2a] possesses pressor activity and produces little nervous stimulation, two additional members of this series, α,α-dimethyl-β-cyclohexylethylamine (IV) and its N-methyl derivative (VII), were prepared and their pharmacological activity was investigated.

The following synthetic scheme was employed[2b].



The condensation of benzaldehyde with 2-nitropropane, using an adaptation of Kamlet's procedure,[3] gave only poor yields (8–12%) of the nitro alcohol (I) whereas substantially higher yields were obtained when the condensation was carried out with sodium ethoxide in alcohol.

Gakenheimer and Hartung[4] observed that the catalytic hydrogenation of certain aliphatic nitro alcohols in neutral medium resulted in a fission of the nitro alkanol chain, but that the reduction proceeded satisfactorily in an acid medium. Similar results were experienced in this investigation. Catalytic hydrogenation of the nitro alcohol (I) in neutral alcoholic solution with a palladium-charcoal catalyst at 80° and sixty pounds pressure appeared to produce a fission of the molecule since a strong amine odor was detectable in the reaction mixture and none of the desired amino alcohol could be isolated. However, in the presence of acetic acid, hydrogenation produced a satisfactory yield of the amino alcohol (II).

In addition, the reduction was also accomplished with sodium amalgam and with zinc and acetic acid, the best yield being obtained by this last method.

α,α-Dimethyl-β-phenylethylamine (III) has been obtained by Shelton and Van Campen, Jr.,[5] by the catalytic hydrogenation of α,α-dimethyl-β-chloro-β-phenylethylamine. Mentzer and co-workers[6] have also reported its preparation by the action of slaked lime on *sym*-bis-(α,α-dimethyl-β-phenylethyl)-urea at 230° and by the hydrolysis of α,α-dimethyl-β-phenylethylisocyanate with concentrated hydrochloric acid, but their melting point of 147–148° for the hydrochloride is not in agreement with the 199–200° obtained by us or with the 195–196° reported by Shelton and Van Campen, Jr.

In the present investigation, an attempt to dehydroxylate the amino alcohol (II) by the catalytic reduction method of Rosenmund and Karg[7] was unsuccessful but the dehydroxylation was accomplished with red phosphorus and hydriodic acid, the method previously employed by Suter and Docken.[2b] The phenylalkylamine (III) obtained was N-methylated by the Becker and Decker method, and these two amines were then converted to their corresponding cyclohexyl analogs (IV and VII) by the general catalytic hydrogenation procedure previously described.[2a]

In order to obtain the secondary amine (VII)

[2a] Zenitz, Macks and Moore, THIS JOURNAL, **69**, 1117 (1947).

[2b] Although only compound III has been described in the literature (refs. 5 and 6), C. M. Suter in a personal communication indicated that compounds I, III, and VI were previously prepared at Northwestern University by Suter and Docken and that II has been obtained in the laboratories of Commercial Solvents Corp. Compound IV has been mentioned in a patent (ref. 5), but no physical constants were given.

directly, an attempt was made to N-methylate the cyclohexyl base (IV) by the Becker and Decker method. Although the intermediate Schiff base (VIII) formed readily, its treatment with methyl iodide in a sealed tube at 100–120° for twenty-eight hours, followed by hydrolysis, failed to produce the desired amine (VII).

A preliminary pharmacological evaluation of the pressor activity in anesthetized dogs of both the phenyl- (III and VI) and the cyclohexylalkylamines (IV and VII) was carried out.[8] The secondary phenylalkylamine (VI) showed practically no activity. The other three amines displayed pressor activity of only low order, the cyclohexyl compounds being somewhat more active than the phenyl and the primary amines more active than the secondary. In general, the activity of the cyclohexyl compounds (IV and VII) is comparable to that of the β,β-dimethyl-β-cyclohexylethylamines, the weaker members of the previously reported series.[2a]

Experimental[9]

1-Phenyl-2-methyl-2-nitropropanol (I).—To a solution prepared from 9.2 g. (0.4 mole) of sodium and 700 ml. of anhydrous methanol was added 187 g. (2.1 moles) of 2-nitropropane and 212 g. (2.0 moles) of freshly distilled benzaldehyde. After twenty-four hours at room temperature, the yellow solution was acidified with acetic acid and the methanol was distilled. The residue was dissolved in a mixture of water and ether. The ether layer was washed with water, extracted with four 200-ml. portions of 15% aqueous sodium bisulfite solution to remove the unreacted benzaldehyde, again washed with water and was dried over anhydrous sodium sulfate.

The ether was distilled. The residual oil was heated on a steam-bath *in vacuo* to remove any remaining benzaldehyde and 2-nitropropane. It was then stirred in an ice-bath with petroleum ether until it solidified. After filtration, the solid was recrystallized from 700 ml. of heptane to give the nitro alcohol as yellow crystals, m. p. 64–66°; reported[2b] m. p. 53–62°; yield of 37%.

1-Phenyl-2-methyl-2-aminopropanol (II). A.—Sodium amalgam, prepared from 27.6 g. (1.2 moles) of sodium and 900 g. of mercury, was added, in portions, over a one-hour period to a stirred solution of 19.5 g. (0.1 mole) of the nitro alcohol (I) in a mixture of 100 ml. of alcohol, 100 ml. of glacial acetic acid and 50 ml. of water. Then, after one-half hour, the mercury was separated. The solution was filtered, diluted with water to 500 ml. and concentrated under reduced pressure to about 250 ml. to remove the alcohol. Acetic acid (6 ml.) and sufficient water to redissolve the sodium acetate which began to precipitate were added.

The solution was washed with ether and made basic with 40% aqueous sodium hydroxide. The amino alcohol which separated was extracted with ether, the ether solution was washed with a little water and dried over anhydrous sodium carbonate. Distillation of the ether and recrystallization of the residue from 200 ml. of heptane gave the amino alcohol as colorless crystals, m. p. 100–101°, in a yield of 41%; reported[2b] m. p. 100–101°.

Anal. Calcd. for $C_{10}H_{15}NO$: N, 8.48. Found: N, 8.68.

B.—A solution of 39 g. (0.2 mole) of the nitro alcohol in a mixture of 150 ml. of alcohol, 165 ml. of glacial acetic acid and 200 ml. of water was stirred with 78.5 g. (1.2 moles) of zinc dust for six hours at 60–70°. Small portions of water were added from time to time to redissolve the precipitate which formed. The mixture was diluted with 350 ml. of water and the unreacted zinc was filtered. The filtrate was washed with ether and made basic with 600 ml. of 40% aqueous sodium hydroxide. The amine which separated was extracted with ether and the ether solution was washed with 40% sodium hydroxide followed by water. After drying over anhydrous sodium carbonate, the ether was distilled and the solid residue was recrystallized from heptane to give the amino alcohol as colorless crystals in a yield of 80–88%, m. p. 101–102°.

The hydrochloride, prepared by adding one equivalent of 2-propanolic hydrogen chloride to a cold solution of the base in 2-propanol and diluting the solution with diisopropyl ether, melted at 201–202° after recrystallization from ethanol–anhydrous ether.

Anal. Calcd. for $C_{10}H_{16}NOCl$: N, 6.95; Cl, 17.58. Found: N, 6.99; Cl, 17.45.

C.—The nitro alcohol (9.8 g., 0.05 mole) was hydrogenated in a mixture of 125 ml. of ethanol and 24 ml. of glacial acetic acid with 2 g. of palladium–charcoal catalyst[10] at 80° and 60 pounds pressure. The theoretical amount of hydrogen was absorbed in about five hours.

The solvent was distilled, the residue was dissolved in 30 ml. of 28% ammonium hydroxide and the solution was saturated with sodium sulfate and cooled. The amino alcohol which separated was extracted with ether, the ether solution was washed with a little cold water and dried over anhydrous sodium carbonate. The crystalline residue remaining after distillation of the ether was recrystallized from a mixture of 10 ml. of benzene and 75 ml. of hexane to give 6.3 g. (76%) of colorless crystals, m. p. 99–101°.

α,α-Dimethyl-β-phenylethylamine (III).—A mixture of 66 g. (0.4 mole) of the amino alcohol (II), 20 g. of red phosphorus and 170 ml. of 57% hydriodic acid was refluxed for twenty-five hours. After standing twelve hours, a large amount of crystalline material had separated from the solution.

The reaction mixture was diluted with 700 ml. of water and was filtered through an asbestos mat to remove the phosphorus. The yellow filtrate was treated with a few crystals of sodium thiosulfate to remove any free iodine and was then made basic with 40% sodium hydroxide. The amine which separated was extracted with ether and the ether solution was washed with water and dried over anhydrous sodium carbonate. After removal of the ether, the residual oil was distilled to give the amine as a colorless oil in a yield of 80–88%, b. p. 89–90° at 10 mm., $n^{20}D$ 1.5130; reported b. p. 88–89° at *ca.* 16 mm.,[2b] 203–205° at 760 mm.,[6a] 100° at 21 mm.[5]

Anal. Calcd. for $C_{10}H_{15}N$: N, 9.39. Found: N, 9.44.

The hydrochloride, prepared by passing hydrogen chloride into a solution of the amine in 2-propanol–diisopropyl ether, melted at 199–200° after recrystallization from a mixture of 2-propanol and diisopropyl ether. Reported m. p. 200–201°,[2b] 195–196°,[5] 147–148°.[6b]

Anal. Calcd. for $C_{10}H_{16}NCl$: N, 7.54; Cl, 19.09. Found: N, 7.49; Cl, 19.01.

N,α,α-Trimethyl-β-phenylethylamine. (VI).—The primary amine (III) was methylated by the Decker and Becker method as described by Woodruff, Lambooy and Burt.[11]

A mixture of 29.8 g. (0.20 mole) of III and 23.3 g. (0.22 mole) of freshly distilled benzaldehyde was heated on a steam-bath for one-half hour and was then distilled. The intermediate Schiff base (V) was obtained as a viscous colorless oil in a yield of 95%, b. p. 146–147° at 2.6 mm., $n^{20}D$ 1.5730.

Anal. Calcd. for $C_{17}H_{19}N$: N, 5.90. Found: N, 5.87.

(11) Woodruff, Lambooy and Burt, THIS JOURNAL, **62**, 922 (1940).

The Schiff base (45 g., 0.19 mole) and 28.4 g. (0.20 mole) of methyl iodide were heated in a sealed tube at 100–110° for twenty-eight hours. The contents of the tube were then refluxed for one-half hour with 160 ml. of ethanol and 20 ml. of water. The solution was acidified with acetic acid, diluted with 500 ml. of water and concentrated under reduced pressure to about one-half of the original volume to remove the alcohol and benzaldehyde.

The solution was washed several times with ether, made basic with 40% aqueous sodium hydroxide, and the amine which separated as an oil was extracted with ether. The extract was washed with water, dried over anhydrous sodium carbonate, and the solvent removed. The amine boiled at 94–97° (9 mm.); n^{20}D 1.5112; yield 76%.

Anal. Calcd. for $C_{11}H_{17}N$: N, 8.58. Found: N, 8.59.

The hydrochloride, prepared by passing hydrogen chloride into a solution of the base in isopropyl ether, melted at 174–175° after several recrystallizations from 2-propanol-diisopropyl ether; reported[2b] m. p. 174–175°.

Anal. Calcd. for $C_{11}H_{18}NCl$: N, 7.01; Cl, 17.75. Found: N, 7.14, Cl, 17.65.

α,α-Dimethyl-β-cyclohexylethylamine (IV) and N,α,α-Trimethyl-β-cyclohexylethylamine (VII).—By the catalytic hydrogenation procedure previously described,[2a] the primary amine (IV) was obtained as a colorless oil in a yield of 89%, b. p. 75–76° at 7 mm., n^{20}D 1.4586, and the secondary amine (VII) as a colorless oil in a yield of 80%, b. p. 84–86° at 6 mm., n^{20}D 1.4640.

Anal. of IV. Calcd. for $C_{10}H_{21}N$: N, 9.02. Found: N, 8.80.

Anal. of VII. Calcd. for $C_{11}H_{23}N$: N, 8.27. Found: N, 8.44.

The hydrochlorides were prepared by passing hydrogen chloride into isopropyl ether solutions of the bases. The hydrochloride of IV melted at 158–159° after several recrystallizations from isopropyl ether containing 5% of 2-propanol.

Anal. Calcd. for $C_{10}H_{22}NCl$: N, 7.31; Cl, 18.49. Found: N, 7.31; Cl, 18.35.

The hydrochloride of VII melted at 153–154° after recrystallization from 2-propanol–diisopropyl ether.

Anal. Calcd. for $C_{11}H_{24}NCl$: N, 6.80; Cl, 17.24. Found: N, 6.70; Cl, 17.11.

Summary

Two β-cyclohexylalkylamines, α,α-dimethyl-β-cyclohexylethylamine and its N-methylated derivative, have been prepared by catalytic hydrogenation of the corresponding phenyl analogs.

The synthesis of the phenyl intermediates is described and a pharmacological summary of the pressor activity of the phenyl and cyclohexylalkylamines is presented.

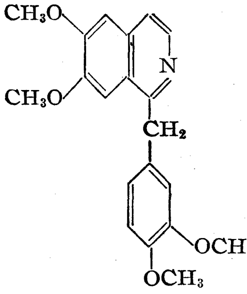
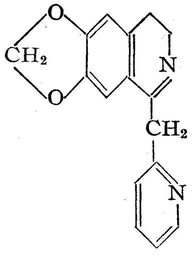
Some Dihydroisoquinolines and their Absorption Spectra

BY JOHN L. BILLS[1] AND C. R. NOLLER

The pharmacological properties of the pyridyl analogs of papaverine (I) would be of interest. Clemo, McIlwain and Morgan[2] have synthesized what was believed to be 1-(α-picolyl)-3,4-dihydro-6,7-methylenedioxyisoquinoline (II). They attempted to dehydrogenate both the dihydroisoquinoline and the tetrahydroisoquinoline derived from it to the isoquinoline, but were unsuccessful. The present work attempted to obtain the isoquinoline by the Pictet and Gams synthesis[3] in which the amide of a β-hydroxy-β-phenylethylamine is dehydrated, and to extend the efforts of Clemo, McIlwain and Morgan to dehydrogenate the hydroisoquinolines, but none of these attempts was successful.



I



II

During the course of the work the greater depth of color of the picolyldihydroisoquinoline and its hydrochloride compared with the 1-methyl or 1-benzyl derivatives prompted an investigation of their absorption spectra in order to obtain further information concerning their structure. Figure 1 gives the absorption in 95% ethyl alcohol of what were considered to be the 1-methyl-, 1-benzyl- and 1-(α-picolyl)-3,4-dihydro-6,7-methylenedioxyisoquinolines. It is seen at once that whereas the curves for the 1-methyl and 1-benzyl derivatives are very similar, they differ markedly from that for the 1-(α-picolyl) derivative. This difference might be due to the presence of the nitrogen in the pyridine ring, or to the position of the double bond which might be either endocyclic or exocyclic to the isoquinoline ring. If one compares the curves for stilbene and α-stilbazole[4] (2 and 3, Fig. 2), it is evident that the introduction of a nitrogen into one of the rings has little effect on the absorption, and it appears, therefore, that the difference in absorption depends on the position of the double bond. Which compound or compounds contain the double bond in the exocyclic position can be determined by recalling that the 1-methyl and 1-benzyl derivatives have practically identical absorption spectra. If the double bor were exocyclic, one would expect the spectrur the 1-benzyl derivative to be shifted marke

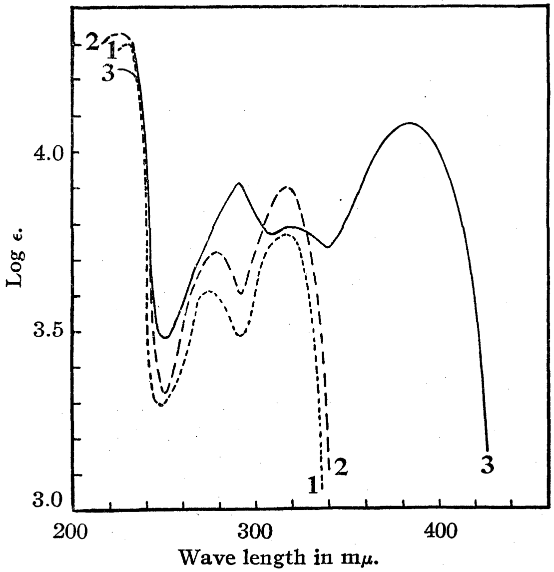

Fig. 1.—Ultraviolet absorption spectra: curve 1, - - - -, structure III; 2, — — — —, structure IV; ——, structure V; all in ethyl alcohol.

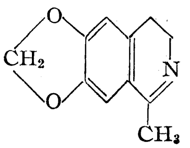
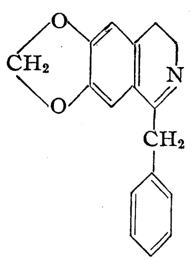
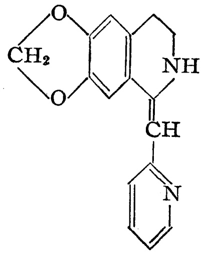
the visible because of the conjugation between the two aromatic rings. For example the maximum for styrene[5] (Curve 1, Fig. 2) is shifted 45 mμ toward the visible, and the intensity of the absorption is greatly increased by conjugation with the second benzene ring in stilbene (Curve 2, Fig. 2). On this basis, the three compounds as free bases can be considered to be 1-methyl-3,4-dihydro-6,7-methylenedioxyisoquinoline (III), 1-benzyl-3,4-dihydro-6,7-methylenedioxyisoquinoline (IV), and 1-(α-picolal)-1,2,3,4-tetrahydro-6,7-methylenedioxyisoquinoline (V).



III



IV



V

If one compares the absorption of the three compounds in 1.5 *N* alcoholic hydrogen chloride, an entirely different result is obtained (Fig. 3). The spectra for the 1-methyl- and 1-benzylisoquinolines have been spread out considerably toward the visible. In the case of the 1-(α-picolyl)-isoquinoline the position of the maximum nearest the visible has not changed appreciably, but the other maxima have shifted to shorter wave lengths, and all intensities have been changed considerably so that the spectrum now closely resembles that of the other two compounds. Hence there is little

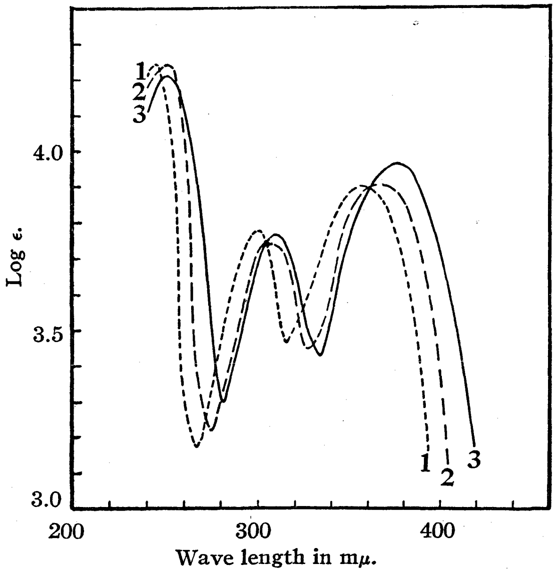


Fig. 3.—Ultraviolet absorption spectra: curve 1, - - - -, hydrochloride of III; 2, — — — —, hydrochloride of IV; 3, ——, dihydrochloride of VI; all in ethyl alcohol.

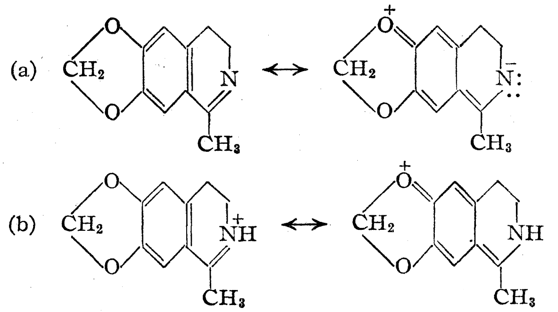
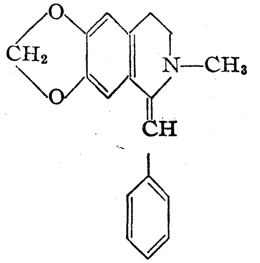
s and Amagat, *Bull. soc. chim.*, [4] 51, 965 (1932).

doubt that the hydrochloride of the 1-(α-picolyl)-isoquinoline has structure VI. It is of interest that the spectra of the hydrochlorides of the 1-methyl and 1-benzyl derivatives in approximately 2×10^{-5} molar solutions in 95% alcohol (not shown in the figures) indicate that they are dissociated to the free base to the extent of 35 and 40%, respectively, whereas the dihydrochloride of the 1-(α-picolyl) derivative shows little dissociation.

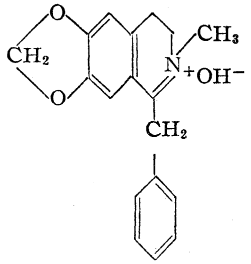
The shift in the absorption toward the visible in going from the free base to the hydrochloride may be explained by assuming that bond resonance for the free base would require a separation of charge within the molecule (a), whereas for the hydrochloride bond resonance can occur without a separation of charge (b). Hence the latter process would take place more readily and could be brought about by light of longer wave length.



As further evidence concerning the structure of the picolyl derivative, it was considered desirable to determine the absorption spectrum of 1-benzal-1,2,3,4-tetrahydro-2-methyl-6,7-methylenedioxyisoquinoline (VII), in the belief that it should resemble the 1-(α-picolal) derivative. Instead, the curve for the free base in 95% ethyl alcohol (1, Fig. 4) was almost identical with that for the chloride in 1.5 *N* alcoholic hydrogen chloride (2, Fig. 4) and for the hydrochloride of the 1-(α-picolyl) derivative (3, Fig. 3). Undoubtedly the free base (VII) is converted in 95% ethyl alcohol into the quaternary ammonium hydroxide (VIII) by the addition of water. To check this point the absorption of the free base in 0.7 *N* alcoholic sodium hydroxide solution was determined. The absorption changed markedly (3, Fig. 4) and now resembled that of the free base of the 1-(α-picolal)-isoquinoline (3, Fig. 1). The presence of sodium hydroxide had no appreciable effect on any of the other bases.



VII



VIII

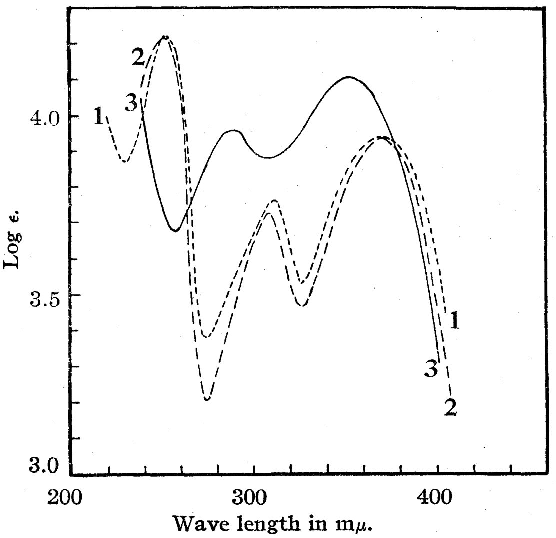


Fig. 4.—Ultraviolet absorption spectra: curve 1, - - - -, structure VIII in ethyl alcohol; 2, — — —, structure VIII in 1.5 *N* alcoholic hydrogen chloride; 3, ——, structure VII in 0.77 *N* alcoholic sodium ethoxide.

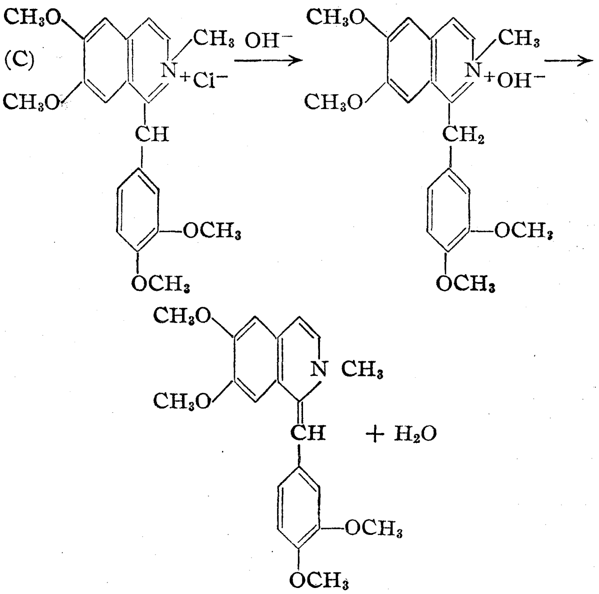
It is known that the quaternary salts of papaverine yield N-alkyl isopapaverines on reaction with concentrated alkali (c). It is evident from the above absorption spectra that the proof of structure of the N-alkylisopapaverines based on the production of veratric acid and N-alkyldimethoxyisoquinolones by oxidation with potassium permanganate[6] depends on the oxidation being carried out in alkaline solution, since in neu-



---

tral solution the N-alkylisopapaverines undoubtedly have a structure analogous to VIII rather than to VII.

The authors are indebted to Professor Melvin Calvin of the University of California for his helpful assistance in interpreting the absorption spectra.

Experimental

β-(3,4-Methylenedioxyphenyl)-ethylamine (Homopiperonylamine).—Piperonal was reduced to piperonyl alcohol in 93% yield in methyl alcohol solution using hydrogen at 800 lb. and 120° and Raney nickel catalyst,[7] or in 90% yields by a crossed Cannizzaro reaction.[8] The piperonyl alcohol was converted to the chloride in 96% yield using concentrated hydrochloric acid and calcium chloride.[7] The chloride was converted to the cyanide in 81% yield by treating 1 mole with 3.5 moles of sodium cyanide and 0.05 mole of mercuric cyanide in 250 cc. of water at 75–80° for six hours.[7] The cyanide was reduced to the amine in 85% yield.[9]

The amine could be prepared in 79% yield by the catalytic reduction of 3,4-methylenedioxy-ω-nitrostyrene.[10] The optimum conditions were the dropwise addition of a solution of 0.01 mole of the nitrostyrene in 50 cc. of dioxane and 0.6 cc. of concentrated sulfuric acid, to a stirred suspension of 0.7 g. of reduced platinum oxide in 50 cc. of dioxane in the presence of hydrogen at atmospheric pressure. Because of the easy preparation of the nitrostyrene this procedure is advantageous for the preparation of small quantities.

Methyl α-Pyridylacetate.—A solution of α-picolyllithium was prepared from 46.5 g. (0.5 mole) of α-picoline according to the procedure given in "Organic Syntheses."[11] While the stream of purified nitrogen continued to flow through the open stopcock of the separatory funnel, the condenser was replaced by a stopper, the stirrer removed, and the central neck fitted with a piece of 8-mm. glass tubing bent in the form of a U and of such dimensions that one leg reached to the bottom of the flask and the other over a 2-liter beaker containing 1 kg. of crushed solid carbon dioxide. When the stopcock of the separatory funnel was closed, the solution was forced onto the solid carbon dioxide which was stirred continuously. After the excess carbon dioxide had evaporated, 500 cc. of water was added, and most of the cream-colored solid dissolved. The mixture was filtered to remove about 10 g. of insoluble material, the filtrate separated with a separatory funnel, and the aqueous layer extracted three times with 100-cc. portions of ether.

The aqueous solution was transferred to a 3-liter beaker, diluted with 1500 cc. of water, and acetic acid added until Hydrion test paper indicated a *p*H of 4. A solution of 37.5 g. (0.15 mole) of copper sulfate pentahydrate in 300 cc. of water then was added gradually with good stirring. After the addition of the first 50 cc. of copper sulfate solution, the mixture was stirred for five minutes to ensure precipitation of the copper salt in a crystalline form before further addition. The precipitate was filtered and washed on the filter with water until the filtrate had only a faint bluish tinge. The air-dried precipitate weighed 40–42 g. (48–50%).

Dry hydrogen chloride was passed into a suspension of 40 g. (0.12 mole) of the dry copper pyridylacetate in 125 cc. of methyl alcohol until solution was complete. Then hydrogen sulfide was passed into the solution, the copper sulfide removed by filtration, and the filtrate saturated with hydrogen chloride. After allowing to stand for three days at room temperature, the solution was concentrated at reduced pressure to 300 cc., and solid sodium bicarbonate was added to neutralize the remaining hydrogen chloride. Dilution with 1500 cc. of water, extraction with two 200-cc. portions of benzene, concentration of the extract at reduced pressure, and distillation of the residue gave 20–22 g. (55–61%), b. p. 126–127° (15 mm.). The boiling point reported for the ester prepared through the anilide, which had been obtained by Beckmann rearrangement of the oxime of 2-phenacylpyridine, is 123° (12 mm.)[12] Ziegler and Zeiser[13] have reported that the carbonation of α-picolyllithium with gaseous carbon dioxide yields only α-picoline.

N-Acetylhomopiperonylamine.—Ten grams (0.06 mole) of homopiperonylamine was added to 10 g. (0.1 mole) of acetic anhydride. After the reaction was complete the acetic acid and excess acetic anhydride were removed by distillation at reduced pressure. The residue solidified on cooling and was recrystallized from ether giving 11.5 g. (93%) of white N-acetylhomopiperonylamine melting at 108–109°. Kaufmann and Radosevic[14] reported 101° for the product obtained by the Beckmann rearrangement of piperonylacetoxime.

N-Phenylacetylhomopiperonylamine.—Ten grams (0.06 mole) of homopiperonylamine and 12 g. (0.08 mole) of phenylacetyl chloride were shaken together in 200 cc. of a 10% potassium hydroxide solution. A thick, viscous, pale yellow oil was formed which soon solidified and was filtered from the aqueous solution. After crystallizing from ethyl alcohol–water, 16 g. (92%) of N-phenylacetylhomopiperonylamine was obtained as fine white needles melting at 96–97°. The compound prepared by Decker[15] from phenylacetic acid and homopiperonylamine melted at 96°.

N-(α-Pyridylacetyl)-β-phenylethylamine.—A mixture of 9.2 g. (0.076 mole) of β-phenylethylamine and 11.4 g. (0.076 mole) of methyl α-pyridylacetate in a 50-cc. round-bottomed flask equipped with an air-cooled reflux condenser was heated in an oil-bath at 200°. At the end of four hours the condenser was removed and the mixture heated an additional two hours. The reaction mixture was poured into a beaker and solidified on cooling. After crystallizing from benzene, 10 g. (55%) of N-(α-pyridylacetyl)-β-phenylethylamine was obtained melting at 74–75°. Three additional recrystallizations from ether raised the melting point to 75–76°.

Anal.[16] Calcd. for $C_{15}H_{16}N_2O$: C, 74.97; H, 6.71. Found: C, 74.81; H, 6.67.

N-(α-Pyridylacetyl)-homopiperonylamine.—A mixture of 3 g. (0.018 mole) of homopiperonylamine and 3 g. (0.020 mole) of methyl α-pyridylacetate was heated at 200° for forty-five minutes in 10 cc. of tetralin[17] contained in a 50-cc. round-bottomed flask. A short air condenser was used to return to the reaction mixture the small amount of tetralin and methyl α-pyridylacetate which distilled. During the heating considerable frothing occurred. At the end of forty-five minutes the contents of the flask was poured into a 50-cc. beaker and allowed to cool. Crystallization was induced either by scratching the side of the beaker or by seeding the supersaturated solution with a trace of the amide. The precipitate was filtered and washed with several portions of petroleum ether to give 4.7 g. (92%) of a white product melting at 90–91°. The compound prepared through the ethyl ester in the absence of a solvent melted at 89°.[2]

1-Methyl-3,4-dihydro-6,7-methylenedioxyisoquinoline Hydrochloride.—A solution of 5 g. (0.024 mole) of N-

acetylhomopiperonylamine and 10 cc. of phosphorus oxychloride in 25 cc. of anhydrous toluene was heated under reflux for one and one-half hours. The mixture was cooled and added to a large volume of petroleum ether (b. p. 55–85°). The phosphate of the base separated as a dark yellow oil and solidified on standing. This material was crystallized from alcohol–ether to give pale yellow crystals melting with decomposition at 239–240°. The phosphate was dissolved in a little 10% hydrochloric acid and neutralized with potassium hydroxide. The pale yellow oil which separated was extracted with ether and an ethereal solution of dry hydrogen chloride added. The hydrochloride separated as a powdery yellow precipitate, which was filtered and crystallized from absolute ethyl alcohol to give 4.3 g. (79%) of 1-methyl-3,4-dihydro-6,7-methylenedioxyisoquinoline hydrochloride melting at 245–247° (dec.). The melting point has been reported as 242°.[14]

Anal. Calcd. for $C_{11}H_{12}ClNO_2$: Cl, 15.71. Found: Cl, 15.80, 15.82, 15.87.

1-Benzyl-3,4-dihydro-6,7-methylenedioxyisoquinoline Hydrochloride.—A mixture of 5 g. (0.018 mole) of N-phenylacetylhomopiperonylamine and 10 cc. of phosphorus oxychloride in 25 cc. of dry toluene was heated under reflux for two hours. The light red solution was cooled and poured into a large excess of petroleum ether (b. p. 55–85°), and a red oil separated which solidified on standing. It was crystallized from alcohol, dissolved in dilute hydrochloric acid, and the aqueous solution neutralized with sodium hydroxide. The pale yellow oil which separated was extracted with ether and an ethereal solution of dry hydrogen chloride added. The 1-benzyl-3,4-dihydro-6,7-methylenedioxyisoquinoline hydrochloride precipitated as minute pale yellow crystals. After crystallizing from anhydrous alcohol–ether, 3.3 g. (70%) of the hydrochloride was obtained melting at 215–216° (dec.).

Anal. Calcd. for $C_{17}H_{16}ClNO_2$: Cl, 11.75. Found: Cl, 11.90, 11.73.

The picrate after crystallization from alcohol melted at 202–206°.[18]

1-(α-Picolal)-1,2,3,4-tetrahydro-6,7-methylenedioxyisoquinoline.—This compound was prepared in 62% yield by the method of Clemo, McIlwain and Morgan,[2] and melted at 102–103°. The dihydrochloride decomposed at 208–209°.

1-Benzyl-2-methyl-3,4-dihydro-6,7-methylenedioxyisoquinolinium Chloride.—A modification of the procedure described by Hamilton and Robinson[19] for the preparation of 1-benzal-2-methyl-1,2,3,4-tetrahydroisoquinoline was used. A mixture of 7 g. (0.026 mole) of 1-benzyl-3,4-dihydro-6,7-methylenedioxyisoquinoline and 4 g. (0.032 mole) of dimethyl sulfate in 75 cc. of benzene was heated, allowing the benzene to distil slowly. The addition compound gradually separated on the bottom of the flask. The sirupy residue which remained after all of the benzene was distilled was dissolved in water, and the aqueous solution was made strongly basic with solid potassium hydroxide. This basic solution was extracted with four 50-cc. portions of ether, the ether extracts dried over sodium sulfate, and an anhydrous ethereal solution of hydrogen chloride added. A pale yellow precipitate formed which was recrystallized from anhydrous alcohol–ether. Six grams (77%) of 1-benzyl-2-methyl-3,4-dihydro-6,7-methylenedioxyisoquinolinium chloride was obtained.

Anal. Calcd. for $C_{18}H_{18}ClNO_2$: Cl, 11.23. Found: Cl, 11.13, 11.41.

Attempt to Dehydrogenate 1-(α-Picolal)-1,2,3,4-tetrahydro-6,7-methylenedioxyisoquinoline.—Dehydrogenation was attempted with nitrobenzene in the presence of Raney nickel, with nitric acid in acetic acid,[20] and with permanganate in acetic acid.[21] In no case could an isoquinoline be isolated.

The picolal derivative was hydrogenated to the picolyl derivative, and a benzene suspension of the latter dropped onto a bed of molybdena-alumina catalyst at 250°. Although the catalyst was capable of dehydrogenating tetralin to naphthalene, and tetrahydroquinoline to quinoline quantitatively, the only product that could be isolated from the picolyl derivative was α-picoline.

Aminomethylphenylcarbinol Hydrochloride.—A saturated solution of 23 g. (0.13 mole) of ω-aminoacetophenone hydrochloride, prepared by the procedure of Rupe,[22] in 95% ethyl alcohol was hydrogenated in the presence 0.52 g. of platinum black at 40 lb. gage pressure. A total of 0.15 mole of hydrogen was absorbed. After no more hydrogen was taken up the catalyst was filtered and the filtrate evaporated to dryness at reduced pressure. Twenty-two grams (97%) of aminomethylphenylcarbinol hydrochloride was obtained melting at 176–177° (dec.). The material could be crystallized from alcohol–ether to give small white crystals of the hydrochloride, but the melting point was not changed. The picrate melted at 153–154° after crystallization from alcohol, and the benzoyl derivative melted at 148.5–149.5° after crystallization from dilute alcohol. Kolshorn[23] prepared the free base by reducing isonitrosoacetophenone with sodium amalgam but could not obtain the hydrochloride in crystalline form. His picrate melted at 146–147° and his benzoyl derivative at 144–145.5°.

Aminomethyl-3,4-dimethoxyphenylcarbinol Hydrochloride.—This compound was prepared by catalytic hydrogenation of ω-aminoacetoveratrone hydrochloride by the same procedure used for the preparation of aminomethylphenylcarbinol hydrochloride. The reduction was nearly quantitative. The material melted at 168–170° after crystallization from ethyl alcohol. Rosenmund[24] reported 163° for the melting point of the hydrochloride prepared by the reduction of α-(3,4-dimethoxyphenyl)-β-nitroethyl alcohol.

N-(α-Pyridylacetyl)-aminomethylphenylcarbinol.—Thirteen grams (0.075 mole) of aminomethylphenylcarbinol hydrochloride was added to 30 cc. of dilute sodium hydroxide. The two layers were separated, and the aqueous layer was extracted with two 15-cc. portions of benzene. The benzene extracts were added to the free amine, the benzene solution was washed once with water, and the benzene removed by distillation at reduced pressure. Ten grams (0.073 mole) of free amine was obtained, which was added to 15 g. (0.10 mole) of methyl α-pyridylacetate, and the mixture was heated for two hours in an oil-bath at 200°. It then was cooled and the green mass poured into 100 cc. of benzene. After several days the material separated as fine white crystals which were filtered and recrystallized from benzene. Nine grams (48%) of N-(α-pyridylacetyl)-aminomethylphenylcarbinol melting at 114–115° was obtained. A sample was prepared for analysis by recrystallizing four times from benzene and drying at 100° at reduced pressure. The melting point of the purified product was unchanged at 114–115°.

Anal.[16] Calcd. for $C_{15}H_{16}N_2O_2$: C, 70.67; H, 6.29. Found: C, 70.91; H, 6.24.

A picrate was prepared by adding an alcoholic picric acid solution to the base dissolved in alcohol. An orange sirup precipitated and solidified on long standing. After recrystallizing once from benzene–alcohol and twice from ethyl acetate the picrate melted at 131–132°.

Attempts to cyclize the free base to 1-(α-picolyl)-isoquinoline using phosphorus pentoxide in toluene[25] or in tetralin[26] were unsuccessful. Red oils were obtained from which only α-picoline could be isolated as the picrate.

N-(α-Pyridylacetyl)-aminomethyl-(3,4-dimethoxyphenyl)-carbinol.—An alcoholic solution of aminomethyl-(3,4-dimethoxyphenyl)-carbinol was prepared by neutralizing 3.5 g. (0.011 mole) of the hydrochloride in 15 cc. of alcohol

with sodium ethylate using phenolphthalein as an indicator. The precipitated sodium chloride was removed by filtration and 2.5 g. (0.016 mole) of methyl α-pyridylacetate added. The mixture was heated gradually in a 50-cc. round-bottomed flask to 200° by allowing the alcohol to escape through a short air-cooled reflux condenser. The mixture was heated at 200° for twenty minutes. On cooling, a thick red-brown resin was obtained which was soluble in benzene, alcohol, or chloroform, but insoluble in ether or petroleum ether. A number of attempts to crystallize the amide were unsuccessful. Some of this sirupy material was dissolved in ethyl alcohol, and an alcoholic solution of picric acid was added. A resinous precipitate formed which could not be made to solidify. An anhydrous alcoholic solution of hydrogen chloride was added to an anhydrous alcoholic solution of the amide. Upon the addition of dry ether a sirupy hydrochloride precipitated which did not crystallize even at −80°. The solvent was decanted and the hydrochloride placed in a vacuum desiccator. The material gradually crystallized but on exposure to the atmosphere immediately became a sticky mass. The dried hydrochloride melted with decomposition at 105–110°. No analysis was made.

Attempts to cyclize the crude free base by the procedures of Clemo, McIlwain and Morgan,[2] of Pictet and Gams,[3] or of Bruckner and Fodor,[27] gave tars from which only α-picoline could be isolated as the picrate.

Absorption Spectra.—Absorption spectra not previously reported were obtained with a Beckman Quartz Spectrophotometer, Model DU, using 1-cm. quartz cells, a hydrogen discharge lamp for the ultraviolet light source, and a tungsten filament lamp for wave lengths above 325 mμ. The concentrations were from 1 to 2 × 10^{-5} molar in 95% ethyl alcohol or alcohol containing dry hydrogen chloride or sodium hydroxide. In each case freshly recrystallized material was used, and the absorption determined immediately without allowing the solutions to stand. If these precautions were not taken, inconsistent results sometimes were obtained. The spectra for styrene,[5] stilbene[4] and α-stilbazole[4] were taken from the literature.

Summary

It is concluded from their absorption spectra that the cyclization products of N-acetyl- and N-phenylacetylhomopiperonylamine are 1-methyl- and 1-benzyl-3,4-dihydro-6,7-methylenedioxyisoquinoline, respectively, whereas the cyclization product of N-(α-pyridylacetyl)-homopiperonylamine is 1-(α-picolal)-1,2,3,4-tetrahydro-6,7-methylenedioxyisoquinoline. Reaction of the last compound with hydrochloric acid converts it into 1-(α-picolyl)-3,4-dihydro-6,7-methylenedioxyisoquinoline hydrochloride. It is further concluded that 1-benzal-1,2,3,4-tetrahydro-2-methyl-6,7-methylenedioxyisoquinoline has the structure corresponding to this name when in solution, only in the presence of strong bases, and that when dissolved in alcohol alone it is largely in the form of the quaternary hydroxide. Further attempts to synthesize 1-(α-picolyl)-isoquinolines have been unsuccessful.

The Reaction of 2,5-Dimethylfuran with *p*-Nitrobenzenediazonium Chloride

BY RICHARD H. EASTMAN AND FRANCIS L. DETERT[1]

The ease with which the furan nucleus undergoes typical aromatic substitution reactions is well known[2] and suggested to us that alkylated furans, as analogs of mesitylene,[3] should undergo a coupling reaction with reactive dizonium halides. Both Gilman and Ochaiai[4] have reported that furan reacts with diazonium halides. Johnson[5] has reported formation of 2-(and some 3-)arylfurans by interaction of furan with a diazotate. Recently, a report[6] of the coupling of sodium *anti-p*-nitrobenzenediazotate with ethyl 2-furylcarbamate has appeared.

We chose for our study of this reaction an available furan with unsubstituted β-positions, 2,5-dimethylfuran and the reactive *p*-nitrobenzenediazonium chloride. These components were combined in an ice-cold aqueous alcoholic solution that contained an excess of potassium acetate as a buffer.[7] The initial coupling product separated as a semi-solid red mass which could not be crystallized to a state of assured purity. When the initial coupling product was heated *in vacuo* or hydrolyzed with dilute acid it was converted in good yield to a substance $C_{12}H_{11}O_3N_3$ which is formulated as 1-*p*-nitrophenyl-3-acetyl-5-methylpyrazole (II) on the basis of its giving a positive iodoform reaction and its smooth oxidation to an acid, $C_{11}H_9O_4N_3$ shown to be identical with 1-*p*-nitrophenyl-5-methyl-3-pyrazolecarboxylic acid (III), m. p.[8] 216–217°, prepared by an unequivocal synthesis.

Consideration of the properties and easy transformation to II of the initial, red coupling product (*cf.* Experimental Part) suggests the tentative structual assignment I for this material.

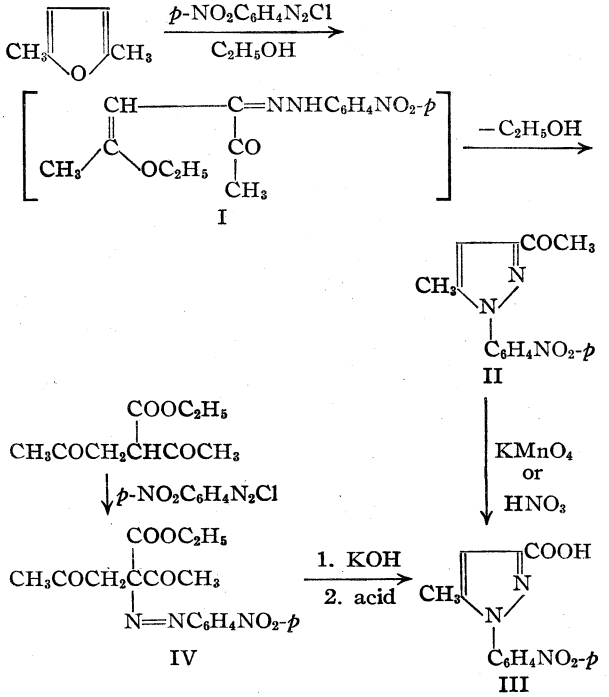
[7] Similar reaction conditions were employed by Fischer and Hepp (*Ber.*, **19**, 2251 (1886)) in the successful coupling of pyrrole with diazonium halides, and by Johnson (Ref. 5).

[8] An isomer of this compound, but reported in Beilstein, 4th ed., **25**, 120, as this compound, was prepared by Knorr and Macdonald, *Ann.*, **279**, 224 (1894). It melted at 122° and was prepared by reaction of 1-phenyl-5-methyl-3-pyrazolecarboxylic acid with fuming nitric acid. On repeating this work we obtained an acid of m. p. 153–154° without establishing its identity.

Synthesis of III was accomplished by reaction of ethyl 2-acetyl-2-*p*-nitrophenylazolevulinate (IV) with alcoholic alkali followed by acidification. IV, prepared by the coupling of ethyl acetonylacetoacetate with *p*-nitrobenzenediazonium chloride changed spontaneously into the ethyl ester of III on standing.

The pyrazolecarboxylic acid III was also obtained as one product of the condensation of *p*-nitrophenylhydrazine with the sodium derivative of oxalacetone followed by alkaline hydrolysis and acidification.



Experimental

Reaction of 2,5-Dimethylfuran with *p*-Nitrobenzenediazonium Chloride.—To an ice-cold solution of 4.8 g. of 2,5-dimethylfuran, 250 ml. of ethanol and 15 g. of potassium acetate was added all at once the diazonium salt solution prepared from 7.0 g. of *p*-nitroaniline in 150 ml. of water, 30 ml. of 10% hydrochloric acid, and 3.5 g. of sodium nitrite. The reaction mixture was kept in ice for three hours and then poured into twice its volume of water, giving a gummy, orange solid that was crystallized from benzene to yield 3.9 g. of golden yellow plates which melted at 129–131° with gas evolution. Attempts to prepare sharply melting samples of assured purity failed. When a sample was heated *in vacuo* at 100°, quantitative conversion to **1-*p*-nitrophenyl-3-acetyl-5-methylpyrazole** (II) of m. p. 134–135° occurred. This initial coupling product is tentatively formulated as I.

When the coupling reaction was carried out under the same conditions but using methanol as solvent the initial product was obtained in the form of a gummy, red solid which could not be purified but which, on acid hydrolysis underwent conversion to II in good yield (see below).

Hydrolysis of Initial Coupling Product.—The above described red product (4.0 g.) from the coupling reaction carried out in methanol was boiled for a few minutes in 25 ml. of alcohol which contained 3 ml. of 6 *N* hydrochloric acid. When the hydrolysis mixture was poured into an excess of water a red solid separated that on crystallization from aqueous alcohol and treatment with decolorizing carbon yielded pale-yellow needles (2.2 g.) of m. p. 134–135°. The substance was 1-*p*-nitrophenyl-3-acetyl-5-methylpyrazole and readily gave iodoform, m. p. 115–118°, with sodium hypoiodite.

Anal. Calcd. for $C_{12}H_{11}O_3N_3$: C, 57.8; H, 4.52. Found: C, 57.9; H, 4.68.

Under the same conditions of hydrolysis the initial deep-yellow coupling product of m. p. 129–131° (1.5 g.) from the coupling reaction carried out in ethanol yielded 0.90 g. of pale-yellow needles of m. p. 134–135° that showed no depression when mixed with the materials of the same melting point obtained as described above.

Anal. Found: C, 58.0; H, 5.00.

Oxidation of 1-*p*-Nitrophenyl-3-acetyl-5-methylpyrazole (II).—To 2.5 g. of II suspended in 200 ml. of water containing 5 ml. of 5% sodium hydroxide solution was added a solution of 3.2 g. of potassium permanganate in water. The mixture was heated at 60° until the permanganate color had disappeared, and after the precipitated manganese dioxide had been destroyed by the addition of sodium bisulfite, the tan solid which remained was separated, extracted with ether, and dissolved in dilute sodium hydroxide. The alkaline solution was filtered, and from the filtrate there was obtained on acidification a gelatinous greenish precipitate which was separated and crystallized from aqueous alcohol to yield 0.4 g. of white micro-crystals of m. p. 216–217°.

Anal. Calcd. for $C_{11}H_9O_4N_3$: C, 53.4; H, 3.67. Found: C, 53.5, 53.9; H, 3.75, 3.61.

The identity of this material and **1-*p*-nitrophenyl-5-methyl-3-pyrazolecarboxylic acid** (III), the synthesis of which is described below, was established in a mixed melting point determination (m. p. 216–217°).

When 1.5 g. of II was boiled with 15 ml. of concentrated nitric acid until brown fumes were no longer evolved there resulted after crystallization of the crude acid product from aqueous alcohol 0.8 g. of white micro-crystals of m. p. 216–217°, taken alone or mixed with the material of the same melting point described above.

Ethyl 2-Acetyl-2-*p*-nitrophenylazolevulinate (IV).—To an ice-cold solution of 17.0 g. of ethyl acetonylacetoacetate[9] and 65 g. potassium acetate in 250 ml. of alcohol was added all at once the filtered diazonium salt solution prepared from 13.8 g. of *p*-nitroaniline in 100 ml. of 6 *N* hydrochloric acid and 7.0 g. of sodium nitrite. The mixture became deep orange immediately and after fifteen minutes at ice temperature the addition of 500 ml. of water threw down a heavy, red-orange precipitate that was separated and crystallized from alcohol to yield 17.0 g. of ethyl 2-acetyl-2-*p*-nitrophenylazolevulinate (IV) of m. p. 80–81°.

Anal. Calcd. for $C_{15}H_{17}O_6N_3$: C, 53.8; H, 5.11. Found: C, 53.7, 53.8; H, 5.70, 5.31.

Both the analytical sample and the less highly purified samples of the red-orange IV after two weeks had decomposed with loss of acetic acid to yield a pale-yellow crystalline solid, 3.0 g. of which on two crystallizations from alcohol yielded 1.5 g. of straw-colored needles of m. p. 96–97° which proved to be **ethyl 1-*p*-nitrophenyl-5-methyl-3-pyrazolecarboxylate** (V).

Anal. Calcd. for $C_{13}H_{13}O_4N_3$: C, 56.7; H, 4.74. Found: C, 56.8; H, 4.93.

1-*p*-Nitrophenyl-5-methyl-3-pyrazolecarboxylic Acid (III): (a) **From Condensation of *p*-Nitrophenylhydrazine with Sodium Oxalacetone.** To 3.06 g. of *p*-nitrophenylhydrazine in 35 ml. of glacial acetic acid was added 3.60 g. of sodium oxalacetone dissolved in 10 ml. of water. The reaction mixture was heated for fifteen minutes on the steam-bath and poured into an excess of water. The tan crystalline precipitate which appeared was separated and one-half of it was hydrolyzed by boiling for fifteen minutes with a solution of 6.0 g. of potassium hydroxide in 10 ml. of water and 30 ml. of methanol. The hot hydrol-

---

[9] Ossipow and Korschun, *Chem. Zentr.*, **74**, II, 1281 (1903). Our material had b. p. 97–104° at 2 mm. and d. 1.061 at 21°.

ysis mixture was diluted with an equal volume of water, decolorized with carbon and acidified. The precipitate which appeared was removed from the hot solution by filtration and the filtrate on being cooled deposited 0.14 g. of tan solid which after three crystallizations from glacial acetic acid yielded yellowish-white crystals of m. p. 215–217° taken alone or mixed with the oxidation product (III) of 1-*p*-nitrophenyl-3-acetyl-5-methylpyrazole (II).

(b) **By Hydrolysis of Ethyl 1-*p*-Nitrophenyl-5-methyl-3-pyrazolecarboxylate** (V).—Five-tenths of a gram of the ester (V) was heated on the steam-bath with a mixture of 1 ml. of concentrated hydrochloric acid and 3 ml. of glacial acetic acid for four hours. The hydrolysis mixture was cooled, the solid which crystallized therefrom was separated and crystallized three times from aqueous alcohol to yield 0.15 g. of pure-white, crystalline 1-*p*-nitrophenyl-5-methyl-3-pyrazolecarboxylic acid of m. p. 216.5–217.5° taken alone or mixed with III.

Anal. Found: C, 53.5; H, 4.14.

(c) **By Hydrolysis of Ethyl 2-Acetyl-2-*p*-nitrophenylazolevulinate** (IV).—To one gram of the dye IV in 20 ml. alcohol and 5 ml. water at the boiling point was added 0.4 g. of potassium hydroxide in 5 ml. of water. After three hours of heating, the dark reaction mixture was acidified, and on being cooled the acidic solution deposited a gelatinous yellowish precipitate that was separated and treated with warm dilute solution bicarbonate solution. The cloudy bicarbonate solution was filtered and acidified to yield a yellowish-white precipitate that gave after separation and three crystallizations from glacial acetic acid 0.10 g. of 1-*p*-nitro-phenyl-5-methyl-3-pyrazole carboxylic acid in the form of white needles of m. p. 215.5–216.5° taken alone or mixed with III.

Summary

The furan nucleus of 2, 5-dimethylfuran on reaction with *p*-nitrobenzenediazonium chloride followed by acid hydrolysis of an initial, unstable coupling product is cleaved with the formation of 1-*p*-nitrophenyl-3-acetyl-5-methylpyrazole.

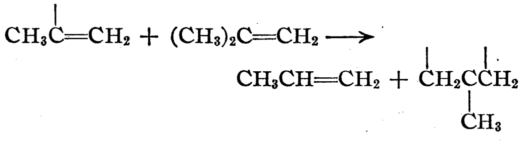
The Thermal Decomposition of Mono-olefins: Isobutylene

BY FRANCIS OWEN RICE AND W. STUART HAYNES[1]

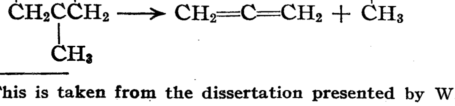
The mechanism of the thermal decomposition of paraffin hydrocarbons from the free radical standpoint[2] has already been studied in considerable detail and appears to give a satisfactory interpretation of the complicated chemical changes that occur in the pyrolysis of saturated, open chain hydrocarbons. Even when this picture is applied to the decomposition of paraffins as high as the octanes, the amounts of products calculated are in reasonable agreement[3] both qualitatively and quantitatively with the amounts found experimentally.

In contrast with the decomposition of paraffin hydrocarbons, the mechanism of olefin decompositions is not well understood in spite of a considerable amount of study. This is surprising because the predictions made on the basis of the free radical theory proposed by Rice[2] are rather straightforward and are shown for example in the case of isobutylene by the equations

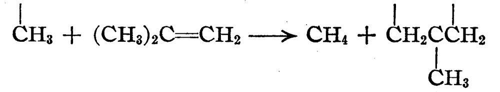
$$(CH_3)_2C{=}CH_2 \longrightarrow \overset{|}{C}H_3 + CH_3\overset{|}{C}{=}CH_2 \tag{1}$$



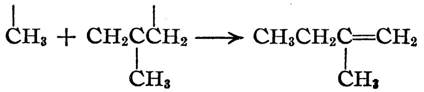
$$CH_3\overset{|}{C}{=}CH_2 + (CH_3)_2C{=}CH_2 \longrightarrow CH_3CH{=}CH_2 + \overset{|}{C}H_2\underset{\underset{CH_3}{|}}{\overset{|}{C}}H_2 \tag{2}$$



$$\overset{|}{C}H_2\underset{\underset{CH_3}{|}}{\overset{|}{C}}H_2 \longrightarrow CH_2{=}C{=}CH_2 + \overset{|}{C}H_3 \tag{3}$$



$$\overset{|}{C}H_3 + (CH_3)_2C{=}CH_2 \longrightarrow CH_4 + \overset{|}{C}H_2\underset{\underset{CH_3}{|}}{\overset{|}{C}}H_2 \tag{4}$$



$$\overset{|}{C}H_3 + CH_2\underset{\underset{CH_3}{|}}{\overset{|}{C}}H_2 \longrightarrow CH_3CH_2\underset{\underset{CH_3}{|}}{C}{=}CH_2 \tag{5}$$

The initial step produces radicals and the final step removes them. Reactions (3) and (4) constitute the chain which yields equal molecular quantities of methane and allene. If the chain is fairly long (50 or more chain cycles), we would expect methane and allene to be the predominant products and to be accompanied by only negligible amounts of other compounds. If, however, the chain is short and consists of only a few cycles, the amount of propylene, methane and other molecules resulting from the non-chain radical reactions would be increased. There are several other non-chain radical reactions that can be written but we have omitted them since they should produce only a small proportion of the decomposition products.

The pyrolysis of isobutylene has been the subject of a number of investigations.[4] Methane, hydrogen, ethylene and propylene were found to constitute the bulk of the gaseous products. Although the conditions were varied widely, allene was found to be completely absent or, at most, present in traces. In all cases the decomposition was accompanied by considerable quantities of oily and tarry material, containing benzene and

---

its homologs and various polynuclear aromatic ring systems.

In view of this last observation we decided to undertake a new investigation of the isobutylene decomposition with the hope of finding conditions for avoiding the formation of tar and oil. These can only have resulted from successive reactions involving the first products of the decomposition and if we are to understand the mechanism we must be able to identify the primary products of the decomposition before they react further, either with themselves or with the substrate to produce finally tars and oils.

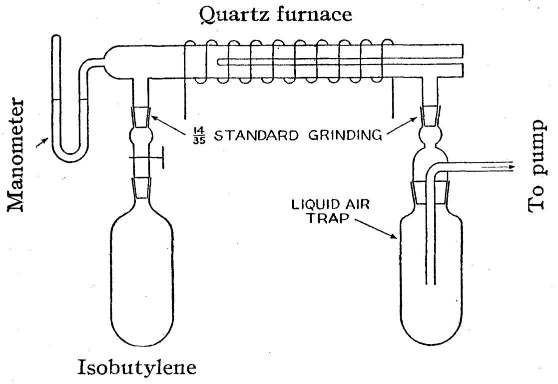

Fig. 1.—Thermal decomposition of isobutylene.

A flow system was used in which the isobutylene was passed through a quartz furnace 8″ × 1″, as shown in Fig. 1. The gases leaving the furnace were passed through two liquid air traps and the non-condensable portion was pumped out through a glycerol pump and collected over a solution of zinc sulfate.

The gases condensed in the traps, consisting of C_1 to C_4 hydrocarbons, were distilled at low temperature in a Podbielniak column and separated into different fractions. Three of our fractions boiled within ±0.3° of the boiling points of methylacetylene, allene and propylene which are reported respectively as −23.3°, −34.3° and −47.7° at 760 mm. pressure. We obtained in this way a fairly good analysis of the condensable products, but in each case the fraction was analyzed in a Shepherd type gas analysis apparatus.[5] The gases not condensed by liquid air were also measured and analyzed.

The identification of the C_3 hydrocarbons was accomplished by hydrogenating a portion of each fraction in the gas analysis apparatus over a nickel catalyst. The lowest boiling fraction (propylene) had one double bond whereas both the other fractions proved to be hydrocarbons having either one triple bond or two double bonds. Additional evidence was obtained by showing that the methylacetylene fraction gave an immediate and copious precipitate with an aqueous solution of ammoniacal silver nitrate. On the other hand, the allene fraction gave a white precipitate with an aqueous solution of mercuric chloride but no precipitate with the ammoniacal silver nitrate solution.

In the series of experiments reported in this paper, the conditions were such that there was practically complete absence of tar or carbon throughout the course of a run. This was accomplished by adjusting the temperature, pressure and contact time to values at which there was no formation of carbonaceous material on the glass walls at the outlet of the furnace. In experimental runs 2, 3, 9 and 10, evidence of some tar formation was noticed, the greatest amounts relative to the quantity of isobutylene used appearing in runs 2 and 10. One observes that in these runs occur the highest temperatures, the greatest contact times, or the highest pressures. Thus by fixing two of these variables and increasing the third, one would get a critical value for each at which incipient tar formation occurs, followed by abundant tar formation for higher values of this variable. The three variables would obviously be interdependent with respect to the conditions under which tar formation will occur.

Table I contains a summary of all the results on the isobutylene decomposition. Figure 2 shows the relation between the pressure and the yield of the various hydrocarbon products. From these results it appears likely that isobutylene decomposes through a free radical mechanism but the chain is rather short since there are appreciable quantities of propylene formed, presumably by some non-chain reaction such as reaction (2). We would not be able to detect the presence of

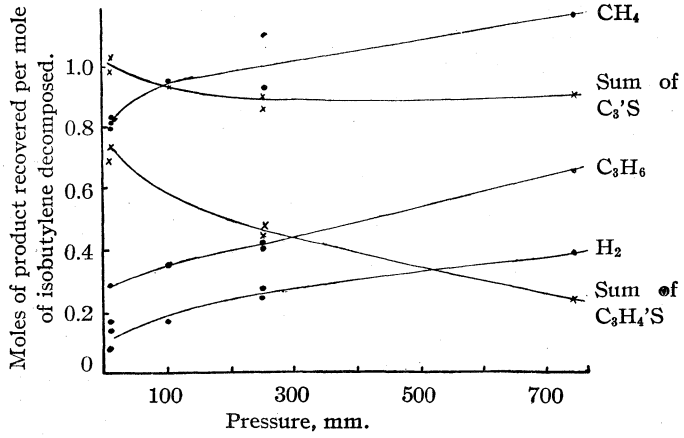

Fig. 2.—Curves showing the relation between the pressure in the furnace and the moles of different products recovered per mole of isobutylene decomposed. Experiments 2 and 3 have been omitted because of the large fraction of isobutylene decomposed and experiment 6 has been omitted because of loss of material.

pentenes because they would be present in only small quantity and since they boil at a higher temperature than isobutylene, they would be reported as this substance.

We are inclined to think that the methylacetylene is formed from allene by means of a radical chain. A free methyl radical, for example, reacting either with methylacetylene or allene would, in each case, give the same radical $\overset{|}{C}H_2{-}\overset{|}{C}{=}\overset{|}{C}H$. When this radical removes a hydrogen atom from an organic molecule, methylacetylene is formed, if a hydrogen atom attaches itself to the left-hand side of the molecule and allene is formed if a hydrogen atom is attached to the right-hand side of the molecule. We plan to investigate this point in a later paper.

Summary

1. The thermal decomposition of isobutylene probably proceeds through a short chain, producing methane and allene.

2. Under proper conditions of temperature, pressure and contact time, the decomposition of isobutylene occurs without appreciable production of carbonaceous and tarry material.

3. Both allene and methylacetylene are major products of the reaction. It has not yet been determined whether the methylacetylene is produced by isomerization of allene or by molecular dehydrogenation of the isobutylene.

4. Under best conditions there were about 60 moles per cent. yields of allene–methylacetylene based on the decomposed isobutylene.

The Apparent Molal Expansibilities of Potassium, Barium and Lanthanum Chlorides as a Function of Concentration and Temperature[1]

BY GRINNELL JONES,[2] E. FOLGER TAYLOR[3] AND RICHARD C. VOGEL[4]

The apparent molal thermal expansibility of a solute may be defined by the equations

$$\phi \bar{E}_2 = V_s\alpha_s - V_w\alpha_w = \left(\frac{\partial \phi V_2}{\partial T}\right)_P \qquad (1)$$

where V_s is the volume of solution containing one mole of solute, V_w is the volume of water used, α_s and α_w are the thermal coefficients of expansion of the solution and water, respectively, and ϕV_2 is the apparent molal volume of the solute.

Gucker[5] has obtained the limiting law for the partial molal expansibility, $\bar{E}_2$ of the solute as a function of the concentration from the Debye–Hückel theory, when $\bar{E}_2$ is defined by the equation

$$\bar{E}_2 = (\partial \bar{V}_2/\partial T)_P \qquad (2)$$

where $\bar{V}_2$ is the partial molal volume of the solute. If each molecule furnishes ν_i ions of charge z_i' then

$$\bar{E}_2 - \bar{E}_2^0 = \frac{A}{2}\,\frac{(\Sigma \nu_i z_i^2)^{3/2}}{D^{3/2}T^{1/2}} f(D,P,V,T)c^{1/2} \tag{3}$$

and

$$f(D,P,V,T) = -1/2\left[\frac{3}{D}\frac{\partial D}{\partial T} + \frac{1}{T} + \alpha\right]\left(\frac{3}{D}\frac{\partial D}{\partial P} - \beta\right) + \frac{\partial}{\partial T}\left[\frac{3}{D}\frac{\partial D}{\partial P} - \beta\right]$$

$$A = \left[\frac{\pi N^3\,\epsilon^6}{1000k}\right]^{1/2} = 2.457 \times 10^{14} \text{ in c. g. s. units}$$

The coefficient of compressibility of the solvent is β, and the dielectric constant is D; T is the absolute temperature, N is Avogadro's number, ϵ the charge on the electron, k is Boltzmann's constant, and c is the volume concentration. On the basis of this equation and by an estimation of the value of $\partial^2 D/\partial T \partial P$, Gucker arrives at the limiting law

$$\phi E_2 = \phi E_2^0 + 8 \times 10^{-3} c^{1/2} \tag{4}$$

for the apparent molal expansibility of uni-univalent electrolytes at 20°.

Without considering the numerical value of the coefficient, Gucker's equations predict three things: (a) at low concentration ϕE_2 should be a linear function of $c^{1/2}$; (b) the limiting slopes, $\partial \phi E_2/\partial c^{1/2}$, should be the same for all electrolytes of the same valence type; and (c) the limiting slopes should be greater for electrolytes of higher valence types. If the numerical value of the slope is considered, a fourth prediction will be that the slope should be positive.

Gucker[5] calculated the apparent molal expansibilities from the data on the density of aqueous solutions found in the literature for sodium chloride, potassium chloride, lithium chloride, hydrochloric acid, lithium hydroxide and sodium sulfate by an approximate method. Gibson and Kincaid[6] have obtained the apparent molal expansibilities of barium chloride, potassium nitrate, potassium bromide, lithium bromide and sodium iodide at 25° and at 35°. The lowest concentration which these investigators studied was 0.25 mole per liter for the barium chloride solutions and about 0.5 mole per liter for the rest of the solutions. The apparent molal expansibility of barium chloride showed an unusually large departure from linearity when plotted against $c^{1/2}$. Gibson and Loeffler[7] recently determined the apparent molal expansibilities of sodium chloride and of sodium bromide from 25° to 85°. The lowest concentration studied was around 0.5 mole per liter.

All of these investigators found that an increase of temperature decreased the apparent molal expansibility for a given concentration and increased the slope of ϕE_2 plotted against $c^{1/2}$. From the data of these investigators it is apparent that of the four predictions made by Gucker's limiting law, only one is correct in the concentration ranges studied, *i. e.*, ϕE_2 is usually a linear function of $c^{1/2}$ for uni-univalent electrolytes. But contrary to the predictions from Gucker's equations, the data show that at 25° the slopes are widely different for various uni-univalent electrolytes, and in the case of the uni-bivalent electrolyte, sodium sulfate, the slope is considerably less than that of any uni-univalent electroyte yet studied.

Perhaps part of the lack of agreement between theoretical predictions and experimental results is because the solutions studied have been no more dilute than about 0.25 mole per liter. In the calculation of apparent molal expansibilities from experimental data, the experimental error in measuring the coefficient of expansion is multiplied by about $1000/c$. Therefore, if a study of dilute solutions is to be undertaken, apparatus capable of giving results more accurate than those yet obtained must be used.

A new type of dilatometer has been developed which is capable of measuring changes in volume of electrolyte solutions over a wide range of temperature to ±0.0003 cc., the total volume being about 275 cc. This apparatus has been used to study solutions of potassium chloride from 20 to 80° and solutions of barium chloride and of lanthanum chloride from 20 to 60° The lowest concentrations which gave reproducible results were 0.06 molar.

Experimental Technique

Dilatometers.—The mercury dilatometer, which measures a change in volume in terms of the weight of mercury expelled or drawn in when the temperature is varied, is a well-known instrument used by a number of investigators. The first dilatometer to employ the unique principle of being a thermal regulator for its thermostat as well as a dilatometer was used by Jones and Jelen[8] for determining the cubical coefficients of expansion of solids. Thus, this type of dilatometer controls the temperature of the bath so that the dilatometer's contents exactly occupy the entire volume. The Jones and Jelen dilatometer was redesigned for use with solutions.

Two dilatometers, as nearly alike as the glassblower could make them, were used in this research. They each (Fig. 1) have an over-all height of 30 cm. and are made of Pyrex glass. The main part of the dilatometer, A, is closed at the top by stopcock F. A smaller tube, B, is attached at the bottom of the main part of the dilatometer. In the upper part of B there is a capillary restriction, D, about 2 cm. long and 1 mm. in inside diameter. A tantalum wire, J, is sealed in tube, B, above the capillary, D, in such a manner that its sharp point extends into the upper end of the capillary. Below the capillary, D, is sealed a platinum wire, K. Both the tantalum wire, J, and the platinum wire, K, extend into wells which may be filled with mercury. By placing wires from a thyratron circuit in the mercury-filled wells, H and C, the dilatometer can be made to control part of the heat input to the thermostat by making or breaking the circuit through the tantalum wire and the mercury in the capillary, D. This principle is exactly the same as that of a conventional mercury thermo-regulator. The capacity of each dilatometer (275 cc.) is such that when they are filled with mercury and water in a typical experiment a temperature change of 0.001° at 25° will produce a change in height of the mercury in capillary D of 0.1 mm. and at 75° of 0.2 mm.

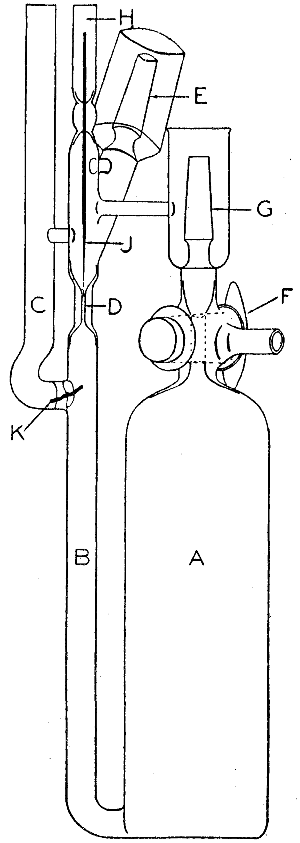

Fig. 1.—Mercury dilatometer.

The tube, E, is provided for the withdrawal or addition of mercury. After one equilibrium temperature has been determined, some mercury is removed from the dilatometer, and the instrument will then equilibrate at a higher temperature. The mercury removed is weighed. It is also possible to go from a higher to a lower equilibrium temperature by adding a weighed quantity of mercury through the tube, E.

The dilatometers are first calibrated, using mercury as a standard. During these runs the instruments are completely filled with mercury. At an equilibrium temperature the mercury is in the capillary, D, just at the tip of the tantalum wire, and thereby controlling the intermittent heaters in the usual manner, through a thyratron tube. When a water (or solution) experiment is being carried out, the mercury fills the tube, B, and forms a layer about 1 cm. deep on the bottom of the dilatometer, A, with water (or solution) on top of this layer of mercury filling the rest of the volume of the dilatometer.

A tantalum wire is much better for the upper contact than platinum because tantalum is not wet by mercury. There is no tendency for a small drop of mercury to cling to the sharp point of the tantalum wire causing erratic regulation of the thermostat. For this reason tantalum is to be highly recommended for use in thermoregulators. The resistance of tantalum to hot nitric and sulfuric acids, which are used in cleaning the dilatometers, was tested, and the metal was found to be quite inert.

Filling the Dilatometers.—There are two different filling techniques. One is used in calibration experiments when the dilatometer is to be entirely filled with mercury. The other is used when the dilatometer is to be partly filled with water or solution. Since the standard on which all the changes in volume of the solutions are based is mercury, the first experiments dealt with this substance.

The stopcock, F, is greased with Dow–Corning silicone stopcock grease. During the first part of this research Fisher's Cellogrease was used, but the new silicone grease was found to be superior at higher temperatures. The empty dilatometer is weighed. Mercury is filtered through a sintered glass disk, and it then is allowed to run down through a long capillary tube which has been inserted through the bore of the stopcock, F. This capillary tube reaches very nearly to the bottom of the dilatometer. When the dilatometer is completely full, the capillary is withdrawn and a rubber tube is attached to the joint, E (Fig. 1). The position of the mercury in the tube, B, of the dilatometer is adjusted to a point slightly above the capillary, D, by increasing or decreasing the pressure through the rubber tube. After this adjustment the stopcock, F, is turned through an angle of 90°, thus closing off A completely, but connecting the bore of the stopcock and the tube above to the side outlet tube on stopcock, F. The excess mercury in the bore of the stopcock and in the tube above it is then removed. There should now be enough mercury in the dilatometer to establish the first thermal equilibrium at about 20°. The dilatometer is weighed on a large balance to the nearest milligram.

If a water run is to be conducted, the stopcock, F, is greased, mercury is placed in the wells, C and H, and the dilatometer is weighed. After weighing, 50 cc. of mercury is placed in the bottom of the dilatometer in the same manner as if the dilatometer were to be completely filled with mercury. The instrument is reweighed.

A special 500-cc. round-bottom flask is used to fill the dilatometer with water. To the bottom of this flask (Fig. 2) is sealed a stopcock, *n*, and below the stopcock is sealed a ground joint, h. The movable plug of the stopcock has a three-way bore. Thus, by facing the bore in a "T" position with respect to the ground joint, h, it is possible to evacuate the bore. On the neck of the flask is a large ground-glass joint, m. The inside diameter of this joint is about 2 cm. The neck of the flask is 20 cm. long, and the 500 cc. graduation mark is about 4 cm. above the body of the flask. The large diameter and length of the neck allows the water (or solution) in the flask to be boiled without liquid being splashed or carried by entrainment from the flask. A special stopper for the flask consists of a large ground glass joint fitting the one on top of the flask; a stopcock, e, is sealed on top of this joint, and above the stopcock is another ground glass joint, d.

This special flask is used in removing the dissolved gases from the water. The flask is connected at the joint, d, to a trap which is cooled externally by a "Dry Ice"–alcohol mixture which is in turn connected to a vacuum pump. Thus, when the stopcocks a, b, and e are opened, and c and e are closed, and tube p is plugged (Fig. 2) the water boils under reduced pressure, and that vaporized is caught in the trap. When the dissolved gases are expelled, the stopcock, e, is closed.

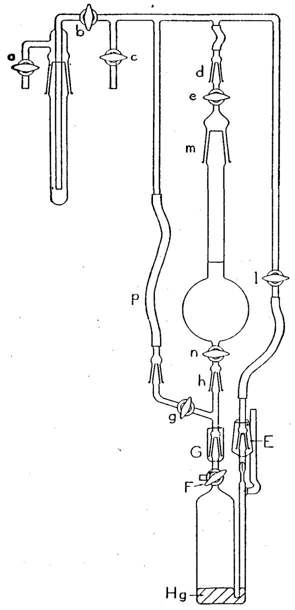

Fig. 2.—Mercury dilatometer and auxiliary apparatus assembled for filling with water or solution.

An extension tube is placed on the dilatometer at the joint, G (Fig. 1), and to the extension tube is attached the filling flask. The joint, E, of the dilatometer and the arm on the extension tube are attached to the vacuum line. The joints, G and E, of the dilatometer are not greased but are mercury sealed. The other joints are greased. The stopcocks, a and b, are closed, and g, l and F are opened. The vacuum supplied by a Langmuir mercury vapor diffusion pump backed by an oil pump is applied to the system by opening stopcock c. When the system is evacuated according to a McLeod gage, the stopcocks c, g and l are closed and n is slowly opened; the water flows into the dilatometer on top of the mercury.

As the water collects on the mercury, the mercury rises up into the tube, B (Fig. 1), of the dilatometer. The position of the mercury in B is adjusted to about 6 mm. above the top of the capillary by opening stopcock e slightly, thus applying pressure to the water in the filling flask. When the dilatometer is full and the position of the mercury above the capillary, D, is adjusted correctly, stopcock F is closed in such a manner that the bore is connected to the outlet tube. Full atmospheric pressure is then applied to the system by opening stopcocks c and l.

The mercury in the mercury seal cups of joints E and G and the water in the bore of the stopcock, F, are removed through the tube on the side of the stopcock barrel, and the apparatus is disassembled. The dilatometer is weighed.

If, instead of water, the dilatometer is to be filled with a solution, the filling procedure is the same except that the proper weighed amount of salt is dissolved in water in the flask. The solution is boiled under reduced pressure until the flask contains exactly 500 cc., and the solution is free of air. However, in the case of lanthanum chloride, because of the indefinite amount of water of crystallization in the salt, it is not possible to make solutions of known concentration by directly weighing the salt. The concentration can be determined by using the equation developed by Jones and Ray[9] giving the density in grams per milliliter at 25° as a function of concentration

$$d = 0.997074 + 0.229398c - 0.011911c^{3/2} \qquad (5)$$

Since the density data are known from the experimental data of the authors, the above equation may be solved for c.

Operation of the Dilatometer.—After the dilatometer has been filled with mercury (or mercury and water or solution) it is clamped in a special brass frame. The dilatometer is then mounted in the thermostat and wires from the thyratron circuit are placed in the mercury wells, C and H (Fig. 1), so that the dilatometer acts as the thermoregulator.

In order that the substance whose coefficient of expansion is to be determined is at a standard pressure of one atmosphere, pressure adjustments are applied. The ground glass joint, E (Fig. 1), is attached to a manometer by means of a rubber tube. If the dilatometer contains only mercury, the air pressure on the mercury in the capillary D is adjusted to 760 mm. The pressure adjustment when mercury alone is in the dilatometer is really only a formality unless the barometric pressure is very high or very low. A pressure change of 34 mm. will change the temperature of the bath by only 0.001°. When there is solution or water in the dilatometer, a pressure change in barometric pressure of 2 mm. will cause the temperature of the bath to change by 0.001° and, therefore, the pressure adjustment must be applied much more carefully. There is a pressure on the water or solution in addition to atmospheric pressure due to the head of mercury in the tube B (Fig. 1). There is also an additional pressure caused by the capillary depression of the mercury. Thus the pressure on the dilatometer's contents must be decreased by the sum of the two amounts in addition to the proper compensation for the difference between the prevailing atmospheric pressure and 760 mm.

After the dilatometer has been placed in the thermostat, the thyratron circuit connected and the pressure adjusted, various thermostat controls (steady heater, intermittent heaters, cooling coils) are adjusted until the dilatometer comes to equilibrium at about 20°. Equilibrium is attained when the intermittent heaters in the thermostat go off and on quite rapidly and the temperature is constant within 0.001°. The temperature is then determined.

The equilibrium temperatures of the thermostat were determined with a 25 ohm four-lead platinum resistance thermometer, made by Leeds and Northrup, provided with a Bureau of Standards certificate giving the constants. The resistance of the thermometer was measured by means of a Mueller bridge (Leeds and Northrup). The bridge was calibrated by using a 10-ohm standard resistance calibrated by the Bureau of Standards. In addition to calibrating the Mueller bridge, the resistance of the thermometer at the ice-point must be determined. The ice-bath used was prepared in the manner recommended by Roper.[10] A table was compiled from these data giving the resistance of the thermometer at various temperatures. A change of 0.001° brings about a change in resistance of about 0.0001 ohm. This change can be reliability determined by the Mueller bridge.

After the first equilibrium temperature is determined, the dilatometer is placed in an auxiliary water-bath whose temperature is 31°. This will cause the mercury to expand up above the capillary, D. Weighed pipets of special design (Fig. 3) are used to withdraw mercury. The tip of a pipet reaches down through the joint E (Fig. 1) of the dilatometer to the mercury which has been expelled from the main volume of the dilatometer through the capillary, D. When a pipet has been inserted into the dilatometer, a ground glass joint attached to a rubber tube is fixed to the pipet at B (Fig. 3), and most of the mercury above the capillary of the dilatometer is sucked out of the dilatometer, through the tube A into the pipet. The slight bend in the main part of the pipet, D, is to slow down the descent of the mercury as it falls to the bottom of the pipet thereby minimizing the scattering of mercury droplets. The constriction C in the tube A of the pipet is to prevent the escape of any mercury drops remaining in A from the pipet.

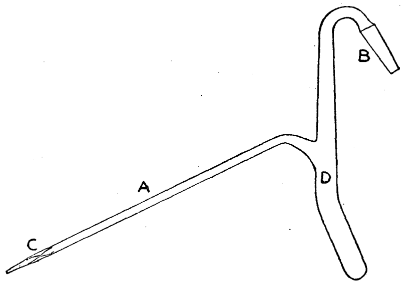

Fig. 3.—Pipet used for withdrawal and addition of mercury.

After the mercury has been withdrawn from the dilatometer, which is in the auxiliary bath, the dilatometer is returned to the thermostat and the thermostat comes to a new equilibrium temperature at about 30°. In the manner just outlined, readings are obtained at approximately 10° intervals from 20° to 60°. In the case of the earlier work on potassium chloride solutions, the observations were carried to 80°. After the dilatometer has been adjusted to regulate the bath at 60° (if this is the highest temperature), the pipets containing mercury are all weighed at once against a tare. In this manner the weights of mercury withdrawn from the dilatometer to produce each new temperature equilibrium are determined.

The procedure followed in going from higher temperatures to lower temperatures is but slightly different from the one used in adjusting the dilatometers on the "up run." After the highest equilibrium temperature has been determined, the dilatometer is placed in the auxiliary bath which is 5° warmer than the equilibrium temperature. The tip of the pipet containing the mercury withdrawn from the dilatometer in the last adjustment is placed below the surface of the mercury which has expanded above the top of the capillary, D, of the dilatometer. The pipet during this step is held in such a manner that the mercury in the bottom of the compartment D (Fig. 3) is undisturbed. The pipet is now rotated about the tube A as an axis until the main part, D, of the pipet is practically horizontal. The mercury in the pipet will run down the tube A into the dilatometer. The tip of the tube A is kept below the surface of the mercury to prevent splashing of drops of mercury. The dilatometer has now been adjusted to equilibrate at 50° (70° if the highest equilibrium temperature was 80° instead of 60°). In this way the "down run" is carried out in ten degree intervals down to 20°. As the pipets are emptied, they are again weighed. There are always a few milligrams of mercury remaining in each pipet. Therefore the tem-

[10] E. F. Roper, *ibid.*, **60**, 866 (1938).

peratures on the down run are not the same as on the up run.

Careful experiments were carried out to determine if there was any possibility that hysteresis of the glass might have introduced an error. The dilatometer was kept at a specific equilibrium temperature in the thermostat for an extended time, then immersed in either colder or hotter water, and kept in this auxiliary bath for several hours. Then the dilatometer was returned to the thermostat, and the same equilibrium temperature was very quickly obtained, thus demonstrating that hysteresis of the glass does not introduce an error.

Purification of Materials.—Mercury is purified by placing a small amount in a large beaker. Concentrated sulfuric acid is poured into it, and the mixture is stirred. The sulfuric acid is allowed to remain on top of the mercury for about half an hour, and it is then poured off. This treatment ensures that all of the Dow–Corning silicone stopcock grease will be removed from the mercury. The mercury is then thoroughly washed with water. The mercury is next allowed to fall in fine drops down a tower filled with 8% nitric acid solution.[11] After treatment in the tower, the mercury is distilled in a stream of air under reduced pressure according to the method of Hulett.[12] The distillate is then pinholed and redistilled. The redistilled mercury is pinholed into a clean storage bottle. Before using in the dilatometer, it is passed through a sintered glass disk to remove any particles of dust or traces of grease it may have picked up while standing in the laboratory.

The water used was conductivity water prepared in a Barnstead still. This water is free from dissolved materials except for air. The dissolved gases were removed by boiling under reduced pressure.

The potassium chloride was purified by recrystallization and fusion according to the method of Jones and Bradshaw.[13]

The barium chloride was purified by recrystallizing twice from an ethyl alcohol–water solution. The alcohol was purified by double distillation. The barium chloride was then further purified by a recrystallization from pure water. The barium chloride dihydrate obtained was dried at room temperature under a bell jar arranged in such a manner that circulation of dust-free air was permitted. After the barium chloride had dried in this manner for about a month, it was removed and ground up in a clean mortar and further dried for another month in the same manner. An analysis showed that the salt contained 14.799% water. The theoretical value is 14.752%. The experimentally obtained value was used in calculating the solution concentrations.

The lanthanum chloride was originally prepared by Professor Charles James[14] of the University of New Hampshire. It was purified by recrystallization from alcoholic hydrochloric acid using gaseous hydrogen chloride. It was then kept over solid sodium hydroxide to remove the excess solvent and hydrochloric acid.

Experimental Data

Mercury.—The dilatometers are first calibrated using mercury as a standard because (a) it is necessary to know the grams of mercury which must be withdrawn per gram of mercury in the dilatometer to raise the equilibrium temperature of the dilatometer one degree centigrade, and (b) it is necessary to know the coefficient of expansion of the Pyrex glass of which the dilatometers are made. Since the density of mercury has been determined at various temperatures in containers whose coefficient of expansion is very well known[15] the coefficient of expansion of the Pyrex can be calculated.

A sample data sheet obtained for one "up run" of dilatometer No. 1 is given in Table I. Column 1 gives the temperatures at which the equilibria were established. Column 2 gives the temperature difference, Δt, between each two successive equilibria. Column 3 gives the average temperature, t_{av}, of two successive equilibria. Column 4 gives the number of grams of mercury, ΔW, which are withdrawn to establish a new equilibrium. Column 5 is the total weight of mercury, W, in the dilatometer at the corresponding equilibrium temperature given in Column 1. Column 6 is the mercury factor, f_{Hg}, and is $\Delta W/W\Delta t$. The weight of mercury in Column 5 used to calculate f_{Hg} is that at the higher temperature. The use of the weight of mercury at the higher temperature may appear arbitrary but can be justified by an algebraic treatment of the method of calculating the ultimate results of the water and solution runs.

TABLE I

SAMPLE DATA SHEET FROM A MERCURY RUN

(1)	(2) Δt	(3) $t_{av.}$	(4) ΔW	(5) W	(6) f_{Hg}
20.048				3766.502_9	
	12.113	26.105	7.8098		0.0001715_3
32.161				3758.693_1	
	7.552	35.937	4.8567		$.0001713_2$
39.713				3753.836_4	
	8.878	44.152	5.6952		$.0001711_5$
48.591				3748.141_2	
	10.574	53.878	6.7619		$.0001709_2$
59.165				3741.379_3	

The mercury factor, f_{Hg}, expresses the grams of mercury withdrawn per degree centigrade per gram of mercury in the dilatometer at the higher temperature.

A linear equation relating f_{Hg} to t_{av} has been obtained for each of the two dilatometers using the method of least squares to evaluate the parameters. For dilatometer no. 1, the early equation (Taylor) used in connection with the potassium chloride solutions is

$$f_{Hg} = 0.0001719_4 - 0.000000017_4 t_{av} \qquad (6)$$

For dilatometers 1 and 2, respectively, the equations (Vogel) used in calculating the barium chloride and lanthanium chloride data are

$$f_{Hg} = 0.0001721_3 - 0.0000000218_5 t_{av} \qquad (7)$$

and

$$f_{Hg} = 0.0001719_4 - 0.0000000161_5 t_{av} \qquad (8)$$

From an analysis of the data based on the differences between the observed values of f_{Hg} and those calculated by means of Equation (6), it is found that the probable error of a single observation is ±0.000000145. The probable error of a single observation for dilatometer no. 1 using Equation (7) is ±0.000000039, and for dilatometer no. 2 using Equation (8) it is ±0.000000114.

[a] Wt. of water in dilatometer = 227.723_6 g.

The slight superiority of dilatometer no. 1 is believed to be due to the unavoidable difference in the shape of the capillary D at the point where the tip of the tantalum wire enters the capillary. Equations (7) and (8) cover a range of temperature from 25° to 55°, while Equation (6) covers a range from 25° to 75°. Since dilatometer no. 2 does not appear to function quite as well as dilatometer no. 1, the former was used for the more concentrated solutions where the experimental error is not as important. The values of f_{Hg} given in Table I were some of those used in arriving at Equation (7).

It is necessary to obtain the cubical coefficient of expansion, a, of the Pyrex glass of the dilatometer. An implicit definition of a is given by

$$V_t = V_{20}[1 + a(t - 20)] \qquad (9)$$

where V_t is the volume of the dilatometer at the temperature t°C., and V_{20} is the volume of the dilatometer at 20°. Since

$$V_t = W_t/d_t \qquad (10)$$

where W_t is the weight of mercury in the dilatometer and d_t is the density in grams per cc. of mercury at t°C., we get

$$\frac{W_t d_{20}}{d_t W_{20}} - 1 \Big/ (t - 20) = a \qquad (11)$$

If a calculation of a is to be made, d_{20}/d_t needs to be known for various temperatures. Accurate densities of mercury have been determined recently by Beattie, Blaisdell, Kaye, Gerry and Johnson.[15] After determining the apparent density of mercury in vitreous silica bulbs these investigators cut cross-sections from the bulbs and determined the coefficient of expansion of the silica by an interferometer method. They then corrected their data for the expansion of the silica.

In addition to d_{20}/d_t, W_{20} needs to be known. This was calculated by determining f_{Hg} for 20° from the equations relating f_{Hg} to t_{av}. Using this value of f_{Hg}, all the weights of mercury observed close to 20° were corrected to exactly 20°. The ratios, W_t/W_{20}, for each up and down run for both dilatometers were determined and hence a number of values of the coefficient of expansion of Pyrex glass, a, were obtained. These were averaged. Using the mercury calibration data obtained by R. C. Vogel in 1945 for dilatometers 1 and 2, a was found to be 0.00000966 for both instruments. Using the mercury calibration data of E. F. Taylor obtained in 1940 for dilatometer no. 1, a was found to be 0.00000968.

Saunders and Tool[16] found that the annealing temperature is the dominant factor in determining the coefficient of thermal expansion of Pyrex. Dilatometer no. 1 was annealed at 594° which should mean that a is 0.00000985 per degree centigrade, according to Saunders and Tool. Dilatometer no. 2 was annealed at 646° and thus should have a coefficient of expansion of 0.00001023 per degree centigrade. Our measurements do not support the idea that the coefficient of expansion of the Pyrex is controlled by the annealing temperature, at least within the range (594–646°) which we used. Moreover, trial calculations have shown that the same coefficient of expansion of Pyrex must be used for both dilatometers in order to get identical results for water.

Water.—Since the coefficient of expansion of water is needed to calculate the apparent molal expansibility of an electrolyte, it is necessary to make water runs with both dilatometers. It is also desirable to be able to compare the specific volumes of water at various temperatures calculated from our data with the best values obtained by other investigators.

A sample data sheet obtained for an up run for one of the dilatometers is given[17] in Table II. Columns 1, 2 and 3 have the same significance for the water data as for the mercury data. Column 4 gives the mercury factor, f_{Hg}, calculated at t_{av} using Equation (7). Column 5 gives the total weight of mercury in the dilatometer at t°C., the equilibrium temperature. Column 7 gives the weight of mercury withdrawn from the dilatometer to establish each new equilibrium temperature. Column 6 gives the grams of mercury expelled from the dilatometer in going from one equilibrium temperature to another due to the expansion of the mercury only. Column 8 shows

the grams of mercury expelled from the dilatometer due to the expansion of water alone and is obtained by subtracting Column 6 from Column 7. Column 9, the water factor f_W, is calculated by dividing Column 8 by Column 2 and by the weight of water in the dilatometer. It represents the grams of mercury expelled from the dilatometer per degree centigrade per gram of water.

By using Newton's method of non-linear interpolation, the water factors, f_W, have been determined at average temperatures, t_{av}, of 25, 35, 45, 55 and for part of the data, 65 and 75°.[2,3] When f_W is multiplied by the specific volume of mercury at the lower temperature of the interval over which f_W is calculated, the apparent change of the specific volume of water in Pyrex glass results. If to this apparent change in specific volume is added the change in specific volume due to the expansion of the Pyrex glass of the dilatometer, the true change in the specific volume over each ten-degree interval is obtained. Thus, to the specific volume at 20° of water, which is taken as a starting point, is added the true change in specific volume due to raising the temperature to 30°. This gives the specific volume at 30°. The specific volumes at other temperatures are calculated in the same manner. The specific volume of water at 20° is assumed to be 1.001796_6 cc. per gram. This is the value given by Tilton and Taylor[18] based on the excellent data of Chappuis.[19] The specific volumes of mercury in cc. per gram given by Beattie, Blaisdell, Kaye, Gerry and Johnson[15] are used. The results are given in Table III.

The integral coefficient of expansion of water at the average temperature of the temperature change in question can be obtained by dividing the change in specific volume by the specific volume of water at the average temperature and by the temperature change. Thus, if $\tilde{V}$ is the specific volume, the coefficient of expansion would be $\tilde{V}_{30} - \tilde{V}_{20} \div 10\ \tilde{V}_{25}$. Since the change in specific volume at best is known to about 0.01%, it is only necessary to know the specific volume at the average temperature, *i. e.*, $\tilde{V}_{25}$, to one part in ten thousand. A linear interpolation of specific volumes between round temperatures ten degrees apart may introduce an error of about one part in ten thousand. Thus, specific volumes calculated in this manner are sufficiently accurate for computing the coefficients of expansion of water and also of salt solutions. These are given in Table IV.

Solutions of Potassium, Barium and Lanthanum Chlorides.—The data for solutions are treated in general in the same manner as those of water. In calculating the specific volume of the solution, the amounts of mercury and of solution in the dilatometer at exactly 40° (50° for potassium chloride solutions) are calculated by adding to the weight of mercury a correction term which compensates for the fact that weights of the contents of the instrument are known at temperatures slightly different from 40°. This correction term consists of the weight of mercury associated with the expansion of solution over the temperature interval between equilibrium temperature and exactly 40°, and a similar term for the expansion of mercury. The solution term is calculated by multiplying the weight of solution by the average value of the factors, f_S, at 35° and 45° (f_S is the same for solutions as f_W is for water) and by the difference between the equilibrium temperature and exactly 40°. The mercury term is calculated by multiplying the weight of mercury by the mercury factor, f_{Hg}, for 40° and by the same difference in temperature. Since the volume of the dilatometer and the specific volume of mercury are known at 40°, the volume of the solution is calculated easily.

After the specific volumes at 40° are calculated for each solution, the specific volumes at other temperatures are then computed by adding or subtracting the sum of the apparent change in volume of solution in Pyrex glass and the change in volume of the Pyrex glass from the value at 40°.

The coefficients of expansion of solutions are calculated in exactly the same manner as they were for water. These are given in Table IV and plotted in Figs. 4, 5 and 6 against temperature.

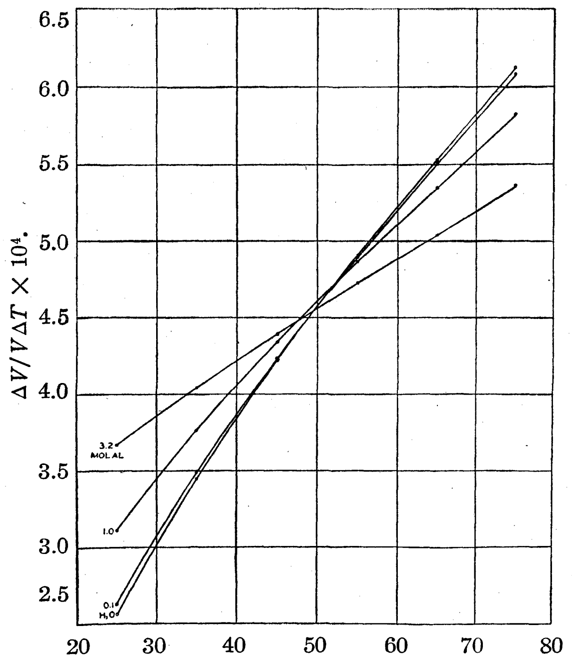

Fig. 4.—Coefficients of expansion of potassium chloride solutions plotted against temperature.

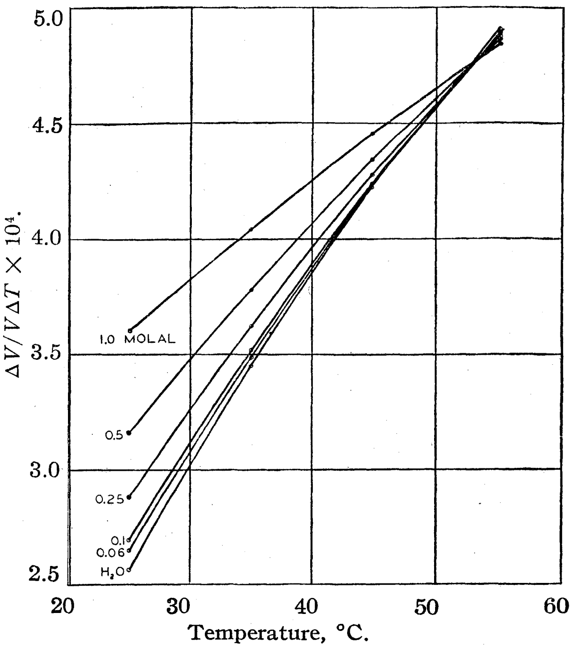

Fig. 5.—Coefficients of expansion of barium chloride solutions plotted against temperature.

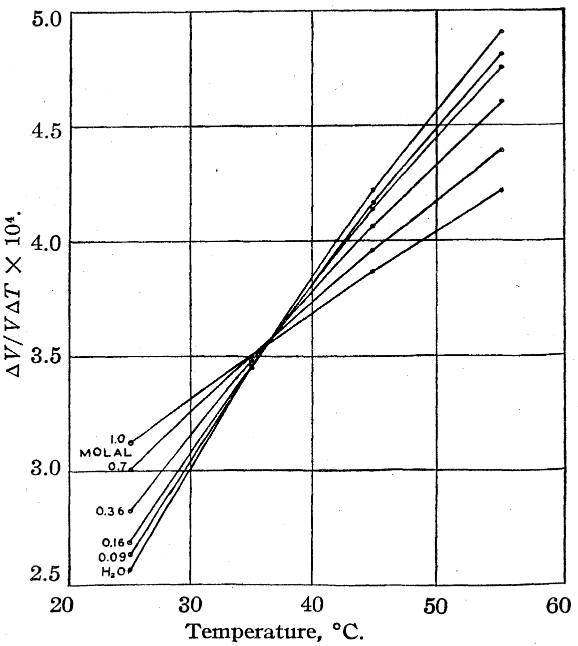

Fig. 6.—Coefficients of expansion of lanthanum chloride solutions plotted against temperature.

As previously mentioned, the concentrations of the lanthanum chloride solutions were determined from the solution densities obtained from the dilatometer data. It was decided that a linear interpolation of the specific volumes at 20° and

30° would not be accurate enough to obtain the specific volume at 25° in this case. The factor f_S is obtained for 27.5° for each solution. This is multiplied by 5°, the temperature interval, and by the specific volume of mercury at 25°. The coefficient of expansion of Pyrex was also multiplied by 5 and by the less accurate specific volume of the solution at 25° obtained by linear interpolation. The sum of these two corrections was subtracted from the specific volumes at 30° to give the specific volume at 25°. The concentration can then be obtained as previously described. This method was checked by calculating the specific volumes of barium chloride solutions from an equation giving the densities as a function of concentration derived by Jones and Ray.[20] These specific volumes checked with those obtained from the dilatometer data within a few parts per one hundred thousand, which shows that the method is sufficiently accurate.

Apparent molal expansibility of the salts may be calculated by means of Equation (1), and these are presented in Table V and plotted against $c^{1/2}$ at various temperatures in Figs. 7, 8 and 9. The value of the integral coefficient of expansion of water used at a given temperature to calculate ϕE_2 was determined by the dilatometer in which the particular solution was studied and the observer (Vogel or Taylor). The values of ϕE_2 for barium chloride are quite erratic when the concentration is as low as 0.01 molar. The reason for this is that at low concentrations the apparent molal expansibility represents the difference between two quantities which are almost identical. In order to obtain significant results for 0.01 molar solutions, the coefficients of expansion will have to be known ten times better than they are now known. The value of the apparent molal expansibility of the 0.06 molal lanthanum chloride solution at 25° appears to be in error. It is difficult to offer an explanation for this.

As has been previously mentioned, the coefficients of expansion obtained by our method of calculation are integral coefficients and not differential coefficients. Strictly speaking, the latter should be used in calculating the apparent molal expansibility. The molal expansibility as we have calculated it is

$$\phi E_2' = \frac{V_s}{\tilde{V}_s}\frac{\Delta \tilde{V}_s}{\Delta t} - \frac{\tilde{V}_w}{\tilde{V}_w}\frac{\Delta \tilde{V}_w}{\Delta t}$$

where $\tilde{V}_s$ and $\tilde{V}_w$ are the specific volumes of solu-

---

[20] Grinnell Jones and Wendell A. Ray, THIS JOURNAL, 63, 288 (1941).

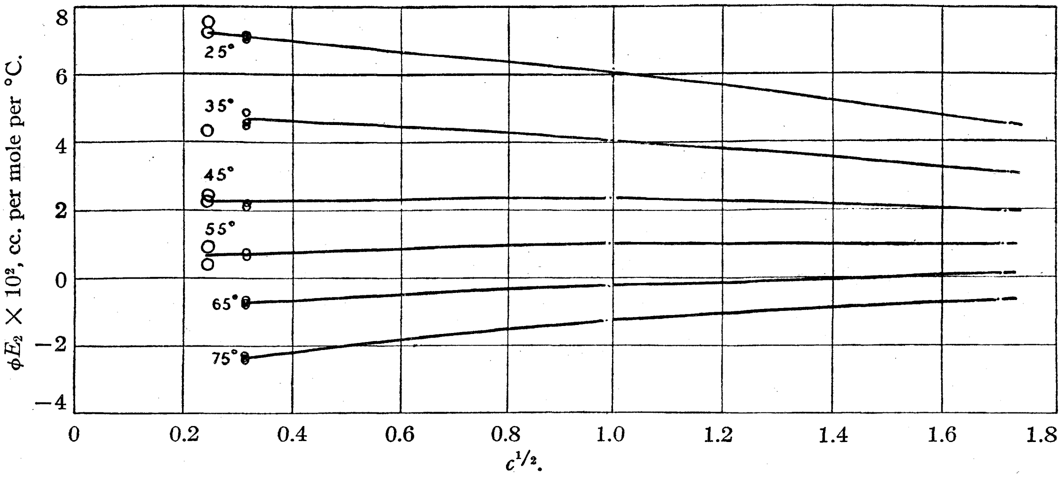

Fig. 7.—Apparent molal expansibility of potassium chloride plotted against $c^{1/2}$.

tion and water, V_s is the volume of solution containing a mole of solute and V_w is the volume of water used to make the solution. Let

$$\frac{\partial \tilde{V}_s}{\partial t} = \frac{\Delta \tilde{V}_s}{\Delta t} + x$$

$$\frac{\partial \tilde{V}_w}{\partial t} = \frac{\Delta \tilde{V}_w}{\Delta t} + y$$

Then if ϕE_2 is the true apparent molal expansibility, as defined by Equation (1)

$$\phi E_2 - \phi E_2' = W_w\,(x - y) + M_2 x$$

where W_w is the weight of water used to make the solution containing one mole of solute and M_2 is the molecular weight of the solute.

When $\tilde{V}_{w,t} - \tilde{V}_{w,25°}$ is plotted against temperature (Fig. 10) on the same graph with plots of $\tilde{V}_{s,t} - \tilde{V}_{s,25°}$ a rather remarkable fact becomes clear for many of the dilute solutions. These points fall approximately on the same curve. This means that

$$\frac{\partial \tilde{V}_s}{\partial t} = \frac{\partial \tilde{V}_w}{\partial t} \text{ and } \frac{\Delta \tilde{V}_s}{\Delta t} = \frac{\Delta \tilde{V}_w}{\Delta t}$$

which leads to the fact that for dilute solutions x equals y.

From the equation derived by Tilton and Taylor[18] giving the density of water as a function of temperature, the differential coefficients of expansion can be obtained.

$$\frac{1}{\tilde{V}_w}\left(\frac{\partial \tilde{V}_w}{\partial t}\right)_{25°} = 0.0002570_4 \text{ and } \frac{1}{\tilde{V}_w}\left(\frac{\partial \tilde{V}_w}{\partial t}\right)_{35°} = 0.0003456_5$$

Since the dilatometer data give $\frac{1}{\tilde{V}_w}\,\frac{\Delta \tilde{V}_w}{\Delta t}$, y can be determined. At 25° and 35° y is 5×10^{-7}.

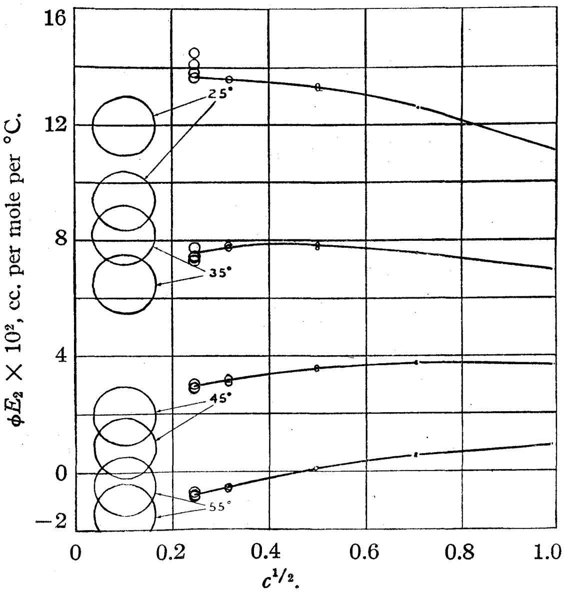

Fig. 8.—Apparent molal expansibility of barium chloride plotted against $c^{1/2}$.

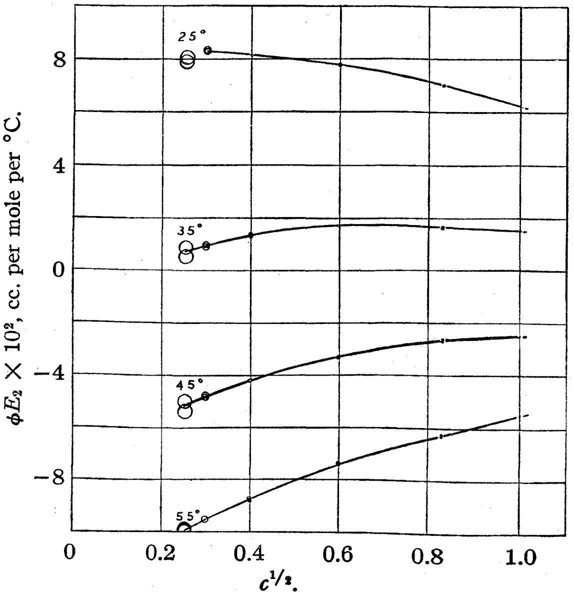

Fig. 9.—Apparent molal expansibility of lanthanum chloride plotted against $c^{1/2}$.

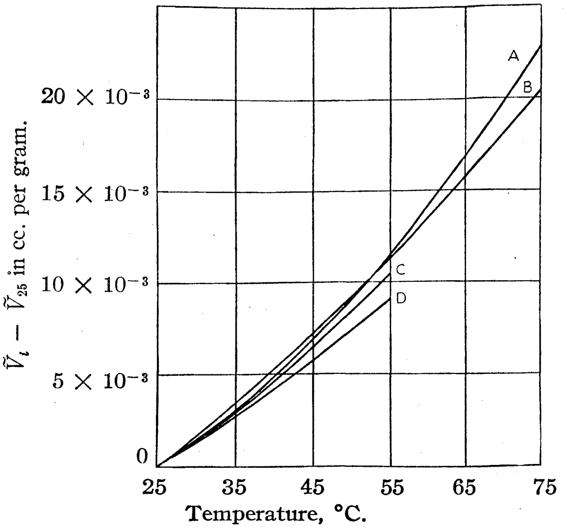

Fig. 10.—$\bar{V}_t - \bar{V}_{25°\text{C.}}$ plotted against temperature for water and solutions: curve A, water, 0.06 *M* KCl, 0.1 *M* KCl, 1 *M* KCl, 0.06 *M* $BaCl_2$, 0.1 *M* $BaCl_2$, 0.5 *M* $BaCl_2$, 1 *M* $BaCl_2$, 0.06 *M* $LaCl_3$ and 0.9 *M* $LaCl_3$; curve B, 3 *M* KCl; curve C, 0.36 *M* $LaCl_3$, curve D, 1 *M* $LaCl_3$.

This is also the value of x. Since as temperature increases the curvature of the plot of $\bar{V}_t - \bar{V}_{25°}$ decreases, the value 5×10^{-7} represents a maximum value of both x and y. Now $\phi E_2 - \phi E_2'$ can be calculated, and it is found that for lanthanum chloride, the salt of largest M_2, the error involved in using the integral coefficient instead of the differential coefficient of expansion would be only 0.0001 cc. per mole per degree. This treatment applies to 0.06, 0.1 and 1 *M* KCl solutions, to 0.06, 0.1 *M* $BaCl_2$ and very nearly to the 0.5 and 1 *M* $BaCl_2$ solutions. It also applies to 0.06 and 0.09 *M* $LaCl_3$ solutions.

A further analysis is needed in the case of the rest of the solutions. An extreme case is the 1 molar lanthanum chloride solution (Curve D, Fig. 10). This curve falls considerably below the curve for water, approaching a straight line. Thus x will tend to become zero. If we assume that x is zero, the error will be approximately $W_w y$ or 0.0005 cc. per mole per degree. The assumption that x is zero is an extreme one since it is quite obvious that the curve for 1 molar lanthanum chloride is still slightly curved. Although 0.0005 cc. per mole per degree is an appreciable error since it is applicable for concentrated solutions and could not possibly influence the shape of the curves of ϕE_2 plotted against $c^{1/2}$ it is clear that a more complicated treatment is not justified.

Discussion of Results.—A study of Figs. 4, 5, and 6, in which the coefficient of expansion of solutions of potassium chloride, barium chloride and lanthanum chloride are plotted against the temperature, show that in all cases, within the range of temperature studied, 20° to 60° (or 80°) and throughout the range of concentrations studied it is true that

$$\frac{\partial V}{V\partial t} > 0, \quad \frac{\partial}{\partial t}\left(\frac{\partial V}{V\partial t}\right) > 0, \quad \frac{\partial^2}{\partial t^2}\left(\frac{\partial V}{V\partial t}\right) < 0$$

At 25° all three salts studied have the effect of increasing the coefficient of expansion of water; $(\partial/\partial c)(\partial V/V\partial t) > 0$. For each salt there is a particular temperature at which the coefficient of expansion becomes independent of the concentration; $(\partial/\partial c)(\partial V/V\partial t) = 0$. In the case of potassium chloride solutions and of barium chloride solutions this temperature is about 52°, whereas for lanthanum chloride solutions it is about 37°. At higher temperatures $(\partial/\partial c)(\partial V/V\partial t) < 0$ in all cases. A qualitative explanation may be that at lower temperatures the introduction of the ions causes a change in the structure of the water (a depolymerization) so as to permit a closer packing, similar to the effect caused by raising the temperature. Then when the temperature of the solutions is raised there is less opportunity for this shift in structure and therefore less compensation for the normal thermal expansion.

Gucker's limiting equations (7 and 14) predict that, at low concentrations, the apparent molal expansibility ϕE_2, should (1) be a linear function of $c^{1/2}$; (2) the slopes $\partial\phi E_2/\partial c^{1/2}$ should be positive; (3) the slopes should increase greatly for salts of higher valence types. An examination of Fig. 7, 8 and 9 and Table V shows that (1) the curves are not linear for any of the salts, although approximately so for potassium chloride. (2) At 25° the slopes are negative throughout the range of concentrations studied, although a study of the curves indicates the possibility that if sufficient precision could be obtained at lower concentrations the slopes might become positive. Raising the temperature tends to increase the slopes and at 55° or above the slopes are all positive. (3) The great influence of the valence type, which is predicted by the theory does not seem to be supported by the curves.

It is therefore concluded that it is not possible to confirm these predictions from Gucker's equation at the concentrations which can be successfully studied experimentally. A substantial further increase in precision would be necessary to obtain significant data in solutions so dilute that they could be used with confidence to test the validity of a limiting law.

Summary

1. A new type of precision dilatometer which also serves as the thermoregulator of its own thermostat is described.

2. The new instrument has been used to determine the thermal expansion of water over the interval from 20° to 80°. Values for the specific volume of water at ten-degree intervals have been computed from these data.

3. Coefficients of expansion of aqueous solutions of potassium chloride ranging in concentration from 0.06 to 2.9 molal have been mea-

sured at ten-degree intervals from 25° to 75°.

4. Coefficients of expansion of aqueous solutions of barium chloride and of lanthanum chloride ranging in concentration from 0.06 to 1 molal have been determined at ten-degree intervals from 25° to 55°.

5. The apparent molal expansibilities of potassium chloride, barium chloride and lanthanum chloride in aqueous solutions have been calculated and their significance in relation to Gucker's theoretical equations is discussed.

Conductivities of Quaternary Ammonium Chlorides Containing Two Long-chain Alkyl Groups

BY A. W. RALSTON, D. N. EGGENBERGER AND P. L. DU BROW

The concentration of colloidal electrolyte at the critical point for micelle formation has repeatedly been shown to decrease with increase in the chain length of the colloidal electrolyte. That this is true for the cationic colloidal electrolytes has been shown by a comparison of the equivalent conductivities of the alkylammonium chlorides of varying chain length[1] and of several of the alkyltrimethylammonium bromides.[2] It has recently been observed[3] that the position of the critical point is not materially influenced by the substitution of short-chain hydroxyalkyl groups for methyl groups in the higher alkyltrimethylammonium chlorides. The opinion has previously been expressed by Hartley[4] that the critical concentration is more dependent upon the chain length than upon the nature of the ionized groups. On the other hand, compounds which form two long-chain ions, such as octyltrimethylammonium octanesulfonate[5] and 1,1-dimethyl-3-hydroxybutylammonium caprylate,[6] form micelles at much lower concentrations than compounds which yield only one of the single long-chain, component ions. When we consider the long-chain alkyltrimethylammonium chlorides it appears that, although the replacement of methyl groups by other short-chain groups may not decidedly influence the electrical behavior, if a methyl group is replaced by a radical the chain length of which is comparable with that of the original long chain, such a substitution should be attended by a decided change in the conductivity values. We have, therefore, determined the equivalent conductivities of aqueous solutions of dioctyl-, didecyl-, didodecyl-, ditetradecyl-, dihexadecyl- and octyldodecyl-dimethylammonium chlorides and have compared the results with those obtained for several of the higher alkyltrimethylammonium chlorides. The comparisons have shown that significant differences exist between the conductivity behaviors of the higher dialkyldimethylammonium chlorides and those of the alkyltrimethylammonium chlorides. This comparison suggests that with the former the total number of carbon atoms in the long chains is determinative as regards their conductivity characteristics.

Experimental

Preparation of Dioctyl-, Didecyl-, Didodecyl-, Ditetradecyl- and Dihexadecyldimethylammonium Chlorides.—All the quaternary ammonium chlorides were similarly prepared. The preparation of didodecyldimethylammonium chloride will be described in detail as an example of the procedure employed.

Predistilled dodecylamine was carefully fractionated through a Stedman-packed column. In a two-necked flask fitted with a mercury-sealed stirrer and an air condenser, 212 g. of this distillate (f. p. 28.26°) and 8.5 g. of 50% Raney nickel suspended in dodecylamine were heated with stirring at 200° for two and one-half hours. The resulting product was taken up in ethyl acetate, the Raney nickel removed by filtration, and the didodecylamine crystallized from the solvent.

To 77 g. of the recrystallized didodecylamine dissolved in 200 cc. of ethanol, 49 cc. of 85% formic acid was slowly added, the temperature being maintained at about 40°. After this addition, 46 cc. of a 36% aqueous formaldehyde solution was added and the temperature raised to 60°. After the evolution of carbon dioxide had subsided, the temperature was maintained at the reflux point for one-half hour. The solution was then neutralized with aqueous sodium hydroxide, and the top layer was drawn off, dried over anhydrous potassium carbonate, filtered, and distilled (b. p. 183° at 0.35 mm.). The didodecylmethylamine so obtained (f. p. 10.4°) was dissolved in ethyl acetate, methyl chloride was added, and the mixture was heated in a bomb at 80° for one hour. The didodecyldimethylammonium chloride was recrystallized twice from ethyl acetate to give a white, crystalline, hygroscopic product. Dioctyldimethyl- and didecyldimethylammonium chlorides are extremely hygroscopic. This property was not observed with ditetradecyldimethyl- and dihexadecyldimethylammonium chlorides. The freezing points of the intermediate methyldialkylamines are as follows: methyldioctyl-, −30.1°; methyldidecyl-, −7.4°; methylditetradecyl-, 26.0°; and methyldihexadecylamine, 36.5–37.5°.

Preparation of Octyldodecyldimethylammonium Chloride.—To 102 g. of dodecyl chloride dissolved in 50 cc. of ethanol was added 38.7 g. of methylamine and the solution was heated in a bomb at 125° for eight hours. The contents of the bomb were neutralized with aqueous sodium hydroxide, the top layer dissolved in Skellysolve F, dried over anhydrous potassium carbonate, filtered, and the methyldodecylamine distilled. To 64 g. of distillate was added 56.3 g. of freshly distilled octyl bromide and the mixture was heated at 90° for five hours. One-half of the

theoretical amount of aqueous sodium hydroxide required for complete neutralization was added at the end of two and one-half hours and the remainder added slowly during the last two and one-half hours. The top layer was extracted with Skellysolve F, dried over anhydrous potassium carbonate, filtered, and the octyldodecylmethylamine distilled (b. p. 170° at 0.25 mm.). This distillate was converted to the quaternary ammonium chloride by heating with methyl chloride in a bomb at 80° for one hour. The product was recrystallized twice from cold ethyl acetate. Octyldodecyldimethylammonium chloride is very hygroscopic.

Conductivity Determinations.—Conductivities were determined in the manner and with the equipment previously described.[7] In order to eliminate errors due to adsorption the cell was brought into equilibrium with the various solutions before the conductance measurements were made.

Results and Discussion

The equivalent conductivities of aqueous solutions of dioctyldimethyl-, didecyldimethyl- and didodecyldimethylammonium chlorides at 30° are shown in Fig. 1. The most significant feature of these is the maxima which occur at concentrations between the critical points and infinite dilution. These inflections increase with increasing length of the alkyl chain, and with didodecyldimethylammonium chloride the equivalent conductivity at 0.0001 N is materially higher than that at infinite dilution. Similar maxima have been found to occur upon the addition of methanol to aqueous solutions of octadecylpyridinium chloride[8] and of ethanol to aqueous solutions of dodecylammonium chloride.[9] The occurrence of a maximum conductivity in dilute solutions of colloidal electrolytes was first observed by Hartley and associates,[10] who reported that at dilutions approximating 0.0004 N the conductivity of methylene blue is approximately 30% higher than at infinite dilution. A recent communication[11] has called attention to the presence of maxima in the conductivity curves of aqueous solutions of hexadecyl- and octadecylpyridinium iodates.

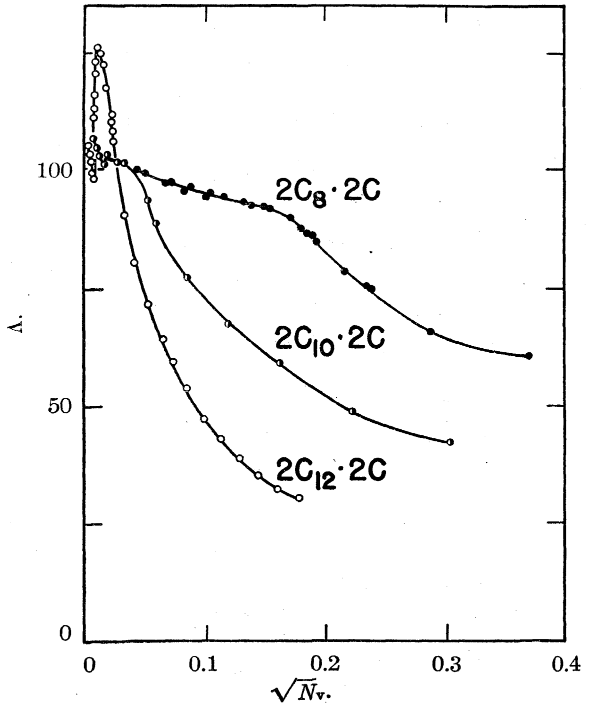

Fig. 1.—Equivalent conductivities of dialkyldimethylammonium chlorides at 30°.

The maxima in the curves shown in Fig. 1 occur at progressively lower concentrations with increase in the number of carbon atoms in the molecule. That the positions of these maxima are a function of the total number of carbon atoms in the two long alkyl chains is shown by a comparison of the equivalent conductivity curves of didecyl- and octyldodecyldimethylammonium chlorides, Fig. 2, both of which contain twenty carbon atoms in the two long alkyl chains. The close similarity of these curves is evident and in contrast to that of didodecyldimethylammonium chloride. Both ditetradecyldimethyl- and dihexadecyldimethylammonium chlorides, Fig. 3, show much larger equivalent conductivities in very dilute solutions than would be anticipated on the basis of their high molecular weights. Since these curves fall very abruptly and since even moderately concentrated solutions of these salts show low values for their equivalent conductivities, we are of the opinion that the high values of the very dilute solutions are evidence of the presence of maxima.

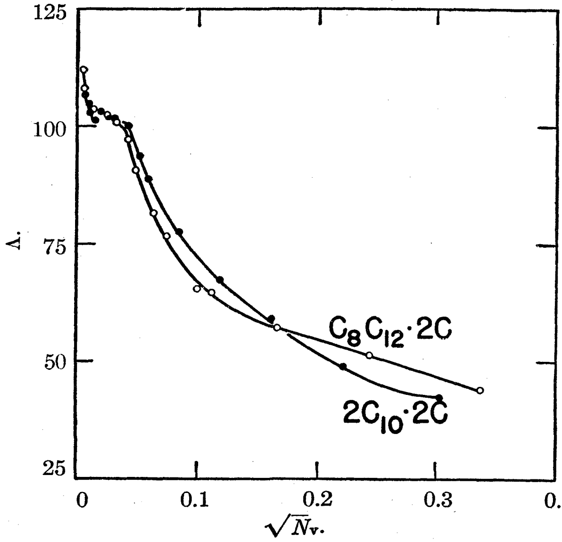

Fig. 2.—Equivalent conductivities of dialkyldimethylammonium chlorides at 30°.

The conductivity behaviors of the abovementioned compounds are strikingly different from those of the alkyltrimethylammonium chlorides which we have examined. These include do-

decyl-, tetradecyl-, hexadecyl- and octadecyltrimethylammonium chlorides. Figure 4 shows a comparison of the equivalent conductivity of dodecyltrimethylammonium chloride with that of didodecyldimethylammonium chloride and also of hexadecyltrimethylammonium chloride with dioctyldimethylammonium chloride. The latter comparison shows that the critical point occurs at a much lower concentration when the carbon atoms are in a single chain, although the curve for the dioctyldimethylammonium chloride shows evidence of a maximum which is not apparent with hexadecyltrimethylammonium chloride. None of the alkyltrimethylammonium chlorides which we have investigated has exhibited a maximum in its equivalent conductivity.

It has formerly been customary to consider the equivalent conductivity curves of colloidal electrolytes to be characterized by three ranges. In the first range the conductivity falls linearly with concentration, in the second range an abrupt drop is encountered, and in the third range the values either remain essentially constant or exhibit a slight rise. All workers are in agreement that this characteristic behavior of colloidal electrolytes is occasioned by the formation of associated particles; however, diverse opinions have been expressed as to the nature of these particles and the concentration at which they first appear. McBain[12] has held that associated ions are present in very dilute solutions, well within the first range, although Hartley[4] has stated that below the critical point for micelle formation the colloidal electrolyte functions as an ordinary strong electrolyte. The occurrence of maxima in the conductivity curves of the higher dialkyl quaternary ammonium chlorides indicates that association into ionic aggregates occurs at low concentrations followed by the formation of less-conducting micelles. This phenomenon can be attributed to the incorporation of undissociated molecules into the ionic aggregates. Since the present study has been confined to a limited number of compounds of a specific type we are not justified in drawing extensive conclusions. High hydrocarbon loading of the molecule apparently favors the formation of maxima, and a number of unpublished observations on long-chain cationic electrolytes lead us to believe that this phenomenon is frequently encountered.

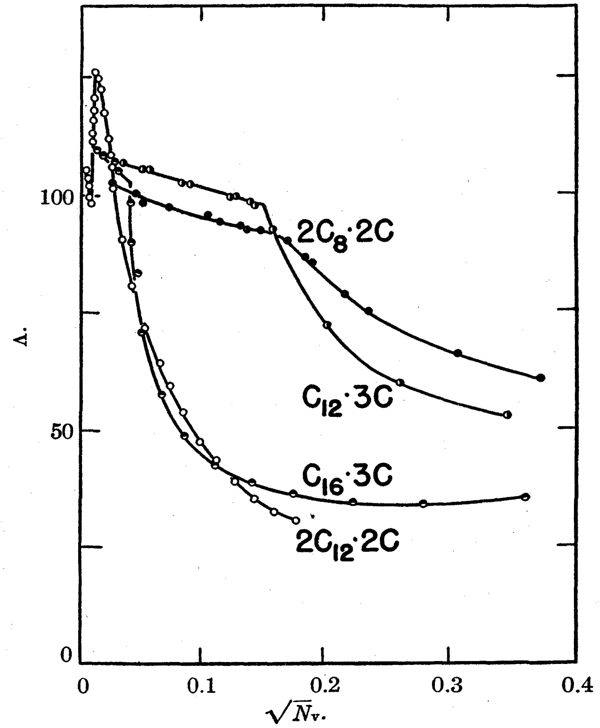

Fig. 4.—Comparison of equivalent conductivities of alkyltrimethylammonium chlorides at 30°.

Summary

The equivalent conductivities of dioctyl-, didecyl-, didodecyl-, ditetradecyl-, dihexadecyl- and octyldodecyldimethylammonium chlorides have been determined. Didodecyldimethylammonium chloride shows a maximum value at concentrations below the critical point and evidences of maxima are also present with both its lower and its higher homologs.

The conductivity behavior of the dialkyldimethylammonium chlorides has been compared with that of several alkyltrimethylammonium chlorides.

The Effects of Electrolytes upon the Conductivity of Aqueous Solutions of Dodecylammonium Chloride[1]

BY A. W. RALSTON AND D. N. EGGENBERGER

The presence of electrolytes is known to have a significant effect upon the behavior of aqueous solutions of colloidal electrolytes. In general, the effect of added salts is to magnify the colloidal properties of the colloidal electrolyte. This manifests itself in a lowered conductivity on the part of the colloidal electrolyte, a lowered concentration of colloidal electrolyte at the critical point, and an increased solvent power for a number of organic non-electrolytes. Several observations of these effects have been recorded in the literature. For example, it has been shown[2] that an increase in the sodium ion concentration materially reduces the concentration of sodium dodecyl sulfate at the critical point for micelle formation. Tartar and Cadle[3] have shown that the presence of sodium chloride reduces the aqueous solubilities of sodium dodecyl sulfate and sodium tetradecyl sulfate and increases their tendencies toward micelle formation. Hartley[4] has observed that the solubility of azobenzene in aqueous solutions of hexadecylpyridinium chloride is greatly increased by the presence of sodium chloride. The addition of salts to both dilute and concentrated soap solutions has been shown by McBain and co-workers[5] to materially increase the solubilizing power of such solutions for water-insoluble dyes. The osmotic studies of McBain and Brady[6] showed that the presence of either potassium chloride or potassium sulfate promotes micelle formation in aqueous solutions of potassium laurate. Quite recently, Corrin and Harkins[7] have described a method by which the critical point can be determined by titration with an aqueous dye solution, the critical concentration being indicated by a visual color change in the dye. This method was employed in an investigation[8] of the effect of the addition of electrolytes upon the critical concentrations of a number of anionic and cationic electrolytes. It was stated that the critical concentration is affected only by the concentration of the ion opposite in charge to that on the colloidal aggregate and that the concentration and nature of the other ion is without effect. More recently, however, Harkins and associates[9] have observed that the increase in solubilizing power of soap solutions upon the addition of an electrolyte is dependent upon both the nature of the cation and the anion of the added salt. This present study reports the effects of several electrolytes upon the equivalent conductivity of aqueous solutions of dodecylammonium chloride. The effects observed are undoubtedly associated with the colloidal behavior of this amine salt.

Experimental

The preparation and properties of the dodecyl- and hexadecylammonium chlorides used in this investigation have been described elsewhere.[10] The conductivities were determined in the manner and with the equipment previously described.[11] The conductivity by difference was calculated by substracting the specific conductance of the added electrolyte from the specific conductance of the solution containing the electrolyte and the amine salt. For example, if a 0.005 *N* sodium chloride solution is employed as the solvent the specific conductance of this solution is subtracted from the observed values.

Results and Discussion

The conductivities of aqueous solutions of dodecylammonium chloride at 30° and the conductivities by difference of this colloidal electrolyte in 0.005 *N* and 0.015 *N* sodium chloride are shown in Fig. 1. The material reduction in equivalent conductivity of the amine salt occasioned by the presence of sodium chloride is clearly evident. This effect can be attributed to the increased chlorine ion concentration which reduces the ionization of the amine salt, the marked reduction of the critical concentration evidencing the presence of undissociated molecules at lower concentration of colloidal electrolyte. The magnitude of this common ion effect may overshadow other changes produced in the system by the presence of the sodium chloride such as dehydration of the micelles resulting from the lowered partial pressure of the water or any possible effects of the sodium ions. If the predominant influence of the sodium chloride is to retard the ionization of the amine salt a similar effect should be noted when the amine salt is a non-colloidal electrolyte. Figure 2 shows that the addition of sodium chloride to a solution of hexylammonium chloride materially lowers the conductivity attributable to the amine salt.

A somewhat more involved problem is presented when we study the effect of electrolytes which do not possess an ion in common with the amine salt.[12] Much of the previous work upon the effect of salts on the physical behavior of solutions of colloidal electrolytes has been confined to salts having an ion in common with the colloidal electrolyte and the common ion effect has been used as the basis for interpretation of many of the observed phenomena. On the other hand, Corrin and Harkins[8] have shown that salts not possessing an ion in common with the colloidal electrolyte are as effective in lowering the critical concentration as those which have a common ion. Figure 3 shows the conductivity by difference at 30° of dodecylammonium chloride in 0.0261 *N* sodium acetate, 0.0169 *N* potassium acetate, and 0.0107 *M* calcium acetate. These salt concentrations were selected because they possess specific conductances comparable with the previously employed 0.015 *N* sodium chloride solution. The effects of these three salts upon the equivalent conductance of the colloidal electrolyte are approximately equal and are comparable with that of the 0.015 *N* sodium chloride solution. This indicates that the effect of a salt not possessing an ion in common with the colloidal electrolyte is similar to that of one which contains a common ion. It also shows that, for the salts investigated, the effect of the salt upon the electrical behavior of the cationic electrolyte is independent of the nature and concentration of the cation of the added salt.

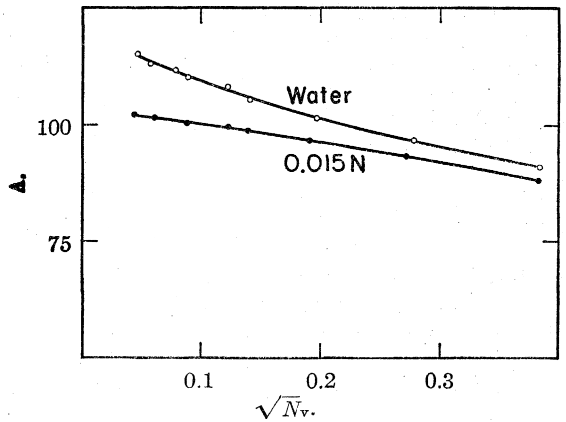

Fig. 2.—Conductance by difference of hexylammonium chloride at 30° in sodium chloride.

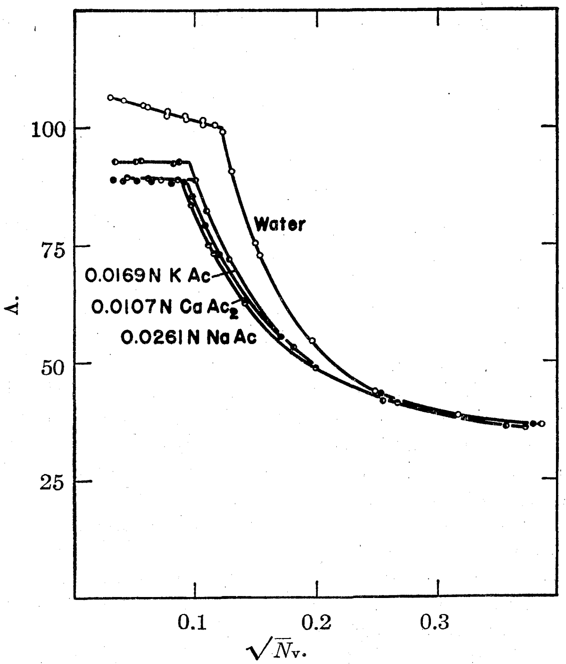

Fig. 3.—Conductance by difference of dodecylammonium chloride at 30° in presence of acetates.

The first of these conclusions is explainable on the basis of a general consideration of the behavior of solutions of colloidal electrolytes. Such solutions differ from solutions of ordinary electrolytes in that at a certain critical concentration the ions and undissociated molecules associate into colloidal particles. For colloidal electrolytes of similar structure the concentration at which this phenomenon occurs is a function of the chain length. The X-ray studies made by Harkins, Mattoon and Corrin[13] on aqueous solutions of mixtures of potassium laurate and potassium myri-

state show only one maximum which is intermediate between the maxima exhibited by the pure soaps. Figure 4 shows the equivalent conductivities at 30° of solutions of pure dodecylammonium chloride and dodecylammonium acetate and of mixtures of these amine salts. These results show that the micelles formed from a solution of dodecylammonium chloride and its acetate incorporate both components and that the position of the critical point is not influenced by the nature of the anion. This is in conformity with previous observations[14] that the concentration of colloidal electrolyte at the critical point is a function of the chain length. When sodium acetate is added to an aqueous solution of dodecylammonium chloride an equilibrium will be set up which involves both the chloride and acetate of the colloidal electrolyte and, as a consequence, both the chloride and acetate ions are common to the components of the micelles. A similar situation will result when any salt is added to a solution of a colloidal electrolyte.

In view of the above-described effect of salts, it is surprising to find that the addition of acids to solutions of dodecylammonium chloride has only a negligible effect upon the position of the critical point. Figure 5 shows that, although the conductivities by difference at 30° of dodecylammonium chloride in 0.00145 and 0.00428 *N* hydrochloric acid are materially lower than that of the salt in pure water, the position of the critical point is not materially shifted. The lowered conductivity can be ascribed to depression of the ionization of the colloidal electrolyte, since it was observed that the conductivity by difference of the non-colloidal electrolyte, hexylammonium chloride, in 0.0043 *N* hydrochloric acid is appreciably lower than its conductivity in pure water. We have no present explanation as to why this effect is not attended by a more significant shift in the critical concentration of the colloidal electrolyte.

The conductivities by difference of dodecylammonium chloride at 30° in 0.15 and 1.43 *N* acetic acid compared to that of the pure salt are shown in Fig. 6. It will again be noted that the addition of acetic acid does not influence the position of the critical point. At concentrations of dodecylammonium chloride beyond the critical point, the presence of acetic acid brings about an appreciable increase in the conductivity attributable to the colloidal electrolyte. It must, however, be borne in mind that the conductivity by difference incorporates all changes brought about in the system as a whole. Incorporation of undissociated dodecylammonium acetate into the micelles will remove it from solution and will result in an appreciable conversion of dodecylammonium chloride to its acetate. The increased conductivity may possibly be attributed to the simultaneous formation of hydrochloric acid attending this conversion.

The effect of tartaric acid upon the conductivity of dodecylammonium chloride is shown in Fig. 7 which compares the conductivity of the amine salt at 30° in pure water with its conductivity by difference in 0.0091 *N* tartaric acid. At concentrations higher than the critical point the effect

---

(14) Ralston and Hoerr, *ibid.*, **69**, 883 (1947).

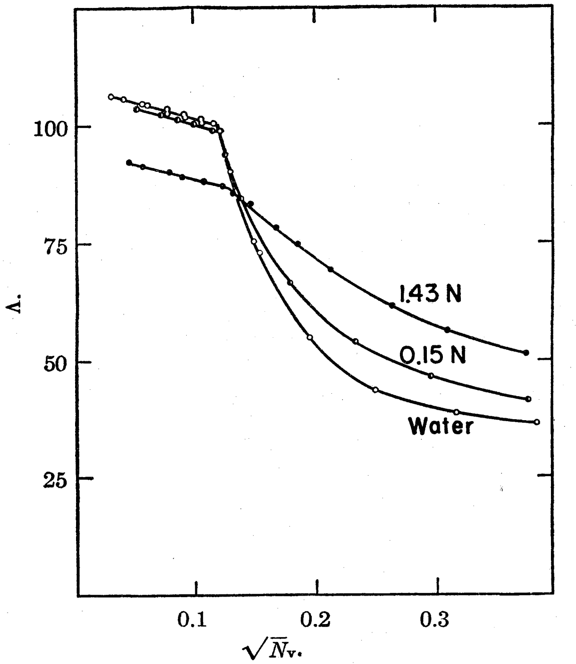

Fig. 6.—Conductance by difference of dodecylammonium chloride in acetic acid at 30°.

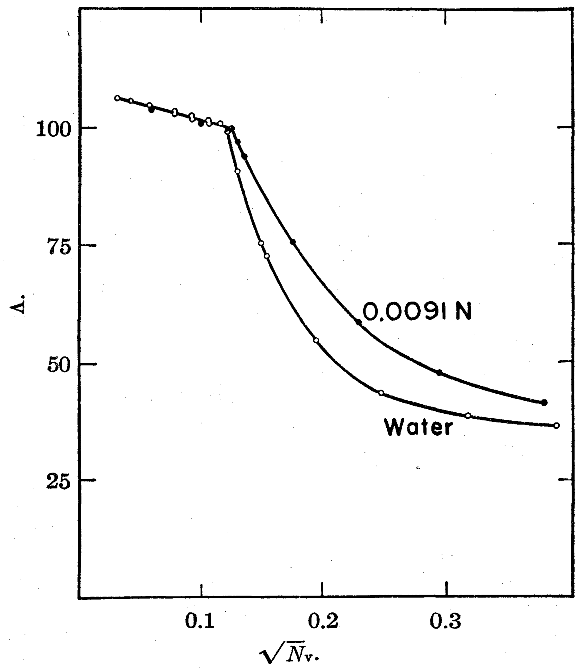

Fig. 7.—Conductance by difference of dodecylammonium chloride in tartaric acid.

of tartaric acid is qualitatively similar to that of acetic acid; however, at lower concentrations the presence of tartaric acid does not influence the conductivity of the colloidal electrolyte. In conformity with this latter observation we have found that the presence of tartaric acid does not lower the conductivity of aqueous solutions of the non-colloidal electrolyte, hexylammonium chloride.

The above observations show that the effect of the addition of acids upon the conductivity of dodecylammonium chloride differs in several respects from the effects resulting from the additions of salts. We have no present explanation for this difference and feel that much more work is required before any explanation should be attempted.

Summary

The effect of the presence of sodium chloride, sodium acetate, potassium acetate, calcium acetate, hydrochloric acid, acetic acid and tartaric acid upon the equivalent conductivity of aqueous solutions of dodecylammonium chloride has been determined.

The results have been discussed in relation to the micelle theory.

The Effect of Organic Non-electrolytes upon the Conductivities of Aqueous Solutions of Cationic Colloidal Electrolytes

BY A. W. RALSTON AND D. N. EGGENBERGER

The ability to solubilize water-insoluble organic non-electrolytes is one of the characteristic properties of aqueous solutions of colloidal electrolytes.[1] McBain and co-workers have made extensive investigations of the solubilization of water-insoluble dyes,[2,3,4] water-insoluble organic liquids,[5] and of hydrocarbon vapors[6] by aqueous solutions of colloidal electrolytes. In 1939, Kiessig and Philipoff[7] observed an increase in the size of the micelles of sodium oleate upon the addition of benzene to aqueous solutions of this soap and this has been subsequently interpreted[3] as indicating that the solubilized material is incorporated in layers within the micelles. A recent X-ray investigation[8] has shown that the thickness of micelles of potassium laurate or potassium myristate

is materially increased by the presence of hydrocarbons such as hexane, benzene or ethylbenzene. The recent work of Harkins and associates[9] has given support to the opinion previously expressed by Hartley[1] that solubilization does not occur below the critical point for micelle formation. Factors such as molecular volume, molecular weight, polarity, and structure exert a marked influence upon solubilization.

Many conductivity measurements upon aqueous solutions of colloidal electrolytes have been published. It is universally accepted that the colloidal electrolytes exhibit conductivity behaviors which distinguish them from ordinary electrolytes. Since solubilization is occasioned by the incorporation of water-insoluble substances into the micelles, it follows that this process should materially influence the conductivities of solutions of colloidal electrolytes. We have, therefore, made a study of the effect of the presence of a number of organic non-electrolytes upon the conductivities of several cationic colloidal electrolytes. The data permit certain generalizations regarding the phenomenon of solubilization and also allow certain speculations regarding the mechanism of micelle formation in aqueous solutions of colloidal electrolytes.

Experimental

The preparation of the hexadecyltrimethylammonium chloride used in this study has been previously described.[10] The dodecyltrimethylammonium chloride was prepared by a similar procedure. The dodecylammonium chloride was from the same lot as that previously employed in recent conductivity determinations.[11] Conductivities were determined in the manner and with the equipment previously described.[12] In all cases the solution of the colloidal electrolyte was saturated with the organic non-electrolyte. This was accomplished by progressively adding the non-electrolyte to the solution, vigorously shaking, and allowing the system to come to equilibrium at the temperature of the determination. In several instances this process required from twelve to forty-eight hours. Excess of non-electrolyte is indicated by the formation of a separate layer which was removed. Conductivity water was used for dilution; however, in all cases care was exercised to make certain that the solution was saturated with the non-electrolyte. All the curves were checked by determining the conductivity of individually prepared samples, and the cell was permitted to come to equilibrium with the solution before any conductivity values were recorded.

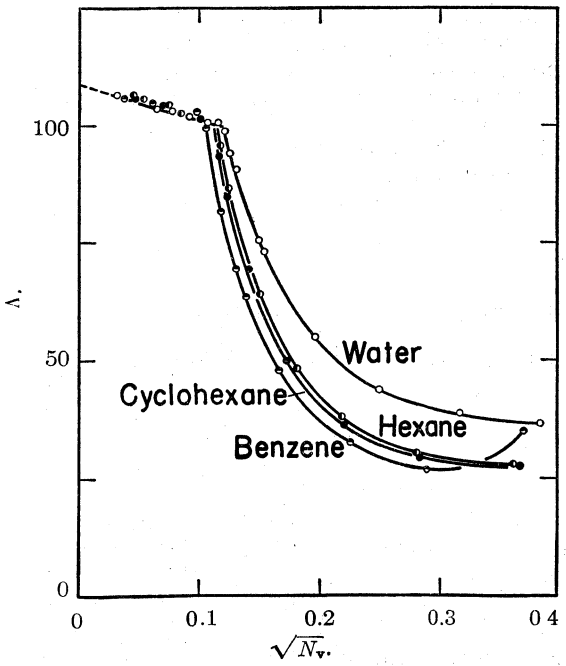

Fig. 1.—Equivalent conductivities at 30° of dodecylammonium chloride in the presence of six-carbon-membered hydrocarbons.

Results and Discussion

The three six-carbon-membered hydrocarbons, *n*-hexane, benzene, and cyclohexane are solubilized in an aqueous solution of dodecylammonium chloride and Fig. 1 shows that their presence brings about an appreciable lowering of the conductivity of the colloidal electrolyte. It is interesting to note that all three of these hydrocarbons lower the concentration at the critical point which indicates that they assist in micelle formation. This is in agreement with the previous observations of McBain and others[2,13] that the presence of water-insoluble, organic, non-electrolytes lowers the critical concentration for micelle formation. The effect of hexane is less than that of benzene, whereas that of cyclohexane is intermediate. This shows that either the benzene is solubilized to a somewhat greater extent than cyclohexane or its effect when incorporated into the micelles is greater. In any event, the curves indicate that the structure of the compound solubilized is a factor in its effect upon the conductivity. The fact that the presence of these hydrocarbons lowers the critical point is explainable on the basis of their affinity for the hydrocarbon portion of the associated ions. Solubility determinations of benzene and cyclohexane in dodecane[14] show that both are extremely soluble in this hydrocarbon; however, the former is somewhat less soluble than the latter.

The influences of the higher straight chain hydrocarbons, octane, dodecane, heptadecane and octadecane upon the equivalent conductivity of

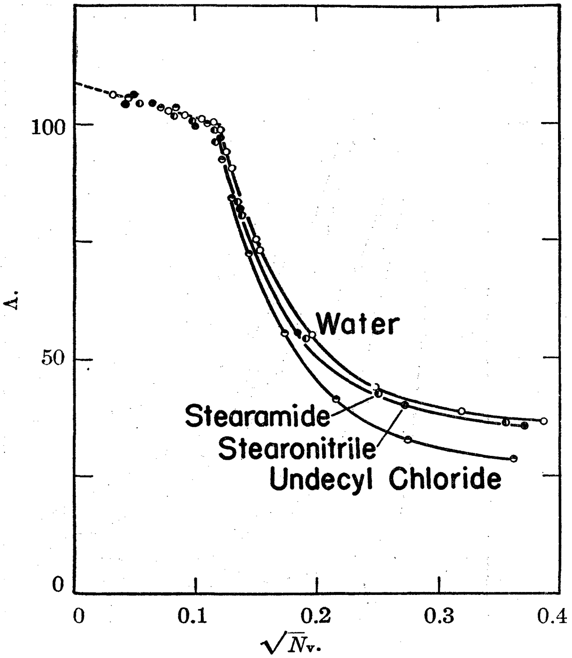

Fig. 3.—Equivalent conductivities at 30° of dodecylammonium chloride in the presence of polar aliphatic compounds.

dodecylammonium chloride are shown in Fig. 2. It is evident that their effects are appreciably less than those of the six-carbon-membered hydrocarbons, and that they decrease progressively with increase in chain length. Both heptadecane and octadecane are without apparent effect on the equivalent conductivity of this colloidal electrolyte. This shows that increase in chain length of the hydrocarbon is attended by a drastic reduction in its ease of solubilization and is in conformity with the previous findings of McBain and Richards[5] that hydrocarbons of high molecular weight are scarcely solubilized. An important observation with regard to the effect of hydrocarbons is that their presence does not significantly influence the conductivity values at concentrations lower than the critical concentration for micelle formation.

If the long-chain compound possesses a polar group, its presence lowers the equivalent conductivity of dodecylammonium chloride. Figure 3 shows that both stearonitrile and stearamide lower the conductivity of this amine salt, in contrast to octadecane, Fig. 2, which was observed to be without effect. The lowering of the conductivity by the presence of undecyl chloride, Fig. 3, is quite similar to that produced by octane and substantially greater than that resulting from the presence of dodecane, Fig. 2. This shows that even though the corresponding hydrocarbon is solubilized, the presence of a polar group increases either the amount of solubilization or the specific conductivity effect. None of the compounds shown in Fig. 3 appear to exert a significant influence on the conductivity of the amine salt at concentrations lower than the critical concentration for micelle formation. This is contrary to our previously published results[15] which reported that dodecane, lauronitrile and N-methyllauramide lower the conductivity of aqueous solutions of dodecylammonium chloride at concentrations below the critical point.

The higher alcohols, hexanol, octanol, dodecanol and octadecanol have a profound influence upon the conductivity of dodecylammonium chloride. Figure 4 shows that these alcohols decidedly lower the conductivity over the entire range of concentration, the lowering being at a maximum with dodecanol and at a minimum with octadecanol. As the concentration of the amine salt is increased all these solutions go from milky liquids to sirupy liquids and finally to gels. We interpret these results as indicating that long-chain compounds which contain a hydrophilic group are not only solubilized but that they can also enter into the structure of the ionic micelles and thus assist in the solubilization process. McBain and McHan[16] have ascribed the solubilization of dodecyl alcohol in solutions of potassium laurate to the polar portion of the detergent.

The effect of the presence of organic nonelectrolytes upon two long-chain alkyltrimethylammonium chlorides has been investigated. The results obtained with aqueous solutions of hexadecyltrimethylammonium chloride in the presence

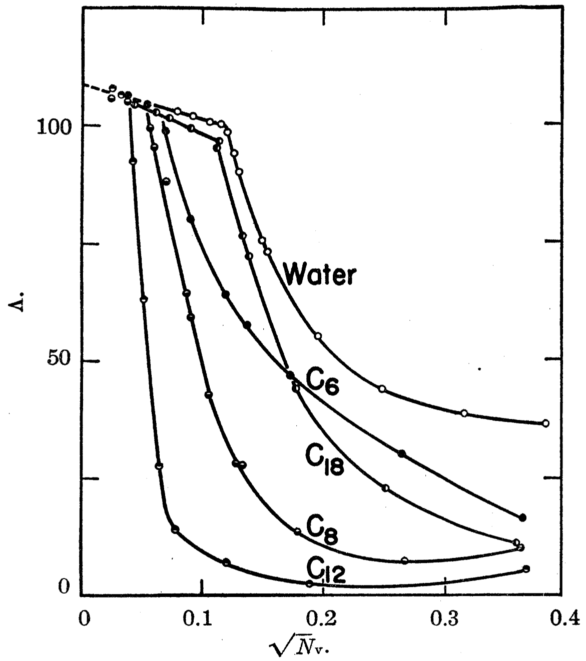

Fig. 4.—Equivalent conductivities at 30° of dodecylammonium chloride in the presence of aliphatic alcohols.

of dodecane, octadecane and lauronitrile agree quite closely with those which would be expected from the above-described observations upon dodecylammonium chloride. Figure 5 shows that the presence of dodecane and lauronitrile lowers the equivalent conductivity of aqueous solutions of dodecyltrimethylammonium chloride. The polar compound exerts the greater effect, and although both compounds lower the critical concentration, they do not significantly influence the conductivity within the first range. These results are qualitatively similar to those observed with dodecylammonium chloride and indicate that the presence of the methyl groups in the colloidal electrolyte is without material influence.

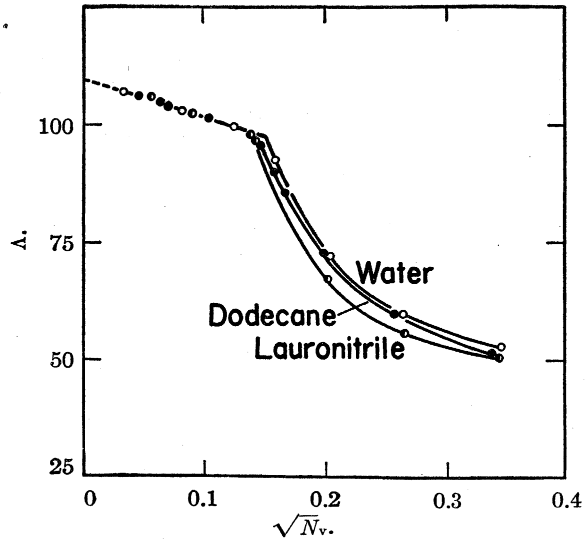

Fig. 5.—Equivalent conductivities of dodecyltrimethylammonium chloride in the presence of dodecane and lauronitrile.

In the above discussion we have assumed that the observed results are dependent upon the incorporation, by solubilization or otherwise, of the organic non-electrolytes into the colloidal aggregates. Although this assumption appears reasonable it certainly requires experimental verification. As a consequence, we have determined the effect of the presence of several organic non-electrolytes upon the conductivity of aqueous solutions of hexylammonium chloride. This salt has been previously shown[17] to function as an ordinary electrolyte even in concentrated solutions. Since it does not form micelles the conductivity of its aqueous solutions should not be influenced by the presence of water-insoluble substances. Figure 6 shows the conductivities of aqueous solutions of hexylammonium chloride and of solutions of this salt in the presence of dodecane, dodecanol, lauronitrile and N-methyllauramide. None of these compounds influence the equivalent conductivity of this amine salt and we are, therefore, safe in assuming that the effects noted above with its higher homologs are dependent upon the colloidal nature of the latter.

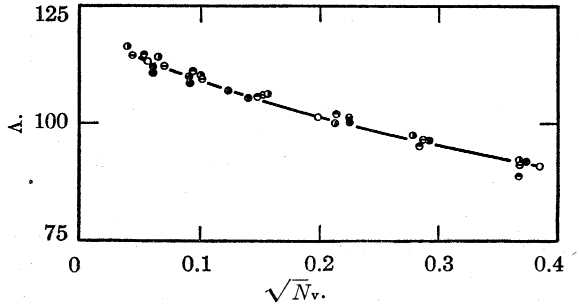

Fig. 6.—Equivalent conductivities of hexylammonium chloride in the presence of non-electrolytes: ○, hexylammonium chloride; ⊖, methyllauramide; ◑, lauronitrile; ●, dodecanol; ◓, dodecane.

The phenomenon of solubilization appears to be of more fundamental significance than has hitherto been considered. The fact that the critical concentration for micelle formation in solutions of colloidal electrolytes is materially lowered by the presence of water-insoluble organic non-electrolytes indicates that the effect is more complex than a simple incorporation of the water-insoluble substance into a previously formed micelle. It is, therefore, possible that solubilization and micelle formation are allied phenomena. As the concentration of an aqueous solution of a colloidal electrolyte is increased, the number of undissociated molecules also increases and these undissociated molecules function as non-electrolytes. Their inclusion into the ionic micelles would be attended

[17] Ralston and Hoerr, *ibid.*, **68**, 2460 (1946).

by a marked and abrupt drop in the equivalent conductivity and by an abnormal increase in the cationic transference number in the case of the cationic colloidal electrolytes. It is well known that both of these effects are observed in aqueous solutions of colloidal electrolytes. The essential difference between ionic and lamellar micelles is that the latter has solubilized the undissociated colloidal electrolyte.

Transference data on the effect of non-electrolytes upon solutions of colloidal electrolytes would be extremely helpful in explaining the mechanism of micelle formation and studies are now underway to determine the effect of various non-electrolytes upon the transference numbers of solutions of dodecylammonium chloride.

Summary

The effect of the presence of benzene, cyclohexane, hexane, octane, dodecane, heptadecane, octadecane, hexanol, octanol, dodecanol, octadecanol, undecyl chloride, stearonitrile and stearamide upon the equivalent conductivity of aqueous solutions of dodecylammonium chloride has been determined. The influence of the presence of dodecane and lauronitrile upon the equivalent conductivity of aqueous solutions of dodecyltrimethylammonium chloride has also been investigated.

With the exception of heptadecane and octadecane all the compounds investigated lowered the equivalent conductivity and the critical concentration for micelle formation in the amine salt solutions.

The results have been discussed in relation to the micelle theory and it has been proposed that solubilization and micelle formation are allied phenomena.

The Dissociation of Diborane by Electron Impact

BY VERNON H. DIBELER AND FRED L. MOHLER

Introduction

The theory of the structures of some electron-deficient molecules, the hydroborons in particular, have recently received considerable attention. In 1942 the most fully developed valence theory of the hydroborons, as reviewed by Bauer,[1] assumed hydrocarbon-like structures. Because of inconsistencies between the hydrocarbon analogy and chemical and physical properties, Pitzer[2] and others further developed the four-membered-bridge bond originally proposed by Dilthey[3] to a "protonated double bond" theory in which two protons are placed symmetrically between the boron atoms, one above and one below an ethylene-like double bond. More recently, Burg,[4] in order to account for the lack of proton–deuteron exchange between ammonia and ammoniated diborane, proposed a "pseudoethane" structure in the form of a trigonal antiprism in which two sp^2 planar BH_3 groups are held together by resonating cross linkages between the B–B and B–H atoms. Another structure which he considers possible is a four-proton-bridge model in which the two boron atoms and four of the hydrogen atoms form the corners of a cube. The remaining two hydrogens extend outward along the diagonal of the cube connecting the two boron atoms.

Rundle[5] accepts Pitzer's developed theory in the case of the hydroborons with an interpretation of the protonated double bond as two hydrogen bridges consisting of "half-bonds." Each hydrogen bonds two boron atoms using its ls-orbital and one electron pair. Thus, the bridge contains two pairs of electrons and should have the properties of the ethylene-like double bond.

Hipple[6] has published a note on the mass spectrum of diborane. An analysis of this mass spectrum made by the authors differs significantly from the results reported by Hipple. As the results have a direct bearing on the structure of the diborane molecule we report in detail the analysis of this spectrum as compared with the mass spectra of ethane and ethylene.

Experimental

The Consolidated mass spectrometer used to obtain the mass spectra has been described elsewhere in detail.[7] The gas to be studied is admitted to the ionization chamber at about 10^{-4} mm. pressure and ionized by a beam of electrons at 50 or 70 electron volts energy. The positive ions formed in the electron beam are accelerated by an electric field and sorted into 180° arcs by a constant magnetic field used as a velocity analyser. By varying the electric field the ions are separately collected and recorded. The ionizing current is automatically maintained constant and the ionization chamber is thermostated to maintain a temperature of about 245°. Two samples of diborane were obtained. Sample 1 was prepared at the U. S. Naval Research Laboratory and supplied by Roman R. Miller. About 25 ml. of gas (S.T.P.) were removed from the liquid phase and transferred from the stainless steel cylinder into a glass bulb. The glass bulb was stored at −78° to minimize decomposition to hydrogen and heavy hydroborons. A mass spectrometric analysis of the original sample showed a purity of about 99.4% with small amounts of tetraborane, ethane and diethyl ether. Sam-

ple 2 was prepared at the University of Southern California by Anton B. Burg. The sample of about 70 ml. at slightly above atmospheric pressure was shipped by air-express in a glass tube with an inner break-off seal. Upon arrival it was stored under the same conditions as Sample 1. Except for a small amount of hydrogen, Sample 2 showed no impurities volatile at −78°. An additional precaution was taken by cooling both samples to −183° and pumping off accumulated hydrogen before each run.

The ethylene and ethane were Phillips Petroleum Company "Research Grade" hydrocarbons.

Results

The mass spectrum of diborane permits a determination both of the isotope abundance ratio of boron and the monoisotopic spectrum of diborane. By trial approximations on Sample 1 it was found that an abundance ratio $B^{10}/B^{11} = 0.251$ gives the best fit with the observed spectrum. In the same manner, Sample 2 showed a ratio $B^{10}/B^{11} = 0.256$. The former value is in good agreement with a value of 0.250 obtained in this Laboratory from the boron trifluoride spectrum. It is not in agreement, however, with a value of 0.232 found by Inghram.[8] It seems probable that there are real differences in the isotope ratio depending on the previous history of the sample used in the experiments. For Sample 1, using the ratio $B^{10}/B^{11} = 0.251$, one derives the abundance ratios $B^{10}B^{11}/B_2^{11} = 2 \times 0.251 = 0.502$, and $B_2^{10}/B_2^{11} = 0.063$. To separate the mixture spectrum into monoisotopic spectra (Table I), one can start at the heavy mass end and use these ratios to compute the contribution of each B_2 and B_1 ion to each value of m/e. The peak at $m/e = 28$ is due entirely to the $B_2^{11}H_6^+$ ion; hence, the $B^{10}B^{11}H_6^+$ ion ($m/e = 27$) is $0.65 \times 0.502 = 0.33$ and the $B_2^{10}H_6^+$ ion ($m/e = 26$) is $0.65 \times 0.063 = 0.04$. The $B_2^{11}H_5^+$ ion ($m/e = 27$) is then $97.28 - 0.33 = 96.95$. From this in turn, the $B^{10}B^{11}H_5^+$ ion ($m/e = 26$) and the $B_2^{10}H_5^+$ ion ($m/e = 25$) are similarly computed. Again, the $B_2^{11}H_4^+$ ion is calculated by difference and the cycle is repeated until all contributions to each peak are computed. There are three checks on the computations. The mass 21 peak is calculated to be 1.94 compared with 2.02 observed. The mass 20 peak agrees exactly with the calculations while the mass 10 peak is computed as 6.47 compared with 6.48 observed. A small change in the B^{10}/B^{11} ratio, *e. g.*, 0.251 to 0.253, materially increases the residuals. A similar calculation for sample 2 using $B^{10}/B^{11} = 0.256$ shows equally good agreement between computed and observed peaks.

TABLE I

SUMMARY OF THE MONOISOTOPIC SPECTRUM CALCULATIONS OF THE SAMPLE 1 MASS SPECTRUM FOR 50-VOLT ELECTRONS

		Monoisotopic spectrum[a]				
m/e	Mixture spectrum	$B^{10}H_x$	$B^{11}H_x$	$B_2^{10}H_x$	$B^{10}B^{11}H_x$	$B_2^{11}H_x$
10	6.48	6.47	0	..	...	...

[a] "*x*" assumes integral values from zero to six.

The polyisotopic diborane dissociation pattern is now obtained by summing the contributions of all ions with the same number of hydrogen atoms regardless of isotopic species. The most abundant ion ($m/e = 27$) is given the value of 100. Other ion abundance values are relative to $m/e = 27$. Table II gives these patterns for 50 and 70-volt energies of the ionizing electrons.

TABLE II

DISSOCIATION PATTERNS OF DIBORANE, ETHYLENE AND ETHANE AT IONIZING VOLTAGES OF 50 AND 70 VOLTS

	Diborane			Ethylene		Ethane	
Ion	50 v.	70 v.	Ion	50 v.	70 v.	50 v.	70 v.
H^+	3.91	3.98	H^+	3.85	4.11	2.14	2.58
H_2^+	2.72	2.71	H_2^+	0.52	0.51	0.22	0.30
B^+	21.2	21.0	C^+	1.73	2.14	0.42	0.56
BH^+	10.2	10.6	CH^+	3.19	3.48	0.96	1.19
BH_2^+	19.9	19.5	CH_2^+	6.16	6.24	3.00	3.41
BH_3^+	0.55	0.62	CH_3^+	0.56	0.54	4.48	4.62
B_2^+	3.05	3.43	C_2^+	3.01	3.71	0.49	0.75
B_2H^+	7.74	7.00	C_2H^+	11.5	11.7	3.47	4.13
$B_2H_2^+$	78.4	76.8	$C_2H_2^+$	61.1	61.9	23.1	23.7
$B_2H_3^+$	27.0	26.2	$C_2H_3^+$	62.1	64.7	33.1	33.5
$B_2H_4^+$	52.9	52.6	$C_2H_4^+$	100	100	100	100
$B_2H_5^+$	100	100	$C_2H_5^+$			21.6	21.7
$B_2H_6^+$	0.67	0.64	$C_2H_6^+$			24.9	24.7

The dissociation patterns obtained for both samples were very similar. Except for the $B_2H_6^+$ ion, the maximum deviation was about 3% (B_2H^+ ion). The disagreement of the $B_2H_6^+$ ion (0.49 compared to 0.67) may be due to a small amount of impurity in the latter sample.

The results differ from the published data of Hipple in several respects. The peaks at masses 11, 12, and 13 are unambiguously interpreted in terms of BH^+ and BH_2^+ polyisotopic ions of abundance 10.6% and 19.5% at 70 volts while Hipple reported BH^+ as zero and BH_2^+ as uncertain. We find a small $B_2H_6^+$ peak of about 0.5% while he reported it as 0 or less than 0.1%. The B_2H^+ ion abundance is 7% here as compared with 2.9%. We have measured the mass pattern at 100 volts and find only minor changes as compared with 50 and 70 volts. Hipple's measurements were at 90 volts. A more important difference in the experiments is that Hipple used an ionization chamber at about room temperature while ours operated at 245°. Relative intensities of mass spectra always depend on the temperature and in diborane there may be some thermal dissociation in the ioniza-

---

(8) M. Inghram, *Phys. Rev.*, **70**, 653 (1946).

tion chamber. It is known that above 100° at pressures of the order of an atmosphere boron and solid boron hydrides of higher molecular weight begin to form (Gmelin's "Handbook"). The mass spectra show that there is no production of heavier boron hydrides within the ionization chamber.

For comparison with ethane and ethylene, the dissociation patterns of these molecules taken under similar conditions are also given in Table II.

Omitted from Table II for the sake of brevity, is a small peak in diborane at $m/e = 11.5$ amounting to 0.39% of the maximum peak at 50 volts and 0.43% at 70 volts. This is a doubly charged ion of mass 23 and can be either $B_2^{11}H^{++}$ or $B^{10}B^{11}H_2^{++}$ or both. These ions give other peaks coincident with the large peaks at $m/e = 11$ and $m/e = 12$. The $B_2^{10}H^{++}$ ion, expected at $m/e = 10.5$ is too small to observe so there is no basis for a unique interpretation of the peak at $m/e = 11.5$. The contribution of these doubly charged ions to peaks 11 and 12 is too small to introduce any serious uncertainty in the computation of monoisotopic spectra. Ethylene shows a small peak at $m/e = 13.5$ due to the $C_2H_3^{++}$ ion which is 0.41% of the maximum peak at 70 volts. Ethane shows two peaks at $m/e = 13.5$ and $m/e = 14.5$ due to the $C_2H_3^{++}$ ion and the $C_2H_5^{++}$ ion. The abundances are 0.07 and 0.72%, respectively, of the maximum. Also omitted from the table are two metastable-ion transition[9] peaks near 21.1 and 22.1. These can be ascribed to the transition $B_2H_4^+ \rightarrow B_2H_2^+ + 2H$, which occurs after the B_2H_4 ion has traversed the electric field. The apparent mass, m_a, is given by the relation $m_a = m_f^2/m_i$ where m_f and m_i are the final and initial masses. For $B_2^{11}H_4$, $m_a = 22.2$; for $B^{10}B^{11}H_4$ $m_a = 21.2$. The observed peak at 22.2 is the larger peak in agreement with the isotope abundance although the peaks are too small for a quantitative check. A corresponding metastable transition $C_2H_4^+ \rightarrow C_2H_2^+ + 2H$ ($m_a = 24.1$) is found in both ethane and ethylene.

Discussion

No certain theoretical basis has yet been proposed for interpreting mass spectra in terms of molecular structure. The general rule is that ionization of a polyatomic molecule by electrons of 50 volts or more energy produces the molecular ion and ions of every possible dissociation process. Were it not for a large number of exceptions to this rule, mass spectra would give very specific information as to the structure of the polyatomic molecules. The mass spectra of ethane and ethylene (Table II) illustrate this fact. The spectrum of ethane clearly suggests that C_2H_6 consists of two distinct methyl groups. In the spectrum of ethylene the structure of two methylene groups is also indicated. However, there is a small CH_3^+ ion, not expected from the ethylene structure. There are plausible explanations for this small peak but its presence is a warning that we cannot uncritically infer structure solely on the basis of mass spectra.

In the diborane mass spectrum the relatively intense BH_2^+ ion and the very small BH_3^+ ion are quite like the ethylene pattern and not at all like ethane. This strongly suggests that the diborane consists of an ethylene-like structure which as a whole binds two additional hydrogen atoms. The very small $B_2H_6^+$ ion is unexpected and unusual. One can only conclude that the $B_2H_6^+$ ion is quite unstable. This, of course, weakens the argument for the ethylene structure for it could likewise be argued that the BH_3^+ ion is unstable and its absence gives no positive evidence that BH_3 radicals do not exist. There is little theoretical basis for predicting which ion configurations are stable and which are not. However, as a matter of experiment, there seem to be relatively few configurations which cannot exist as single-charged ions. Thus, it is probable but not certain that BH_3 is not the unit structure.

The existence of a metastable transition $B_2H_4^+ \rightarrow B_2H_2^+ + 2H$ gives no further evidence as to the structure. The corresponding transition $C_2H_4^+ \rightarrow C_2H_2^+ + 2H$ is observed in both ethylene and ethane.

The fact that the H_2^+/H^+ ratio is much larger in diborane than the hydrocarbons may not be significant since there is some doubt as to whether all of the H_2^+ is from the ionization of diborane. It has been noted in the experimental section that diborane slowly decomposes at room temperature to give hydrogen, and in spite of the precaution of pumping off hydrogen immediately before measuring the spectrum, some hydrogen may accumulate in the inlet system during the run

Summary

The mass spectrum of diborane at ionizing voltages of 50 and 70 volts resembles ethylene more than ethane. This suggests that BH_2 is a unit structure in diborane rather than BH_3 and that two of the hydrogen atoms are not bound directly to the boron. The $B_2H_6^+$ ion is apparently quite unstable as evidenced by the low abundance of this ion in the mass spectrum.

The Configurations of Active 2,3-Epoxybutane and *erythro*-3-Chloro-2-butanol

BY HOWARD J. LUCAS AND HAROLD K. GARNER

At the time when the lower boiling 2,3-epoxybutane was shown to be the *trans* isomer,[1] it was not possible to determine the configuration of the active form, since the configuration of the active 2,3-butanediols had not yet been established. Also the stereochemical relationships of the various compounds involved in passing from the glycol to the oxide, although correctly surmised, were not definitely determined until later.[2] Moreover, the sample of active oxide obtained in the earlier work was not optically pure, for it possessed only a relatively low rotation.

Now that levorotatory 2,3-butanediol has been obtained in a high state of optical purity,[3,4,5] and the configurations of the active forms have been established,[6,7] it has been possible to prepare an optically pure 2,3-epoxybutane by methods which establish its configuration. In the changes, which are shown by I to V in Fig. 1, the stereo relationships of the compounds involved are based upon previous results, as discussed below. In addition, the configuration of the C-3 carbon atom in dextrorotatory *erythro*-3-chloro-2-butanol has been independently established as L, by converting the chlorohydrin, through the bromoform reaction, to levorotatory α-chloropropionic acid, VI, which is known to have the L configuration.[8]

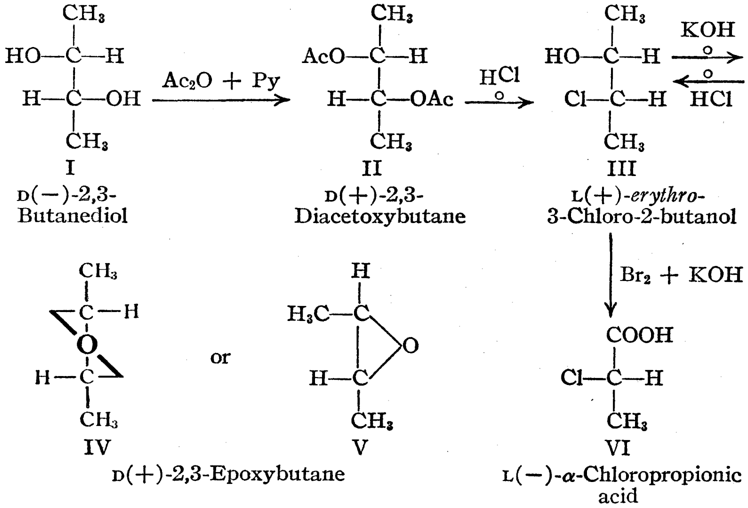

Fig. 1.—Configurational relationships of D(+)-2,3-epoxybutane and L(+)-*erythro*-3-chloro-2-butanol to D(−)-2,3-butanediol.

In D(−)-2,3-butanediol, I, each carbon atom has the D configuration.[6,7] When the glycol is converted to D(+)-2,3-diacetoxybutane, II, by acetic anhydride with either sulfuric acid or pyridine as a catalyst, the configuration of each carbon atom is still D. When II is converted to L(+)-*erythro*-3-chloro-2-butanol, III, by hydrochloric acid, the configuration of carbon atom C-3 is inverted, for a single Walden inversion has been shown to accompany the displacement of one of the acetoxy groups by chlorine in the change of DL-2,3-diacetoxybutane to DL-*erythro*-3-chloro-2-butanol.[9,10] In the last step, III to D(+)-*trans*-2,3-epoxybutane, IV, the configuration of carbon atom C-3 is again inverted, for a single Walden inversion accompanies the closing of the oxide ring. This has been shown to be the case when DL-*trans*-2,3-epoxybutane is formed from DL-*erythro*-3-chloro-2-butanol.[9,11] There could not have been an odd number of inversions, otherwise the final product would have been the optically inactive *cis* oxide, rather than the active *trans* oxide. Thus it seems reasonable to conclude, on the basis of the changes I to IV, that the configuration of each carbon in IV is D, since there has been no inversion at C-2, and two inversions at C-3.

The conversion of the chlorohydrin, III, to chloropropionic acid, VI, by establishing the configuration of carbon atom C-3 as L, presents additional proof that one inversion is associated with each of these changes, *viz.*, II to III, and III to IV. In addition, it confirms the earlier evidence that the higher boiling chlorohydrin has the *erythro* configuration.[9]

The configuration of α-chloropropionic acid cannot be unequivocally established by relating it directly to hydroxy compounds such as lactic

[10] In the analogous change of DL-2,3-diacetoxybutane to DL-*erythro*-3-bromo-2-butanol by hydrobromic acid, the single Walden inversion has been located at the step where DL-*threo*-3-acetoxy-2-butanol is changed to DL-*erythro*-2-acetoxy-3-bromobutane.[2b]

[11] A single Walden inversion is known to be associated with closing of the epoxy ring when *cis*-2,3-epoxybutane is formed from DL-*threo*-3-bromo-2-butanol.[2a]

acid by reactions not involving the asymmetric center. Neither can the Walden inversions in the steps II to III, III to IV, and IV to III be proven unequivocally, although there is no reason to doubt that they occur. Nevertheless, the evidence presented here is consistent with the accepted configuration of α-chloropropionic acid, and with the assumption that one inversion accompanies each of the changes mentioned above. We believe that there can, therefore, no longer be any doubt in regard to the configuration of the active α-chloropropionic acids, for the satisfactory way in which active 3-chloro-2-butanol forms a configurational link with active 2,3-butanediol confirms the conclusions reached by Freudenberg, Ingold, *et al.*[8]

When the carbon chain is written vertically, the configuration of the dextrorotatory oxide is correctly represented by IV. However, since this is an awkward looking formula, it seems preferable to write the oxide ring on one side, as shown by V. This, therefore, is the preferred way of writing the configuration of D(+)-*trans*-2,3-epoxybutane, or more simply, D(+)-2,3-epoxybutane, since there are only two active isomers of 2,3-epoxybutane. Structures IV and V are equivalent.

The configurations of the dextrorotatory oxide and the dextrorotatory chlorohydrin are reasonably certain, since carbon atom C-2 is unaffected during the changes, and the configuration of carbon atom C-3 in the chlorohydrin is established by its conversion to levorotatory α-chloropropionic acid. The designation of these compounds as D or L is somewhat arbitrary, however, since there are no rules of nomenclature which specifically apply in this case. Either of the two asymmetric centers in the molecule might be taken as the point of reference. It seems preferable to take carbon atom C-3 as the point of reference, so as to correlate the nomenclature with that of the carbohydrates.[12] This is in agreement with the designation of the 2,3-butanediols given by Morell and Auernheimer.[7] On this basis, the configuration of the highest numbered asymmetric carbon atom determines the family to which the compound belongs. Thus I, II and IV belong to the D family, since in these the functional group at carbon atom C-3 lies on the right, and III belongs to the L family, since the functional group lies on the left, as a result of inversion during its formation from II.

The oxide is believed to be of high optical purity for the following reasons: (1) the active glycol used as starting material had one of the highest optical rotatory powers recorded for this compound in the literature; (2) the reactions involved have been shown to yield configurationally pure compounds; (3) absence of *cis* oxide was indicated by agreement in physical properties with previously prepared DL-oxide[2a]; (4) rotations of two preparations agreed well, *viz.*, 58.65 and 59.05°.

The importance of (3) as an argument for optical purity is based on the assumption that if any reaction proceeded otherwise than with 100% retention or inversion of the configuration of carbon atom C-3, the resulting diastereomeric compound would lead to the presence of some *cis*-oxide in the final product. This would be the main contaminant, not the L(−)-oxide. In order for the latter to be formed there would have to be inversion at carbon atom C-2, as well as at C-3.

Rotations and some other physical constants of the compounds involved are shown in Table I. The rotation of the cyclic oxide is one more example of the well-known effect of ring structure in enhancing rotations.

The specific rotation of the chlorohydrin prepared by the action of hydrochloric acid on the active oxide was +8.87°, only 0.05° less than that of the chlorohydrin prepared from the diacetate, +8.92°. This indicates that in going from III to IV and back to III, the reactions proceed with essentially 100% inversion of configuration.

The sample of optically active 2,3-butanediol was furnished by the Northern Regional Research Laboratory, Peoria, Illinois. The authors express their appreciation to the Laboratory and especially to Dr. A. F. Langlykke for this courtesy.

Experimental

D(−)-2,3-Butanediol.—Dr. A. F. Langlykke of the Northern Regional Research Laboratory stated that the glycol was produced in a fermentation of starch induced by *Bacillus polymyxa*. The glycol contained a small amount

---

[12] This has been done in conformity with the third progress report of the Committee on Carbohydrate Nomenclature, Charles D.

of water and had an observed rotation, −12.4°. This became −13.00° ($[\alpha]^{25}\mathrm{D}$ −13.17°) after one distillation at reduced pressure.

D(+)-2,3-Diacetoxybutane; **Acid Catalyzed Reaction.**—The diacetate could be prepared, as previously described for the inactive diacetate,[1] from the glycol and acetic anhydride using as catalyst one drop of sulfuric acid per 0.5 mole of glycol. Vacuum fractionation of the reaction mixture gave a 90% yield of material with an observed rotation of +13.8°. On standing at room temperature (approximately 22°) overnight, about two-thirds of the material crystallized in large, clear prisms. The liquid was decanted from these, and the solid recrystallized from 30–60° petroleum ether and redistilled. The diacetate thus obtained melted at 25.7–25.9° and had an observed rotation of +14.10°. These values could not be raised by further purification. Additional amounts of pure diacetate could be obtained by crystallization and distillation of the liquid fraction. The total yield of purified diacetate was 70%.

The amount of sulfuric acid used to catalyze the acetylation should not exceed two drops per mole and the temperature should not rise above 80°; otherwise some optical inversion may occur.

Pyridine Catalyzed Reaction.—In a 1-liter Erlenmeyer flask were placed 90.0 g. (1 mole) of redistilled active 2,3-butanediol and 400 g. (5 moles) of redistilled anhydrous pyridine. The contents were thoroughly mixed, and then 224 g. (2.2 mole) of acetic anhydride were added slowly from a dropping funnel with stirring. As the mixture warmed, cooling was supplied to keep the temperature below 40°. After the reaction had subsided, the mixture was allowed to stand overnight, and was then fractionally distilled at reduced pressure, the final cut being taken at 82.1–82.2° (cor.), at 10 mm. The product weighed 170 g. (98%) and had an observed rotation of +13.94°. This material could be further purified so that finally $\alpha^{25}\mathrm{D}$ obs. +14.06° and $[\alpha]^{25}\mathrm{D}$ +13.72°; but this was found to be unnecessary since the chlorohydrin and oxide prepared from it had the same rotation as those from the more highly purified material.[13]

L(+)-*erythro*-3-Chloro-2-butanol.—This was prepared as previously described for the inactive chlorohydrin,[9] from the active diacetate and concentrated aqueous hydrochloric acid saturated with dry hydrogen chloride at −20°. The crude material isolated in 70% yield from the reaction mixture contained some 3-chloro-2-acetoxybutane. Three fractionations of a portion of the crude product gave a pure sample of the chlorohydrin for the measurement of physical properties, but it is not necessary to separate the chlorohydrin from the chloroacetate in the preparation of 2,3-epoxybutane, since both are converted into the oxide.

D(+)-2,3-Epoxybutane.—This was prepared, as previously described for the inactive oxides,[1] from active chlorohydrin and concentrated potassium hydroxide. The material was dried over potassium hydroxide and purified by fractional distillation; no trace of the higher boiling *cis*-oxide was detected. The over-all yield of purified active oxide from the glycol was 49%. The rotations of two preparations were $[\alpha]^{25}\mathrm{D}$, 59.05° and 58.65°.

DL-α-Chloropropionic Acid.—Inactive 3-chloro-2-butanol was prepared, in the manner previously described,[8] from a supply of inactive oxide (mixture of *cis* and *trans*) and concentrated hydrochloric acid. The yield was 79%.

A three-necked 1-liter flask was fitted with a mechanical stirrer and two dropping funnels. In the flask was placed 27 g. (0.25 mole) of the inactive chlorohydrin, and in the two separatory funnels 160 g. (1.00 mole) of liquid bromine and 195 g. of potassium hydroxide (Baker C.P., 86%; 3 moles) dissolved in 500 ml. of water, respectively. The stirrer was started, and the bromine added rapidly, about fifteen minutes being required for the addition. When about one quarter of the bromine had been added, the addition of the base was begun and continued at such a rate that the bromine was always present in the reaction mixture in good excess. The mixture became hot, and cooling was supplied with an ice-bath to keep the temperature around 50°. After all the bromine was in, addition of the base was continued until the reaction mixture became colorless, and then a slight excess was run in. A yellow color developed in the presence of the excess base.

Stirring was continued for about fifteen minutes, after which the mixture was transferred to a separatory funnel, and the heavy layer of bromoform drawn off. The aqueous layer was washed once with 50 ml. of chloroform, and then acidified with 50% sulfuric acid, a 20-ml. excess of the acid being used. The bromine which formed was destroyed with formic acid, and the solution extracted five times with 100-ml. portions of ethyl ether. Following removal of the ether by ordinary distillation, the α-chloropropionic acid was distilled at 30 mm., b. p. 100–105°, yield, 3.5 g. (13%). The product was redistilled at atmospheric pressure, the fraction boiling at 184–186° being collected. The product gave a strong positive test for chlorine and had a neutralization equivalent of 115 (theoretical, 108.5). Its anilide melted at 89.5–90.5° (cor.),[14] and its salt with phenylhydrazine at 95–96° (cor.).[15]

Other modifications of the above procedure were tried, but no improvement of the yield could be realized. It is important that there be no excess of base until all of the bromine has been added; otherwise considerable amounts of the chlorohydrin are lost by conversion to oxide.

L(−)-α-Chloropropionic Acid.—The active chlorohydrin used in the oxidation was prepared from the active oxide and concentrated hydrochloric acid as previously described for the inactive compound,[8] and had the following constants: b. p. 55.9–56.0° (cor.) at 30 mm.; $\alpha^{25}\mathrm{D}$ +9.42; $[\alpha]^{25}\mathrm{D}$ +8.87°; $n^{25}\mathrm{D}$ 1.4394. The yield was 75%.

The oxidation of the active chlorohydrin was carried out similarly to that of the inactive material. From 12.0 g. of chlorohydrin was obtained 1.9 g. (16%) of α-chloropropionic acid, b. p. 100–102° (cor.) at 30 mm.; 184–187° (cor.), at 745 mm.; neutralization equivalent, 108 (theoretical, 108.5). The rotations were as follows: pure liquid, $\alpha^{25}\mathrm{D}$ −14.2°, $[\alpha]^{25}\mathrm{D}$ −11.3°; aqueous soln. (0.0433 g. in 2.00 ml. water soln.), $[\alpha]^{25}\mathrm{D}$ −9.1°; sodium salt (0.0736 g. made up to 2.00 ml. with 3.94 *f* NaOH) $[\alpha]^{25}\mathrm{D}$ +3.8°.[16,17]

Summary

Optically active 2,3-epoxybutane has been prepared through the following series of reactions: D(−)-2,3-butanediol → D(+)-2,3-diacetoxybutane → L(+)-*erythro*-3-chloro-2-butanol → D(+)-2,3-epoxybutane. In addition, the configuration of carbon atom C-3 in the chlorohydrin has been established by conversion to L(−)-α-chloropropionic acid.

It has been possible to assign absolute configurations to the compounds prepared, since levorotatory 2,3-butanediol is known to belong to the D series, and the mechanisms of all the reactions used are known. Thus dextrorotatory 2,3-diacetoxybutane and dextrorotatory 2,3-epoxybutane belong to the D series, while dextrorotatory *erythro*-3-chloro-2-butanol belongs to the L series.

(13) K. A. Clendenning, *Can. J. Research*, **24B**, 269 (1946), gives these values for active diacetate: $n^{25}\mathrm{D}$ 1.4132; d^{20}_{4} 1.029; $[\alpha]^{28}\mathrm{D}$ 13.65°.

(14) R. L. Shriner and R. C. Fuson, "Identification of Organic Compounds," second ed., John Wiley and Sons, Inc., New York, N. Y., 1940, p. 181, give the m. p. of the anilide as 92°.

(15) G. Stempel and G. Schaffel, THIS JOURNAL, **64**, 470 (1942), give the m. p. of the phenylhydrazine salt as 95°.

(16) P. Levene and H. Haller, *J. Biol. Chem.*, **81**, 703 (1929), observed that the sign of rotation changed in going from acid to basic solution.

(17) K. Freudenberg, W. Kuhn and I. Bumann[8b] report the rotation of L-α-chloropropionic acid as $\alpha_{578} = -19.30°$; $[\alpha]_{578} = -15.4°$, pure liquid.

[Contribution from the Noyes Chemical Laboratory, University of Illinois]

Polyalkylene Sulfides from Diolefins and Dimercaptans

By C. S. Marvel and R. R. Chambers[1a]

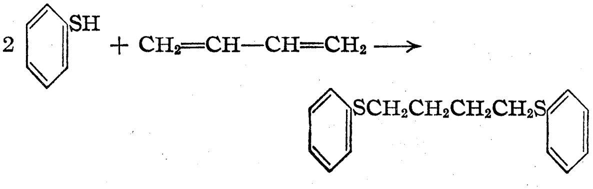
The addition of a thiol to an olefin in the presence of a peroxide catalyst[1b] or under the influence of ultraviolet light[2] has been demonstrated to be a general reaction which proceeds smoothly to give high yields of a product of definite composition. Thus, the reaction meets the requirements for a suitable polymer-forming reaction.

$$nHS(CH_2)_xSH + nCH_2{=}CH{-}(CH_2)_x{-}CH{=}CH_2 \longrightarrow H[S(CH_2)_x{-}SCH_2CH_2(CH_2)_x]_n{-}CH{=}CH_2$$

$$nCH_2{=}CH{-}(CH_2)_xSH \longrightarrow CH_2{=}CH(CH_2)_x{-}S[CH_2CH_2(CH_2)_x{-}S]_{n-1}H$$

Cahours and Hoffman,[3] who first made allyl mercaptan, did not mention any loss due to polymer formation, but Braun and Hahn[4] did report a loss of product in non-distillable residue each time they distilled their product. Braun and Plate[5] also found that several other unsaturated mercaptans gave liquid polymers. Vaughan and Rust[2a] obtained low molecular weight (less than 300) polyalkylene sulfides from hydrogen sulfide and diallyl or diallyl ether. Coffman,[6] using dithiols and diolefins without a solvent, obtained a wide variety of liquid polymeric alkylene sulfides with molecular weights up to about 1300.

In the present work we have tried to extend the reaction described by Coffman[6] and to obtain larger polymers which might have more interesting properties. Some experiments using 1,3-butadiene showed that an aromatic thiol would add readily to give the expected sulfide. However, with an aliphatic mercaptan the addition reaction was accompanied by some diene polymerization and the nature of the product was not immediately evident. Hence, in further studies non-conjugated diolefins were selected for study so that this side reaction might be avoided.



The preliminary search for conditions which favor formation of large molecules was made using hexamethylenedithiol and 1,5-hexadiene (diallyl). When these two reagents were mixed in Pyrex test-tubes and exposed to a source of ultraviolet light only a little solid polymer was formed. When the reaction was carried out in an open beaker with an excess of 1,5-hexadiene, polymerization took place quickly and a white waxy product was formed in about five minutes. However, the product was of low molecular weight (about 1100) due to loss of much butadiene by evaporation. By use of cyclohexane as a solvent a polymer with a molecular weight of about 1700 was obtained by the open-beaker method. These experiments indicated that if large molecules were to be obtained it would be necessary to balance closely the quantities of the two reacting species so that one would not be in excess and thus stop the growth of the polymer chain.

A series of reactions was run with one-hundredth molar quantities of hexamethylenedithiol and 1,5-hexadiene in cyclohexane solution in closed quartz test-tubes. The monomers were weighed out with an accuracy of somewhat better than one-half of one per cent. Cyclohexane proved to be a fairly satisfactory solvent since it does not absorb ultraviolet light nor react with the free radical intermediates produced during polymerization. Chloroform is a better solvent for the polymers but gave lower-molecular-weight products and yellow-colored by-products which makes it seem probable that it reacts with free radical intermediates formed in the polymerization reaction.[7] The polymers were separated as solids from cyclohexane and were isolated by filtration. The reaction time was varied from two to three hours to forty-eight hours. Usually the shorter period of time was sufficient, and the time factor did not seem to affect the type of polymer obtained. These polymers were white solids soluble in benzene or cold chloroform. The low-molecular-weight materials (mol. wt. about 1400) were waxy and the higher-molecular-weight materials (about 8000 to 14000) were solids. They were insoluble in ethanol, acetone and low-boiling petroleum ether.

In order to determine whether these polymers had the expected structure resulting from a non-Markownikoff type of addition the infrared absorption of an addition polymer ($[\eta] = 0.206$) was compared with those of two synthetic polymers made from alkali, hexamethylenedithiol and 1,6-dibromohexane and 2,5-dibromohexane, respectively.[8] The two polymers made from the bro-

Polymer C

Figure 1 contains the infrared absorption patterns[9] of polymer Samples A, B and C. It is evident that A and B are very similar and C is markedly different. Polymer C shows the typical methyl group deformational frequency at 1375 cm.$^{-1}$ and bands at 1225 and 1300 cm.$^{-1}$ which are not present in the spectrum of B and A. This seems fairly conclusive evidence that the expected linear non-Markownikoff polymers result from the addition reaction. The differences in the spectra of A and B samples can probably be attributed to the different end-groups present.

Other polymers were obtained from a variety of dithiols and diolefins. Where the monomers were unbranched, solid products resulted. Where there were side groups in the monomers which would be responsible for optical isomerism in the polymer, only liquid products were obtained. In Table I the various polymers which have been obtained in this work are listed. All were prepared by the procedure described for hexamethylenedithiol and 1,5-hexadiene. All had essentially the same solubility in benzene and chloroform as reported for that polymer.

Since the solid polymers had sharp melting points, some X-ray diffraction patterns were taken

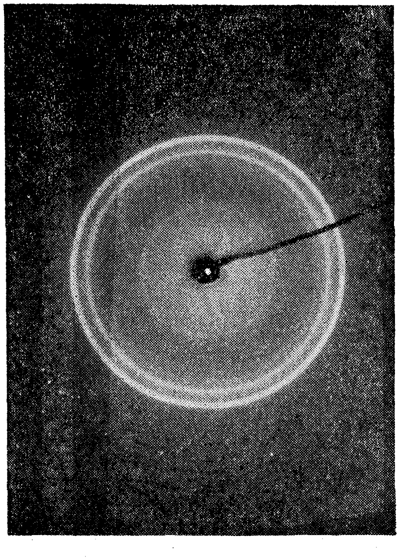

Fig. 2.—Hexamethylenedithiol–1,5-hexadiene polymer.

---

[9] We are indebted to Dr. F. A. Miller and Mrs. J. L. Johnson for the infrared measurements and their interpretation.

TABLE I

Monomers Dithiol	Diolefin	M. p., °C.	(η)	Calculated, % C	H	S	Found, % C	H	S
Ethanedithiol	1,5-Hexadiene	82–86		54.49	9.15	36.36	54.65	9.06	36.56

[a] This gel did not melt or otherwise change at 220°.

to see if they would furnish evidence of crystallinity.[10] Figures 2, 3 and 4 are the patterns for the hexamethylenedithiol–1,5-hexadiene polymer, ethanedithiol–1,5-hexadiene polymer and decamethylenedithiol–1,10-undecadiene polymer, respectively. These diagrams indicate that the polymers are crystalline and that the spacings that can be calculated from their measurement show the roughly paraffinic packing of the chains that might be expected.

The various liquid polymers described in Table I did not tend to crystallize even when cooled, whereas the solids were crystalline as shown for the above samples by X-ray methods. It was thought that some interesting products might be attained by making polymers from the three components hexamethylenedithiol, 1,5-hexadiene and 3,4-dimethyl-1,5-hexadiene. Table II gives the results of three such experiments.

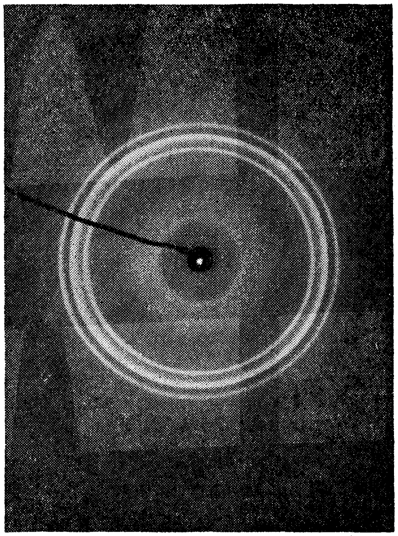

Fig. 3.—Ethanedithiol–1,5-hexadiene polymer.

TABLE II

Expt.	Hexamethylenedithiol mole	1,5-Hexadiene, mole	3,4-Dimethyl-1,5-hexadiene, mole	Softening point of product, °C.
1	0.005	0.004	0.001	62.5–65
2	.005	.003	.002	56–60
3	.005	.002	.003	Greasy

No analysis of these polymers is reported since the results do not indicate whether the two olefins are both present in the chain.

Attempts have been made to oxidize the polymer from hexamethylenedithiol and 1,5-hexadi-

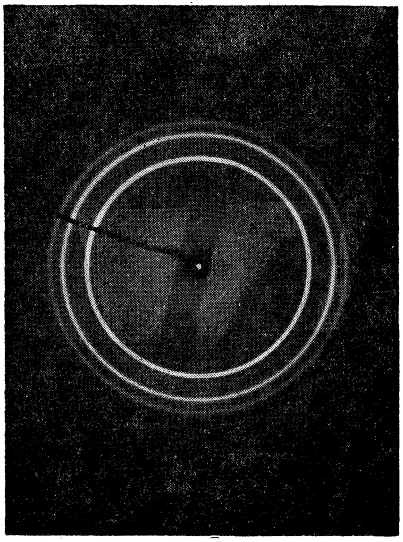

Fig. 4.—Decamethylenedithiol–1,10-undecadiene polymer.

---

[10] We are indebted to Professor G. L. Clark and Mr. D. L. Leussing for these X-ray diffraction measurements and their interpretation.

ene with bromine, potassium permanganate solution, perbenzoic acid and hydrogen peroxide. The polymer took up a large amount of bromine and liberated hydrogen bromide, giving a heavy liquid product which solidified on standing but was intractable. The other three oxidizing agents gave a white solid polymer insoluble in benzene and chloroform as well as other common solvents. It could be dissolved in hot *m*-cresol.

Some attempts were made to determine the end-groups in the polyhexamethylene sulfide but they were not very satisfactory. As indicated above, bromine appears to react with the sulfide sulfur atoms. Using traces of perbenzoic acid or iodine as oxidizing agents did produce polymers with increased intrinsic viscosities which would indicate mercaptan end-groups. These experiments, however, are somewhat inconclusive.

The authors are glad to acknowledge their indebtedness to Professor H. A. Laitinen and Mrs. H. E. Fritz for amperometric titration of the mercaptans used.

Experimental

1,4-bis-(Phenylmercapto)-butane.[11]—In a Pyrex tube were placed 11 g. of thiophenol and 5 g. of liquid butadiene. The tube was cooled and sealed and exposed to a source of ultraviolet light for sixteen hours and then allowed to stand about two weeks. It was then cooled and opened, the unreacted butadiene evaporated and the residue cooled in an ice-bath. From the unreacted thiophenol, a small amount of crystalline material separated and it was collected on a filter and recrystallized. The yield was 0.47 g. of 1,4-bis-(phenylmercapto)-butane, m. p. 84–84.5°. Bennett and Mosses[12] report a melting point of 85° for a sample of this material prepared in a different manner.

1,4-bis-(*p*-Tolylmercapto)-butane.[11]—In a similar manner 4.6 g. of butadiene and 13.8 g. of *p*-thiocresol were exposed to ultraviolet light for eighteen hours and allowed to stand fifteen days. The butadiene was evaporated and the thiocresol removed by distillation under 6 mm. pressure. The residue solidified and on recrystallization from 90% alcohol there was obtained 6.4 g. of bis-1,4-(*p*-tolylmercapto)-butane, m. p. 65–65.5°.

Anal. Calcd. for $C_{18}H_{22}S_2$: C, 71.45; H, 7.33. Found: C, 71.49; H, 7.50.

Butadiene and *n*-Butyl Mercaptan.[11]—Three grams of butadiene and 10 g. of *n*-butyl mercaptan were sealed in a Pyrex tube and exposed to ultraviolet light for eighteen hours and then allowed to stand for about two weeks. The tube was opened and the contents distilled. A 0.97-g. fraction of material boiling at 53–55° at 3 mm. was obtained; n^{20}_D 1.4749; d^{20}_4 0.9002. Analysis indicated the ratio of butadiene to mercaptan was approximately 1 mole to 1 mole, yet the boiling point is too high for such a molecule. It was not further identified.

Anal. Calcd. for $C_4H_8 \cdot C_4H_9SH$: C, 64.6; H, 12.7; S, 21.25. Calcd. for $C_4H_8 \cdot 2C_4H_9SH$: C, 60.9; H, 11.85; S, 27.00. Found: C, 66.93; H, 10.39; S, 22.71.

Addition of Hexamethylenedithiol and 1,5-Hexadiene.—In a typical polymerization a solution of 1.5 g. of hexamethylenedithiol and 0.82 g. of 1,5-hexadiene in 10 cc. of cyclohexane was placed in a tightly stoppered quartz test-tube under an ultraviolet lamp. After twelve hours the white solid was filtered off and dried. The yield was 1.69 g. This polymer softened in a melting point tube at 70° and was liquid at 74°. A solution of 0.4188 g. in 100 cc. of benzene showed an intrinsic viscosity of 0.156.

Anal. Calcd. for $(C_6H_{12}S)_x$: C, 62.00; H, 10.41; S, 27.59. Found: C, 62.19; H, 9.98; S, 27.88.

To the mother liquor from which this product had been isolated was added 1 cc. of absolute alcohol. A second crop of solid material weighing 0.13 g. was obtained. This polymer melted at 63–67° and had an intrinsic viscosity of only 0.082.

In other similar experiments the various polymers of hexamethylenedithiol and 1,5-hexadiene listed in Table III were isolated. One polymer isolated from cyclohexane solution by the open vessel method melted at 63–67° and had a molecular weight of 1700 as determined ebullioscopically in benzene. Another polymer made in an open vessel without solvent melted at 60–65° and had a molecular weight of 1100.

Table III

Expt.	[η]	Melting range, °C.	Cryoscopic mol. wt.	Approximate molecular weights
57	0.139	70–72	..	4500– 5600
55	.271	73–76	..	9000–11000
58	.293	74–76	..	12000–14000
3B1[a]	.05	50–56	1400	....
5B2[a]	.07	62–64	2100	....

[a] These low molecular weight polymers were characterized by Paul H. Aldrich and used as a basis for approximating the molecular weights of those products with a greater intrinsic viscosity.

Hexamethylenedithiol and 1,6-Dibromohexane.—To a solution of 0.26 g. of sodium in 20 cc. of absolute alcohol in a 50-cc. Erlenmeyer flask was added 1.5 g. of hexamethylenedithiol and then dropwise 2.44 g. of hexamethylene dibromide. The reaction proceeded rapidly and the product separated. It was filtered off and the alcohol diluted with water and filtered again. The two precipitates were taken up in benzene and the polymer precipitated with methanol. This process was repeated. There was obtained about 0.26 g. of product.

Anal. Calcd. for $(C_6H_{12}S)_x$: C, 62.00; H, 10.41; S, 27.59. Found: C, 58.57; H, 9.65; S, 29.07; Br, 3.19. This is Polymer B used in the infrared study.

Hexamethylenedithiol and *meso*-2,5-Dibromohexane.—To a solution of sodium ethylate prepared from 15 cc. of absolute alcohol and 0.24 g. of sodium hydride was added 1.5 g. of hexamethylenedithiol and 2.44 g. of *meso*-2,5-dibromohexane[13] (m. p. 37–39°) dissolved in 15 cc. of absolute alcohol. This solution was refluxed for about four hours. To the mixture was added 50 cc. of water and 20 cc. of ether. The ether solution was separated and the solvent evaporated. The remaining liquid was treated with sufficient methanol to dissolve about half of it and the methanol solution was decanted. The undissolved liquid was taken up in low-boiling petroleum ether. The solution was decolorized with Norite and filtered. The solvent was evaporated and the residue heated to 100° for two hours to remove traces of solvent. The product was a yellow, fairly mobile liquid containing some halogen.

Anal. Calcd. for $(C_6H_{12}S)_x$: C, 62.00; H, 10.41; S, 27.59. Found: C, 54.83; H, 9.60; Br, 6.45. It is perhaps significant to note that a polymer of the expected type with a molecular weight of 2500 having bromine end group would have the following analysis: C, 58.01; H, 9.74; Br, 6.43. This liquid product was used as sample C in the infrared work.

Oxidation of Polyhexamethylene Sulfide.—In a 500-cc. Erlenmeyer flask was placed a solution of 1.16 g. of polyhexamethylene sulfide in 150 cc. of chloroform and to it was added 150 cc. of a chloroform solution containing

---

[13] Wislicenus, *Ber.*, **34**, 2580 (1901).

0.0287 mole of perbenzoic acid.[14] The mixture was shaken on a shaking machine for twenty four hours. Titration of an aliquot portion indicated that about 0.01 mole of perbenzoic acid had been used up. To the original reaction mixture was added 150 cc. of methanol and the precipitate was collected on a filter. The precipitate was extracted in a Soxhlet extractor for five hours with hot benzene. The undissolved material melted at 189–194°. Another similar oxidation carried out at −10° for two and a half hours, at 0° eleven hours and at room temperatures for five hours showed that the oxidation was complete in the first hour and a half at −10° since after that no more perbenzoic acid was used up. This gave a 66% yield of solid melting at 190–194°. This polymer was slightly brown after purifying by solution in hot *m*-cresol and precipitation with benzene.

Anal. Calcd. for $C_6H_{12}SO$: C, 54.50; H, 9.15. Calcd. for $C_6H_{12}SO_2$: C, 48.62; H, 8.16. Found: C, 49.16; H, 8.38.

It therefore appears that a polysulfone is the oxidation product. A similar product was obtained using aqueous potassium permanganate as the oxidizing agent.[15] Carothers[15] has oxidized the polyhexamethylene sulfide made from hexamethylene bromide and sodium hexanedithiol to a polysulfone which melted at 196–198°. Our product is apparently similar if not identical with his.

End Group Oxidation.—A one-tenth gram sample of polyhexamethylene sulfide (intrinsic viscosity of 0.293, m. p. 74–76°) in 25 cc. of benzene was treated with 3 drops of dilute perbenzoic acid solution in chloroform (0.186 millimoles of perbenzoic per cc. solution) and shaken ten minutes. Then an additional 3 drops of oxidizing solution was added and the mixture shaken again for two minutes. The polymer was precipitated with methanol. In benzene solution the oxidation product had an intrinsic viscosity of 0.326. It melted at 75–77°.

A similar experiment using 0.1 g. of polymer in 20 cc. of benzene, 0.01 g. of iodine and 10 cc. of very dilute sodium hydroxide solution changed the intrinsic viscosity of the polymer from 0.293 to 0.443 and the melting point increased from 74–76° to 75–77°.

Pentamethylenediisothiouronium Bromide.—In a 500-cc. Erlenmeyer flask was placed 82 g. ($^1/_3$ mole) of pentamethylene dibromide, 54 g. ($^2/_3$ mole) of thiourea and 200 cc. of 95% ethanol. The mixture was refluxed on a steam cone for six hours, and then cooled in an ice-bath. When scratching the side of the beaker did not induce crystallization, the solvent was removed from a small sample of solution on a metal spatula and the mixture seeded with the residue. The crystals were filtered and dried in a vacuum desiccator over calcium chloride. There was obtained 124.5 g. (91% of the theoretical amount). After recrystallization from a concentrated water solution, the compound melted at 160–160.5°. This intermediate does not appear to have been isolated before.

Anal. Calcd. for $C_7H_{18}S_2N_4Br_2$: C, 22.00; H, 4.75. Found: C, 22.16; H, 4.75.

bis-(*p*-β-Mercaptoethylphenyl)-methane Diacetate.—A mixture of 10 g. of crude bis-(*p*-vinylphenyl)-methane[16] containing about 1 g. of water, and 16 g. of thiolacetic acid were placed in a quartz flask and irradiated with ultraviolet light. In a half hour the mixture became quite hot, but in another half hour it had cooled and solidified. The compound was recrystallized twice from methanol and once from low petroleum ether. There was obtained 6.5 g., melting point 75–77°. Upon further recrystallization from low petroleum ether small shiny flakes were obtained which melted at 75.5–77.5°.

Anal. Calcd. for $C_{21}H_{24}S_2O_2$: C, 67.70; H, 6.50; S, 17.21. Found: C, 67.74; H, 6.70; S, 17.06.

bis-(*p*-β-Mercaptoethylphenyl)-methane.—To a hot solution of 5 g. of bis-(*p*-β-mercaptoethylphenyl)-methane diacetate in 50 cc. of ethanol was added 10 cc. of 10% sodium hydroxide solution, and the mixture heated on the steam cone for twenty minutes. Then the solution was poured into 100 cc. of water containing 25 cc. of concentrated hydrochloric acid. The milky solution was extracted with ether, and the ether solution dried over magnesium sulfate. Removal of the ether left an oil which crystallized from low petroleum ether. A further small amount of the product was recovered from the aqueous solution by allowing it to remain in the refrigerator for several days. Further recrystallization of a sample of this compound from low petroleum ether gave white flakes melting at 34.5°. There was obtained 1.5 g. which is 39% of the theoretical yield.

Anal. Calcd. for $C_{17}H_{20}S_2$: C, 70.78; H, 6.99; S, 22.23. Found: C, 70.80; H, 6.97; S, 22.23.

2-Methylbutenethiol Acetate.—The method of adding thiolacetic acid used here was that of Frank and Hein.[17] A mixture of 22.6 g. of isoprene and 55 g. of thiolacetic acid was placed in a quartz flask cooled by an ice-bath and irradiated by ultraviolet light for fifteen minutes. On distillation fractions came over at 34–75° (12.2 g.); 85–90° (37.2 g.); and 40° (2 mm.) (12.8 g.). Apparently the first fraction is unchanged isoprene and the second unchanged thiolacetic acid. On redistillation, the third fraction, a colorless liquid, distilled at 49–51° (2 mm.), $n^{20}D$ 1.4916. This appeared to be an addition product of one mole of thiolacetic acid to one mole of isoprene.

Anal. Calcd. for $C_7H_{12}SO$: C, 58.29; H, 8.39; S, 22.23. Found: C, 58.52, 58.66; H, 8.74, 8.55; S, 22.64.

2-Methyl-1,4-butanedithiol Diacetate.—The thirty-seven grams of thiolacetic acid recovered from the previous experiment, and 16.5 g. of isoprene were placed in a quartz flask under the ultraviolet light for thirty minutes while in an ice-bath. Then the flask was removed from the ice-bath, and irradiated for an hour, during which time it heated up considerably. On distillation 3.9 g. of material was obtained which distilled at 38–75°, while the remainder distilled at 75–100° (1 mm.). On redistillation of the latter through a six-inch helices packed column, there was obtained 36.3 g. (a quantitative yield) of material distilling at 97–99° (1 mm.); $n^{20}D$ 1.5137. A sample from the middle of this fraction was analyzed.

Anal. Calcd. for $C_9H_{16}S_2O_2$: C, 49.06; H, 7.32; S, 29.10. Found: C, 49.65; H, 7.26; S, 29.46.

2-Methyl-1,4-butanedithiol.—A mixture of 36 g. of 2-methyl-1,4-butanedithiol diacetate, 40 g. of potassium hydroxide, 180 cc. of water and 200 cc. of 95% ethanol was refluxed for a half hour. The solution was then neutralized with acetic acid, and extracted with ether. The ether solution was dried over sodium sulfate, and then the ether removed. The residue, which existed in two layers, was distilled. The first fraction which distilled at 30° (80 mm.) was colorless, but the second fraction which distilled at 47–49° (3 mm.) was yellow and had an unpleasant odor. The second fraction which contained 8.3 g. of material was redistilled through a six-inch helices packed column at 46–48° (1 mm.), $n^{20}D$ 1.5202. There was obtained 6.4 g. (35% of the theoretical amount).

Anal. Calcd. for $C_5H_{12}S_2$: C, 44.07; H, 8.88; S, 47.05. Found: C, 44.61; H, 8.87; S, 47.22.

Summary

Hexamethylenedithiol and 1,5-hexadiene react in cyclohexane solution under the influence of ultraviolet light to produce polymers having molecular weights varying upward from 1000. The addition gives a linear polyhexamethylene sulfide.

The reaction is general for other dimercaptans and unconjugated diolefins. The polyalkylene

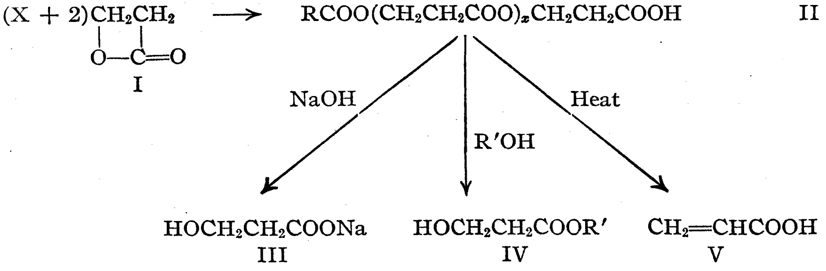
β-Propiolactone. I. Polymerization Reactions

By T. L. Gresham, J. E. Jansen and F. W. Shaver

β-Propiolactone (I) was first prepared[1] from the silver salt of β-iodopropionic acid. Only a few reactions such as its hydrolysis with acids and bases were described. Apparently no further investigations of this interesting β-lactone have been made.

The availability of I, by the practical synthesis from ketene and formaldehyde discovered by Küng,[2] has made possible an extensive study of its many reactions. This has revealed that β-propiolactone is a highly reactive and synthetically useful chemical.

Pure I polymerizes slowly when heated, and several hours at 150° are required for complete reaction. This polymerization is markedly catalyzed by acids, bases or salts. The most effective catalysts, such as ferric chloride, stannic chloride, sulfuric acid and sodium hydroxide, are moderately soluble in the lactone. Such catalyzed reactions are extremely vigorous and explosive in nature and are highly exothermic. Less effective catalysts are sodium chloride, calcium hydroxide, anhydrous hydrogen chloride and acetic acid. Solutions of polymerization catalysts in I at 0° are relatively stable. The polymerization reaction may be controlled by adding I slowly to a solution of the catalyst in an inert solvent. It is of interest to note that polymerization does not occur with sulfuric acid in ether solution even at the reflux temperature.



R represents $CH_2{=}CH$—(IIa) or $HOCH_2CH_2$—(IIb)

The polymers of I, prepared with or without added catalysts, are similar and are poly-ester acids (II). They vary from colorless viscous oils to white solids depending on the degree of polymerization and their alkali metal salts are soluble in water. Precipitation of the higher molecular weight fractions by dilution of hot acetone solutions with water yields solid polymers melting about 86°, with an average molecular weight in the range of 800–1000 as determined ebullioscopically in chloroform. Titration with base indicates a similar molecular weight range and thus shows that the polymers contain one carboxyl group per molecule. The other end group is either vinyl or a β-hydroxyethyl. The analysis for carbon and hydrogen and iodine number indicate that there are more vinyl than β-hydroxyethyl groups present in the mixture. These analyses are characteristic of a certain polymer since less unsaturation but similar molecular weights are sometimes obtained without known variants in the preparation. This could be due to variations in traces of moisture.

In boiling aqueous caustic, the polymers are saponified to salts of hydracrylic acid (III) and saponification equivalents are in close agreement with those expected for the basic unit of 72. Prolonged treatment of the polymers with alcohols when catalyzed by acids results in almost complete conversion to hydracrylate esters (IV). Basic catalysts are unsatisfactory for this alcoholysis due to the sensitivity of the hydracrylate esters to alkali. Pyrolysis[3] of the poly-ester acids to acrylic acid (V) is rapid and complete at 150°.

Other reactions of β-propiolactone to be reported in later papers include reactions with salts of inorganic acids, salts of dithiocarbamic acids, salts of carboxylic acids, alcohols, phenols and thiophenols, amines, organic and inorganic acid chlorides, metal organic compounds, inorganic acids and compounds with labile hydrogen or active methylene groups. Further work is now being undertaken to determine the mechanisms of these reactions.

Experimental

β-Propiolactone (I).—Physical constants: b. p. 51° at 10 mm., 150° at 750 mm., (with extensive decomposition); m. p. −33.4°; d^{20}_{4} 1.1460; n^{20}_{D} 1.4131; dipole moment 3.8 ± 0.1 *D*.

Anal. Calcd. for $C_3H_4O_2$: C, 50.0; H, 5.56; neut. equiv., 72; *MR*D, 15.51; mol. wt., 72. Found: C, 49.87; H, 5.57; neut. equiv., 72.3; *MR*D, 15.67; mol. wt. (cryoscopic in benzene), 74.

Pure I is relatively stable at room temperature. There is no evidence of change in two to three months. However, it reacts rapidly and exothermically at room temperature with a wide variety of organic and inorganic compounds. In many cases polymerization of I is a competing reaction and in general this polymerization is minimized by operating at low temperatures.

The lactone is miscible at room temperature with most organic solvents such as ether, acetone, alcohol, benzene and acetic acid. It is 37% soluble (by volume) in water at 25° but the lactone is slowly hydrolyzed to hydracrylic acid and at least five days are required for complete reaction. With an equal molar quantity of water the hydracrylic acid obtained contains about 20% poly-hydracrylic acids as determined by acid and saponification equivalents.

Polymerization to Poly-ester Acids (II).—A. With Heat.—Three hundred grams (4.16 moles) of I was heated at 130–150° for five hours with stirring. The material gradually became more viscous and the cooled product (300 g.) was a viscous oil which partially solidified. No materials volatile at 100° under vacuum were present.

B. With Ferric Chloride.—A trace of ferric chloride (0.1 g.) was added to 25 g. of I in an open beaker at 25°. Within thirty seconds a violent exothermic reaction occurred and the entire contents were expelled.

A controlled polymerization was carried out by adding 300 g. of I dropwise to a stirred solution of ferric chloride (3 g.) in 125 ml. of benzene. Reflux was maintained by the rate of addition which required thirty minutes. The benzene was decanted from the poly-ester acid (300 g.) which partially solidified on cooling.

C. With Sulfuric Acid.—Addition of I (3 moles, 216 g.) slowly (one hour) to 1 g. of concentrated sulfuric acid at 60–80° with external cooling gave a semi-solid reaction product (210 g.). The product was melted, dissolved in 1000 ml. of hot acetone which in turn was poured into 3000 ml. of cold water. The solid which separated was filtered, washed with water, and dried; wt. 176 g. (82%), m. p. 84–86°.

Anal. Calcd. for $C_{36}H_{48}O_{24}$, IIa: C, 50.00; H, 5.56; neut. equiv., 864; mol. wt., 864; sapn. equiv., 72; iodine no., 29.4. Calcd. for $C_{36}H_{50}O_{25}$, IIb: C, 48.98; H, 5.67; neut. equiv., 882; mol. wt. 882; sapn. equiv., 73.5; iodine no., 0. Calcd. for 63% IIa and 37% IIb: C, 49.61; H, 5.60; neut. equiv., 870; iodine no., 18.5. Found: C, 49.48; H, 5.70; neut. equiv., 870; mol. wt. (ebullioscopic in chloroform), 850; sapn. equiv., 74; iodine no. (by perbenzoic acid oxidation), 18.5.

The agreement of the calculated mixture analysis with that found is significant only to establish a possible composition of poly-ester acids with an average molecular weight of about 870.

Alcoholysis of II, Ethyl Hydracrylate (IV).—A mixture of 100 g. of II (prepared by procedure A, B, or C) and 192 g. anhydrous ethanol containing 1 g. of concentrated sulfuric acid was refluxed for thirty-six hours. The acid catalyst was neutralized with calcium carbonate, most of the excess alcohol distilled at atmospheric pressure, and the residual oil filtered to remove calcium salts. Distillation of the residue at 13 mm. yielded 16.4 g. of forefraction, b. p. 60–81°, and 137 g. (84%) of ethyl hydracrylate, b. p. 81–83°, n^{20}_D 1.4222, d^{20}_4 1.0545.

Anal. Calcd. for $C_5H_{10}O_3$: sapn. equiv., 118. Found: sapn. equiv., 118.2.

Pyrolysis of II, Acrylic Acid (V).—Three hundred grams of II and 3 g. of anhydrous copper acetate (to inhibit polymerization of acrylic acid) were heated to 200° at 80 mm. A fraction of crude acrylic acid (275 g.), b. p. 84–131°, was collected. Redistillation gave 200 g. (67%) of acrylic acid, b. p. 79–80° at 80 mm., m. p. 12–13°. A mixture melting point with an authentic sample of acrylic acid was not depressed.

Summary

The polymers of β-lactone are poly-ester acids. The polymerization is markedly catalyzed by certain acids, bases and salts. The poly-ester acids are characterized by pyrolysis to acrylic acid and by alcoholysis to hydracrylates.

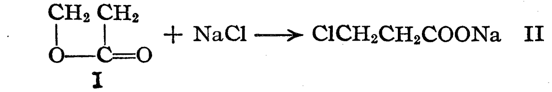
β-Propiolactone. II. Reactions with Salts of Inorganic Acids

By T. L. Gresham, J. E. Jansen, F. W. Shaver and J. T. Gregory

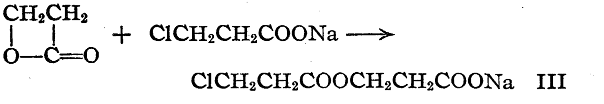
In the previous paper[1] the rapid polymerization of β-propiolactone (I) as catalyzed by certain inorganic salts was described. In water solutions of inorganic salts beta substituted propionic acid salts are formed in good yields.

With aqueous sodium chloride I yields sodium β-chloropropionate (II) and a considerable quantity of sodium β-(β-chloropropionoxy)-propionate (III) and higher analogs.



I

II



III

The secondary reaction of I with the primary product is minimized by increasing the molar ratio of salt to I and by the addition of hydrochloric acid. This latter effect may be due to reduction in the concentration of the chloropropionate ion at the lower *p*H.

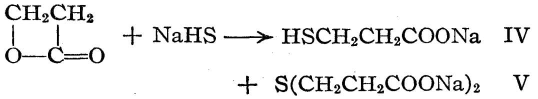
Reactions of I with lithium, ammonium, calcium, barium or ferric chloride in aqueous solution give salts of β-chloropropionic acid in a manner similar to that with sodium chloride. With sodium bromide and iodide there is less tendency for the secondary reactions to occur. The yields of *beta* substituted propionic acids under similar conditions increase in the order: NaCl < NaBr < NaI. In all of the above reactions some hydrolysis of I occurs.

The reaction of I with aqueous sodium hydrogen sulfide results in excellent yields of sodium β-mercaptopropionate (IV). The secondary reaction occurs only at the mercapto group to give

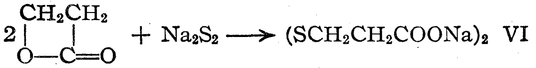
---

[1] Gresham, Jansen and Shaver, This Journal, **70**, 998 (1948).

a small amount of the salt of bis-(2-carboxyethyl) sulfide (V) and is not minimized by the use of an excess of sodium hydrogen sulfide. The addition of I to a solution containing equal molar amounts of sodium chloride and sodium hydrogen sulfide results in almost exclusive reaction with the sodium hydrogen sulfide. With aqueous sodium sulfide the reaction is more complex and hydrolysis occurs to a major extent. In concentrated solutions, however, a mixture of sodium β-mercaptopropionate (IV) and bis-(2-carboxyethyl) sulfide (V) is obtained in poor yield. The ratio of IV to V is about 1:2 even when an excess of sodium sulfide is present, indicating a preference for I to react at the alkyl mercapto group. With aqueous sodium disulfide a high yield of bis-(2-carboxyethyl) disulfide (VI) is obtained.

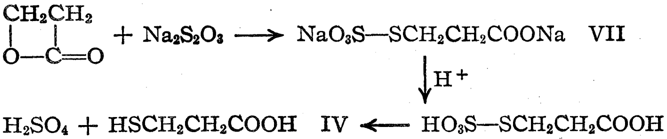


$$\begin{matrix}\text{CH}_2\text{CH}_2\\ |\quad\ |\\ \text{O—C=O}\end{matrix} + \text{NaHS} \longrightarrow \text{HSCH}_2\text{CH}_2\text{COONa}\ \ \text{IV} + \text{S(CH}_2\text{CH}_2\text{COONa)}_2\ \ \text{V}$$



$$2\begin{matrix}\text{CH}_2\text{CH}_2\\ |\quad\ |\\ \text{O—C=O}\end{matrix} + \text{Na}_2\text{S}_2 \longrightarrow (\text{SCH}_2\text{CH}_2\text{COONa})_2\ \ \text{VI}$$

β-Mercaptopropionic acid is the product formed from I and sodium thiosulfate. An intermediate thiosulfate (VII) and the corresponding acid are both stable in the solution at 25° but the acid is hydrolyzed by boiling. A by-product of this reaction is bis-(2-carboxyethyl) disulfide (VI) formed by the oxidation of IV with the small amount of sodium thiosulfate present when the solution is acidified.



$$\begin{aligned}&\begin{matrix}\text{CH}_2\text{CH}_2\\ |\quad\ |\\ \text{O—C=O}\end{matrix} + \text{Na}_2\text{S}_2\text{O}_3 \longrightarrow \text{NaO}_3\text{S—SCH}_2\text{CH}_2\text{COONa}\ \ \text{VII}\\ &\qquad\qquad\qquad\qquad\qquad\qquad\downarrow \text{H}^+\\ &\text{H}_2\text{SO}_4 + \text{HSCH}_2\text{CH}_2\text{COOH}\ \ \text{IV} \longleftarrow \text{HO}_3\text{S—SCH}_2\text{CH}_2\text{COOH}\end{aligned}$$

Experimental

β-Choropropionic Acid (II).—One mole (72 g.) of I was added (five minutes) to a solution of one mole (58.5 g.) of sodium chloride in 400 ml. of water. The reaction was stirred and held at 25° with external cooling for one hour after which there was no detectable temperature rise. After three hours, the clear solution was acidified with concentrated hydrochloric acid. The product, part of which separated as a heavy oil layer, was separated by continuous extraction with ether. The residue from evaporation of the ether extract was distilled at reduced pressure to give 37.2 g. (34%) of β-chloropropionic acid, b. p. 69–75° (1 mm.); m. p. 36–39°; m. p. 41–42° (after one recrystallization from ether–petroleum ether).

Anal. Calcd. for $C_3H_5O_2Cl$: C, 33.19; H, 4.61; Cl, 32.7; neut. equiv., 108.57. Found: C, 33.16; H, 4.57 Cl, 32.6; neut. equiv., 108.7.

The residue (35.7 g.) from the above distillation was a viscous slightly colored oil consisting of a mixture of β-(β-chloropropionoxy)-propionic acid III and higher analogs.

Anal. Calcd. for $C_6H_9O_4Cl$ (III): Cl, 19.66; neut. equiv., 180.5; for $C_9H_{13}O_6Cl$: Cl, 14.06; neut. equiv., 252.2. Found: Cl, 14.8; neut. equiv., 229.

When the above experiment was carried out with one mole of I and three moles of salt in 400 ml. of water the yield of III was 73.7% and the residue weighed 17 g.

With one mole of I, 1.4 moles of salt and 1.1 moles of concentrated hydrochloric acid in 338 ml. of water a yield of 91.2% of β-chloropropionic acid was obtained. The residue weighed 2 g.

β-Bromopropionic Acid.—This experiment was carried out similar to the preparation of II but substituting one mole (103 g.) of sodium bromide. After cooling and acidification the product was extracted in a continuous manner with a mixture of one part of ether and fifteen parts of hexane and finally with ether alone. The combined residues from the extracts were distilled at reduced pressure to give 88.5 g. (58%) of β-bromopropionic acid, b. p. 88° (0.5 mm.); m. p. 58–60°. After recrystallization from hexane the acid melted at 61–62°.

Anal. Calcd. for $C_3H_5O_2Br$: C, 23.55; H, 3.29; Br, 52.23; neut. equiv., 152.9. Found: C, 23.69; H, 3.43; Br, 52.17; neut. equiv., 153.8.

The residue (15 g.) was a slightly colored viscous oil.

Anal. Calcd. for $C_6H_9O_4Br$: Br, 35.55; neut. equiv., 255. Calcd. for $C_9H_{13}O_6Br$: Br, 26.85; neut. equiv., 297. Found: Br, 28.1; neut. equiv., 252.

β-Iodopropionic Acid.—An experiment similar to that for the preparation of II but substituting one mole (150 g.) of sodium iodide was held at 0° after acidification. The crystals of β-iodopropionic acid which separated were filtered, washed with cold water and dried at 25°; m. p. 75–82°; yield, 123 g. (61.5%); m. p. 82–83° (after recrystallization from chloroform–hexane).

Anal. Calcd. for $C_3H_5O_2I$: C, 18.01; H, 2.52; I, 63.5; neut. equiv., 200. Found: C, 18.10; H, 2.59; I, 63.4; neut. equiv., 201.

β-Mercaptopropionic Acid (IV) (From Sodium Hydrogen Sulfide).—Seventy-two grams (1 mole) of I was added while stirring (15 min.) to a solution of 1.06 moles (59 g.) of sodium hydrogen sulfide, freshly prepared from sodium hydroxide and hydrogen sulfide, in 160 ml. of water. A reaction temperature of 5° was maintained. After an additional hour the solution was acidified with concentrated hydrochloric acid and the product isolated by continuous extraction with ether. Distillation of the ether extract residue at reduced pressure gave 85.6 g. (80.7%) of β-mercaptopropionic acid; b. p. 114–115.5° at 13 mm.; d^{20}_4 1.2188; n^{20}_D 1.4921.

Anal. Calcd. for $C_3H_6O_2S$: C, 34.0; H, 5.66; S, 30.19; neut. equiv., 106. Found: C, 34.0; H, 5.84; S, 30.21; neut. equiv. (neutral red), 105.4.

The residue (13.4 g.) from the above distillation was dissolved in acetone, the solution decolorized with Nuchar and evaporated. The solid residue was recrystallized from hot water yielding 8 g. (9.0%) of bis-(2-carboxyethyl) sulfide; m. p. 128–130°.

Anal. Calcd. for $C_6H_{10}O_4S$: C, 40.45; H, 5.65; S, 17.97; neut. equiv., 89. Found: C, 40.50; H, 5.67; S, 18.04; neut. equiv., 88.8.

A similar experiment but using two moles of sodium hydrogen sulfide gave 89 g. (84%) of β-mercaptopropionic acid and 6.6 g. (7.4%) of bis-(2-carboxyethyl) sulfide.

A third experiment wherein the water was replaced with 500 ml. of anhydrous ethanol gave a reaction mixture containing a heavy precipitate of the mono-sodium salt of β-mercaptopropionic acid. The suspension was acidified with 128 ml. of concentrated hydrochloric acid, filtered from sodium chloride, and concentrated by distillation at atmospheric pressure. Fractional distillation of the residue at 20 mm. gave a forerun (25 g., b. p. 23–76°) the water insoluble portion of which was returned to the distillation flask. Completion of the rectification gave two fractions. The first fraction, 47.7 g. (35.6%), b. p. 79–79.5° (20 mm.), was redistilled to give pure ethyl β-mercaptopropionate, b. p. 79–79.5° (20 mm.); n^{20}_D 1.4561; d^{20}_4 1.0550.

Anal. Calcd. for $C_5H_{10}O_2S$: C, 44.78; H, 7.52; S, 23.87; sapn. equiv., 134.1; MR_D, 34.53. Found: C, 44.79; H, 7.58; S, 23.91; sapn. equiv., 136; MR_D 34.63.

The second fraction, b. p. 122–123.5° (20 mm.), wt.

158.8 g. (55.5%) was β-mercaptopropionic acid, $n^{20}D$ 1.4902; d^{20}_4 1.2169.

Anal. Calcd. for $C_3H_6O_2S$: neut. equiv., 106. Found: neut. equiv., 108.5 (neutral red).

β-Mercaptopropionic Acid (IV) (From Sodium Sulfide).—One mole (72 g.) of I was added slowly (thirty minutes) to a stirred solution of 1.2 moles (288.5 g. nonahydrate) of sodium sulfide in 200 ml. of water with control of the temperature at 15°. Part of the sodium sulfide was undissolved at the start. After several hours the clear solution was acidified with concentrated hydrochloric acid and the product isolated by ether extraction. Distillation of the ether extract residue at reduced pressure gave 11 g. (10%) of β-mercaptopropionic acid, b. p. 100° (7 mm.); $n^{20}D$ 1.4921.

Anal. Calcd. for $C_3H_6O_2S$: neut. equiv., 106. Found: neut. equiv., 108 (neutral red).

The solid residue from the above distillation was recrystallized twice from ether–petroleum ether to give 16.2 g. (18.2%) of bis-(2-carboxyethyl) sulfide, m. p. 128–130°. The melting point of a mixture with an authentic sample was not depressed.

An experiment carried out as above but with no control of the temperature resulted in its rise to 99°. The product was a mixture consisting of 9 g. (8%) of β-mercaptopropionic acid and 20.5 g. (22%) of bis-(2-carboxyethyl) sulfide.

Another experiment at 0° and at greater dilution, 1000 ml. of water, resulted in no ether extractable product.

bis-(2-Carboxyethyl) Disulfide (VI) (From Sodium Disulfide).—A solution of 0.5 mole (43.5 g.) sodium disulfide was prepared from 61 g. (1.1 mole) of sodium hydrogen sulfide and 16 g. (0.5 mole) of sulfur in 400 ml. of water by warming the suspension at 50° while stirring. To the orange-red solution was added slowly (thirty minutes) 72 g. (1 mole) of I at 0°. After an additional hour the clear yellow solution was acidified with concentrated hydrochloric acid, diluted with water and the copious white precipitate filtered, washed with water and recrystallized from 1000 ml. of hot water. The yield of impure bis-(2-carboxyethyl) disulfide was 98.5 g. (94%), m. p. 135–149°. The mixture melting point with an authentic sample (m. p. 153–155°) was 148–153°.

β-Mercaptopropionic Acid (IV) (From Sodium Thiosulfate).—I (144 g., 2 moles) was added slowly (two hours) to a stirred solution of 496 g. (2 moles) sodium thiosulfate pentahydrate in 400 ml. water at 30°. After acidification with 330 ml. concentrated hydrochloric acid an ether extraction yielded no product. However, after heating the water layer for three hours at 100° a white precipitate of bis-(2-carboxyethyl) disulfide separated. This was filtered and recrystallized from hot water, m. p. 153–155°; wt. 29 g. (13.8%).

Anal. Calcd. for $C_6H_{10}O_4S_2$: C, 34.25; H, 4.79; S, 30.42. Found: C, 34.28; H, 4.77; S, 30.46.

The above filtrate was continuously extracted with ether and the residue, after evaporation of the ether, was distilled at reduced pressure. β-Mercaptopropionic acid, 148.5 g. (70%) was collected, b. p. 94° (5 mm.); $n^{20}D$ 1.4921; d^{20}_4 1.2188.

Anal. Calcd. for $C_3H_6O_2S$: neut. equiv., 106. Found: neut. equiv., 105.4 (neutral red).

The residue (12 g.) from the distillation yielded 11 g. (5%) of crude bis-(2-carboxyethyl) disulfide after recrystallization from hot water, m. p. 131–144°.

bis-2-(Carboxyethyl) Disulfide (VI) (By Oxidation).—A solution containing 95.4 g. (0.9 mole) β-mercaptopropionic acid, 25 g. (0.1 mole) sodium thiosulfate pentahydrate in 360 ml. of water was acidified with 16.5 ml. of concentrated hydrochloric acid. The solution was held at 100° for one hour during which time the small sulfur deposit disappeared and hydrogen sulfide was evolved. An equal volume of hot water was added and after cooling, the precipitate of bis-(2-carboxyethyl) disulfide was filtered and recrystallized from 600 ml. of hot water; wt. 80 g. (84.5%); m. p. 150–152.5°. A mixture melting point with an authentic sample was not depressed.

Summary

Reactions of β-propiolactone with aqueous solutions of alkali halides, sodium hydrogen sulfide, sodium sulfide, sodium disulfide and sodium thiosulfate are described. The primary products are salts of *beta* substituted propionic acids. In certain cases salts of poly-ester acids are formed as secondary reaction products.

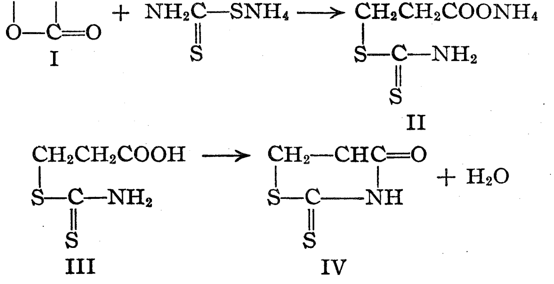
β-Propiolactone. III. Reactions with Dithiocarbamic Acids, their Salts and Thiourea

BY T. L. GRESHAM, J. E. JANSEN AND F. W. SHAVER

The previous work[1] showed that salts of *beta*-substituted propionic acid were formed from β-propiolactone (I) and salts of inorganic acids. Similar products are formed from salts of dithiocarbamic acids and there is no tendency for secondary reactions to occur.

With ammonium dithiocarbamate, an excellent yield of ammonium β-dithiocarbamyl propionate (II) is obtained and the corresponding acid is readily cyclized to 2-thiono-4-keto-1,3-thiazane (IV). Similarly salts of N-alkyl and N,N-dialkyl dithiocarbamic acids form salts of *beta*-substituted propionic acids. Ring closure occurs only with the mono alkyl substituted acids.



β-Dithiocarbamylpropionic acids III are also formed from I and the free dithiocarbamic acids in water solution. The yields are equally high.

With thiourea, I forms β-isothioureido propionic

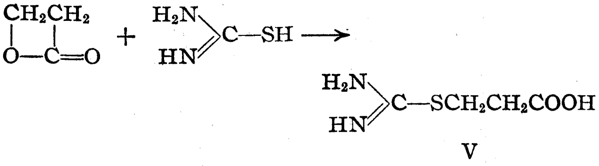
acid (V). In polar solvents such as water, the reaction is rapid and nearly quantitative but it does not occur at all in non-polar solvents such as ether.



Experimental

β-Dithiocarbamylpropionic Acid (III).—One mole (72 g.) of β-propiolactone was added dropwise (twenty minutes) to a solution of 110 g. (1 mole) of ammonium dithiocarbamate[2] in 300 ml. of water at 20° with stirring. The clear solution was acidified with concentrated hydrochloric acid and after two hours the copious white precipitate was filtered, washed with water and dried; m. p. 124–126°; yield, 152 g. (92%). After recrystallization from ether–petroleum ether the product was collected as small prisms, m. p. 125–126°.

Anal. Calcd. for $C_4H_7O_2NS_2$: C, 29.10; H, 4.24; N, 8.50; S, 38.80; neut. equiv., 165. Found: C, 29.17; H, 4.25; N, 8.59; S, 38.85; neut. equiv., 168.

A solution of dithiocarbamic acid was prepared by carefully acidifying a solution of ammonium dithiocarbamate (110 g., 1 mole in 500 ml. of water) with 100 g. concentrated hydrochloric acid at 0°. One mole (72 g.) of β-propiolactone was added dropwise (thirty minutes) to this solution while stirring. The temperature was maintained at 0° throughout and after three hours the copious white precipitate which had separated was filtered, washed thoroughly with water, and dried; yield, 152 g. (92%); m. p. 124–126°. A mixture melting point with the above sample of β-dithiocarbamylpropionic acid was not depressed.

Reactions with other dithiocarbamates were carried out in a manner similar to the above. Solutions of sodium N-ethyl dithiocarbamate were prepared from ethylamine, carbon disulfide and sodium hydroxide in the usual manner. Solutions of sodium N,N-dimethyl and N,N-diethyl dithiocarbamate were prepared by dissolving the salts in water.

β-(N-Ethyl Dithiocarbamyl)-propionic Acid.—The product separated as fine needles on recrystallization from ether–hexane; m. p. 97–98°; yield, 35 g.[3] (20%).

Anal. Calcd. for $C_6H_{11}O_2NS_2$: C, 37.30; H, 5.74; N, 7.26; S, 33.18; neut. equiv., 193. Found: C, 37.36; H, 5.73; N, 7.25; S, 33.25; neut. equiv., 194.

β-(N,N-Dimethyldithiocarbamyl)-Propionic Acid.—The product separated as prisms from ether–petroleum ether; m. p. 142–143°; yield, 187 g. (97%).

Anal. Calcd. for $C_6H_{11}O_2NS_2$: C, 37.30; H, 5.74; N, 7.26; S, 33.18; neut. equiv., 193. Found: C, 37.24; H, 5.67; N, 7.11; S, 33.25; neut. equiv., 194.

β-(N,N-Diethyldithiocarbamyl)-Propionic Acid.—Yield after recrystallization from ether–petroleum ether, 175 g. (80%); m. p. 97–98°.

Anal. Calcd. for $C_8H_{15}O_2NS_2$: C, 43.44; H, 6.79; N, 6.34; S, 29.00; neut. equiv., 221. Found: C, 43.48; H, 6.78; N, 6.38; S, 29.08; neut. equiv., 222.

2-Thiono-4-keto-1,3-thiazane[4] (IV).—A suspension of 47 g. of III in 100 ml. of acetic anhydride containing 0.1 g. of concentrated sulfuric acid, was stirred and warmed to 50°. The resulting deep yellow solution was poured into ice and water and the solid which separated was filtered, dried, and recrystallized from benzene; m. p. 119–120°; yield, 42 g. (92%).

Anal. Calcd. for $C_4H_5ONS_2$: C, 32.61; H, 3.42; N, 9.52; S, 43.56. Found: C, 32.91; H, 3.52; N, 9.66; S, 43.82.

2-Thiono-3-ethyl-4-keto-1,3-thiazane.—Using a procedure similar to that for IV above this product was obtained as yellow plates, m. p. 65–66°; yield, 78%.

Anal. Calcd. for $C_6H_9ONS_2$: C, 41.15; H, 5.14; N, 8.00; S, 36.60; mol. wt., 175. Found: C, 41.27; H, 5.15; N, 8.04; S, 36.67; mol. wt., 175 (ebullioscopic in benzene).

β-Isothioureidopropionic Acid (V).[5]—One mole (72 g.) of β-propiolactone was added all at once to a solution of 76 g. of thiourea in 300 cc. of water while stirring. The temperature rose about 30° and the product started to separate in a few minutes. After standing for two hours at 10°, the solid hydrate was filtered and recrystallized from hot water. After drying at 100°, anhydrous crystals were obtained; yield, 132 g. (90%); m. p. 178–179°. The mixture melting point with a sample, prepared as directed by Andreasch, was not depressed.

Anal. Calcd. for $C_4H_8O_2N_2S$: N, 18.90. Found: N, 18.72.

Acknowledgment.—The authors express their thanks to Marie Prendergast and R. W. Dundon for their part in the experimental work.

Summary

Reactions of β-propiolactone with dithiocarbamic acids, their salts, and with thiourea are described. In certain cases the products were cyclized to substituted 1,3-thiazanes.

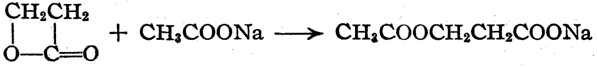
β-Propiolactone. IV[1,2] Reactions with Salts of Carboxylic Acids

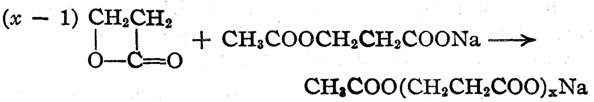
BY T. L. GRESHAM, J. E. JANSEN AND F. W. SHAVER

Salts of β-acetoxypropionic acid II and poly-ester acids (III) are formed in the reaction of β-propiolactone (I) with aqueous sodium acetate. The strong tendency for the reaction of I with the primary products is minimized by increasing the mole excess of sodium acetate.



$$\begin{array}{l}CH_2CH_2\\ |\quad\;\; |\\ O{-}C{=}O\end{array} + CH_3COONa \longrightarrow CH_2COOCH_2CH_2COONa$$

I II



$$(x-1)\begin{array}{l}CH_2CH_2\\ |\quad\;\; |\\ O{-}C{=}O\end{array} + CH_3COOCH_2CH_2COONa \longrightarrow CH_3COO(CH_2CH_2COO)_xNa$$

III

β-Acetoxypropionic acid (IV) is completely pyrolyzed to acetic acid and acrylic acid by distillation at atmospheric pressure.

$$\underset{\text{IV}}{CH_3COOCH_2CH_2COOH} \longrightarrow CH_3COOH + CH_2{=}CHCOOH$$

Attempts to prepare esters of IV by direct esterification result in alcoholysis and esterification to hydracrylates and acetates.

The poly-ester acids V are colorless oils and they differ from polymers obtained from I by heat or with catalysts[3] only in the end acetoxy group. Alcoholysis with methanol, using acid catalysis, results in a mixture of methyl acetate and methyl hydracrylate in amounts as expected from the average molecular weight, assuming one acetoxy group per molecule.

$$\underset{\text{V}}{CH_3COO(CH_2CH_2COO)_xH} + CH_3OH \longrightarrow CH_3COOCH_3 + xHOCH_2CH_2COOCH_3 + H_2O$$

With several moles of I and one mole of sodium acetate the products are exclusively salts of poly-ester acids (III). Low temperatures are required to avoid hydrolysis of I. Since the yield of polymer is higher than that expected from the molecular weight if each polymer molecule contains an acetoxy group, some polyhydracrylic acid is present due to hydrolysis of the polymers or polymerization of I.

Products similar to those with sodium acetate are formed with salts of other carboxylic acids. The poly-ester acids from sodium caprate (VI) and disodium phthalate (VII) were viscous oils.

$$\underset{\text{VI}}{CH_3(CH_2)_8COO(CH_2CH_2COO)_{2.5}H}$$

$$\underset{\text{VII}}{C_6H_4[(COO(CH_2CH_2COO)_{2.5}H]_2}$$

Direct esterification of these products resulted in alcoholysis to esters of the parent acids and esters of hydracrylic acid.

Experimental

β-Acetoxypropionic Acid (IV).—One mole (72 g.) of I was added (fifteen minutes) to a stirred solution of 82 g. (1 mole) of sodium acetate in 300 ml. of water at 20° with cooling. After stirring for one hour the colorless solution was cooled to 0°, acidified with concentrated hydrochloric acid and the product extracted with ether. The ether extract was dried over anhydrous sodium sulfate, evaporated under reduced pressure and the residue fractionally distilled at reduced pressure. After removal of some acetic acid, 42.5 g. (32%) of β-acetoxypropionic acid was collected; b. p. 83–84° (0.4 mm.); n^{25}_D 1.4311; d^{25}_4 1.1963.

Anal. Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.06; neut. equiv., 132; sapn. equiv., 66; *MR*D 28.48. Found: C, 45.32; H, 6.16; neut. equiv., 132; sapn. equiv., 68; *MR*D, 28.56.

The residue (46 g.) from the above distillation was a viscous colorless oil and consisted of a mixture of poly-ester acids. These poly-ester acids are soluble in acetone, chloroform and aqueous sodium hydroxide from which they are reprecipitated on acidification.

Anal. Calcd. for $C_{11}H_{16}O_8$ (V, $x = 3$): neut. equiv., 276; sapn. equiv., 69. Found: neut. equiv., 268; sapn. equiv., 67.

When the above reaction was repeated, except that two moles of sodium acetate were used, 75 g. (57%) of β-acetoxypropionic acid and 22 g. of residue were obtained. Similarly, with four moles of sodium acetate, 97 g. (73%) of β-acetoxypropionic acid and 9.5 g. of residue resulted.

Ethyl β-Acetoxypropionate.—β-Acetoxypropionic acid (23 g.) was treated with thionyl chloride (40 g.) for five hours at 25°. The excess thionyl chloride was removed at reduced pressure and absolute ethanol (16 g.) was added to the crude acid chloride residue. After standing for two hours, the mixture was diluted with ether, washed with aqueous sodium carbonate and water and dried over anhydrous sodium sulfate. Distillation of the residue at reduced pressure, after evaporation of the ether, gave ethyl β-acetoxypropionate; b. p. 33.5–35° (0.3 mm.); n^{20}_D 1.4163.

Anal. Calcd. for $C_7H_{12}O_4$: C, 52.50; H, 7.50; sapn. equiv., 80. Found: C, 52.36; H, 7.54; sapn. equiv., 83.

Pyrolysis of β-Acetoxypropionic Acid (IV).—β-Acetoxypropionic acid (122 g.) was rapidly distilled through a short open column at atmospheric pressure. Distillation started at a flask temperature of 190° and 118 g. of colorless distillate was collected, b. p. 130–150°. One gram of anhydrous copper acetate was added to the distillate, to inhibit polymerization of acrylic acid, and it was fractionally distilled. The first fraction was acetic acid; b. p. 118°; n^{20}_D 1.3790.

Anal. Calcd. for $C_2H_4O_2$: neut. equiv., 60. Found: neut. equiv., 63.

The second fraction was acrylic acid; b. p. 135–140°; m. p. 6°; after redistillation, m. p. 12–13°; mixture melting point with an authentic sample, 12–13°.

Alcoholysis of V.—A solution of the poly-ester acid residues (115 g., neut. equiv., 268) and 1 g. of sulfuric acid in 320 g. of methanol was refluxed for sixteen hours. The catalyst was neutralized with 3 g. of calcium carbonate; the solution filtered from calcium salts and fractionally distilled using a 30-plate Oldershaw column and a reflux ratio of 20:1. The first fraction was methyl alcohol–methyl

acetate binary; b. p. 53–53.8°; $n^{20}\mathrm{D}$ 1.3531; wt. 28 g. (81.3%, 22.7 g. methyl acetate). After removal of the excess methanol, the residue was distilled through a 10 × 2 cm. packed column at reduced pressure and gave 81 g. of methyl hydracrylate; b. p., 70–71° (13 mm.); $n^{20}\mathrm{D}$ 1.4213; d^{20}_4 1.1205.

Anal. Calcd. for $C_4H_8O_3$: sapn. equiv., 104. Found: sapn. equiv., 104.5.

The residue, due to incomplete alcoholysis, weighed 38 g.

β-(β-Acetoxypolypropionoxy)-propionic Acids (V).—One mole (72 g.) of I was added (thirty minutes) to a stirred solution of 0.2 mole (16.4 g.) of sodium acetate in 100 ml. of water at 15° while cooling. After four hours, heat was no longer evolved and the clear solution was acidified with 25 g. of concentrated hydrochloric acid. The oil layer was separated, washed with water and dried to constant weight at 40° and 0.5 mm.; wt. 62 g. (76%).

Anal. Calcd. for $C_{11}H_{16}O_8$ (V, $x = 3$): neut. equiv., 276. Found: neut. equiv., 280.

A similar experiment but adding 2 moles (144 g.) of I resulted in a mixture of solid and oil after acidification of the reaction mixture. This was dissolved in chloroform, the solution washed with water and the chloroform distilled, partly at atmospheric pressure and finally at reduced pressure (40° (1 mm.)) until there was no further weight loss (four hours). The resulting oil slowly crystallized to a waxy solid; wt. 140.5 g. (90%); m. p. 30–40°.

Anal. Calcd. for $C_{20}H_{28}O_{14}$ (V, $x = 6$): neut. equiv., 492. Found: neut. equiv., 506.

Acknowledgment.—The authors wish to thank Marie Prendergast for assistance in the experimental work.

Summary

The reaction of β-propiolactone with aqueous sodium acetate gives a mixture of salts of β-acetoxypropionic acid, β-(β-acetoxypropionoxy)-propionic acid and higher analogs. The effect on the mixture of varying mole ratios of reactants is described and the poly-ester acids are characterized by pyrolysis and alcoholysis. Similar reactions occur with other carboxylic acid salts.

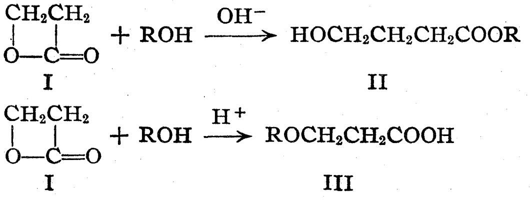
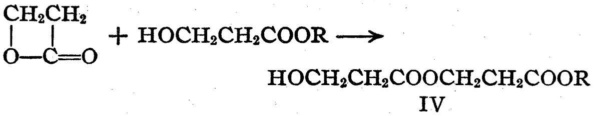
β-Propiolactone. V. Reaction with Alcohols

By T. L. Gresham, J. E. Jansen, F. W. Shaver, J. T. Gregory and W. L. Beears

With alcohols, β-propiolactone (I) forms two products, depending on the catalysis. With base catalysis the ring opens at the oxygen–carbonyl carbon bond forming hydracrylate esters II. Without added catalysts or with acid catalysis *beta*-alkoxy acids III are formed as a result of ring opening at the oxygen–methylene carbon bond. This latter ring opening is similar to that observed in the previously described salt reactions.[1]



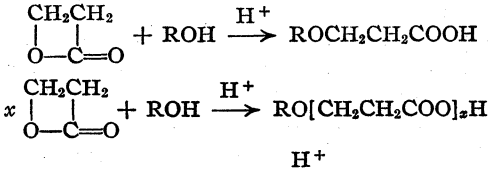
The base catalyzed reaction gives high yields of hydracrylates. It is extremely rapid with primary alcohols and must be run at low temperatures and in the presence of an excess of alcohol to avoid polymerization. Strong bases, such as sodium hydroxide, sodium alkoxide or trimethylbenzylammonium hydroxide are satisfactory catalysts. The polymers differ from the poly-ester acids previously described[1] in that they are esters of polyhydracrylic acid. Their formation may be due to the reaction of I with the hydracrylate or by the alcoholysis of the hydracrylates with themselves. With secondary alcohols it is more difficult to avoid the polymerization of I, probably due to a slower rate of the primary reaction.



$$2HOCH_2CH_2COOR \longrightarrow HOCH_2CH_2COOCH_2CH_2COOR + ROH$$
IV

The non-catalyzed reaction of I with alcohols[2] is extremely slow and β-alkoxypropionic acids and polymers are the only products. Some esterification of the alkoxy acids occurs, especially with the lower alcohols at higher temperatures. With secondary and tertiary alcohols these non-catalysed reactions are indeed slow, more of I polymerizes and no esters of the alkoxy acids are isolated.

The acid catalyzed reaction of I with alcohols is complex. β-Alkoxypropionic acids and their esters, hydracrylic acid esters and poly-ester acids



$$RO[CH_2CH_2COO]_xH + ROH \xrightarrow{H^+} ROCH_2CH_2COOR + (x-1)HOCH_2CH_2COOR + H_2O$$

$$ROCH_2CH_2COOH + ROH \xrightarrow{H^+} ROCH_2CH_2COOR + H_2O$$

with terminal alkoxy groups are formed. The composition of the mixture obtained is dependent on the reaction conditions employed, the most important factors of which are the acid catalyst concentration, the temperature, time and the molar excess of alcohol. The primary reaction of I gives β-alkoxypropionic acids. A competing reaction is polymerization. Secondary reactions of esterification and alcoholysis account for the other products.

The rate of the acid catalyzed reaction is intermediate between that of the non-catalyzed and base catalyzed. As is shown in Table II, the amount of hydracrylate formed by the secondary reaction increases with time with a corresponding decrease of polymer and none of it is formed in incomplete reactions. Also, more esterification occurs with increased time while the combined yields of alkoxy acid and ester remain constant.

The polymerization, alcoholysis and esterification are favored with increasing catalyst concentration and temperature. However, with high acid concentration only insoluble higher molecular weight polymers result. These, therefore, are alcoholized very slowly.[1a] Decrease in the excess alcohol favors the polymerization.

Both the primary and secondary reactions are slower with the higher primary alcohols. Secondary and tertiary alcohol reactions are still slower and little if any secondary reactions occur.

The polymeric residues from these acid catalyzed reactions contain poly-ester acids with end alkoxy groups. It was possible to isolate methyl β-(β-methoxypropionoxy)-propionate from the methyl alcohol residues in fair amounts. Neutralization equivalents show, however, that most of the residue consists of poly-ester acids.

Experimental

Base Catalyzed Reactions.—One mole of β-propiolactone was added dropwise with stirring to a solution of 2 g. of sodium hydroxide in six moles of the alcohol. The reactions were highly exothermic and a Dry Ice–acetone-bath was employed to maintain the temperature at 0° with a fifteen-minute addition time. The catalyst was neutralized with an equivalent of concentrated hydrochloric acid, the solution filtered from salt, and the alcohol and the product were distilled at reduced pressure. Yields and other data are listed in Table I.

Methyl β-(Hydroxypropionoxy)-propionate (IV).—The oily residues from base catalyzed reactions with methanol were insoluble in aqueous caustic. Distillation of 34 g. gave a fraction of IV (30 g.), b. p. 85–86° (0.3 mm.); $n^{20}\text{D}$ 1.4429; d^{20}_4 1.1902.

Anal. Calcd. for $C_7H_{12}O_5$: sapn. equiv., 88; *MR*D, 39.36. Found: sapn. equiv., 89; *MR*D, 39.21.

Acid Catalyzed and Non-catalyzed Reactions.—One mole of β-propiolactone was added dropwise over a twenty minute period to six moles of the alcohol. A three-neck ground-glass jointed flask fitted with a glass stirrer, thermometer, dropping funnel and a reflux condenser was used and the desired reaction temperature maintained by immersing the flask in a constant temperature bath. Stirring was continued throughout the experiment. With the acid catalyzed experiments the sulfuric acid was added at the start and neutralized at the end by the addition of two grams of calcium carbonate per gram of acid used and the solution filtered from calcium salts before distillation. The excess alcohol was distilled rapidly at reduced pressure keeping the flask temperature below 30° and the residue was fractionally distilled through a 1″ × 24″ packed column. The experimental data are listed in Table II and the physical and analytical data for the products in Table III.

Summary

The base catalyzed reaction of β-propiolactone with alcohol is rapid and results in hydracrylates. Without added catalysts, alkoxy acids are slowly formed. The acid catalyzed reaction gives alkoxy acids by direct reaction and hydracrylates by alcoholysis of poly-ester acids formed in the competing polymerization of the lactone. The effects of time, temperature and catalyst concentration on the proportions of products in the mixture are demonstrated.

Evidence of an Induction Period in the Alkylation of Isobutane by 2-Butene

BY T. D. STEWART AND WILLIAM H. CALKINS

The reaction between isobutane and 2-butene at 0° in the presence of 96% sulfuric acid is not extremely rapid. This may be shown by passing 2-butene gas at a constant rate into a stirred mixture of sulfuric acid and isobutane. In our experiments the isobutane was initially at atmospheric pressure; the isobutane consumption was measured by observing the input of isobutane required to maintain a constant pressure in the reactor. Figure 1 shows the observations made during a typical experiment.

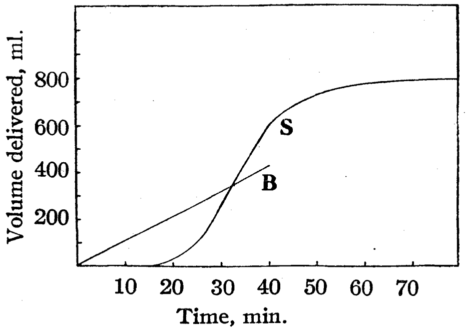

Fig. 1.—Rate of consumption of isobutane (S) gas produced by the addition of 2-butene (B) gas at a constant rate, in sulfuric acid.

At first little or no isobutane is consumed. After about twenty minutes, during which about 200 ml. of 2-butene has been introduced, the consumption of isobutane approaches a constant rate. When the 2-butene supply is shut off the consumption of isobutane continues for over an hour. These periods will be referred to as the induction period, the steady state period and the terminal reaction period, respectively. When the steady state is established the rate of consumption of isobutane is two to three times that of 2-butene. The best yields of alkylate accompanied the higher ratios. An approximate calculation shows that if the alkylation reaction involves a ratio of unity and if the condensed isoöctanes dissolve the expected amount of isobutane, a ratio of about three should be observed. Any ratio less than that involves polymerization or other consumption of 2-butene apart from alkylation.

The reaction studied is a complex one leading to a variety of products.[1a,b,c] Under the conditions

(1) (a) S. H. McAllister, J. Anderson, S. A. Ballard and W. E. Ross, *J. Org. Chem.*, **6**, 647 (1941), list two main fractions of trimethylpentanes and some 2,3-dimethylbutane from the reaction catalyzed by sulfuric acid. (b) L. Schmerling, THIS JOURNAL, **68**, 275 (1946), lists nineteen products from the reaction catalyzed by aluminum chloride. (c) M. H. Gorin, C. S. Kuhn and C. B. Miles, *Ind. Eng. Chem.*, **38**, 795 (1946), list six fractions from the reaction catalyzed by hydrogen fluoride.

described here, a poor yield of liquid alkylate is obtained prior to establishment of the steady state; but if a liter or more of the alkene is used up, and the reaction is allowed to run to saturation with the isobutane, a good yield (5–6 ml. per liter of gaseous alkene) of alkylate can be obtained. About half of the alkylate distils above the isoöctane range. For present purposes the initial predominating net reaction will be considered to be

$$C_4H_8(\text{gas}) + C_4H_{10}(\text{gas}) \xrightarrow{H_2SO_4} C_8H_{18} \text{ (liquid and dissolved } C_4H_{10})$$

and attention centered upon the factors which start the series of events leading to the formation of the actual products.

The Rate of Solution of 2-Butene.—It was necessary to know the instantaneous partial pressure of 2-butene in the reactor during introduction of the gas. This was observed with the reactor filled with nitrogen gas. As the flow of 2-butene was started the pressure in the reactor rose from five to twenty mm., depending upon the rate of flow of the 2-butene. A rise of 1 mm. of pressure corresponded to about 1 ml. of gas. This increase in pressure does not represent merely an accumulation of 2-butene as gas in the reactor, however, since whenever the flow of 2-butene was stopped the decrease in pressure was only 1–3 mm., and was complete in about one minute. Part of the permanent pressure increase, after starting and stopping the 2-butene, was eventually shown to be mechanical, *i. e.*, some 2-butene lodged in the manometer line. The remainder was due to an actual evolution of isobutane, produced through dismutation of the alkene, and will be dealt with separately. A pressure increase would operate to delay an apparent consumption of isobutane during alkylation, since isobutane entered the system only as a result of pressure drop. However, delay from this cause was a minor effect, inasmuch as the isobutane consumption eventually reached 20–30 ml. per minute; the observed induction is therefore extended by not more than one minute by this gas accumulation. Neither is the apparent induction due to slowness in the rate of solution of the 2-butene.

The Steady State Concentrations.—The delay in apparent isobutane consumption could have been due merely to a low specific reaction rate, in which case a finite concentration of 2-butene in the system would have to be built up before a steady-state condition would be reached. Experiments were accordingly made in which a part of the 2-butene was introduced rapidly, followed by a waiting period, with finally the usual slow addition of the alkene at a constant rate. Such a course is plotted in Fig. 2. It is seen that the isobutane consumptions of Figs. 1 and 2 are similar; the rate of reaction is not dependent merely upon the amount of 2-butene present but involves the production of a steady-state concentration of some intermediate compound.[2] The type of experiment shown in Fig. 2, which arrived at a given steady-state condition through a variation in the time of input of a critical amount of reactant, was performed many times and never failed to show a period of induction.

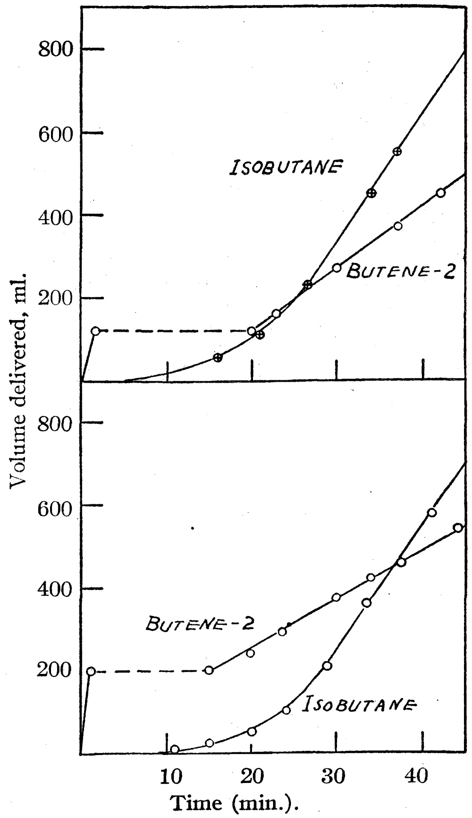

Fig. 2.—Rate of consumption of isobutane gas with interrupted addition of 2-butene.

Factors Affecting the Induction Period.—The length of the induction period may be varied by changing the rate of introduction of 2-butene and the amount of sulfuric acid present in the reactor. Table I presents some typical data.

TABLE I

INDUCTION PERIOD AS A FUNCTION OF RATE OF BUTENE INPUT

Volume acid, ml.	Rate of butene-2 input, ml./min.	Induction period, min.
25	7.5	35
25	7.5	32
25	10	25
25	13	18
25	24	18
25	30	15
100	10	40
100	12	38
100	30	22

---

(2) We see no evidence for the assumption that removal of inhibitors is responsible for the induction period.

It is seen that with increasing rate of input with either 25 ml. or 100 ml. of catalyst present, the induction time is decreased; a three-fold increase in rate of alkene input about halves the induction period. The four-fold increase in acid at a given rate of input less than doubles the induction period. It is evident that isobutane consumption is not related to a concentration of accumulated 2-butene as such; at the lower rates of input the time available for production of the critical intermediates tends to shorten (relatively) the induction period. Both a time and a concentration factor are required for the production of the steady-state condition.

The addition of about 0.005 mole of secondary butyl alcohol shortened the induction period from twenty-five minutes to seventeen minutes, but a similar amount of *t*-butyl alcohol more than halved the induction period (Fig. 3). The reaction of isobutylene with isobutane passes through a similarly shortened induction period.

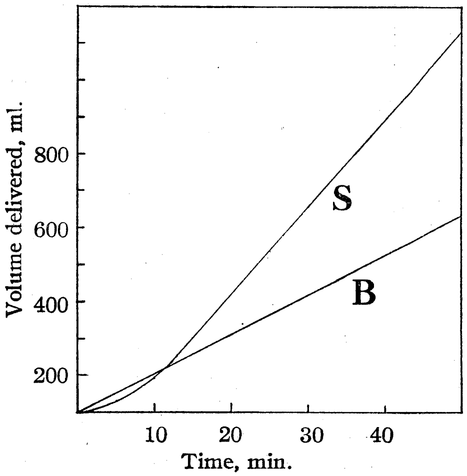

Fig. 3.—The effect upon the induction period of added *t*-butyl alcohol: S, isobutane; B, butene-2.

The presence of liquid alkylate made no difference in the length of the induction period. This was shown in two ways. A sample of the alkylate was recovered by steam distillation from the diluted contents of the reactor; after drying, this sample was added to fresh sulfuric acid in the reactor, with the same result as in the absence of the alkylate. In other cases the 2-butene was shut off, and saturation of the system with isobutane was started. In varying times after cessation of the flow of the alkene, a new run was started. The length of the new induction period depended upon the time of saturation. After two hours the used catalyst behaved as fresh catalyst and the induction period was normal; after one hour of saturation the induction period was about half of normal (see Table II). After twenty minutes the consumption of isobutane was slow but readmission of 2-butene was accompanied by only a short induction period.

Table II

Comparison of the Induction Periods in Fresh and Used Catalyst; the Effect of Saturation Time

Rate of butene input, ml./min.	Time of saturation, min.	Induction period	
		Used acid	Fresh acid
5	19	10	Long
7.5	35	15	32
10	42	15	25
8	50	16	30
16	100	16	18
11	120	18–20	20

Apparently a long-lived intermediate reacts with isobutane and also promotes establishment of the steady state condition.

The induction period was not affected by the partial pressure of the isobutane. In one experiment, using 25 ml. of sulfuric acid, the reactor was filled with equal partial pressures of nitrogen and isobutane, and the 2-butene introduced at 10 ml./min. The induction period was twenty-five minutes. In this case the ratio of isobutane to 2-butene during the steady state was about 1.5, since, at the reduced partial pressure of the isobutane, less of the alkane dissolved in the alkylate.

Discussion of Results.—A mechanism of the type suggested by Schmerling[1b] lends itself to an explanation of an induction period in the reaction studied. The essential feature of this mechanism is based upon the fact that isobutane acts as a reducing agent upon certain carbinol derivatives in the presence of alkylation catalysts.[3] In so doing it is oxidized to the *t*-butyl derivative.

$$(CH_3)_3CH + R'X \xrightarrow{\text{catalyst}} (CH_3)_3CX + R'H$$

The latter reacts with the alkene component of the alkylation, under the influence of the catalyst, to produce RX, which is reduced by isobutane either before or after isomerization to a form R'X.

$$C_nH_{2n} + (CH_3)_3CX \longrightarrow RX \text{ and } R'X \xrightarrow{\text{iso-}C_4H_{10}} RH \text{ and } R'H + (CH_3)_3CX$$

The intermediates RX and R'X may be considered as solvated carbonium ions, R^+ and R'^+ as outlined by Bartlett and co-workers.[3] The multiplicity of products is accounted for by side reactions and by the multiplicity of possible rearrangement products and their specific reaction rates toward isobutane, 2-butene and cracking. The reaction of isobutane, however, rests upon the above transhydrogenation with these intermediates, the concentrations of which are initially zero and reach a steady state value as 2-butene is introduced. The rate-determining step[4] in the

---

(3) See also Ciapetta, *Ind. Eng. Chem.*, **37**, 1210 (1945); Paul D. Bartlett, Francis E. Condon and Abraham Schneider, This Journal, **66**, 1531 (1944); L. Schmerling, *ibid.*, **66**, 1422 (1944).

(4) An editorial referee points out that the main reactions occurring during the induction period are of the type classified by Ipatieff and Pines (*J. Org. Chem.*, **1**, 464 (1936)) as conjunct polymerization. This is polymerization accompanied by *trans*-hydrogenation and results in saturated and unsaturated hydrocarbons; the latter are considered to undergo transhydrogenation with isobutane; the

formation of the final products could be a reaction rearrangement. The time required to approach steady-state conditions is largely independent of the activity of the isobutane, but is influenced by the rate of input of 2-butene, by the stirring and by the amount of catalyst. The steady-state concentration of a *t*-butyl derivative can be approached by adding *t*-butyl alcohol or isobutylene; otherwise it is built up by isomerization of the normal butene or through transhydrogenation reactions involving polymers of 2-butene and isobutane.

Further evidence pointing toward the viewpoint outlined above is observed in a study of the kinetics of the terminal reaction which will be reported separately.

Apparatus and Materials.—The reactor vessel was a 500-ml. three-necked flask fitted with a separatory funnel and a Hershberg-type stirrer made of nichrome wire. The stirrer shaft was housed in a vacuum and pressure tight bearing; the stirrer was of such size that it was not completely covered by 25 ml. of sulfuric acid but was completely covered by 100 ml. of acid. At the bottom of the flask a glass capillary tube, which carried a stopcock, was sealed in. The reactor could be filled, emptied, and washed without disturbing any of the connections; it was surrounded by a metal tub which held cracked ice and water. The degree of agitation could be varied; normally there was violent spattering of the liquid phase.

Into an opening of the reactor was passed one arm of a T-tube; a second arm was connected to a mercury manometer, while the third arm was used to lead in the desired gases. The isobutane and 2-butene were stored over 85% phosphoric acid under a hydrostatic head held constant automatically. The 2-butene line contained a pump designed to deliver gas at small, constant, rates of flow even against minor changes in pressure; the pump was bypassed by a line used for rapid delivery of 2-butene. The flow of isobutane was controlled by an automatic gas valve which was actuated by a mercury manometer connected to the line of the main manometer. The gas pressure in the isobutane gasometer was always constant and essentially the same as the total pressure in the reactor, since rates of flow were low.

A typical procedure involved testing for leaks under both vacuum and pressure; evacuation of the reactor to less than 1 cm. pressure; delivery of the desired amount of 96% sulfuric acid to the cooled reactor; flushing out and filling the reactor with isobutane gas; stirring to assure saturation of the sulfuric acid and adjusting the pressure; starting the 2-butene pump and thereafter recording the delivered volume of the two gases.

The sulfuric acid used was Baker and Adamson C.P. 96% acid. The 2-butene and isobutane were of highest purity, supplied by the Shell Development Co., Emeryville, California. Several different batches, of better than 99% purity, gave the same results.

Acknowledgment.—We wish to acknowledge the assistance of the Shell Development Co. in furnishing the pure isobutane and 2-butene for this investigation. We are also indebted to Miss Eva Herzberg, of this Laboratory, whose preliminary work suggested the existence of an induction period in the reaction studied.

Summary

Gaseous 2-butene was passed at a constant slow rate into a vessel filled with isobutane and containing vigorously stirred 96% sulfuric acid at 0°. The 2-butene dissolved rapidly without reaction of the isobutane; after from ten to twenty-five minutes, consumption of isobutane started and from then on the ratio of the two gases consumed was constant. The length of the induction period was largely independent of the time required to introduce a given amount of 2-butene, and was not affected by the presence or absence of an oil phase initially. It was affected by the rate of continued addition of the alkene, by the amount of acid present, and by the addition of small amounts of *t*-butyl alcohol. It is concluded that steady state concentrations of intermediate compounds develop during an inhibition period, consisting of (1) *t*-butyl derivatives, which react with the incoming 2-butene, and (2) the products of that condensation, which undergo transhydrogenation with isobutane, in accordance with Schmerling's mechanism.

BERKELEY, CALIFORNIA RECEIVED AUGUST 7, 1947

---

former conceivably dealkylate and the resulting alkene portions also engage in transhydrogenation. The initial rate of reaction of isobutane, he considers, "may be dependent on the actual concentration of olefinic polymer present, and the rate of transhydrogenation of isobutene with the polymers of 2-butene and also the rate of the dealkylation reaction." These factors would be influenced by the experimental conditions and "would not require the assumption of long-lived intermediates of the carbonium type." The point at issue seems to be whether a single course is set for the whole reaction at the start, or whether, after some time, a new course develops which finally predominates. If there is a single path followed from the start, then our induction period is an accident of the experimental conditions, and, we feel, would not be so little influenced by changes in those conditions. But if the Schmerling mechanism operates during our steady state, and is self-perpetuating, then the major, if not only, role of conjunct polymerization is that of a side-reaction which aids in producing a critical intermediate.

The reactions of dealkylation are not observable, nor do they seriously affect the observed rate during the steady state. This is because they are slow compared to the major reaction and are likely to generate as much isobutane as they consume. If the steady-state reaction does not depend largely upon either conjunct polymerization or dealkylation, but rather upon transhydrogenation of products formed from 2-butene and a tertiary butyl derivative present in small amount, there remains in question the identity of the rate-determining step during the steady-state reaction.

The Inhibition of D-Amino Acid Oxidase by Benzoic Acid and Various Monosubstituted Benzoic Acid Derivatives

BY GRANT R. BARTLETT

Benzoic acid has been reported to give a marked and selective inhibition of the enzyme D-amino acid oxidase.[1] This inhibition is apparently due to a reaction with the activating protein rather than with the flavine-nucleotide prosthetic group, and involves a competitive reversibility with substrate amino acid.[1,2]

In this paper enzyme inhibition is used as a tool to study the influence of ring substitution on the reaction between benzoate and amino acid oxidase protein. There is also presented a more rigorous proof of the substrate competitive nature of the benzoate inhibition and more information on the specificity of the reaction.

Experimental

The D-amino acid oxidase preparation was essentially that described by Krebs.[3]

Pig kidney acetone powder was extracted with five volumes of water in a Waring Blendor, centrifuged and the supernatant lyophilized. The dry powder retains its activity for at least six months at room temperature. Enzyme activity was assayed by oxygen consumption with DL-alanine as substrate in standard Warburg manometric equipment. Unless otherwise specified, conditions were as follows: 1.0 ml. containing 10 mg. of lyophilized pig kidney extract, 0.5 ml. 0.2 *M* *p*H 7.6 pyrophosphate buffer, 0.3 ml. of 0.3 *M* DL-alanine added from side arm at −3 min., 0.3 ml. of inhibitor solution, water to 3.0 ml. total volume in main part of vessel, 0.2 ml. of 20% potassium hydroxide in center cup, air as gas phase, oxygen consumption measured from 0 to thirty minutes, temperature 38°. Substrate, inhibitor and other solutions were neutralized before adding to vessels.

To check the degree of inhibition each benzoate was tested at 10^{-2}, 10^{-3}, 10^{-4}, and 10^{-5} molar concentrations. Inhibitory values between 10 and 90%, when plotted against the log of the inhibitor concentration fell on a straight line. There was some deviation at each end of the curve. The slopes for all benzoates tested were identical; 50% inhibition values were calculated from the log benzoate–per cent. inhibition curves. A typical analysis is given in Table I, demonstrating the relationship of inhibitory capacity to concentration of benzoate and showing the reproducibility of data obtainable with two different enzyme preparations.

TABLE I

SAMPLE ANALYSIS. INHIBITION OF D-AMINO ACID OXIDASE BY *p*-TOLUIC ACID[a]

	10^{-2} *M*	0	100

Calcd. 50% inhibition: 2.5×10^{-4} *M*

[a] Warburg manometric analyses, see text for details.

All benzoates used were commercial products, which when necessary were recrystallized until melting points and titration equivalents checked with accepted values. *o*-Fluorobenzoic acid was kindly supplied by Dr. M. Kilpatrick. The author is indebted to Mr. and Mrs. Francis E. Fowler, Jr., and members of their family, whose generosity has made these studies possible. The helpful encouragement and advice of Dr. E. M. MacKay is gratefully acknowledged.

Results and Discussion

Benzoic acid inhibited D-amino acid oxidase approximately 50% at 10^{-4} *M*, less than 10% at 10^{-5} *M*, and more than 90% at 10^{-3} *M*; see Table II for 50% inhibition values for benzoic acid and a number of ring monosubstituted derivatives. A wide variety of other enzyme systems were inhibited less than 10% by the relatively high benzoate concentration of 10^{-2} *M*; oxidation of acetate by baker's yeast, hydrolysis of edestin by pepsin, decarboxylation of pyruvate by dried brewer's yeast, hydrolysis of acetylcholine by serum, hydrolysis of urea by urease, glycolysis of hexosediphosphate by muscle acetone powder, hydrolysis of monobutyrin by liver esterase, decomposition of hydrogen peroxide by catalase, and oxidation of succinate, choline, uricate and tyramine by a minced, washed rat liver preparation. These results provide a more extensive verification of Klein and Kamin's[1] observations on the highly selective action of benzoate toward D-amino acid oxidase.

From the viewpoint of structural similarity one would not expect benzoate to compete reversibly with the substrate amino acid. However, such a relationship does occur. Concentrations of D-alanine from 0.0032 to 0.316 *M* were tested with 10^{-3} and 10^{-4} *M* benzoate. In Fig. 1, the per cent. inhibitions are plotted against the log concentration of D-alanine. At all ratios of alanine to benzoate there was strict reversible competition. The inhibition is independent of the absolute amount of benzoate and a function of the ratio of alanine to benzoate. Fifty per cent. inhibition results at a ratio of D-alanine to benzoate of 100 to 1. High concentrations (0.1 *M*) of potassium chloride, glycine or of L-alanine had no reversing effect on the inhibition of the oxidation of D-alanine by benzoate. Glycine and L-amino acids are not acted upon by the enzyme nor do they affect the oxidation of D-amino acids. The competition

experiments prove that substrate displacement adequately accounts for the inhibition: probably both substrate and inhibitor having a high affinity for the same position on the protein.

Various other compounds were tested in order to give some definition of the relationship of structure to enzyme inhibition. Phenyl carboxylate ion proved to be the essential structural unit. At the *p*H of the test system more than 99% of any of the benzoates used would exist as carboxylate ion. Substitutions on carboxyl, replacement of carboxyl by another acidic radical, replacement with alkyl carboxylates, all resulted in negative activity. For example, the following compounds gave less than 10% inhibition at 10^{-2} *M* concentrations: benzamide, ethyl benzoate, phenyl acetate, phenyl propionate, mandelate, sulfanilate, phenyl phosphate, benzenesulfonate.

Although alteration of carboxyl completely destroys the toxicity, ring substitution results in a wide variation in the inhibiting capacity, probably by altering the electron configuration at carboxyl carbon or in the case of *ortho* substituents, giving rise to steric hindrance. The inhibiting power of a series of monosubstituted benzoates is given in Table II. The following points can be emphasized. Except for hydroxy and amino, *meta* gives the greatest inhibition, *para* is intermediate and *ortho* is very low. With hydroxy and amino there is not a marked *ortho* effect, the *para* position giving the lowest inhibitions. In general, halogen, methyl and nitro are stronger inhibitors than hydroxy, amino, methyl and a second carboxyl. The dicarboxylic acids give practically no inhibition. The halogens show a striking series of increasing inhibition in order of increasing electronegativities. *Ortho* substitution apparently blocks access of phenyl carboxylate to the reacting position on protein. It is felt that this can best be looked upon as a geometrical steric hindrance following the notions originally postulated by Victor Meyer for the *ortho* blocking of esterification of benzoates. No analysis will be given here of the relationship of structure to the benzoate protein reaction in terms of current notions on the influence of inductive and resonance effects. However, it is suggested that the quantitative data on the monosubstituted benzoates should provide an interesting series for checking such theories.

[a] Figures represent the molar concentration giving 50% inhibition.

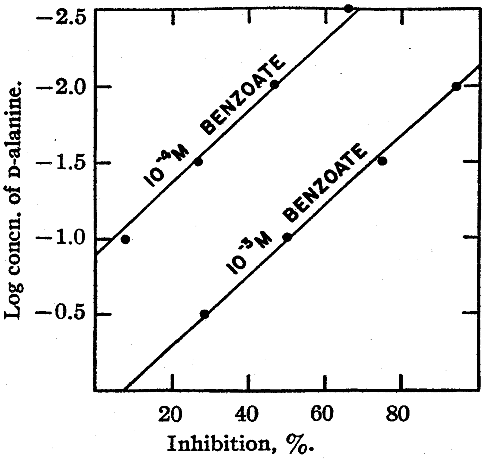

Fig. 1.—Substrate competitive nature of the inhibition of D-amino acid oxidase by benzoate.

Summary

Benzoate was incubated with a variety of enzyme systems and found to be highly specific for inhibiting D-amino acid oxidase.

Benzoate and D-alanine showed a reversible competition for protein over a wide range of concentrations, 50% inhibition of enzyme resulting at a ratio of alanine to benzoate of 100 to 1.

Phenyl carboxylate proved to be the essential structural unit necessary for the D-amino acid oxidase inhibition. Quantitative data is given on the affinities for D-amino acid oxidase of a number of ring monosubstituted derivatives of benzoic acid.

Quinolines. V. Some Polysubstituted 4-(4′-Diethylamino-1′-methylbutylamino)-quinolines[1]

BY EDGAR A. STECK, LOUIS L. HALLOCK, ARNOLD J. HOLLAND AND LYNN T. FLETCHER

Chloroquine (SN 7618, 7-chloro-4-(4′-diethylamino-1′-methylbutylamino)-quinoline)[2,3] has been found to be the most effective of the quinoline antimalarials bearing the basic chain in position 4. In our program, which has involved the preparation of numerous analogous compounds bearing an alkyl group in the pyridine moiety,[4] we have attempted to evaluate the influence of the position and nature of several groups upon antiplasmodial activity. The 4-(4′-diethylamino-1′-methylbutylamino)-quinolines here discussed will include all possible bz-fluoro-3-methyl types, 3,6,5/7-trimethyl, 7-chloro-2-methyl, and also the 5/7-chloro-3-propyl.

As in our previous work,[4] the fundamental plan of synthesis was based upon the Conrad–Limpach synthesis, employing several recent modifications in the technique of cyclization. The bz-fluoro-3-methylquinoline series were obtained from the requisite fluoroanilines by reaction with ethyl α-ethoxalylpropionate. To separate the ethyl 5/7-fluoro-4-hydroxy-3-methylquinoline-2-carboxylates, which were prepared from *m*-fluoroaniline, fractional crystallization was required (*cf.* 4 c,d). Oxidation of the acids derived from the esters (which had been crystallized to constant m. p.) by use of alkaline permanganate solution was unexpectedly difficult. No pure specimens of the oxidation products from either series could be identified with certainty as 4-fluoroanthranilic acid,[5] and the attempt was abandoned. The series giving rise to the higher melting 4-chloro compound, was designated as the 7-fluoro type; the parent ester was not only the higher-melting of the two, but, more characteristically, less soluble in alcohol. The earlier experiences with the other isomeric 5/7-halo-3-methylquinolines[4c,d] have formed the basis for this decision. Separation of the ethyl 3,6,5/7-trimethyl-4-hydroxyquinoline-2-carboxylates by crystallization from alcohol was not attended by noteworthy difficulties. The attempts to prove conclusively the location of the 5/7-methyl group by oxidative means were not successful. Intractable mixtures of high-melting materials (polycarboxylic acids?) resulted. It was necessary to resort to an arbitrary designation of structure upon the above-noted basis.

The investigations of Strukov (1932), which were referred to by Gal'perin,[6] indicated a lack of antimalarial activity among several quinaldine types, but disagreement[7,8] or lack of testing data[9,10] concerning similar compounds led to interest in 7-chloro-4-(4′-diethylamino-1′-methylbutylamino)-quinaldine. Although it was expected[4c,d] that application of the Conrad–Limpach procedure to *m*-chloroaniline and ethyl acetoacetate would lead to both 5- and 7-chloro-4-hydroxyquinaldine, such was not the case. Despite careful study, only one discrete compound could be isolated. Oxidation with alkaline permanganate[4c] led to 4-chloroanthranilic acid, hence the product was proven to be the 7-chloro isomer. Price, *et al.*,[11] prepared 7-chloro-4-hydroxyquinaldine by this method, but a proof of structure was lacking. Conversion of the 4-hydroxy compound to the desired base was accomplished in the usual manner.

The application of the Conrad–Limpach procedure to *m*-chloroaniline and ethyl α-ethoxalylvalerate[12] was designed to yield a series of 5- and 7-chloro-3-propylquinolines. This investigation was hampered by poor yields, as in the preparation of the β-keto ester and its cyclization to the quinoline derivatives, and the tedious fractional crystallization required for the isomer separation. The fraction having the lower solubility in alcohol was demonstrated to be ethyl 7-chloro-4-hydroxy-3-propylquinoline-2-carboxylate through oxidation of its derived acid.

Of the bz-fluoro-4-(4′-diethylamino-1′-methylbutylamino)-3-methylquinolines which were tested, none showed activity comparable to the related chloro compound. Neither 4-(4′-diethylamino-1′-methylbutylamino)-3,5,6-trimethylquinoline nor its 3,6,7-trimethyl isomer exhibited marked antiplasmodial action. Although 7-chloro-4-(4′-diethylamino-1′-methylbutylamino)-quinaldine did show promise at first, its toxicity was unfavorable. This behavior was of interest because several other quinaldine types had not been of particular value.[6,8] Insufficient amounts of the bases of the 5/7-chloro-3-propylquinoline compounds were available for testing. Most of the antimalarial tests were carried out under the direction

of the National Research Council, and the data have been tabulated.[13]

Experimental

Fluoroanilines.—The fluoronitrobenzenes were prepared from the corresponding nitroanilines by the method of Schiemann.[14,15] Conversion of the diazonium borofluorides, which were obtained in 92–99% yields, into the fluoronitrobenzenes was best accomplished by mixing the salts with sand before decomposition. The yield of pure *o*-fluoronitrobenzene was 11–16%; *m*-, 48–51%; *p*-, 40–49%. Neutral iron reduction[16,4c] of the nitro compounds led to yields of 72–83% of the corresponding fluoroanilines.

Ethyl α-ethoxalylpropionate and ethyl α-ethoxalylvalerate were prepared as described in previous contributions.[4a,12]

Bz-Fluoro-3-methylquinoline Series.—The general pattern of synthesis for the isomeric bz-fluoro-3-methylquinolines was that earlier described by us.[4] Separation of the 5/7-fluoro compounds, obtained from *m*-fluoroaniline, was accomplished by fractional crystallization from alcohol. The isomer which was the less soluble (designated as the 7-fluoro, see discussion) of higher m. p., was considerably more facile of purification. In Table I are the data relative to the several series. Distillation of all the 4-(4′-diethylamino-1′-methylbutylamino)-bz-fluoro-3-methylquinolines was tedious.

3,6,5/7-Trimethylquinoline Series.—3,4-Dimethylaniline[17] was employed in the preparation of the trimethylquinoline derivatives. The isomeric esters were fractionally crystallized from alcohol and each obtained pure with fair ease; the lower-melting isomer was the more soluble of the two. Unequivocal designation as to structures could not be made, as noted in the discussion. The data presented in Table II relate to the compounds of this series.

7-Chloro-4-(4′-diethylamino-1′-methylbutylamino)-quinaldine.—Only one compound was obtained from the reaction of *m*-chloraniline with ethyl acetoacetate after the method of Conrad and Limpach. An oxidation of the 4-hydroxy compound by permanganate (*cf.* ref. 4c) demonstrated that the chlorine was in position 7, as shown in Table III, wherein the several quinaldines are described.

5/7-Chloro-3-propylquinoline Series.—The use of ethyl α-ethoxalylvalerate[12] as the β-keto ester in the usual

synthesis left much to be desired, for the first steps were accompanied by many difficulties. Considerable gum formation during the pyrolytic cyclization was responsible for much of the tediousness involved in the separation of isomers by fractional crystallization. Since there was but slight success in use of the method employed with the related 3-methyl type (*cf.* ref. 4c), fractionation was accomplished from alcohol, or, alternating, alcohol and aqueous acetone. The less soluble of the fractions was the 7-chloro isomer, for the bz-chloro-4-hydroxy-3-propylquinoline-2-carboxylic acid produced by its hydrolysis was oxidized to 4-chloroanthranilic acid by alkaline permanganate.[4c] An inadequate amount of the desired 5- and 7-chloro-4-(4′-diethylamino-1′-methylbutylamino)-3-propylquinolines was obtained for screening as antimalarials, but all pertinent information relative to them and intermediates required is given in Table III.

Acknowledgement.—The authors are pleased to have had the advantage of advice and encouragement from Drs. C. M. Suter and J. S. Buck during the course of these investigations. The analytical staff of the Institute, under the direction of Mr. M. E. Auerbach, has shown great patience and care in carrying out the many determinations required. Mrs. N. P. Gorman and Mrs. E. J. Altier have rendered further valuable technical assistance.

Summary

A group of 4-(4′-diethylamino-1′-methylbutylamino)-quinolines has been prepared, including all possible bz-fluoro-3-methyl derivatives, and also 3,6,5/7-trimethyl, 7-chloro-2-methyl and the 5/7-chloro-3-propyl types.

Paralytic Shellfish Poison. I. Occurrence and Concentration by Ion Exchange[1,2,3]

BY HERMANN SOMMER, ROBERT P. MONNIER, BYRON RIEGEL, D. WARREN STANGER, JAMES D. MOLD, DONALD M. WIKHOLM AND ELIZABETH SHANESY KIRALIS

The paralytic form of shellfish poisoning in man has been recognized for over a century as a clinical entity.[4] Shellfish become poisonous when they feed on the marine plankton organism, *Gonyaulax catenella* Whedon and Kofoid. This was established by Sommer and co-workers,[5] who showed: (1) that in the three-year period studied, there was a close correlation between the toxicity of shellfish and the number of *Gonyaulax catenella* per liter present in sea water; (2) that non-toxic bivalves kept in the laboratory became toxic when supplied with fresh sea water rich in this dinoflagellate; and (3) that the poison could be obtained directly from this plankton organism.

The California mussel, *Mytilus californianus* Conrad, has proved to be a better source of the poison, on a scale sufficient for chemical study, than the dinoflagellate. It has been estimated that the average mussel filters 38 liters of sea water a day to obtain its food supply of plankton.[5] Extensive beds of these mussels are found along the rocky Pacific coast of North America. From April to November selected beds along the coast 150 miles north and south of San Francisco were sampled semimonthly and the poison titer of the mussels determined. A large-scale collection was made when the poison content reached or exceeded 4000 MU. per 100-g. mussel.[6]

Daily collections can be made only during the last four or five days of the minus tide period, which occurs every two weeks with the new or full moon. Usually there is only one such period in the entire season during which the mussels are sufficiently toxic to warrant collection. In summer the lower low tide is at daybreak or shortly afterward. In the two-hour period when the beds were accessible, the mussels were pried loose from the rocks and carried up on the beach above tidewater. There they were sorted, washed and opened.[7] The "livers" or digestive glands were dissected out and preserved in acidified ethanol.

In the three-year period, 1944–46, a total of 4360 kg. of mussels containing 160×10^6 MU of poison was collected. The extraction of one of the many collections is shown in Table I. This collection was made south of Pedro Point, San Mateo County, California, on July 18, 1946.

[1] The work described in this paper was initiated under a contract between the Federal Security Agency and the University of California and Northwestern University. It was continued under a contract with the Chemical Corps, Camp Detrick, Frederick, Maryland.

[2] Since the mass poisoning in the San Francisco area in 1927, Dr. Karl F. Meyer, Director of the George Williams Hooper Foundation for Medical Research, University of California, has sponsored research on shellfish poison. He was responsible for renewed interest in the problem in 1944, when the contracts for further research in this field were made. The members of the Northwestern group are greatly indebted to Dr. Meyer for making the facilities of the Foundation available to them each summer during the collection period.

[3] The authors wish to thank Dorothy Butler, Ardath Clark Van Tuyl, Patricia Garbutt, Esther Kline and Ruth Nell for their technical assistance.

[6] The mouse unit (MU.), or average lethal dose, is defined as the amount of mussel poison contained in 1.0 ml. of aqueous solution that, injected intraperitoneally into a 20-g. white mouse, will cause death in fifteen minutes. Directions for carrying out this bioassay, together with the tables for calculating the number of MU in the test solution from the weight of the mouse and the dying time, were furnished by H. Sommer to the other workers in this field. These tables are based on graphs[4b] recorded in the literature.

[7] Many of the people in the collecting party were members of the Hooper Foundation who volunteered their services. The authors are especially indebted to Lucile Foster, Florence Hockin, Vera Kreekis, Adelien Larson, Alma McDole, Ethel Meyer, Edward Sherry, Susanne Sommer and Richard Sommer.

6	3,820	54	2.77	0.150
	31,910	1540	3.73 av.	5.738

[a] The livers were preserved in ethanol containing 4 ml. of concentrated hydrochloric acid per liter. [b] They were ground in a meat grinder and the *p*H of the *brei* was adjusted to approximately 4.5 by the addition of 60 ml. of concentrated acid. [c] Extract no. 1 was made by centrifuging the suspension of ground livers. Subsequent extracts were made in a similar manner after resuspending the residue in ethanol containing 2 ml. of concentrated hydrochloric acid per liter and stirring overnight. The final extracts were made by heating the suspension at 70° during the stirring.

Extracts of comparable toxicity were combined and divided into aliquot portions, each containing about 10^6 MU. of poison. Since the first extract of each day's collection contained large amounts of lipid material, it was advantageous to remove this by extraction with ether before proceeding further. With subsequent extracts it was immaterial whether defatting was done before or after decolorization. The ether extract usually contained less than 1000 MU. of poison.

Decolorization was carried out by adding 10–20 g. of active carbon (Nuchar C or XXX) to the extract and shaking. After standing overnight, the extract was filtered through a layer of the carbon on a Bücher funnel. The first portion of the filtrate was set aside and the remainder passed through a second lot of fresh carbon. This was continued until the desired degree of decolorization (dark red-brown to pale yellow) was attained. As much as 10% of the poison was lost due to irreversible adsorption or actual destruction. For this reason, the minimum weight of carbon (10–60 g.) was used and only partial decolorization carried out.

To remove a large portion of the ethanol, the decolorized extract was concentrated to 400–500 ml. With some extracts it was possible to improve the toxicity greatly by an additional step. The extract was concentrated *in vacuo* at 35–40° to a thin sirup By the very slow addition of absolute ethanol to the sirup, a white granular material was precipitated. This contained almost none of the poison and was in part taurine. However, the precipitate was often gummy and contained a large proportion of the poison. For this reason the step was omitted in most preparations.

The low concentration of the poison in the crude extract and its chemical and physical properties, insofar as they were known, determined the limited number of methods available for its purification. Evidence pointed to a minimum toxicity of 1 MU./0.001 mg.[8] for the purified poison. In a crude extract with a toxicity of 4–8 MU /mg. the poison would be present at most to the extent of 0.4–0.8%.

Mussel poison has been shown to be soluble in water, methanol, ethanol, glacial acetic acid and aqueous acetone.[4a] The effectiveness of these solvents for extracting the poison appeared to increase if small amounts of hydrochloric acid were added. The poison was insoluble in ether, chloroform, ethyl acetate, butanol and toluene. It could not be extracted from an aqueous alkaline solution by any of these solvents.

Studies were made of the effect of *p*H and temperature on the stability of the poison in aqueous solution as measured by its toxicity (Figs. 1 and 2). The results of these studies set further limits on the methods which might be used in purification. The decrease in toxicity with an increase in *p*H and in temperature showed that the poison must be handled in acid or, under certain conditions, in neutral solution and for all operations the temperature must be kept as low as possible.

Previous attempts to isolate the poison by precipitation with reagents, such as gold chloride, Reinecke salt, and phosphomolybdic, picric and rufianic acids, had been disappointing.[8] In general, either the compound, if it were formed, was too soluble to be obtained as a precipitate, or there was a loss of up to 100% in the toxicity of the poison, or the complex could be decomposed only by the use of alkali which destroyed the poison.

The isolation of betaine from a partially purified extract of mussel poison indicated that the properties of betaine and the poison were enough alike that the substances tended to accompany each other. This fact and the solubility behavior of the poison suggested that it might be a nitrogenous base.[4a] In an attempt to take advantage of the basic properties of the poison, ion exchange was tried as a method of concentration.[8] This proved to be highly successful and experimentally demonstrated the basic nature of the poison.

A commercial zeolite, sodium Permutit, was used by Sommer and Müller, but further studies[9] indicated that the barium compound was more

suitable. The poison was adsorbed according to the equation

$$BaZ + BCl_2 \rightleftharpoons BZ + BaCl_2$$

where BaZ is barium Decalso (Permutit) and BCl_2, mussel poison hydrochloride. After the column had been well washed with water, the poison was eluted with a 20% solution of barium chloride. Concentration of the eluate and treatment with absolute ethanol removed most of the barium chloride.

The conditions for the concentration of mussel poison by ion exchange were determined by the properties of the poison and of the cation exchanger. The pH range of the poison extract for

[a] A suspension of 1 kg. of commercial Decalso in water was evacuated to remove the entrapped air. The suspension was poured into a tube provided with a stopcock and a pad of absorbent cotton to form a column of Decalso 7 × 50 cm. It was washed with 3 liters of water, 3 liters of 2% acetic acid, 6 liters of water and 1.5 liters of a 20% aqueous solution of crystalline barium chloride ($BaCl_2 \cdot 2H_2O$). To convert the column from barium to sodium Decalso, it was treated with 2 liters of saturated sodium chloride solution and washed with water. The aqueous poison extract (1.5 liters) was passed through the column followed by 4 liters of wash water. The poison was eluted with 1.5 liters of a 20% solution of barium chloride. [b] The collection of mussels from which this extract was prepared had been made in 1936 at a time when the average mussel liver contained 10,000 mu. of poison. After decolorization, the extract was concentrated to a sirup and treated with 200 ml. of absolute ethanol which precipitated a white insoluble material containing no poison. The filtrate was treated with 1 liter of ether and placed in the cold room overnight. The ether was decanted and the gummy residue was dissolved in 1 liter of water. The pH was adjusted to 5.0 with 0.2 N barium hydroxide solution before adsorption on Decalso.

adsorption was limited by the fact that the poison is unstable in alkali and the Decalso becomes less stable as the acidity increases. In the early experiments, the *p*H of the extract was adjusted to 5.0 by the addition of 0.2 *N* barium hydroxide solution in the presence of ice (preparation 1, Table II). This introduced barium ions, which tended to drive the above reaction to the left by either preventing the adsorption of the poison or causing its elution. Later experiments showed that, within the limits 2.5–5.0, the *p*H of the extract is not a critical factor. A poison extract, within these limits, may be passed through the column without adjustment of the *p*H (preparation 2).

A comparison of preparations 2 and 3 shows that a decrease from 60 to 10 g. in the amount of carbon used for decolorization of the crude extract may actually increase the poison content and toxicity of the subsequent Decalso eluate. There was no improvement in the toxicity of the poison when the amount of wash water passed through the Decalso column was increased from 4 to 14 liters before its elution.

The amount of poison found in the filtrate and washings depends upon two factors. The first of these is the toxicity, which obviously is inversely proportional to the amount of inert material mixed with the poison. When an extract with a toxicity of 1.93 MU./mg. was passed through barium Decalso, 67.8% of the poison was found in the filtrate and washings; but when one with a toxicity of 27.5 MU./mg. was used, only 9.9% of the poison passed through. The second factor is the cation of the zeolite. After considerable experience had been gained in the use of barium Decalso as the ion exchanger, a second study was made of the properties of sodium Decalso. The change from the divalent barium to the monovalent sodium ion resulted in a decrease from 27.4% to 7.7% of the poison which passed into the filtrate and washings (preparations 4 and 5), and an increase in the recovery of purified poison.

Zeolites using cations other than sodium or barium were also investigated. Copper Permutit adsorbed the poison, which in turn could be eluted with potassium sulfate. It was found unsatisfactory, since the copper ions could be removed only by precipitation with hydrogen sulfide, and this resulted in a loss of about 40% of the poison. Tetramethylammonium Permutit adsorbed the poison quantitatively, but tetramethylammonium bromide was ineffective as an eluant. Concentrated potassium sulfate eluted the poison, but no great improvement in toxicity was obtained.

Lloyd's reagent adsorbs the poison almost quantitatively even in the presence of acid or alcohol. However, until recently it has not been possible to find a satisfactory eluant. This work, which is now in progress, will be reported later.

Synthetic resins prepared by the condensation of polyhydroxy phenols with formaldehyde[10] were investigated as cation exchangers for the concentration of the poison. The condensation product of phloroglucinol and formaldehyde adsorbed the poison, which could be eluted with dilute hydrochloric acid. Since the toxicity of the poison was not improved by this process, it was not further studied.

The following recommended procedure is based on the experience gained in the preparation of more than seventy-five mussel poison concentrates by ion exchange on Decalso. An aliquot portion of the crude extract containing 10^6 MU. of poison with a toxicity of 4–8 MU./mg. is partially decolorized with 10–60 g. of Nuchar. The filtrate is concentrated and extracted with ether to remove the lipids. These steps result in the loss of 10–20% of the poison. The solution of the poison is diluted to 1.5 liters with water and passed through a column containing 1 kg. of sodium Decalso. The Decalso is washed with 4 liters of water and the poison is eluted with 1.5 liters of a 20% barium chloride solution. Concentration of the eluate and extraction with alcohol furnishes a 50–70% yield of the poison with a toxicity of 70–140 MU./mg.

Summary

1. The collection of poison mussel livers and the preparation of the extract are described.

2. Studies show that the toxicity of the poison in aqueous solution decreases with an increase in *p*H and an increase in temperature.

3. The low concentration of the poison and its chemical and physical properties limit the methods available for its purification.

4. A procedure is described for the preparation of mussel poison concentrates by the use of ion exchange on barium or sodium Decalso. It is possible to obtain a 50–70% yield of the poison with a toxicity of 70–140 MU./mg., an enrichment of eighteen-fold.

5. Results obtained by varying the cation of the zeolite or by the use of synthetic resins have proved less satisfactory than those obtained by the method described.

Paralytic Shellfish Poison. II. Purification by Chromatography[1]

BY HERMANN SOMMER, BYRON RIEGEL, D. WARREN STANGER, JAMES D. MOLD, DONALD M. WIKHOLM AND MARGARET B. MCCAUGHEY

Mussel poison concentrates prepared by ion exchange on Decalso[2] contain salts of other organic bases as well as inorganic salts. Sommer and Bendien[3] investigated the use of chromatography for further purification and found active carbon to be the most satisfactory adsorbent.

Preliminary tests were conducted to determine the optimum conditions for the chromatography. The results were accepted as the basis for all further work and corroborative tests have not been made using purer concentrates. Of the four carbons tested (Darco G-60, Norit A, and Nuchar C and XXX), Norit A appeared to be the most suitable. The mussel poison was not adsorbed completely from solutions much more dilute than 1.0 *N* in acid. Similarly, traces of ethanol in the extract caused a partial elution of the toxic material.

All of the succeeding runs were made by adsorbing the poison from 1.0 *N* hydrochloric acid solution. The mussel poison hydrochloride was retained by the carbon and the major portion of the inorganic as well as organic contaminants passed through at once. The use of distilled water to develop the chromatogram was sufficient to carry the poison through into the filtrate. The toxicity of the material in each fraction collected was calculated from the bioassay[4] and the determination of total solids. The most toxic fraction usually had a *p*H of about 2.3. The chromatography of a typical concentrate obtained by ion exchange on Decalso is described in Table I. Mussel poison hydrochloride with a toxicity greater than 3.3 MU./γ has been prepared by rechromatographing combined lots of material of high toxicity obtained from carbon columns. In this way the ash content of these samples has been reduced to 3–4%.

[a] The adsorbent was commercial acid-washed Norit A which was further digested with 10% hydrochloric acid. Treatment was repeated until a negative test for the ferric ion was obtained with 10% potassium ferrocyanide solution. The carbon was well washed with water and dried. A smooth suspension of 15 g. of the carbon in methanol containing 10 ml. of concentrated hydrochloric acid per liter was poured into a Pyrex column provided with a stopcock at the bottom and a cotton plug to support the carbon. The solvent was allowed to run through until level with the top of the adsorbent, and the amount remaining (38 ml.) was considered the hold-up of the carbon column (21 × 85 mm.). The column was operated under an air pressure of 125 cm. of water. The chromatogram was developed with distilled water. The final traces of material remaining on the column were eluted with the acidified methanol.

The use of dilute aqueous hydrochloric acid in place of acidified methanol in preparing the column for chromatography has little or no effect on the recovery of the poison. However, the rate of filtration of the water is more rapid in the latter type of column.

For crude mussel liver extracts with toxicities less than about 3.3 MU./mg., the concentration by ion exchange on Decalso proved unsatisfactory.[2] A method, which was suggested by the work of Sommer and Bendien,[3] was applied to this material with some success. This involved the direct chromatography of partially decolorized and defatted crude extracts on active carbon after removal of traces of ethanol by successive evaporations with water. It is possible to obtain fractions of mussel poison hydrochloride with toxicities greater than 1.0 MU./γ by this method (Table II). A decided advantage is that an over-all recovery of 60–80% is usually obtained. The poorer fractions may be rechromatographed for further purification. This method was not used for material of greater toxicity, since the Decalso procedure was less time-consuming and provided enriched poison concentrates in fairly good yield.

Since the preparation of the carbon for chromatography involved a rather lengthy procedure, it seemed advisable to attempt the repeated use

[a] Acid-washed Norit A (60 g.) was used to prepare a 31 × 190 mm. column which had a hold-up of 138 ml.

of these columns. This provided some unexpected results. The used carbon gave a better return of eluted material as well as fractions of higher toxicity in most cases. However, after the passage of several lots through the same column or the use of very impure starting material, the column had to be discarded. A typical series of repeated runs with mussel poison prepared by ion exchange on Decalso is given in Table III. When crude material was chromatographed on a column of acid-washed Norit A which had been used once, a similar improvement in yield and enrichment was observed.

An experiment in which used carbon was reactivated by digestion with 10% hydrochloric acid indicated that it could be used again for chromatography of crude extracts with somewhat higher yields and greater enrichment than could be obtained with fresh acid-washed Norit A.

The adsorption behavior of mussel poison on acid-washed Norit A appears to be dependent upon the nature of the anion. Experiments in which solutions of mussel poison in 1.0 *N* hydrobromic, trichloroacetic and Reinecke acids were passed through columns of the active carbon provided widely varying results. The hydrobromide of the poison was found to be much more strongly adsorbed than the hydrochloride and was only eluted by acidified methanol. The trichloroacetate was not adsorbed under these conditions and passed through the column into the acid filtrate. The Reineckate was dissociated, the Reinecke acid being irreversibly adsorbed on the carbon and the poison reappearing as the hydrochloride in the eluate. None of these acids appeared

[a] Three grams of acid-washed Norit A was used to prepare a 11.5 × 80 mm. column which had a hold-up of 9 ml.

[b] The starting material was a Decalso eluate containing 152,000 MU. with a toxicity of 86.2 MU./mg. This material was dissolved in 75 ml. of 1.0 *N* hydrochloric acid and divided into three portions of 25 ml. each for the first three runs. The fourth run was carried out on combined fractions with toxicities greater than 0.296 MU./γ from the first three runs, a total of 42,900 MU. (0.436 MU./γ). The starting material for the fifth run was made up of fractions with toxicities greater than 0.908 MU./γ from the first four runs, a total of 88,200 MU. (1.00 MU./γ).

to offer any advantage over hydrochloric acid for chromatography.

The recommended procedure for purifying mussel poison concentrates by chromatographic fractionation on acid-washed Norit A is based on experience gained from carrying out over one hundred chromatograms. Though it is difficult to obtain exactly duplicate results even with aliquots of the same material on columns prepared in an identical manner, the average total recovery of poison in chromatography is from 60–80%. The most toxic fraction of the eluate contains 30–50% of the poison. This fraction will often show an enrichment of as great as twenty-fold if the starting material is a concentrate obtained by ion exchange on Decalso and as great as seventy-five-fold if the starting material is a crude, partially decolorized mussel poison extract. Poison concentrates obtained from ion exchange on Decalso contain 50–70% of the poison in the crude extract and usually have a toxicity of 0.07–0.14 MU./γ. Chromatography of these eluates on acid-washed Norit A results in a recovery of 30–50% of this poison with a toxicity greater than 1 MU./γ. The over-all recovery of poison with a toxicity greater than 1 MU./γ, after purification by ion exchange on Decalso and subsequent chromatography on acid-washed Norit A, is 18–30%.

Summary

1. A procedure is described for the chromatographic fractionation of mussel poison concentrates on active carbon.

2. Repeated use of carbon columns for the chromatographic fractionation of mussel poison hydrochloride usually results in a better recovery of poison as well as in fractions of higher toxicity.

3. The adsorption behavior of mussel poison on active carbon varies widely with different anions.

4. By chromatography on Norit A of mussel poison concentrates obtained from ion exchange on Decalso, it is possible to obtain a 30–50% yield of twenty-fold enriched material with a toxicity greater than 1 MU./γ.

5. The chromatography of partially decolorized, defatted, crude mussel poison extracts on Norit A yields 30–50% of seventy-five-fold enriched material.

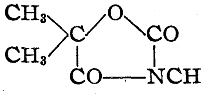
Some N-Alkyl-2,4-oxazolidinediones and their Anticonvulsant Properties

BY M. A. SPIELMAN AND GUY M. EVERETT

An earlier communication[1] has described the synthesis of some N-alkyl derivatives of 2,4-oxazolidinedione and their effect as analgesic agents. Subsequently, Everett and Richards[2] investigated the anticonvulsant properties of this type of compound, and as an outgrowth of their studies 3,5,5-trimethyl-2,4-oxazolidinedione under the trade name Tridione (I) has come into wide use in the treatment of petit mal epilepsy.[3] This paper presents results obtained in an expansion of the series.



I

The new N-alkyl-2,4-oxazolidinediones are much like those previously reported. They are liquids or low-melting solids, neutral in reaction and rapidly destroyed by strong aqueous alkali. They were synthesized along conventional lines as described below.

Experimental Part[4]

The parent 2,4-oxazolidinediones were prepared by the Stoughton method[5] in which an α-hydroxyester is condensed with urea by means of sodium ethoxide.

One α-hydroxyester is new. Methyl *n*-propyl ketone cyanhydrin on alcoholysis gave ethyl α-hydroxy-α-methylvalerate; b. p. 91–95° at 40 mm., n^{25}_{D} 1.4135. *Anal.* Calcd. for $C_8H_{16}O_3$: C, 59.98; H, 10.09. Found: C, 59.84; H, 9.88.

The following three new 2,4-oxazolidinediones were prepared by condensing the appropriate α-hydroxyester with urea.[5]

5-*n*-Propyl-2,4-oxazolidinedione boiled at 122–127° at 0.5 mm. After three crystallizations from ether–petroleum ether it formed thin blades which melted at 53–55°. *Anal.* Calcd. for $C_6H_9NO_3$: N, 9.80. Found: N, 9.63.

5-Isopropyl-2,4-oxazolidinedione boiled at 118–119° at 1.5 mm., n^{25}_{D} 1.4671. *Anal.* Calcd. for $C_6H_9NO_3$: N, 9.80. Found: N, 9.87.

5-Methyl-5-*n*-propyl-2,4-oxazolidinedione is a thick, colorless oil; b. p. 115–118° at 1 mm., n^{25}_{D} 1.4583. *Anal.* Calcd. for $C_7H_{11}NO_3$: N, 8.91. Found: N, 8.75.

N-Methylation was carried out with dimethyl sulfate as described before[1] except that the use of methanol as solvent gave more consistent yields.

Introduction of higher alkyls by reaction of silver salts with alkyl iodides[1] gave poor yields and the method was soon abandoned.[6] Better results were obtained by preparing the potassium salt of the 2,4-oxazolidinedione in Cellosolve (glycol monoethyl ether) and heating with the appropriate halide. Chlorides, bromides and iodides were substantially equivalent, although with iodides it was found best to add the halide slowly to the cooled solution or suspension of the salt.

[a] Ahlquist, *J. prakt. Chem.*, 99, 45 (1919), gives 119.5° at 12 mm. [b] The hydrochloride melted at 192°. *Anal.* Calcd. for $C_{11}H_{21}ClN_2O_3$: N, 10.60. Found: N, 10.75.

Typically, to 100–150 cc. of Cellosolve in a 3-neck flask assembly was added 0.2 mole of the 2,4-oxazolidinedione and 13 g. of potassium hydroxide pellets with heating to effect solution. To the refluxing mixture 0.2 mole of the halide was added dropwise. Heating was continued one hour. The solution was cooled, filtered, and the solvent was removed under diminished pressure. The product was taken up in ether, washed with sodium bicarbonate solution, dried and distilled. Yields were 50% or better with primary halides and less with secondary halides. No individual reaction was studied extensively with the idea of obtaining maximum yield.

The 5,5-dimethyl-2,4-oxazolidinedione-3-acetic acid was prepared in 40% yield by refluxing the sodium salt of the 5,5-dimethyl-2,4-oxazolidinedione and sodium chloroacetate in water for sixteen hours with subsequent acidification. It was crystallized from benzene.

Physical properties and analyses are shown in Table I.

Pharmacology

The compounds were tested for their ability to suppress in mice the convulsions induced by Metrazole (pentamethylenetetrazole) or electroshock. The method was that described in the earlier work[2] and was considered adequate as a preliminary test for the two types of anticonvulsant activity. The compounds of the present series are low in toxicity and mildly depressing. They were administered in doses up to those producing ataxia, and it may be seen in Table II that only a few compounds have anticonvulsant activity and only at levels where ataxia was evident. The results are in contrast to those obtained from 3,5,5-trimethyl-2,4-oxazolidinedione (Tridione), 3,5-dimethyl-2,4-oxazolidinedione and 5-ethyl-3,5-dimethyl-2,4-oxazolidinedione which are particularly active against Metrazole, and which have been demonstrated in clinical trial to have anti-epileptic action against petit mal.

TABLE II

ANTICONVULSANT ACTIVITY IN MICE

No.	Dose, mg./kg.	Symptoms	Protection Metrazole	Protection Electroshock
1	1500	None	−	
2	400	Ataxia	+	+
3	200	Ataxia	−	−
4	200–800	Slight ataxia	−	+
5	400	Ataxia	−	−
6	100	Ataxia	−	−
7	400	Ataxia	+	−
8	400	Ataxia	−	−
9	200	Ataxia	−	−
10	200	Ataxia	−	−
11	400	Ataxia		−
12	200	Ataxia	−	−
13	800	Excitement	−	−
14	800	None	−	−
15	1000	None	−	−

An interesting observation in the series is that compound 13, 5,5-dimethyl-3-*s*-amyl-2,4-oxazolidinedione, is not depressing as are the other compounds but instead exerts a stimulating effect and at high levels produces convulsions. On the other hand, compound 15, which has the diethylaminoethyl group on the nitrogen atom and therefore might reasonably be expected to prove stimulating, is practically devoid of pharmacological activity.

Summary

A series of N-substituted derivatives of 2,4-oxazolidinedione has been prepared and tested for anticonvulsant activity. None has sufficient potency to be of therapeutic interest.

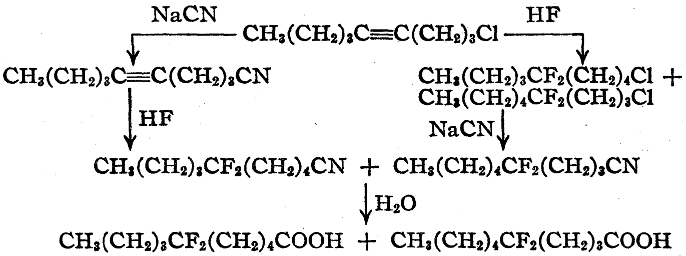
Synthesis and Reduction of Difluorodecanoic Acid Derivatives

BY MELVIN S. NEWMAN, MARY W. RENOLL[1] AND IRVING AUERBACH[1]

In this paper we describe the synthesis of 5,5- and 6,6-difluorodecanoic acids (mixture of isomers) and some reactions of their derivatives. The synthetic scheme is indicated below.



The starting compound, 1-chloro-4-nonyne, was best prepared by alkylation of 1-hexyne with 1-chloro-3-bromopropane using lithium amide in liquid ammonia. Of the two succeeding alternate paths, addition of hydrogen fluoride to the acetylenic nitrile proved superior.[2] In each case a mixture of isomeric difluoro compounds was obtained as was expected since the chloro or cyano groups were too far removed from the triple bond to cause directed addition. Because of the stability of the fluorinated compounds it is certain that CF_2 groups are present. The mixtures thus obtained were carried through to the corresponding difluoro acids, no attempt being made to separate pure individuals in any case.

Of particular interest are certain reduction reactions carried out in order to prepare the corresponding difluorodecanols. High pressure catalytic hydrogenation over copper chromite caused complete decomposition. Bouveault–Blanc reduction[3] was partly successful but considerable amounts of fluoride ion were detected in the reaction mixture. Reduction of the thiol esters by lithium aluminum hydride[4] gave the desired alcohol but the best method involved desulfurization of the thiol esters with Raney nickel.[5]

Experimental[6]

1-Chloro-4-nonyne.—Lithium amide, prepared in two liters of liquid ammonia from 42 g. (6 moles) of lithium, in presence of 1.8 g. of ferric nitrate nona-hydrate as catalyst, as described for sodamide by Greenlee and Henne[7] was treated with 492 g. (6 moles) of 1-hexyne[8] and then 946 g. (6 moles) of 1-chloro-3-bromopropane was added and allowed to react during fourteen hours.[9] Lithium amide, prepared and used *in situ*, was found to give higher yields of 1-chloro-4-nonyne than either sodium or potassium amide. After addition of 320 g. of ammonium chloride and subsequent evaporation of most of the ammonia, about 1500 ml. of water was added. Extraction with ether removed the organic product which was subsequently purified by fractional distillation. The yield of 1-chloro-4-nonyne boiling at 100–106° (23 mm.), $n^{20}D$ 1.4595, was 515.5 g. (54.2%). Approximately 180 g. of 1-hexyne was recovered, together with 51 g. of still residue.

4,4- and 5,5-Difluoro-1-chlorononane (Mixture of Isomers).—The addition of hydrogen fluoride to 1-chloro-4-nonyne was accomplished by adding a solution of 79 g. (0.5 mole) of 1-chloro-4-nonyne in 60 ml. of dry ether during one and three-fourths hours to a stirred mixture of 37 g. of dry ether and 83 g. (4.1 moles) of hydrogen fluoride in an ice-cooled stainless steel flask. After stirring for eight hours in the cold, the reaction mixture was poured on ice and extracted with ether. The ether extract was washed with 5% sodium hydroxide solution until free from acid and dried over calcium chloride. On distillation two fractions of incompletely fluorinated product were obtained: 37 g., b. p. 85–95° (11 mm.), $n^{20}D$ 1.4312; and 7 g., b. p. 95–105° (11 mm.), $n^{20}D$ 1.4297; together with 37.5 g. of heavy oil as still residue. The partly fluorinated material, 211 g., from a number of runs, was again treated with hydrogen fluoride (27 g.) at 0° as above, followed by stirring at room temperature overnight, to yield two fractions, 87 g., b. p. 87–92° (11 mm.), $n^{20}D$ 1.4232 and 84 g., b. p. 92–97° (11 mm.), $n^{20}D$ 1.4235. These completely fluorinated fractions were combined for conversion to the nitrile (see below). There was a still residue of 30.5 g. The pure chlorodifluorononane foams badly when redistilled.

Anal. Calcd. for $C_9H_{17}F_2Cl$: F, 19.1. Found: F, 19.7.

Increasing the time of contact of 1-chloro-4-nonyne with hydrogen fluoride (twenty-four hours) and allowing the temperature to rise to 7° during the latter part of this time (eight to twelve hours) afforded lower yields of fluorinated product and a larger amount of polymeric residue. The substitution of dimethyl or diisopropyl ether for ethyl ether as solvent gave slightly lower yields of fluorinated product.

5-Decynenitrile.—1-Chloro-4-nonyne (100 g., 0.63 mole) was refluxed, with stirring, with a solution of 123 g. of sodium cyanide in 175 ml. of water and one liter of ethanol for eighteen hours. After removal of nearly all of the alcohol under reduced pressure the residue was poured into water and extracted with ether. From the ether solution there was obtained 70 g. (74.5%) of 5-decynenitrile, b. p. 106–8° (5 mm.), $n^{20}D$ 1.4540.

5,5- and 6,6-Difluorodecanenitriles (Mixture of Isomers).—A solution of 202 g. (1.36 moles) of 5-decynenitrile in 140 ml. of ether was added to 268.5 g. (13.4 moles) of hydrogen fluoride in 106 g. of ether at 0° during two hours as described for 1-chloro-4-nonyne. The reaction flask was then placed in a vacuum-jacketed bath at 6° and stirring was continued for seventeen hours while allowing the temperature to rise to 18°. This was followed by four hours of stirring at 29°. From the washed and dried ether solution there was obtained 10 g. of fore-run, b. p. below 112° (5 mm.), 141 g. of incompletely fluorinated nitrile, b. p. 112–118° (5 mm.), $n^{20}D$ 1.4230, and 78 g. of crystalline still residue. A second treatment of 151 g. of

[9] Henne and Greenlee, THIS JOURNAL, **67**, 484 (1945).

the crude fluorinated nitrile in 85 ml. of ether with 160 g. (8 moles) of hydrogen fluoride in 65 g. of ether at 0°, followed by stirring for five hours at 25° gave a product consisting of 1 g. of fore-run, b. p. below 111.5° (5 mm.), $n^{20}D$ 1.4178, 135 g. of completely fluorinated nitrile, b. p. 111.5–118° (5 mm.), $n^{20}D$ 1.4145 and 15 g. of residue.

The crystalline still residue was hydrolyzed to difluorodecanoic acid by refluxing with potassium hydroxide in aqueous ethanol. From 176 g. of residue there was obtained 106 g. of acid.

1-Chloro-4,4- and 5,5-difluorononane mixture was converted to 5,5- and 6,6-difluorodecanenitrile mixture by sodium cyanide in 60% yield, as described for 1-chloro-4-nonyne. Approximately one-third of the starting material remained unreacted after twenty hours.

Difluorodecanoic Acid.—Hydrolysis of 265 g. (1.4 moles) of the nitrile by refluxing with a solution of 240 g. of potassium hydroxide in 1580 ml. of ethanol and 316 ml. of water, with stirring, for twenty-seven hours gave 274 g. (94%) of difluorodecanoic acid, b. p. 125–131° (2 mm.). When recrystallized from Skellysolve-B it melted at 44–46°, with softening at 40°.

Anal. Calcd. for $C_{10}H_{18}F_2O_2$: neut. equiv., 208; F, 18.3. Found: neut. equiv., 210; F, 18.4.

Taking into account the acid obtained by hydrolysis of the difluorodecanenitrile still residue (18%), the over-all yield of acid from 5-decynenitrile was 65%.

The **acid chloride** was prepared from the acid and excess thionyl chloride in 98% yield, b. p. 103–106° (4 mm.).

Ethyl Difluorodecanoate.—Esterification of 21 g. (0.1 mole) of difluorodecanoic acid with 25 ml. of ethanol in 150 ml. benzene, using *p*-toluenesulfonic acid as catalyst, gave 23 g. (97.4%) of ester, b. p. 107.5–108.5° (4 mm.), $n^{20}D$ 1.4126.

Reduction of Ethyl Difluorodecanoate.—Hydrogenation of 24 g. (0.1 mole) of ester over copper chromite catalyst (37 KAF)[10] in glass-lined equipment at 250° and 2500 lb. pressure resulted in almost complete decomposition of the ester.

A preliminary distillation of the Bouveault–Blanc[3] reduction product of 23 g. of ethyl ester separated 16 g. of material, b. p. 105–150° (3 mm.), and a small amount of still residue. Redistillation through a small helices-packed column gave 7 g. of 5,5- and 6,6-difluorodecanols (mixture of isomers),[11] b. p. 109–115° (5 mm.).

In order to identify the difluorodecanol, the phenylurethan, m. p. 73.6–74.2°, after recrystallization from Skellysolve-B, was prepared.[12]

Anal. Calcd. for $C_{17}H_{25}NO_2F_2$: F, 12.1. Found: F, 11.6.

Ethyl Thioldifluorodecanoate.—A solution of 120 g. (0.53 mole) of difluorodecanoyl chloride in 200 ml. of dry benzene and 100 g. (1.6 moles) of ethyl mercaptan was treated with 63 g. (0.78 mole) of pyridine in 100 ml. of dry benzene as described by Jeger.[5] The yield of ethyl thioldifluorodecanoate was 91 g. (68%), b. p. 118–121° (2 mm.). Thirty-one grams of difluorodecanoic acid was recovered.

***n*-Butyl Thioldifluorodecanoate.**—From 31 g. (0.14 mole) of difluorodecanoyl chloride, 50 g. (0.55 mole) of *n*-butyl mercaptan, 16.5 g. (0.21 mole) of pyridine, and 75 ml. of benzene there was obtained[5] 24 g. (88.9%) of *n*-butyl thioldifluorodecanoate, b. p. 125–130° (1.5 mm.).

Reductive Desulfurization of Ethyl and *n*-Butyl Thiol Esters.—(a) With Raney nickel[5]: Freshly prepared Raney nickel from 480 g. of Raney alloy[13] was washed by decantation several times with absolute ethanol and covered with 100 ml. of ethanol. A solution of 24–30 g. of the ester in 100 ml. of absolute ethanol was added slowly, with shaking, and agitation continued for one hour longer. Most of the supernatant liquid was decanted from the nickel through filter paper. The nickel residue was washed repeatedly with ethanol in a chromatographic adsorption tube plugged with cotton. The total volume of the combined ethanol solutions was about one liter. Because of foaming encountered in the removal of solvent by distillation, the alcohol solution was allowed to evaporate in an open dish at room temperature. The yield of difluorodecanol, b. p. 112–115° (5 mm.), was 15–18 g. (*ca.* 80%). There was no fore-run or residue in the distillation. It solidified at room temperature and had a pleasant odor.

Anal. Calcd. for $C_{10}H_{20}F_2O$: F, 19.6. Found: F, 18.9.

The reduction with Raney nickel is probably quantitative, but the removal of the last traces of product adsorbed on the nickel is most difficult.[5]

(b) With Lithium Aluminum Hydride: The preparation of lithium aluminum hydride and procedure for use as a reducing agent were as described.[4] A solution of 31 g. of mixed ethyl and butyl thiol esters in 50 ml. of dry ether was added to 50 ml. of an ether solution of lithium aluminum hydride containing 0.00136 mole of $LiAlH_4$ per ml. After removal of solvent, there was obtained 3.5 g. of fore-run, b. p. 103–110° (5 mm.), 17 g. of difluorodecanol, b. p. 110–115° (5 mm.), and 2.5 g. of still residue. All fractions had a mercaptan-like odor. It was obvious that by-products were formed in this reduction, in contrast to the complete absence of such substances in the Raney nickel reduction.

From 91 g. of ethyl thiol ester and 40 g. of *n*-butylthiol ester there was obtained a total of 78 g. (76%) of difluorodecanol by both reduction methods.

Summary

5,5- and 6,6-difluorodecanoic acids (mixture of isomers) have been synthesized from the corresponding nitrile which was formed by the addition of hydrogen fluoride to 5-decynenitrile. An alternate synthesis from 1-chloro-4,4- and 5,5-difluorononane (mixture of isomers) is described.

5,5- and 6,6-difluorodecanols (mixture of isomers) were prepared in good yield by Raney nickel reduction and by lithium aluminum hydride reduction of the ethyl thiol and *n*-butyl thiol esters.

Fluorinated Derivatives of Ethane and Ethylene. VII

BY ALBERT L. HENNE AND ROBERT P. RUH

In the preparation of fluorinated derivatives of ethane and ethylene by conventional methods,[1] several hundred grams of various compounds have been available for purification. Physical measurements were thus made possible which are believed to be more precise than those in the literature and are claimed to be accurate to the extent shown by the significant decimals appearing in the table. Indications of high purity were: freezing ranges of about 0.1°; boiling points constancy of better than 0.1°; and atomic refractions for fluorine (AR_F) very close to 1.0.

In general, the literature values hover closely around those reported here; data which diverge widely are as follows: The boiling point of $CHCl{=}CF_2$ is $-17.7°$, and not "about $+2.4°$" as we erroneously reported[2] when we had only traces of this material. Next in importance is the correction for CCl_2FCF_3, previously reported[3] as "about $-2°$," and now found to be $+3.6°$; the former sample had been obtained from distillation heads of the industrial preparation of $CClF_2CClF_2$ and was found contaminated by some CF_3CClF_2; the present sample was synthesized from pure CCl_3CF_3.

Few freezing points appear in the literature. We are in contradiction with Booth[4] on the freezing point of $CClF{=}CCl_2$, which he gives as $-82°$ while we observed $-108.93°$, with a total range of less than 0.1°. We agree fully with Booth's boiling point, and we note in his paper that his freezing point was not determined by himself.

TABLE OF PHYSICAL CONSTANTS

	F. p., °C.	B. p., °C.	$t°$	$dt/4$	nt/D	MR	AR_F
$CH_2{=}CFCl$	−169	−24.0

Isomerization During Allylic Fluorination

BY A. M. WHALEY AND H. W. DAVIS

In the attempt to prepare $CCl_2{=}CClCHF_2$ (I) by the allylic fluorination of $CCl_2{=}CClCHCl_2$ (II) unexpected results were obtained. The fluorination was conducted in the usual way for allylic polychlorides[1] except that some antimony pentachloride was added. This was done to make sure that no material remained in the monofluoride stage. The boiling point of the above difluoride was predicted to be approximately 112°; however, the entire product distilled at about 53°. This material was found to be $CHCl{=}CClCF_3$ (III), the formation of which is explained by an allylic rearrangement during fluorination.

In order to determine if the antimony pentachloride was the isomerization agent, a fluorination was carried out using only antimony trifluoride. The product upon fractionation, yielded the following compounds: (III), 26%; $CHCl{=}CClCF_2Cl$ (IV), 21%; (I), 24%. There was also a small amount of material boiling at 150°, the predicted boiling point of $CCl_2{=}CClCHFCl$ (V). The course of the reaction is indicated by the following scheme:

$$\begin{array}{ccc}
CCl_2{=}CClCHCl_2 & \longrightarrow & (CHCl{=}CClCCl_3) \\
\downarrow & & \downarrow \\
CCl_2{=}CClCHFCl & & (CHCl{=}CClCFCl_2) \\
\downarrow & & \downarrow \\
CCl_2{=}CClCHF_2 & & CHCl{=}CClCF_2Cl \\
 & & \downarrow \\
 & & CHCl{=}CClCF_3
\end{array}$$

This experiment shows that even in the reaction with antimony trifluoride alone there is partial isomerization. Moreover, this isomerization becomes more complete as the reaction progresses. This was evidenced by the fact that the temperature of the reaction distillate was approximately 54° during the last part of the process.

This appears to be a novel case of rearrangement during allylic fluorination. It is of interest to note that it does not occur when compounds containing an allylic $—CCl_3$ group are fluorinated. For example, $CHCl{=}CClCCl_3$ (VI) is known to give (III)[1] and $CHCl{=}C(CH_3)CCl_3$ forms $CHCl{=}C(CH_3)CF_3$.[2] Hexachloropropene gives $CCl_2{=}CClCF_3$; however, in this case isomerization would not lead to a different product.

To study further the fluorination of allylic $—CHCl_2$ groups, $CHCl{=}CClCHCl_2$ (VII) was prepared by the method of Prins[3] and fluorinated. Only $CHCl{=}CClCHF_2$ (VIII) was found, but as in the case of hexachloropropene, even if rearrangement occurred, only one product would be formed.

The fluorination of $CCl_2{=}CHCHCl_2$ (IX) has been mentioned in the literature[4] with the formation of $CCl_2{=}CHCHF_2$ (X); however, the tetrachloroölefin actually obtained from the $CHCl_2CHClCHCl_2$ (XI) used as an intermediate is (VII)[3,5] and not (IX). Therefore, the difluoride reported to be (X) was in reality (VIII). Moreover, fluorination of (IX), if isomerization occurred as it does in the case of (II), would give $CHCl{=}CHCF_3$.

The rearrangement herein reported can be clarified by the mechanism

$$\begin{array}{ccl}
CCl_2{=}CClHCl_2 & \longrightarrow & CCl_2{=}CClC^*HCl + Cl^- \\
 & & \qquad\qquad\downarrow \\
 & & \qquad C^*Cl_2CCl{=}CHCl
\end{array}$$

This last then reacts with antimony trifluoride to form (III). The isomerization apparently occurs during the actual process of fluorination since no $CHCl{=}CClCCl_3$ (VI) was obtained when (II) was refluxed for one hour with antimony pentachloride. Generally, when it is possible for a $—CF_3$ group to form, one is obtained. Thus it is possible that the tendency to form the stable $—CF_3$ group is the driving force causing this allylic rearrangement. In any event, this isomerization represents a new method of preparation of $—CF_3$ groups. In our work at no time was there any evidence of the migration of a fluorine atom.

The physical constants, b.p. 186.7°, $n^{20}D$ 1.5333, obtained for our starting material (II), differed somewhat from those reported by Prins,[3] which were 183° and 1.5313, respectively. The structure of (II), however, could hardly be other than $CCl_2{=}CClCHCl_2$ since we prepared it from $CHCl_2CCl_2CHCl_2$, a compound which can only give one pentachloroölefin on dehydrochlorination. The presence of an allylic $—CHCl_2$ group was confirmed by the method of Prins,[3] the phenylhydrazone obtained having the same melting point as reported by that author. The above values were again found when (II) was made (a) from $CCl_3CHClCHCl_2$ formed by condensing $CHCl_3$ with $CHCl{=}CCl_2$ and (b) from the hexachloride fraction obtained in the chlorination of 1,2,3-trichloropropane.

That the properties of the material assumed to be (III) agreed with published values[1] was taken as sufficient proof of structure. Also, exhaustive chlorination in sunlight led to a compound melting at 109°, which agrees with the value reported for

(5) Gerding, Prins and Rijnders, *Rec. trav. chim.*, **65**, 165–167 (1946).

$CCl_3CCl_2CF_3$.[6] To prove the structure of (I), it was stirred at room temperature with excess sulfuric acid for six hours and poured in water. During the acid treatment hydrogen fluoride was evolved. An irritating oil was obtained which reacted with phenylhydrazine to give a hydrazone identical with that from (II), melting at 97–98°. The fluorinated material boiling at 97° is without doubt (IV) since its boiling point is 43° higher than that of (III). This is in agreement with the general change in boiling point caused by replacing a chlorine atom by an atom of fluorine in such groups.

Experimental

Fluorination of $CCl_2=CClCHCl_2$ (II) with Catalyst.—Ground antimony trifluoride, 537 g. (3 moles), was placed in a two-liter round-bottom flask surmounted by a 550-mm. air condenser. The top of this tube contained a thermometer and a bent tube connected to a water cooled downward condenser for distillation. A filter flask, containing about 200 ml. of concentrated hydrochloric acid and attached to the condenser with an adapter, served as a receiver. Fifteen milliliters of antimony pentachloride was added as catalyst. Then (II), 500 g. (2.35 moles), was added gradually from a dropping funnel, heat being applied at the same time. The reaction soon started and product distilled smoothly at 54°. Fresh olefin was added at the same rate at which product was removed. The distillate was washed three times with concentrated hydrochloric acid, once with dilute sodium hydroxide solution, dried and distilled to give 357 g., 92%, of (III), b. p. 53.7°.

Fluorination of (II) without Catalyst.—The apparatus was the same in this case as before. Ground antimony trifluoride, 970 g. (5.4 moles), was placed in the reaction flask, addition of 852 g. (4 moles) of (II) started and heat applied. The reaction was slow to start, rather strong heat being required. The distillate temperature at the start was 140° but it gradually went down, staying for awhile around 110°. During the addition of the last 300 g. of (II) the temperature was in the vicinity of 54°. The product was purified as before and distilled with the following results: 175 g., 26%, of (III), b. p. 53.7°; 157 g., 21%, (IV), b. p. 97°, n^{20}_{D} 1.4253; 179 g., 24%, (I), b. p. 114.4°, n^{20}_{D} 1.4452; 44 g. of material boiling from 115 to 180°.

Fluorination of $CHCl=CClCHCl_2$ (VII).—Two-hundred forty-eight grams (1.33 moles) of (VII) and 230 g. of ground antimony trifluoride (1.3 moles) reacted without catalyst as described above. The temperature of the distillate during the reaction was 100–110°. Purification gave 160 g., 82%, of (VIII), b. p. 89°, n^{20}_{D} 1.4150. The use of a small amount of antimony pentachloride as catalyst was found to hasten the reaction. However, when more than about 5 ml. of catalyst was used, the yield was decreased considerably.

Summary

The fluorination of two allylic polychlorides, $CCl_2=CClCHCl_2$ and $CHCl=CClCHCl_2$, has been studied. In the case of the first one, an isomerization leading to the formation of a $-CF_3$ group was observed. Two new compounds, $CHCl=CClCF_2Cl$ and $CCl_2=CClCHF_2$, are reported.

Reactions of Some Highly Chlorinated Unsaturated C_5 Hydrocarbons with Chlorine and Copper[1]

BY R. W. BOST AND J. A. KRYNITSKY[2]

In connection with a study of some highly chlorinated hydrocarbons, it was of interest to investigate some chlorination and coupling reactions of some polychlorinated unsaturated C_5 hydrocarbons which were used as intermediates in the preparation of hexachlorocyclopentadiene.[3]

Early work by Prins[4] showed that hexachloropropene can be made to add chlorine, in the presence of sunlight, to give almost quantitative yields of the octachloro compound. Later, McBee and co-workers[5,6] reported that the action of chlorine at high temperatures and pressures on polychloropentanes and heptanes results in a chlorinolysis with the formation of carbon tetrachloride, hexachloroethane, and a substance which was later shown to be octachlorocyclopentene. Recently, Prins[7] has reported that hexachlorocyclopentadiene reacts readily with chlorine to form octachlorocyclopentene yet octachloro-1,3-pentadiene (I) does not add the halogen but does give a small amount of hexachloroethane on continual exposure.

In this work, chlorinations of both octachloro-1,3-pentadiene (I) and 1,1,2,3,3,4,5,5,5-nonachloro-1-pentene (II) were carried out in the presence of direct sunlight. It was found that at temperatures of 100–130°, (I) undergoes a chlorinolysis reaction to form considerable amounts of hexachloroethane and carbon tetrachloride. However, at lower temperatures (36–52°), the extent of reaction was found to be much reduced and only small amounts of the chlorinolysis products were obtained. Experiments with (II) showed that this compound, like (I), is also cleaved through the action of chlorine to form hexachloroethane and *s*-heptachloropropane. With (II), however, reaction was found to proceed more rapidly than

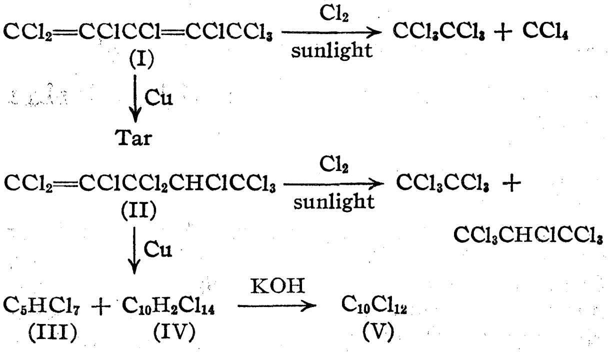
with (I) and considerable amounts of hexachloroethane were obtained even at the lower temperatures (35–47°). In neither case was there any evidence of chlorine having been added to form the higher chlorinated pentanes.

Prins[4] found that certain compounds having chlorine atoms activated by a double bond undergo a coupling reaction when treated with an agent such as copper–bronze. Thus hexachloropropene yielded a compound C_6Cl_8 which is probably a perchloromethylenecyclopentene.[8] In the present work, this coupling reaction was extended to the compounds (I) and (II). When (I) was treated with equimolar quantities of freshly precipitated copper, a reaction took place with the evolution of heat. From this reaction mixture, no recognizable products were obtained except for a small amount of the starting (I). With (II), however, two definite compounds were obtained having the empirical formulas C_5HCl_7 (III) and $C_{10}H_2Cl_{14}$ (IV). (III) was found to react quantitatively with one mole of alcoholic potassium hydroxide while (IV) reacted with two moles. In the latter case, a compound $C_{10}Cl_{12}$ (V) was isolated. From their methods of formation and the quantitative reaction of (IV) with potassium hydroxide, (IV) is believed to be 3,4-bis-(α,β,β,β-tetrachloroethyl)-hexachloro-1,3,5-hexatriene and (V), 3,4-bis-(trichlorovinyl)-hexachloro-1,3,5-hexatriene.



Experimental

Action of Chlorine on Octachloro-1,3-pentadiene (I).—Into a 500-ml. quartz flask fitted with a gas inlet tube was placed 90 g. of (I). A slow stream of chlorine was admitted in the presence of direct sunlight for a total of thirty-two hours. During this period, the contents of the flask was maintained at 100–130° by means of an electric heater. Upon cooling, the reaction mixture turned to a semi-solid mass. This was found to be soluble in hot alcohol and was accordingly recrystallized three times from this solvent. There resulted 30 g. of a white crystalline material having a strong camphor odor, which was identified as being hexachloroethane by means of melting point, sublimation point and molecular weight determinations.

A later experiment was performed under similar conditions but employing ice-cooled traps to condense volatile products. Upon treatment of 90 g. of (I) with chlorine for seven hours, the traps were found to contain 17 g. of carbon tetrachloride which was identified by its boiling point, refractive index and density.

Action of Chlorine on 1,1,2,3,3,4,5,5,5-Nonachloro-1-pentene (II).—Into a flask, as above, was placed 90 g. of (II). Chlorine was admitted slowly in the presence of direct sunlight over a period of twenty-seven hours. During this addition, the temperature varied between 35 and 47°. The reaction mixture was transferred to a Claisen flask and distilled. A white, crystalline solid was noted to sublime and a total of 14 g. of this solid was collected at 30 mm. pressure in an ice-cooled receiver along with a small amount of a colorless liquid. No definite temperature could be obtained for the collection of this material. After removal of all solid, further distillation yielded fraction (a) 22 g., b. p. (4 mm.) 94–105° and fraction (b) 30 g., b. p. (3 mm.) 123–30°. Fraction (b) was identified as being recovered (II). Three recrystallizations of the solid material from alcohol gave a white crystalline compound which was identified as being hexachloroethane.

Inasmuch as fraction (a) was collected over a rather wide range, it was fractionated through a 50 cm. column of the Whitmore–Lux type packed with glass helices. There was obtained 10 g. of a colorless liquid b. p. (3–4 mm.) 93.2–93.5°. This was found to react quantitatively with 1 mole of alcoholic potassium hydroxide, proving it to contain one hydrogen. This together with molecular weight determinations showed it to have the molecular formula C_3HCl_7. Comparison with known unsymmetrical heptachloropropane showed the two compounds to be dissimilar. Since only one other structure is possible for a compound having this formula, the compound was concluded to be *s*-heptachloropropane: calcd. for C_3HCl_7: mol. wt. 285.2. Found: mol. wt. 290, 294 (titration with potassium hydroxide).

Reaction of (II) with Copper.—Into a flask fitted with a stirrer, thermometer and reflux condenser were placed 170 g. (0.45 mole) of (II) and 250 ml. of methanol. The temperature was raised to 60° and 29 g. (0.46 mole) of freshly precipitated copper was added in small portions, with stirring, over a period of two and one-half hours so as to maintain the temperature at 60–64°. The mixture was then refluxed overnight. After cooling, the material was washed three times with water. The organic layer contained a precipitate which was removed by filtration. Fractionation of the clear, dark amber, viscous filtrate through the Whitmore–Lux column yielded 34 g. of light golden (III) b. p. (1–2 mm.) 95–100° and a deep red resinous residue. (III) was found to react quantitatively with one mole of alcoholic potassium hydroxide showing it to contain one hydrogen. This and molecular weight determinations established its formula as being C_5HCl_7. Calcd. for C_5HCl_7: mol. wt., 309.2. Found: mol. wt., 285 (ebullioscopic), 303, 293 (titration with potassium hydroxide).

Two recrystallizations of the precipitate from carbon tetrachloride yielded 7 g. of white crystalline (needles) (IV) having a strong biphenyl-like odor and melting at 205–206°. (IV) was found to react quantitatively with two moles of alcoholic potassium hydroxide indicating the presence of two hydrogens. This together with the molecular weight determinations and analyses established its formula as being $C_{10}H_2Cl_{14}$. *Anal.* Calcd. for $C_{10}H_2Cl_{14}$: Cl, 80.27; mol. wt., 618.4. Found: Cl, 80.31, 80.57; mol. wt., 584 (ebullioscopic), 610, 622 (titration with potassium hydroxide).

Reaction of (I) with Copper.—When 91 g. (0.26 mole) of (I) was treated with 17 g. (0.27 mole) of copper under the conditions described above, a tarry reaction mixture was obtained. From this, no identifiable materials except for 23 g. of recovered (I) were obtained.

Reaction of (IV) with Potassium Hydroxide.—Five grams of (IV) dissolved in 30 ml. of hot carbon tetrachloride was treated with an excess of an alcoholic potassium hydroxide solution (approx. 0.35 *N*) to a strong permanent pink of phenolphthalein. The mixture was boiled on a steam-bath for five minutes and the excess base was neutralized carefully with dilute hydrochloric acid. Upon evaporation to one-half volume and cooling in an ice-bath, a white crystalline solid separated. Two

recrystallizations from carbon tetrachloride yielded 3 g. of white crystalline (V). (V) had practically no odor and melted at 113–113.5°. From analyses and molecular weight determinations, the formula of (V) was established as being $C_{10}Cl_{12}$.

Anal. Calcd. for $C_{10}Cl_{12}$: Cl, 78.00; mol. wt., 545.5. Found: Cl, 77.94; mol. wt., 537.

Summary

1. Octachloro-1,3-pentadiene (I) when treated with chlorine in the presence of direct sunlight at elevated temperatures undergoes chlorinolysis to yield hexachloroethane and carbon tetrachloride.
2. 1,1,2,3,3,4,5,5,5-Nonachloro-1-pentene (II) reacts as above but at lower temperatures to give hexachloroethane and *s*-heptachloropropane.
3. (II) reacts with copper to yield chiefly a dehalogenated product, C_5HCl_7 (III), and a smaller amount of a coupled product, $C_{10}H_2Cl_{14}$ (IV).
4. No definite products were obtained through the reaction of (I) with copper.
5. (IV) is dehydrohalogenated by potassium hydroxide to give $C_{10}Cl_{12}$ (V).
6. Structural formulas are suggested for compounds (IV) and (V).

The Electric Moments of Some *p*-Substituted Phenyl Selenocyanates and Thiocyanates

BY TOD W. CAMPBELL AND MAX T. ROGERS

The electric moments of a series of *para* substituted phenyl thiocyanates and phenyl selenocyanates have been studied to obtain information concerning the nature of resonance in these compounds. None of the substances whose dipole moments are reported here have been measured previously, but values have been reported for phenyl thiocyanate,[1] *p*-chlorophenyl thiocyanate,[1] *p*-tolyl selenocyanate[2] and *p*-chlorophenyl selenocyanate[2] so that group moments may be calculated for the thiocyano- and selenocyano- groups in aromatic compounds.

Experimental Part

Materials

Benzene.—Baker C. P. benzene was dried over sodium and filtered before use, d^{25}_4 0.87344, n^{25}_D 1.4978.

***p*-Dimethylaminophenyl Thiocyanate and *p*-Aminophenyl Thiocyanate.**—These were prepared by the method of Brewster and Schroeder[3]: *p*-dimethylaminophenylthiocyanate, white needles, m. p. 75°; *p*-aminophenyl thiocyanate,[3a] m. p. 57°.

***p*-Dimethylaminophenyl Selenocyanate and *p*-Aminophenyl Selenocyanate.**[4]—These were prepared from cyanogen triselenide[5] and, respectively, dimethylaniline (m. p. product 105°) and aniline (m. p. of product 91–92°).

***p*-Nitrophenyl Thiocyanate and *p*-Nitrophenyl Selenocyanate.**—These were prepared from diazotized *p*-nitroaniline and, respectively, ferric thiocyanate (m. p. of product 133°) and potassium selenocyanate (m. p. of product 137–138°).[6]

***p*-Selenocyanophenyl Thiocyanate** was prepared from diazotized *p*-aminophenyl thiocyanate and potassium selenocyanate in a buffered solution.[7] The product melted at 111.5–112° after repeated recrystallization from a ligroin–benzene mixture.

***p*-Methoxyphenyl selenocyanate** was synthesized from diazotized anisidine and potassium selenocyanate. The product[8] melted at 65°.

Apparatus and Method

Electric moments were measured in benzene solution at 25° using a heterodyne-beat apparatus and technique previously described.[9] The experimental data and molar polarizations are shown in Table I; the derived values of the molar polarization at infinite dilution (P^{∞}), the molecular refraction, MR_D, and the dipole moment, are shown in Table II. The molecular refraction of each compound was obtained from the refractive indices of the solutions[2] (Table I) or, in the cases of *p*-aminophenyl selenocyanate and *p*-methoxyphenyl selenocyanate, from empirical atomic and group refractions.[10]

Discussion of Results

The observed dipole moments are compared in Table III with the vector sums of the moments of the substituents, assuming free rotation about single bonds. The group moments and angles used are: $C_{aromatic}$–H, 0.4 (assumed), 180°; C_{ar}–NO_2, 3.55, 0°; C_{ar}–NH_2,[11] 1.86, 143°; C_{ar}–$N(CH_3)_2$,[11] 1.98, 180°; C_{ar}–OCH_3,[11] 1.37, 119°; C_{ar}–SCN,[2] 3.36, 58°30′; C_{ar}–SeCN,[2] 3.83, 53°30′. (The angle is 0° when the negative end of the dipole is directed away from the ring.)

There is an increase in dipole moment when an electron donating group is *para* to the selenocyano or thiocyano group and this increment may be attributed to enhancement of resonance. The effect is greater with the dimethylamino group

than with the amino group and is least with the methoxy group. The enhancement is larger for the thiocyano than for the selenocyano group for the same *para* substituent; thus, the increment (1.0) observed for *p*-dimethylaminophenylthiocyanate is almost as large as found for *p*-nitrodimethylaniline (1.35).

TABLE II

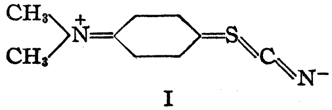
NO_2	SeCN	3.58	3.34	.24
SCN	SeCN	4.02	4.23	− .21

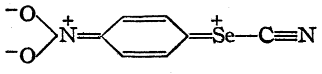
It is unlikely that the larger increments, at least, could be accounted for by a widening of the angles alone since the angle of the dimethylamino group is already small (or zero) and we would not expect a large change in the angle C_{ar}–SCN. It seems more likely that structures such as I are somewhat stabilized in the molecules with a strong electron-receiving group (–SCN or –SeCN) *para* to a strong electron-donating group (–$N(CH_3)_2$, NH_2, OCH_3) and contribute to a small extent to the ground state of the molecule. Since the charge separation is large such structures have a large effect on the dipole moment.



I

Selenium might be expected to be able to expand its octet more easily than sulfur since it belongs to a higher period; however, structures such as I appear to be less important in the selenocyanates, probably because of the smaller tendency of selenium to form multiple bonds.

The thiocyanate and selenocyanate groups might also act as electron donating groups and the increment observed for *p*-nitrophenyl selenocya-



II

nate could be due to a small contribution of structures such as II; this explanation is made doubtful by the observed decrement in the case of *p*-nitrophenyl thiocyanate.

An alternative explanation of the observed increments might be that they arise from an abnormally large vibration polarization[12] such as is found in *p*-dinitrobenzene. The large increments observed here and, especially, the large differences between the thio- and selenocyanates suggests that these are principally resonance effects.

---

(12) L. E. Sutton, *Annual Reports Chem. Soc.*, **37**, 36 (1940).

Summary

The electric moments of some *para* substituted phenylthiocyanates and phenylselenocyanates have been measured in benzene solution at 25°; the substituents used were the amino, dimethylamino, nitro, and methoxyl groups. A rather large enhancement of resonance is observed when the thiocyano- and, to a smaller extent, the selenocyano- group is *para* to an electron-receiving group. The results have been briefly discussed in terms of resonance.

Properties of Polymers as Functions of Conversion. IV. Composition Studies of Rubber-like Copolymers[1]

BY F. T. WALL, R. W. POWERS,[2] G. D. SANDS[3] AND G. S. STENT

It is generally recognized that the products obtained at different stages of conversion in a polymerization reaction will exhibit wide variations in chemical and physical properties. For example, the intrinsic viscosity can show changes of several hundred per cent.,[4] and the molecular weight can likewise vary several fold.[5] In the case of copolymers, the composition of the product, which is generally different from that of the reaction mixture, can also change during the conversion.

Numerous copolymer systems have been investigated from a composition standpoint by Mayo,[6] Alfrey[7] and others. For bulk and solution polymerizations, relatively simple theories have been devised for the compositional relationships,[6a,7a,8] but for emulsion systems, the situation is much more complicated. A considerable amount of experimental work, however, has been done on emulsion copolymerizations. For example, Meehan[9] studied the GR-S system in some detail and observed that the styrene content varied from 17 to 25% in the course of a reaction when the initial charge was 25% styrene. Fordyce and Chapin[10] also have investigated several emulsion systems. The investigations here reported deal with the dependence of composition on conversion for a number of rubber-like copolymers other than GR-S.

Theory

During recent years considerable thought has been given to the theoretical aspects of the compositional relationships in copolymers.[6a,7a,8] These theories ultimately give rise to a basic differential equation governing the relative rates of disappearance of the monomers. This differential equation, which is valid for single phase polymerizations, is

$$\frac{dM_1}{dM_2} = \frac{M_1(r_1M_1 + M_2)}{M_2(M_1 + r_2M_2)} \qquad (1)$$

where M_1 and M_2 equal the number of moles of unreacted monomer and the parameters r_1 and r_2 represent the ratios of certain specific reaction rate constants for the chain growth steps.[11] The general validity of equation (1) has been established by many experiments, although it is not obvious that it should be valid for emulsion reactions. However, it will be seen later that an equation of the same type does empirically agree with the observations for many emulsion systems, although considerable doubt can be raised as to its full validity in some cases. Actually it is possible to derive such an equation for emulsion systems by making certain assumptions such as the following:

(1) It is first supposed that the reaction does not take place in the oil phase of the emulsion. (If the reaction occurs in the oil phase, then equation (1) would be expected to hold right off and the present discussion would be irrelevant except for the perturbing effect of the monomer solubility in water.)

(2) Secondly, it is assumed that the amount of monomeric material in the actual reaction environment (supposed not to be the oil phase) repre-

---

sents only a small fraction of the total monomer present.

(3) Finally it is postulated that the distribution of monomers between the oil and reaction phases is subject to the ideal solution laws. This is equivalent to assuming that the ratio of the reactants in the oil phase is proportional to (but not necessarily equal to) their ratio in the reaction phase. Although we speak of "reaction phase," it must be understood that the reaction may take place in the neighborhood of some interface or in soap micelles as well as in a distinct phase of the system.

In accordance with the above assumptions, the desired relationship can readily be derived. Letting M_1 and M_2 represent the total amounts of the monomers, and letting M'_1 and M'_2 equal the amounts in the reaction phase, we can write the following differential equation for the relative rates of disappearance of the two monomers

$$\frac{\mathrm{d}M_1}{\mathrm{d}M_2} = \frac{M'_1(r_1M'_1 + M'_2)}{M'_2(M'_1 + r_2M'_2)} \qquad (2)$$

According to the ideal solution laws

$$\frac{M'_1}{M'_2} = k\,\frac{M_1}{M_2} \qquad (3)$$

it being assumed that M'_1 and M'_2 are very small compared to M_1 and M_2. Substituting the above relationship (3) into the differential equation (2), we find

$$\frac{\mathrm{d}M_1}{\mathrm{d}M_2} = \frac{M_1(kr_1M_1 + M_2)}{M_2(M_1 + r_2/kM_2)} = \frac{M_1(r'_1M_1 + M_2)}{M_2(M_1 + r_2'M_2)} \qquad (4)$$

where $r'_1 = kr_1$ and $r'_2 = r_2/k$. This equation has the same form as the basic relationship valid for single phase polymerizations, except that r_1 and r_2 are respectively multiplied and divided by the distribution coefficient k. The above derivation suggests that the copolymerization equation might be applicable to emulsion systems even if the polymerization occurs outside the oil phase. Accordingly the results here reported will be interpreted on that basis. To emphasize the fact that the copolymerization parameters for emulsion systems are not necessarily ratios of specific reaction rate constants, they will be represented as primed quantities (r'_1 and r'_2). Of course if the reaction occurs in the oil phase, this distinction is unnecessary.

Partial Conversion Composition

In earlier publications[4,5] the concept of partial conversion properties of polymers was introduced using intrinsic viscosities and molecular weights as examples. At this time it is appropriate to define what we shall mean by the partial conversion composition of a copolymer. If $\bar{F}_i$ represents the average weight fraction of monomer i in the copolymer, then the partial conversion composition, $\bar{\bar{F}}_i$ will be given by the relationship

$$\bar{\bar{F}}_i = \bar{F}_i + W\frac{\mathrm{d}\bar{F}_i}{\mathrm{d}W} \qquad (5)$$

where W is the weight conversion. Taking account of the definitions of $\bar{\bar{F}}_i$ and W, it can be shown from (5) that

$$\bar{\bar{F}}_1 = \frac{m_1\mathrm{d}\mathbf{M}_1}{m_1\mathrm{d}\mathbf{M}_1 + m_2\mathrm{d}\mathbf{M}_2} \qquad (6)$$

where $\mathbf{M}_1$ and $\mathbf{M}_2$ are the molecular weights of the monomers. It is evident that $\bar{\bar{F}}_i$ represents the composition of the copolymer increment which forms at any given instant during the reaction. Assuming the validity of differential equation (4), this can be rewritten as

$$\bar{\bar{F}}_1 = \frac{\mathbf{M}_1M_1(r'_1M_1 + M_2)}{\mathbf{M}_1r'_1M_1^2 + (\mathbf{M}_1 + \mathbf{M}_2)M_1M_2 + \mathbf{M}_2r'_2M_2^2} \qquad (7)$$

Experimental Section

The polymerizations studied include butadiene with 2,5-dichlorostyrene, with *p*-chlorostyrene, with acrylonitrile, and with 1-cyanobutadiene. Using dodecyl mercaptan as a modifier and Procter and Gamble SF Flakes as the emulsifying agent, these copolymerizations were carried out for various initial charges. In every case, potassium persulfate was the catalyst used.

The polymerizations were carried out in 12 and 28-ounce beverage bottles fitted with special self-sealing caps. During the polymerizations the reaction bottles were immersed in a water-bath maintained at 50 ± 0.02°, and were rotated end-over-end at the rate of 20 revolutions per minute. Samples of the latex were removed at various times by means of a brass syringe, the needle of which was inserted into the latex through the self-sealing bottle cap.[12] The polymers were coagulated by adding the latex dropwise to absolute ethanol with vigorous mechanical stirring.

To check the validity of the sampling technique, a special experiment was conducted using butadiene with 2,5-dichlorostyrene. In this experiment the composition of a very high conversion sample obtained from a 12-ounce bottle, from which several samples had been removed in the course of the reaction, was compared with the composition of a polymer formed in a 4-ounce bottle from which no low conversion samples had been taken. The experiment was carried out for three different initial monomer ratios, *i. e.*, 85/15, 60/40, and 40/60 by weight. As long as the final percentage conversion was the same, no significant composition differences were observed between the products obtained in the two different ways. This suggests that the sampling technique is truly representative; if unrepresentative samples had been removed, the effect would have been evident in the composition of the final product.

The following materials were used in these studies: 1. Butadiene: Phillips "Research Grade" 1,3-butadiene was used throughout the investigation. 2. 2,5-Dichlorostyrene: This material was obtained from the Monsanto Chemical Company. It was redistilled immediately before use, as were all other liquid monomers employed in this investigation. At a pressure of 1–2 mm., it boiled between 57 and 58°. 3. *p*-Chlorostyrene: The *p*-chlorostyrene used in this study was obtained from the Dow Chemical Company and boiled at 114° at 6 mm. pressure. 4. Acrylonitrile: Redistilled Eastman "Practical Grade" acrylonitrile was used for this investigation. At atmospheric pressure, it was distilled at 77°. 5. 1-Cyanobutadiene: This chemical consisted mostly of the *trans*-isomer and was obtained from the Organic Division at the University of Illinois. It distilled at 49° under a pressure of 31 mm. 6. *n*-Dodecyl Mercaptan: Very pure *n*-dodecyl mercaptan was prepared by the Organic Division at the University of Illinois by the hydrolysis of

---

[12] R. L. Frank, C. E. Adams, J. R. Blegen, R. Deanin and P. V. Smith, *Ind. Eng. Chem.*, **39**, 887 (1947).

n-dodecylisothiouronium chloride prepared from pure *n*-dodecyl bromide. The boiling range of this mercaptan was 127–129° at 9 mm., and the material was believed to be 99.5% pure.

Two samples from each batch of latex removed from the reactor were used to determine the conversion by a method of total solids. The composition of the copolymers of butadiene with chloro-substituted styrenes was determined by chlorine analyses. These analyses were accomplished by fusing the copolymer samples with sodium and titrating the chloride formed with silver nitrate, using the amperometric technique of Laitinen and Kolthoff.[13] The compositions of butadiene–acrylonitrile copolymers were determined by nitrogen analyses carried out by a macro-Kjeldahl method.[14]

Discussion and Analysis of Results

Each monomer pair investigated will be considered separately, with each set of data, calculations, and conclusions treated as a unit. In every case, butadiene will be considered the first monomer of the pair and will be given the subscript "1."

To determine the copolymerization parameters for butadiene with 2,5-dichlorostyrene, three different monomer ratios were used. These ratios were 85/15, 70/30, and 50/50 parts of butadiene to parts of 2,5-dichlorostyrene by weight. Samples were taken from the polymerization bottle at intervals corresponding roughly to 10, 20, 30, and 40% conversion. As indicated earlier, the conversions were determined in duplicate, whereas the compositions were measured either in triplicate or duplicate for each sample. The results for this system are given in Tables I-A, I-B, and I-C. From a knowledge of the composition as a function of conversion, it is possible to determine the copolymerization parameters.

Theoretically, a single run with analyses corresponding to several conversions should suffice to determine the parameters. In practice, however, it is much better to use each of several different initial charging ratios to make the calculations. The procedure finally adopted was the following: The logarithm of the amount of unreacted butadiene was plotted against the logarithm of the amount of unreacted comonomer. It was found empirically that these plots gave straight lines, at least for moderate conversions. Taking the initial slope of such a line, one obtains a relationship between the two parameters, r'_1 and r'_2. Letting the slope of the log plot equal m, it is readily seen that

$$m = \frac{d \ln M_1}{d \ln M_2} = \frac{r'_1 M_1 + M_2}{M_1 + r'_2 M_2} \qquad (8)$$

Evidently if one has experimental data for two different initial charging ratios, one can calculate r'_1 and r'_2 from the two simultaneous equations of

type (8) involving the two m's. To get an indication of the experimental error, at least three runs were always made, and the best over-all value for the parameters was selected. The procedure adopted was to plot r'_1 *versus* r'_2 and note the points of intersection for the three (or more) lines so plotted. After inscribing a circle in the triangle resulting from three such lines, one can take the center of that circle to determine the best set of values for the parameters. For purposes of illustration, the graphs will be given for the butadiene–2,5-dichlorostyrene system (Figs. 1–2), but similar plots will not be included for all the other pairs investigated. The procedure employed here differs from that used by Mayo and Lewis,[6a] who used the integrated form of the equation instead of the differential form.

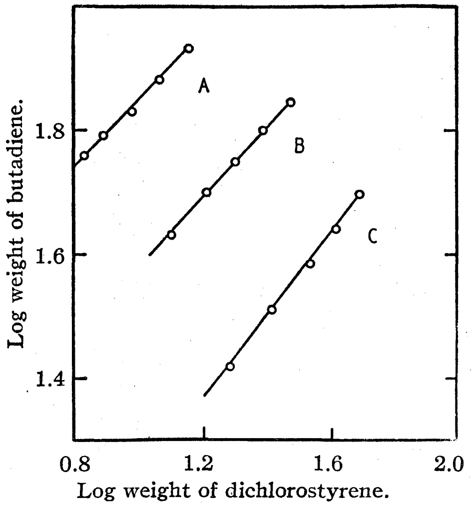

Fig. 1.—Log weight butadiene *vs.* log weight dichlorostyrene for determining values of m. Curves labeled A, B and C correspond to data in Tables 1-A, I-B and I-C.

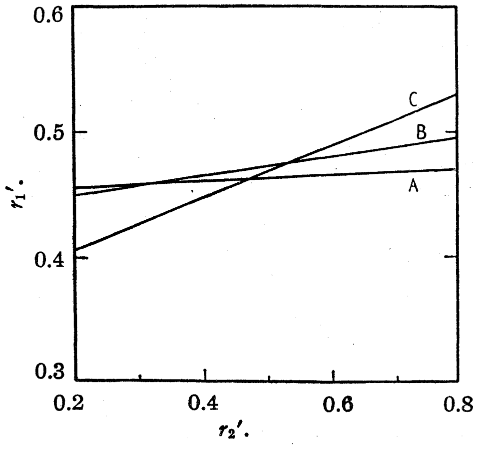

Fig. 2.—Plot for determining copolymerization parameters for dichlorostyrene–butadiene system. Lines A, B and C correspond to data in Tables I-A, I-B and I-C.

The parameters r'_1 and r'_2 were each found to equal 0.46 for butadiene with 2,5-dichlorostyrene. This suggests that the system butadiene with 2,5-dichlorostyrene can form an azeotropic copolymer[8] of composition 75 parts 2,5-dichlorostyrene to 25 parts of butadiene by weight (this is a one-to-one molar ratio). To test this prediction, an experiment was carried out with that initial charge. The results are given in Table II. It will be observed that the composition was indeed very constant over a wide range of conversion, justifying the theory in this connection.

The validity of the theory was further tested by carrying out a special experiment involving a 3 to 1 weight charging ratio of butadiene with 2,5-dichlorostyrene, and comparing the observed compositions with those calculated using the parameters obtained from the experiments described earlier. The results are shown in Fig. 3, which gives the calculated average and partial conversion compositions together with the observed average compositions. Bearing in mind the fact that the parameters were determined by completely independent experiments not involving use of any of the points included in Fig. 3, it is

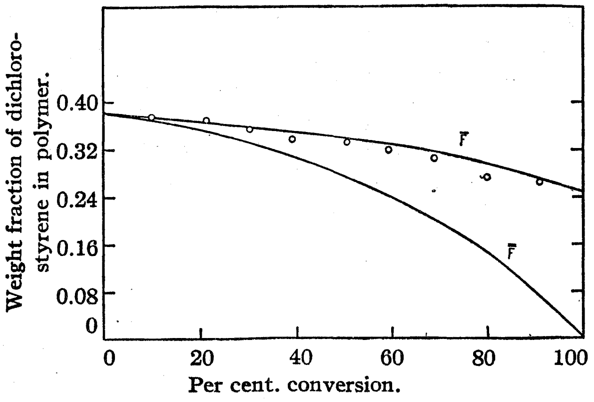

Fig. 3.—Predicted ($\bar{F}$) and partial conversion ($\bar{\bar{F}}$) compositions of dichlorostyrene in copolymer with butadiene together with experimental average compositions (indicated by circles).

clear that the theory agrees well with observation. It will be noted that although the composition of the charge was only 25% (by weight) of the substituted styrene, the partial conversion composition was initially 38%. This figure falls off with conversion, finally ending up at zero.

Butadiene and *p*-chlorostyrene were polymerized for charging ratios of 80/20, 60/40, and 40/60, butadiene to the substituted styrene, by weight. The results for this system are given in Tables III-A, III-B, and III-C. The values for r'_1 and r'_2 were found to be 1.07 and 0.42, respectively.

Butadiene and acrylonitrile were copolymerized in the weight ratios 85/15, 75/25, and 65/35. The data for these polymerizations are compiled in Tables IV-A, IV-B, and IV-C. The values of the parameters r'_1 and r'_2 appear to be 0.4 and -0.1. The negative value found for r'_2 is of course meaningless as far as the theory is concerned. Nevertheless, the agreement for the several compositions was excellent, as seen in Fig. 4, demonstrating that the copolymerization equation may have only empirical significance for emulsion systems. The negative value in the case of the acrylo-

nitrile copolymer is doubtless due to the appreciable water-solubility of the nitrile, which would render invalid one of the basic assumptions that went into the derivation of the emulsion equation.

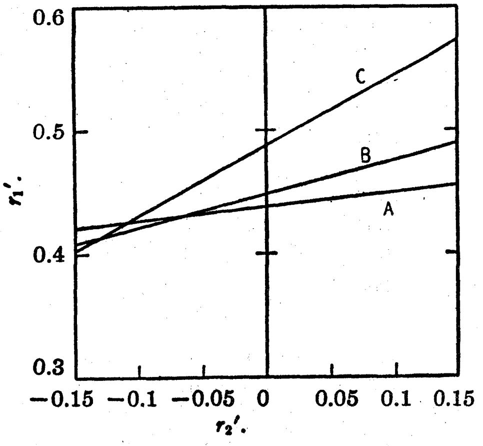

Fig. 4.—Plot for determining copolymerization parameters for acrylonitrile–butadiene system. Lines A, B and C correspond to data in Tables IV-A, IV-B and IV-C.

Butadiene was polymerized with 1-cyanobutadiene in emulsion using weight ratios of 75/25, 60/40, and 40/60, and the results are given in Tables V-A, V-B, and V-C. In this case r'_1 was found to be -0.08, although a value 0 would probably be satisfactory; r'_2 was found to have a value of 1.7. This implies that butadiene cannot grow onto a free radical whose last member is a cyanobutadiene unit, although a cyanobutadiene can add onto a butadiene. Accordingly, the first polymer to form will be abnormally high in cyanobutadiene, but as soon as that monomer is depleted, the consumption of butadiene increases. This strange behavior also manifests itself in the conversion *versus* time curve (Fig. 5). The initial rate of conversion is found to be very high, but after about 25% reaction, the rate falls off considerably.

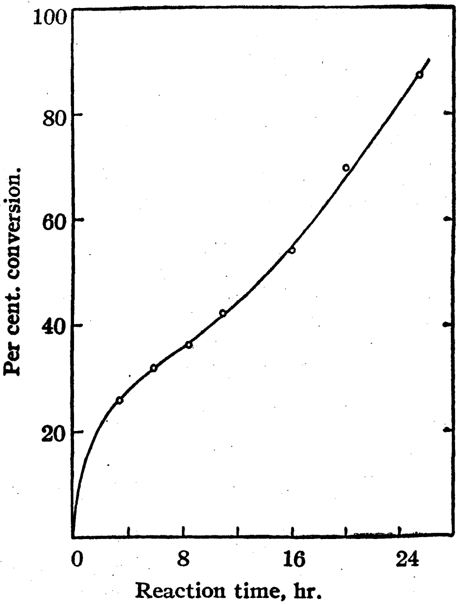

Fig. 5.—Conversion *vs.* reaction time for cyanobutadiene–butadiene copolymer (data in Table V-A).

The experimental results given above demonstrate empirically the validity of the basic copolymerization equation. Theoretically it was shown that the equation might be expected to hold whether the polymerization occurs in the oil or in the aqueous phase. Therefore the experimental observations here reported do not prove which phase the reaction occurs in. As a matter of fact, Fordyce and Chapin[10] have suggested that the oil phase is the seat of the reaction in the case of styrene copolymerized with acrylonitrile. To arrive at a similar conclusion here, it would be

necessary to have more data than are available at present.

Summary

Copolymerizations of butadiene with various other monomers have been carried out in emulsion systems. It is found that the copolymerization equations of Mayo and others have empirical validity for all of the systems examined. The equations are also believed to be theoretically significant in most cases, an exception being butadiene with acrylonitrile. The anomalous results obtained for that pair are attributed to the high solubility of acrylonitrile in water.

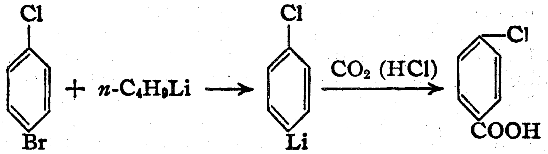
The Application of the Halogen–Metal Interconversion Reaction to Syntheses with Isotopic Carbon[1]

BY ARTHUR MURRAY, III, W. W. FOREMAN AND WRIGHT LANGHAM

The extensive application of the halogen–metal interconversion reaction to a wide variety of aryl halides has resulted in the preparation of organometallic compounds having additional functional groups.[2a,b,c,d]

Because of the rapidity of the reaction, the halogen–metal interconversion between an alkyllithium compound and an aryl halide is uniquely suited to the preparation of organolithium compounds with additional functional groups. As an example, *p*-chlorobromobenzene and *n*-butyllithium react to give a 90% yield of *p*-chlorophenyllithium in ten minutes.[2a] Subsequent carbonation results in the formation of the corresponding carboxylic acids according to the reaction.



The use of isotopic carbon in biological studies is complicated by the relatively small quantities of isotope available and by the unavoidable high dilution of the isotope when introduced into biological systems. In order to conserve isotopic carbon and to achieve maximum specific activity required for certain investigations, we have adapted the halogen–metal interconversion reaction to the micro synthesis of certain compounds of biological significance.

p-Aminobenzoic acid, labelled with C^{14} in the carboxyl group, was prepared by an adaptation of the reaction of Gilman and Stuckwisch.[3a,b] The *p*-aminophenyllithium derivative[4] was isolated and washed free of *n*-butyllithium before carbonation with gaseous $C^{14}O_2$.

(4) This compound is believed to be *p*-$LiC_6H_4N(Li)_2$. C. G. Stuckwisch, private communication.

Good yields of carboxyl-labelled nicotinic acid were obtained by the method of Gilman and Spatz,[5] when the reaction was scaled down to the millimole level and adapted to carbonation with gaseous carbon dioxide.

Experimental

Apparatus and General Procedure.—A compact vacuum system was designed and constructed as outlined in Fig. 1. The total volume of the system was kept at a minimum. The apparatus was attached at (V) to an oil pump by means of a three-way stopcock that permitted independent evacuation of both main sections of the system. A source of dry carbon dioxide and oxygen-free nitrogen was attached to the system at (N).

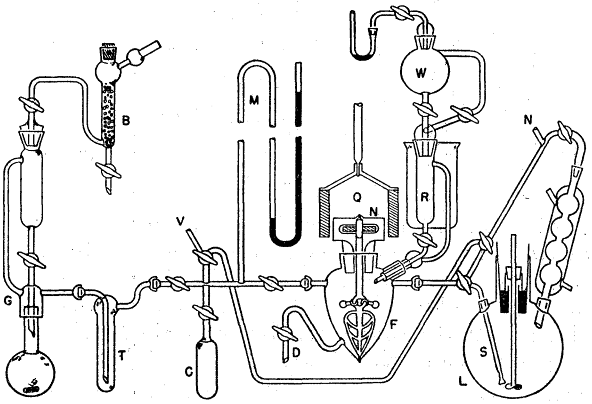

Fig. 1.—Apparatus for the preparation and gaseous carbonation of organolithium compounds.

After evacuation isotopic carbon dioxide was prepared in generator (G) by slowly adding outgassed concentrated sulfuric acid to isotopic barium carbonate. The stopcock involved was lubricated with a paste of paraffin and mineral oil. Quantitative evolution of carbon dioxide was attained by warming the acid and stirring by means of a magnet and glass encased iron core. The gas was passed through a trap (T), immersed in a Dry Ice–acetone bath, and condensed in storage bulb (C) by means of liquid air. Any non-condensable gas was pumped off.

The required volume of *n*-butyllithium[2a] solution (assayed before every run by the differential titration method of Gilman and Haubein[6]) was transferred from the preparation flask (L) to the calibrated cone-shaped reaction flask (F) which had been previously evacuated, flamed and swept out with nitrogen gas. The transfer was made by applying a positive pressure of nitrogen, thus forcing the solution through a filter of glass wool in siphon (S). The addition tube (R), equipped with an outside jacket for a Dry Ice–acetone cooling mixture, was filled with the aryl halide in ether solution. This solution was added to the *n*-butyllithium in flask (F) which had been filled with nitrogen. Moderate stirring was achieved by means of a vacuum-tight glass-enclosed magnetic induction stirrer (N) motivated by two motor-driven permanent bar magnets (Q). In cases where the aryllithium compound was washed free of excess *n*-butyllithium, a siphon (D) controlled by a stopcock was used for drawing off supernatant liquid into an evacuated flask immersed in a freezing bath. Wash ether was stored over sodium wire in reservoir (W) and was added through the addition tube (R).

Before carbonation the reaction flask (F) was cooled to −80°, and pumped down to the vapor pressure of ether. The storage bulb (C) was then warmed and carbonation effected by opening the stopcock connecting the bulb with the reaction flask (F). The absorption of carbon dioxide was followed by observing the fall in pressure on the manometer (M). Rapid stirring of the reaction mixture facilitated the absorption of the gas. When the pressure became constant, the reaction mixture was alternately frozen solid with liquid air and then thawed several times. Unabsorbed gas was then distilled back into the storage bulb (C) and nitrogen was admitted to the reaction flask. The addition tube (R) was quickly filled with dilute acid. The mixture was hydrolyzed while still cold by adding the dilute acid from (R) to the well stirred solution. Any liberated carbon dioxide was frozen back into the storage bulb (C) from which it was recovered, at convenience, by sweeping out the system with nitrogen through the absorption column (B).

***p*-Aminobenzoic Acid.**—To 23.8 mM. of *n*-butyllithium in 29 ml. of ether was added 4.74 mM. of vacuum dried *p*-bromoaniline in 8 ml. of ether. The *p*-bromoaniline was added over a five-minute period, and the reaction mixture cooled during the addition. Stirring was continued at room temperature for one and one-half hours after the bright yellow precipitate of the aryllithium compound first appeared. This precipitate began to form in twenty to ninety minutes, depending upon the age of the *n*-butyllithium. The yields were unaffected by varying the reaction time from one to three hours. The *p*-aminophenyllithium was washed several times with anhydrous ether. The supernatant liquors were siphoned off under nitrogen into an evacuated flask immersed in a Dry Ice–acetone mixture (the dry *p*-aminophenyllithium derivative is explosive in contact with air[4]). Carbonation was effected with 1.029 mM. of carbon dioxide (2 millicuries of C^{14}) of which 32.5% was recovered. The reaction mixture was hydrolyzed with 8 ml. of 6 *N* hydrochloric acid. The strongly acidic reaction mixture was transferred to a modified Soxhlet and continuously extracted with ether for eight hours. The ether phase was discarded. The aqueous phase was made strongly alkaline with potassium hydroxide and again extracted for eight hours. The aqueous phase was then adjusted to *p*H of 3 and the *p*-aminobenzoic acid extracted with ether (sixteen hours). The crude yield of product was 32.8% based on the barium carbonate or 48.2% based on the carbon dioxide absorbed in the reaction. Recrystallization from water gave 35 mg. of colorless needles (m. p. 184–185°). The final product had a specific activity of approximately 30 million disintegrations per minute per mg.

Similar experiments with 1.01–1.59 mM. of ordinary carbon dioxide consistently gave yields of 31.3–38.5%. Ether extraction was found to be superior to the formation of the copper and silver salts for isolating the small amounts of product.

3-Pyridine-carboxylic Acid (Nicotinic Acid).—To 1.63 mM. of *n*-butyllithium in 2.76 ml. of ether cooled to −35° was added, over a four-minute period, 2.44 mM. of redistilled 3-bromopyridine in 5 ml. of ether (also cooled to −35°). Carbonation was effected after one minute, with 0.81 mM. of isotopic carbon dioxide (one millicurie of activity, 160.8 mg. barium carbonate) at −80°. The reaction mixture was quickly hydrolyzed with 3 ml. of 2.5 *N* nitric acid. The acid phase was placed in a modified Soxhlet and continuously extracted with ether (three to four hours), then made alkaline and re-extracted (four to six hours). The crude product was then isolated by adjusting the aqueous phase to *p*H of 3 and continuing the extraction for twenty-four to forty-eight hours. The yield of crude material was 62.4% based on the weight of barium carbonate or 70.3% based on carbon dioxide absorbed. Vacuum sublimation and recrystallization from methanol yielded 30 mg. of colorless powder, m. p. 225–228° (authentic purified specimen m. p. 228–229°). The specific activity of the purified material was approximately 16 million disintegrations per minute per mg.

By the above methods, two different experiments were carried out with 10.6 and 10.4 mM. of C^{13}O$_2$[7] (approx. 6 isotopic per cent. C^{13}) and the same ratio of reagents used

above. The combined reaction mixtures gave a crude yield of 81.9%. Purification by means of the silver salt gave 55.4% of pure acid (m. p. 227–229°).

Acknowledgment.—We gratefully acknowledge the assistance of Dr. Henry Gilman in whose laboratory one of the authors spent several days becoming acquainted with the latest techniques of handling organolithium compounds. We also acknowledge helpful suggestions from Dr. C. G. Stuckwisch.

Summary

The halogen–metal interconversion reaction between the appropriate aryl halide and *n*-butyllithium has been applied on a one millimole scale to the preparation of *p*-aminobenzoic and nicotinic acids marked in the carboxyl groups with C^{14}. These biologically important compounds have been prepared with extremely high specific activities.

Nicotinic acid containing approximately 6 isotopic per cent. of C^{13} in the carboxyl group was also prepared by the same procedure.

Some Systems of Silicon Halides with Dioxane

BY S. M. SCHOLASTICA KENNARD[1] AND P. A. MCCUSKER

Molecular compounds of dioxane with inorganic halides, in dioxane solution and in the crystalline state, have been the subject of previous studies in these laboratories[2,3] and elsewhere.[4]

Most of these molecular compounds, whose dielectric properties have been studied in solution, appear to be formed as a result of coördination between dioxane and the central atom of the halide. It has been further observed that those halides which coördinated strongly with dioxane in solution also formed relatively stable crystalline complexes. Since silicon tetrachloride gave no evidence of coördination with dioxane in solution, it was considered of interest to determine whether any solid molecular compounds would be formed between silicon tetrahalides and dioxane. For this reason a study was made of the solid–liquid equilibria in silicon tetrahalide–dioxane systems. Dielectric constant and density data were also obtained for silicon tetrabromide in solution. During the course of this work it became desirable to obtain melting point–composition data for the cyclohexane–dioxane system.

Experimental

Preparation and Purification of Materials.—Dioxane was purified as described previously.[2] Silicon tetrabromide was prepared by passing bromine in a stream of nitrogen over granular silicon, in a vertical, 24 mm. Pyrex tube electrically heated. The exothermic reaction was maintained, with slight heating, by a rapid flow of bromine over the heated silicon. Under carefully controlled conditions silicon tetrabromide, essentially free of bromine, was distilled out of the reaction tube. Purification was effected by shaking with mercury and several distillations in a 4 ft. glass helix-packed distilling column. The final product boiled at 154° and was further purified by fractional freezing. The purity was established by separating into two fractions each melting sharply at 5.4°. The melting point reported by Pohland[5] for highly purified silicon tetrabromide is 5.2–5.3°. Silicon tetrachloride was prepared by a similar procedure and purified by fractional distillation. C. P. cyclohexane was refluxed over phosphorus pentoxide and fractionally distilled.

Determination of Melting Points.—Temperatures were measured with a calibrated tenth-degree mercury thermometer. The apparatus for the determination of the melting points was designed for convenience and rapidity in obtaining data. A motor-actuated reciprocating glass ring stirrer surrounded the bulb of the thermometer immersed in the liquid. The system contained a side arm through which measured volumes of liquid could be added from a buret. A thin rubber finger was used to connect the stirring rod and its glass shaft and permitted the complete exclusion of moisture. In a typical determination, a measured volume of liquid was run into the apparatus and a cooling bath placed around the tube. The liquid was cooled and stirred slowly so as to obtain considerable undercooling. In all this work undercooling of from 5 to 10° was readily obtained. The undercooling is an essential feature of this method of determining melting points. By intermittent application of a bath, held at about 10° below the expected melting point, and control of the rate of stirring, sufficient undercooling could be obtained to cause separation of a large quantity of solid in finely divided form. When solid separated, the bath was removed and the mixture allowed to warm up while being vigorously stirred. With finely divided solid and rapid stirring equilibrium between solid and liquid was closely approached. The equilibrium temperature was taken as the point of visible clarification of the mixture and this temperature checked by observation of the increased rate of temperature rise. In all cases these two readings checked within the precision of the thermometer, and numerous checks demonstrated the reproducibility of the data. Subsequent addition of measured volumes of a second component enabled a considerable number of determinations to be made with one original charge. Warming curves were obtained in a similar manner, temperature–time readings being taken during the warming and vigorous stirring of the mixture, after considerable solid had separated.

Dielectric Constants and Densities.—These were determined as previously described.[2] The molar refraction for silicon tetrabromide was computed from the density and refractive index data of Pohland[5] and this value used for the electron polarization. Ten per cent. of the electron polarization was taken as the value for the atomic polarization. The method of Hedestrand[6] was used for calculat-

ing the electric moment. Measurements of dielectric constants and densities were made at 25.0°.

Results and Discussion

I. The Silicon Tetrabromide–Dioxane System.—The melting point–composition data for this system are listed in Table I and plotted in Fig. 1. The stable eutectic mixture contains 39.5 mole % dioxane and melts at −11.4°. When pure silicon tetrabromide was undercooled 5° or more a metastable crystalline form frequently separated. This was sufficiently less opaque than the stable form to be readily recognized although the smallness and instability of the crystals did not permit further characterization. In some cases the metastable form would persist until it melted sharply at 2.3°. In other cases, transformation to the stable form melting at 5.4° would occur suddenly. When solutions of composition between pure silicon tetrabromide and the eutectic mixture were undercooled, the stable form of silicon tetrabromide usually separated. Frequently, however, the metastable form separated and persisted until liquefaction was complete. In some instances, after separation of the metastable form, a sudden transition to the stable, higher melting form would occur. Some typical warming curves illustrating the three different modes of behavior are given in Fig. 2. The curve for the melting point obtained when metastable silicon tetrabromide was the solid phase is shown as a broken line in Fig. 1.

It may be observed that there is an approximately constant difference in the melting points when the two different forms separate, over a range of composition. The metastable eutectic mixture melts at 13.5°.

The silicon tetrabromide–dioxane system is a simple eutectic giving no evidence of strong interaction between the two components except for a slight but definite change of curvature between 60 and 80 mole % dioxane.

Some carefully obtained warming curves for mixtures between 77 and 85 mole % dioxane revealed a reproducible temperature halt in the region 79–83 mole % dioxane. Some representative data from these warming curves are plotted in Fig. 3. A maximum temperature halt shows up at 80 mole % dioxane with temperature halts of shorter duration at neighboring compositions. This behavior is commonly interpreted as due to the existence of a molecular compound with incongruent melting point. Thus the existence of a 1:4 complex between silicon tetrabromide and dioxane is indicated by the warming curve results.

Dielectric Constant and Density Data.—The dielectric constants and densities of dilute solu-

.0300	2.234	1.1030
	Carbon tetrachloride solutions	
.0000	2.2300	1.5856
.0122	2.2356	1.6035
.2190	2.2389	1.6177

The calculated polarization and electric moments are listed in Table III.

TABLE III

POLARIZATIONS AND ELECTRIC MOMENTS OF SILICON TETRABROMIDE

Solvent	$P_E + A$	$P_{2\infty}$	μ
Dioxane	44.66	51.15	0.55 ± 0.09
Carbon tetrachloride	44.66	45.20	.00 ± .10

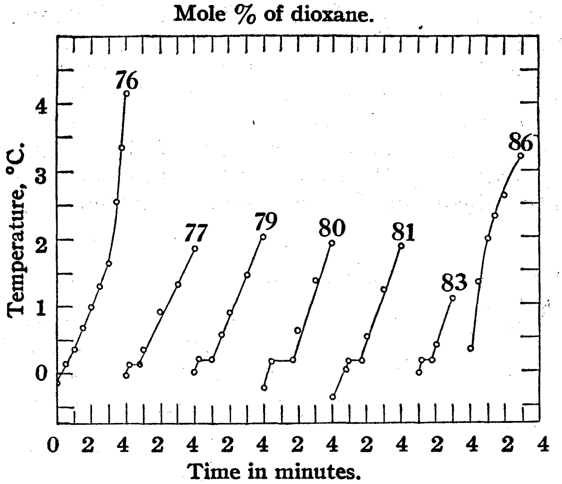

Fig. 3.—Warming curves for some silicon tetrabromide–dioxane solutions.

The value obtained for the electric moment of silicon tetrabromide in carbon tetrachloride is the expected zero value for the tetrahedral structure indicated by electron diffraction,[7] and Raman spectra studies.[8] The value for the electric moment in dioxane is small but is significantly different from zero. A slight but definite electronic interaction between dioxane and silicon tetrabromide is probably responsible for this small moment. The composition of the unstable crystalline compound between silicon tetrabromide and dioxane, indicated by the warming curve data, suggests that interaction at higher temperatures in the same molecular ratio would lead to a zero moment since the moment vectors would cancel. The small electric moment observed for silicon tetrabromide in dioxane is not sufficient evidence to assume extensive interaction between the halide and dioxane in the liquid state. It may, however, indicate a diminished tendency for such interaction with the symmetrical 1:4 complex being partly dissociated.

Measurements of the densities of solutions of silicon tetrabromide in dioxane were made over the whole range of composition. The results obtained are listed in Table IV.

TABLE IV

DENSITY DATA FOR SILICON TETRABROMIDE–DIOXANE

Volume % dioxane	d^{25}_4	Volume % dioxane	d^{25}_4
0.00	2.7715	71.72	1.5141
16.06	2.4853	75.54	1.4483
25.12	2.3236	79.63	1.3770
42.62	2.0184	82.35	1.3312
53.01	1.8380	87.98	1.2342
64.11	1.6457	100.00	1.0279
68.49	1.5703		

Plotting of the density against volume fraction gives a straight line and shows no abnormal change in density at 80 mole per cent. dioxane. This is evidence that no appreciable concentration of the 1:4 complex persists in the liquid state at 25.0°.

II. The Cyclohexane–Dioxane System.—While few solid–liquid equilibrium diagrams are available in the literature for systems containing dioxane, the system with water has been investigated.[9,10] In this system a considerable change occurs in the curvature of the liquids at approximately the same temperature as observed in the silicon tetrabromide–dioxane system. Since molecular interaction is probable between the highly polar water and dioxane, comparable data were sought for a substance which should be completely inert to dioxane. Cyclohexane was chosen for this purpose, since its melting point was convenient and its geometric similarity to dioxane would minimize steric factors influencing the composition of the solid phase. The melting point data for this system are listed in Table V and diagrammed in Fig. 4.

TABLE V

III. The Silicon Tetrachloride–Dioxane System.—For the purpose of comparison, a portion of the solid–liquid equilibrium diagram for silicon tetrachloride–dioxane was worked out.

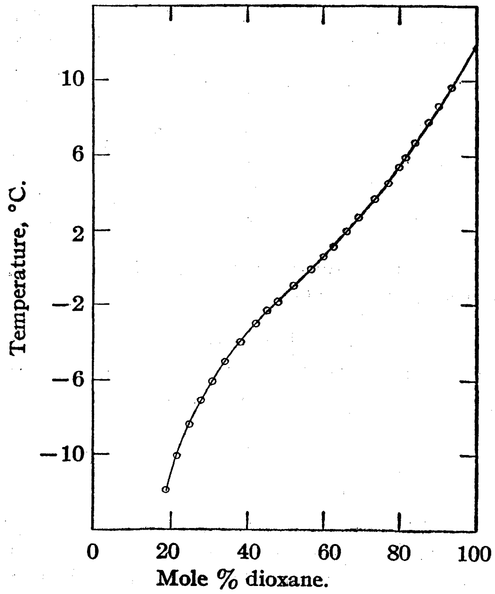

Fig. 5.—Melting point–composition diagram for a portion of the silicon tetrachloride–dioxane system.

---

(9) Gillis and Delaunois, *Rec. trav. chim.*, **53**, 186 (1934).

(10) Hovorka, Schaeffer and Dreisbach, THIS JOURNAL, **58**, 2264 (1936).

The selected portion includes all compositions at which molecular compound formation might reasonably be expected to occur. The melting point data for this system are listed in Table VI and are diagrammed in Fig. 5.

An examination of the diagram shows a considerable degree of similarity with the silicon tetrabromide and cyclohexane systems with dioxane. No stable compound is indicated and the same type of curvature change occurs in the liquidus at about the same temperature.

Previous determinations[2] of the electric moment of silicon tetrachloride in dioxane gave zero value. If the small moment obtained for silicon tetrabromide in dioxane is attributed to an electronic interaction between the halogens and the donor oxygens of dioxane, the zero value of the moment for silicon tetrachloride in dioxane would indicate a lessened tendency for such interaction. Attempts to obtain reproducible warming curves for silicon tetrachloride–dioxane solutions in the neighborhood of 80 mole % dioxane were unsuccessful.

Summary

1. Melting point–composition diagrams for the systems of silicon tetrabromide, silicon tetrachloride and cyclohexane with dioxane have been determined.

2. A metastable form of solid silicon tetrabromide, m. p. 2.3°, has been observed.

3. Thermal analysis of the system silicon tetrabromide–dioxane indicates the existence of an unstable 1:4 complex.

4. A characteristic curvature change in the liquidus for several systems containing dioxane was found to occur at approximately 0°.

5. Dielectric constant and density data indicate a small degree of electronic interaction between silicon tetrabromide and dioxane. The electric moment of silicon tetrabromide in carbon tetrachloride was found to be 0.0.

Phenyl and Ethoxy Silicon Isocyanates

BY GEORGE S. FORBES AND HERBERT H. ANDERSON

This paper describes two complete series of new mixed silicon isocyanates. The phenyl silicon isocyanates were prepared from phenylchlorosilanes and silver isocyanate, and the three ethoxy silicon isocyanates from ethoxychlorosilanes and silver isocyanate.

Preparation of Phenyl Silicon Isocyanates.—In the usual manner,[1] each phenylchlorosilane was changed into the corresponding isocyanate through reaction with an excess of silver isocyanate; the yields varied from 75 to 90%. All three phenyl silicon isocyanates were distilled at 3 mm. pressure through a plain column 4 mm. i. d. and 300 mm. long. Triisocyanate, collected from 101 to 102°; diisocyanate, 142–143°; monoisocyanate, 177.5–178.5°.

Physical Properties and Analyses of Phenyl Silicon Isocyanates (see Table I).—Dynamic vapor pressure measurements were made on each of the three compounds—six values on the triisocyanate, five on the diisocyanate and four on the monoisocyanate. Frozen phenyl silicon triisocyanate melted over the range −50 to −20°, approximately. Possibly two solid forms were present; diphenyl silicon diisocyanate supercooled to −70°, but formed a crystalline solid of sharp m. p. after addition of a small clay chip to promote crystallization; triphenyl silicon isocyanate supercooled less than 20°. Needless to say, vigorous stirring was essential in obtaining melting points. When shaken with water, the triisocyanate hydrolyzed slowly at first and then with increasing speed; the diisocyanate hydrolyzed at a moderate rate only, even with vigorous shaking; the monoisocyanate, however, hydrolyzed very slowly, if at all. Analyses employed the Dumas method for nitrogen, combustion for carbon and hydrogen, and the hydrolysis and ignition of the triisocyanate to obtain silica as the end-product. Calcd. for $(C_6H_5)Si(NCO)_3$: Si, 12.2; C, 46.8; H, 2.2. Found: Si, 12.3; C, 47.1; H, 2.3. Calcd. for $(C_6H_5)_2Si(NCO)_2$: N, 10.5; H, 3.8. Found: N, 10.8; H, 3.5. Calcd. for $(C_6H_5)_3Si(NCO)$: N, 4.6; H, 5.0. Found: N, 4.4; H, 5.3 The observed molecular weights in camphor solution were 212, 250 and 290, respectively, corresponding to the calculated values 231, 266 and 301.

Preparation of Ethoxy Silicon Isocyanates.—Methanol reacts with silicon isocyanate to produce methoxy silicon isocyanates,[2] the boiling points of which are 15° apart; however, the reaction between ethanol and silicon isocyanate yields products difficultly separable. It was much easier to obtain the desired products from the ethoxychlorosilanes. Ethoxytrichlorosilane, prepared from tetrachlorosilane and ethanol, boiled at 102.1° at 758 mm.[3]; diethoxydichlorosilane boiled at 137.4–137.6° at 754 mm.[3] Triethoxychlorosilane boiled from 154 to 157°,[4] even upon repeated distillation on a plain column 4 mm. i. d., 125 cm. long; apparently redistribution limited the purity of the sample. Following the general method,[1] a solution of the individual ethoxychlorosilane in benzene was heated with a 30% excess of silver isocyanate for thirty minutes at 90°, and then filtered with washing of the silver salts; benzene was removed by distillation at atmospheric pressure. The middle fraction of ethoxy silicon triisocyanate boiled at 178.5° uncor. at 764 mm. with little variation; that of diethoxy silicon diisocyanate boiled at 174.8–174.9° uncor. at 760 mm. in a column without spiral or packing, and 4 mm. i. d. and 50 cm. long.

Triethoxy silicon isocyanate could not be purified by distillation alone; the main contaminant was probably diethoxy silicon diisocyanate, the boiling point of which is only 2.5° higher, and the minor contaminant was the more easily removed ethyl orthosilicate (tetraethoxysilane). The first preparation showed a b. p. of 173.5°, d^{20}_4 1.025 and n (index of refraction) 1.3933, leading to R (molar refraction, n^2 formula) 47.82 ml., none of which agreed with values interpolated in the series. A product of apparently higher purity was next obtained by treatment of the above material with ethanol in excess. Prob-

[a] Average of acceptable published data. [b] Solana and Moles, *C. A.*, **27**, 1252 (1933). [c] Estimated from d^{25}_4 1. 434. [d] Bygden, *Z. physik. Chem.*, **90**, 243 (1915).

ably the diethoxy impurity was thus converted into the desired triethoxy compound. As shown below, the diisocyanate is destroyed by alcohol or water more rapidly than is the monohalide. Eighteen milliliters of absolute ethanol was added to 90 g. of triethoxysilicon isocyanate, over a period of forty minutes, and then unchanged ethanol was removed by distillation; after further purification, the triethoxy derivative was found to have the analyses given below and the following physical properties: b. p. 172.9°, d^{20}_4 1.015, n 1.3922, R, 48.19 ml. A second similar treatment with ethanol produced a sample of b. p. 172.8°, d^{20}_4 1.009, n 1.3917 and R 48.41. A third treatment with ethanol followed by shaking with a moderate amount of 0.06 M sodium hydroxide, drying and repurification resulted in a product of b. p. 173.2°, d^{20}_4 1.003, n 1.3902 and R 48.51 ml. When values of d^{20}_4 and of n were graphed for the series from silicon tetraisocyanate to tetraethoxysilane exclusive of the triethoxy compound, the curves were quite smooth and predicted the following values: d^{20}_4 1.013 ± 0.005, n 1.3921 ± 0.0003. Corresponding data, as yet unpublished, for the methyl silicon isocyanates, and for the methyl silicon isothiocyanates, also lie on smooth curves. It was concluded that the product of boiling point 172.9°, obtained through a single treatment with ethanol, was the purest of the four.

Analyses of Ethoxy Compounds.—Carbon and hydrogen were obtained by combustion, and the Dumas method was used for nitrogen. Calcd. for $(C_2H_5O)_3Si(NCO)$: C, 41.0; H, 7.3; N, 6.8. Found: C, 40.8; H, 7.4; N, 6.7. Calcd. for $(C_2H_5O)_2Si(NCO)_2$: C, 35.6; H, 5.0; N, 13.9. Found: C, 36.0; H, 4.9; N, 13.6. Calcd. for $(C_2H_5O)Si(NCO)_3$: C, 30.1; H, 2.5; N, 21.1. Found C, 29.8; H, 2.6; N, 21.2. The molecular weights observed by the Dumas method were 208, 206 and 205 respectively, corresponding to calculated values of 205, 202 and 199.

Physical Properties of Ethoxy Silicon Isocyanates (See Table II).—Dynamic vapor pressure measurements, made on the day of final purification and using calibrated thermometers, served for calculations of heats of vaporization. The vapor pressure equations fit eighteen observed points with an average deviation of three mm. Swarts' rule of linear progression[4] of boiling points predicts 170.5, 175.5 and 180.6° for the new isocyanates, in reasonable agreement with observed values. All were colorless liquids. Densities were taken using a special 2-ml. micropycnometer. Rates of hydrolysis decreased strikingly from silicon isocyanate to tetraethoxysilane.

Summary

Each of the three phenylchlorosilanes and also each of the three ethoxychlorosilanes yielded the corresponding new isocyanate upon treatment with silver isocyanate. Triphenylsilicon isocyanate, $(C_6H_5)_3Si(NCO)$, boiled at 372°; diphenylsilicon diisocyanate, $(C_6H_5)_2Si(NCO)_2$, at 320°; phenylsilicon triisocyanate, $(C_6H_5)Si(NCO)_3$, at 252°; triethoxysilicon isocyanate, $(C_2H_5O)_3Si(NCO)$, at 172.9°; diethoxysilicon diisocyanate, $(C_2H_5O)_2Si(NCO)_2$, at 175.4°; ethoxysilicon triisocyanate, $(C_2H_5O)Si(NCO)_3$, at 179.6°.

Densities, refractive indices, molar refractions and vapor pressure equations were determined.

Substitution of phenyl or of ethoxy groups progressively decreases rates of hydrolysis of the isocyanate groups present.

Some Exchange Experiments Involving Hexacyanoferrate(II) and Hexacyanoferrate(III) Ions[1]

BY ROY C. THOMPSON[2]

Exchange reactions involving the following pairs of ions have been investigated using radioactive iron: hexacyanoferrate(II) and hexacyanoferrate (III) ions, iron(III) and hexacyanoferrate(III) ions, iron(III) and hexacyanoferrate(II) ions, iron(II) and hexacyanoferrate(II) ions, and iron (II) and hexacyanoferrate(III) ions. The exchange of activity between hexacyanoferrate(II) and hexacyanoferrate(III) ions can be accomplished by an oxidation–reduction reaction involving only the transfer of an electron. The other reactions investigated require the exchange of an atom between molecules.

Most of these exchange reactions were previously investigated by Kennedy, Ruben and Seaborg, who also studied the exchange between iron (II) and iron(III) ions. The results of this earlier investigation were referred to in a review article by Seaborg,[3] but the details of the work have not been published. The experiments reported here will confirm the absence of any detectable exchange in the case of the atomic interchanges studied. However, complete and rapid exchange was observed in the case of the hexacyanoferrate (II)–hexacyanoferrate(III) ion pair, whereas Kennedy, *et al.*, detected no exchange in this case.

Experimental

The radioactive iron employed as tracer was a mixture of the beta-emitting $^{59}_{26}$Fe of forty-seven day half-life[4] and the four year $^{55}_{26}$Fe which decays by orbital electron capture.[5] These isotopes were prepared by bombardment of an iron plate with 22 Mev. deuterons obtained from the 60 inch cyclotron of the University of California.

A sample of potassium hexacyanoferrate(II) containing radioactive iron was synthesized by addition of a solution of active iron(II) chloride to a saturated solution of potassium cyanide. The product was purified by crystallization from ethanol–water mixtures. Active potassium hexacyanoferrate(III) was synthesized by oxidation of active potassium hexacyanoferrate(II) with chlorine and purified by crystallization from ethanol–water mixtures.

Hexacyanoferrate(II)-Hexacyanoferrate(III) Exchange.—Equal volumes of 0.2 *M* solutions of active potassium hexacyanoferrate(II) and inactive potassium hexacyanoferrate(III) were mixed and samples taken from this mixture at intervals of from one minute to five days after mixing. The *p*H of this mixture was 8.1 as measured with a Beckman *p*H meter. A solution of cerium(III) nitrate was added to the samples immediately after removal from the mixture, which resulted in the selective precipitation of the hexacyanoferrate(II) ion as $KCeFe(CN)_6$.[6] This precipitate was separated by centrifugation, washed, slurried onto platinum plates and the radioactivity measured with a bell-type Geiger tube having a 3 mg./sq. cm. mica window. The supernatant solution and washings were combined, evaporated on platinum plates and also counted. Of the activity recovered in these two fractions, an average of 56% was found in the hexacyanoferrate(II) precipitate and the remainder in the hexacyanoferrate(III) supernatant solution. The range of values observed in six determinations over a five-day interval was 53 to 60%. From 87 to 94% of the initial activity was recovered in each experiment.

The experiment was then repeated, starting with active potassium hexacyanoferrate(III) and inactive potassium hexacyanoferrate(II). Practically identical results were obtained with an average of 58% of the total recovered activity being found in the potassium cerium(III) hexacyanoferrate(II) precipitate. The *p*H of the exchange mixture in this case was 7.3.

The exchange between 0.1 *M* solutions of hexacyanoferrate(II) and hexacyanoferrate(III) ions was also studied in 1.0 *M* hydrochloric acid and in 0.05 *M* sodium hydroxide solutions, and the exchange between 0.009 *M* solutions of hexacyanoferrate(II) and hexacyanoferrate (III) ions was studied in neutral solution. In all of these cases complete exchange was observed within one minute after the time of mixing.

Cerium(III) ion was chosen to effect the separation of hexacyanoferrate(II) and hexacyanoferrate(III) ions after experiments had shown iron(III) ion to be unsatisfactory for this purpose. The addition of iron(III) ion to a mixture of hexacyanoferrate(II) and hexacyanoferrate(III) ions resulted in the precipitation of more than 75% of the radioactivity regardless of whether this activity was added in the form of hexacyanoferrate(II) or hexacyanoferrate(III) ion. Because cerium was employed in its more stable oxidation state and because essentially identical results were obtained in approaching the equilibrium from both directions it can be assumed that the presence of cerium does not induce an exchange.

Iron(III)-Hexacyanoferrate(III) Exchange.—A mixture 0.07 *M* in active potassium hexacyanoferrate(III) and 0.14 *M* in inactive iron(III) chloride was allowed to stand in the dark at room temperature for six days. Iron (III) hydroxide was then precipitated from the mixture by addition of 0.5 *M* sodium hydroxide. The iron(III) hydroxide precipitate was completely inactive.

Iron(III)-Hexacyanoferrate(II) Exchange.—Excess inactive iron(III) chloride solution was added to 0.05 ml. of a 0.2 *M* solution of active potassium hexacyanoferrate(II). The precipitate was separated by centrifugation, washed and allowed to stand in the dark at room temperature for six days. The precipitate was then converted to iron(III) hydroxide by addition of 0.5 *M* sodium hydroxide and the product was separated, washed and the radioactivity measured. The iron(III) hydroxide was found to be completely inactive.

Iron(II)-Hexacyanoferrate(II) and Iron(II)-Hexacyanoferrate(III) Exchange.—In similar experiments, no exchange was observed between iron(II) and hexacyanoferrate(II) ions, and none between iron(II) and hexacyanoferrate(III) ions.

Discussion

The rapid electronic exchange between hexacyanoferrate(II) and hexacyanoferrate(III) ions is not surprising since exchange has been observed in all cases in which pairs of ions differing only in electronic charge have been studied, *e. g.*, iron

(II) and iron(III) ions,[3] lead(II) and lead(IV) acetates,[7] manganese(II) and manganese(III) (oxalate complex) ions,[8] thallium(I) and thallium (III) ions,[9] manganate and permanganate ions,[10] and mercury(I) and mercury(II) ions.[11]

Kennedy, Ruben and Seaborg studied the hexacyanoferrate(II)–hexacyanoferrate(III) equilibrium from only one direction, by mixing active hexacyanoferrate(II) and inactive hexacyanoferrate(III) ions followed by precipitation of the hexacyanoferrate(II) ion with iron(III) chloride.[12] This fact no doubt accounts for their erroneous conclusion, since it was demonstrated in the present investigation that a satisfactory separation of hexacyanoferrate(II) from hexacyanoferrate(III) could not be obtained by precipitation with iron(III) chloride.

The fact that in the present investigation slightly more than 50% of the radioactivity was precipitated with the potassium cerium(III) hexacyanoferrate(II) is clearly due to partial coprecipitation of the hexacyanoferrate(III) ion and not due to incomplete exchange, since an essentially equal excess activity was present in the precipitate regardless of whether the active iron was originally added as hexacyanoferrate(II) or hexacyanoferrate(III) ion.

The failure to observe any atomic exchange between iron(III) and hexacyanoferrate(III) ions, iron(III) and hexacyanoferrate(II) ions, iron (II) and hexacyanoferrate(III) ions and iron(II) and hexacyanoferrate(II) ions adds to our knowledge of the nature of the various compounds formed between these ions. It is now certain that the two kinds of iron atoms which enter into the formation of such compounds as iron(III) hexacyanoferrate(III), iron(II) hexacyanoferrate(II), iron(III) hexacyanoferrate(II), etc., do not occupy equivalent positions in the compound, nor do they exchange positions with each other.

The structures of substances such as $KFeFe(CN)_6$ have been the subject of X-ray analyses by Keggin and Miles.[13] The iron atoms were found to occupy the corners of a single cubic lattice, each being linked with its six neighboring iron atoms by —CN— groups extending along the edges of the cube. Potassium ions and water molecules are contained within these cubes. This structure was further elucidated by the magnetic susceptibility measurements of Davidson and Welo.[14] These data show that, in effect, half of the iron atoms are diamagnetic and the other half are paramagnetic, which Pauling[15] has interpreted to mean that half of the iron atoms are bonded by essentially covalent links (presumably to six surrounding carbon atoms) and half (presumably those surrounded by nitrogen atoms) are held by ionic bonds. We may now add that the iron–carbon bonds which are present in the hexacyanoferrate (II) and hexacyanoferrate(III) ions are not broken in the solid precipitate and remain intact when the precipitates are decomposed by the addition of dilute sodium hydroxide.

Acknowledgments.—The author wishes to express his indebtedness to Professor G. T. Seaborg who suggested the problem, to Dr. J. G. Hamilton under whose direction the cyclotron bombardment of the iron was performed, and to Mr. R. C. Lilly who effected the initial purification of the iron tracer.

Summary

1. An exchange of electrons between hexacyanoferrate(II) and hexacyanoferrate(III) ions in neutral solution, 1.0 *M* hydrochloric acid, and 0.05 *M* sodium hydroxide has been observed to occur within the time interval required for separation of the ions (one minute).

2. No exchange of iron atoms was observed between any of the following pairs of ions: iron (III) and hexacyanoferrate(III), iron(III) and hexacyanoferrate(II), iron(II) and hexacyanoferrate(II), and iron(II) and hexacyanoferrate (III).

The Coulometric Titration of Arsenic by Means of Electrolytically Generated Bromine and an Amperometric End-point

BY ROLLIE J. MYERS AND ERNEST H. SWIFT

Introduction

A method and apparatus for the determination of thiodiglycol has been described by Sease, Niemann and Swift.[1] This method involved passing a known constant current for a measured time between two platinum electrodes (called the "generator electrodes") immersed in an acetic acid solution containing a soluble bromide, thus at a constant rate generating bromine which oxidized the thiodiglycol. The end-point was obtained by noting the increase in current, caused by excess bromine, between a second pair of platinum electrodes (called the "indicator electrodes") which had a small potential difference impressed across them. The method was developed as part of a war project and time was not available for a detailed study. However, the results obtained, together with the rapidity of the method and the simplicity and cheapness of the apparatus, appeared to justify further investigations in order to establish the accuracy of the method, to obtain a better understanding of certain of the phenomena observed, and to determine the applicability of the method to other constituents. As a part of these investigations a study of the titration of arsenious acid has been made and the results obtained are presented below.

Experimental

Chemicals.—One formal sulfuric acid solutions were prepared from "Reagent Grade" concentrated acid. Immediately after dilution these solutions were found to contain up to 10^{-8} equivalent per milliliter of reducing material; after standing for a day or longer this quantity diminished by 50 to 90%.

Two formal sodium bromide solutions were prepared from "Reagent Grade" material; no reducing material was found present.

Bureau of Standards arsenious oxide was used after being dried for one hour at 115°. Stock 0.005 formal solutions were prepared by dissolving 500 mg. of the oxide in 10 ml. of water containing 1 g. of Reagent Grade sodium hydroxide, then acidifying the solution with 25 ml. of the one formal sulfuric acid and diluting to 500 ml. These solutions were kept for not more than five days.

The laboratory distilled water was found at times to contain as much as 10^{-8} equivalent per milliliter of an oxidizing agent, thought to be chlorine, which could be removed by boiling. A stock of water free of oxidizing agent was used throughout the work.

Apparatus.—The titration cell is outlined in Fig. 1, a basic diagram of the apparatus is shown in Fig. 2, and the details of the electrical circuits are shown in Fig. 3.

The Titration Cell.—The various components of the cell are arranged to give the greatest mechanical strength and to permit the maximum stirring with the minimum fluctuation of solution level; oscillations of the solution level cause variation of the indicator current. Under the conditions of these experiments, changes in the relative positions of the indicator anode and cathode caused no significant difference in the sensitivity of the indicator system. For reasons discussed below the cathode guard shown in Fig. 1 was used to prevent most of the generated hydrogen from being swept into the solution. The small hole in the side of this guard permits sufficient circulation to prevent solution from being trapped in the guard. The amount of hydrogen passing into the solution can be controlled by vertical adjustment of the electrode.

A Cenco variable speed stirrer was used. In order to stabilize the sensitivity of the indicator system the stirrer speed was adjusted by means of a stroboscopic disc consisting of two perpendicular white stripes on a black background illuminated by a fluorescent light or a small neon bulb; a stirrer speed of 1800 r.p.m. was used.

The Indicator System.—All electrodes were made from 0.003 inch platinum foil; the sizes are shown in Fig. 1.

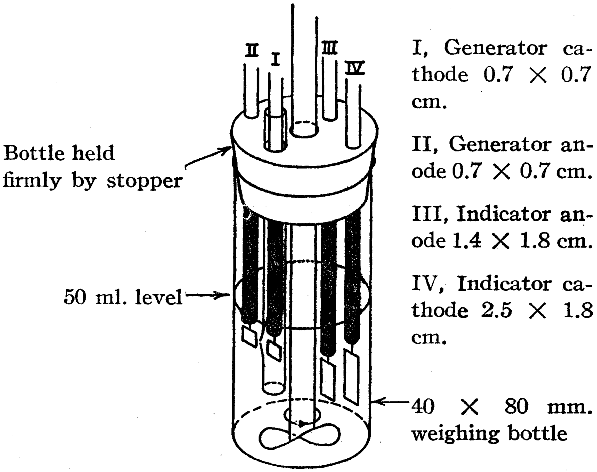

Fig. 1.—Titration cell.

The applied potential difference across the indicator electrodes was usually 200 millivolts. The switch S-8 controlling the sensitivity of the microammeter, M-2, was left in the "high" sensitivity position except in the case of a badly over-run end-point. The switch S-1 was used to short the electrodes during preliminary treatment and storage; otherwise they were found to develop a potential difference.

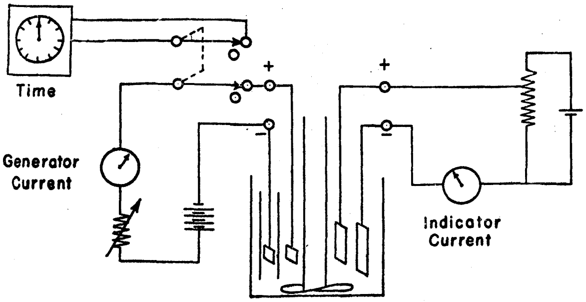

Fig. 2.—Basic diagram of electrical circuits.

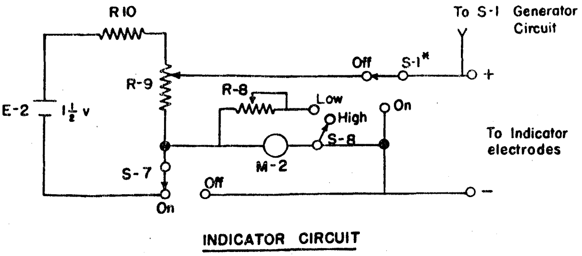
---

(1) John Sease, Carl Niemann and Ernest H. Swift, *Anal. Chem.*, **19**, 197 (1947).



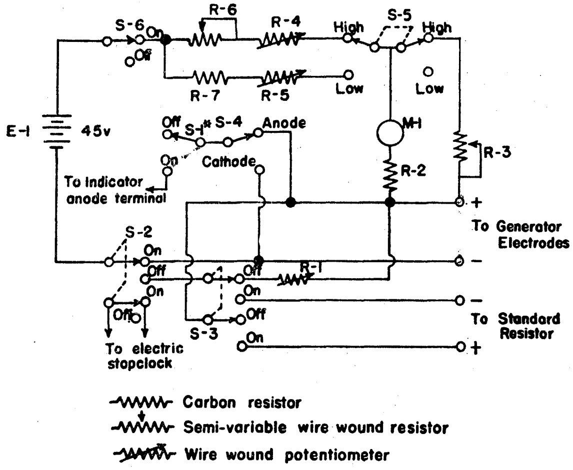


Fig. 3.—Details of generator circuit: *S-1 indicator ganged with S-1 generator: S-1, S-2, S-3, S-5, DPDT radio toggle switches; S-4, S-6, S-7, S-8, SPDT radio toggle switches; M-1 Weston meter, model 301, 0–1 milliampere; M-2 Weston meter, model 301, 0–50 microamperes; E-1 Burgess battery 2308 45v.; E-2 Burgess battery 4F4 1.5v.; R-1 3000Ω, R-2 600Ω2w, R-3 350Ω10w, R-4 1500Ω, R-5 15,000Ω, R-6 5000Ω10w, R-7 45,000Ω2w, R-8 2000Ω10w, R-9 100Ω10w, R-10 240Ω2w.

The indicator anode size is not important. The sensitivity of the indicator system depends linearly on the size of the cathode.

The Generator System.—The switch S-5 provides for "high" and "low" bromine generating rates of approximately 10 and 1 milliamperes, respectively, corresponding to 10^{-7} and 10^{-8} equivalent per second. The generating rate could be adjusted within a reproducibility of ±0.05% by making use of a fixed point near the 10 milliampere calibration on the scale of meter M-1; calibrations over a ten minute period were found to agree to within ±0.1%. With batteries in good condition the current through a fixed resistance would normally remain constant to within ±0.1% over a ten minute period.

Because of temperature and other variations the current value for a specific setting was checked every ten minutes by setting the calibration switch, S-3, to the "on" position and measuring the potential across a standard 200 ohm resistance by means of a potentiometer.

The switch controlling bromine generation, S-2, was ganged so that a Standard Electric Time Co., model S-10, time clock, calibrated to one-tenth second was started and stopped with the generation current.

Resistance R-1 was provided so that between consecutive titrations and during the "warm up" period the current through the meter and battery would be the same as during a titration; this resistance has to be adjusted to correspond to the generation rate. Resistance R-2 was provided so that the contact resistance of switch S-5 had little effect on the resistance in shunt with milliammeter, M-1; switch S-5 has to be of better quality than the other switches.

Accuracy of Standards and Measurements.—The absolute accuracy of the current determination was dependent upon the accuracy of the standard resistor and the standard cell used. The resistance was a 200 ohm coil from a Leeds and Northrup no. 4716 resistance decade, rated by the manufacturer as ±0.05%.[2] The standard cell used was checked against a Weston standard cell which had been calibrated by the U. S. Bureau of Standards; however, during the period of its use the value of the cell changed 1 millivolt. Therefore the uncertainty in the current determination was ±0.1%. The error in the potentiometer readings should have been less than ±0.1%.

The errors in the preparation of the solutions and in the volumetric measurements involved are believed to be less than ±0.1%.

The value used for the faraday was 96,500 coulombs.

Procedure.—When not in use the electrodes are immersed in a solution prepared from 5 ml. of 1 *F* sulfuric acid, 5 ml of 2 *F* sodium bromide and 40 ml of water; the switch S-1 should be in the "on" position. This procedure minimizes changes in the sensitivity of the indicator electrodes and the development of potential differences between them.

First the apparatus is allowed to equilibrate for ten minutes with S-6 and S-7 on, with S-2 and S-3 off, with S-5 set for the appropriate rate, and with R-1 set to the approximate cell resistance for that rate. (After this period the voltage of the generator battery should have become constant and the reading of M-1 stable.) Then before use after a period of storage the electrodes are treated as follows: With switch S-1 on, the generator switch S-2 is turned on for an arbitrary time of nine seconds (at either rate); during this time the treatment selector switch, S-4 is turned to the "cathode" position for three seconds and to the "anode" position for six seconds.

Because the sensitivity of the indicator electrodes tends to change, end-point correction measurements are then made. These values are obtained by generating bromine in the titration medium, at the rate to be used in the titration, for five periods (one or five seconds each for the high or low rate, respectively) and noting the microammeter reading when the needle becomes stable after each of these periods. The stirrer speed should be checked after each period. Two series of such measurements are made. These readings should agree within 3 microamperes at currents of 40 microamperes. Each reading should be stable for twenty seconds and at 40 microamperes momentary fluctuations of the needle should not exceed 1 microampere. With proper reagents the initial current, zero generation time, should not exceed 1 microampere. After completion of each of the end-point correction measurements the indicator electrodes are again treated in the anode position for five seconds as directed above. In Figure 4 the data obtained from a series of three such measurements made on the low generation rate have been plotted in order to show the reproducibility of the measurements and the linearity of the current–time curve. At the high generation rate the end-point correction time is of the order of 1% of the titration time, therefore if the indicator system is reproducible to within ±10%, the uncertainty introduced into the titration should not exceed ±0.1%.

The switch S-3 is then turned on and the desired setting of M-1 calibrated for its exact current value. This calibration should be made every ten minutes or at the end of every titration.

The titrations were made by pipetting the arsenite solu-

---

(2) Not until after the termination of this investigation did a resistance standard become available, a Wolff potentiometer calibrated to within 0.01%. The 200 ohm. coil was then checked against this standard, and was found to be 0.06% low. Since this correction opposed a possible hydrogen current correction, mentioned later, of 0.1% or less, the uncorrected value of 200.0 ohms was used in the calculations.

tion into the titration cell, which contained 5 ml. of 1 *F* sulfuric acid and 5 ml. of 2 *F* sodium bromide, and then diluting the solution to 50 ml. Generation at the appropriate rate is then begun and continued until the first sign of a definite decrease or increase in the indicator current. If the indicator current is less than 2 microamperes, generation is continued until it becomes greater than this value. The indicator current at the end-point should be less than 40 microamperes for the high generation rate and less than 20 microamperes for the low rate. The end-point correction in seconds is obtained by interpolation between the values obtained from the end-point correction measurements.

After each titration the indicator electrodes are treated as was done after the end-point correction measurements, use being made of the titrated solution.

Discussion of the Method

Limitations.—The predominant reaction at the generator anode is the oxidation of bromide to bromine, and at the cathode the reduction of hydrogen ion. One would predict that the method as described would be limited in application to substances which do not establish reversible electrode potentials, otherwise there would be appreciable reduction at the generator cathode of the oxidation product and also the possibility of significant current flow through the indicator system throughout the titration. Also, the assumption is made that the oxidation of hydrogen gas at the generator anode is not a significant factor in the total current through the generator circuit. The results obtained show that in the solution used the arsenic in the quinquepositive state is inert to the generator cathode and to both indicator electrodes. The possibility of extending the method to substances which establish reversible electrode potentials by isolating the generator cathode and by modifications of the end-point procedure is being investigated.

Indicator Current Phenomena.—In solutions 0.1 *F* in sulfuric acid, 0.2 *F* in sodium bromide and varying from 5 to 50 $\times 10^{-7}$ *F* in bromine, this bromine concentration corresponding to indicator currents of from 5 to 50 microamperes, the predicted indicator electrode reactions could be represented as

$$\text{Cathode}\quad Br_2 + 2e^- = 2Br^-$$
$$\text{Anode}\quad 2Br^- - 2e^- = Br_2$$

Making use of a saturated calomel cell and salt bridge, measurements were made (under the conditions of an end-point correction measurement) of the potentials of the generator cathode, generator anode, and of an independent platinum electrode immersed in two such solutions. The values obtained are summarized in Table I.

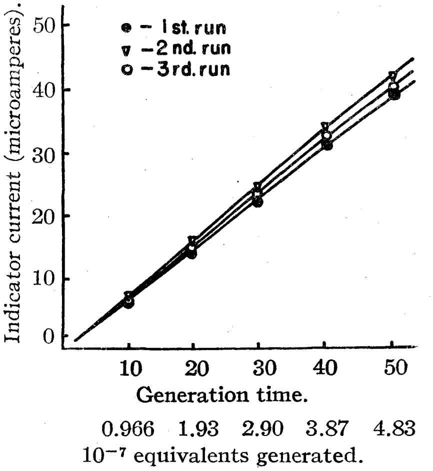

Fig. 4.—Reproducibility of end-point correction measurements: solutions prepared from 5 ml. of 1 *F* sulfuric acid and 5 ml. of 2 *F* sodium bromide diluted to 50 ml.; titrated on the low rate at 0.932 milliampere: ●, first run; ▽, second run; ○, third run.

It appears that the indicator current in the system described is limited by the diffusion of bromine to the cathode. The following formula for such a diffusion current has been derived by Laitinen and Kolthoff[3] with the aid of Fick's law

$$i = (AD/l)\, nFc$$

Here i is the diffusion current, A is the area of the electrode, D is the diffusion constant for the diffusing substance, l is the thickness of the diffusion layer, n is the number of electrons involved, F is the Faraday, and c is the concentration of the diffusing substance in solution.

From this formula it can be seen that an increase in the area of the cathode should increase the bromine diffusion current. This was observed by Sease, Niemann and Swift.[1] Also the current should be a linear function of the bromine concentration, and Fig. 4 shows this to be true. Also one would expect that stirring the solution would decrease the thickness of the diffusion layer, thereby increasing the sensitivity.

Laitinen and Kolthoff[4] used a rotating microcathode (at 600 r. p. m.) with a total surface area of 0.047 sq. cm. and obtained a sensitivity of 1.77 microamperes/10^{-5} mole of Br_2/liter. Using a cathode with a total surface area of 9.0 sq. cm. and the stirring means described we obtain a sensitivity of 1.0 microamperes/10^{-7} mole of Br_2/liter.

The Effect of Hydrogen Gas.—In the apparatus used by Sease, Niemann and Swift[1] the hydrogen produced at the generator cathode was swept into the solution. During a titration the indicator current was found to increase slowly, and before the end of a two-hundred second

[3] H. A. Laitinen and I. M. Kolthoff, *J. Phys. Chem.*, **45**, 1061 (1941).

[4] H. A. Laitinen and I. M. Kolthoff, *ibid.*, **45**, 1079 (1941).

titration the current would have become 10–30 microamperes. Shortly before the equivalence point of the titration the current would begin to decrease, would reach zero, reverse direction and temporarily a meter reading below zero would be obtained; then after a few seconds the meter reading would increase rapidly. This decrease and reversal are hereinafter called the **Current Decrease** and the **Current Reversal.**

If hydrogen is bubbled into a solution such as is used for end-point corrections the indicator current will rise, apparently because of oxidation of hydrogen gas at the indicator anode and simultaneous reduction of hydrogen ion at the indicator cathode. However, when bromine generation is started the current will behave as described above. The data from two such experiments are illustrated in Fig. 5.

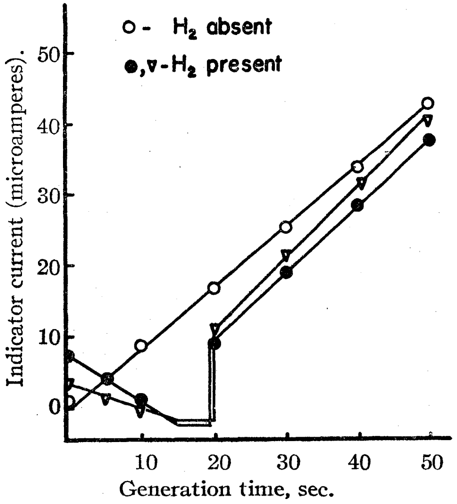

Fig. 5.—The effect of hydrogen gas on end-point correction measurements: solution prepared from 5 ml. of 1 *F* sulfuric acid and 5 ml. of 2 *F* sodium bromide diluted to 50 ml. The hydrogen was bubbled into the solution till the current indicated at zero time was obtained, then bromine was generated in five to ten second intervals and the value of the current read five to fifteen seconds after termination of generation. Portions of curves between ten and twenty seconds describe the general behavior of the meter during this period. Generation rate was 0.90 milliampere.

It is evident from the figure that if hydrogen were present at the end-point, and the normal end-point correction made, the titration would give high results. This is illustrated by the titration graph shown in Fig. 6.

A series of titrations was run (as illustrated in Fig. 6) in which the hydrogen produced at the generator cathode was allowed to pass into the solution. When the normal end-point correction was used the results were 1% too high; when nitrogen was bubbled into the solution to eliminate the dissolved hydrogen, the few measurements made were within 0.3%. The use of nitrogen was not investigated further, since by the use of the cathode shield satisfactory results and certain advantages were obtained.

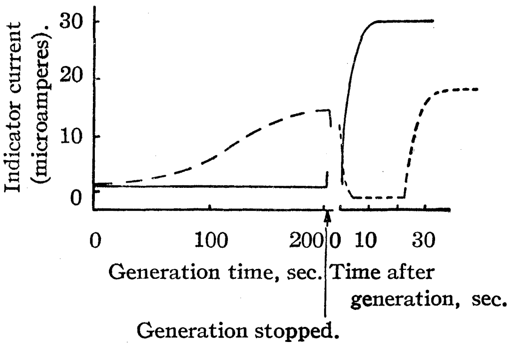

Fig. 6.—Titration characteristics with and without hydrogen present: the solid line represents a titration in which hydrogen was excluded from the solution; the dashed line represents a titration in which hydrogen was allowed to accumulate. The flat portion of the dashed curve represents time during which the meter needle is held fixed below zero by reversal of current. Solution was prepared from 5 ml. of 1 *F* sulfuric acid, 5 ml. of 2 *F* sodium bromide, and 10 ml. of 2×10^{-3} *N* arsenite solution diluted to 50 ml.; generation rate, 9.65 milliamperes.

Since the area of the generator anode is approximately one fifth that of the indicator anode, and the maximum concentration of hydrogen in the solution is obtained only near the end-point, it has been assumed that the error caused by oxidation of hydrogen at the generator anode is relatively small.

Current Decrease.—Kolthoff and Miller[5] have described the action of the polarograph in a solution exhibiting what they term a "mixed potential." Solutions containing hydrogen and bromine have been found to have such a potential, and the explanation advanced by Kolthoff and Miller for the current–voltage phenomena with a single electrode system can be applied to our two electrode system. According to this explanation the time of zero current should correspond to equal quantities of hydrogen and bromine diffusing to an electrode in the solution.

In Figure 5 the measurements obtained from end-point correction experiments with and without hydrogen are plotted. It is seen there that the number of equivalents per second of hydrogen diffusing to the anode can be calculated by the initial indicator current, and at zero current the amount of bromine which has been generated would in the absence of hydrogen, cause a diffusion current which is represented by the normal end-point correction curve. On this normal curve, this current would represent the number of equivalents per second of bromine diffusing to the cathode at the time of zero current. In Table II such values are calculated for the amount of hydrogen and bromine arriving at 1 sq. cm. of electrode surface per second at zero current for different values of initial hydrogen current.

TABLE II

THE EFFECT OF HYDROGEN GAS

I_{H_2}[a] microamperes	N_{H_2}[b] 10^{-11} eq.	I_{Br_2}[c] microamperes	N_{Br_2}[d] 10^{-11} eq.
1.8	0.37	3.0	0.35
4.0[e]	0.83	7.9	0.91
4.3	0.90	7.8	0.90
5.0	1.1	8.3	0.95
7.4[e]	1.5	9.3	1.1
13.0	2.7	21.0	2.4
15.0	3.1	18.0	2.1

[a] I_{H_2}, initial hydrogen current. [b] N_{H_2}, equivalents of hydrogen arriving at 1 sq. cm. of anode per second for I_{H_2}. [c] I_{Br_2}, bromine current at time of zero current if no hydrogen were present. [d] N_{Br_2}, equivalents of bromine arriving at 1 sq. cm. of cathode per second for I_{Br_2}. [e] Note: I_{H_2} of 4.0 and 7.4 are taken from Fig. 5, other values are from unpublished measurements.

It can be seen that at the lower values of hydrogen current, when the rate at which the hydrogen leaves the solution is small, the calculated values of bromine and hydrogen which arrive at an electrode are approximately equal at the time of zero current.

Current Reversal.—In the upper portion of Fig. 7 the potential of the indicator cathode *versus* a saturated calomel half cell is shown during generation of bromine with and without hydrogen being initially present in the solution.

As would be expected, during the period of current decreases and current reversal there is a great change in the potential of the indicator electrodes and of the solution. If because of a local condition about one of the indicator electrodes the potential of that electrode were to lag or lead the potential of the other electrode during this change, a transient condition could exist whereby the potential between the indicator electrodes could be greater than the applied potential, thus causing a reversal of current.

During hydrogen diffusion current, before the addition of bromine, hydrogen is being produced at the indicator cathode and being removed at the indicator anode. One might expect then that at the time of zero current, when equal quantities of bromine and hydrogen are arriving at the anode, there would be an adsorbed layer of hydrogen on the indicator cathode. A cell would then be established in opposition to the applied potential, and could cause a current reversal until this hydrogen was removed. Thereafter bromine predominates at the cathode and the current behaves essentially as during bromine generation in the absence of hydrogen.

It is of interest to note that the number of equivalents of hydrogen which would be discharged to cause the current reversal as illustrated in Fig. 6 would be about 4 × 10^{-10} equivalent. A monomolecular layer of hydrogen on the 9.0 sq. cm. cathode, assuming one hydrogen molecule per 10 Å.^{2}, would amount to 3.0 × 10^{-8} equivalent.

Titration of Arsenite Solutions.—In Table III are shown the data collected from a series of titrations of arsenious acid solutions in which there was no guard tube over the generator cathode and in which the hydrogen evolved was allowed to pass freely into the solution. The error is in all cases positive and is attributed to the hydrogen effect discussed above.

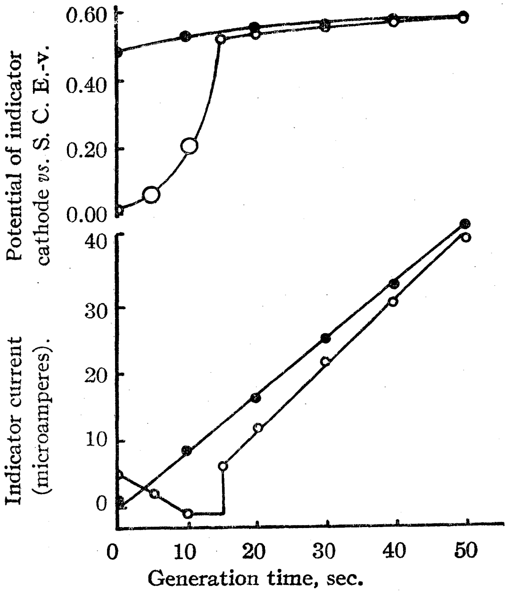

Fig. 7.—Change of potential of indicator cathode during generation (with and without hydrogen): solution prepared from 5 ml. of 1 *F* sulfuric acid and 5 ml. of 2 *F* sodium bromide, diluted to 50 ml.; generation rate, 0.90 milliampere: ●, hydrogen absent; ○, hydrogen present.

TABLE III

TITRATIONS OF ARSENITE SOLUTIONS (NO GUARD TUBE OVER GENERATOR CATHODE)

The arsenious acid was added to 5 ml. of 1 *F* sulfuric acid and 5 ml. of 4 *F* potassium bromide, then the volume was adjusted to 50 ml. In all cases current decrease and current reversal were obtained; the indicator current at the beginning of current decrease varied from 20–40 microamperes.

Expt.	Generation time, sec.	Generator current, milliamperes	End-point correction, sec.	Arsenic, micrograms Taken	Arsenic, micrograms Found	Arsenic, micrograms Error
Ia	199.8	9.77_0	6.4	726.3	733.4	7.1
Ib	198.3	9.77_0	5.0	726.3	733.0	6.7
IIa	249.7	9.68_0	3.5	919.1	925.0	5.9
IIb	249.1	9.68_0	3.0	919.1	924.6	5.5
IIIa	392.2	9.72_0	3.6	1452.5	1466.1	13.6
IIIb	390.6	9.72_0	3.0	1452.5	1462.3	9.8

A series of titrations was run using the apparatus with the guard shown in Fig. 1 around the generator cathode. During a two-hundred second titration the cathode guard permitted sufficient hydrogen to pass into the solution to give an indicator current of about 1.2 microamperes just before the end-point. This hydrogen diffusion current was adequate to give a small decrease and a distinct current reversal. Since on the high rate bromine is being generated at such a rate as to cause an indicator current rise of 10 microamperes per second after passing the equivalence-point it was decided that the current reversal, especially for an inexperienced operator, was a convenient end-point indication, and at times resulted in a smaller end-point correction.

From the above discussion of the current decrease, it is seen that 1.2 microamperes of hydrogen diffusion current would correspond to a decrease of 2.2 microamperes in the bromine diffusion current at the end-point. For a two-hundred second titration this would be a correction of −0.10%. Since the accuracy of the standards is of this magnitude, this correction was not used. Therefore, in the calculation of the values of arsenic found shown in Table IV no hydrogen correction was made.

TABLE IV

TITRATIONS OF ARSENITE SOLUTIONS (GUARD TUBE OVER GENERATOR CATHODE)

The arsenious acid was added to 5 ml. of 1 *F* sulfuric acid and 5 ml. of 2 *F* sodium bromide, then the volume was adjusted to 50 ml.

Generation time, sec.	Generator current, milli-amperes	End-point corrn., sec.	Arsenic found, micrograms	Error
Solution I—860.3 micrograms of arsenic taken				
227.1	9.81_0	1.3	859.7	−0.6
226.5	9.82_0	0.9	859.9	− .4
227.0	9.83_5	1.7	860.0	− .3
227.1	9.83_5	1.8	860.0	− .3
			Average 859.9	−0.4
Solution II—800.0 micrograms of arsenic taken				
210.4	9.82_5	0.7	799.7	−0.3
210.5	9.82_5	0.7	800.1	.1
211.0	9.82_0	1.0	800.4	.4
210.5	9.82_0	0.6	800.0	.0
			Average 800.1	0.1

In order to demonstrate the general accuracy of the method, another series of titrations was run. In this case the first member of each set was an unknown for the operator. The operator knew only that the end-point would not occur during the first thirty seconds of the titration period. This allowed him to correct for the initial fluctuations in the generator current. Two operators were used, one of the authors (RM) and an inexperienced operator. (We are indebted to Mr. W. S. Wooster for making these determinations.)

A good current reversal was obtained, in the titrations made on the high rate which were longer than one-hundred seconds; those made on the low rate gave no current reversal. The results of this series of determinations are tabulated in Table V. An inspection of this table shows that the absolute error appears to be independent of the amount of arsenic being determined, that the maximum deviation is about 1 microgram, and the average deviation is 0.5 microgram.

TABLE V

TITRATIONS OF ARSENITE SOLUTIONS (GUARD TUBE OVER GENERATOR CATHODE)

The arsenious acid was added to 5 ml. of 1 *F* sulfuric acid and 5 ml. of 2 *F* sodium bromide, then the volume was adjusted to 50 ml.

Summary

A coulometric method is described for the determination of approximately 30–1000 microgram quantities of tripositive arsenic. The arsenic is oxidized by electrolytically generated bromine, and an amperometric method is used for the determination of the end-point. The accuracy of this amperometric method has been improved by limiting the amount of hydrogen passing into the solution from the generator cathode. The causes of the decrease and reversal of the indicator current near the equivalence-point have been investigated.

Preparation of Aluminum Di-Soaps[1]

BY GEROULD H. SMITH,[2] HAROLD H. POMEROY, CHARLES G. MCGEE AND KAROL J. MYSELS[3]

The existence of mono-, di- and tri-aluminum soaps has been in question for a decade. Extreme opinions on the subject have been set forth. Lawrence[4] maintains that the mono-, di- and tri-soaps of aluminum all exist and exhibit a similar behavior. He has asserted that the tri-soap is most easily prepared. Indeed a so-called tri-soap has long been an article of commerce. On the other hand, Eigenberger and Eigenberger–Bittner[5] obtained none of these soaps but only a basic compound intermediate between mono- and di-soaps, and a still more basic sorption compound. Alexander[6] suggested that only the mono-soap exists; McBain and McClatchie[7] were unable to prepare aluminum tri-palmitate even under the most anhydrous conditions. The third equivalent of fatty acid could always be immediately extracted as such by an anhydrous solvent, leaving a di-soap. Even the di-soap was partially hydrolyzed by moisture or aqueous media. Ostwald and Riedel[8] also found that precipitation from aqueous solution resulted in an aluminum di-soap. Markowicz[9] had earlier reported that aluminum palmitate, prepared in an aqueous medium, was such an aluminum dipalmitate.

In the present work the region in the immediate neighborhood of the di-soap has been explored thoroughly, that of the tri- and mono-soap less intensively. It is concluded that di-soaps such as dilaurate, $AlOHL_2$, definitely exist as chemical entities, and that the existence of the tri-soaps, AlL_3, AlP_3 and $AlStr_3$, remains unproven and improbable. On the basis of work not recorded here and of subsequent work by C. G. McGee, it is concluded that polymerized mono-soaps approximating such empirical formulas as $Al(OH)_2L$ also exist. This will be published separately.

Addition of aqueous solution of potassium soaps to an excess of aqueous solution of aluminum chloride leads to the formation of a *di-soap*. However, this is usually associated with 20–30% of free or loosely bound fatty acid which is extractable with anhydrous solvents, leaving the di-soap.

When the extraction is carried out with highly dried acetone at 20°, the first few hundred cc. of acetone used per gram of soap removed practically all the excess of fatty acid above the di-soap, showing that the excess of acid was partly free and partly merely sorbed. Only in the case of the stearate, where the stearic acid is but little soluble at 0° was the extraction slower. Further exhaustive extraction with 5 or 6 liters of acetone per gram removed very little further acid. However, extraction at 53° definitely caused further removal of acid below the di-soap which could be accounted for by hydrolysis due to the irreducible trace of water in the dried acetone. Further moisture increased the rate and amount of extraction.

Extraction of aluminum stearate with boiling anhydrous isoöctane yielded a clear jelly of aluminum distearate, $Al(OH)Str_2$, with ash value of 8.74%; calcd. 8.52%.

The present paper deals with dilaurate, distearate, dioleate, dicyclohexane carboxylate, and dinaphthenate.

Materials

Baker's C.P. Reagent grade aluminum chloride hexahydrate and potassium hydroxide were used. Lauric and stearic acids were obtained from the Eastman Kodak Company and were found to have neutralization numbers of 279.4 and 198, respectively (calcd., 277.5 and 197.3). Potassium soaps were prepared by mixing carbonate-free solutions of potassium hydroxide and fatty acid in methanol. They precipitated in a fine, white, flocculent state and filtered easily. They were washed with portions of methanol, and then with acetone to purify and dry the soap. Final drying was carried out over phosphorus pentoxide in an evacuated desiccator. The dried soaps were white, light and powdery. Kahlbaum potassium oleate was used directly.

Procedure

After numerous tests, the following standardized procedure was developed. A 2% freshly prepared aqueous solution of potassium soap was slowly added to a 1.5% solution of aluminum chloride with vigorous agitation in a blender provided with an electrically heated jacket. The amount of aluminum chloride present (in the ratio of one mole aluminum chloride to one mole potassium soap, each 0.00775 *m* in the case of stearate) was approximately twice that necessary for the complete precipitation of all the fatty acid as aluminum disoap. Under these conditions, a precipitate formed which contained all of the fatty acid either as free or loosely bound molecular fatty acid or as aluminum soap, while the mother liquor contained the chlorides of aluminum and potassium.

The precipitate was washed with water in the blender, and filtered until the filtrate gave no turbidity with a silver nitrate solution. The soap was finally dried to constant weight over phosphorus pentoxide. This was the "unextracted" soap. Extraction at 0° with acetone dried over Drierite (calcium sulfate), or with dried isoöctane at room temperature, frees the aluminum soap from all free and loosely bound acid, leaving an "extracted" soap of nearly the theoretical composition of aluminum disoap.

Samples of all aluminum soaps, both extracted and unextracted, were ashed at 900–1000°, duplicate results on a given sample agreeing within 0.04%. The ash was calculated as aluminum oxide, since it was repeatedly found

to be free from water-soluble salts. Some of the aluminum soaps were also analyzed by decomposing with excess of strong acid, titrating the excess, and also determining the liberated fatty acid. Conditions of mixing and stirring have no appreciable effect on the properties of the resulting soap, nor does varying concentration of the reactants.

Aluminum Dilaurate, $AlOHL_2$.—The precipitation of aluminum laurate when carried out at 25–30° resulted in free-floating flocs that were readily filtered and washed. However, temperatures above 40° resulted in a sticky aluminum soap that on cooling became hard and brittle, necessitating grinding to permit satisfactory washing. The ash content of the dried extracted aluminum soap varied but little with the temperature of precipitation from room temperature to the boiling point, and was close to 11.56–11.62% as compared with a theoretical value[10] of 11.49 for the dilaurate, $Al(OH)L_2$, whereas that of a monolaurate, $Al(OH)_2L$, would be 19.6%. The pure aluminum dilaurate melted between 195 and 197°.

A composition much closer to the theoretical (ash contents 11.56-11.62%) was obtained if extraction was conducted so as to minimize hydrolysis, *e. g.* Soxhlet extraction with isoöctane at room temperature, or with acetone at 0°, or rapid washing in a fritted glass funnel with 80 cc. of acetone per gram of salt. The product obtained by this last method contained 89.3% of lauric acid by titration (theory 90.5) melted over a range of one degree centigrade at 193–196° and was used for most of subsequent studies.[11]

When 0.4 equivalent excess of potassium hydroxide was added to the potassium laurate used for precipitation, the ash of the resulting extracted soap was 12.4%, only about 0.8% higher than before.

Aluminum Distearate, $AlOHStr_2$.—Aluminum stearate precipitated at temperatures from 0° up to about 50–60° usually formed soft and slow-filtering sludges. However, samples prepared at a higher temperature separated easily as coagula from the clear aqueous medium. The dried aluminum soap from batches precipitated at temperatures below 50–60° was flaky and compact, whereas higher temperatures resulted in light, powdery and very finely divided aluminum soaps. The composition of extracted aluminum stearate depends largely on the temperature of precipitation; the ash content is constant at 9.55% between 0 and 40°, but then decreases linearly with temperature to 100° where it is within 0.1 to 0.15% of the theoretical value for the ash of distearate, 8.38%; the ash of monostearate would be 14.86%. The distearate melts between 175 and 177°.

Aluminum Dioleate, $AlOHOl_2$.—Dry unextracted aluminum oleate was an orange-tan, granular powder at 0–5° which became gummy when the free oleic acid was allowed to melt. The extracted soap was in the form of small friable granules, with no definite melting point. Like laurate, temperature of precipitation had but little effect on the composition of the extracted oleate. It remained close to 8.64% ash as compared with 8.42%, the theoretical value for $Al(OH)Ol_2$.

Aluminum Dicyclohexanecarboxylate, $Al(OH)(C_6H_{11}COO)_2$.—Cyclohexanecarboxylic acid (Eastman Kodak Company) differs from fatty acids in being somewhat water soluble and some part of the original precipitate of the free or loosely bound acid is removed when washing with water. The extracted, white, powdery, odorless product had an ash content of 16.95%; Calcd. for $Al(OH)(C_6H_{11}COO)_2$: 17.09%. It is insoluble and apparently inert in water, acetone, ethyl alcohol, and diethyl ether. A slight tendency toward swelling occurs in *n*-amyl alcohol, diisobutylene, cyclohexane and dioxane. It swells to a gel in carbon tetrachloride and toluene. It exhibits a remarkable thermal stability, showing no decomposition upon prolonged heating at 360° in a sealed, evacuated glass tube; but at about 450° it melts with decomposition.

Aluminum Naphthenates.—Several samples of aluminum naphthenate were prepared from purified samples of commercial naphthenic acids of different molecular weights. The sodium soaps of the naphthenic acids were prepared and then washed exhaustively with acetone. This removed most of the color and residual oil. Following this treatment, the aluminum soaps were prepared in the usual manner. Some fractionation of the original impure naphthenic acids occurs as a result of the drastic acetone extraction of the sodium naphthenates. As determined from the extracted ash value and the neutralization value of the acids freed from the finished soap, the white powdery products had a composition corresponding to about $^1/_3$ dinaphthenate and $^1/_3$ mononaphthenate.

Summary

Aluminum dilaurate, dicyclohexanecarboxylate, moderately pure dioleate, distearate and a product intermediate between dinaphthenate and mononaphthenate were prepared by aqueous precipitation, followed by thorough extraction with dried isoöctane or acetone. The original precipitates, at least of the first three, are aluminum di-soaps, together with free or loosely bound molecular fatty acid.

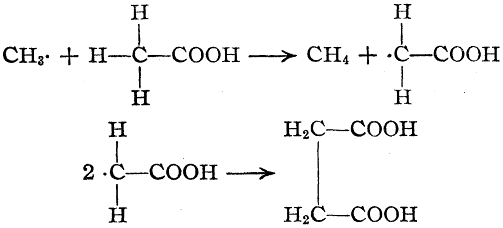
Reactions of Atoms and Free Radicals in Solution. XII. The Addition of Bromo Esters to Olefins

BY M. S. KHARASCH, P. S. SKELL AND PAUL FISHER

Introduction

Investigation of the additions of a number of substances to olefins has demonstrated that some of these additions proceed by a free radical chain reaction. Among the reactions observed, are radical-induced polymerizations or copolymerizations, and additions of the following types of atoms and free radicals[1]: $Br\cdot$,[(a)] $RS\cdot$,[(b)] $\cdot SCH_2COOH$,[(c)] $HO_3S\cdot$,[(d)] $Cl_3C\cdot$, $Br_3C\cdot$, $Cl_2BrC\cdot$, $Br_2HC\cdot$,[(e)] $C_2H_5OCOCCl_2\cdot$,[(f)] $Cl_2P\cdot$,[(g)] $Cl_3Si\cdot$,[(h)] $(C_6H_5)_3C\cdot$[(k)]. The present paper deals with the free radical chain reactions involved in the additions of various bromo esters to olefins.

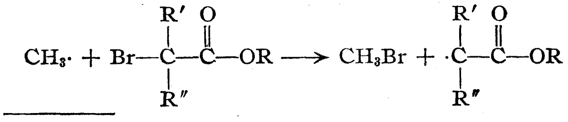
Addition of Bromo Esters to Olefins.—It has been shown that a free methyl radical, generated in solution by the thermal decomposition of diacetyl peroxide, abstracts an α-hydrogen atom from carboxylic acids,[2a] esters, nitriles,[2c] ketones,[2b] etc. Where carboxylic acids are used, the products of the reaction[2a] are methane and a free carboxylic acid radical, which then dimerizes to the corresponding succinic or substituted succinic acid



$$CH_3\cdot + H{-}\overset{H}{\underset{H}{C}}{-}COOH \longrightarrow CH_4 + \cdot\overset{H}{\underset{H}{C}}{-}COOH$$

$$2\,\cdot\overset{H}{\underset{H}{C}}{-}COOH \longrightarrow \begin{array}{l} H_2C{-}COOH \\ \;| \\ H_2C{-}COOH \end{array}$$

The method cited for producing free carboxymethyl radicals or free carbalkoxymethyl radicals cannot, however, be used to study the reactions of these free radicals with olefins because olefins successfully compete with the acid or the ester for the free methyl radical. The same type of free carbalkoxymethyl radical is however produced when a free methyl radical acts on an α-bromo ester.



$$CH_3\cdot + Br{-}\overset{R'}{\underset{R''}{C}}{-}\overset{O}{\overset{\|}{C}}{-}OR \longrightarrow CH_3Br + \cdot\overset{R'}{\underset{R''}{C}}{-}\overset{O}{\overset{\|}{C}}{-}OR$$

Since an α-bromine atom in an α-bromo carboxylic ester is more susceptible to attack by a free methyl radical than is an α-hydrogen atom of an ester[3] or any hydrogen atom in an aliphatic olefin, it should be possible, by using α-bromo esters, to generate free ester radicals in olefinic solvents and to study their reactions with those solvents.

When a small amount of diacetyl peroxide (5-10 mole per cent.) is decomposed in a solution of octene-1 in ethyl bromoacetate a good yield of ethyl γ-bromocaprate and a small quantity of methyl bromide are obtained. The reaction presumably takes place according to the following scheme:

$$CH_3\cdot + BrCH_3COOC_2H_5 \longrightarrow CH_3Br + \cdot CH_2COOC_2H_5 \quad (1)$$

$$n\text{-}C_6H_{13}CH{=}CH_2 + \cdot CH_2COOC_2H_5 \longrightarrow n\text{-}C_6H_{13}\dot{C}HCH_2CH_2COOC_2H_5 \quad (2)$$

$$n\text{-}C_6H_{13}\dot{C}HCH_2CH_2COOC_2H_5 + BrCH_2COOC_2H_5 \longrightarrow n\text{-}C_6H_{13}CHBrCH_2CH_2COOC_2H_5 + \cdot CH_2COOC_2H_5 \quad (3)$$

Step (1) is the initiating step. Steps (2) and (3) constitute a self-sustaining chain reaction; hence the number of condensations per free methyl radical is relatively large.

The requisites for such a self-sustaining chain reaction are as follows: (a) the free carboxylic ester radical and the olefin must be so constituted that they can condense rapidly (step 2); otherwise the concentration of the radical increases to the point where dimerization becomes a successfully competitive chain-breaker; (b) the nature of the bromo ester and the new radical produced by the addition of the free carboxylic ester radical to the olefin must be such as to permit the rapid transfer of a bromine atom from the former to the latter (step 3).

The type of condensation reaction described yields (as end-products) substituted γ-bromo esters. It has been successfully applied to bromo esters (both straight-chain and branched), and to α-bromo dicarboxylic esters, but it fails with β-bromo esters. The reason for this failure is that the bromine atom in the β-position is but little affected by the carbalkoxy group; hence this atom is so strongly bound that condition (b) is not fulfilled.

Branching of the carbon skeleton of the ester in the neighborhood of the position α to the carbalkoxy group shortens the chain length of the condensation reactions. Thus, under comparable conditions α-bromoisobutyric and α-bromoiso-

(3) It is noteworthy that in the α-chlorinated acetic esters the chlorine atom is less active than the α-hydrogen atoms.

valeric esters give poorer yields of condensation products than do the corresponding esters of the normal acids. If the amount of diacetyl peroxide is increased, the yield of the condensation product (formed from the bromo ester) increases. This fact indicates that some chain-breaking reaction operates with greater efficiency in the additions of branched free radicals to olefins than it does in the additions of the corresponding normal free radicals.

The question therefore arises whether this chain-breaking mechanism is a failure to meet condition (a) or a failure to meet condition (b). In order to obtain evidence on this point a number of experiments were carried out. It is to be borne in mind that octene-1 and the esters of α-bromoacetic acid, when treated as described, give good yields of γ-bromo capric esters per unit of peroxide used; whereas octene-1 and the esters of bromoisobutyric acid give poor yields of γ-bromo-α,-α-dimethylcapric esters. If diacetyl peroxide is decomposed in an octene-1 solution of a mixture of ethyl α-bromoacetate and methyl α-bromoisobutyrate, then the following results are to be anticipated. If the bromine atom in the bromoacetic ester is more easily attacked by the secondary alkyl free radical (step 3) than is the bromine atom in the bromoisobutyric ester then the chain should be carried mostly by the bromoacetate; here the predominant product should be ethyl γ-bromocaprate and this product should be obtained in good yield per unit of peroxide used. On the other hand, if the bromine atom in the isobutyric ester is more easily attacked, then the chain should be carried mostly by the bromoisobutyrate; here the predominant product should be methyl γ-bromo-α,α-dimethylcaprate and this product should be obtained in poor yield. Actually the reaction product, when converted to a lactone by distillation at 150° is principally a poor yield of α,α-dimethyl-γ-caprolactone. Even with an (undetected) impurity of 10% of γ-caprolactone in the reaction product, this result would still indicate that the bromine atom in the α-bromoisobutyrate is at least eight times as easily attacked by secondary alkyl radicals (step 3) as is the bromine atom in the bromoacetate.

The experiment just described shows clearly that the α-bromoisobutyric ester complies with condition (b) even better than does the bromoacetic ester. Hence the poor yields obtained from the α-bromoisobutyrate must be due to inadequate compliance (on the part of this ester) with condition (a). Supporting this conclusion is the fact that when the α-bromoisobutyric esters alone are added to olefins (under the condition stated) the reaction products always contain considerable quantities of tetramethylsuccinic esters. This result is exactly what would be predicted on the basis of the experiment cited. The free radical produced from α-bromoisobutyric ester (step 1) adds so slowly to the olefin that it accumulates in the solution to the point where dimerization effectively competes with the addition reaction.

Competition experiments similar to those already cited were carried out to determine the relative reactivities of the bromine atoms in ethyl bromoacetate and ethyl α-bromo-*n*-butyrate. The condensation product was converted to the lactone, which proved to be a mixture of 45 mole per cent. of γ-caprolactone and 55 mole per cent. of α-ethyl-γ-caprolactone. This difference, (10%), is only slightly greater than the experimental error of the method. Hence, it may be concluded that, toward a secondary free alkyl radical, the bromine atom in ethyl α-bromo-*n*-butyrate is only slightly more reactive than the bromine atom in ethyl bromoacetate. This result taken in conjunction with those already mentioned shows that, if only one hydrogen atom in bromoacetic ester is replaced by an alkyl radical, the reactivity of the bromine atom is but slightly increased. On the other hand, substitution of both hydrogen atoms by alkyl radicals greatly increases the reactivity of the bromine atom.

The nature of the alcoholic alkyl radical in the ester is not critical, so long as this radical contains no chain-breaking substituent. When tertiary butyl α-bromopropionate is condensed with octene-1, the yield of condensation product is only slightly less than that obtained from the corresponding ethyl ester. In general, methyl esters appear to give slightly better yields than do ethyl esters; but, so far, there is no evidence to show whether the ethyl group exerts a chain-breaking effect by virtue of its active α-hydrogen atom or whether it exerts a steric influence.

Varying the structure of the olefinic component has demonstrated that straight-chain aliphatic olefins with either terminal or non-terminal double bonds, participate successfully in the chain reaction. When styrene or ethyl acrylate are used under comparable conditions they yield products of moderate molecular weight rather than 1:1 condensation products. Judging from the ease with which these olefins undergo radical-induced polymerization, there can be little doubt that in the reactions tested condition (a) is fulfilled. Neither compound, however, fulfills condition (b) for the free radicals which they produce ($C_6H_5\underset{\cdot}{C}HCH_2CH_2COOC_2H_5$ and $C_2H_5OCO\underset{\cdot}{C}HCH_2CH_2COOC_2H_5$, respectively) have so little ability to abstract a bromine atom from a molecule of α-bromo ester that they cannot continue the reaction chain. On the other hand, these radicals can add to other molecules of styrene or ethyl acrylate and thus produce polymers. This latter type of reaction is of only slight importance when straight-chain aliphatic olefins are employed because (1) these olefins are not reactive enough to polymerize and (2) the radical produced from either of these (by addition of a free ester radical) is so reactive that it readily removes a bromine atom from the α-bromo ester to continue the chain. But, even with these aliphatic olefins, there is always a small amount of residue left after removal of the 1:1 condensation product. This residue is probably a 2:1 condensation product formed as follows

$$R\underset{\cdot}{C}HCH_2CH_2COOC_2H_5 + RCH{=}CH_2 \longrightarrow RCHCH_2\underset{\cdot}{C}HRCH_2CH_2COOC_2H_5$$

$$R\underset{\cdot}{C}HCH_2CHRCH_2CH_2COOC_2H_5 + BrCH_2COOC_2H_5 \longrightarrow RCHBrCH_2CHRCH_2CH_2COOC_2H_5 + \cdot CH_2COOC_2H_5$$

The γ-bromo esters prepared in this study have been successfully converted to the corresponding γ-lactones both by alkaline hydrolysis followed by lactonization, and by direct thermal decomposition at 150–180°. This latter treatment results in the rapid formation of a γ-lactone and an alkyl bromide. Most of the γ-lactones hereafter described are new compounds; it was however possible to establish the identities of γ-valerolactone and γ-caprolactone by comparison with authentic samples of these compounds.

As a synthetic method, the free radical addition of an α-bromo ester to an olefin is a simple one-step reaction which lengthens the carbon chain by two carbon atoms and simultaneously introduces a bromine atom in position gamma to the carboxyl group. The bromo compounds thus formed are not readily accessible by any other preparative method.

The over-all reaction where the double bond in the olefin is terminal may be formulated as

$$BrCR_1R_2COOCH_3 + R_3CH{=}CH_2 \longrightarrow R_3CHBrCH_2CR_1R_2COOCH_3$$

where the R's are either hydrogen atoms or alkyl groups.

Experimental

The choice of the procedure to be used (as hereafter described) for the addition of bromo esters to olefins was governed by the physical properties of the olefin used. For gaseous olefins, a Pyrex pressure apparatus fitted with pressure stopcocks was employed; where the olefin was a liquid at the reaction temperature, no special equipment was needed.

It was found most convenient to add the diacetyl peroxide (dissolved in a small amount of bromo ester) in small portions (over a period of three to six hours) to a mixture of the olefin and the bromo ester contained in a flask held at a temperature of approximately 90°. When gaseous olefins were used, the bromo ester (held at 90°) was saturated with the olefin under a pressure of 40–55 pounds per square inch, absolute. The reactions were not markedly exothermic when the ratio of the reactants was as described. An inert atmosphere was maintained throughout all the reactions. Previous to the addition of the peroxide, air was always removed from the apparatus by flushing either with nitrogen or with the gaseous olefin.

Most of the addition products studied were stable when distilled *in vacuo* at pressures of 0.1–1.0 mm. However, in the cases of the α-bromoisobutyrates, α-bromoisovalerates, bromomalonate, and bromosuccinate, some decomposition was noticed when the γ-bromo ester addition products were distilled in ordinary vacuum apparatus. The low values for the bromine content of some of the products (see Table I) are probably due to thermal decomposition of the γ-bromo esters to form the corresponding γ-lactones, by the elimination of ethyl or methyl bromide. In several of the experiments, molecular distillation was used: here the bromine values and the saponification equivalents were satisfactory. To demonstrate the homogeneity of the condensation products the distillates were collected in many small fractions. The product was considered pure when both the boiling point and the index of refraction of successive fractions were constant. The following are typical procedures.

Addition of Ethyl Bromoacetate to Octene-1.—A solution of 27.4 g. (0.244 mole) of octene-1 in 160 g. (0.96 mole) of ethyl bromoacetate was treated with 3.1 g. (0.0254 mole) of diacetyl peroxide in 6.8 g. (0.041 mole) of ethyl bromoacetate. To isolate the addition product, the unreacted starting materials were removed by distillation at 20 mm. pressure. Distillation of the residue yielded 37 g. of ethyl γ-bromocaprate boiling at 93–94° (0.2 mm.), $n^{20}D$ 1.4599. There was 1.6 g. of high-boiling residue.

Addition of Ethyl Bromoacetate to Propylene.—To 173 g. (1.03 mole) of ethyl bromoacetate which was kept saturated with propylene at 90° and 45 lb./sq. in. (absolute), was added (over a period of five hours) 1.8 g. (0.015 mole) of diacetyl peroxide dissolved in 8.0 g. (0.048 mole) of ethyl bromoacetate. The apparatus was vented three times during the addition of the peroxide to eliminate carbon dioxide. Distillation of the residue left after recovering unchanged ethyl bromoacetate yielded 22 g. of ethyl γ-bromo-*n*-valerate boiling at 103–104° (22 mm.), $n^{20}D$ 1.4553. There was 1.5 g. of high-boiling residue.

Formation of γ-Caprolactones from Ethyl γ-Bromocaprate. Proof of the Structure of Ethyl γ-Bromocaprate.—Ethyl γ-bromocaprate (19.0 g., 0.0681 mole) was refluxed at 160–180° for two hours, during which time the external pressure was maintained at 55 mm. Volatile materials evolved during the pyrolysis were caught in a liquid nitrogen trap. Distillation of the residue gave 9.6 g. of γ-caprolactone (83% yield), b. p. 84° (0.2 mm.), $n^{20}D$ 1.4489.

Anal. Calcd. for $C_{10}H_{18}O_2$: saponification equivalent, 170. Found: sapon. equiv., 170.7; Br, 0.00.

This lactone was converted to the *p*-toluidide of γ-hydroxycapric acid,[4] m. p. 133.4–134°. A sample of γ-caprolactone, made by the method of Fittig and Schneegans,[5] gave a *p*-toluidide, which melted at 133.5°. The mixture of the two toluidides melted at 133–134°. In the liquid nitrogen trap there was collected 6.1 g. of material which proved to be ethyl bromide, b. p. 38°, contaminated with hydrogen bromide. This ethyl bromide was further identified by conversion to ethyl mercuric bromide (m. p. 193°).[6]

In the distillation of the reaction mixture, 2.0 g. of a low-boiling fraction was collected. This material which gave a positive test for unsaturation when treated with a carbon tetrachloride solution of bromine, may possibly consist of unsaturated esters or acids formed by elimination of hydrogen bromide from the ethyl γ-bromocaprate during the heating period. The appearance of unsaturated material also accounts for the presence of hydrogen bromide in the cold trap.

In all cases the γ-bromo esters were converted to lactones by pyrolysis at 150–180°.

Proof of the Structure of Ethyl γ-Bromo-*n*-valerate.—The structure of the addition product, ethyl γ-bromo-*n*-valerate, obtained by the addition of ethyl bromoacetate to propylene, was proved in the following manner. A mixture of 10.6 g. of the addition product, 20 g. of sodium hydroxide and 30 cc. of water was heated under reflux for five hours. During this period the reaction mixture became homogenous. The solution was acidified with dilute hydrochloric acid, and then extracted with ether. The ether solution was washed with water and dried over anhydrous sodium sulfate. After the ether had been removed from the extract, a colorless liquid was obtained by distillation (4.0 g., b. p. 70° (6 mm.); $n^{20}D$ 1.4328). This substance was identified as γ-valerolactone (80% yield)

Table I

Experimental Data of Addition Reactions[c, d]

Bromo ester, moles	Olefin, moles	Peroxide, moles	Addition product
Ethyl bromoacetate (1.00)	Octene-1 (0.244)	(0.025)	Ethyl γ-bromocaprate
Ethyl α-bromopropionate (1.02)	Octene-1 (.265)	(.019)	Ethyl α-methyl-γ-bromocaprate
t-Butyl α-bromopropionate (0.726)	Octene-1 (.196)	(.044)	*t*-Butyl α-methyl-γ-bromocaprate
Ethyl α-bromo-*n*-butyrate (1.05)	Octene-1 (.25)	(.014)	Ethyl α-ethyl-γ-bromocaprate
Ethyl α-bromoisobutyrate (0.838)	Octene-1 (.178)	(.022)	Ethyl α,α-dimethyl-γ-bromocaprate
Methyl α-bromoisobutryate (0.739)	Octene-1 (.258)	(.027)	Methyl α,α-dimethyl γ-bromocaprate
Ethyl α-bromo-(d) isovalerate (0.521)	Octene-1 (.132)	(.027)	Ethyl α-isopropyl-γ-bromocaprate
Methyl α-bromoisovalerate (0.676)	Octene-1 (.206)	(.024)	Methyl α-isopropyl-γ-bromocaprate
Dimethyl bromosuccinate (0.437)	Octene-1 (.089)	(.012)	Methyl α-carbomethoxy-γ-bromocaprate
Diethyl bromomalonate (0.40)	Octene-1 (.44)	(.012)	Ethyl α-carbethoxy-γ-bromocaprate
Ethyl bromoacetate (0.786)	Propylene 45 psia[b]	(.040)	Ethyl α-bromovalerate
Ethyl α-bromopropionate (0.602)	Propylene 45 psia[b]	(.025)	Ethyl α-methyl-γ-bromovalerate
Ethyl α-bromoacetate (0.807)	Butene-2 45 psia[b]	(.029)	Ethyl β-methyl-γ-bromovalerate
Ethyl α-bromopropionate (0.656)	Isobutylene 45 psia[b]	(.015)	Ethyl α,γ-dimethyl-γ-bromovalerate
Ethyl α-bromopropionate (0.944)	Styrene (.25)	(.023)	Styrene polymer
Ethyl α-bromopropionate (1.01)	Ethyl acrylate (.253)	(.019)	Acrylate polymer

by converting it to the amide of γ-hydroxy-*n*-valeric acid, m. p. 49–50°, according to the method of Boorman and Linstead.[7] The melting point of this derivative and the melting point of a mixture with the amide from an authentic sample of γ-valerolactone was 49–50°. For purposes of comparison, γ-valerolactone (b. p. 70–71° (6 mm.), $n^{20}\text{D}$ 1.4328) was prepared by the reduction of levulinic acid according to the method of Schuette and Thomas.[8]

γ-Valerolactone, 20.0 g., was converted into ethyl γ-bromo-*n*-valerate by dissolving it in 50 cc. of absolute ethanol and saturating the solution with hydrogen bromide at a temperature of 5°. The solution was allowed to stand for twenty-four hours at room temperature and was then resaturated with hydrogen bromide. After an additional twelve hours of standing at room temperature, an equal volume of water was added to the solution. The heavy organic layer which separated was extracted with ether, washed with dilute sodium bicarbonate solution, and dried over anhydrous sodium sulfate. Distillation of the residue through a 15-inch column packed with helices yielded pure ethyl γ-bromo-*n*-valerate, b. p. 78° (9 mm.) $n^{20}\text{D}$ 1.4552, identical in all its properties with the ethyl bromoacetate–propylene addition product.

Anal. of the synthetic sample. Calcd. for $C_7H_{13}O_2Br$: Br, 38.2. Found: Br, 38.3.

Boorman and Linstead[9] report for ethyl γ-bromo-*n*-valerate, b. p. 105–107° (20 mm.), $n^{20}\text{D}$ 1.4533. This last figure is not in agreement with the observations here recorded. When the lactone was saturated with hydrogen bromide only once (instead of twice as above), the product was a mixture the constituents of which could not be separated by distillation through the packed column. This mixture had the following physical properties: b. p. 63–69° (6 mm.), $n^{20}\text{D}$ 1.4460–1.4520.

Tetramethylsuccinic Acid from the Reaction of Methyl α-Bromoisobutyrate with Octene-1.—By distillation of the product of the reaction between methyl α-bromoisobutyrate and octene-1 (see Table I), a low-boiling fraction, 2.6 g., b. p. 40–95° (0.3 mm.) was separated. This fraction was saponified by refluxing it for one-half hour with an excess of alcoholic sodium hydroxide solution. All solvents were removed by distillation *in vacuo*. The residue was believed to be a mixture of the dry sodium salts of γ-hydroxyisobutyric acid, γ-hydroxy-α,α-dimethylcapric acid and tetramethylsuccinic acid. The dry material was treated with 30 cc. of hot anhydrous ethyl alcohol in order to dissolve all the salts except the salt of the dicarboxylic acid. The insoluble residue was collected on a filter, and added to 5 cc. of water, the solution was carefully acidified with sulfuric acid, and extracted with 15 cc. of ether. The ethereal solution was dried with anhydrous sodium sulfate, and the ether was then removed by evaporation. The white granular residue, 0.45 g., was washed well with ligroin and collected on a filter. The solid thus obtained melted at 190–192°; sublimation *in vacuo* did not raise its melting point. This melting point showed no depression when the material was mixed with an authentic sample of tetramethylsuccinic acid melting at 192°. The reported melting point of tetramethylsuccinic acid is 200°.[10] However, it has been found that this melting point varies from 180 to 200°, depending upon the rate at which the sample is heated. This variation is due to the partial formation of the anhydride.

Isolation and Identification of Methyl Bromide from the Reaction of α-Bromo Esters with Octene-1.—Methyl bromide was isolated and identified as a product in the condensations of octene-1 with dimethyl bromosuccinate, ethyl α-bromopropionate, or ethyl α-bromoisovalerate when these reactions were started by the decomposition of small amounts of diacetyl peroxide.

In the experiment with dimethyl bromosuccinate described in Table I, 0.012 mole of diacetyl peroxide was used for the initiation of the free radical chain. The methyl bromide was isolated by attaching a Dry Ice–ether trap to the reflux condenser of the reaction vessel. All volatile materials evolved during the addition of the peroxide solution were caught in this trap. At the conclusion of the reaction, the Dry Ice–ether was replaced by liquid nitrogen and the entire system was evacuated to 0.1 mm. The material collected in the trap was distilled into a vacuum line, weighed and identified by its molecular weight and vapor pressure. The molecular weight found was 92.4; that calculated for methyl bromide is 95. The vapor pressure at Dry Ice–ether temperature was 6.5 mm.; that reported[11] for methyl bromide is 5 mm. at −80.6°, and 10 mm., at −72.8°. The amount of methyl bromide isolated was 0.29 g. (0.0031 mole).

Reaction of Ethyl β-Bromopropionate with Octene-1.—Ethyl β-bromopropionate (188 g., 1.04 moles) was treated with 28 g. of octene-1 (0.25 mole) in the presence of 2.2 g. of diacetyl peroxide (0.019 mole). Removal of the unreacted starting materials left 4.0 g. of high-boiling residue. The compound formed under these conditions is diethyl α-bromo-α'-methylsuccinate. This reaction will be discussed in a subsequent publication.

[a] These products were molecularly distilled. [b] The amount of olefin added was not determined. [c] The over-all yield is based upon the amount of olefin used. [d] These reactions were heated between 70–80°.

Competition Experiments. (A) **Methyl α-Bromoisobutyrate *versus* Ethyl Bromoacetate.**—A mixture of 49.2 g. of ethyl bromoacetate, 57.1 g. of methyl α-bromoisobutyrate and 10.8 g. of octene-1 was heated for fourteen hours at 88°, in the presence of 1.1 g. of diacetyl peroxide. After distillation of the unreacted materials, the residue, upon distillation at reduced pressure, gave 6.5 g. of a material which contained 9.65% bromine. This material was heated at 150–180° for two hours to convert it to the lactone. Upon distillation at reduced pressure a material was collected which had an index of refraction of 1.4436 at 20°.

Anal. Calcd. for $C_{10}H_{18}O_2$: saponification equivalent, 170. Calcd. for $C_{12}H_{22}O_2$: saponification equivalent, 198. Found: sapn. equiv., 197, 202.

(B) **Ethyl α-Bromo-*n*-butyrate *versus* Ethyl Bromoacetate.**—A mixture of 50.8 g. of ethyl bromoacetate (304 mmoles), 59.7 g. of ethyl α-bromo-*n*-butyrate (306 mmoles), and 11.6 g. of octene-1 (104 mmoles) was heated for fourteen hours at 83° in the presence of 1.18 g. of diacetyl peroxide (10 mmoles). After distillation *in vacuo* of the unreacted materials, a residue (23.9 g.) was obtained. This residue was a mixture of the two possible γ-bromo esters. To convert these γ-bromo esters to the lactones, the material was heated at 150–180° for three hours, and then subjected to distillation at reduced pressure (b. p. 73–75° (0.02 mm.), n^{20}_D 1.4488).

Anal. Calcd. for $C_{10}H_{18}O_2$: saponification equivalent, 170. Calcd. for $C_{12}H_{22}O_2$: saponification equivalent, 198. Found: saponification equivalent, 184.6, 186.3.

Preparation of α-Substituted γ-Caprolactones.—These substances were prepared by the addition of the appropriate α-bromo esters to octene-1; in each instance the reaction product was distilled *in vacuo* to obtain the α-substituted γ-bromocaprate formed. When these γ-bromocaprates were refluxed for two hours at 160–180°, alkyl halides were evolved, and α-substituted γ-caprolactones were formed. These lactones were then distilled at reduced pressures. By following this procedure

1. α,α-Dimethyl-γ-caprolactone was obtained from methyl α-bromoisobutyrate and octene-1.

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.7; H, 11.1. Found: C, 72.3; H, 11.0.

2. α-Carbethoxy-γ-caprolactone was obtained from diethyl α-bromomalonate and octene-1.

Anal. Calcd. for $C_{13}H_{22}O_4$: C, 64.4; H, 9.12. Found: C, 63.8; H, 9.0.

3. α-Isopropyl-γ-caprolactone was obtained from methyl α-bromoisovalerate and octene-1.

Anal. Calcd. for $C_{13}H_{24}O_2$: C, 73.5; H, 11.3. Found: C, 73.0; H, 11.4.

TABLE II

PHYSICAL CONSTANTS OF BROMO ESTERS USED

Bromo ester	Boiling point °C.	Mm.	n^{20}_D
Ethyl α-bromoacetate	58–59	15	1.4489
Ethyl α-bromopropionate	58	16	1.4461
Ethyl α-bromobutyrate	63	12	1.4479
t-Butyl α-bromopropionate	62.2	15	1.4392
Ethyl α-bromoisobutyrate	59.9	18	1.4438
Methyl α-bromoisobutyrate	52.2	21	1.4509
Methyl α-bromoisovalerate			1.4530
Ethyl α-bromoisovalerate	73–74	12	1.4496
Dimethyl bromosuccinate	61	3	1.4630
Diethyl bromomalonate	123	20	1.4521

Ethyl α-bromopropionate	69.7	15	1.4578

Acknowledgment.—The authors are grateful to Mr. P. Silverman for the preparation of some of the starting products used, and to Mr. I. S. Bengelsdorf for the analyses reported in this paper.

Summary

Good yields of γ-bromo esters are formed by free-radical chain reactions between aliphatic olefins and α-bromo carboxylic esters. These reactions involve the addition of radicals of the

$\cdot\overset{R}{\underset{R}{C}}\text{—COOCH}_3$ type to the double bond. The chain is initiated by the thermal decomposition of diacetyl peroxide. The mechanism and necessary requisites for the chain reaction are discussed.

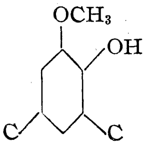
Interpretation of Lignin. I. The Synthesis of Gymnosperm Lignin

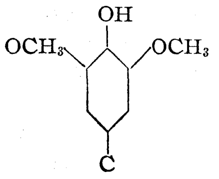
BY ALFRED RUSSELL[2]

Lignin, from whatever source it is obtained, is an amorphous material with none of the usual criteria of purity. It cannot be assumed to have a constant composition since it seems to undergo changes easily. It is a plant product without definite character and is probably best described as the residual plant structural material after carbohydrates, coloring matters, waxes, resins and the like have been removed. The fission products are in harmony with a simple structure of the familiar 2-phenylbenzopyran type but it is impossible for lignin to be a single such unit. It is certain that lignin in the plant is sensitive enough to undergo some structural change during the process of extraction. The alteration may be minor when extraction is carried out with nondestructive solvents, such as alcohols containing traces of mineral acids, but it is impossible to ignore the likelihood that the use of strong mineral acids, aqueous alkalies and alkaline bisulfites may cause extensive structural changes. This has been recognized by a few workers who have tried to look on the process of extraction as a reaction to which unaltered lignin is exposed and of which the material extracted represents the product. There is general evidence in favor of this idea in the fact that totally inert solvents will not dissolve lignin.

The available evidence indicates that there are two varieties of lignin both largely aromatic in character. As significant cleavage products one variety (from gymnosperms) gives, on degradation, only derivatives of catechol-2-methyl ether (guaiacol) with carbon atoms attached in the -4- and -6- positions (I); and the other (from angiosperms) gives the same derivatives of catechol-2-methyl ether and of pyrogallol-1,3-dimethyl ether with a carbon atom attached in the -5- position (II).

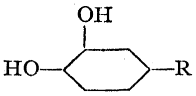


I

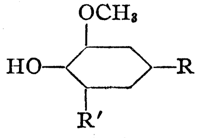


II

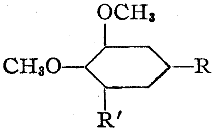
As examples of the cleavage products of a typical gymnosperm, those of spruce lignin, the most exhaustively examined one, may be described (a) alkali fusion gives protocatechnic acid (III, R = CO_2H) and catechol (III, R = H); (b) methylation with dimethyl sulfate and alkali followed by oxidation with potassium permanganate, gives veratric acid (V, R′ = H, R = CO_2H), isohemipinic acid (V, R = R′ = CO_2H) and veratrole (V, R = R′ = H) and dehydrodiveratric acid; (c) treatment of sulfonated lignin with alkali at 160° gives vanillin (IV, R′ = H, R = CHO), acetovanillone (IV, R′ = H, R = $COCH_3$) and guaiacol (IV, R = R′ = H); (d) dry distillation gives guaiacol (IV, R = R′ = H), vanillic acid (IV, R′ = H, R = CO_2H) and eugenol (IV, R′ = H, R = $CH_2CH{=}CH_2$); (e) zinc dust distillation gives guaiacol (IV, R′ = R = H) and 4-*n*-propylguaiacol (IV, R′ = H, R = *n*-C_3H_7); (f) Oxidation with nitrobenzene gives vanillin-5-carboxylic acid (IV, R = CHO, R′ = CO_2H) and vanillin (IV, R = CHO, R′ = H). It is clear from these cleavage products that the changes (VI) → (VII) → (VIII) occur readily.



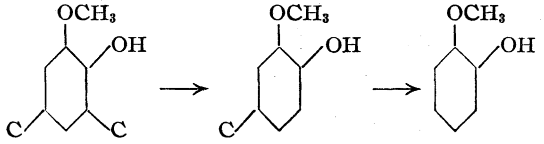
(III)



(IV)



(V)



(VI) (VII) (VIII)

The occurrence among lignin degradation products of small amounts of formaldehyde, methanol, acetic acid and the like has little significance. Decomposition of any carbon chain will rise to similar products. It is significant, however, that there is no report of a simple fission product containing more than two carbon atoms (the products of hydrogenation of hydrogenolysis are, naturally, excluded).

Now, referring to the lignin from gymnosperms, it has to be inferred that one or both of the carbon atoms free in the skeleton (I) must be joined to at least one other carbon atom. The occurrence of an oxygen atom in (I) in the *ortho* position to an attached carbon atom and the absence of typical free phenolic hydroxyl groups in this lignin makes the benzopyran structure almost inevitable, hence, (I) may be expanded to (IX). Specific examples of such a structure among natural products are common. The occurrence of 4-*n*-propyl-

---

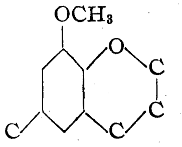
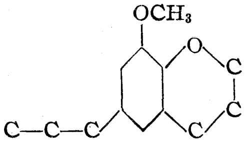
[2] Chemist, Industrial Chemical Section, Agricultural Residues Division.

guaiacol (IV, R = H, R = n-C_3H_7) and similar compounds as cleavage products of this lignin under certain conditions means that the skeleton (IX) must be expanded to (X) to explain the occurrence of a three-carbon chain *para* to the hydroxyl group in such cleavage products.



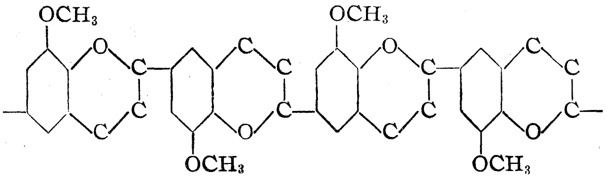
IX



X

Few, if any, common natural products have very complicated structures. Consequently the elaborations proposed by Cross and Bevan,[3] Fuchs,[4] Pavolini,[5] Schrauth,[6] and the meticulous detail of the structure proposed by Brauns[7] have little to recommend them.

It is much more likely, as has long been supposed in a general way, that lignin (in this case, that from gymnosperms) is composed of a series of n-propylbenzene units. If this, as most likely, is true, then referring to the skeleton (X), the three carbon atoms in the chain *para* to the pyranose oxygen must be the three carbon atoms of a *second* pyranose ring. This implies a continuing structure of the type (XI).



XI

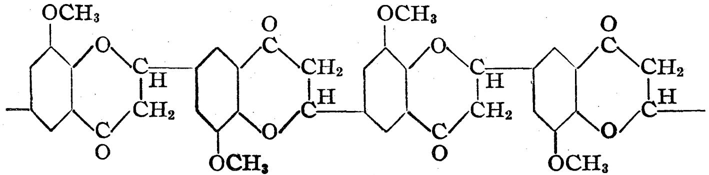
With other suggested structures, one, not dissimilar to the above, but containing methyl furan rings has been tentatively put forward by Erdtman and, separately, by Freudenberg, and Hibbert has come close to advocating a benzopyran unit structure.

To account for the hydrogen and oxygen content of the lignin under consideration, the skeletal structure (XI) must be completed by adding an oxygen atom and three hydrogen atoms to each pyran ring. The most plausible way to do this, by analogy with other plant products, such as flavanones, flavones, and flavonols is to make it the poly-8-methoxydihydrobenzopyrone (XII).

This material is available synthetically by the following steps: vanillin mono-acetate (XIII), by Fries rearrangement, will give 2-hydroxy-3-methoxy-5-formyl acetophenone (XIV). This will undergo easy condensation polymerization (aldolization, loss of water—Claisen condensation) to give (XV) which, in turn, will cyclicize to the product required. Under most conditions (XV) and (XI) will be in equilibrium.

The intermediate ketoaldehyde (XIV) is sufficiently reactive that, in any conditions under which it is formed, the final product (XII) is likely to result at once. By Fries rearrangement of vanillin monoacetate, then, the product (XII) is likely to be obtained with no intermediates.

The properties of the product (XII) should be entirely analogous to those recorded for lignin. The carbonyl group would not be very typical and lignin does not give satisfactory carbonyl derivatives. Enolization would be easy and this, with the easily opened pyranose ring and the possible occurrence of a hydrated form, would give a series of enolic derivatives. The hydrogens of the methylene group in the cyclic form would be rather reactive; consequently, halogens would substitute more easily in this form than add to the enol form. Lignin, again, undergoes a substitution rather than an addition reaction with halogens. Moreover, the product (XII) would have to give the same cleavage products as the lignin from gymnosperms.



(XII)

The synthesis described has been carried out and the synthetic material, apart from being somewhat darker in color, has the same qualitative properties as those recorded for spruce lignin and, where direct comparison has been made, with those observed for a specimen of "alkali" lignin obtained from the saccharification processing of corncobs. The solubility characteristics are the same; like lignin, the synthetic material is soluble in aqueous alkali, ethanol, acetone and dioxane; insoluble in dilute mineral acids, water, ether, hydrocarbons and halogenated solvents. Parallel to the solubility of unaltered natural lignin in alkaline bisulfites, the synthetic product is soluble in aqueous sodium bisulfite. In all probability this corresponds to the formation of a stable sulfonic acid by the familiar 1,4-addition process to the open chain form.

The synthetic material suspended on paper pulp and treated in succession with chlorine, aqueous sulfur dioxide, and aqueous sodium sulfite gives the pink color characteristic of lignin specimens. For purposes of comparison the test was run simultaneously on a specimen of alkali lignin from the saccharification processing of corncobs. Moreover, dispersed on filter paper, the synthetic material gives the pink color typical of lignin with

phloroglucinol dissolved in 12% aqueous hydrochloric acid.

There never has been any way of measuring the purity or degree of alteration of any lignin specimen or derivative. Consequently no recorded experiment could ever be repeated exactly, using the synthetic product for comparison purposes. The synthetic material must give the same recognizable simple cleavage products as gymnosperm lignin. Apart from such simple products, lignin does not give derivatives that can be positively identified. It may be methylated, acetylated and so on but the reactions must be regarded as stepwise since the analytical values of the products vary continuously. However, so many methylations, acetylations, and the like have been carried out that the *maximum* values on record should correspond rather closely to those for total reaction. Indeed, it is obvious that such maxima are the only values to which any meaning may be attached.

Apart from an anticipated low methoxyl value (aluminum chloride is an effective demethylating agent) and consequent lowering of hydrogen content, the analytical values for the synthetic material are close enough to the range reported for gymnosperm lignins and to the calculated range for the monomer ($C_{10}H_{10}O_4$) and the polymer ($C_{10}H_8O_3$).

Many "acetyl" values are on record for the acetylated lignin from gymnosperms and the maximum is 27.2%. Acetylation of the synthetic material with acetic anhydride gives a product having an "acetyl" content of 29.5%. Two acetyl groups for each monomeric residue is the maximum number that could be introduced and this would correspond to an acetyl content of 30.9%. It is evident that the triacetate implied by the open-chain formula is most improbable since the carbonyl oxygen, in this form, is chelated with the hydrogen of the phenolic hydroxyl group and, furthermore, the same carbonyl group forms part of a stable, total crossed conjugated system. The diacetate formed is the geminal diacetate of the pyranose form.

Like the acetylation, the methylation of lignin appears to be a continuous process. The maximum value reported for "methoxyl" is 32.4% corresponding to the calculated (32.3%) value for two methoxyl groups in each monomeric residue and implying the methylation of one free hydroxyl group in each. By exhaustive treatment with dimethyl sulfate and alkali, the synthetic material gives a methylated product containing 29.6% of "methoxyl."

It is, of course, very evident that the alkaline conditions of methylation and the acid conditions of acylation favor, respectively, the open and closed ring forms.

Reports on halogenation experiments indicate that the maximum halogen content of chlorinated spruce lignin is about 38%. This corresponds to the introduction of three chlorine atoms into each monomeric residue in the polymer (requires: Cl, 38.1%). There have been few attempts to brominate lignins and not enough figures are on record for comparison. However, bromination of the synthetic material with excess bromine in acetic acid in the presence of iodine gives a product containing about 57% of the halogen. For three bromines in each monomeric residue the calculated value is 58.1%. In a word, three hydrogen atoms in each monomeric residue may be replaced by halogens. The replaceable hydrogens are, of course, the active ones in the pyranose ring. Halogenation values then for spruce lignin and the synthetic material are in good agreement.

Although experimental verification might be difficult, it is worth recording that the methoxyl values for methylated spruce lignin sulfonic acid (20.7–25.4%) are in agreement with the calculated value for the synthetic material having two methoxyl groups and one sulfonic acid group for each monomeric residue (22.8%).

Again, although its significance is obscure, a Klason lignin determination run on the synthetic material gave a value of 85.7%. A simultaneous determination run on a purified specimen of alkali lignin from the saccharification processing of corncobs gave a value of 88.3%.

Finally, although in the ordinary way the comparison of two analytical values obtained from amorphous materials provides questionable evidence of constitution; in each instance quoted in this particular case it is impossible for the repeated coincidence of *three* values to be fortuitous. There cannot be anything casual about such repeated agreements. When the additional evidence of what is, under the circumstances, an unambiguous synthesis, and the same fission products with, almost complete qualitative identity is taken into account, the matter must be considered reasonably well established.

Experimental[8]

Vanillin Monoacetate.—Vanillin (15.2 g., 1 mole) was dissolved in dry pyridine (40 cc.) and acetyl chloride (10 g., 1.25 mole tech. grade) added portionwise over ten minutes with occasional shaking. The hot orange-colored reaction mixture was heated on the steam-bath for thirty minutes. The somewhat-cooled reaction mixture was poured into ice and water, the precipitate collected, washed (water) and recrystallized from dilute ethanol (charcoal); slender white needles, m. p. 77–78°, yield 62%.

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.8; H, 5.15; "OMe," 15.9; "CH_3CO," 22.16. Found: C, 61.6; H, 5.18; "OMe," 15.88, 15.98; "CH_3CO," 22.2, 22.8, 22.8.

Fries Rearrangement of Vanillin Monoacetate into Poly-8-methoxydihydrobenzopyrone.—Vanillin monoacetate (9.7 g., 1 mole) was dissolved in anhydrous nitrobenzene (50 g.) and dry aluminum chloride (13.3 g., 2 mole) added portionwise with shaking. The temperature rose and as addition proceeded the straw-colored reaction mixture became very dark and viscous. After all the aluminum chloride had been added the reaction mixture was heated to 93–100° (oil-bath temperature) for two hours. The cooled reaction mixture was treated with sufficient dilute hydrochloric acid and the nitrobenzene removed by steam distillation. The dark-colored, resinous residue was collected and washed with water. It could not be crystallized and was reprecipitated several times from solution in ethanol by cold, very dilute hydrochloric acid. The flocculent, near-gelatinous, light-brown precipitate was collected and dried and formed a dark-brown (almost black), brittle solid. After nearly complete drying (six days at 23 mm. over potassium hydroxide) the material was no longer totally soluble in ethanol or acetone. It could not easily be reduced to a powder because of its electrical properties.

Anal. Calcd. for $C_{10}H_8O_5$: C, 68.2; H, 4.55; "OMe," 17.6. Calcd. for $C_{10}H_{10}O_4$: C, 61.8, H, 5.15; "OMe," 15.9. Found: C, 65.9, 66.0; H, 4.35, 4.44; "OMe," 9.96, 9.95. Lignin recorded: C, 62–64; H, 5–6; "OMe," 15–17.

Acetylation of Poly-8-methoxydihydrobenzopyrone.—Poly-8-methoxydihydrobenzopyrone (1 g.) was dissolved in acetic anhydride (5 cc.) and the solution boiled for two hours. The reaction mixture was decomposed with water and the brown precipitate collected. It was insouble in ethanol and was precipitated several times from solution in acetone with ice water. Finally, it was collected and dried (at least six days, 23 mm., potassium hydroxide). The "acetyl" value corresponds to two acetyl groups for each monomeric residue.

Calcd.: "OAc," 30.9. Found: "OAc," 29.4, 29.5.

Methylation of Poly-8-methoxydihydrobenzopyrone.—Poly-8-methoxydihydrobenzopyrone (1 g.) was dissolved (heat) in aqueous sodium hydroxide (20 cc., 10%). Dimethyl sulfate (6 g.) was added portionwise with shaking at about 70°. Then with heating and shaking, more dimethyl sulfate (12 g.) was added portionwise and the reaction mixture kept hot and alkaline by addition, from time to time, of aqueous sodium hydroxide (20%). In about ninety minutes a considerable amount of alkali-insoluble material had separated. This was collected after dilution with water, washed and reprecipitated several times from solution in acetone with water. The finely divided precipitate was very hard to handle. It was dried (six days, 23 mm., potassium hydroxide).

Anal. Calcd.: (two "OMe" groups for each monomeric residue) "OMe," 32.3. Found: "OMe," 29.3, 29.6.

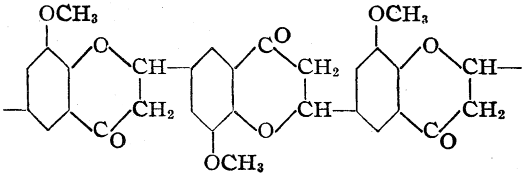
Bromination of Poly-8-methoxydihydrobenzopyrone.—Poly-8-methoxydihydrobenzopyrone (1 g.) was suspended in glacial acetic acid (25 cc.), a crystal of iodine and bromine (10 cc.) added. The reaction mixture was heated at 90° for ten hours, diluted with water (200 cc.) and the dark-red, finely-divided precipitate collected, washed three times with water and reprecipitated twice with water from solution in ethanol. The finely-divided dark-orange colored, flocculent precipitate was collected and dried (six days, 23 mm., potassium hydroxide).

Anal. Calcd.: (for three bromines for each monomeric residue) Br, 58.1. Found: Br, 56.3, 57.4.

Summary

The existence of at least two varieties of lignin appears to be definitely established. One of these is associated with gymnosperms and gives, as significant fission products, only derivatives of catechol monomethyl ether (guaiacol). The other is associated with angiosperms and gives, as significant cleavage products, the same derivatives of catechol monomethyl ether and some derivatives of pyrogallol-1,3-dimethyl ether. The possible occurrence of other varieties of lignin giving other fission products is not excluded.

Examination of the analytical evidence accumulated over the past, some seventy years, excludes the improbable elaborate formulas previously proposed and what appears to be a reasonable structure has been advanced. It is concluded from a study of the existing evidence that the lignin from gymnosperms is a poly-8-methoxydihydrobenzopyrone (XII). The lignin from angiosperms is likely constituted in the same way but with pyrogallol-1,3-dimethyl ether groups terminally, or otherwise, attached. The pyrogallol-1,3-dimethyl ether nuclei could not form part of a continuing chain as in (XII) unless the migration of a methyl group occurs during degradation. However, such nuclei could form part of the open chain form and a "mixed" chain is easily visualized.



XII

The proposed polymeric structures may not be absolutely correct and may need some modification later but it is in harmony with the known facts and with such plausible suggestions as have been made in the past. It is a cyclized condensation polymer of 2-hydroxy-3-methoxy-5-formyl-

---

[8] All analyses are micro determinations by Mr. Van Etten and Mrs. Wiele of this Laboratory.

acetophenone and is available in a single step by Fries rearrangement of vanillin monoacetate.

A polymeric material having its proposed structure has been synthesized and properties found not to differ qualitatively or, quantitatively from those recorded for spruce lignin. Solubility characteristics and general behavior are identical and it may be methylated, acetylated and halogenated (brominated) in the same fashion giving entirely analogous derivatives. The methoxyl content is noticeably lower than the calculated values but aluminum chloride is a good demethylating agent, and the introduction of free phenol groups could easily be responsible for the darker color.

Methyl 2,4:5,6-Dimethylene-D-gluconate

BY C. L. MEHLTRETTER, R. L. MELLIES AND C. E. RIST

In an attempt to prepare polyesters of 2,4:3,5-dimethylene-D-gluconic acid by heating the methyl ester (I)[2] *in vacuo*, there was obtained by sublimation a mixture of compounds from which a new methyl dimethylene gluconate was isolated in 22% yield. This compound has now been shown to be methyl 2,4:5,6-dimethylene-D-gluconate (II). It is apparent from structures (I) and (II) that a methylene cyclic acetal rearrangement has occurred from carbons 3,5 to 5,6 of the gluconic acid chain. Cyclic acetal rearrangements were observed by Hibbert and his associates[3] who found that isomeric methylene, benzylidene and *p*-nitrobenzylidene cyclic acetals of glycerol were readily interconverted in the presence of hydrogen chloride. More recently Hann, Maclay and Hudson[4] have reported a cyclic acetal shift in the benzoylation of α-diacetone dulcitol.

The separation of the methyl dimethylene gluconate (II) from unchanged methyl 2,4:3,5-dimethylene-D-gluconate (I) and other products was effected by fractional crystallization of the sublimate mixture from methanol. The purified product, which melted at the same temperature as methyl 2,4:3,5-dimethylene-D-gluconate (152°), formed a crystalline amide and a crystalline tosyl derivative. The new product gave a specific rotation of −14.4° in methanol, as compared to +13.3° for methyl 2,4:3,5-dimethylene-D-gluconate. Efforts to establish the presence of a primary or secondary alcohol group in the methyl dimethylene gluconate by subjecting the tosylated compound to iodination by the Oldham and Rutherford[5] procedure gave only anomalous results.

The removal of a methylene group from the methyl dimethylene gluconate (II) would provide a monomethylene acetal, the structure of which if known would aid considerably in establishing the structure of the original ester. Hudson and Hann and their associates[6] have shown that the controlled acetolysis of a number of methylene sugar alcohol acetals by an acetic anhydride–acetic acid solution containing 1 to 2% sulfuric acid results in the preferential cleavage of certain methylene acetal linkages. Those formed through primary hydroxyl groups are readily cleaved. Where two secondary alcoholic acetal linkages are involved, such as in 2,4:3,5-dimethylene-D-sorbitol, the 2,4-methylene acetal ring is the more stable to acetolysis.

The acetolysis reaction was first applied to methyl 2,4:3,5-dimethylene-D-gluconate (I) to ascertain whether it would proceed according to rule. A crystalline substance was produced which was presumed to be methyl 3-acetoxymethyl-5,6-diacetyl-2,4-methylene-D-gluconate (IV). Catalytic removal of the acetyl and acetoxymethyl groups of this compound with sodium methoxide and reaction of the crude product with methanol–ammonia gave crystalline 2,4-methylene-D-gluconamide (V). The structure of the latter compound was established by the oxidative degradation of the product obtained by saponification of (IV) to 2,4-methylene-xylotrihydroxyglutaric acid. This substance was esterified and isolated as the methyl ester[7] (VII). Thus the acetolysis of methyl 2,4:3,5-dimethylene-D-gluconate results in the cleavage of only the 3,5-methylene cyclic acetal linkage as was found to be the case with 2,4:3,5-dimethylene-D-sorbitol.[6]

When analogous reactions were carried out with the methyl dimethylene gluconate, 2,4-methylene-D-gluconamide was again produced. This fact not only is evidence that the methyl dimethylene gluconate contains a 2,4-methylene acetal linkage but it also limits its structure to methyl 2,4:3,6-dimethylene-D-gluconate or methyl 2,4:5,6-dimethylene-D-gluconate (II). Conclusive proof for the latter structure was obtained from a study of

(VIII) 3-Methyl-2,4-methylene-xylotrihydroxyglutarodiamide

the methyl ether of the methyl dimethylene gluconate (III). Acetolysis of this crystalline derivative, followed by saponification, gave a sirupy product which was oxidized with alkaline permanganate solution at 5 to 10°. The resulting acid was esterified with methanol and after treatment with methanol–ammonia yielded the diamide of 3-methyl-2,4-methylenexylotrihydroxyglutaric acid (VIII).[7] This substance could have been derived only from methyl 2,4:5,6-dimethylene-D-gluconate (II) by the series of reactions used.

Experimental

Isolation of Methyl 2,4:5,6-Dimethylene-D-gluconate (II).—Twenty grams (0.085 mole) of methyl 2,4:3,5-dimethylene-D-gluconate (I)[2] was heated for seven hours in a sublimation apparatus at 1 mm. pressure and a bath temperature of 150°. The sublimate, which consisted of both crystalline and oily substances, weighed 11.8 g. Recrystallization from methanol gave 4.4 g. (22%) of methyl 2,4:5,6-dimethylene-D-gluconate as colorless needles: m. p. 151–152°; $[\alpha]^{25}D$ −14.4° (*C*, 4.3; methanol). The melting point of a mixture of this compound with methyl 2,4:3,5-dimethylene-D-gluconate (m. p. 152–153°) was approximately 125°.

Anal. Calcd. for $C_9H_{14}O_7$: C, 46.2; H, 6.0; OCH_3, 13.3. Found: C, 46.2; H, 6.2; OCH_3, 13.4.

2,4:5,6-Dimethylene-D-gluconamide.—A 0.45-g. (0.002 mole) sample of methyl 2,4:5,6-dimethylene-D-gluconate was dissolved in 50 ml. of methanol which had been saturated with ammonia at 0°. After the solution had remained at 5 to 10° for five days it was concentrated *in vacuo* to dryness. The crude product was recrystallized from ethanol, giving 0.35 g. (83%) of 2,4:5,6-dimethylene-D-gluconamide as fine needles; m. p. 168–169°; $[\alpha]^{25}D$ +52.3° (*C*, 1.3; water).

Anal. Calcd. for $C_8H_{13}O_6N$: C, 43.8; H, 6.0; N, 6.4. Found: C, 44.1; H, 5.8; N, 6.4.

Methyl 3-Tosyl-2,4:5,6-dimethylene-D-gluconate.—To a solution of 5.85 g. (0.025 mole) of methyl 2,4:5,6-dimethylene-D-gluconate in 80 ml. of dry pyridine was added 5.50 g. (0.029 g. mole) of *p*-toluenesulfonyl chloride. After the mixture had remained at room temperature for four days it was poured into 500 ml. of ice water. The crystalline substance that precipitated (6.5 g., 67%) melted at 90–91°. After recrystallization from methanol, colorless prisms of methyl 3-tosyl-2,4:5,6-dimethylene-D-gluconate were obtained; m. p. 91–92°; $[\alpha]^{25}D$ −35.7° (*C*, 2.2; acetone).

Anal. Calcd. for $C_{16}H_{20}O_9S$: C, 49.5; H, 5.2; S, 8.3; OCH_3, 8.0. Found: C, 49.5; H, 5.1; S, 8.0; OCH_3, 7.9.

Samples of the tosylated compound upon treatment with an acetone solution of sodium iodide at 100° for two and for four hours gave, respectively, 50% and 57% of sodium *p*-toluenesulfonate. However, when the tosyl derivative was refluxed for two hours with an acetic anhydride solution of sodium iodide, 98% of sodium *p*-toluenesulfonate was obtained. A considerable quantity of free iodine was liberated in these reactions, and no desoxyiodo-derivative could be isolated.

Acetolysis of Methyl 2,4:3,5-Dimethylene-D-gluconate (I).—To 4.7 g. (0.02 mole) of methyl 2,4:3,5-dimethylene-D-gluconate was added an ice-cold acetolyzing solution consisting of 35 ml. of acetic anhydride, 15 ml. of acetic acid and 1 ml. of concentrated sulfuric acid. The resulting mixture was allowed to stand at 0° for forty-five minutes and then was agitated at room temperature for fifteen minutes to dissolve the ester completely. The solution was poured upon 400 g. of crushed ice and nearly neutralized to litmus by the addition of 70 g. of sodium bicarbonate. The white crystalline product was removed by filtration and washed with ice water. After recrystallization of the crude product from ethanol, 1.0 g. of methyl acetoxymethyl diacetyl methylene D-gluconate (probably methyl 3-acetoxymethyl-5,6-diacetyl-2,4-methylene-D-gluconate) (IV) was obtained as elongated hexagonal plates; m. p. 95–96°.

A further yield of 2.6 g. of product was obtained from the mother liquor; m. p. 95–96°. The total yield of methyl acetoxymethyl diacetyl methylene D-gluconate was 3.6 g. (48%).

Anal. Calcd. for $C_{15}H_{22}O_{11}$: C, 47.6; H, 5.9; OCH_3, 8.2. Found: C, 47.6; H, 5.7; OCH_3, 8.3.

Oxidation of the Saponified Acetolysis Product of Methyl 2,4:3,5-Dimethylene-D-gluconate.—To 12.6 g. (0.033 mole) of methyl acetoxymethyl diacetyl methylene D-gluconate obtained by acetolysis of methyl 2,4:3,5-dimethylene-D-gluconate was added 500 ml. of a solution which contained 21.1 g. (0.067 mole) of barium hydroxide octahydrate. The latter solution was added in portions at 60° over a one-hour period so that saponification occurred gradually under conditions of low alkalinity. The barium salt was decomposed with the calculated amount of dilute sulfuric acid and the barium sulfate removed by filtration. Concentration of the filtrate *in vacuo* gave 7.0 g. of crude 2,4-methylene-D-gluconic acid as a colorless sirup. A solution of this sirup in 200 ml. of water containing 5 g. of potassium hydroxide was cooled to 5° to 10° in an ice-bath. To the stirred mixture was added a solution of 14 g. of potassium permanganate in 250 ml. of water over a period of thirty minutes. Two grams more of permanganate was introduced and the mixture stirred at 10° for one hour. Excess permanganate was destroyed with ethanol, and the manganese dioxide that had precipitated was separated by centrifugation. The clear supernatant liquor was made slightly acid to litmus with sulfuric acid and concentrated *in vacuo* to dryness. The residue was suspended in 300 ml. of methanol and 3 ml. of concentrated sulfuric acid was added with stirring. The potassium sulfate that precipitated was removed, and the solution was refluxed for seven hours. After neutralizing the sulfuric acid with barium carbonate and removing the barium sulfate by filtration the clear filtrate was concentrated *in vacuo* until crystallization occurred. The crude crystals weighed 3.8 g. and melted at 175°. Recrystallization from water gave 2.0 g. of dimethyl 2,4-methylene-xylotrihydroxyglutarate (VII); m. p. 204°; $[\alpha]^{25}\text{D}$ 0°.

Anal. Calcd. for $C_8H_{12}O_7$: C, 43.7; H, 5.5; OCH_3, 28.2. Found: C, 43.7; H, 5.3; OCH_3, 28.1.

A further quantity of product (1.5 g., m. p. 203–204°) was obtained from the original mother liquor. The diamide of 2,4-methylene-xylotrihydroxyglutaric acid was prepared from the methyl ester and melted at 286° with decomposition. The melting points of these substances agree with the values recorded by Jones and Wiggins.[7]

Acetolysis of Methyl 2,4:5,6-Dimethylene-D-gluconate (II).—A solution of 4.7 g. (0.02 mole) of methyl 2,4:5,6-dimethylene-D-gluconate in 50 ml. of an ice-cold acetolyzing mixture (35 ml. of acetic anhydride, 15 ml. of acetic acid and 1 ml. of concentrated sulfuric acid) was allowed to stand at 0° for thirty minutes and then poured into 400 ml. of ice water. The solution was neutralized to slight acidity with 70 g. of sodium bicarbonate and extracted with chloroform. The dried chloroform solution was concentrated *in vacuo* to a nearly colorless sirup (5.0 g.) which would not crystallize. The product was presumed to be methyl 5-acetoxymethyl-3,6-diacetyl-2,4-methylene-D-gluconate. In a subsequent experiment this acetolysis product was converted to crystalline 2,4-methylene-D-gluconamide by the action of methanol–ammonia.

2,4-Methylene-D-gluconamide (V). (a) From the Acetolysis Product of Methyl 2,4:3,5-Dimethylene-D-gluconate.—To 1.90 g. (0.005 mole) of methyl acetoxymethyl diacetyl methylene D-gluconate obtained by acetolyzing methyl 2,4:3,5-dimethylene-D-gluconate was added 30 ml. of chloroform. After the addition of 3 ml. of 0.2 *N* sodium methylate solution the mixture was allowed to stand at 0° for nineteen hours and was then concentrated *in vacuo* to dryness. The residue was extracted with hot ethanol and the extract concentrated to a colorless sirup (1.05 g.). A solution of 0.70 g. of this sirup in 30 ml. of methanol–ammonia was allowed to stand at 5 to 10° for two days. Concentration of the solution to dryness *in vacuo* and recrystallization of the residue from 90% ethanol gave 0.40 g. (60%) of 2,4-methylene-D-gluconamide as colorless fine needles; m. p. 195–196°; $[\alpha]^{25}\text{D}$ +55.8° (*C*, 2.1; water).

Anal. Calcd. for $C_7H_{13}O_6N$: C, 40.6; H, 6.3; N, 6.8. Found: C, 40.7; H, 6.2; N, 6.8.

It was found that methyl acetoxymethyl diacetyl methylene D-gluconate, on direct treatment with methanol–ammonia, was deacetylated and converted to 2,4-methylene-D-gluconamide.

(b) From the Acetolysis Product of Methyl 2,4:5,6-Dimethylene-D-gluconate.—To 1.0 g. of the sirup obtained from the acetolysis of methyl 2,4:5,6-dimethylene-D-gluconate was added 40 ml. of methanol which had been saturated with ammonia at 0°. After the mixture was allowed to remain at 5 to 10° for forty hours, it was concentrated *in vacuo* to dryness. The residue was recrystallized from ethanol and gave 0.3 g. of 2,4-methylene-D-gluconamide; m. p. 195–196°; $[\alpha]^{25}\text{D}$ +55.7° (*C*, 2.1; water). The melting point of this compound was not depressed when it was mixed with a sample of 2,4-methylene-D-gluconamide prepared from the acetolysis product of methyl 2,4:3,5-dimethylene-D-gluconate.

Methyl 3-Methyl-2,4:5,6-dimethylene-D-gluconate (III).—A solution of 7.8 g. (0.033 mole) of methyl 2,4:5,6-dimethylene-D-gluconate in 25 ml. of hot methanol was added to 80 ml. of methyl iodide. The resulting mixture was stirred vigorously and refluxed for six hours with 12 g. of silver oxide, the latter being added in portions over a four-hour period. The silver salts were filtered off and extracted with hot methanol and the combined filtrate and washings concentrated *in vacuo* to dryness. The dry reaction product was suspended in 70 ml. of methyl iodide and methylated again with the aid of 10 g. of silver oxide. After two more methylations in this manner 6.3 g. of crude crystalline product was isolated. Recrystallization from ethanol gave 4.8 g. (58%) of methyl 3-methyl-2,4:5,6-dimethylene-D-gluconate as long fine needles; m. p. 124–125°; $[\alpha]^{25}\text{D}$ −6.5° (*C*, 1.5; water).

Anal. Calcd. for $C_{10}H_{16}O_7$: C, 48.4; H, 6.5; OCH_3, 25.0. Found: C, 48.3; H, 6.5; OCH_3, 25.2.

Oxidation of the Saponified Acetolysis Product of Methyl 3-Methyl-2,4:5,6-dimethylene-D-gluconate.—A solution of 4.20 g. (0.017 mole) of methyl 3-methyl-2,4:5,-6-dimethylene-D-gluconate in 50 ml. of an acetolyzing mixture (35 ml. acetic anhydride, 15 ml. of acetic acid and 1 ml. of concentrated sulfuric acid) was allowed to remain at 0° for thirty minutes and then diluted with 400 ml. of ice water. The resulting solution was then neutralized with 75 g. of sodium bicarbonate, extracted with chloroform, and the dried chloroform solution concentrated *in vacuo* to a sirup (6.8 g.). This crude reaction product was presumed to be methyl 3-methyl-5-acetoxymethyl-6-acetyl-2,4-methylene-D-gluconate. The 6.8 g. of sirup was saponified at 60° with a solution of 11.30 g. (0.036 mole) of barium hydroxide octahydrate in 250 ml. of water. The barium salt was treated with the calculated amount of sulfuric acid and the barium sulfate that precipitated was removed by filtration. After concentrating the clear filtrate *in vacuo*, 2.2 g. of a nearly colorless sirup was obtained which presumedly was 3-methyl-2,4-methylene-D-gluconic acid.

For the oxidation all of the sirup was dissolved in a solution of 1.2 g. of potassium hydroxide in 50 ml. of water. The mixture was stirred and cooled to 5 to 10° and a solution of 5 g. of potassium permanganate in 90 ml. of water was introduced slowly over a thirty-minute period. Stirring was continued for thirty minutes after which the excess permanganate was destroyed with ethanol. The precipitated manganese dioxide was removed and washed with hot water by centrifugation. The supernatant solutions were combined and made slightly acid to litmus with sulfuric acid. The residue obtained by concentrating this solution *in vacuo* was suspended in 200 ml. of methanol and 3 ml. of concentrated sulfuric acid was added with stirring. Potassium sulfate precipitated and was removed and washed with methanol by centrifugation. The supernatant solution and washings were combined (500 ml.) and refluxed for ten hours. The sulfuric acid was then neutralized with barium carbonate, the barium sulfate removed, and the clear solution concentrated *in vacuo* to dryness. The residue was allowed to stand at 5 to 10° for two days with 200 ml. of methanol–ammonia. After concentrating this solution to dryness *in vacuo* the crude product was recrystallized twice from 80% ethanol. The yield of purified 3-methyl-2,4-methylene-xylotrihydroxyglutarodiamide was 0.3 g.; m. p. 305–306° (dec.); $[\alpha]^{25}\text{D}$ 0°. Jones and Wiggins[7] reported a melting point of 295° for this compound. An authentic sample prepared by their procedure[7] was found to melt at 305–306° (dec.).

Acknowledgment.—The authors are indebted to C. H. Van Etten of the Analytical and Physical Chemical Division of this Laboratory for performing the microanalyses.

Summary

A new methyl dimethylene gluconate has been isolated from the sublimate mixture obtained by heating methyl 2,4:3,5-dimethylene-D-gluconate *in vacuo* at 150°. The structure of the new diacetal has been shown to be methyl 2,4:5,6-dimethylene-D-gluconate. The rearrangement of a six-membered methylene acetal ring to a five-membered ring has thus been demonstrated.

The application of the procedure of Hudson and Hann and their associates[6] for the limited acetolysis of the methylene acetals of sugar alcohols to methyl 2,4:3,5-dimethylene-D-gluconate and methyl 2,4:5,6-dimethylene-D-gluconate has resulted in further confirmation of the relative stability of the 2,4-methylene acetal linkage to acetolysis.

Sulfanilamide Derivatives Containing Urea, Thiourea or Hydrazide Groupings

BY EVA NIEMIEC[1]

Urea has been used in therapy along with sulfanilamides, its alleged effect being to counteract the action of *p*-aminobenzoic acid. It appeared of interest to prepare sulfanilamides containing urea or related groupings and study their bacteriostatic effects.

In the preparation of sulfanilamidourea (I) and sulfanilamidothiourea (II) from acetylsulfanilyl chloride and the appropriate semicarbazide hydrochloride (condensed in the presence of aqueous sodium acetate), deacetylation was accomplished by boiling for three hours in aqueous alcoholic hydrochloric acid solution. Alkaline hydrolysis causes liberation of ammonia; even ten hours of boiling with concentrated hydrochloric acid results only in partial hydrolysis.

(I) p-$H_2NC_6H_4SO_2NHNHCONH_2$
(II) p-$H_2NC_6H_4SO_2NHNHCSNH_2$
(III) p-$H_2NCH_2C_6H_4SO_2NHNHCONH_2$
(IV) p-$CH_3CONHC_6H_4SO_2NHNH_2$
(V) p-$CH_3CONHC_6H_4SO_2NHNHCOC_6H_5$
(VI) p-$CH_3CONHC_6H_4SO_2NHNHCOCH_3$
(VII) p-$CH_3CONHC_6H_4SO_2NHN(COCH_3)_2$
(VIII) p-$H_2NC_6H_4SO_2NHNH_2$

Marfanil or homosulfanilamide is interesting because its bacteriostatic action is not counteracted by *p*-aminobenzoic acid; its urea derivative (III) was prepared as above. Sulfanilylhydrazides should be available by either (1) treatment of acetylsulfanilyl chloride with the hydrazide, or (2) acylation of N^4-acetylsulfanilylhydrazine (IV), and hydrolysis at the N^4-position. Haslewood[2] prepared sulfanilylbenzhydrazide using the first method. Since acethydrazide is difficult to prepare, the second method was employed in this work. N^4-Acetylsulfanilylhydrazine[3] was prepared in good yield by grinding hydrazine dihydrochloride in a mortar with dry acetylsulfanilyl chloride and crystalline sodium carbonate.

If N^4-acetylsulfanilylhydrazine is treated in pyridine solution with one mole of benzoyl chloride, N^4-acetylsulfanilylbenzhydrazide[2] (V) is obtained; this yields sulfanilylbenzhydrazide on alkaline hydrolysis. Excess benzoyl chloride gives a product which appears to be a mixture of the mono- and dibenzhydrazide. This is in agreement with the experience of McFadyen and Stevens.[4] Acetylsulfanilylhydrazine in pyridine can be converted into either N^4-acetylsulfanilacethydrazide (VI) or the diacetate VII. When either product is subjected to acid hydrolysis[3] with 12 *N* hydrochloric acid or even with 6 *N* or 3 *N* hydrochloric acid, all acetyl groups are split off and only sulfanilylhydrazine[3] (III) is obtained.

Studies of the bacteriostatic properties of these compounds by Miss Aida Djanian at the Department of Bacteriology of this University indicate that sulfanilamidourea and 4-homosulfanilamidourea are superior to sulfathiazole in their inhibitory action upon *Clostridium welchii*, *Cl. tetani*, *Cl. sporogenes*, and *Cl. chauvei*. Sulfanilamidourea and sulfanilamidothiourea are approximately one-tenth as active against *Streptococcus viridans* as sulfathiazole, whereas homosulfanilamidourea has no inhibitory effect.

Experimental[5]

N^4-Acetylsulfanilamidourea.[6]—A mixture of 5 g. of semicarbazide hydrochloride, 10.5 g. of dry acetylsulfanilyl chloride, and 30 g. of crystalline sodium acetate is thoroughly ground in a mortar with a few cc. of water. The thick paste is then transferred with the minimum amount of water and heated for thirty minutes at 60°. After cooling the product is filtered, washed, and crystallized from boiling water, in which it is not very soluble; needles, m. p. 223–224° with decomposition, yield 6 g.

(6) After the completion of these experiments, Roth and Degering, THIS JOURNAL, **67**, 126 (1945), reported the preparation of this compound in comparable yield in pyridine solution

Anal. Calcd. for $C_9H_{12}N_4O_4S$: N, 20.58. Found: N, 20.41, 20.05.

Sulfanilamidourea (I).—N^4-Acetylsulfanilamidourea (6.0 g.) is refluxed for three hours with 21 cc. of concentrated hydrochloric acid (density 1.19) and 70 cc. of 95% alcohol. The crystals that separate on cooling are filtered and neutralized with sodium carbonate to litmus. The needles that separate on cooling are recrystallized from boiling water; m. p. 229° with decomposition; yield 4.5 g.

Anal. Calcd. for $C_7H_{10}N_4O_3S$: C, 36.51; H, 4.38; N, 24.34. Found: C, 37.1, 37.2; H, 4.6, 4.7; N, 24.25, 24.20.

N^4-Acetylsulfanilamidothiourea.[6]—A mixture of 5 g. of thiosemicarbazide, 13 g. of acetylsulfanilyl chloride, and 23 g. of crystalline sodium acetate is allowed to react as described for the urea derivative; needles (from water), m. p. 186°; yield 2 g.

Anal. Calcd. for $C_9H_{12}N_4O_3S_2$: C, 37.49; H, 4.20; N, 19.43. Found: C, 37.1, 36.8; H, 4.6, 4.9; N, 19.0, 18.8.

Sulfanilamidothiourea (II).—The hydrolysis is carried out exactly as described for the urea derivative; needles (from water) m. p. 224–225° with decomposition.

Anal. Calcd. for $C_7H_{10}N_4O_2S_2$: C, 34.13; H, 4.09; N, 22.75. Found: C, 34.45, 34.30; H, 4.3, 4.3; N, 23.0, 23.2.

N^4-Acetyl-4-homosulfanilamidourea.—A mixture of 7 g. of N-acetyl-4-homosulfanilyl chloride,[7] 7 g. of semicarbazide hydrochloride, and 20 g. of crystalline sodium acetate is treated as described for the lower homolog. The product is crystallized from boiling water, in which it is quite soluble; rods, m. p. 193–194° with decomposition; yield 5 g. The air-dried product contains 1 mole of water of crystallization, which is removed by drying in vacuum over phosphorus pentoxide at 100°.

Anal. Calcd. for $C_{10}H_{14}N_4O_4S \cdot H_2O$: N, 18.41. Found: N, 18.5, 18.2.

4-Homosulfanilamidourea Hydrochloride (III).—One gram of N^4-acetyl-4-homosulfanilamidourea is refluxed for eight to nine hours with concentrated hydrochloric acid and 56 cc. of absolute alcohol. On cooling the hydrochloride separated in the form of clusters melting at 225–226° with decomposition; yield 0.7 g.

Anal. Calcd. for $C_8H_{13}N_4O_3SCl$: N, 19.96. Found: N, 19.8, 19.9.

N^4-Acetylsulfanilylhydrazine (IV).—Hydrazine dihydrochloride (5 g.), dry acetylsulfanilyl chloride (12 g.), and crystalline sodium carbonate (28 g.) are ground in a mortar. The reaction is marked by a strong evolution of gas. When the gas stops evolving a few cc. of water is added and the reaction mixture is left for one hour at room temperature. The product is filtered, washed with water, and crystallized from 500 cc. of boiling water; plates, m. p. 183–184° with decomposition. Prolonged boiling results in decomposition of the product.

Anal. Calcd. for $C_8H_{11}N_3O_3S$: C, 41.91; H, 4.84; N, 18.33. Found: C, 41.9, 42.1; H, 4.9, 5.3; N, 18.2, 18.4.

N^4-Acetylsulfanilylbenzhydrazide (V).—N^4-Acetylsulfanilylhydrazine (1 g.) is dissolved in a minimum amount of dry pyridine. The solution is cooled and treated slowly with 0.5 cc. of benzoyl chloride. After standing for twenty-four hours at room temperature the pyridine is removed *in vacuo*. The residue is treated with dilute hydrochloric acid and the precipitate is collected and crystallized three times from water or alcohol; m. p. 219–220° with decomposition; yield 0.5 g. It shows no depression with Haslewood's product.

N^4-Acetylsulfanilylmonoacethydrazide (VI).—To a cooled solution of 3 g. of N^4-acetylsulfanilylhydrazine in dry pyridine, 0.93 cc. of acetyl chloride is slowly added. After standing for twenty-four hours and after evacuation of the pyridine, the residue is treated with dilute hydrochloric acid and kept for several hours in the icebox. The product is filtered and crystallized twice from water; m. p. 204–205° with decomposition.

Anal. Calcd. for $C_{10}H_{13}O_4N_3S$: N, 15.49. Found: N, 15.79, 15.68.

N^4-Acetylsulfanilyldiacethydrazide (VII).—N^4-Acetylsulfanilhydrazine (3 g.) in pyridine is treated without cooling with acetic anhydride (3 cc.). The procedure is the same as for the monoacethydrazide; needles (from water), m. p. 191–192° with decomposition.

Anal. Calcd. for $C_{12}H_{15}N_3O_5S$: C, 46.00; H, 4.83; N, 13.41. Found: C, 45.8, 46.1; H, 4.8, 4.6; N, 13.6, 13.3.

Summary

Sulfanilamidourea, sulfanilamidothiourea, and 4-homosulfanilamidourea were prepared and tested for bacteriostatic activity.

A simplified method for the preparation of N^4-acetylsulfanilylhydrazine is described. The latter compound can be used for the preparation of sulfanilylbenzhydrazide and of N^4-acetylsulfanilyl-mono- and diacethydrazide. Acid hydrolysis of the last two compounds yields sulfanilylhydrazine.

Esters of Dithiodiglycolic Acid

BY JOHN F. MULVANEY, JAMES G. MURPHY AND RALPH L. EVANS

The esters of dithiodiglycolic acid reported here were prepared as a part of the general program of research in these laboratories on compounds reacted to thioglycolic acid and its derivatives.

Although the methyl[1] and ethyl[1,2] esters of dithiodiglycolic acid were described many years ago, to our knowledge only one other ester, namely, the dimethylaminoethyl ester,[3] has been reported during the intervening years.

Claesson prepared the ethyl ester by direct esterification of the dithio acid with alcohol, using dry hydrogen chloride as a catalyst. As noted by Price and Twiss the ester that Claesson obtained was impure. These authors[1] prepared the dimethyl and diethyl esters by electrolysis of the Bunte salts prepared from ethyl or methyl bromoacetate and sodium thiosulfate.

In a later report[4] these same authors describe the preparation of the dimethyl ester by the oxidation of the Bunte salt with iodine.

All the esters reported here were prepared by direct esterification of dithiodiglycolic acid with the corresponding alcohol. The usual acid catalyst, sulfuric acid, benzene- or toluenesulfonic acid, was used. Several of the esters were also prepared by oxidation of the corresponding ester of thioglycolic acid with the hydrogen peroxide. The average yield of crude ester was about 95%. The physical properties of the liquid esters were determined on the middle fraction of a doubly distilled product. All esters were distilled in presence of a slow stream of nitrogen.

Dithiodiglycolic acid was prepared by the oxidation of thioglycolic acid with hydrogen peroxide, or by the reaction of chloroacetic acid with sodium polysulfide. It was recrystallized from ethylene dichloride or from a mixture of benzene and ethyl acetate (9:1), m. p. 106–107° (uncor.).

In general 0.5 mole of dithiodiglycolic acid was refluxed with 1.0–1.1 moles of the alcohol in the presence of 150 cc. of toluene or benzene and 2 g. of benzene- or toluenesulfonic acid. The vapors were condensed and the lower layer of the benzene–water azeotrope was separated in a Dean–Stark trap. Esterification was generally completed in thirty minutes to two hours. The solution of the ester was washed with 5% bicarbonate solution and water, dried over anhydrous sodium sulfate, and then distilled in vacuum.

The tetra-, hexa- and octadecyl esters separated when the reaction mixture was cooled. The cyclohexyl ester crystallized after the toluene was removed.

All liquid esters are colorless when pure and are practically odorless. They are immiscible with water but soluble in most organic solvents.

Carcinogenic Hydrocarbons. 9,11-Dimethylbenz[*a*]anthracene and 8,9,11-Trimethylbenz[*a*]anthracene

BY BYRON RIEGEL AND JOHN G. BURR, JR.[1]

The possibility that some tumors may arise from abnormal steroid metabolism has stimulated a search for the carcinogenic agents. A plausible substance is 3,5-dimethylcholanthrene, the synthesis of which is described in the second paper of this series. The positions of interest in this hydrocarbon are C-5, where the steroid side chain would appear, and C-3, where the C-20 methyl group of the steroid side chain appears. To test this hypothesis further, the cumulative effect of methyl groups in the corresponding 9 and 11 positions[2] of the benz[*a*]anthracene system was investigated. The parent hydrocarbons selected are of varying carcinogenic activity so that any coupling effect by the addition of methyl groups in the 9 and 11 positions should be clearly evident. Two hydrocarbons that would best demonstrate this effect are 9,11-dimethylbenz[*a*]anthracene (I) and 8,9,-11-trimethylbenz[*a*]anthracene (II).

These two hydrocarbons (I and II) have been prepared by a new method, which incorporates certain features of the Cook and Robinson synthesis of 11-methylbenz[*a*]anthracene[3] and of the Bachmann and Chemerda synthesis of 10-methylbenz[*a*]anthracene.[4] 3-Acetylphenanthrene (III) was condensed with diethyl succinate under the conditions of the modified Stobbe reaction, as developed by Johnson and his co-workers.[5] The yield of the half ester (IV) obtained in this reaction was found to depend upon the concentration of potassium *t*-butoxide in the solvent *t*-butyl alcohol, and to be nearly independent of the duration of heating or the excess of diethyl succinate. The use of a solution of potassium *t*-butoxide in *t*-butyl alcohol nearly saturated at the boiling point gave a 72% yield of the half ester (IV). The lactone (V) was produced in 70% yield by repeated hydrolysis of IV with a boiling mixture of acetic and hydrobromic acids. This lactone (V) was reduced to the corresponding γ-(3-phenanthryl)-valeric acid by several agents. Clemmensen reduction of the lactone produced the acid in 62–85% yields with a quantitative recovery of unreduced lactone. Catalytic reduction gave a 95% yield of the acid. The most convenient reducing agent, as determined by the results of the ensuing cyclization, was a mixture of iodine and red phosphorus in glacial acetic acid. In all of these experiments, the substituted valeric acid was obtained as an oil, although it has been reported[4] as a solid melting at 75–77°. Cyclization of this non-crystalline acid, however, produced the known[4] 8-keto-11-methyl-8,9,10,11-tetrahydrobenz[*a*]anthracene (VI) in a 72–97% yield.

The ketone (VI) when condensed with methyl oxalate by the usual procedure[4] gave a quantitative yield of the glyoxalate (VII), which was decarbonylated by heating with powdered soft glass to the β-ketoester (VIII). The sodium salt of the keto ester was refluxed with methyl iodide, and the resulting methyl keto ester was repeatedly hydrolyzed with a boiling mixture of acetic and hydrochloric acids. 8-Keto-9,11-dimethyl-8,9,-10,11-tetrahydrobenz[*a*]anthracene (IX) was thus obtained in a 75% yield from the ketone (VI), as colorless needles melting at 169–170°.

Reduction of this ketone (IX) with aluminum isopropoxide, and subsequent dehydration (through an intermediate 8-chloro compound) of the carbinol, led to 9,11-dimethyl-10,11-dihydrobenz[*a*]anthracene (X) which was obtained as colorless massive plates melting at 70–71°. The aromatization of X was accomplished by the Linstead solution method.[6] 9,11-Dimethylbenz[*a*]-anthracene (I) forms colorless plates which melt at 154–154.5°.

The ketone (IX) was refluxed with an excess of methylmagnesium iodide, and the resulting carbinol (XI) was then heated with 5% palladium–charcoal at 300° to give the 8,9,11-trimethylbenz-[*a*]anthracene (II) which was isolated (63% overall yield from IX) from the fusion mass as yellowish plates melting at 201–203.5°.

Samples of these hydrocarbons have been sent to Dr. M. J. Shear, of the National Cancer Institute, for biological testing.

Experimental[7]

Stobbe Half Ester (IV).—A solution of 10.6 g. of potassium (cleaned and weighed under kerosene) in 150 ml. of anhydrous *t*-butyl alcohol was prepared by heating. This solution was mixed with 73.5 g. of diethyl succinate and 46.0 g. of 3-acetylphenanthrene[8] (m. p. 69–72°). The flask containing this mixture was repeatedly evacuated and filled with nitrogen, and the solution then refluxed for five hours in a nitrogen atmosphere. The warm solu-

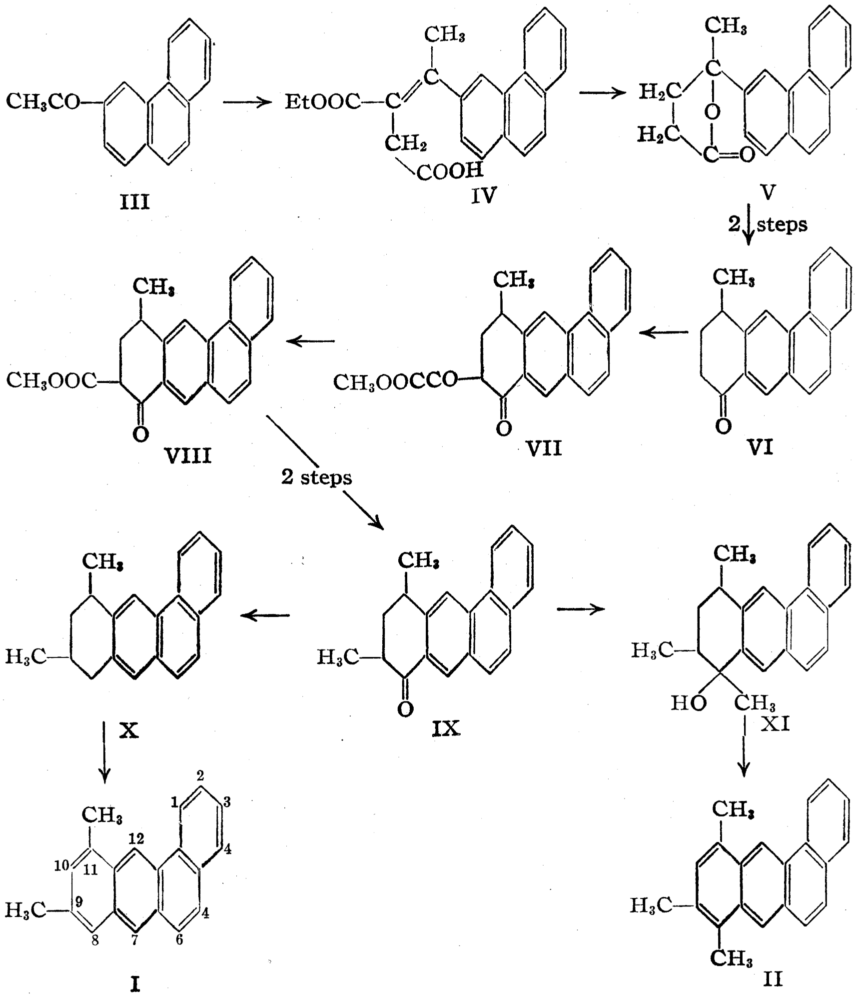
[7] All melting points were taken on a Fischer–Johns apparatus. Microanalyses by Patricia Craig and Nelda Mold, Northwestern University.

[8] Prepared by the method of E. Mosettig and J. van der Kamp, THIS JOURNAL, **52**, 3704 (1930), as modified by W. E. Bachman and C. H. Boatner, *ibid.*, **58**, 2097 (1936).



tion was hydrolyzed with dilute hydrochloric acid, and organic solvents removed by distillation. The viscous product was dissolved in ether and the half ester extracted from the ether with dilute ammonium hydroxide. Acidification of the alkaline solution precipitated the half ester. From 85 g. of 3-acetylphenanthrene was obtained 98.5 g. (72%) of the half ester (IV) as a dark, clear, very viscous oil. The neutral material obtained by evaporation of the ether was crystallized from methanol and unreacted ketone (III) recovered as yellow needles, m. p. 64–67°.

Employment of a more dilute solution of potassium *t*-butoxide lowers the yield of half ester to 42–45% with proportionate recovery of the ketone (III).

γ-(3-Phenanthryl)-valerolactone (V).—A suspension of 98.5 g. of the half ester (IV) in a mixture of 95 ml. of water, 188 ml. of 48% hydrobromic acid, and 285 ml. of glacial acetic acid was refluxed for six and one-half hours. The product of this reaction was a brown sandy solid which weighed 80.1 g. This solid was dissolved in chloroform, decolorized, and the solution concentrated and diluted with a large volume of ether. The lactone (V) crystallized (38.7 g.) as pale tan plates. The material remaining in solution was recovered and hydrolyzed with an acid mixture of the same composition and quantity as used originally. In this way, an additional 14.5 g. of the lactone was obtained, making a total yield of 53.2 g. (70%). Two crystallizations of this solid from chloroform–ether gave colorless needles melting at 150–151°.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.6; H, 5.80. Found: C, 82.2; H, 5.92.

γ-(3-Phenanthryl)-valeric Acid. A.—To reduce the lactone (V), 18.64 g. of it with a mixture of 250 ml. of glacial acetic acid, 15 g. of red phosphorus, 5 g. of iodine, and 5 ml. of water was heated to boiling for six hours. This solution was filtered through sintered glass, and poured into two liters of water containing a little sodium bisulfite. The precipitated product was dissolved in ether–benzene, and the acid extracted from this solution with 10% potassium carbonate. The alkaline extract was acidified and the acid taken up in ether. Evaporation of the ether gave the acid as a clear brown viscous liquid weighing 18.86 g. (100%). When 38.7 g. of the lactone was reduced with the same quantities of reagents, 18.3 g. of the acid was obtained, and 20.0 g. of pure lactone was recovered. The reduction of 34 g. of the lactone with double the above quantities of reagents produced the acid in 84% yield, with recovery of 13% of lactone. The acid was identified by cyclization to the known 8-keto-9-methyl-8,9,10,11-tetrahydrobenz[*a*]anthracene (VI), as described below.

B. A 1.14-g. sample of the lactone was reduced by the use of 26 g. of amalgamated zinc, 20 ml. of water, 50 ml. of concentrated hydrochloric acid and 30 ml. of toluene. The reaction mixture was refluxed vigorously for forty-eight hours; during the first eight hours, 10-ml. portions of concentrated hydrochloric acid were added hourly. After cooling, the reaction mixture was diluted with water and ether and worked up essentially as described in A. A yield of 0.98 g. (85%) of acidic material was obtained. Crystallization of the neutral fraction from chloroform–ether gave 0.21 g. (18%) of recovered lactone melting at 150–151°. On other runs the modified Clemmensen reduction did not give as consistent yields as the first method.

C. To a solution of 1.0 g. of the lactone in 50 ml. of glacial acetic acid containing 1.0 ml. of sulfuric acid was added 0.10 g. of palladium–charcoal catalyst. This solution was shaken with hydrogen at an initial pressure of 33.5 lb. At the end of four hours the catalyst was separated by filtration and most of the acetic acid removed under reduced pressure. The residue was poured into water and the precipitated oil extracted with ether and benzene. From the organic solution was obtained 0.95 g. (95%) of acidic material as a yellow viscous liquid. It was cyclized to the ketone in a nearly quantitative yield.

8-Keto-11-methyl-8,9,10,11-tetrahydrobenz[*a*]anthracene (VI).—γ-(3-Phenanthryl)-valeric acid (18.86 g.) was dissolved in 100 ml. of benzene, and converted to the acid chloride with 19 g. of phosphorus pentachloride. The acid chloride was cyclized with 20 ml. of stannic chloride; after the bright orange crystalline complex had stood for one-half hour, it was hydrolyzed with a mixture of ice, hydrochloric acid, and ether. The product of this reaction was 16.0 g. (91.5%) of brown prisms. It was crystallized from ethanol–benzene to give 13.8 g. (79%) of shining tan crystals which melted at 126–130°. A sample of this ketone was dissolved in benzene, passed through alumina, and then crystallized from ethanol–benzene.

It then formed massive pale yellow prisms melting at 129–130.5° (lit.[4] 130–131.5°). The yield of crude ketone varied from 72–97%, depending upon the source of the acid.

The **oxime** crystallizes from alcohol as massive colorless plates melting at 192–193° (dec.).

Anal. Calcd. for $C_{19}H_{17}ON$: N, 5.09. Found: N, 4.88.

8-Keto-11-methyl-8,9,10,11-tetrahydrobenz[*a*]anthracene-9-glyoxalate (VII).—A mixture of 13.8 g. of the ketone (VI), the dry sodium methoxide from 2.21 g. of sodium, and 11.3 g. of dimethyl oxalate was dissolved in 500 ml. of dry benzene by shaking and gentle warming. After standing at room temperature for nine and one-half hours, the deep red solution was hydrolyzed with 100 ml. of water and the product extracted with 2% sodium hydroxide. The alkaline solution was acidified and the crude glyoxalate obtained as a clear deep red gum weighing 18.68 g. (100%). This gum crystallized on standing overnight. A portion was dissolved in acetone, decolorized with Nuchar and the first crop of crystals was again crystallized from ethanol. The glyoxalate forms pale chartreuse leaflets melting at 122–123.5° and gives a dark-brown color with alcoholic ferric chloride.

Anal. Calcd. for $C_{22}H_{18}O_4$: C, 76.3; H, 5.23. Found: C, 76.7; H, 5.57.

8-Keto-11-methyl-9-carbomethoxy-8,9,10,11-tetrahydrobenz[*a*]anthracene (VIII).—A mixture of 18.68 g. of the glyoxalate and 10 g. of powdered glass was heated at 180–190° for forty-five minutes at which time the evolution of gas had ceased. The keto-ester was extracted with benzene and crystallized from benzene–methanol to give 6.80 g. of brown prisms and 8.42 g. of an orange oil. Both fractions were suitable for the next step. A portion of the solid (in benzene solution) was passed through alumina, and crystallized from dioxane–methanol to give light tan prisms melting at 121–122.5°. It gives a green color with alcoholic ferric chloride.

Anal. Calcd. for $C_{21}H_{18}O_3$: C, 79.2; H, 5.71. Found: C, 79.7; H, 5.85.

8-Keto-9,11-dimethyl-8,9,10,11-tetrahydrobenz[*a*]anthracene (IX).—To a solution of sodium methoxide, prepared from 0.4 g. of sodium and a mixture of 5 ml. of methanol and 25 ml. of benzene, was added 2.50 g. of the crystalline keto ester (VIII). A pasty green solid precipitated. The solution was refluxed with 5 ml. of methyl iodide (a second 5-ml. portion was added after two hours) overnight. Volatile substances were stripped out by distillation, and the residue was taken up in benzene and passed through alumina. In some runs, the pink precipitate of sodium iodide formed in the reaction clogged the alumina column, so the suspension was filtered first. The methyl keto ester was obtained from the eluate as 2.72 g. (100%) of a yellow viscous oil. When cruder keto ester was methylated, the yield dropped to 84–89%.

The methyl keto ester (33.4 g.) was decarbomethoxylated by refluxing it for five hours with a mixture of 300 ml. of glacial acetic acid and 300 ml. of concentrated hydrochloric acid. The solvents were slowly distilled under reduced pressure, and the red granular residue (28.7 g.) was crystallized from benzene–methanol. The ketone, IX (19.5 g.), was obtained as pinkish needles. The material remaining in solution was recovered and refluxed with 200 ml. of the acid mixture. An additional 4.2 g. of the ketone was so produced. The total yield was 23.7 g. (75%); m. p. 169–172°. One crystallization from benzene–methanol, after treatment with Nuchar, gave a product which separated as colorless needles and melted at 169–170°.

Anal. Calcd. for $C_{20}H_{18}O$: C, 87.6; H, 6.61. Found: C, 87.5; H, 6.77.

The **oxime** crystallized in long silky needles from ethanol and melted at 220–220.5°.

Anal. Calcd. for $C_{20}H_{19}ON$: N, 4.84. Found: N, 4.89.

8-Hydroxy-9,11-dimethyl-8,9,10,11-tetrahydrobenz[*a*]anthracene.—Aluminum isopropoxide was prepared from 1.4 g. of aluminum wire and 190 ml. of dry isopropyl alcohol. Three grams of the ketone (IX) was dissolved in this solution, and isopropyl alcohol distilled out slowly. After 115 ml. of the alcohol had distilled during seven hours, a negative test for acetone was obtained in the distillate. Hydrolysis of the residual solution gave 3.19 g. of the carbinol as an oily solid.

9,11-Dimethyl-10,11-dihydrobenz[*a*]anthracene (X).—A rapid stream of dry hydrogen chloride was passed into a chilled solution of 3.19 g. of the above carbinol in 50 ml. of benzene containing 2.3 g. of calcium chloride. After twenty minutes the hydrogen chloride flow was stopped and the reaction mixture filtered through a sintered glass funnel. The solvent was evaporated and the residue heated *in vacuo* on a steam-bath. It evolved hydrogen chloride vigorously. The residue was sublimed at 1 mm., and the white solid sublimate crystallized from ethanol containing a few drops of water. The dihydrodimethyl hydrocarbon (X) was obtained as colorless, massive plates (1.44 g.) m. p. 68–70°. One crystallization from absolute ethanol raised the melting point to 70–71°.

Anal. Calcd. for $C_{20}H_{18}$: C, 93.0; H, 7.02. Found: C, 92.8; H, 6.76.

9,11-Dimethylbenz[*a*]anthracene (I).—To a solution of 1.06 g. of the dihydrodimethyl hydrocarbon (X) in 35 ml. of mesitylene was added 0.19 g. of 5% palladium–charcoal, and the resulting mixture was heated to vigorous boiling in a stream of carbon dioxide. The evolved gases were collected in a nitrometer. During three hours and twenty minutes, 110 ml. of hydrogen was collected. The product obtained from this reaction was crystallized from ethanol–benzene to give 0.75 g. of colorless plates melting at 154–155°. One crystallization from ethanol gave a product melting at 154–154.5°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.7; H, 6.29. Found: C, 93.7; H, 6.39.

The **picrate** crystallized from alcohol as deep red-brown needles which melted at 191–192°.

Anal. Calcd. for $C_{20}H_{16}\cdot C_6H_3O_7N_3$: N, 8.7. Found: N, 8.5.

The **trinitrobenzene complex** crystallized from alcohol as long thin orange needles which melted at 188–190°.

Anal. Calcd. for $C_{20}H_{16}\cdot C_6H_3O_6N_3$: N, 9.0. Found: N, 8.7.

8,9,11-Trimethylbenz[*a*]anthracene (II).—To a solution of methylmagnesium iodide prepared from 3.4 g. of methyl iodide and 0.67 g. of magnesium in 40 ml. of ether was added a solution of 1.64 g. of the ketone (IX) in 50 ml. of benzene. The reaction mixture was refluxed for one and one-half hours. The carbinol obtained after hydrolysis was a clear, amber, viscous liquid (2.29 g.). It was mixed with 200 mg. of 5% palladium–charcoal, protected with a nitrogen atmosphere, and during a one-hour period the temperature was gradually raised to 310°. The product was extracted from this melt and crystallized from benzene. There was obtained 1.02 g. (63%) of yellowish plates; m. p. 196–201°. A portion of this substance was crystallized twice more from ethanol–benzene, passed (in benzene solution) through an alumina column, and finally crystallized again from ethanol–benzene. 8,9,11-Trimethylbenz[*a*]anthracene thus purified has a melting point of 201–203.5°, and forms large regular faintly yellow diamond-shaped plates.

Anal. Calcd. for $C_{21}H_{18}$: C, 93.3; H, 6.71. Found: C, 93.5; H, 6.67.

The **picrate** crystallized as fine red-brown needles which melted at 190–191°.

Anal. Calcd. for $C_{21}H_{18}\cdot C_6H_3O_7N_3$: N, 8.4. Found: N, 8.3.

The **trinitrobenzene derivative** crystallized as orange micro-needles which melted at 199–200°.

Anal. Calcd. for $C_{21}H_{18}\cdot C_6H_3O_6N_3$: N, 8.7. Found: N, 8.5.

Summary

1. 9,11-Dimethylbenz[*a*]anthracene and 8,9,-11-trimethylbenz[*a*]anthracene have been prepared by an improved synthesis for benz[*a*]anthracene derivatives.

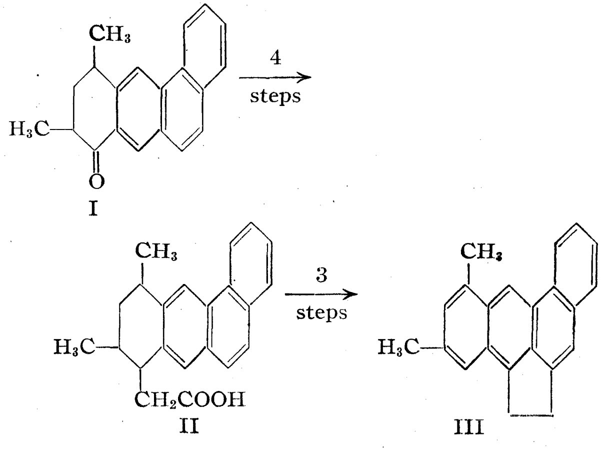
Carcinogenic Hydrocarbons. 3,5-Dimethylcholanthrene[1]

BY BYRON RIEGEL, JOHN G. BURR, JR.,[2] MICHAEL A. KUBICO AND MARVIN H. GOLD[3]

Since the preparation of methylcholanthrene from desoxycholic acid,[4] and from cholic acid[5] by a series of reactions whose types are known to occur in the animal body, it has been a natural speculation[6] that some tumors may be caused by carcinogenic agents produced by an abnormal metabolism of sterols or bile acids. The formation of substituted cholanthrenes from steroids requires a ring closure between the steroid side chain and ring C of the nucleus. The residue of the side chain will then occupy the 5 position in cholanthrene, and the C-20 methyl group of the steroid will be at the 3 position of cholanthrene (present system of numbering[7]). To date, 3,5-dialkylcholanthrenes have not been prepared and tested for carcinogenic activity. The biological reasons for desiring such information are obvious.

The first member of this series, 3,5-dimethylcholanthrene (III), has been prepared by general methods already recorded in the literature[8] for the preparation of substituted cholanthrenes. The starting material was 8-keto-9,11-dimethyl-8,9,10,11-tetrahydrobenz[a]anthracene (I).[9] By means of a Reformatsky reaction followed by dehydration, hydrogenation, and saponification, the ketone (I) was transformed into 9,11-dimethyl-8,9,10,11-tetrahydrobenz[a]anthryl-8-acetic acid (II). Cyclization of this acid by the action of stannic chloride upon the acid chloride produced a viscous liquid ketone which after reduction and dehydrogenation gave 3,5-dimethylcholanthrene. The action of liquid hydrogen fluoride upon the acid gave two products, one of which was an acetone-soluble viscous liquid, and the other (35%) was an acetone-insoluble substance crystallizing in bright yellow needles with a melting point of 267–270°. The physical properties and analysis of this substance conform well with those expected for 1-keto-3,5-dimethylcholanthrene. It is evident that extensive dehydrogenation has occurred, presumably by hydrogen transfer during the cyclization, although the low hydrogen content found in the acid indicates the possibility that dehydrogenation occurred in an earlier step. At the time this experimental work was performed, the extent of the dehydrogenation was not suspected, and both the non-crystalline and the crystalline cyclization products were combined, after reduction of the keto group, and carried through to 3,5-dimethylcholanthrene which was obtained in fair yield from the mixture.

The reduction of the ketonic material was accomplished by the Martin modification of the Clemmensen reduction.[10] The reduction products from both the solid and the oily ketone were combined. Two methods were used for aromatization of this material: (1) the Linstead liquid phase method[11] which gave pure 3,5-dimethylcholanthrene (III) but in poor yield, and (2) the heating of the crude tetrahydro hydrocarbon with palladium–charcoal at 300°. This last method was distinctly superior, giving the 3,5-dimethylcholanthrene (III) in a 51% yield.



From ethanol or ethanol–acetone 3,5-dimethylcholanthrene crystallized as orange-yellow needles melting at 183–184°, but from acetone alone, it crystallized either as diamond-shaped plates or

stout rods all having the same melting point alone or admixed. An acetone or alcohol solution of the hydrocarbon has a strong violet fluorescence. When 3,5-dimethylcholanthrene is dissolved in concentrated sulfuric acid, a rose colored solution with a yellow fluorescence is formed. The hydrocarbon was characterized[12] by means of its ultraviolet absorption spectrum. The curve for this exhibits the maxima characteristic of the benz[*a*]-anthracene system which show a bathochromic shift of 30–40 Å. units when compared to positions of the maxima of cholanthrene (Table I). The same shift has been observed for the two methyl groups in 3,11- and 4,11-dimethylcholanthrene (Table I).

TABLE I

MAXIMA IN THE ULTRAVIOLET ABSORPTION SPECTRA OF CHOLANTHRENES (λ IN Å. UNITS) AND CORRESPONDING INTENSITIES (LOG E_M); SOLVENT, ETHANOL

[a] L. F. Fieser and E. B. Hershberg, THIS JOURNAL, 60, 940 (1938).

The method which has been most widely used for the preparation of substituted cholanthrenes is the Elbs pyrolysis of the appropriately substituted naphthoylhydrindenes.[13] In spite of the fact that pyrolysis of the ketone (VIII) could yield two possible isomers, caused by ring closure to either the *o*-methyl group or the *o*-methylene group, several efforts were made to prepare this substance with the aim of pyrolyzing it to 3,5-dimethylcholanthrene (III). By the chlorination of xylene,[14] 4-chloro-1,3-dimethylbenzene (V) was prepared. A Friedel–Crafts condensation of this compound with β-chloropropionyl chloride should produce theoretically three different isomeric chlorodimethyl-β-chloropropiophenones. Two of these possible isomers, *i. e.*, where substitution has taken place at the 5 or 6 positions of the 4-chloro-1,3-dimethylbenzene (V), would give the same and desired hydrindene (VII) after cyclization and Clemmensen reduction of the chlorodimethylhydrindones. One of these isomers, tentatively assigned the structure written as VI, was obtained as a sharp melting crystalline product. It gave a high yield (94%) of chlorodimethylhydrindone on ring closure with concentrated sulfuric acid. The chlorine atom in VII proved so highly hindered that a negligible yield of VIII was obtained by condensation of the lithium derivative with α-naphthonitrile. Attempts to exchange the chlorine atom in 4-chloro-5,7-dimethylhydrindene (VII) for a cyano group and then condense the resulting 4-cyano-5,7-dimethylhydrindene with α-naphthylmagnesium bromide were likewise fruitless.

An alternative path was sought in the reaction of 3′-keto-3,4-dihydro-1,2-cyclopentenophenanthrene (IX) with ethyl α-bromopropionate. It was planned to extend the side chain of the resulting acid (X) by the Arndt–Eistert procedure and then by aromatization and cyclization to arrive at the ketone (XI). 3,5-Dimethylcholanthrene could be derived from this ketone (XI) by an obvious series of reactions. However, the reaction of the ketone (IX) with ethyl α-bromopropionate gave a product which could not be characterized either as the ester or as the free acid.

Several other synthetic schemes were also explored but with less success than those described. Samples of 3,5-dimethylcholanthrene have been submitted to Dr. M. J. Shear, National Cancer Institute, and Dr. A. M. Seligman, for biological testing.

Experimental[15]

9,11-Dimethyl-8,9,10,11-tetrahydrobenz[*a*]anthryl-8-acetic Acid (II).—On warming a mixture of 2.0 g. of 8-keto-9,11-dimethyl-8,9,10,11-tetrahydrobenz[*a*]-anthracene,[9] 3 ml. of ethyl α-bromoacetate, 0.2 g. of iodine, 4.0 g. of 20-mesh zinc (thoroughly cleaned and dried), 20 ml. of dry ether and 20 ml. of dry benzene, a brisk spontaneous reaction set in. When the reaction subsided (fifteen minutes), the solution was refluxed for three hours, and hydrolyzed with dilute hydrochloric acid. The aqueous layer was extracted three times with ether, then the combined organic solutions were dried and concentrated. The deep red residue was warmed gently *in vacuo* and dissolved in a mixture of 30 ml. of dry alcohol and 20 ml. of dry benzene containing some anhydrous sodium sulfate. Dry hydrogen chloride was passed into the solution (chilled in an ice-bath) for one-half hour. The chloro compound was recovered by diluting the solution with water and extracting with ether. The ether solution was washed with dilute potassium carbonate solution, dried, and the solvent was removed. Dehydrohalogenation was effected by distilling the dark residue under two microns pressure at a bath temperature of 140–190°. The distillation was carried out very slowly to minimize a persistent tendency to bump. The light amber viscous distillate weighed 2.43 g. (98%). On one larger run, the distillation was stopped when 14.0 g. (78%) of the unsaturated ester had distilled during a period of one-hundred forty-four hours at 10^{-4} mm. (bath at 115–120°). In this case the still residue was a dark stiff glass which weighed 5.46 g. (31%).

The unsaturated ester (2.43 g., 0.0071 mole) was hydrogenated in absolute ethanol, using 0.34 g. of platinum oxide. During one and three-quarters hours, it absorbed 136 ml. of hydrogen at 27° (78% of the theoretical). This same hydrogen uptake was observed in a number of runs which varied in size. The saturated ester was obtained as a viscous yellow liquid. It was saponified in a nitrogen atmosphere with alcoholic potassium hydroxide. The alkaline solution was diluted with water, extracted with ether and acidified. The acid (II) precipitated as light yellow flakes and crystals which weighed 2.04 g. (87%) after filtering and air-drying. In other runs, yields as high as 95% were observed, based on the dimethyl ketone (I). A portion of the acid was crystallized once from ethanol, then from methanol, and was obtained as colorless needles which melted at 192.5–194°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 83.0; H, 6.96. Found: C, 83.3; H, 6.30.

1-Keto-3,5-dimethylcholanthrene.—The acid (II), 11.36 g. (including 3.06 g. of non-crystalline material), was cyclized by dissolving it in about 150 g. of anhydrous liquid hydrogen fluoride contained in a copper beaker surrounded by an ice-bath. After evaporation of the hydrogen fluoride, the residue was washed with water and with a solution of potassium carbonate, then triturated with acetone. The resulting solid was suspended in boiling benzene which was cooled slightly and diluted with ether. The solid product (yellow-brown crystals) was separated by filtration and crystallized twice from chloroform and twice from benzene. It was very difficultly soluble in both solvents, as well as acetone. The ketone forms brilliant yellow needles melting at 267–270°, and it gives a precipitate when heated with alcoholic 2,4-dinitrophenylhydrazine.

Anal. Calcd. for $C_{22}H_{16}O$: C, 89.2; H, 5.40. Found: C, 89.6; H, 5.57.

The **oxime** crystallized from chloroform as fluffy yellow needles which darkened at 245° and decomposed without melting at 254–258°.

Anal. Calcd. for $C_{22}H_{17}ON$: N, 4.50. Found: N, 4.42.

A total of 4.7 g. of this solid ketone was obtained. The acetone-soluble fraction composed 8.75 g. of a stiff red-brown oil. This was considered to be the tetrahydro ketone.

The solid ketone (3.5 g.), and the oily ketone (8.75 g.) were dissolved separately in 34-ml. portions of glacial acetic acid. To each of these solutions was added 50 ml. of toluene, 34 ml. of water, 200 ml. of concentrated hydrochloric acid, and 65 g. of amalgamated mossy zinc. The solutions were refluxed for forty-eight hours; 150 ml. of concentrated hydrochloric acid was added in 50-ml. portions at twelve-hour intervals. From each of these experiments, when worked up, was obtained a deep red gum. During the work-up, 1.3 g. of acidic material was recovered, presumably uncyclized (II). The products were combined, giving 10.1 g. of hydrocarbon.

3,5-Dimethylcholanthrene (III). A.—A 2-g. sample of the above product was dissolved in 50 ml. of *p*-cymene (terpene-free), 0.15 g. of 5% palladium–charcoal added and the solution heated to brisk boiling in a stream of carbon dioxide. The gases were collected in a nitrometer. In all, 202 ml. of inert gas (uncorrected for blank) were obtained during several days. The product recovered from this solution was an amber viscous substance (1.46 g.) which could not be made to crystallize. It was distilled under 4 microns pressure (bath at 140–170°). The 0.90 g. of light orange distillate (a viscous liquid) was crystallized from ethanol–benzene, giving 0.30 g. of orange-yellow needles, m. p. 170–173°. 3,5-Dimethylcholanthrene, after three crystallizations from ethanol–acetone, formed pale orange-yellow needles melting at 183–184°.

Anal. Calcd. for $C_{22}H_{18}$: C, 93.6; H, 6.45. Found: C, 93.4; H, 6.49.

B. Another sample of the Clemmensen product, 10.1 g., was heated with 1.50 g. of 5% palladium–charcoal at 300–310° for forty minutes. A brisk evolution of gas occurred at 285–310°. The cooled melt was repeatedly extracted with benzene; and the benzene solution, after filtering, was concentrated. The solution was diluted with an equal volume of ethanol, decolorized, and filtered. The filtrate gave 2.2 g. of yellow-brown plates, m. p. 175–179°. The mother liquors were evaporated to dryness and the residue triturated with boiling ethanol. An additional 2.7 g. of crystalline hydrocarbon was thus obtained. The ethanol solution deposited 0.5 g. of hydrocarbon, making a total yield of 5.5 g. (51%). The crude hydrocarbon was decolorized in acetone solution, then a benzene solution of it passed through alumina. The material recovered from the eluate was crystallized from acetone. A total of 3.28 g. of shining yellow-brown plates was obtained, which melted at 179–181°. A mixture of this material with the needle form of the hydrocarbon showed no depression of the melting point; it crystallized from ethanol as needles.

3,5-Dimethylcholanthrene forms a **picrate**, m. p. 179–180°, which dissociates when recrystallized from ethanol.

Anal. Calcd. for $C_{22}H_{18}\cdot C_6H_3N_3O_7$: N, 8.22. Found: N, 8.22.

The **trinitrobenzene derivative** forms massive dull red needles from ethanol, which melt at 189–190°.

Anal. Calcd. for $C_{22}H_{18}\cdot C_6H_3N_3O_6$: N, 8.48. Found: N, 8.24.

The **trinitrofluorenone derivative** crystallizes as blue microneedles, melting at 252–255°.

A Beckmann spectrophotometer was used for observation of the ultraviolet spectrum. The hydrocarbon, weighed on a microbalance, was dissolved in absolute ethanol, and the solution diluted accurately to a concentration of 0.0025 mg./ml.

β-(α-Naphthoyl)-propionic Acid.—The intermediate used for the preparation of compound (IX) was 1-keto-1,2,3,4-tetrahydrophenanthrene. Several methods were investigated for the preparation of this intermediate because it is a laborious task. One of the possible starting materials for its synthesis is β-(α-naphthoyl)-propionic acid. The following new method for the preparation of this starting material was explored. A benzene solution of di-α-naphthylcadmium (prepared by the general method

---

[15] All melting points were taken on a Fischer–Johns apparatus. Microanalyses are by Patricia Craig and Nelda Mold, Northwestern University.

of Cason and Prout[16] from 20.7 g. of α-bromonaphthalene and 9.7 g. of anhydrous cadmium chloride) reacted with 16.5 g. of carbomethoxypropionyl chloride. The crude ester isolated from this reaction was a pale yellow oil boiling at 184–188° (1 mm.). It was saponified with alcoholic potassium hydroxide, giving 10.2 g. (45%) of the free acid which after one crystallization from dilute ethanol melted at 133–134° (lit.[17] 132–133°).

This acid was also prepared by the customary[17] acylation of naphthalene with succinic anhydride, using tetrachloroethane as solvent in place of nitrobenzene.

Reaction between 3'-Keto-3,4-dihydro-1,2-cyclopentenophenanthrene (IX)[18] and Ethyl α-Bromopropionate.—A mixture of 2.20 g. of the ketone (X) (m. p. 214–216°), 2.09 g. of ethyl α-bromopropionate, 5 g. of thoroughly cleaned and dried 20-mesh zinc, 0.10 g. of iodine, 70 ml. of benzene, and 30 ml. of toluene was refluxed for four and one-half hours. The iodine color faded immediately, and the pale yellow solution became orange as the reaction progressed. Two additions of 2.5 g. of zinc were made at forty-five minute intervals, and 1.90 g. of bromoester was added after one and one-half hours. The neutral material isolated from this reaction was distilled in high vacuum; and the distillate, after numerous fruitless attempts at crystallization, was saponified with alcoholic potassium hydroxide. The acidic material so obtained was 2.52 g. (93%) of a very viscous liquid, which could not be made to crystallize. Only a small fraction of it was volatile in a high vacuum. When this reaction was carried out in ether-benzene solution, the ketone (IX) was recovered almost quantitatively.

Chloro-*m*-dimethyl-β-chloropropiophenone (VI).—Aluminum chloride, 72 g., was added in portions to a solution of 36 g. of β-chloropropionyl chloride and 40 g. of 4-chloro-1,3-dimethylbenzene[14] (b. p. 187–194° (760 mm.)) in 145 ml. of carbon disulfide. The addition required two to three hours. Stirring was continued overnight, and the reaction then heated briefly to 45°. The mixture was hydrolyzed, and the solvent layer after drying was distilled (keeping the temperature below 60°). The residue crystallized on chilling; it weighed 67.5 g. Trituration of this solid with methanol gave 20.7 g. of slightly yellow solid, m. p. 84–87°, suitable for cyclization. Seven crystallizations of this solid from petroleum ether produced the β-chloroketone (VI) with a melting point of 93–93.5°.

Anal. Calcd. for $C_{11}H_{12}OCl_2$: C, 57.1; H, 5.24. Found: C, 57.2; H, 5.32.

***x*-Chloro-*m*-dimethylhydrindone.**—A solution of 19 g. of the crude crystalline β-chloroketone (VI) in 50 ml. of benzene was slowly run into 150 ml. of concentrated sulfuric acid at 105–120°, with rapid stirring. The mixture was stirred for twenty minutes, then poured onto cracked ice. The precipitated solid, 15 g. (93.5%), when recrystallized once from methanol melted at 110–111°.

The non-crystalline substance recovered from the methanol washings above was cyclized separately. An additional 8 g. of hydrindone was so obtained.

Anal. Calcd. for $C_{11}H_{11}OCl$: C, 67.8; H, 5.70. Found: C, 67.8; H, 5.77.

4-Chloro-5,7-dimethylhydrindene (VII).—The chlorohydrindone, 10 g., was reduced by the Martin modification of the Clemmensen procedure.[10] The hydrindene was isolated as a colorless liquid, 8.67 g. (94%), which boiled at 126–129° (12 mm.); d^{26} 1.116; $n^{19}\text{D}$ 1.5549.

Anal. Calcd. for $C_{11}H_{13}Cl$: C, 73.1; H, 7.25. Found: C, 73.0; H, 7.15.

Attempts to Condense the Hydrindene (VII) with α-Naphthonitrile.—A mixture of 3.77 g. of the hydrindene (VII), 30 ml. of absolute ether and 0.32 g. of lithium metal cut into tiny pieces was refluxed and stirred in a nitrogen atmosphere for twenty-four hours. Although some of the lithium remained unreacted, 3.19 g. of α-naphthonitrile dissolved in 40 ml. of dry benzene was added and reflux with stirring continued for three hours. The material obtained from hydrolysis of the reaction mixture was refluxed with alcoholic hydrochloric acid, then distilled under reduced pressure. A large amount of the hydrindene (VII) was recovered and a very small amount of high boiling material. When di-*n*-butyl ether was used as the solvent for this reaction, 2.0 g. of the hydrindene required nineteen hours to react with 0.19 g. of lithium metal. However, treatment of the solution with 1.69 g. of the nitrile resulted in almost quantitative recovery of both starting materials.

Summary

1. 3,5-Dimethylcholanthrene has been prepared from 8-keto-9,11-dimethyl-8,9,10,11-tetrahydrobenz[a]anthracene and characterized by means of its ultraviolet spectrum. This dimethylcholanthrene has a second methyl group in the same position that would be occupied by the steroid side chain.

2. Attempts to prepare 3-naphthoyl-5,7-dimethylhydrindene, with the intention of pyrolyzing this ketone to 3,5-dimethylcholanthrene, were unsuccessful. Apparently the two *ortho* groups offer too much hindrance for the preparation of the ketone.

3. The Reformatsky reaction of 3'-keto-3,4-dihydro-1,2-cyclopentenophenanthrene with ethyl α-bromopropionate gave a product which could not be characterized.

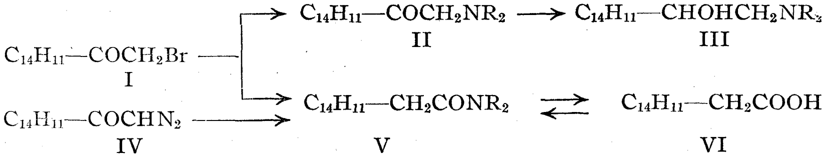
Studies in the Anthracene Series. V. A Novel Rearrangement in the Reaction of Halomethyl Ketones with Secondary Amines

BY EVERETTE L. MAY AND ERICH MOSETTIG

This investigation was undertaken with the purpose of synthesizing, for biological testing, alkamines in which the chain —$CHOHCH_2NR_2$ is attached to the *meso* position of 9,10-dihydroanthracene.

When 9-ω-bromoacetyl-9,10-dihydroanthracene (I) was allowed to react with secondary aliphatic amines, the expected amino ketones (II) were formed in yields of 30–40%. In addition, the isomeric 9-(9,10-dihydroanthryl)-acetamides (V) were obtained in yields of 40–50%.[1] It appears that a rearrangement has taken place similar to that of diazomethyl ketones to the corresponding homo-acid amides in the presence of amine and catalyst.[2]

The amides of type V proved to be exceedingly resistant to hydrolysis, but prolonged acid treatment ultimately gave the acid VI from which V ($R = C_2H_5$) was resynthesized. It was also obtained from 9,10-dihydro-9-anthroic acid in the Arndt–Eistert procedure *via* the diazomethyl ketone IV. A few attempts to convert IV directly to an amino ketone of type II failed. The amino ketones II ($R = C_2H_5$, C_3H_7, C_5H_{11}) were readily hydrogenated (platinum oxide) to the corresponding amino alcohols (III).



$C_{14}H_{11}$ = 9-(9,10-dihydroanthracyl), R = C_2H_5, C_3H_7, C_5H_{11}

Fig. 1.

In the course of this work we developed two convenient methods for the preparation of 9,10-dihydro-9-anthroic acid.[3] In the first, 9-cyanoanthracene[4] was saponified to the acid amide, which was reduced with hydriodic acid and phosphorus to the corresponding dihydro amide. Hydrolysis of the latter gave the acid in a yield of 82%, based on nitrile (70% based on anthracene). Secondly, reduction of 9-anthroic acid with sodium amalgam gave the dihydro acid in a yield of 80%. Reduction of 9-anthroic acid with hydriodic acid and phosphorus led to the desired acid in a yield of only 20%.

The amino alcohols III (R—C_2H_5, C_5H_{11}) were ineffective in blood-inoculated *gallinaceum* malaria.[5]

Acknowledgment.—The microanalyses were carried out by the microanalytical Laboratory of this Institute under the direction of C. A. Kinser. We are indebted to H. George Latham, Jr., for technical assistance.

Experimental[6]

9-Anthramide.—A mixture of 18.8 g. of 9-cyanoanthracene,[4] 17 g. of potassium hydroxide, 10 cc. of water and 75 cc. of ethylene glycol monoethyl ether (Cellosolve) was refluxed for two and one-half hours and diluted with water to give 20.5 g. of amide, m. p. 212–215°. It crystallized from aqueous ethanol in pale yellow needles, m. p. 215–216°.

Anal. Calcd. for $C_{15}H_{11}NO$: C, 81.4; H, 5.0. Found: C, 81.4; H, 5.3.

9,10-Dihydro-9-anthroic Acid.[3] (a) **From 9-Anthramide.**—A mixture of 20.5 g. of 9-anthramide, 5.6 g. of red phosphorus, 14 cc. of 57% hydriodic acid and 150 cc. of acetic acid was refluxed for seven hours, filtered hot, and diluted with twice its volume of water. The precipitate was washed with water and refluxed for two hours with 120 cc. of acetic acid and 60 cc. of concentrated hydrochloric acid. After dilution to 450 cc. with water and ice-cooling, the acid was collected and digested with an excess of dilute, boiling sodium carbonate. Filtration and acidification of the filtrate gave 17 g. (82%) of the dihydro acid of m. p. 199–202°.

(b) **By Sodium Amalgam Reduction of 9-Anthroic Acid.**—To a stirred mixture of 8.8 g. of 9-anthroic acid,[7] 2.4 g. of sodium carbonate and 100 cc. of water was added during forty-five minutes 200 g. of 2.5% sodium amalgam. The temperature was kept at 10°. After an additional ninety minutes the solution was decanted, treated with decolorizing carbon (Norit), filtered hot, and acidified; yield of acid 7.3 g., m. p. 201.5–203.5°.

N,N-Diethyl-9,10-dihydro-9-anthramide.—A mixture of 0.5 g. of 9,10-dihydro-9-anthroic acid and 1 cc. of thionyl chloride was refluxed for one hour and evaporated to dryness *in vacuo*. The residue, in dry ether, was treated slowly with 1 cc. of diethylamine. After filtration, the filtrate was evaporated to dryness to give a residue which crystallized from aqueous ethanol in long prisms of m. p. 99.5–100.5°; yield 0.5 g. (81%).

Anal. Calcd. for $C_{19}H_{21}NO$: C, 81.7; H, 7.6. Found: C, 81.5; H, 7.9.

9,10-Dihydro-9-anthroylguanidine (NIH 2932).[8]—To a stirred, ice-cooled mixture of 2 g. of guanidine hydrochloride, 2.1 g. of sodium hydroxide, 4 cc. of water and 4 cc. of acetone was added during thirty to forty minutes 4 g. of 9,10-dihydro-9-anthroyl chloride[3] in 16 cc. of acetone. After an additional one-half hour of stirring at

---

[1] Amide V ($R = C_2H_5$) was also obtained from 9-ω-chloroacetyl-9,10-dihydroanthracene. Piperidine, the only heterocyclic amine allowed to react with I, gave the homo-acid amide in a yield of only 15%.

N,N-Diethyl-9,10-dihydro-9-anthrylacetamide (V, R = C_2H_5).—A mixture of 5.0 g. of I,[3] 5 cc. of diethylamine, and 40 cc. of dry ether was shaken for one-half hour (slight cooling is necessary at first), diluted with about 20 cc. of ligroin (b. p. 30–60°) and cooled in ice to give 4.4 g. of precipitate which, when digested with water, yielded 2.2 g. (45%) of amide, m. p. 133–135°. It crystallized from methanol in long prisms of m. p. 134–135°.

Anal. Calcd. for $C_{20}H_{23}NO$: C, 81.9; H, 7.9; N, 4.8. Found: C, 81.4; H, 7.8; N, 4.7.

9-(2-Diethylamino-1-oxoethyl)-9,10-dihydroanthracene (II, R = C_2H_5) **Picrate.**—The filtrate from the 4.4 g. of precipitate above was washed three times with water, dried, and acidified with hydrogen chloride gas to give 1.5 g. of hydrochloride, m. p. 198–202°, after recrystallization from absolute ethanol–ether. A small sample was treated with aqueous alcoholic picric acid. The resulting picrate crystallized from 95% ethanol in yellow prisms, m. p. 127–129°.

Anal. Calcd. for $C_{26}H_{26}N_4O_8$: C, 59.8; H, 5.0. Found: C, 60.2; H, 5.2.

9-(2-Diethylamino-1-hydroxyethyl)-9,10-dihydroanthracene (III, R = C_2H_5) **Hydrochloride** (NIH 2874).—A mixture of 1.5 g. of the hydrochloride of II (R = C_2H_5), 0.05 g. of platinum oxide and 10 cc. of methanol absorbed one mole of hydrogen in three-fourths of an hour. The filtered solution was concentrated to about 3 cc. and diluted with ether to give 1.3 g. of the amino alcohol hydrochloride; prisms from methanol–ether, m. p. 200–202°.

Anal. Calcd. for $C_{20}H_{26}ClNO$: C, 72.4; H, 7.9. Found: C, 72.1; H, 7.8.

Synthesis of V (R = C_2H_5) **by the Arndt–Eistert Reaction.**—A solution of 1.7 g. of 9,10-dihydro-9-anthroyl chloride in 25 cc. of dry ether was added dropwise to 25 cc. of an ice-cooled, stirred ether solution of diazomethane (from 2.5 g. of nitrosomethylurea). After stirring for fifteen minutes in ice and for two hours at room temperature, the mixture was concentrated and diluted with ligroin to give 1.2 g. of IV, m. p. 104–106.5° (frothing). This diazo ketone (0.4 g.) in 4 cc. of dioxane was treated at 50–60° with a mixture of 0.5 cc. of diethylamine, 0.7 cc. of 10% silver nitrate, and 0.5 cc. of water. After refluxing for fifteen minutes the solution was filtered, diluted with a little water and cooled to give 0.3 g. (66%) of V (R = C_2H_5) of m. p. 132–134°. Recrystallized from methanol, it melted at 134–135°; the m. p. was not depressed by amide prepared as described above.

Hydrolysis of V (R = C_2H_5) **to 9,10-Dihydro-9-anthrylacetic Acid (VI).**—A mixture of 1 g. of the amide, 8 cc. of concentrated hydrochloric acid, and 2 cc. of acetic acid was refluxed vigorously for one week. During this time 4 cc. of concentrated hydrochloric acid and 1 cc. of acetic acid were added. The mixture was diluted with water, cooled, filtered, and the precipitate digested with boiling, dilute sodium carbonate. Filtration gave 0.15 g. of starting material. Acidification of the filtrate gave 0.6 g. (90% based on used amide) of VI, m. p. 165–168°. It crystallized from methanol–water in oblong plates of m. p. 168–169.5°. It appears to be oxidized slowly in air.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.7; H, 5.9. Found: C, 80.5; H, 6.2.

The acid VI was converted to the oily acid chloride with thionyl chloride. This acid chloride, in ether, was treated with diethylamine to give V (R = C_2H_5) in a yield of 90%.

9-(ω-Chloroacetyl)-9,10-dihydroanthracene.—To 0.3 g. of IV in ether was added dropwise 15% alcoholic hydrogen chloride until gas evolution had ceased. Dilution of the mixture with ligroin (b. p. 30–60°) gave 0.3 g. of needles. The analytical sample, from methanol, melted at 113–114°.

Anal. Calcd. for $C_{16}H_{13}ClO$: C, 74.9; H, 5.1. Found: C, 75.2; H, 5.2.

When this chloro ketone, in ether, was allowed to react with diethylamine, V (R = C_2H_5) was obtained in a yield of 45%.

9-(2-Dipropylamino-1-hydroxyethyl)-9,10-dihydroanthracene Hydrochloride (III, R = C_3H_7).—A mixture of 2 g. of I, 1.4 g. of dipropylamine and 15 cc. of dry ether was shaken for one-half hour, cooled in ice and filtered. The filtrate was shaken with three portions of dilute hydrochloric acid, dried, and the ether evaporated to give 1.2 g. of oily amide (V, R = C_3H_7) which was hydrolyzed to VI as described above. The combined aqueous fractions were basified with aqueous ammonia and the resulting oil dried in ether. The ethereal solution was acidified with 15% alcoholic hydrogen chloride to give, after recrystallization from acetone–ether, 0.6 g. of hydrochloride. This in 15 cc. of methanol with 0.01 g. of platinum oxide absorbed one mole of hydrogen during one hour. The filtered solution was evaporated to dryness *in vacuo*. The residue crystallized from acetone–ether in a yield of 0.5 g., m. p. 160–167°. The analytical sample melted at 171–172.5° after drying in a vacuum desiccator.

Anal. Calcd. for $C_{22}H_{30}ClNO$: C, 73.4; H, 8.4. Found: C, 73.6; H, 8.7.

The picrate crystallized from ethanol in yellow hexagons, m. p. 182–184°.

Anal. Calcd. for $C_{28}H_{32}N_4O_8$: C, 60.9; H, 5.8. Found: C, 61.0; H, 5.9.

9-(2-Diamylamino-1-hydroxyethyl)-9,10-dihydroanthracene (III, R = C_5H_{11}) **Hydrochloride** (NIH 2885).—A mixture of 3 g. of I, 3.3 g. of diamylamine and 25 cc. of dry ether was shaken for one-half hour, cooled in ice and filtered. The filtrate was acidified to congo red with hydrogen chloride gas, diluted with ligroin (b. p. 30–60°) and filtered. The 2 g. of solid was recrystallized from acetone–ether to give 1.6 g. of a mixture of II (R = C_5H_{11}) and diamylamine hydrochloride. This in 15 cc. of methanol with 0.05 g. of platinum oxide absorbed 0.85 mole of hydrogen in three-fourths hour. The filtered solution was evaporated to dryness *in vacuo*. The residue was triturated with ether–ethyl acetate to give 0.3 g. of diamylamine hydrochloride. Slight dilution of the filtrate with ligroin gave 1.0 g. of III (R = C_5H_{11}) hydrochloride. It crystallized from acetone–ether in triangles, m. p. 113–115.5°.

Anal. Calcd. for $C_{26}H_{38}ClNO \cdot {}^1/_2CH_3OH$: C, 73.7; H, 9.3; CH_3OH, 3.7. Found: C, 73.8; H, 9.2; loss in wt. (97° at 1 mm.), 4.5.

After the loss-in-weight determination, the sample was analyzed for carbon and hydrogen.

Anal. Calcd. for $C_{26}H_{38}ClNO$: C, 75.0; H, 9.2. Found: C, 74.6; H, 9.0.

The picrate crystallized from ethanol in yellow crusts of m. p. 143–145°.

Anal. Calcd. for $C_{32}H_{40}N_4O_8$: C, 63.1; H, 6.6. Found: C, 63.1; H, 6.5.

The ether–ligroin filtrate from the 2 g. of II (R = C_5H_{11}) above was washed with water, dried and evaporated to dryness. The residual oily amide (V, R = C_5H_{11}), hydrolyzed as described above, gave VI in a yield of 37%.

9,10-Dihydro-9-anthrylacetpiperidide (V, NR_2 = piperidino).—A mixture of 1.0 g. of I and 15 cc. of dry ether was swirled while adding 1 cc. of piperidine. The mixture was shaken vigorously for fifteen minutes and extracted three times with water. The dried ether solution was acidified with dry hydrogen chloride. The resulting semisolid was recrystallized from methanol–ether to give 0.9 g. of a precipitate which was digested with water and filtered. The crystals (0.15 g., m. p. 109–110.5°) were recrystallized from methanol–water to give the amide in long prisms, m. p. 108–110°.

Anal. Calcd. for $C_{21}H_{23}NO$: C, 82.6; H, 7.6. Found: C, 82.4; H, 7.6.

This compound was also prepared from VI as described above for V ($R = C_2H_5$).

9-(2-Piperidino-1-oxoethyl)-9,10-dihydroanthracene Hydrochloride.—The aqueous filtrate from the 0.15 g. of amide above was basified with aqueous ammonia and the liberated base dried in ether. The ethereal solution was acidified with 1.7 cc. of 15% alcoholic hydrogen chloride. Enough acetone and absolute ethanol were added to dissolve the precipitated oil. The amino ketone salt crystallized in a yield of 0.5 g., m. p. 221–223°; flakes from methanol–ether, m. p. 222–224° (d.).

Anal. Calcd. for $C_{21}H_{24}ClNO$: C, 73.8; H, 7.1. Found: C, 74.0; H, 7.1.

Summary

In the reaction of 9-ω-bromoacetyl-9,10-dihydroanthracene with secondary aliphatic amines, the 9-(2-dialkylamino-1-oxoethyl)-9,10-dihydroanthracenes and the corresponding amides of 9-(9,10-dihydroanthryl)-acetic acid were obtained in nearly equal amounts.

Two convenient methods for the preparation of 9,10-dihydro-9-anthroic acid are described.

Studies in the Anthracene Series. VI. Derivatives of 1,2,3,4-Tetrahydroanthracene

BY H. GEORGE LATHAM, JR., EVERETTE L. MAY AND ERICH MOSETTIG

As a key substance for further synthetic work, 9-bromo-1,2,3,4-tetrahydroanthracene was needed in quantity. Bachmann and Cronyn[1] have shown that the bromination of tetrahydrophenanthrene gives exclusively and in good yield, the 9-bromo derivative. When tetrahydroanthracene was similarly treated,[2] 9-bromo-1,2,3,4-tetrahydroanthracene (VIII) was formed in a yield of *ca.* 30%. In addition, varying amounts of a dibromo-1,2,3,4-tetrahydroanthracene (IX) could be isolated.

The position of the bromine atom in VIII was established in the following way: VIII was converted, with cuprous cyanide, to the nitrile VI, which was also synthesized from 9-anthroic acid (I) *via* II and III as shown in Fig. 1. Furthermore, we hydrolyzed VI to amide V which, again, was obtained in the catalytic hydrogenation of IV. The dibromo derivative IX appears to be identical with the compound cursorily described by Schroeter[3] as the only bromination product of tetrahydroanthracene. Since it can also be prepared from VIII, one of its bromine atoms must be located in position 9.

The conversion of VI into ketone X constitutes additional evidence for the structure of the latter[4] and supports the formula assigned to the oily acetyltetrahydroanthracene, obtained together with the 6 isomer in the Friedel–Crafts reaction on tetrahydroanthracene.[5]

9-Anthroic acid was conveniently prepared in a yield of 60–70% by heating under reflux, anthracene and oxalyl chloride in nitrobenzene.[6] When 9-bromoanthracene was treated under the same conditions, carboxylation took place to the extent of only 12%. The acid is obviously identical with the 9-bromo-10-anthroic acid of Beyer and Fritsch,[7] since it can be readily oxidized to 9,10-anthraquinone.

Acknowledgment.—We are indebted to Edward A. Garlock, Jr., for much of the preliminary work on the bromination of tetrahydroanthracene and the hydrogenation of 9-anthroic acid.

Experimental[8,9]

9-Anthroic Acid (I).—A mixture of 50 g. of anthracene,[10] 30 cc. of oxalyl chloride, and 150 cc. of dry nitrobenzene in a one-liter flask was heated in a metal-bath. A gentle reflux was maintained by raising the temperature of the bath from 120 to 240° during five to six hours. After steam-distillation of the nitrobenzene, 100 cc. of 10 *N* sodium hydroxide and enough water to make the total volume 700 cc. were added, and the mixture was refluxed for one-half hour. Insoluble material (11 g. of anthracene after purification)[11] was collected. The filtrate was washed with ligroin (b. p. 30–60°), treated with decolorizing carbon (Norit), filtered hot, and the Norit washed with 2 *N* sodium carbonate. Acidification of the combined filtrate and washings gave 41.6 g. (67%) of I, m. p. 208–212°.

9-Bromo-10-anthroic Acid.[7]—This acid was prepared from VIII, as described for I (reaction time twenty-five hours), in a yield of 12%, m. p. 263–266° (dec.). The

[6] We were unable to duplicate the experiments of Liebermann and Zsuffa [*Ber.*, **44**, 208 (1911)] who obtained 9-anthroic acid in yields of 70–80% by heating anthracene and oxalyl chloride in a sealed tube at 160–170°. In our hands the experiment yielded only 15–20% of 9-anthroic acid. Furthermore, Nenitzescu, *et al.* [*Ann.*, **491**, 210 (1931)] prepared 9-benzoylanthracene in nearly quantitative yields by refluxing a solution of anthracene and benzoyl chloride in nitrobenzene. In repeated attempts to reproduce the results of these authors, anthracene was hardly attacked and was recovered nearly quantitatively.

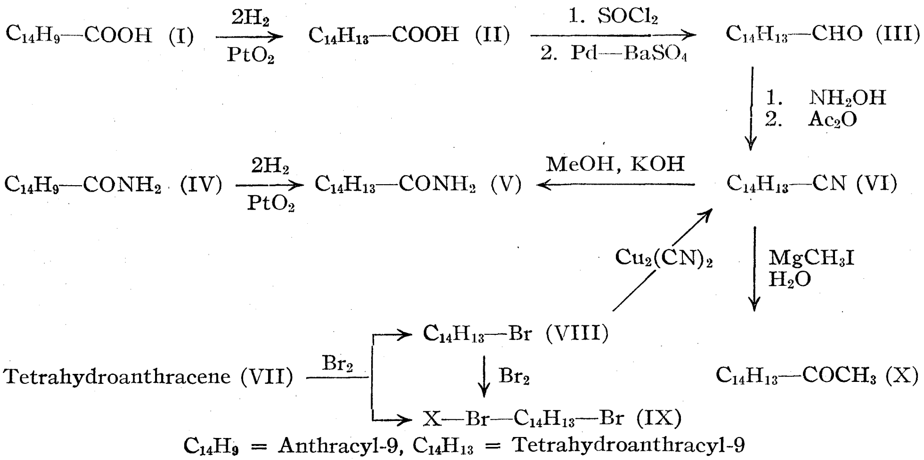
[11] During some preliminary work on this reaction, appreciable amounts of a yellow solid, m. p. 260–262°, were encountered.

Anal. Calcd. for $C_{29}H_{18}O$: C, 91.1; H, 4.7. Found: C, 90.8; H, 5.0.

This analysis indicates that the compound might be 9,9′-dianthryl ketone.



$C_{14}H_9$ = Anthracyl-9, $C_{14}H_{13}$ = Tetrahydroanthracyl-9

Fig. 1.

methyl ester melted at 112–114°. Oxidation of the acid with chromic acid gave 9,10-anthraquinone in a yield of 70%, m. p. 277–278°. The m. p. of the quinone was not depressed by authentic material.

1,2,3,4-Tetrahydro-9-anthroic Acid (II).[12]—A mixture of 10 g. of I (recrystallized from aqueous acetic acid), 0.3 g. of platinum oxide and 200 cc. of absolute ethanol absorbed 2000 cc. of hydrogen during two to three hours. The reaction was interrupted, catalyst was filtered, and the filtrate concentrated to one-fourth its volume. Ice-cooling gave 6.4 g. of II, m. p. 198–201°. This material was pure enough for use in the next reaction.

1,2,3,4-Tetrahydro-9-anthracenecarboxaldehyde (III).—A mixture of 5 g. of II and 10 cc. of thionyl chloride was refluxed for two hours, and excess reagent was distilled *in vacuo*. The resulting acid chloride was dissolved in 20 cc. of dry decalin, 0.6 g. of 5% palladium–barium sulfate was added, and a rapid stream of dry hydrogen bubbled through the mixture, heated to 175–180°. After one and one-half to two hours, hydrogen chloride evolution had almost ceased. The catalyst was filtered, and the solvent was distilled *in vacuo*. The residue was distilled at 0.05 mm. (bath temperature 175°) and the distillate crystallized from ether–ligroin (b. p. 30–60°) to give 2.0 g. (49%) of III, m. p. 53.5–55°. The analytical sample melted at 54.5–56°; light yellow prisms.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.7; H, 6.7. Found: C, 85.9; H, 6.8.

The oxime, prepared from hydroxylamine hydrochloride, sodium carbonate, and aqueous ethanol, crystallized from methanol in long prisms of m. p. 158.5–160°.

Anal. Calcd. for $C_{15}H_{15}NO$: C, 80.0; H, 6.7. Found: C, 79.8; H, 6.7.

1,2,3,4-Tetrahydro-9-anthronitrile (VI).—The above oxime (0.5 g.) and 5 cc. of acetic anhydride were refluxed for fifteen minutes. Addition of water and cooling gave a solid which, after recrystallization from ethanol (Norit), weighed 0.3 g. (65%), m. p. 84.5–86°. The analytical sample melted at 85–86.5°, plates.

Anal. Calcd. for $C_{15}H_{13}N$: C, 86.9; H, 6.3. Found: C, 87.0; H, 6.4.

9-Bromo-1,2,3,4-tetrahydroanthracene (VIII).—To a mixture of 100 g. of VII,[5] 10 g. of reduced iron powder, and 800 cc. of benzene was added (stirring at 3° to 6°) during three-fourths hour, 90 g. of bromine in 200 cc. of benzene. After stirring at 0 to 5° for four hours, the mixture was filtered. The filtrate was washed three times with 5 *N* sodium carbonate and dried over sodium sulfate. Evaporation of solvent and distillation of the residue at 3 mm. gave (1) 10–15 g. of mainly VII, b. p. 160–170°, (2) 85 g., b. p. 180–190° and (3) about 10 g., b. p. 190–201°. Fraction (2) was dissolved in about 60 cc. of ligroin (b. p. 85–100°) and the solution cooled in ice for fifteen minutes. The supernatant liquid was decanted from a mass of prisms which were washed with a little cold ligroin. The prisms were dissolved in 300 cc. of absolute ethanol to give, after cooling at room temperature for three to four hours, 27 g. of VIII, m. p. 59–61°. It crystallized from ethanol in prisms of m. p. 60.5–61.5°.

Anal. Calcd. for $C_{14}H_{13}Br$: C, 64.4; H, 5.0. Found: C, 64.7; H, 4.8.

The ligroin filtrate and washings above gave an additional 19 g. of VIII (total yield 32%) after tedious fractional crystallizations from ethanol and from ligroin.

9,x-Dibromo-1,2,3,4-tetrahydroanthracene (IX).—Fraction (3) was recrystallized three times from ligroin (b. p. 85–100°) to give 3.2 g. of IX, m. p. 165–166°[7]. In addition 5 g. of IX was obtained in the course of the isolation of the 19 g. of VIII; needles.

Anal. Calcd. for $C_{14}H_{12}Br_2$: C, 49.4; H, 3.6. Found: C, 49.4; H, 3.6.

Compound IX was also obtained in a yield of 20% by brominating VIII according to the above procedure. It melted at 164–166° and the m. p. was not depressed by the IX isolated as described above.

Conversion of VIII to VI.—A mixture of 5 g. of VIII and 2.5 g. of cuprous cyanide was heated for two to three hours at 245–255°. Distillation at 0.1 mm. (bath temperature 180–200°) followed by recrystallization of the distillate from 95% ethanol gave 3.0 g. (75%) of plates, m. p. 85–87.5°. Mixed with VI prepared from I *via* II and III, it melted at 85.5–87°.

1,2,3,4-Tetrahydro-9-anthramide (V). (a) By Hydrolysis of VI.—A mixture of 0.5 g. of VI, 5 g. of potassium hydroxide, 25 cc. of methanol and 1 cc. of water was refluxed for twenty hours and diluted with water to give 0.4 g. of V, m. p. 203–207°. It crystallized from methanol–water in prisms, m. p. 210–211.5°.

Anal. Calcd. for $C_{15}H_{15}NO$: C, 80.0; H, 6.7. Found: C, 80.3; H, 6.7.

(b) **By Hydrogenation of 9-Anthramide.**—A mixture of 0.5 g. of 9-anthramide,[13] 0.05 g. of platinum oxide, and 10 cc. of methanol absorbed two moles of hydrogen in seventeen hours. The filtered solution was concentrated to about 5 cc. and diluted with a little water to give 0.4 g. of prisms, m. p. 209–211°. When mixed with the V prepared as described under (a), the melting point was unchanged.

9-Acetyl-1,2,3,4-tetrahydroanthracene (X).—Two grams of VI in 10 cc. of dry benzene was added dropwise to a

stirred mixture of 12 cc. of 1 *M* methylmagnesium iodide in 25 cc. of dry benzene. The mixture was stirred and refluxed for 3.5 hours and poured into 75 cc. of saturated ammonium chloride. The benzene layer was extracted with two 50-cc. portions of *N* hydrochloric acid. To the combined extracts was added 10 cc. of concentrated hydrochloric acid and the solution refluxed for fifty hours. The resulting dark oil was dried in ether and evaporatively distilled at 150–170° (0.5 mm.). Recrystallization of the distillate from methanol gave 0.15 g. of prisms, m. p. 71–73°. The m. p. was not depressed by mixture with X previously prepared.

Summary

In the bromination of tetrahydroanthracene, 9-bromo-1,2,3,4-tetrahydroanthracene is formed in a yield of *ca.* 30%.

Its structure has been established by linking it with 9-anthroic acid.

A simple and efficient preparative method for 9-anthroic acid is described.

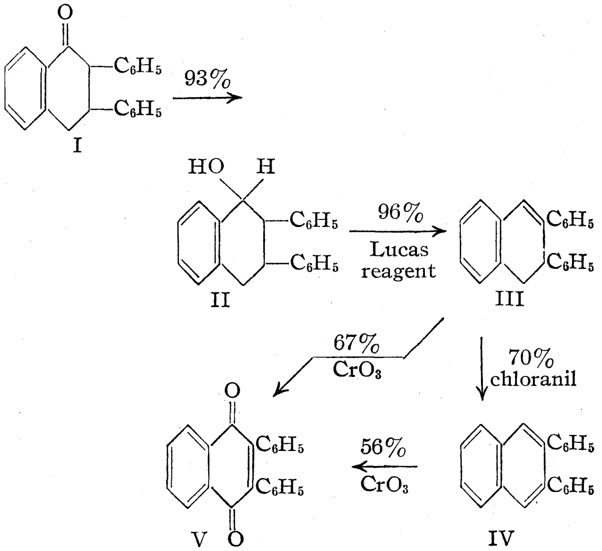
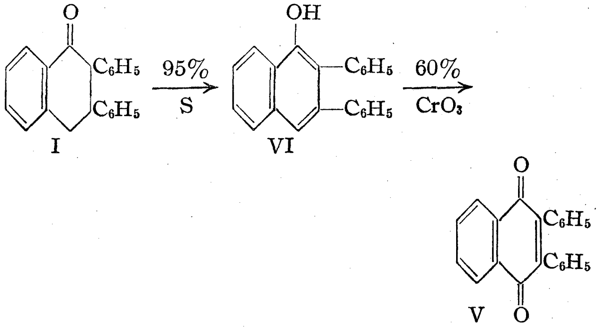
The Preparation of 2,3-Diphenyl-1,4-naphthoquinone and its Reaction with Phenylmagnesium Bromide and Phenyllithium

BY H. MARJORIE CRAWFORD

2,3-Diphenyl-1,4-naphthoquinone has been prepared by Crawford and Nelson[1] by the series of reactions



and by Bergmann and Szmuszkovic[2] as follows:



In preparing this quinone in larger quantities for the study reported here, variations in these procedures were carried out in attempts to improve the yield. Direct oxidation of 2,3-diphenyl-1,2-dihydronaphthalene (III) with chromium trioxide in glacial acetic acid gave 67% of the quinone (V). This makes the over-all yield of the quinone from the tetralone about 60% as compared to 35% when the dehydrogenation step is included. This is a more satisfactory method of preparing the quinone than that described by Bergmann[2] for, although three steps are involved instead of two, the yield is about the same and the products are much more easily purified.

Dehydrogenation of the tetralone (I) by sulfur gave the naphthol (VI) in 85–90% yields but there were red products formed which made the purification of the naphthol by recrystallization very difficult. In variations of the dehydrogenation reaction, selenium and chloranil gave poorer yields than sulfur. In the oxidation of the naphthol (VI) with chromium trioxide, the quinone (V) was obtained in 30–60% yields, accompanied by a high molecular weight white compound melting at 265–267°, and considerable quantities of yellowish oils.

As it has already been shown,[3,4,5] the reactions of phenylmagnesium bromide with methyl substituted naphthoquinones give complex mixtures of products. The solid compounds isolated from these mixtures resulted from both 1,2-additions to the carbonyl group and 1,4-additions to the conjugated systems, as well as reduction of the quinones to the hydroquinones and the accompanying formation of biphenyl. When phenyllithium reacted with these methyl substituted naphthoquinones the only products isolated were those resulting from the 1,2-addition of two molecules of the reagent to the carbonyl groups.

The behavior of 2,3-diphenyl-1,4-naphthoquinone has now been studied, hoping that the phenyl groups would be large enough to prevent the 1,4-

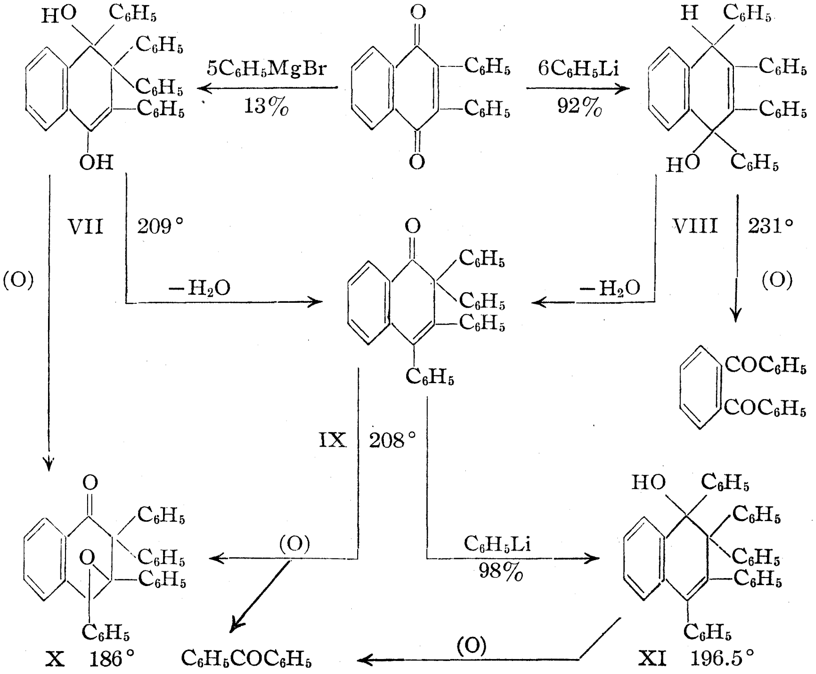
addition of the phenylmagnesium bromide to the conjugated system. This hope has not been realized, for the only addition product isolated was that resulting from the 1,2- and 1,4-addition of two molecules of phenylmagnesium bromide to one molecule of the quinone. Biphenyl and the hydroquinone were formed as in the other cases. Phenyllithium, on the other hand, gave excellent yields (92%) of the 1,2-1,2-diaddition product.

The two diols resulting from these reactions were dehydrated with great ease to give practically quantitative yields of a single rearrangement product.

The relationships of these compounds are summarized below.



The structure of VIII was established by oxidation to benzoic acid and *o*-dibenzoylbenzene (38%). It was impossible to obtain direct evidence for the structure of VII since attempts to oxidize it with potassium permanganate gave only unchanged starting material, and oxidation with chromium trioxide in glacial acetic acid gave the same product (X) which was formed by the oxidation of IX. Later it was shown that simply boiling VII in glacial acetic acid for one hour caused dehydration and rearrangement to give IX. In other cases of the addition of phenylmagnesium bromide to naphthoquinones[3,5,6] the principal product has always been the compound resulting from 1,2- and 1,4-additions of two molecules of phenylmagnesium bromide to one molecule of the quinone. Analytical data show that VII is a diaddition product, and it is different from VIII which is the 1,2-1,2-diaddition compound. The structure proposed for VII would represent the first product of the reaction but it may well exist in the keto form.

Compound IX is quite inert, having been recovered unchanged from boiling for one hour with potassium permanganate or potassium dichromate, from attempts to make a 2,4-dinitrophenylhydrazone, from treatment with perbenzoic acid, and from treatment with alkaline hydrogen peroxide. Oxidation of IX with chromium trioxide in glacial acetic acid gave benzoic acid, benzophenone (identified as the 2,4-dinitrophenylhydrazone) and compound X. This type of rearrangement accompanying dehydration has been encountered before[4] in compounds similar in structure to VII and VIII and the formation of benzophenone locates two of the phenyl groups on the same carbon atom. Compound IX reacted readily with phenyllithium to give a 98% yield of a product for which structure XI is proposed. Phenylmagnesium bromide also reacted readily and gave a mixture of products which have not been identified. Compound X corresponds to the addition of one atom of oxygen to IX, and the epoxide structure is suggested as the most probable one although it is inert toward every reagent tried with the exception of phenyllithium. It was recovered unchanged from attempts to make the 2,4-dinitrophenylhydrazone, from heating for forty hours with acetic acid and potassium iodide or for eight hours with dilute sulfuric acid. Its inertness to oxidation is indicated by its mode of formation.

Experimental

Preparation of 2,3-Diphenyl-1,4-naphthoquinone, V.—This quinone was prepared by the oxidation of various compounds by chromium trioxide in glacial acetic acid. The oxidation of 2,3-diphenylnaphthalene[1] (IV) gave 56% of the quinone. The oxidation of 2,3-diphenyl-1-naphthol[2] (VI) gave 30–60% of the quinone. The oxidation of 2,3-diphenyl-1,2-dihydronaphthalene (III) is described here for the first time.

Oxidation of 2,3-Diphenyl-1,2-dihydronaphthalene, III.—2,3-Diphenyl-1,2-dihydronaphthalene (16 g.) was refluxed for fifteen minutes with 32 g. of chromium trioxide, 25 ml. of water and 200 ml. of glacial acetic acid. After pouring onto ice and diluting with water, the solid was filtered off and crystallized from ethyl alcohol. The resulting 2,3-diphenyl-1,4-naphthoquinone (11.9 g., 67%) melted at 133–140°. Another crystallization from ethyl alcohol or glacial acetic acid raised the melting point to 138–140°.

Dehydrogenation of 2,3-Diphenyl-1-keto-1,2,3,4-tetrahydronaphthalene (I) by Selenium and by Chloranil.—Heating 4.5 g. of the tetralone (I) and 1.3 g. of selenium at 290° for twelve hours, dissolving the cooled mass in ether,

---

(6) Smith and Hoehn, This Journal, **61**, 2619 (1939).

boiling with Norite and filtering from Norite and selenium gave 0.9 g. (20%) of the naphthol (VI) and much black tar.

The tetralone (4.5 g., 0.015 mole) was refluxed for five hours with 4.5 g. (0.018 mole) of chloranil and 20 ml. of xylene. The mixture was cooled, diluted with petroleum ether and allowed to stand overnight, after which most of the tetrachlorohydroquinone could be removed by filtration. The last traces could be removed by extraction with 4% potassium hydroxide solution, as the 2,3-diphenyl-1-naphthol was not dissolved under these conditions. Evaporation of the solvent gave 1.03 g. of unchanged tetralone and black tar. This result is in marked contrast to the good yield (70%) of 2,3-diphenylnaphthalene (IV) obtained from 2,3-diphenyl-1,2-dihydronaphthalene (III) by means of chloranil.[1]

The Reaction between 2,3-Diphenyl-1,4-naphthoquinone and Phenylmagnesium Bromide.—As in other studies of this type[3,5,7] the quantities of reactants and the method of procedure were varied. In some cases the phenylmagnesium bromide (0.1 mole) was added to a solution of 6.2 g. (0.02 mole) of the quinone in ether. In other cases the quinone (0.02 mole) in ether was added to the phenylmagnesium bromide (0.1 mole) in ether. In still other cases the quinone (0.025 mole) was extracted from a soxhlet by a boiling solution of phenylmagnesium bromide (0.15 mole) in ether. After standing overnight, the reaction mixtures, usually containing a brown solid, were decomposed with ice and either dilute hydrochloric acid or ammonium chloride solution. The dried ether extracts of these mixtures were allowed to stand and various crops of solids were filtered off and recrystallized.

These variations made little difference in the amounts of the products obtained from this quinone. The only solid addition product which could be isolated was the white compound VII which was obtained in about 13% yield. The quinone or the hydroquinone could always be isolated and steam distillation of the residue gave biphenyl. The final residue was a dark oil. Even when the hydroquinone was detected among the products, recrystallization in the presence of air caused its oxidation to the quinone and there was always the problem of separating the quinone from VII. This could be best accomplished by using a mixture of benzene and petroleum ether as the solvent for recrystallization.

1,2,2,3-Tetraphenyl-1,4-dihydroxy-1,2-dihydronaphthalene, VII, m. p. 208–210°.—This white solid was the only addition product isolated (13%) from the reaction between 2,3-diphenyl-1,4-naphthoquinone and phenylmagnesium bromide. It is soluble in the usual solvents such as ether, ethyl alcohol, ethyl acetate and benzene, but is only slightly soluble in petroleum ether. The best solvent for separating it from quinone (after first filtering the mixture of solids from the oily reaction mixture) was a mixture of benzene and petroleum ether. VII was recovered unchanged after three hours of refluxing with alkaline potassium permanganate. When 1 g. of VII was refluxed for six hours with 3 g. of potassium dichromate, 25 ml. of glacial acetic acid, 1 ml. of water and 10 drops of concd. sulfuric acid, the only product isolated was benzoic acid. When 1 g. of VII was boiled for five minutes with 1 g. of chromium trioxide and 10 ml. of glacial acetic acid the only product obtained was X, which was the same compound obtained by the oxidation of IX. When 0.75 g. of VII was refluxed for one hour with 0.4 g. of iodine in 10 ml. of glacial acetic acid it lost a molecule of water and was converted quantitatively into IX. After the oxidation of VII was found to give the same product as the oxidation of IX, experiments were carried out to show that the iodine was not necessary in the dehydration. Boiling VII with acetic anhydride or with glacial acetic acid for one hour converted it into IX. Since this was the case, no conclusion could be drawn as to the structure of VII from the oxidation experiments.

Anal. Calcd. for $C_{34}H_{26}O_2$ (466.6): C, 87.5; H, 5.6. Found: C, 87.6, 87.1; H, 5.8, 5.8; mol. wt., 456.

1,2,3,4-Tetraphenyl-1,4-dihydroxy-1,4-dihydronaphthalene, VIII, m. p. 231–233°.—This white solid was the only product of the reaction between 2,3-diphenyl-1,4-naphthoquinone and phenyllithium. The phenyllithium (0.15 mole) in ether was refluxed and the quinone (0.025 mole) was extracted from a soxhlet. The extraction required about one hour. The mixture was then decomposed with ice and dilute hydrochloric acid. The clear ether and water layers were separated from the white solid and the water layer was discarded. Evaporation of the ether layer gave more solid identical with that separated earlier. Crystallization from ethyl alcohol and ethyl acetate gave a pure compound melting 231–233° (yield 92%). Refluxing VIII (3 g.) for one hour in 50 ml. of glacial acetic acid with 0.5 g. of iodine gave IX (yield, 90%). Refluxing VIII (0.5 g.) with 10 ml. of acetic anhydride gave a quantitative yield of IX. Oxidation of VIII (2 g.) by refluxing for five minutes with 2 g. of chromium trioxide and 10 ml. of glacial acetic acid gave *o*-dibenzoylbenzene (38%) and benzoic acid, identified by comparison with known samples. Oxidation of VIII (2 g.) by boiling for four hours with 6 g. of potassium dichromate in 50 ml. of glacial acetic acid gave 1.75 g. of solid, which was a mixture of IX and a small amount of an unidentified white solid, m. p. 168–170°, which may have been impure X.

Anal. Calcd. for $C_{34}H_{26}O_2$ (466.6): C, 87.5; H, 5.6. Found: C, 85.9, 86.3; H, 6.2, 6.0; mol. wt., 468.

2,2,3,4-Tetraphenyl-1-keto-1,2-dihydronaphthalene, IX, m. p. 208–210°.—This pale yellow compound was formed very readily and in excellent yields (90–100%) from either VII or VIII by the loss of a molecule of water, accompanied by the migration of a phenyl group. The dehydration could be brought about by boiling either of the diaddition products with acetic anhydride, with glacial acetic acid and a trace of iodine, or with glacial acetic acid alone if a longer time were allowed. The solution was diluted with water, the solid filtered off and recrystallized from ethyl alcohol and ethyl acetate. IX was quite soluble in the latter and only slightly soluble in the former. The only reagents which had any effect on IX were phenylmagnesium bromide, phenyllithium and chromium trioxide. Treatment of IX (2.24 g.) with a large excess of phenyllithium caused the ether to boil vigorously. After refluxing for five minutes, the mixture was poured onto ice and made acid with dilute hydrochloric acid. The ether layer gave 2.58 g. (98%) of XI. IX does not react in such a clean cut fashion with phenylmagnesium bromide but gave a mixture of yellow products. IX does not react with cold chromium trioxide but is oxidized on heating. Two grams of IX, 2 g. of chromium trioxide and 10 ml. of glacial acetic acid were refluxed for five minutes, then poured onto ice. After the ether extract was treated with potassium hydroxide solution, benzoic acid was isolated from the alkaline layer and benzophenone and X (46%) were recovered from the ether layer. The benzophenone was identified as the 2,4-dinitrophenylhydrazone. IX was recovered unchanged after boiling for two hours with potassium dichromate in glacial acetic acid, after boiling with neutral or acid potassium permanganate, after treatment with perbenzoic acid or alkaline hydrogen peroxide, and after attempts to make a 2,4-dinitrophenylhydrazone.

Anal. Calcd. for $C_{34}H_{24}O$ (448.5): C, 91.0; H, 5.4. Found: C, 91.1, 91.0; H, 5.7, 5.7; mol. wt., 453.

2,2,3,4-Tetraphenyl-1-keto-3,4-epoxy-1,2,3,4-tetrahydronaphthalene, X, m. p. 186–187°.—This white compound was formed by the chromium trioxide oxidation of IX or VII (probably following its rearrangement to IX). It is very inert, having been recovered unchanged after attempts to make a 2,4-dinitrophenylhydrazone, after eighteen hours heating on the steam-bath with 10 ml. of glacial acetic acid, 8 ml. of water and 2 ml. of concd. sulfuric acid, and after refluxing for six days with sodium hydroxide in alcohol, or forty hours with potassium iodide and acetic acid. It turns yellow when exposed to light. With phenyllithium it reacts to give a white compound, melting about 260°, which was not identified.

Anal. Calcd. for $C_{34}H_{24}O_2$ (464.5): C, 87.9; H, 5.2. Found: C, 87.4, 87.4; H, 5.4, 5.2; mol. wt., 467.

1,2,2,3,4-Pentaphenyl-1-hydroxy-1,2-dihydronaphthalene, XI, m. p. 196.5–197.5°.—This white compound was formed in 98% yield from the reaction of phenyllithium on IX. Oxidation of 1.5 g. of XI by boiling for five minutes with 1.5 g. of chromium trioxide in 10 ml. of glacial acetic acid gave only a pinkish oil from which a small amount of benzophenone could be isolated as the 2,4-dinitrophenylhydrazone.

Anal. Calcd. for $C_{40}H_{30}O$ (526.6): C, 91.2; H, 5.7. Found: C, 90.4, 89.9; H, 5.9, 6.2; mol. wt., 520.

Summary

The reactions of 2,3-diphenyl-1,4-naphthoquinone with phenylmagnesium bromide and phenyllithium have been studied.

Structures have been proposed for the main products of these reactions and for the compound which results from the dehydration of both of them.

Five new compounds are described.

An improved method is described for the preparation of 2,3-diphenyl-1,4-naphthoquinone in three steps from 2,3-diphenyl-1-keto-1,2,3,4-tetrahydronaphthalene in 60% over-all yield.

Amines Related to 2,5-Dimethoxyphenethylamine. IV. 2,5-Diethoxy, 2-Hydroxy-5-methoxy and 2-Hydroxy-5-ethoxyphenylalkanolamines[1]

BY WALTER S. IDE AND RICHARD BALTZLY

In continuation of our studies on this interesting family of pressors, we report the preparation of the primary and secondary β-hydroxy-β-(2,5-diethoxyphenyl)-ethylamines and isopropylamines, and their analogs having hydroxyl groups in the 2-position with methoxyl or ethoxyl groups in the 5-position.

The 2,5-diethoxy family (I–IV) was prepared by a line of synthesis shown in the upper part of Chart I. In the main, this approach resembles that used in Paper II[2] of this series to prepare the corresponding dimethoxy compounds. The 2,5-diethoxyphenylalkanolamines and their precursors tend to be more soluble and less readily crystallized than their methoxy analogs and were usually isolated in lower yield.

The preparations of the 2-hydroxy-5-alkoxyphenylalkanolamines (V–XII) largely followed the scheme used in Paper III of this series[3] for the 2-hydroxy-5-methylphenylalkanolamines. These syntheses are outlined in the lower part of Chart I. A few comments are in order.

In the first preparation of the aminoalcohol VII, the isonitrosoketone VIIb was reduced directly with platinum in ethanolic hydrogen chloride solution. Compound VII was obtained without difficulty although it later became apparent that other substances were present in the mother liquors. In a later preparation, palladized charcoal was used for the first stage of the reduction and the 2-benzyloxyaminoketone hydrochloride, VIIa, was isolated as the major product. It is rather surprising that the 2-benzyl group was retained in the presence of this catalyst; the only rational explanation is that the sample of palladized charcoal had been partially inactivated. Successive hydrogenations of VIIa with fresh palladized charcoal and with platinum yielded VII.

In the preparation of Compound IX, the usually reliable hexamethylenetetramine method broke down, only traces of chloroform-insoluble material being obtained from the reaction of hexamethylene tetramine and IXc.[4] The bromoketone was then treated with benzhydrylamine[5] but apparently considerable tertiary as well as secondary amine was formed and the desired product was not readily separated. The synthesis of IX was finally accomplished by treating IXc with dibenzylamine. The reaction was slow and far from quantitative (in contrast to similar reactions with benzylmethylamine) but the tertiary amine IXb was isolated easily. On hydrogenation with palladized charcoal, IXb absorbed two mols of hydrogen rapidly at room temperature and a third more slowly at 65°.[6]

At the time this work was started, attempts were made to prepare amino alcohols having the

[1] This work is part of a joint research being carried out in collaboration with a pharmacological group in the same laboratories.

[2] Baltzly and Buck, THIS JOURNAL, **62**, 164 (1940).

[3] Ardis, Baltzly and Schoen, *ibid.*, **68**, 591 (1946).

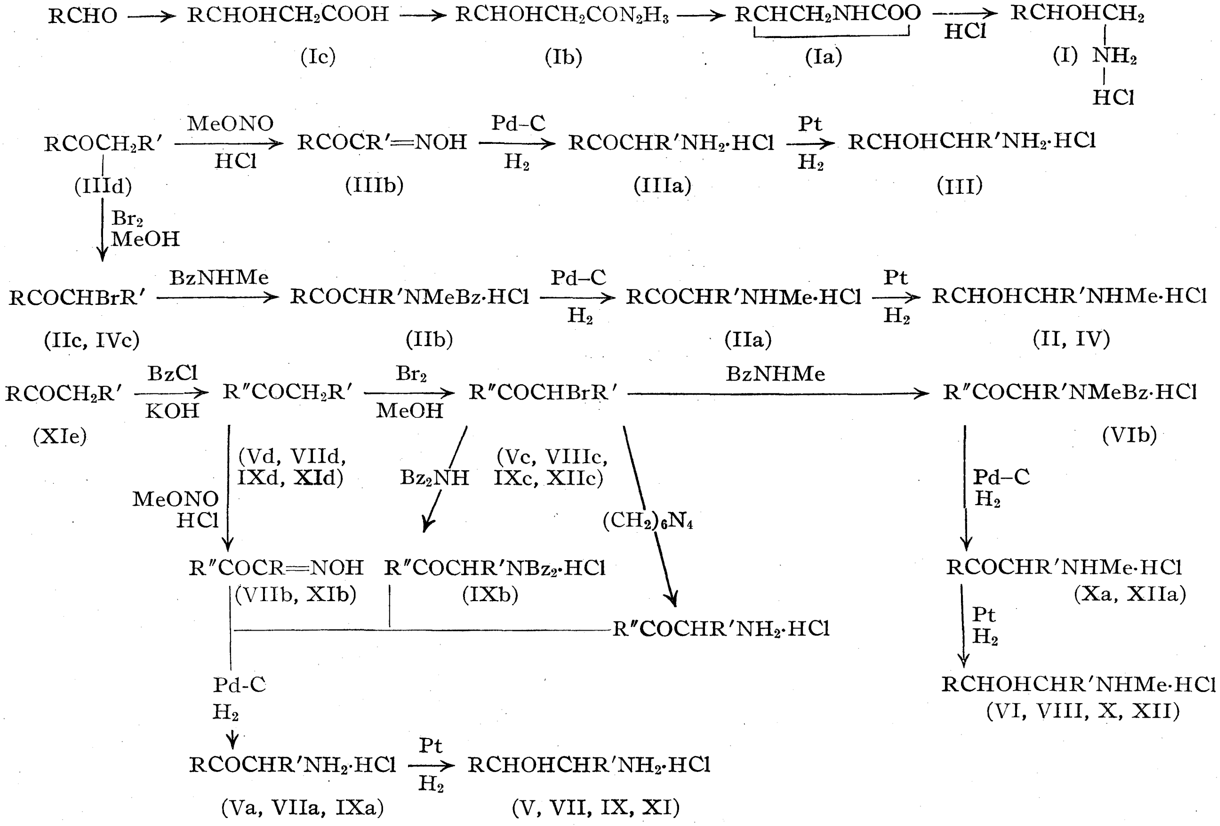
[4] Although this bromoketone is not especially active the failure of the preparation cannot be attributed to sluggishness since IXc reacts with reasonable speed with benzylmethylamine, benzhydrylamine and dibenzylamine. We are inclined to suspect that the initial reaction product was relatively soluble in chloroform and was accordingly exposed to the further reactions with bromoketone that should be possible from the conventional formula for hexamethylenetetramine but which are usually avoided by the precipitation of the first reaction-product. In the work reported in Paper III of this series it was found that if the temperature in a hexamethylenetetramine reaction was above 30–40°, the usual reaction product sometimes failed to precipitate. The original paper on this method as applied to phenacyl halides (Mannich and Hahn, *Ber.*, **44**, 1542 (1911) states that the reactions were carried out at room temperature but gives no indication that this condition is essential.

[5] *Cf.* Suter and Ruddy, THIS JOURNAL, **66**, 747 (1944).

[6] *Cf.* Simonoff and Hartung, *J. Amer. Pharmaceutical Assoc.*, **35**, 306 (1946). Obviously, this method involves a cleavage of benzylphenacylamine. It has gradually become apparent that although the benzyl group is usually removed preferentially from benzylphenacyl, benzyl β-hydroxyphenethyl and benzyl phenethylamines, these other groups have considerable labilizing effect, cleavage being achieved under conditions comparable with those required for cleavage of dibenzylamines.

CHART I

The numbers are those of new substances isolated in pure form: Bz = benzyl; R = 2,5-diethoxyphenyl for I, II, III, IV; R = 2-hydroxy-5-methoxyphenyl for V, VI, VII, VIII; R = 2-hydroxy-5-ethoxyphenyl for IX, X, XI, XII; R = 2-benzyloxy-5-methoxyphenyl for VIIa; R″ = benzyl ether of corresponding hydroxyphenyl compound; R′ = H for II, V, VI, IX, X; R′ = Me for III, IV, VII, VIII XI, XII.



2-hydroxyl group protected in form of an ester. The acetylation of 2-hydroxy-5-methoxypropiophenone yielded 2-acetoxy-5-methoxypropiophenone (XIIId) which was brominated in methanol (with de-esterification) to 2-hydroxy-5-methoxy-α-bromopropiophenone (XIIIc). Carbethoxylation of 2-hydroxy-5-methoxypropiophenone followed by nitrosation gave 2-ethylcarbonato-5-methoxy-α-isonitrosopropiophenone (XIVb). On hydrogenation it was found that the carbethoxyl was lost and this line of synthesis was abandoned.[3]

Since Compounds III, IV, VII, VIII, XI and XII were prepared by hydrogenation of ketones in weakly acidic solution, it is reasonable to assume that they possess the ephedrine rather than the pseudo ephedrine configuration.

Physiological Properties.—An extended report on the pharmacology of these substances will be published elsewhere. Briefly, the 2-hydroxy-5-methoxyphenylalkanolamines resemble rather closely their 2,5-dimethoxy analogs which are powerful, long-acting pressors, but are somewhat less potent and less toxic. Potency falls off in the other two classes, the 2,5-diethoxyphenylalkanolamines being the least active, and also the most toxic. Of the Compounds I–IV, only Compound III is at all comparable to the 2,5-dimethoxy series in length of action.

Experimental

Physical and analytical data on the substances isolated in pure form are presented in Table I. All melting points are corrected.

2-Hydroxy-5-alkoxyketones and 2,5-Diethoxyketones.—These compounds were prepared by Friedel–Crafts reactions between hydroquinone dialkyl ethers and the appropriate acyl chlorides or anhydrides. Since in these Friedel–Crafts reactions there is little tendency to form tarry or polymeric material, anhydrides were not superior to acyl chlorides for our purposes. In our hands some *o*-hydroxy ketone was always formed even under conditions designed to minimize dealkylation (addition of aluminum chloride to the other reactants below 5° and short reflux times). The amount of dealkylation could, however, be held below 20% under mild conditions. When more drastic conditions were employed (addition of acyl chloride last without temperature control and with longer reflux times) up to about 40% of 2-hydroxy-5-alkoxyketone could be obtained. With hydroquinone dimethyl ether the 2,5-dimethoxyketones were still isolated in 45–60% yield together with small amounts of starting material. With hydroquinone diethyl ether, dealkylation seemed to be easier and the more drastic conditions resulted in extensive formation of 2,5-dihydroxyketones which were not conveniently separated at this point. Mixtures of the 2-hydroxy-5-ethoxy and of 2,5-dihydroxyketones were usually benzylated, giving products easily separable by distillation.

2-Benzyloxy-5-alkoxyketones.—The crude alkali-soluble fractions from Friedel–Crafts reactions were benzylated in methanol with potassium hydroxide and benzyl chloride, slightly less than one equivalent of each being added initially with two later additions of half equivalents at two-hour intervals. Stirring was found to be desirable in order to minimize bumping. The products were washed with alkali, dried over potassium carbonate and distilled *in vacuo*. Yields varied from 60–90% dependent largely on the amount of dihydroxyketone present.

α-Bromoketones.—Bromination was carried out in methanol solution as described in Paper III of this series.[3] Yields of pure product varied between 55 and 90%, the lower yields corresponding to the lower-melting and more soluble compounds.

α-Isonitrosopropiophenones.—The propiophenones were nitrosated by the methyl nitrite method of Hartung and Crossley.[7] Yields were from 50–75% of pure isonitrosoketone.

Tertiary Aminoketones.—The technique used in the reaction of benzylmethylamine with the α-bromoketones was that of Ardis, Baltzly and Schoen.[3] It became apparent during the course of this work that the acetic anhydride treatment was not adequate to remove traces of secondary amine from the tertiary aminoketones and, due largely to this defect, only two of the six α-benzylmethylamines were obtained analytically pure. One of these, IIb, was isolated in an 89% yield, the other (VIb) in only 20%. The quantities of benzylmethylamine hydrobromide precipitated from the reaction mixture were in all cases approximately the calculated amount and it is believed that the reaction itself is effectively quantitative. Of the four tertiary aminoketones that had to be reduced as crude preparations, two afforded pure α-methylaminoketones (Xa and XIIa) after debenzylation. The yields of Xa and XIIa were 90 and 55%, respectively, reckoned on the crude tertiary aminoketones employed. In the other two lines of synthesis, only the final aminoalcohols (IV and VIII) were completely pure—the intermediates were crystalline but apparently contaminated with tenacious impurities.

Compound IXb (2-benzyloxy-5-ethoxy-α-dibenzylaminoacetophenone) was prepared by treating 0.05 mole of the corresponding bromoketone (IXc) with 0.1 mole of dibenzylamine in 500 cc. of absolute ether at room temperature. After standing 40 hours, 7 g. (0.025 mole) of dibenzylamine hydrobromide was obtained. Only 3 g. more separated after standing three days longer. The filtrate from the salt was extracted with water, allowed to stand three hours with 5 cc. of acetic anhydride and then shaken with 1 *N* hydrochloric acid solution. At this point, a copious precipitate formed and was filtered off. After recrystallization of this solid, analysis showed it to be the desired product (IXb). The yield was 60%. The technique of Simonoff and Hartung[6] might have given better results but seemed inadvisable at the time.

α-Methylaminoketones.—The palladized charcoal reduction of the α-benzylmethylaminoketone hydrochlorides removed the N-benzyl groups smoothly and the 2-benzyl group when present. Compounds IIa, Xa and XIIa were isolated in good yield. The product of the reduction of VIb was hydrogenated directly with platinum without attempting the isolation of the intermediate. The precursors of IV and VIII, although crystalline, could not be purified so as to give satisfactory analyses. When debenzylation can be applied to a pure substance the reaction is usually quantitative. The reduction of IIb, for example, gave the calculated quantity of IIa, and after two recrystallizations the yield was 75%.

α-Aminoketones.—Compound Va was prepared by the hexamethylenetetramine method. The initial product of the hydrolysis with alcoholic hydrogen chloride of the addition compound from hexamethylenetetramine and Vc was not readily separated from ammonium chloride. The crude product, contaminated with ammonium chloride, was debenzylated with palladized charcoal yielding Va which was purified easily. The yield was 55% from the bromoketone Vc. A similar situation had been found with the 5-methyl analog.[3] The debenzylation of IXb afforded IXa in quantitative yield.

The aminopropiophenones IIIa and VIIa were prepared by reduction of the corresponding isonitroso ketones with palladized charcoal in alcoholic hydrogen chloride solution. Yields were 60–70% of pure material. The reduction of XIb to XI was performed in two stages with no attempt to isolate the intermediate aminoketone.

Aminoalcohols.—With the exception of Compound I, all the aminoalcohols were prepared by hydrogenation of the corresponding aminoketone hydrochlorides with platinum catalyst. Yields of pure compounds were 40 to 90% dependent largely on losses in crystallization.

Compound I was prepared by the line of synthesis indicated in Chart I and followed by Baltzly and Buck,[2] in the preparation of the 2,5-dimethoxy analog. The substances shown in Chart I are those actually isolated. The 2,5-diethoxybenzaldehyde was prepared in 57% yield by the Gattermann reaction. The product from the Reformatzky reaction of this aldehyde and ethyl bromoacetate was saponified in the cold and the β-hydroxy acid Ic (yield 72%) was purified by recrystallization. Reesterification was accomplished by the use of diazomethane (to avoid dehydration) and the ester was refluxed directly with alcoholic hydrazine hydrate forming Ib, in effect quantitatively. The azide obtained from Ib by the action of cold nitrous acid was taken up in benzene and dried briefly. Cautious warming of the benzene solution of the azide produced the oxazolidone Ia in 67% yield from the hydrazide. Cleavage with cold concentrated hydrochloric acid[8] afforded I, yield 50% after two crystallizations.

Acknowledgment.—The authors wish to express their gratitude to Mr. Samuel W. Blackman for the microanalyses here reported.

Summary

The primary and secondary aminoalcohols of the 2,5-diethoxy, 2-hydroxy-5-methoxy and 2-hydroxy-5-ethoxyphenethyl and phenylisopropylamine series have been prepared.

Pyrimidine. III. Study of the Bromination of 5-Acetyl-4-methyl-2-phenylpyrimidine[1]

BY RAY A. CLARKE, BRUCE GRAHAM AND BERT E. CHRISTENSEN

An amino alcohol substituent in the 5-position of the pyrimidine nucleus has recently been reported in the literature.[2] A series of these compounds were prepared by coupling various secondary amines with 5-acetyl-4-methyl-2-phenylpyrimidine by means of the Mannich reaction. Since this procedure gives one type of amino alcohol, the preparation of amino alcohols by reaction of amines with bromomethyl ketones was investigated.

The bromomethyl ketones are usually prepared either by direct bromination of the acetyl derivative or by the diazomethane synthesis. Whenever possible this latter method is preferable since it utilizes the acid rather than the less common acetyl derivatives of the desired nucleus.

4-Methyl-2-phenyl-5-pyrimidinecarboxylic acid was prepared according to the directions of Mitter and Bardham.[3] Preliminary attempts to convert the acid to the bromomethyl ketone by means of the diazomethane synthesis were unsuccessful.

For this reason, the direct bromination of the easily prepared 5-acetyl-4-methyl-2-phenylpyrimidine (Fig. 1, I) was studied. Bromination in chloroform solution at room temperature gave over a 90% yield of crude bromination product. Analysis and solubility characteristics indicated the crude product to be the hydrobromide salt of the bromo derivative.

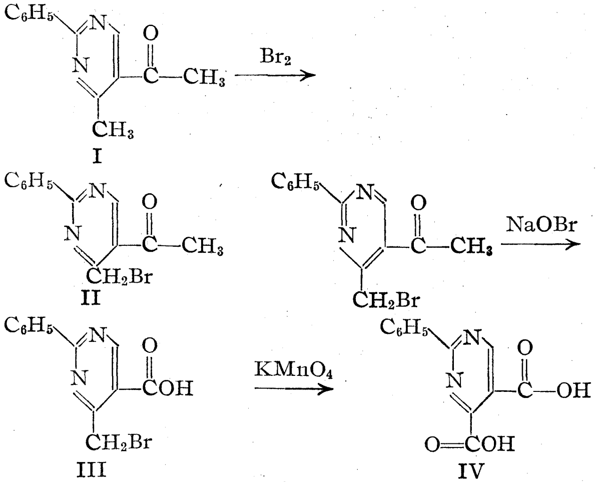

Fig. 1.

It was very evident from initial tests that this brominated derivative was probably an isomeric mixture. The crude product loses the ionizable bromine atom very readily. Shaking the material with chloroform containing a small amount of water converted it to the free base.

The principal product of the bromination was a petroleum ether insoluble compound. The structure of this compound was established to be 5-acetyl-4-bromomethyl-2-phenylpyrimidine (II) on the basis of oxidation studies. Sodium hypobromite oxidized the compound to an acid (III) which still retained one bromine atom. The same procedure using 5-acetyl-4-methyl-2-phenylpyrimidine gave a product which was identical with 4-methyl-2-phenyl-5-pyrimidinecarboxylic acid. Potassium permanganate oxidation of the bromo acid gave a dicarboxylic acid which analysis indicated to be the 2-phenyl-4,5-dicarboxylic acid (IV).

The 5-acetyl-4-bromomethyl-2-phenylpyrimidine reacted readily with amines in a benzene–ether solution. The 5-acetyl-4-morpholinomethyl-2-phenylpyrimidine hydrochloride was oxidized with sodium hypobromite to the 5-carboxyl-4-morpholinomethyl-2-phenylpyrimidine hydrochloride which confirmed the position of the amino substituent.

Experimental

Bromination of 5-Acetyl-4-methyl-2-phenylpyrimidine.—Eleven and one-half grams (0.054 mole) of 5-acetyl-4-methyl-2-phenylpyrimidine was dissolved in 75 ml. of chloroform. Two and eight-tenths milliliters (0.054 mole) of bromine in 15 ml. of chloroform was added to the solution of the acetylpyrimidine. The solution was then placed in a quartz beaker, fitted with a cover and exposed to ultraviolet light. After one and one-fourth hours the bromine color had disappeared and the solution was diluted with an equal volume of dry ether to precipitate a white to light yellow solid, 18.5 g. (92% yield).

Anal. of crude mixture. Calcd. for $C_{13}H_{12}Br_2N_2O$: Br total, 43.0; ionizable, 21.5. Found: Br total, 44.5; ionizable, 21.3.

Separation and Purification of 5-Acetyl-4-bromomethyl-2-phenylpyrimidine.—Hydrogen bromide was removed from the crude bromine-containing mixture (10 g.) by shaking it in a separatory funnel with 35 ml. of chloroform and 5 ml. of water. The chloroform was removed from the extract by distillation under reduced pressure leaving 7.5 g. of a white solid.

This solid was placed in a soxhlet thimble and extracted in a soxhlet apparatus with petroleum ether (boiling range, 36–65°). The insoluble material (4.10 g.) left in the thimble was the crude 5-acetyl-4-bromomethyl-2-phenylpyrimidine. As an alternate purification procedure 0.50 g. of the crude bromination product was dissolved in 15 ml. of hot isopropyl alcohol. Upon cooling, crystals (0.23 g.) deposited which were identical with petroleum ether insoluble fractions. The pure material (m. p. 168–170°) was obtained as white needles by several recrystallizations from ligroin (boiling range 97–140°).

Anal. Calcd. for $C_{13}H_{11}BrN_2O$: Br, 27.5; C, 53.61; H, 3.81. Found: Br, 27.4; C, 53.23; H, 4.16.

4-Bromomethyl-2-phenylpyrimidine-5-carboxylic Acid.—5-Acetyl-4-bromo-methyl-2-phenylpyrimidine (1.00 g., 0.00344 mole) was dissolved in 20 ml. of warm dioxane. A sodium hypobromite solution was prepared by adding a solution of 1.30 g. (0.0275 mole, assuming 85% purity) of sodium hydroxide in 10 ml. water to 0.71 ml. (0.0138 mole) of bromine. The sodium hypobromite was then added to the dioxane solution. The temperature immediately rose to 60° and the solution became reddish brown in color. After about two minutes, the solution was cooled and diluted with 50 ml. of cold water. A small amount (0.25 g.) of starting material precipitated and was removed by filtration. The aqueous solution was extracted with ether to remove bromoform and was then treated with an aqueous sodium bisulfite solution, until a negative starch-potassium iodide test was obtained, to reduce excess sodium hypobromite. Acidification with nitric acid precipitated a solid. This was filtered by suction and washed with water. The yield of the crude acid was 0.48 g. (62%).

Anal. Calcd. for $C_{12}H_9BrN_2O_2$: Br, 27.3; neutral equivalent, 293. Found: Br, 25.6; neutral equivalent, 290.

2-Phenylpyrimidine-4,5-dicarboxylic Acid.—The crude 4-bromomethyl-2-phenyl-5-pyrimidinecarboxylic acid (0.66 g. 0.00225 mole) was dissolved in an equivalent molar amount of dilute sodium hydroxide solution. A solution of 1.19 g. (0.075 mole) of potassium permanganate in 60 ml. of water was added and the resulting solution was refluxed for one and one-half hours. After cooling to room temperature, the excess permanganate was reduced with sulfur dioxide and the manganese dioxide was removed by centrifuging. The supernatant liquid was evaporated to a volume of 25 ml. and the hot solution was acidified with nitric acid. The dicarboxylic acid gradually crystallized on cooling and was removed by filtration and washed with water. The weight of product was 0.32 g. This acid was purified for analysis by one recrystallization from hot water. It melted (capillary tube) at 279–281° with decomposition.

Anal. Calcd. for $C_{12}H_8N_2O_4$: N, 11.47; neutral equivalent, 122. Found: N, 11.36; neutral equivalent, 123.

Directions for Reaction of Amines with 5-Acetyl-4-bromomethyl-2-phenylpyrimidine.—Three-tenths gram (0.00103 mole) of 5-acetyl-4-bromomethyl-2-phenyl-pyrimidine was dissolved in 5 ml. of warm benzene. To this solution was added 0.00206 mole of the free base. Usually after a few minutes the hydrobromide of the free base (*i. e.*, morpholine hydrobromide) formed. Dry ether was then added to the mixture and the solid removed by filtration and washed with dry ether. Dry hydrogen chloride was passed into the filtrate to precipitate the product as a white solid. This was removed by filtration and washed with dry ether.

5-Acetyl-4-dimethylaminomethyl-2-phenylpyrimidine Hydrochloride.—The product was purified by recrystallization from absolute ethanol to obtain a white crystalline product, 63% yield, m. p. 236° with decomposition:

Anal. Calcd. for $C_{15}H_{18}ClN_3O$: C, 61.75; H, 6.18; N, 14.40; Cl, 12.17. Found: C, 61.97; H, 6.50; N, 14.30; Cl, 12.05.

5-Acetyl-4-morpholinomethyl-2-phenylpyrimidine Hydrochloride.—The product was purified by recrystallization from 3 *N* hydrochloric acid. The yield was 84% of fine white needles which started to decompose at 213° and finally melted with decomposition at 220°.

Anal. Calcd. for $C_{17}H_{20}ClN_3O_2$: N, 12.60; Cl, 10.63. Found: N, 12.51; Cl, 10.40.

5-Acetyl-4-diethylaminomethyl-2-phenylpyrimidine Hydrochloride.—The yield of crude product was 95%. This was purified by recrystallization (twice) with absolute ethanol resulting in white crystals, m. p. 215–220° with decomposition.

Anal. Calcd. for $C_{17}H_{22}ClN_3O$: N, 13.15; Cl, 11.10. Found: N, 13.10; Cl, 11.02.

Directions for the Reduction of the Amino Ketones.—Two to two and one-half grams of the amino ketone hydrochloride was dissolved in 100 ml. methanol and reduced with hydrogen at 30 pounds pressure using platinum oxide catalyst (50 mg.). After shaking for a few hours, the catalyst was removed by filtration and the filtrate evaporated to dryness.

4-Dimethylaminomethyl-5-(1-hydroxyethyl)-2-phenylpyrimidine Hydrochloride.—The residue from the reduction was dissolved in 75 ml. of hot absolute ethanol, and diluted with equal volume of dry ether. The crystalline product which formed on standing was removed by filtration. This product melted at 236–237°; yield was 75%.

Anal. Calcd. for $C_{15}H_{20}ClN_3O$: C, 61.33; H, 6.81; N, 14.31; Cl, 12.08. Found: C, 61.36; H, 7.11; N, 14.36; Cl, 12.0.

A mixed melting point determination of the reduced and unreduced dimethylamine derivative indicated that they were not identical compounds, m. p. 220–225° with decomposition.

5-(1-Hydroxyethyl)-4-morpholinomethyl-2-phenylpyrimidine Hydrochloride.—Since the acetylmorpholinomethylphenylpyrimidine was only slightly soluble in ethanol or methanol it was first converted to the free base. Two and one-half grams of 5-acetyl-4-morpholinomethyl-2-phenylpyrimidine hydrochloride was converted to the free base with 5% sodium bicarbonate, extracted with ether and the ether evaporated. The residue was reduced in the usual manner. The reduction product (a sirupy residue) was dissolved in dry ether and dry hydrogen chloride was added to precipitate the product as the hydrochloride. The solid was removed by filtration and dissolved in 50 ml. of hot absolute ethanol. The alcohol solution was diluted with an equal volume of dry ether and the solution allowed to stand. The crystals which gradually formed were removed. This solid was recrystallized again in a similar manner to give 42% yield of white crystals, m. p. 230–232°, softening and darkening at about 220°.

Anal. Calcd. for $C_{17}H_{22}ClN_3O_2$: C, 60.80; H, 6.56; N, 12.52; Cl, 10.57; Found: C, 60.87; H, 6.76; N, 12.22; Cl, 10.50.

4-Diethylaminomethyl-5-(1-hydroxyethyl)-2-phenylpyrimidine Hydrochloride.—The residue from the reduction was dissolved in 20 ml. of hot absolute ethanol and diluted with 40 ml. of dry ether. The crystalline solid which formed on standing was removed and recrystallized again in a similar manner to give 71% yield of a crystalline product, m. p. 185–187°.

Anal. Calcd. for $C_{17}H_{24}ClN_3O$: C, 63.45; H, 7.47; N, 13.07; Cl, 11.03. Found: C, 63.75; H, 7.69; N, 13.19; Cl, 10.95.

5-Carboxy-4-morpholinomethyl-2-phenylpyrimidine Hydrochloride.—5-Acetyl-4-morpholinomethyl-2-phenylpyrimidine hydrochloride (0.50 g., 0.0015 mole) was suspended in 5 ml. of dioxane. A sodium hypobromite solution was prepared by adding a solution of 0.636 g. of sodium hydroxide in 10 ml. of water to 0.31 ml. (0.006 mole) of bromine. The sodium hypobromite solution was added to the dioxane suspension. The reaction was exothermic, and the solution became dark red in color. After standing for fifteen minutes the solution was diluted with 40 ml. of water and extracted with ether. The excess sodium hypobromite was reduced by adding a few drops of a saturated sodium bisulfite solution and the solution was then acidified with concentrated hydrochloric acid. A fine crystalline solid gradually formed on standing. This was removed by filtration yielding 0.24 g. of a tan-colored solid. Two-tenths gram of this material was recrystallized from isopropyl alcohol containing dry hydrogen chloride to yield 0.13 g. of product.

Anal. Calcd. for $C_{16}H_{18}ClN_3O_3$: N, 12.52; Cl, 10.58; neutral equivalent, 168. Found: N, 12.92; Cl, 10.34; neutral equivalent, 173.

Summary

Bromination of 5-acetyl-4-methyl-2-phenyl-

pyrimidine gave 5-acetyl-4-bromomethyl-2-phenylpyrimidine as one of the bromination products. Its structure was established by oxidation to 4-bromomethyl-2-phenyl-5-pyrimidine-carboxylic acid and 2-phenyl-4-,5-pyrimidinedicarboxylic acid.

By the coupling of 5-acetyl-4-bromomethyl-2-phenylpyrimidine with various secondary amines (dimethylamine, diethylamine, morpholine) followed by catalytic reduction, compounds of the type 4-dialkylaminomethyl-5-(1-hydroxyethyl)-2-phenylpyrimidine have been prepared.

Condensation of Some Tertiary Octyl Alcohols with Benzene

BY RALPH C. HUSTON, GORDON L. GOERNER, E. ROBERT BREINING,[1a] CHARLES O. BOSTWICK,[1b] KENNETH D. CLINE[1c] AND LOUIS J. SNYDER[1d]

Previous communications[2] from this Laboratory have reported the condensation of eight of the seventeen possible tertiary octyl alcohols with benzene in the presence of aluminum chloride. The purpose of this investigation was to condense the remaining tertiary octyl alcohols with benzene and to determine the boiling points, refractive indices and surface tensions of the resulting octylbenzenes. To this end, the alcohols shown in Table I were prepared.[3] Of these, 3,4-dimethyl-3-hexanol has not been reported previously. This alcohol was synthesized successfully from 3-methyl-2-pentanone and ethyl Grignard reagent and from 3-methyl-4-hexanone and methyl Grignard reagent. Attempts to prepare it from butanone and secondary butyl Grignard reagent failed, the product being contaminated with large amounts of homomesityl oxide, which boils at approximately the same temperature as the desired alcohol.[4]

[h] Whitmore and Laughlin, *ibid.*, **54**, 4392 (1932).

In general the condensations of the alcohols with benzene were carried out as described previously.[2c,5] The products were distilled under diminished pressure, traces of octyl chloride were removed from the octylbenzene fraction by refluxing with alcoholic potassium hydroxide or alcoholic silver nitrate, and the octylbenzene fraction was carefully distilled through a Fenske-type column.

Our results agree with previous observations from this Laboratory[2b,5] that branching on the β-carbon atom of the alcohol results in a decreased yield of the octylbenzene (see Table II). The alcohols without branching on the β-carbon atom, namely, 3-methyl-3-heptanol, 4-methyl-4-heptanol, 3-ethyl-3-hexanol and 2,4-dimethyl-4-hexanol gave their respective octylbenzenes in yields of 19 to 31%. These hydrocarbons possess closely related physical properties and the determined molecular refractions are within 0.1 unit of the theoretical value. Because of the large yields of pure hydrocarbons with practically constant boiling points and indices of refraction, the accuracy with which the physical constants of these compounds were determined is greater than for the other four octylbenzenes.

Those alcohols with branching on one β-carbon atom, 2,3-dimethyl-3-hexanol, 3,4-dimethyl-3-hexanol, and 2-methyl-3-ethyl-3-pentanol fall into a second group. The crude octylbenzene fraction obtained from these is more complex than that obtained from the alcohols in the first group. Fractionation gave only a few grams (5 to 9%) of ma-

(3) The condensation of 2,3,3-trimethyl-2-pentanol is now being reinvestigated along with the condensation of 2,2,3-trimethyl-3-pentanol.

(4) Grignard and Fluchaire, *Ann. chim.*, **9**, 27 (1927), have shown that butanone yields homomesityl oxide when treated with bromo- or iodo-magnesium butoxides. Since appreciable quantities of 2-butanol were recovered in our work, the bromo-magnesium alkoxide of this alcohol was probably responsible for the condensation.

terial with nearly constant boiling point and index of refraction. Figure 1 shows the weight of hydrocarbon plotted against index of refraction for 3,4-dimethyl-3-phenylhexane and 2-methyl-3-ethyl-3-phenylpentane. The portions with constant index of refraction at 1.4850 and 1.4860 are considered to be hydrocarbons of maximum obtainable purity under the experimental conditions used. Although the 2,3-dimethyl-3-phenylhexane was passed through a spinning band column[6] 80 cm. in length rather than through the Fenske-type column, its constants are almost identical with those of the two hydrocarbons just described. The observed molecular refractions for these three compounds varied from the theoretical by 0.35 to 0.61 unit.

The alcohol with branching on two β-carbon atoms, 2,3,4-trimethyl-3-pentanol, gave a low yield of the corresponding octylbenzene. Although the 2,3,4-trimethyl-3-phenylpentane has a high refractive index, the value corresponds quite closely to the 1.4958 reported for 2,3,4-trimethyl-2-phenylpentane.[2c] The observed molecular refraction checks the theoretical very closely.

Each of these eight octylbenzenes was nitrated, reduced, diazotized and hydrolyzed to the corresponding para-tertiary octylphenol.[7] The phenols were identified by the melting points of their derivatives. Nitration was shown to be *para* to the alkyl group by oxidizing the nitro derivatives to *p*-nitrobenzoic acid.

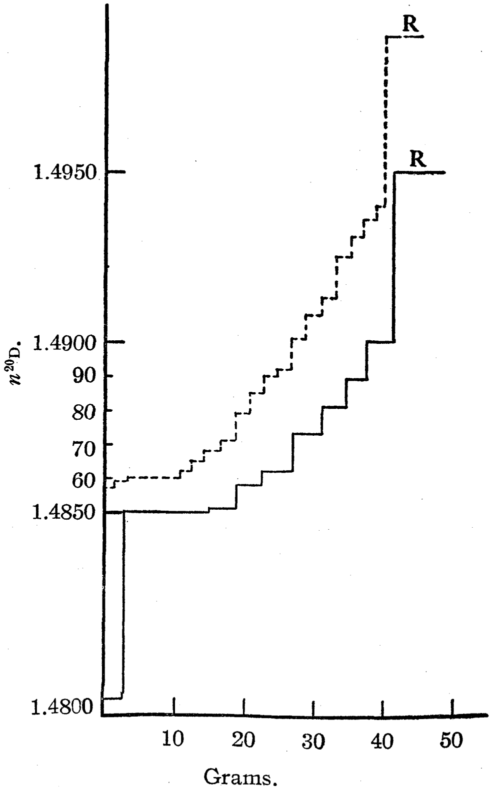

Fig. 1.—Refractive index *vs.* weight for distillation of crude octylbenzene fraction of 2-methyl-3-ethyl-3-phenylpentane — (from 1.25 moles of alcohol) and 3,4-dimethyl-3-phenylhexane - - - - (from 1 mole of alcohol). R is the residue in each distillation.

Experimental

Boiling points are uncorrected unless otherwise noted.

Preparation of Alcohols.—The alcohols were prepared by the reaction of the appropriate carbonyl compound and Grignard reagent as shown in Table I.

3,4-Dimethyl-3-hexanol. (a) From 3-Methyl-2-pentanone and Ethylmagnesium Bromide.—One mole of *s*-butylmagnesium bromide was added dropwise to one mole of acetyl chloride. After standing overnight, the reaction mixture was hydrolyzed, acidified, washed with dilute sodium carbonate solution and dried over anhydrous sodium sulfate. Removal of the ether followed by fractionation gave the ketone distilling at[8] 118°. The ketone was added dropwise to an equimolecular solution of ethylmagnesium bromide. The reaction mixture was worked up as usual and the alcohol fractionated under diminished pressure; b. p. 59–61° (14 mm.); 150–152° (740 mm.); yield, 61% based on the ketone, d^{25} 0.8345. *Anal.* Calcd. for $C_8H_{18}O$: C, 73.78; H, 13.93. Found: C, 73.72; H, 13.67.

(b) From 3-Methyl-4-hexanone and Methylmagnesium Bromide.—The ketone was prepared as follows: to 53 g. (2.3 moles) of powdered sodium,[9] suspended in 200 ml. of anhydrous ether in a two-liter, three-neck flask equipped with strrer, condenser and dropping funnel, was added 63 ml. (1.1 moles) of absolute ethyl alcohol. The condenser was replaced by a 60-cm. Fenske-type column packed with 3/32 inch glass helices. Eight hundred fifty grams of ethyl propionate was added portionwise and the reactants maintained at reflux temperature. The ether slowly distilled and was followed by a mixture of ethyl alcohol and ethyl propionate. After four hours, the condensation of the ethyl propionate and the sodium enolate of ethyl α-propionylpropionate[10] was considered to be complete as judged by the boiling point (95°+) and the refractive index (1.3840). To this solution was added 150 ml. of toluene (dried over sodium). In a period of three to four hours, the sodium enolate was alkylated[11] to ethyl α-methyl-α-propionylbutyrate by slowly adding 316 g. of ethyl bromide (65 g. excess). During this addition and for one additional hour, the reaction mixture was maintained at the reflux temperature.

The solid sodium bromide was removed by suction and the liquid layer A saved for fractionation. The sodium bromide was dissolved in water, the solution acidified with acetic acid, the oil separated and the water layer extracted with ether. The liquids were washed with 10% sodium carbonate and, after drying over anhydrous potassium carbonate, were combined with the liquid layer A. Distillation through the Fenske-type column gave 239 g. (1.285 moles) of ethyl α-methyl-α-propionylbutyrate, b. p. 94–95° (11 mm.); n^{20}D 1.4288; reported,[12] b. p. 98–100° (15 mm.); yield, 55.8% based on sodium.

Ketone hydrolysis of the ester[13] required fourteen hours. The reaction mixture was poured onto ice and made alkaline with sodium hydroxide. The oil was separated and the water layer extracted with ether. The combined oil and ether extracts were dried and distilled. The average yield for the hydrolysis of two 250-g. batches of the keto ester was 84%. The 3-methyl-4-hexanone boiled at 76–76.4° (107 mm.); micro b. p. 135.2 (743 mm.) (cor.); n^{20}D 1.4069; d^{20}_4 0.8162; reported,[13] (b. p. 135–136 (760 mm.).

To the methylmagnesium bromide prepared from 3.3 moles of magnesium and methyl bromide (Dow Chemical) in 900 ml. of anhydrous ether was added dropwise 262 g. (2.3 moles) of 3-methyl-4-hexanone. After standing overnight, large colorless crystals settled around the sides of the flask and on the stirrer. These were identified by analysis (Mg, 11.1%) as the complex $C_{16}H_{46}O_5Mg_4Br_6$ observed in this Laboratory in the preparation of tertiary alcohols from acids and the Grignard reagent.[14] Five hundred milliliters of ether was distilled from the reaction mixture, 200 ml. of dry benzene was added and the whole refluxed four or five hours at a temperature of 60°. After hydrolysis, and after washing and drying the ethereal solution, distillation gave 261 g. of 3,4-dimethyl-3-hexanol (87% yield based on the ketone).

Condensation of the Alcohols with Benzene.—All but three of the alcohols were condensed according to the method described by Huston, *et al.*,[5] using 0.5 mole of aluminum chloride per mole of alcohol. The technique described by Huston and Krantz[2c] was used for the condensation of 2,3-dimethyl-3-hexanol, 3,4-dimethyl-3-hexanol and 2-methyl-3-ethyl-3-pentanol, using, respectively, 0.33, 0.41 and 0.25 mole of aluminum chloride per mole of alcohol. No gaseous organic compounds were obtained in these reactions. The condensation of 2,3-dimethyl-3-hexanol was varied further in that dry hydrogen chloride gas was bubbled into the reaction flask during the addition of the last 0.7 mole of alcohol.

After standing for two to twelve hours, the reaction mixture was hydrolyzed by adding water. If the aqueous layer did not become clear, a small volume of C. P. hydrochloric acid was added. The benzene layer was removed and the aqueous layer extracted with benzene. The combined benzene extracts were washed with 10% sodium carbonate solution and dried over anhydrous potassium carbonate.

Fractionation of Crude Product.—Distillations were through the Fenske-type column described above except for the products obtained from the condensation of 2,3-dimethyl-3-hexanol (spinning band column[6]) and of 2,3,4-trimethyl-3-pentanol (Vigreux). After removal of the benzene, the following fractions were obtained in each case:

1. **Alkane–Alkene Fraction.**—B. p. 50–60° at 90 to 100 mm.: from alcohols with branching on the β-carbon atom, unsaturated (bromine in carbon tetrachloride), chloride-free liquids were obtained, probably alkenes formed by dehydration of the alcohols. From alcohols without branching on the β-carbon atom, saturated, chloride-free liquids with physical constants approximating alkanes were obtained. Product from 4-methyl-4-heptanol: yield, 24.2%; b. p. 56° (93 mm.); micro b. p. 117.2° (744 mm.) (cor.); n^{20}D 1.3980; d^{20}_4 0.7036. These values agree fairly well with the physical constants of 4-methylheptane.[15] These liquids are under further investigation.
2. **Chloride Fraction.**—B. p. 50–55° at 10–12 mm.: these liquids were not identified but were probably the chlorides derived from the respective alcohols since they gave heavy precipitates with alcoholic silver nitrate.
3. **Crude Octylbenzene Fraction.**—B. p. 102–110° at 10–15 mm.: these fractions usually contained an appreciable quantity of chlorides.
4. **Residue.**—B. p. above 110° (11 mm.) and refractive index greater than 1.5000.

Purification and Isolation of Pure Octylbenzenes.—In each case fraction 3 was refluxed for three to six hours with an equal volume of alcoholic potassium hydroxide solution (1 g. potassium hydroxide to 10 ml. 95% ethyl alcohol). (2,3-Dimethyl-3-phenylhexane required additional treatment with alcoholic silver nitrate.) To this solution was added 200 ml. of water, the oil was separated and the aqueous layer extracted with benzene. The combined oil–benzene solution was washed with 10% acetic acid, 10% sodium carbonate and water and dried over anhydrous potassium carbonate.

The dry liquids were fractionated at reduced pressure through the columns described above. The head was maintained at total reflux until equilibrium was reached. A small volume of liquid was then removed and the head

returned to total reflux. When equilibrium was again attained, the process was repeated. Individual samples of one to three grams of liquid were taken and the refractive index determined. Samples of nearly constant boiling point and equal refractive index were combined. The yields of the octylbenzenes recorded in Table II are based on the weight of the liquid where the refractive index varies by no more than 0.001 unit (the 2,3,4-trimethyl-3-phenylpentane was repeatedly distilled through a Vigreux column until pure). The physical constants were determined on the largest combined sample of constant refractive index. In Fig. 1, the fractions of constant refractive index were obtained by combining a number of samples of the same refractive index.

Surface tensions were determined by the drop-weight method. The correction factor was calculated according to the "International Critical Tables."[16]

Summary

Eight tertiary octyl alcohols have been condensed with benzene to produce the corresponding tertiary octylbenzenes. The physical constants of the latter have been determined.

3,4-Dimethyl-3-hexanol has been synthesized by two methods.

Allylic Chlorides. IV. Relative Reactivities with Potassium Iodide in Acetone[1]

BY LEWIS F. HATCH, LEON B. GORDON AND JOHN J. RUSS[2]

A number of different reactions has been used to demonstrate marked differences in relative reactivity between various types of organic halides. Of these methods, the most satisfactory bimolecular ($S_{\mathrm{N}}2$) reaction for alkyl chlorides is the metathetical reaction between the chloride and potassium iodide in dry acetone.[3] This reaction usually proceeds at an easily measured rate for most chlorides, at readily obtainable temperatures, and without side reactions.

Although this reaction has been used to compare the relative reactivities of a large number of alkyl chlorides, it was not until 1941 that the reaction was utilized in a study of the relative reactivities of several allylic chlorides.[4] The reaction proved to be entirely satisfactory for this type of chloride.

Recent work[5] on the cuprous chloride catalyzed acid hydrolysis of the isomeric 1,3-dichloropropenes has shown that geometrical configuration has a marked influence on the rate of reaction. The present investigation was undertaken to reinvestigate the reaction between allylic chlorides and potassium iodide and to determine if the previously noted effect of geometrical configuration on the hydrolysis reaction also applied to a bimolecular metathetical reaction.

Materials

Potassium Iodide.—C. P. potassium iodide was recrystallized from water and dried three hours at 120°. It failed to give a positive test for iodate ion.

Acetone.—The actone used boiled at 56.6° and did not color anhydrous copper sulfate in one hour. It retained a faint pink color of potassium permanganate for thirty minutes and liberated neither iodine nor hydriodic acid from 0.04 molar potassium iodide when kept in the dark.

1-Chloro-1-propene.—A mixture of *cis*- and *trans*-1-chloro-1-propene[6] was distilled to obtain a fraction with a boiling range of 33–34°. This fraction, being intermediate in boiling range between the two isomers (*cis* 32.0–32.2°; *trans* 36.7°), contained both isomers.

Allyl Chloride.—Allyl chloride boiling at 44.9° was obtained by distillation from crude allyl chloride[7] with a boiling range of 44.5–45.1°. It was used without further purification.

2-Bromo-3-chloro-1-propene.—2-Bromo-3-chloro-1-propene, obtained from Halogen Chemicals of Columbia, S. C., was distilled at 150 mm. pressure. The fraction used had the following constants: b. p. 61.6° (150 mm.); $n^{25}\mathrm{D}$ 1.4968; $d^{25}{}_4$ 1.6290; *MR* (calcd.) 28.22, (obsd.) 27.61.

2,3-Dichloro-1-propene.—2,3-Dichloro-1-propene[6] with a boiling range of 93–94° was distilled at 150 mm. pressure and a fraction boiling at 48.0° was used.

Methallyl Chloride.—Methallyl chloride[7] was redistilled and a fraction boiling at 72.1° was used.

1,3-Dichloropropene.—In the still bottoms remaining from the distillation of crude allyl chloride, prepared by the high temperature substitutive chlorination of propylene, there remains an appreciable quantity of higher boiling material containing a dichloride fraction consisting of approximately 63% 1,3-dichloropropene (*cis* and *trans*), 35% 1,2-dichloropropane and 2% 2,3-dichloro-1-propene. This material[7,8] was separated by distillation into fractions containing the low and high boiling isomers of 1,3-dichloropropene. These fractions were redistilled at 150 mm. pressure and the following data were obtained: low boiling 1,3-dichloropropene, b. p. 57.0°, $n^{20}\mathrm{D}$ 1.4673; high boiling 1,3-dichloropropene, b. p. 64.7°, $n^{20}\mathrm{D}$ 1.4745.

1,3-Dichloro-2-methyl-1-propene.—The isomeric 1,3-dichloro-2-methyl-1-propenes were prepared from methallyl chloride.[9] The methallyl chloride was chlorinated to 1,2,3-trichloro-2-methylpropane using sulfuryl chloride. The trichloride was dehydrochlorinated and hydrolyzed to a mixture of the 3-chloro-2-methyl-2-propen-1-ols which were separated using a Podbielniak Hypercal distillation column. The chloroalcohols were converted to the corresponding dichlorides using concentrated hydrochloric acid.

[a] A mixture of the *cis* and *trans* isomers. [b] Tamele, Ott, Marple and Hearne (*Ind. Eng. Chem.*, **33**, 119 (1941)) give $k = 0.226$. [c] Tamele, Ott, Marple and Hearne give $k = 0.354$. [d] Probably low.

The following physical data were obtained: low boiling 1,3-dichloro-2-methyl-1-propene: b. p. 130° (741 mm.); n^{25}_{D} 1.4698; d^{25}_{4} 1.1629; *MR* (calcd.) 29.94, (obsd.) 29.97. High boiling 1,3-dichloro-2-methyl-1-propene: b. p. 132.0° (754 mm); n^{25}_{D} 1.4740; d^{25}_{4} 1.1667; *MR* (calcd.) 29.94, (obsd.) 30.08.

1,1,3-Trichloro-2-methyl-1-propene.—1,1,3-Trichloro-2-methyl-1-propene was obtained from Halogen and Perfume Chemicals, Columbia, S. C., and was distilled at 150 mm pressure. A center fraction gave the following constants: b. p. 101.0° (150 mm); n^{25}_{D} 1.4933; d^{25}_{4} 1.3211; *MR* (calcd.) 34.81, (obsd.) 35.08.

Experimental

The rate studies were carried out in 16 × 150 mm. Pyrex tubes maintained at 20.00 ± 0.01° in a constant temperature bath. The procedure used was the same as that described by Tamele, *et al.*[4], and the same equation was used to calculate the specific reaction rate constant, *k*. The data obtained are given in Table I.

Discussion

Table II lists the allylic chlorides for which rate constants were obtained. These compounds are listed in the increasing order of their relative reactivity with the rate constant of allyl chloride taken as unity. Allyl chloride was taken as unity because all the other allylic chlorides may be considered as derived from it by replacing one or more hydrogen atoms.

TABLE II

RELATIVE REACTIVITIES OF ALLYCLIC CHLORIDES WITH KI IN ACETONE

Compound		Relative reactivities
$\mathrm{Cl{-}\underset{\underset{H}{\vert}}{C}{=}\underset{\underset{H}{\vert}}{C}{-}CH_3}$	*cis* and *trans*	0.00
$\mathrm{H{-}\underset{\underset{H}{\vert}}{C}{=}\underset{\underset{Cl}{\vert}}{C}{-}CH_2Cl}$		0.72
$\mathrm{H{-}\underset{\underset{H}{\vert}}{C}{=}\underset{\underset{Br}{\vert}}{C}{-}CH_2Cl}$		0.87

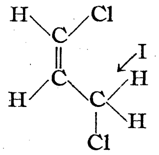
$\mathrm{Cl{-}\underset{\underset{H}{\vert}}{C}{=}\underset{\underset{CH_3}{\vert}}{C}{-}CH_2Cl}$	Low boiling	32.8
$\mathrm{Cl{-}\underset{\underset{Cl}{\vert}}{C}{=}\underset{\underset{CH_3}{\vert}}{C}{-}CH_2Cl}$		>33

Because several of the compounds contain a vinyl halogen as well as an allylic chlorine, it was necessary to determine if a vinyl chlorine reacts with potassium iodide in acetone at 20°. 1-Chloro-1-propene was used as the test compound, for it was available as a mixture of the *cis* and *trans* isomers. It was desirable to use a mixture of geometrical isomers because geometrical configuration might cause some difference in reactivity. A mixture of these two isomers did not give a measurable reaction in eight hours, and it has been assumed that only the allylic chlorine reacts in those compounds containing both types of halogen.

The influence of the relative electronegativity of the atom or group on the number 2 carbon ($\overset{1}{C}{=}\overset{2}{C}{-}\overset{3}{C}$) is not great, but nevertheless definite. The rate of reaction increases with a decrease in the relative electronegativity of the group or atom in the order: $CH_3 > H > Br > Cl$. This effect would be expected if the reaction takes place through an attack of the iodide ion on the carbon atom opposite the point of attachment of the allylic chlorine. The influence of a negative group on the number 2 carbon in this position is to cause the allylic carbon to become relatively less positive and consequently to exert less attraction for the negative iodide ion.

The nature of the effect of a substituent on the number 1 carbon is more involved than for substituents on the number 2 carbon because of the role played by geometrical configuration. This effect may be through steric hindrance or electrostatic interference or both. A group with a large negative field in the *cis* position would offer electrostatic impedance to the approach of the negative iodide ion. In *cis*-1,3-dichloropropene, for example, it is assumed that the allylic chlorine is oriented in a position away from the vinyl chlorine. If this were true, the iodide ion must approach the carbon through the negative field of the vinyl chlorine.



A scale model of this molecule also indicates that there would be considerable steric hinderance to the approach of the iodide ion. The *trans* isomer should have a greater reactivity than the *cis* isomer, provided the other group (H in this case) is relatively less negative than chlorine and smaller in size. With 1,1,3-trichloro-2-methyl-1-propene the activating influence of another vinyl chlorine apparently is somewhat greater than the deactivating effect of a chlorine in the *cis* position. This compound is somewhat more reactive than *trans*-1,3-dichloro-2-methyl-1-propene.

The two isomers of both 1,3-dichloropropene and 1,3-dichloro-2-methyl-1-propene have distinctly different rates of reaction with the *low* boiling isomer in each case being the *more* reactive. If the foregoing reaction mechanism applies, it would seem that the *low* boiling isomer of 1,3-dichloropropene and of 1,3-dichloro-2-methyl-1-propene is the *trans* isomer and the high boiling isomer the *cis* form.

This conclusion is the same as that drawn by Hatch and Roberts[5] from the fact that the *low* boiling isomer of 1,3-dichloropropene reacts more *slowly* in its cuprous chloride catalyzed acid hydrolysis. Andrews and Kepner,[10] however, have pointed out that the data presented to substantiate this conclusion are amenable to other interpretations.

The only previously reported investigation of the relative reactivities of allylic chlorides with potassium iodide is that of Tamele and co-workers[4] on allyl and methallyl chlorides, crotyl chloride and 1-chloro-2-methyl-2-butene. With neither of the latter two compounds is it possible to determine from the data given if the compound used was the *cis* or the *trans* isomer or a mixture of the two. A confirmation of their conclusions as to the influence of the position of the methyl group must await the establishment of configuration and the determination of the reaction rate of both isomers of each compound. This investigation is now in progress.

[10] Andrews and Kepner, THIS JOURNAL, **69**, 2230 (1947).

Acknowledgment.—The authors wish to thank both the University of Texas Research Institute and the Research Corporation for their support of these and related researches on allylic chlorides.

Summary

The reaction of allylic chlorides with potassium iodide in acetone has been used to elucidate the influence of substitutents on both the number 1 and number 2 carbons and also of geometrical isomerism on the relative reactivity of the allylic chlorine.

The greater the relative electronegativity of the group on the number 2 carbon, the less is the activity of the allylic chlorine toward iodide ion. The differences in reactivity, however, are small.

Because the reaction of potassium iodide with allylic chlorides is an S_N2 type reaction, either a relatively negative group or a relatively large group, or both, in the *cis* position on the number 1 carbon would inhibit the reaction.

Since the low boiling geometrical isomers of both 1,3-dichloropropene and 1,3-dichloro-2-methyl-1-propene react more readily than the high boiling isomers, the low boiling isomers have tentatively been assigned the *trans* structure.

Pteroic Acid Derivatives. I. Pteroyl-α-glutamylglutamic Acid and Pteroyl-α,γ-glutamyldiglutamic Acid

BY J. H. MOWAT, B. L. HUTCHINGS, R. B. ANGIER, E. L. R. STOKSTAD, J. H. BOOTHE, C. W. WALLER
J. SEMB AND Y. SUBBAROW

In the course of the degradation of the fermentation *L. casei* factor[1] this compound was found to contain three molecules of glutamic acid in contrast to the liver *L. casei* factor (pteroylglutamic acid) which contained only one molecule of glutamic acid.

The synthesis of the fermentation *L. casei* factor became of particular interest when Lewisohn and his associates[2] reported that the substance caused regression of spontaneous breast tumors in mice.

This communication describes the synthesis of one of the two possible isomers of pteroyldiglutamic acid and one of the five possible isomers of pteroyltriglutamic acid. These compounds were prepared during the course of our work on the structure and synthesis of the fermentation *L. casei* factor.

In the preparation of pteroyl-α-glutamylglutamic acid (I) the dipeptide α-glutamylglutamic acid[3] was treated with *p*-nitrobenzoyl chloride and after reduction of the nitro group the resulting *p*-aminobenzoyl-α-glutamylglutamic acid was condensed with 2,4,5-triamino-6-hydroxypyrimidine and 2,3-dibromopropionaldehyde by the procedure of Waller, *et al.*[4]

The purified product was only slightly active when assayed with *Lactobacillus casei* or *Streptococcus faecalis R.* The low activity with *Lactobacillus casei* indicated that the fermentation *L. casei* factor probably contained at least one gamma-linkage in the peptide side chain. It therefore seemed desirable to prepare pteroyl-α,γ-glutamyldiglutamic acid (II).

This substance was prepared by condensing diethyl glutamate[5] with the γ-acid chloride of carbobenzoxy-α-glutamyldiethylglutamate[3] to give carbobenzoxy-α,γ-glutamyldiglutamic acid tetraethyl ester. The carbobenzoxy group was removed in the usual manner with hydrogen and palladium charcoal catalyst in the presence of acetic acid, giving the acetate of α,γ-glutamyldiglutamic acid tetraethyl ester which was then converted to the *p*-nitrobenzoyl derivative. After reduction of the nitro group, the resulting *p*-aminobenzoyl-α,γ-glutamyldiglutamic acid was condensed with 2,4,5-triamino-6-hydroxypyrimidine and 2,3-dibromopropionaldehyde by the procedure of Waller, *et al.*[4]

The crude product, pteroyl-α,γ-glutamyldiglutamic acid, was not available in quantities sufficient for a satisfactory purification but the biological assay of both the crude and the partially purified material did not differ appreciably from that of pteroyl-α-glutamylglutamic acid and it

I $$R = -\overset{H}{N}-\underset{(CH_2)_2-COOH}{\overset{COOH}{CH}} \qquad R' = -OH$$

[5] Chiles and Noyes, *ibid.*, **44**, 1798 (1922).

was evident that this α,γ-isomer was not identical with the fermentation *L. casei* factor.

Since the above procedure was not entirely satisfactory for the preparation of useful quantities of the pure α,γ-compound, other methods of synthesis have been investigated and will be described in a later communication.

Experimental

***p*-Nitrobenzoyl-α-glutamylglutamic Acid.**—A mixture of α-glutamylglutamic acid[3,6] (17.0 g.), 43 cc. of water, and 111 cc. of 2 *N* sodium hydroxide solution was treated with 22.88 g. of *p*-nitrobenzoyl chloride and 104.8 cc. of 2 *N* sodium hydroxide solution. These reagents were added in several portions during about twenty minutes with vigorous stirring. After about forty-five minutes the mixture was acidified by the addition of 51 cc. of 6 *N* hydrochloric acid, cooled and filtered. The filter-cake was then extracted several times with a total volume of 200 cc. of hot water. The combined aqueous extracts were filtered while hot and then allowed to cool. The crystalline precipitate was collected, washed with cold water and dried; yield, 17.8 g. (68%). A sample of the material was recrystallized from hot water and dried at 60° *in vacuo* for analysis; m. p. 146–148°, cor.; $[\alpha]^{29}_{D}$ +8.12° (*C* 4, acetone).

Anal. Calcd. for $C_{17}H_{19}O_{10}N_3$: C, 48.00; H, 4.50; N, 9.88. Found: C, 47.71; H, 4.86; N, 9.77.

***p*-Aminobenzoyl-α-glutamylglutamic Acid Triethyl Ester Hydrochloride.**—A mixture of *p*-nitrobenzoyl-α-glutamylglutamic acid (35.0 g.) glacial acetic acid (32 cc.), water (750 cc.), and platinum oxide catalyst (0.6 g.) was shaken with hydrogen at room temperature and atmospheric pressure until 6.57 l. of hydrogen had been absorbed. After filtering off the catalyst, the solution was adjusted to *p*H 3.0 and extracted several times with ether to remove any traces of *p*-aminobenzoic acid which might be present. The aqueous solution contained 28.8 g. of *p*-aminobenzoyl-α-glutamylglutamic acid as determined by the method of Bratton and Marshall.[7] After evaporation to dryness *in vacuo* 21.6 g. of the non-crystalline residue was esterified at room temperature for eight hours with absolute ethanol containing 0.1 g. of hydrogen chloride per cc. of solution. After cooling overnight the crystalline precipitate was collected, washed with ethanol and dried; wt. 16.9 g., m. p. 164–167°. This was recrystallized from 140 cc. of ethanol for analysis; wt. 12.6 g., m. p. 166–168°, cor.

Anal. Calcd. for $C_{23}H_{33}O_8N_3 \cdot HCl$: C, 53.54; H, 6.64; N, 8.14. Found: C, 53.34; H, 6.63; N, 8.19.

***p*-Aminobenzoyl-α-glutamylglutamic Acid Triethyl Ester.**—A suspension of the above hydrochloride (12 g.) in 120 cc. of water at 60° was treated with 8 cc. of pyridine. The oily precipitate crystallized upon cooling; wt. 10.7 g., m. p. 113–115°. This material was recrystallized from 75 cc. of ethanol; wt. 6.8 g., m. p. 114–115°, cor.; $[\alpha]^{28}_{D}$ −8.75° (*C* 2, ethanol).

Anal. Calcd. for $C_{23}H_{33}O_8N_3$: C, 57.61; H, 6.94; N, 8.76. Found: C, 57.99; H, 7.32; N, 8.69.

Pteroyl-α-glutamylglutamic Acid.—*p*-Nitrobenzoyl-α-glutamylglutamic acid (35 g.) was reduced as previously described, and the solution, containing about 29 g. of *p*-aminobenzoyl-α-glutamylglutamic acid, was diluted to a volume of 2 liters. To this solution was added 2,4,5-triamino-6-hydroxypyrimidine dihydrochloride (31.2 g.) and sufficient sodium hydroxide to bring the mixture to *p*H 4.0. Then with vigorous stirring, a solution of 2,3-dibromopropionaldehyde (31.5 g.) in 750 cc. of ethanol was added during about thirty minutes, together with sufficient sodium hydroxide solution to maintain the reaction mixture at *p*H 4.0. After adding all of the reagents, the mixture was stirred for about thirty minutes. The precipitate was collected on the filter, washed with water, ethanol, acetone and ether and dried. The crude product weighed 36.8 g. Chemical assay[8] indicated that the crude material contained 22.2% by weight of pteroyl-α-glutamylglutamic acid.

Purification.—The above crude product, containing 8.17 g. of activity, was dissolved in 22.8 l. of 0.2 *N* sodium hydroxide solution and treated with 557 g. of barium chloride dihydrate. Alcohol was then added to 2.5% by volume and the mixture was filtered. The filtrate, containing 6.45 g. of activity, was diluted with water to a volume of 75 liters and the barium was removed as barium sulfate. The filtrate was treated with 18.75 liters of alcohol and diluted with water to a volume of 125 liters. After adjusting the solution to *p*H 6.0, 225 g. of zinc acetate was added and the mixture was then adjusted to *p*H 6.9, heated to 70° and filtered. The filter cake, containing the active material, was suspended in about 125 liters of water, treated with sodium hydroxide to 0.05 *N* and the active material was then precipitated with zinc at *p*H 6.9 as described above. After again precipitating with zinc, the zinc salt precipitate was extracted with 7 liters of 0.1 *N* sodium hydroxide solution. The alkaline extract, containing 4.46 g. of activity, was decolorized with 5 g. of Norite A, filtered and made up to 0.2 *N* with sodium hydroxide. The solution was treated with barium chloride to 0.2 *N* and then alcohol was added to 2% by volume. After filtering off the precipitate, the filtrate was acidified to *p*H 2.8, cooled and filtered. The filter-cake was dissolved in hot water (8 liters) and on cooling, the active material precipitated. After repeating this precipitation from hot water, 2.11 g. of material was obtained; chemical assay,[8] 93.9%. Extinction coefficient: calcd. 164. Found: 151–152; 151/164 = 92.2% which compares favorably with the above chemical assay. After further purification from hot water a sample was obtained for analysis.

Anal. Calcd. for $C_{24}H_{26}O_9N_8$: C, 50.52; H, 4.59; N, 19.64. Found (corrected for 1.1% ash): C, 50.40; H, 5.11; N, 19.86. Biological assay: *S. faecalis R.* 0.5%; *L. casei* 0.8%; (pteroylglutamic acid, 100%). The compound was fully active (on a molar basis) in the chick assay.[9]

Carbobenzoxy-α,γ-glutamyldiglutamic Acid Tetraethyl Ester.—To a cold (−10°) well-stirred solution of diethyl carbobenzoxy-α-glutamylglutamate[3] (43 g.) in 140 cc. of dry, alcohol-free chloroform was added 29.5 g. of phosphorous pentachloride in several portions during thirty minutes. The mixture was stirred at −10° for an additional forty-five minutes and the solution was then decanted from a small amount of residual solid matter and evaporated *in vacuo* (below 0°) to remove most of the chloroform. The residue was quickly washed several times by decantation with 400 cc. of cold, dry heptane and then dissolved in 90 cc. of cold, dry chloroform. This solution was added immediately to a solution of 47 g. of diethyl glutamate in 66 cc. of cold (−30°) dry chloroform. After about ten minutes, the reaction mixture was removed from the cooling bath and allowed to stand at room temperature for about three hours.

The reaction mixture was then extracted several times with each of the following, 0.2 *N* hydrochloric acid, water, 10% sodium bicarbonate solution, water, 0.1 *N* hydrochloric acid, and water. The chloroform solution was then dried over magnesium sulfate, clarified with charcoal, filtered and evaporated to dryness *in vacuo*. The waxy residue was triturated with ether and the crystalline product was collected, washed with ether and petroleum ether and dried; wt. 27.5 g. This material was recrystallized from 28 cc. of warm, dry chloroform by the addition of ether; wt. 22 g. A sample of the material was recrystallized several times from chloroform and ether for analysis; m. p. 140.5–142.0°, cor. (sintering 105–107°).

---

(6) The melting point of this peptide was found to be 184–185°, cor. instead of 205°, cor. All other properties of this material and of its precursors agreed with the values reported by Bergmann and Zervas.[3]

Anal. Calcd. for $C_{31}H_{45}O_{12}N_3$: C, 57.13; H, 6.96; N, 6.45. Found: C, 57.13; H, 7.56; N, 6.52.

The Acetate of α,γ-Glutamyldiglutamic Acid Tetraethyl Ester.—Carbon dioxide-free hydrogen was passed into a well-stirred mixture of carbobenzoxy-α,γ-glutamyldiglutamic acid tetraethyl ester (10 g.), ethanol (150 cc.), water (50 cc.), glacial acetic acid (3.0 cc.), and 10% palladium–charcoal catalyst (0.7 g.) for two hours. An additional 0.6 g. of catalyst was added and the reduction was continued until carbon dioxide was no longer evolved. The carbon dioxide liberated in the reaction was absorbed in potassium hydroxide solution, and then precipitated as barium carbonate which was collected and weighed. Nearly the theoretical amount of barium carbonate was obtained. The reduction mixture was filtered and the filtrate was evaporated to dryness *in vacuo*. The residue was shaken with dry ether, giving a white, crystalline precipitate which was collected, washed with dry ether and petroleum ether and dried; wt. 7.05 g. This material was satisfactory for the subsequent *p*-nitrobenzoylation. Some difficulty was experienced in recrystallizing the material directly, and finally an analytical sample was prepared as follows: The above crude product (0.222 g.) was suspended in about 5 cc. of dry ether and a small excess of diethylamine was added. The mixture was filtered to remove diethylamine acetate and the filtrate was evaporated to dryness *in vacuo* several times with small portions of ether to remove excess diethylamine. The final residue was taken up in a little dry ether, filtered and treated with a few drops of acetic acid. The crystalline acetate precipitated, and after washing with ether and petroleum ether it was dried *in vacuo*.

Anal. Calcd. for $C_{25}H_{43}O_{12}N_3$: C, 51.98; H, 7.50; N, 7.28. Found: C, 52.30; H, 7.40; N, 7.20.

No sharp melting point was obtained. The sample softened between 71.5 and 78.0° and melted at 78.0–81.0°, cor.

***p*-Nitrobenzoyl-α,γ-glutamyldiglutamic Acid Tetraethyl Ester.**—A stirred solution of the acetate of α,γ-glutamyldiglutamic acid tetraethyl ester (3.0 g.) in 50 cc. of dry ether was treated with 1 cc. of diethylamine. The ether solution was decanted and the gummy residue was washed twice with dry ether. The combined ether solution was filtered and treated with a solution of *p*-nitrobenzoyl chloride (1.0 g.) in 10 cc. of dry ether. After thirty minutes the precipitate was collected and washed with ether and then with water. The residue was dried *in vacuo*; wt. 1.72 g. For analysis a sample (0.070 g.) was twice recrystallized from 2 cc. of alcohol and 3 volumes of water; m. p. 144.0–145.0° cor. (sintering about 130°).

Anal. Calcd. for $C_{30}H_{42}O_{13}N_4$: C, 54.04; H, 6.35; N, 8.40. Found: C, 53.88; H, 6.75; N, 8.15.

***p*-Aminobenzoyl-α,γ-glutamyldiglutamic Acid Tetraethyl Ester.**—A well-stirred mixture of *p*-nitrobenzoyl-α,γ-glutamyldiglutamic acid tetraethyl ester (0.666 g.), ethanol (20 cc.), water (10 cc.), concentrated hydrochloric acid (0.25 cc.), and iron dust (0.333 g.) was warmed to 50° for about thirty minutes and then allowed to react at room temperature for an additional four hours. The reduction of the nitro group was then 95% complete as determined by the method of Bratton and Marshall.[7] The mixture was filtered and the filtrate was adjusted to *p*H 8.2. The precipitate was removed and washed with a little ethanol and the combined filtrates were acidified to *p*H 6.5. After evaporation to dryness *in vacuo*, the residue was suspended in a little water, collected on the filter, washed with water and dried; wt. 0.435 g. The material was recrystallized from aqueous alcohol and dried *in vacuo*; wt. 0.344 g.; m. p. melted to a semi-solid at 146.5–147.5° and became completely liquid at 149.0–150.0°, cor.

Anal. Calcd. for $C_{30}H_{44}O_{11}N_4$: C, 56.59; H, 6.97; N, 8.81. Found: C, 56.76; H, 7.19; N, 9.00.

Pteroyl-α,γ-glutamyldiglutamic Acid.—A mixture of *p*-aminobenzoyl-α,γ-glutamyldiglutamic acid tetraethyl ester (0.158 g.), ethanol (1.0 cc.), and 0.1 *N* sodium hydroxide solution (10 cc.) was warmed to about 60° for a few minutes and then allowed to stand at room temperature for about ninety minutes. The solution was filtered to remove a trace of insoluble material. The filtrate was acidified with 1 cc. of acetic acid and treated with 0.107 g. of 2,4,5-triamino-6-hydroxypyrimidine dihydrochloride. The mixture was then adjusted to *p*H 4.0 and reacted at *p*H 4.0 with 1.5 cc. of an acetic acid solution containing 0.108 g. of 2,3-dibromopropionaldehyde during twenty minutes. The precipitated crude product was collected, washed with ethanol, acetone, and ether and air dried; wt. 0.064 g.; chemical assay,[8] 26.8%. Microbiological assay: *S. faecalis R.* 0.14%; *L. casei* 0.17% (pteroylglutamic acid, 100%).

Acknowledgment.—The authors wish to acknowledge the assistance of Messrs. Willard McEwen, William Kinley and Albert Gazzola in preparing various intermediates, Mr. Louis Brancone and associates for the microanalyses, Miss Eleanora Boggiano for the biological assays, and Mrs. Anna deGrunigen for the chemical assays.

Summary

Pteroyl-α-glutamylglutamic acid and pteroyl-α,γ-glutamyldiglutamic acid have been prepared. The latter compound was not identical with the fermentation *L. casei* factor.

Pearl River, New York Received October 14, 1947

Pteroic Acid Derivatives. II. Pteroyl-γ-glutamylglutamic Acid and Pteroyl-γ-glutamyl-γ-glutamylglutamic Acid

BY J. H. BOOTHE, J. H. MOWAT, B. L. HUTCHINGS, R. B. ANGIER, C. W. WALLER, E. L. R. STOKSTAD
J. SEMB, A. L. GAZZOLA AND Y. SUBBAROW

In the course of its degradation the fermentation *L. casei* factor was shown to contain three molecules of glutamic acid in contrast to the liver *L. casei* factor which contained only one molecule of glutamic acid.[1] Because pteroyl-α-glutamylglutamic acid and pteroyl-α,γ-glutamyldiglutamic acid which are described in the preceding communication showed[2] very low activities when assayed biologically against *S. faecalis R* or *L. casei*, it was decided to prepare some glutamic acid peptides in which only the γ-carboxyl groups were involved in the peptide linkages. This communication deals with the preparation of the dipeptide and the tripeptide of this type, and the subsequent preparation of their pteroyl derivatives. The general method used in this synthesis was to start with α-ethyl carbobenzoxyglutamate[3] which could not be satisfactorily crystallized from ether as described by Neuberger. Therefore, the crude mono ester was converted to the acid chloride[4,5] and treated with diethyl glutamate to form the carbobenzoxy dipeptide which was then reduced to triethyl γ-glutamylglutamate and crystallized as the hydrochloride.

For the preparation of pteroyl-γ-glutamylglutamic acid this dipeptide was *p*-nitrobenzoylated by the Schotten–Baumann method which at the same time hydrolyzed the esters to form *p*-nitrobenzoyl-γ-glutamylglutamic acid. The nitro group was reduced and without isolation of the intermediate *p*-aminobenzoyl dipeptide, the product was condensed with α,β-dibromopropionaldehyde and 2,4,5-triamino-6-hydroxypyrimidine as described for pteroylglutamic acid.[6] The pteroyl-γ-glutamylglutamic acid was isolated from the crude reaction product and was found to be in the range of 60 to 70% as active as pteroylglutamic acid when assayed against *S. faecalis R*, or *L. casei*.

For the preparation of the pteroyl tripeptide, triethyl γ-glutamylglutamate was condensed with the acid chloride of α-ethyl carbobenzoxyglutamate to form tetraethyl carbobenzoxy-γ-glutamyl-γ-glutamylglutamate. This carbobenzoxy tripeptide was reduced to tetraethyl γ-glutamyl-γ-glutamylglutamate hydrochloride which was *p*-nitrobenzoylated in benzene in the presence of diethyl amine. The *p*-nitrobenzoyl tripeptide was reduced to the corresponding *p*-aminobenzoyl derivative and condensed with α,β-dibromopropionaldehyde and 2,4,5-triamino-6-hydroxypyrimidine to form the pteroyl derivative.

The amount of pteroyl-γ-glutamyl-γ-glutamylglutamic acid prepared by this method was too small to isolate and completely characterize. It was biologically assayed, however, and showed the same ratio of activity for the two test organisms as does the fermentation *L. casei* factor, *i. e.* a low activity for *S. faecalis R* and a high activity for *L. casei*.

This method of synthesis served to indicate the probable structure of the fermentation *L. casei* factor but was not a desirable method from a preparative standpoint. Therefore, relatively little further work was done on this procedure, and efforts were directed toward finding a method more feasible for large scale preparations. This work will be the subject of future communications.

Experimental[7]

Triethyl Carbobenzoxy-γ-glutamylglutamate.—Seventy-eight grams of crude α-ethyl carbobenzoxyglutamate was dissolved in 250 cc. of anhydrous ether and cooled to −10°. With stirring and exclusion of moisture, 67.8 g. of phosphorus pentachloride was added in portions over a twenty minute period, not allowing the temperature to rise over −5°. The mixture was stirred thirty-five minutes more at −5 to 0°, filtered quickly and concentrated *in vacuo* to a residual sirup keeping the temperature below 0°. This residue was washed four times by decantation with cold, dry heptane, and then dissolved in 250 cc. of cold, dry chloroform and put in a Dry Ice-bath. It was then mixed with 114 g. of diethyl glutamate in 250 cc. of cold, dry chloroform and allowed to stand at room temperature two and one-half hours. The chloroform solution was then extracted several times with 0.2 *N* hydrochloric acid until the excess diethyl glutamate had been removed. It was then extracted twice with 0.2 *N* sodium bicarbonate solution and washed with water. This solution was dried over magnesium sulfate and the chloroform distilled off *in vacuo*. The oily residue changed to a hard wax-like material which was used directly for the next step; wt. 90.3 g. A small amount was purified by dissolving in hot ether and cooling. It tended to gel but by alternate warming and cooling it changed over to a white solid which was filtered off and dried; m. p. 91–92°.

Anal. Calcd. for $C_{24}H_{34}O_9N_2$: C, 58.2; H, 6.9; N, 5.66. Found: C, 59.0; H, 6.89; N, 5.54.

Triethyl γ-Glutamylglutamate Hydrochloride.—Sixty-five grams of crude triethyl carbobenzoxy-γ-glutamylglutamate was dissolved in 435 cc. of alcohol, treated with Norite and filtered. Two hundred seventeen cc. of water, 17 cc. of acetic acid and 2.6 g. of 10% palladium–charcoal catalyst were added. A stream of hydrogen was passed through with good stirring and carbon dioxide was evolved. After two hours the carbon dioxide evolution had almost ceased. Another 2.6 g. of catalyst was

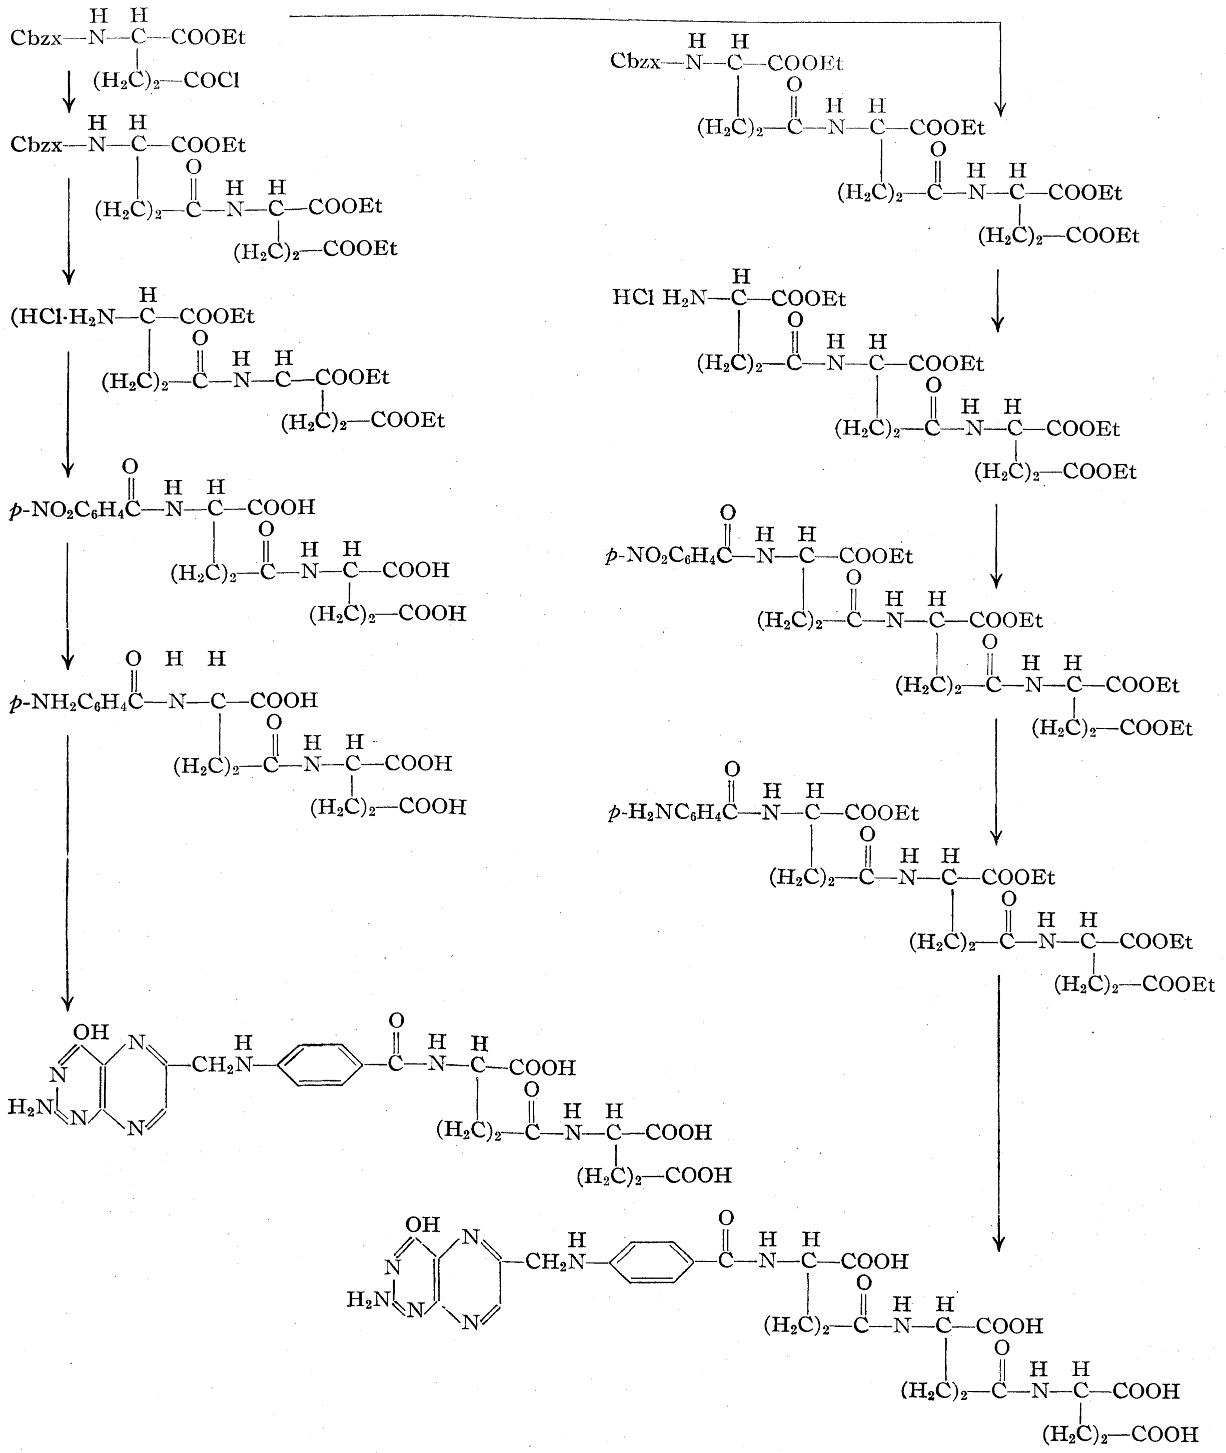
(7) All melting points are corrected and were taken by U. S. P. prescribed conditions.



added and the reduction was complete in another hour. Some runs of this reaction took much longer to reduce and required more catalyst, apparently due to catalyst poisons. The catalyst was filtered off and the filtrate was concentrated to complete dryness *in vacuo*. The residue was dissolved in 100 cc. of dry chloroform, hydrogen chloride was bubbled through for twenty minutes, and 650 cc. of anhydrous ether was added which precipitated an oil. This oil slowly crystallized and was filtered off and dried; wt. 36.5 g. Upon repeated crystallization from ethyl acetate or from chloroform and ether, a constant m. p. was reached at 132–133°, $[\alpha]^{26}_{D}$ −5.6° (*c* 4 in water).

Anal. Calcd. for $C_{16}H_{28}O_7N_2 \cdot HCl$: C, 48.4; H, 7.31; N, 7.08; α-amino N, 3.54. Found: C, 48.7; H, 7.62; N, 7.26; α-amino N, 4.18.

***p*-Nitrobenzoyl-γ-glutamylglutamic Acid.**—Four hundred twenty milligrams of triethyl γ-glutamylglutamate hydrochloride was dissolved in 0.7 cc. of water and 1.8 cc. of 2 *N* sodium hydroxide. Three hundred sixty-two milligrams of *p*-nitrobenzoyl chloride and 1.7 cc. of 2 *N* sodium hydroxide was added concurrently over a ten to fifteen minute period. The solution was stirred twenty minutes more and 0.425 cc. of concentrated hydrochloric acid was added. The precipitated *p*-nitrobenzoic acid was quickly filtered off and on cooling the filtrate, the product crystallized out rather slowly. After filtering and drying the product weighed 0.370 g. After repeated crystallization from water the m. p. was 194–195°.

Anal. Calcd. for $C_{17}H_{19}O_{10}N_3$: C, 48.0; H, 4.51; N, 9.88. Found: C, 48.28; H, 5.01; N, 9.97.

This reaction was also run in the same way on crude triethyl γ-glutamylglutamate before forming the hydrochloride. The same product was obtained in lower yield and the aqueous solution had to be concentrated after filtering off the *p*-nitrobenzoic acid.

Pteroyl-γ-glutamylglutamic Acid.—Eighteen grams of *p*-nitrobenzoyl-γ-glutamylglutamic acid was mixed with 720 cc. of water, 72 cc. of acetic acid, and 0.9 g. of platinum oxide. This mixture was shaken with hydrogen until 3.28 liters was absorbed, which required about two and one-half hours. The catalyst was removed by filtration and the filtrate was diluted to 1170 cc. A Bratton–Marshall amine test showed that the solution contained 14.0 g. (83.5% yield) of *p*-aminobenzoyl-γ-glutamylglutamic acid. Eighteen grams of 2,4,5-triamino-6-hydroxypyrimidine dihydrochloride was dissolved in the solution and while the *p*H was maintained at 4.0 by the addition of sodium hydroxide, 8.35 cc. of α,β-dibromopropionaldehyde in 600 cc. of alcohol was added slowly. After stirring one hour the precipitated product was filtered off and dried; yield 12.5 g. This crude material contained 2.4 g. of pteroyl-γ-glutamylglutamic acid by chemical assay.[8] The 12.5 g. of crude material was dissolved in 10 liters of 0.2 *N* sodium hydroxide, barium chloride was added to make 0.2 *N* and ethanol was added to the extent of 3%. The precipitate was discarded, the filtrate was diluted to 40 liters, and the barium ions were removed with sulfate ions. Zinc chloride was then added to *p*H 6.8 and the precipitate containing the desired material was filtered off and stirred with 65 liters of dilute sodium hydroxide containing 15% ethanol.

The *p*H was brought to 6.8 with zinc chloride, then heated to 90° and filtered, the active material remaining in the precipitate. This hot zinc salt precipitation was repeated twice and then the material was dissolved in 10 l. of 0.2 *N* sodium hydroxide and treated with barium chloride and alcohol as previously described. After removal of the barium ions the *p*H of the solution was brought to 3 and the precipitate was collected. It was then reprecipitated four times from 2 liters of hot water, by cooling and after filtering and drying weighed 0.522 g.

Anal. Calcd. for $C_{24}H_{26}O_9N_8$: C, 50.5; H, 4.56; N, 19.65. Found (corrected for 1.46% ash): C, 49.55; H, 4.96; N, 19.53. Microbiological assays: *S. faecalis R.*, 70.9%; *L. casei*, 62.9%. Both assays used pteroylglutamic acid as a standard.

Tetraethyl Carbobenzoxy-γ-glutamyl-γ-glutamylglutamate.—Twenty-five g. of triethyl γ-glutamylglutamate hydrochloride was dissolved in 100 cc. of chloroform. A solution of 1.448 g. of sodium in 50 cc. of ethanol was added to the chloroform solution which formed a colloidal precipitate of sodium chloride. The solution was evaporated to complete dryness *in vacuo*, taken up in 30 cc. of chloroform, and treated with a chloroform solution of the acid chloride of α-ethyl carbobenzoxyglutamate as already described for the dipeptide. The reaction mixture was worked up the same way and on concentrating the chloroform solution to dryness *in vacuo* a solid residue was obtained which was shaken with ether and filtered off; yield 9.5 g. A small portion was crystallized from chloroform and ether; m. p. 109–110°.

Anal. Calcd. for $C_{31}H_{45}O_{12}N_3$: C, 57.2; H, 6.91; N, 6.45. Found: C, 56.4; H, 6.57; N, 6.52.

Tetraethyl γ-Glutamyl-γ-glutamylglutamate Hydrochloride.—Tetraethyl carbobenzoxy-γ-glutamyl-γ-glutamylglutamate (11.32 g.) was reduced in 125 cc. of alcohol, 40 cc. of water, 4 cc. of acetic acid, and 0.4 g. of 10% palladium–charcoal catalyst as described above. It was necessary to add 0.4 g. more of catalyst after two hours and the total reduction time was five hours. The catalyst was filtered off and the filtrate was concentrated to 40 cc. and diluted with 75 cc. of water which precipitated a small amount of white flocculent material. This was removed by filtration and the filtrate was concentrated to dryness *in vacuo* and dried under vacuum over phosphoric anhydride. The residue was dissolved in 30 cc. of chloroform, hydrogen chloride was bubbled through, and the product was precipitated by adding 150 cc. of ether. The dried product weighed 7.5 g. A portion was precipitated twice from hot ethyl acetate by cooling but was apparently amorphous; m. p. 147–150°.

Anal. Calcd. for $C_{23}H_{39}O_{10}N_3$: C, 49.8; H, 7.07; N, 7.59. Found: C, 49.45; H, 7.8; N, 7.45.

Tetraethyl *p*-Nitrobenzoyl-γ-glutamyl-γ-glutamylglutamate.—A mixture of 5.32 g. of tetraethyl γ-glutamyl-γ-glutamylglutamate hydrochloride, 50 cc. of dry benzene, and 1.94 cc. of diethylamine were mixed well and the diethylamine hydrochloride was filtered off. To the filtrate was added a solution of 3.56 g. of *p*-nitrobenzoyl chloride in 15 cc. of ether and 50 cc. of benzene. The solution changed to a jelly-like solid in a few minutes and was then shaken well for thirty minutes. The mixture was then diluted with ether and the solid was removed by filtration and washed well with ether. After drying, the product was powdered, washed well with water, and again dried; yield 4.2 g. A small portion was crystallized twice from hot alcohol by cooling very slowly to prevent gelling: m. p. 173–174°,[9] $[\alpha]^{28}_{D}$ −4.0° (*c* 2 in acetic acid).

Anal. Calcd. for $C_{30}H_{42}O_{13}N_4$: C, 54.0; H, 6.34; N, 8.40. Found: C, 54.0; H, 6.95; N, 8.60.

Tetraethyl *p*-Aminobenzoyl-γ-glutamyl-γ-glutamylglutamate.—A mixture of 3.0 g. of tetraethyl *p*-nitrobenzoyl-γ-glutamyl-γ-glutamylglutamate, 25 cc. of water, 50 cc. of ethanol, 1.5 g. of iron powder, and 1 cc. of concentrated hydrochloric acid was warmed to 35–40° and stirred vigorously for two and one-half hours during which time the solid all dissolved. Two cc. of 28% ammonium hydroxide was added and hydrogen sulfide was bubbled in for twenty minutes. The mixture was filtered and the precipitate was washed with ethanol. A Bratton–Marshall amine test on the filtrate indicated that it contained an 87% yield of the product. Eighty per cent. of the solution was adjusted to *p*H 7.5 and evaporated to a small volume *in vacuo*. Ethanol and several drops of ammonium hydroxide were added and the solution was evaporated to complete dryness. The residue was taken up in 35 cc. of ethanol, filtered to remove the ammonium chloride and evaporated to dryness. The product was taken up in 12 cc. of ethanol and 30–40 cc. of water was added which caused an oil to separate. This oil crystallized on standing overnight; yield 1.6 g. One gram of this material was dissolved in 10 cc. of ethanol, 60 cc. of water, and 0.3 cc. of concentrated hydrochloric acid and was filtered to remove traces of unreduced nitro compound. To the filtrate was added 0.6 cc. of pyridine which caused the product to oil out and later crystallize. A portion of this was recrystallized twice from alcohol and ether; m. p. 147–148°.

Anal. Calcd. for $C_{30}H_{44}O_{11}N_4$: C, 56.6; H, 6.90; N, 8.80. Found: C, 56.57; H, 6.56; N, 8.71.

Pteroyl-γ-glutamyl-γ-glutamylglutamic Acid.—One hundred milligrams of tetraethyl *p*-nitrobenzoyl-γ-glutamyl-γ-glutamylglutamate was reduced as described

---

[8] Hutchings *et al.*, *J. Biol. Chem.*, **168**, 705 (1947).

[9] In some other preparations of this compound by the same method, it was obtained in a form melting at 158–159°. One form could not be changed to the other at will by seeding although this occasionally happened during recrystallization. *Anal.* C, 54.08; H, 5.48; N, 8.34. This compound was later prepared by other methods and the same m. p. behavior was noted.

above. After one and one-half hours the excess iron was filtered out and washed with 0.5 cc. of acetic acid and 3 cc. of water. The filtrate was diluted to 8 cc. and a Bratton–Marshall amine test showed that 97% of the theoretical amine was present. Sixty-five milligrams of 2,4,5-triamino-6-hydroxypyrimidine dihydrochloride was added to the reduced solution and the *p*H was adjusted to 3.8. Sixty-six milligrams of dibromopropionaldehyde in 1 cc. of acetic acid was added slowly with stirring and maintaining the *p*H at 3.5 to 4. The precipitate was rather sticky so the water was poured off and precipitate was washed with alcohol and ether; yield, 25 mg. Chemical assay: 23.4%. Microbiological assays after hydrolysis of the esters for twelve hours in 0.1 *N* sodium hydroxide: *S. faecalis R.*, 0.6%; *L. casei*, 16.5%. If these assay figures are corrected for the inert material present in the crude reaction mixture the values are then: *S. faecalis R.*, 2.57%; *L. casei*, 70.6%. These figures are very similar to those obtained for the fermentation of *L. casei* factor.

Acknowledgments.—The authors wish to acknowledge the able assistance of Miss Eleanora Boggiano in doing microbiological assays and Mrs. Anna deGrunigen in doing chemical assays. The chemical analyses were performed by Mr. Louis Brancone and co-workers. We are also indebted to Mr. Willard McEwen and Mr. William Kinley for the preparation of intermediates used in this synthesis.

Summary

Pteroyl-γ-glutamyl-glutamic acid has been synthesized and found to stimulate the growth of the two test organisms, *S. faecalis R.* and *L. casei*, to the extent of 60–70% as well as does pteroylglutamic acid.

Pteroyl-γ-glutamyl-γ-glutamylglutamic acid has been synthesized and found to show the same ratio of activity for the two test organisms as does the fermentation *L. casei* factor. This synthetic compound was not isolated from the reaction mixture and was only characterized to the extent of its microbiological activity.

Configuration of Vaccenic Acid[1]

BY P. C. RAO AND B. F. DAUBERT

Recent interest in the purported growth-promotional activity for the rat of vaccenic acid, a fatty acid reportedly isolated from several animal fats by Bertram[2] in 1928, has prompted a reinvestigation of the presence of the fatty acid in animal fat and a confirmation of its configuration.

Several investigators,[3,4] including Bertram,[2] had observed that the iodine value of the solid fatty acids separated from the mixed fatty acids of an animal fat (tallow) by the Twitchell lead salt procedure invariably showed a higher iodine value than the solid acids separated from vegetable fat. This seemed to indicate the presence of a solid unsaturated fatty acid. It therefore seemed desirable to Bertram[2] to prove the presence of the fatty acid in beef tallow and, if present, to accomplish its isolation. As a result of his investigation, Bertram[2] reported the isolation of a solid unsaturated acid from beef tallow and furthermore, on the basis of a study of the fatty acid, concluded that it was an 11,12-octadecenoic acid of *trans* configuration (11,12-elaidic acid). He also reported its isolation from sheep fat and butterfat.

Subsequently other investigators[5,6,7] have confirmed the presence of vaccenic acid in animal fat but, to the authors' knowledge, the *trans* configuration of vaccenic acid as postulated by Bertram[2] has not been confirmed. However, the preparation of an 11,12-elaidic acid (vaccenic) has been reported by Böeseken and Hoagland[8] on partial hydrogenation of α-eleostearic acid.

In view of the alleged nutritional significance of vaccenic acid, the purpose of the current communication is to present further evidence concerning its configuration.

Experimental

Preparation of Vaccenic Acid.—The vaccenic acid was isolated from beef tallow essentially by the procedure described by Bertram.[2] However, a final lead salt separation of the acids from the liquid mercury salts was made in order to free the vaccenic acid of liquid unsaturated fatty acids. The vaccenic acid (10 g.) so obtained was esterified to the methyl ester, and fractionated in an efficient fractionating column. A highly purified methyl ester fraction (2.2 g.) was obtained of iodine value 84.0 (calcd. 85.6), and b. p. 172–173° at 3 mm. The vaccenic acid obtained after saponification of the methyl ester was crystallized several times from cold acetone, and had the constants as listed in Table I.

TABLE I

	This study	Bertram[2]
Iodine value, Wijs	87.6 (calcd. 89.9)	86.5
Saponification equivalent	282.1 (calcd. 282.4)	281.5
Melting point, °C.	42.5	39.0
Saturated acids	Trace	0.9%
Refractive index	1.4439[a] at 60°	1.44071 at 70°

[a] Assuming d*n*/d*t* to be 0.00037, the calculated value at 70° is 1.4402.

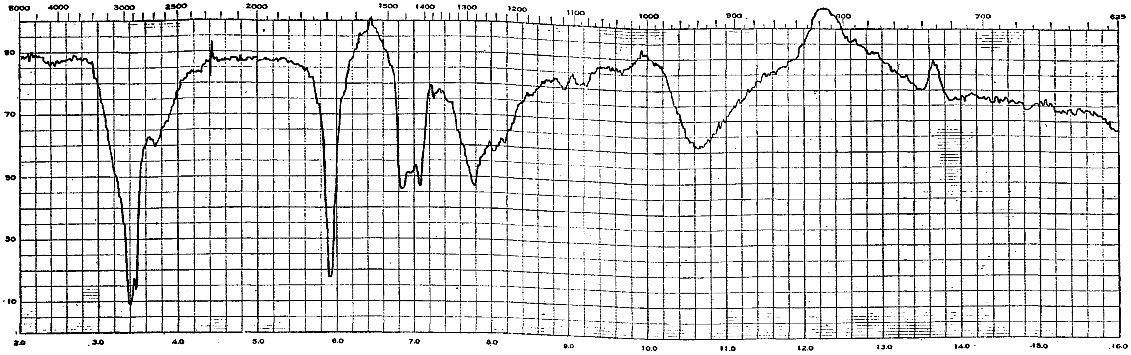

Fig. 1.—Infrared absorption curve for oleic acid.

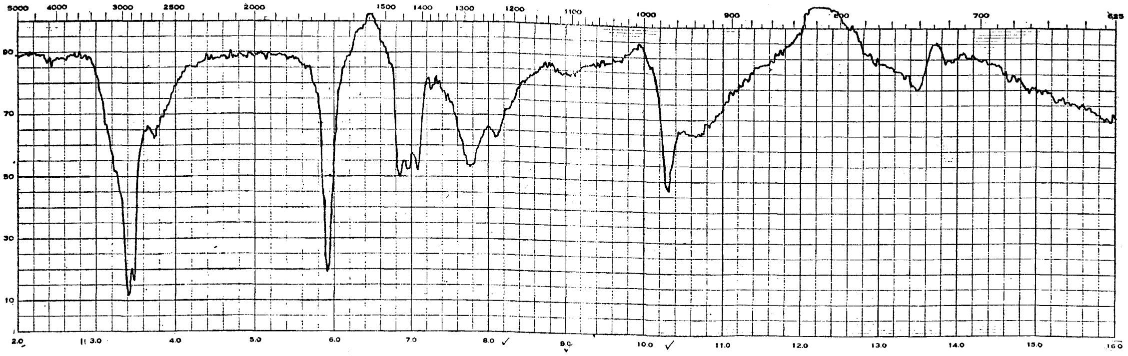

Fig. 2.—Infrared absorption curve for vaccenic acid.

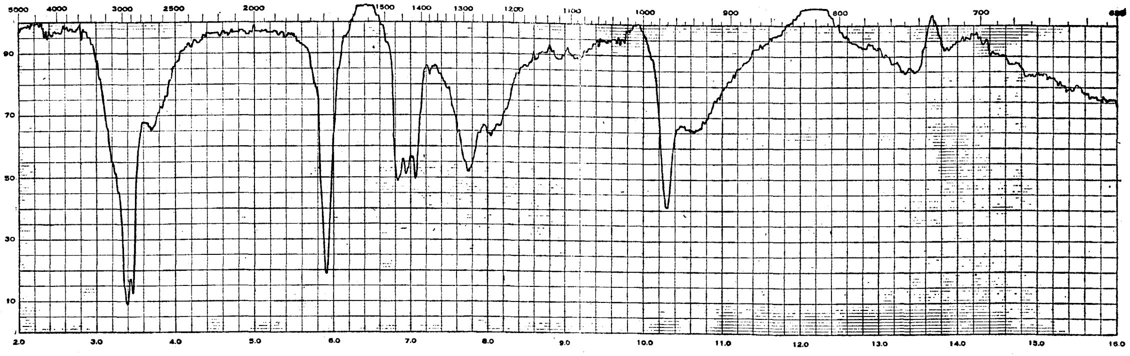

Fig. 3.—Infrared absorption curve for elaidic acid.

Preparation of Oleic and Elaidic Acids.—The oleic acid was prepared by fractional distillation and low-temperature crystallization of the methyl esters of the fatty acids of olive oil. Subsequent saponification of the highly purified methyl oleate and fractional distillation of the oleic acid gave a product of iodine value 89.8 (calcd. 89.9) containing a trace of dienoic acid. The purity of the oleic acid was comparable to the oleic acid prepared for use in the synthesis of glycerides as previously reported.[9]

Elaidic acid, m. p. 44.5°, I. V. 89.7, was prepared from the oleic acid by elaidinization according to the method of Lyutenberg.[10]

Infrared Spectra.—Infrared absorption curves for the vaccenic, oleic and elaidic acids were obtained using a Baird infrared spectrophotometer.[11] Solution of the respective fatty acids (10%) in carbon tetrachloride using 0.01-cm. cells was found satisfactory for measurement of the infrared absorption.

Discussion of Results

Essentially all of the evidence presented by Bertram in support of his conclusion that vaccenic acid is of *trans* configuration was based on a comparison of its freezing point and the constant *K* of van der Steur with those of oleic and elaidic acids, and the fact that on elaidinization the original vaccenic acid was recovered unchanged. Al-

though all of the above evidence certainly seemed to support the conclusions of Bertram,[2] it was felt that additional proof of the configuration of vaccenic acid could be obtained by infrared absorption measurements in comparison with oleic and elaidic acids. The infrared absorption curves for oleic, elaidic and vaccenic acids, respectively, are given in Figs. 1, 2, and 3. On the assumption that oleic acid is *cis* and elaidic acid *trans*, it may be seen from the general similarity of the infrared patterns of elaidic and vaccenic acids that the latter is probably of *trans* configuration. Comparison of the curves for the three fatty acids in the region of wave length 3 to 7.5 μ shows a striking similarity. The minimum at 10.25 μ in the pattern for elaidic acid is also present in the vaccenic acid pattern, but absent for oleic acid. However, the doublets in the region of 8.8 to 9.2 μ present in the oleic acid curves are absent in the infrared pattern for vaccenic acid. Perhaps this may be attributed to the difference in the position of the double bond. Because of light scattering, no particular significance is attributed to small differences in the region 13 to 16 μ.

Although the vaccenic acid is probably of greater purity than the acid isolated by Bertram, the magnitude of the melting point in comparison with that reported by Bertram is somewhat surprising.

X-Ray diffraction analysis of the vaccenic acid is in progress and the results of this study will be reported in a separate communication.

In view of the pronounced similarity in infrared absorption of elaidic and vaccenic acids, additional evidence is therefore presented to confirm the *trans* configuration of vaccenic acid.

Infrared absorption measurements of highly purified vaccenic acid are reported in comparison with values for oleic and elaidic acids.

Acknowledgment.—The technical assistance of Miss Leatrice Klein in the preparation of the vaccenic acid is gratefully acknowledged.

Summary

Comparison of the infrared patterns of the three fatty acids seems to confirm the *trans* configuration of vaccenic acid.

Kinetics of the Fumarase System[1]

BY E. M. SCOTT AND RUTH POWELL

Dakin[2] in 1922 showed that an enzyme, fumarase, catalyzed the equilibrium reaction

$$\text{fumarate} + H_2O \rightleftarrows l\text{-malate}$$

Clutterbuck[2a] found that phosphate affected both the solubility of the enzyme and the rate of the reaction. Borsook and Schott[3] studied the equilibrium and calculated the heat of formation of *l*-malic acid. It was reported by Ionescu, *et al.*,[4] that the *p*H of optimum activity of the enzyme with *l*-malate as substrate was more alkaline than that with fumarate. Jacobsohn[5] found that while the reaction with both substrates appeared to follow the first-order course, the well-known relation of the first-order reaction constants to the equilibrium constant

$$K_1/K_2 = K_{\text{eq.}} \qquad (1)$$

did not apply.

The present investigation was designed to test Jacobsohn's observations and to determine why equation (1) did not hold. In contrast to the experiments cited above, highly purified enzyme prepared according to the crystallization procedure of Laki and Laki[6] was used in our investigations.

A titrimetric determination of fumarate similar to the method of Straub[6a] was found to be much more convenient and somewhat more accurate than the polarimetric methods used in earlier kinetic studies.[2a,4,5]

Experimental

Eastman Kodak Co. fumaric acid was recrystallized from water, dissolved and neutralized as one substrate; Eastman *l*-malic acid was dissolved and neutralized to provide the other. Purity of the substrates for present purposes was established by the following evidence: (1) Both acids gave correct neutral equivalents; (2) *l*-malic acid gave no reaction with permanganate under the conditions stated below; (3) both substrates gave the same equilibrium concentration of fumarate; and (4) no evidence of inhibition by either substrate was found (*vide infra*, "Effect of Substrates on Stability").

The enzyme used was an amorphous fraction, obtained after crystallization of the protein described by Laki and Laki. This preparation had about three times as much activity per unit protein N as did the crystals. The initial rate of hydration of fumarate at *p*H 7.29 and 30° by this enzyme was 0.015 mole/sec. g. of protein N.

Unless otherwise indicated, the enzyme tests were run in 10 ml. of a solution containing phosphate buffer (*p*H 7.29, ionic strength 0.2), 0.1 *M* sodium fumarate or *l*-malate, and enzyme to give a protein N concentration of 4.2 p. p. m. One ml. samples were removed, added to 10 ml. of water containing 0.5 ml. of concentrated

hydrochloric acid, and titrated with 0.02 *M* potassium permanganate. The end-point of the titration was taken when one drop (0.03 ml.) of potassium permanganate solution gave a pink color which persisted for sixty seconds. Analyses by this method of mixtures of known amounts of fumarate and *l*-malate without enzyme were accurate within 0.5% total substrate content. Acetic acid–acetate buffers were used below *p*H 5.8, phosphate buffers between 5.8 and 8.0, and ammonia–ammonium chloride buffers above *p*H 8.0. All buffers had an ionic strength of 0.2. Temperatures were maintained by immersion in a water-bath, controlled to within 0.05°.

Since the reaction did not follow a path predictable from an equation for a reaction of integral order, rates were expressed in terms of the initial value as determined graphically. This appeared to be justified by the data in Fig. 1, from which it was concluded that initial rate was directly proportional to enzyme concentration.

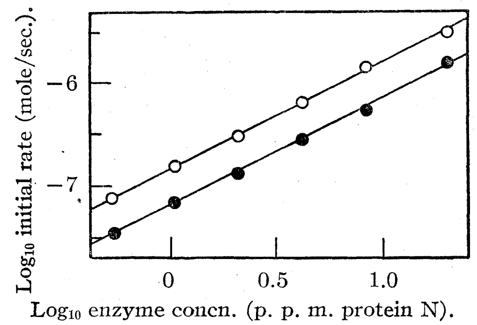

Fig. 1.—Effect of enzyme concentration on initial rate of reaction: –○–○–, fumarate as substrate; –●–●–, *l*-malate as substrate.

Results

Equilibrium Constant.—The equilibrium constant was found to be independent of substrate or enzyme concentration. It was independent of *p*H, except that below *p*H 6.0, *l*-malate was favored. Since *l*-malic is a somewhat weaker acid than fumaric, this was expected. The variation of equilibrium constant with temperature is shown in Fig. 2. From this figure, the heat change of hydration of fumarate ion was calculated as −3560 cal./mole and the free energy change at 25° was −826 cal./mole. These values agree satisfactorily with those of previous investigators.[3,5]

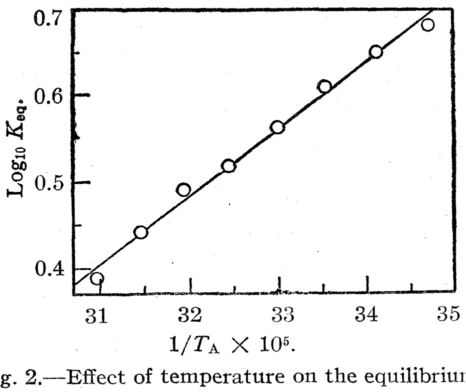

Fig. 2.—Effect of temperature on the equilibrium.

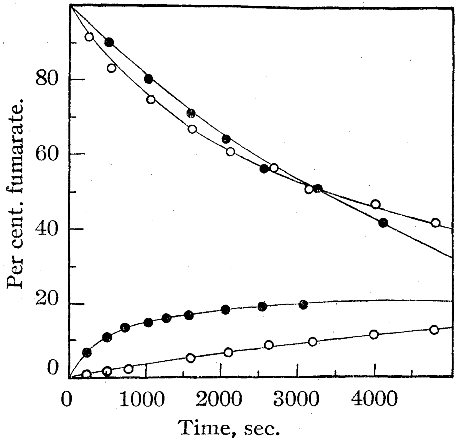

Fig. 3.—Path of the reaction: –○–○–, *p*H 8.46; –●–●–, *p*H 5.97.

Course of Reaction.—Typical curves of the course of the reaction are shown in Fig. 3. When these were plotted according to the first-order equilibrium reaction equation

$$K_{\mathrm{F}} + K_{\mathrm{M}} = 1/t \ln\left(\frac{x_0 - x_e}{x - x_e}\right) \qquad (2)$$

(where x_0 is original concentration x_e the equilibrium concentration, x the concentration of fumarate at time t, and K_{F} and K_{M} the first-order reaction constants with fumarate and *l*-malate, respectively), the curves shown in Fig. 4 were obtained. As is apparent, the slopes of the curves do not agree when the reaction starting with 100% *l*-malate is compared with that starting with 100% fumarate. This confirms the work of Jacobsohn.

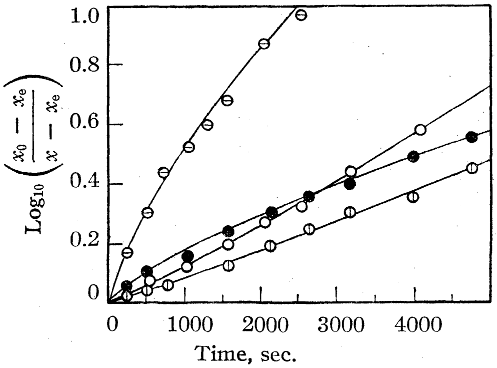

Fig. 4.—The reaction as fitted to the first order equation: –●–●–, fumarate, *p*H 5.97; –⦶–⦶–, *l*-malate, *p*H 5.97; –○–○–, fumarate, *p*H 8.46; –⊖–⊖–, *l*-malate, *p*H 8.46.

Effect of *p*H.—The relative rates of the reaction starting with either *l*-malate or fumarate varied greatly with *p*H as shown in Fig. 5. Thus, at *p*H 6.0 equilibrium was reached with fumarate in about one-half the time required for the reaction with *l*-malate, but at *p*H 9.0, over six times as long was required with fumarate as with *l*-malate.

Effect of Temperature.—Variation of initial rate of reaction with temperature at *p*H 7.29 is shown in Fig. 6. The apparent activation

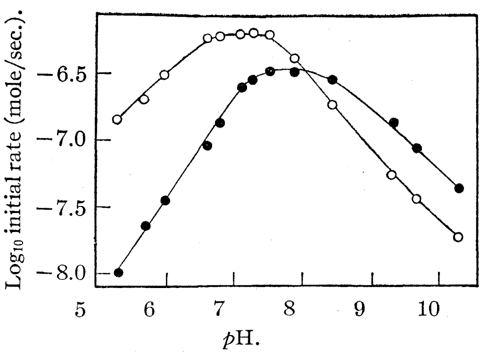

Fig. 5.—Effect of pH on reaction rate: –○–○–, fumarate; –●–●–, l-malate.

energies starting with the two substrates were: fumarate, 8,100 cal./mole; l-malate, 12,200 cal./mole.

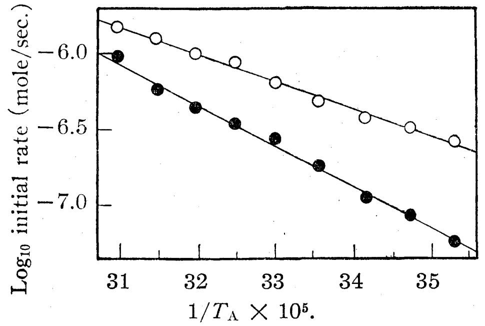

Fig. 6.—Effect of temperature on reaction rate: –○–○–, fumarate; –●–●–, l-malate.

Effect of Substrates on Stability.—In one experiment l-malate was added, the system brought to equilibrium, and then fumarate was added. The rate of hydration of fumarate was found to be the same as when fumarate was added, the system brought to equilibrium, and more fumarate added. This indicated that no inhibitors were being added with either substrate, and that the substrates had no differential effect on stability of the enzyme. Independent tests showed that under the usual conditions of our experiments, enzyme destruction was very slow or negligible.

Effect of Substrate Concentration.—Over the range shown in Table I, the initial rate of reaction at pH 7.29 appeared to be independent of substrate concentration. This could have been true only if the rate-controlling step of the reaction was not of the first order but was, at least at the start, of the zero order.

TABLE I

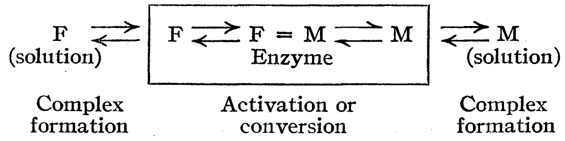
EFFECT OF SUBSTRATE CONCENTRATION ON INITIAL RATE

Substrate concentration, M	Initial rate, mole/sec. $\times 10^7$ Fumarate	l-Malate
0.4	5.0	2.8
.2	6.0	3.2
.1	5.9	3.2
.05	5.6	4.0
.025	5.4	2.5
.0125	6.0	3.0

Discussion

It is evident from the results that the reason equation (1) does not apply to the case of fumarase is that the reaction is not of the first order. Superficially it appears to follow the course predicted by the first-order equation because, in an equilibrium system, the reverse reaction is so important in determining rate that different orders of reaction are not clearly distinguishable. Equation (1) will apply ordinarily only to those reactions in which there is a single step conversion of one reactant to the other. Accordingly, these results can be interpreted as indicating that the fumarate–l-malate interconversion proceeds through a series of steps, any one of which may limit the rate. Consequently, the rate with one substrate may bear no obvious relationship to the rate with the other.

The only steps in enzyme-catalyzed reactions of which we have some conception at present are those of activation and complex formation. By complex formation is meant the fact that the substrate must combine with, or be adsorbed on, or at least come in contact with, the enzyme for the reaction to proceed. The reaction might then be pictured as



in which water is assumed to be present in great excess. The processes within the rectangle take place on the surface of the enzyme.

A priori, one cannot decide whether the process of complex formation involves a change in free energy, nor can one predict whether complex formation has an appreciable activation energy of its own. Three possibilities exist: (1) one can assume that the energy of activation of complex formation is small (*i. e.*, complex formation is much more rapid than conversion; this was the assumption of Michaelis and Menten[7]); (2) it can be assumed that the energy of activation of complex formation is appreciably greater than the energy of activation of the conversion process (*i. e.*, complex formation limits the rate); or (3) one can assume that the rates of complex formation and conversion are approximately the same, as did Briggs and Haldane.[8] In all three cases, one arrives at the following equation for the kinetic process

$$\alpha(x_0 - x) + \beta \ln \left(\frac{x_0 - x_e}{x - x_e}\right) = t \qquad (3)$$

α and β are constants which differ in meaning depending on the assumptions made.

---

[7] Michaelis and Menten, *Biochem. Z.*, **49**, 1333 (1913).

[8] Briggs and Haldane, *Biochem. J.*, **19**, 338 (1925).

Equation (3) fits much of the data in a quite satisfactory manner. Its essential applicability was indicated by the fact that, unlike several other possible equations, the same values of the constants were found whether starting with fumarate or with *l*-malate as substrate. In Fig. 3, the lines were drawn from this equation with values of α and β as follows: *p*H 5.97, $\alpha = -27{,}800$, $\beta = 2040$; *p*H 8.46, $\alpha = 35{,}700$, $\beta = 570$. Considering the great uncertainties in the processes involved in the fumarase reaction, however, the exact meaning of α and β is questionable, and equation (3) can be regarded as little more than an empirical expression that fits observed data. Thus, there is no indication in these data as to which of the three assumptions above may be correct, nor whether the real mechanism may not be in fact much more complicated than any of those here visualized.

Summary

The initial rate of the forward reaction in the system

$$\text{fumarate} + H_2O \underset{}{\overset{\text{fumarase}}{\rightleftharpoons}} l\text{-malate}$$

bears no obvious relation to the initial rate of the reverse reaction. This was shown to be due to the reaction being composed of a series of steps of which the rate-controlling step was of the zero order. The effect on the system of temperature, *p*H, and enzyme and substrate concentrations was studied, and an equation derived which described the data obtained.

Rate of Exchange of Cellulose with Heavy Water

BY V. J. FRILETTE,[1a] J. HANLE AND H. MARK

Introduction

The interchain structure of cellulose has aroused considerable interest in recent years. As with other polymers, there is reason to believe that the physical and chemical properties of cellulose are strongly influenced by the supermolecular texture that exists in a given sample. A generally accepted hypothesis concerning the texture of cellulose is[1b] that individual chain molecules having average extended lengths of several thousand Ångströms pass successively through regions of lower and higher lateral order. These ordered and disordered domains are not sharply distinguished and separated from each other but may be connected by areas of intermediate order. They are usually as a matter of convenience referred to as amorphous and crystalline constituents. One could expect different portions of a chain in such a structure to have different degrees of reactivity with small reagent molecules, for the behavior of an individual chain segment would depend upon how tightly it is bound laterally to its nearest neighbors. The reacting groups in the most disordered regions of a sample would be expected to be most easily accessible, while they would be inaccessible in the areas of high lateral order. Consequently, one would expect hydroxyl groups or glucoside bonds in amorphous regions to be most susceptible to reactions so that if the rate or extent of a particular reaction is followed quantitatively, it may be interpreted in terms of structural accessibility.

Until now, three chemical reactions have been used to characterize the reactivity of cellulose samples. Goldfinger, Siggia and Mark[2] measured the rate of periodate oxidation of various cellulose samples and established the existence of a rapid and a slow reaction. Assaf, Haas and Purves[3] treated cellulose with thallous ethylate in different solvents and found that only a fraction of the existing hydroxyl groups were converted to the thallium salt. Finally, Nickerson[4] and Conrad and Scroggie[5] studied the oxidative hydrolysis of cellulose to carbon dioxide and water. The rate of carbon dioxide evolution, which at first is rapid, gradually decreases to an almost constant value. It is claimed that by an analysis of the rate curves an estimate can be made of the amount of easily accessible (amorphous) cellulose originally present in the sample.

In this paper we shall describe a fourth reaction suitable for characterizing cellulose. It was first observed by Bonhoeffer[6] that the hydroxyl groups of cellulose react with heavy water. Champetier and Viallard,[7] who made a more systematic study of this effect, reported that a moderately slow reaction occurred and that practically all of the hydroxyl groups exchanged. The curves reported by these investigators showed little promise of yielding any information on accessibility, but a careful reading of the paper revealed that the cell in which the reaction was conducted had been

---

opened for each density measurement made on the water, thus introducing the possibility that exchange with moisture vapor from the air may have occurred. While the errors thus introduced would not affect the over-all shape of the exchange curve, the calculated extent of the reaction would be too high. We felt, therefore, that a few more experiments along these lines would be of interest and observed, in fact, that the exchange is not of moderate speed, but very fast; to properly follow it, one must introduce some device for agitating the cellulose.

The mild conditions under which the cellulose–heavy water reaction can be carried out is a very advantageous feature from the point of view of characterization, for there is hardly a question but that the investigated sample remains chemically and physically unchanged during the course of the reaction.

Experimental

Treatment of Samples.—Through the courtesy of Drs. Conrad and Scroggie of the Rayon Department, E. I. du Pont de Nemours and Company, a variety of cellulose samples were obtained which had already been characterized for accessibility by the Nickerson method as modified by Conrad and Scroggie.[6] In addition to these samples, two native cottons which exhibited the normal X-ray fiber patterns were analyzed.

All of the samples were air-dried and contained considerable amounts of moisture (6–13%). It was not considered desirable to dry at elevated temperatures the samples which were actually to be used for the exchange reaction, since such a procedure might change the accessibility. As an alternative, about 100–200 g. of each cellulose was kept in a screw-cap jar for one week in order to ensure that all parts of the gross sample had achieved moisture equilibrium. Small portions of the conditioned gross sample were then used for the exchange reaction, while another portion was used to determine the moisture content. The latter analysis was made in duplicate by drying in an air oven at 110° in accordance with standard practice. To the experimentally determined values was added in all cases an arbitrary correction of 0.5%, since it is well known that cellulose dried under the conditions described tends to retain about this amount of water.[8]

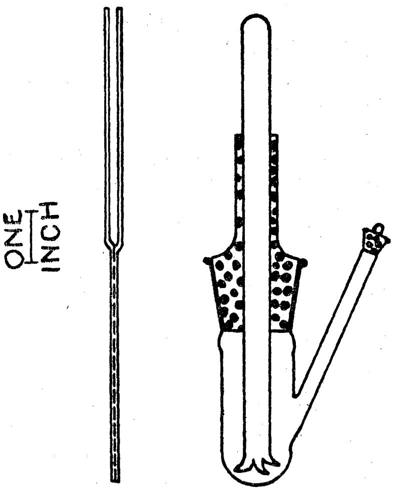

Fig. 1.—Reaction cell and micropipet.

Apparatus and Techniques.—The reaction cell is shown in Fig. 1. It was designed to permit intermittent agitation and the removal of microsamples of water without exposing the contents to air.

Approximately 2 g. of the conditioned sample was quickly weighed into the tared reaction cell, and 8 to 10 g. of heavy water of known specific gravity added. During transfer and weighing, the obvious precautions were taken to minimize changes in the moisture content of the cellulose as well as changes in the specific gravity of the heavy water.

When the weighings were completed, the glass stopper (not shown) was removed from the reaction cell and the ground-glass stirring assembly inserted in its place, where it remained until the run was completed. The cellulose was alternately loosened and compressed for about twenty minutes by manually manipulating the glass rod. After this initial period it was found sufficient to loosen and compress the wet cellulose only two or three times every half hour. The efficiency of the recommended agitation may be judged by the fact that if no agitation at all is used, one obtains what is apparently a very slow reaction which requires twenty-four to thirty-six hours to achieve maximum exchange,[7] but with the cell described above, if one breaks up and compresses the cellulose just once, a process requiring about three minutes, is found that exchange has proceeded to within a few per cent. of the value found after one or two hours. In other words, the reaction is diffusion-controlled, and is such a fast reaction that with a slight amount of agitation it goes practically to completion within a matter of minutes.

In order to follow the reaction, samples of water were removed and purified at intervals, and specific gravity measurements then were made. Purification was necessary in order to remove the buffer salts, suspended cellulose particles, and also any traces of impurities that might have been extracted from the cellulose. Before taking a sample of the free water, the reaction cell was tilted and the stirring rod pressed into the cellulose in such a way that a drop of water would run into the narrow side-arm to form an air-lock. To obtain the sample, the capillary pipet shown in Fig. 1, fitted with a medicinal dropper bulb (not shown), was inserted through the side-arm of the reaction cell and a sample drawn up from the cellulosic mass. The capillary was then removed and wiped dry with hard filter paper.

The pipets were calibrated to contain 0.1 cc. of water. Manipulation of the sample was facilitated by a small hole at the top of the rubber bulb which was closed and opened at will by the index finger.

The water sample in the pipet was then transferred to a microdistillation flask. In Fig. 2 the construction and use of the flasks are illustrated. The flask at stage (3) is ready to receive the sample. The pipet was inserted until it touched the back wall of the flask, and the sample was run into the bulb. The tip of the pipet was then rotated against the portion of the horizontal tube adjoining the bulb in order to remove any large excess of water, after which it was carefully withdrawn so as to avoid contaminating the "receiver" portion of the flask. The flask containing the sample was then evacuated to *ca.* 20 mm. and the neck quickly sealed off with a hand torch. By simply hanging the flask with the "receiver" portion in ice water, distillation to dryness is attained in about one-half hour.

Several precautions should be observed in using the described distillation technique. It is advisable, for example, to store the retorts (stage 3) in a desiccator to provide a dry atmosphere for the sample; otherwise, large errors may be incurred. Also, in the evacuation step, one must be careful not to distil off any appreciable quantity of water before the seal is made.

After complete distillation, the flask was removed from ice-bath. The tube, maintained in a vertical position, was dried and then cut; the "receiver" portion of the flask thus became a convenient microbeaker containing the purified water. The specific gravity was immediately determined by the falling-drop method. This analysis

required 9 cu. mm. of the sample, and provided an accuracy of 1 × 10^{-6} specific gravity units. The method is in principle the same as that described previously by D. Rittenberg, *et al.*,[9] with some modifications by the present authors.[10]

Calculation of Extent of Exchange.—To derive a simple expression for calculating the extent of the exchange reaction, it is desirable to make two assumptions. It is assumed that the moisture present in the cellulose sample very rapidly dilutes the heavy water. It is further assumed that all three cellulose hydroxyls are indistinguishable so far as rate of exchange is concerned.

Now, the following definitions are adopted

x = grams of cellulose used;
m = percentage moisture content of x (wet basis);
Σ = moles of water ($D_2O + H_2O$) added to cellulose;
ξ_0 = initial mole fraction of D_2O in heavy water;
ξ_t = mole fraction of D_2O in heavy water at time t;
F = extent of reaction; *i. e.*, number of cellulose hydroxyls which have exchanged D for H divided by the number of such groups which would exchange if all of them were in equilibrium with the water.

If we write the exchange equilibrium as

$$2/3R(OH)_3 + D_2O \rightleftharpoons 2/3R(OD)_3 + H_2O$$

then, for complete reaction, the number of moles of D_2O consumed from an infinite excess of 100% D_2O is given by

$$\frac{(1 - 0.01m)x}{108.1} \tag{1}$$

For a *finite* amount of *dilute* heavy water, the number of moles consumed at time t is given by

$$\xi_t F\left[\frac{(1 - 0.01m)x}{108.1}\right] \tag{2}$$

By definition

$$\xi_t = \frac{\text{Moles } D_2O \text{ initially present} - \text{moles } D_2O \text{ consumed}}{\text{Total moles } (D_2O + H_2O)} \tag{3}$$

The assumption made at the beginning of this derivation regarding the moisture in the cellulose permits us to write

$$\xi_t = \frac{\xi_0\Sigma - \xi_t F\left[\frac{(1 - 0.01m)x}{108.1}\right]}{\Sigma + \frac{0.01mx}{18.02}} \tag{4}$$

Now, if W is the original weight of the heavy water added to the cellulose, it is evident that

$$W = 20.0\ \xi_0\Sigma + 18.0(1 - \xi_0)\Sigma \tag{5}$$

and this equation may be used to eliminate Σ from equation (4).

To eliminate the mole fractions ξ_0 and ξ_t, let the corresponding specific gravities be S_0 and S_t. The relationship between ξ and the corresponding S may be written

$$\xi = (S - 1.00000)/0.1080 \tag{6}$$

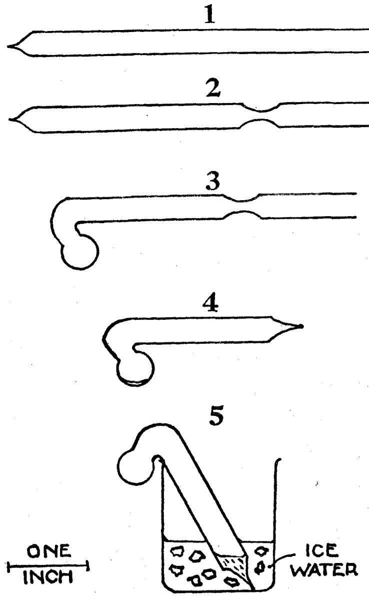

Fig. 2.—Preparation and use of microdistillation flasks.

Consideration of equations (4, 5, 6) with appropriate transpositions leads to the final relationship for F in terms of the weights of materials used and the observed specific gravities

$$F = A\left[\frac{S_0 - S_t}{S_t - 1}\right] - B \tag{7}$$

where A and B are constants in any given reaction, and their equivalents are

$$\left.\begin{aligned} A &= \frac{108.1W}{(18.02 + 2\xi_0)(1 - 0.01m)x} \\ B &= \frac{1.081m}{18.02(1 - 0.01m)} \end{aligned}\right\} \tag{8}$$

From a consideration of the quantities of cellulose and heavy water used, together with the precision attainable in the heavy water analysis,[10] it can be estimated that the value of F should be precise to within about (1 to 2) × 10^{-2}; in terms of percentage of the hydroxyls exchanged, the precision should be about 1% over the entire range.
