The Isolation of the Fermentation *Lactobacillus casei* Factor

BY BRIAN L. HUTCHINGS, E. L. R. STOKSTAD, NESTOR BOHONOS,[1] NATHAN H. SLOANE[2] AND Y. SUBBAROW

On aerobic culture an unidentified organism belonging to the genus *Corynebacterium*[3] produces a compound that is essential for the growth of *Lactobacillus casei* under the conditions described for the detection of the "norite eluate factor."[4,5] The compound, therefore, belongs to the group of substances variously known as the "norite eluate factor,"[4,5] folic acid[6] and vitamin Bc.[7] A preliminary note on the isolation of the fermentation *L. casei* factor has appeared.[8]

The fermentation *L. casei* factor has been isolated as described herein. Before crystallization could be induced the solution had to contain small amounts of electrolytes. If the electrolytes were not present in the crystallizing solvent, gels were invariably formed. Under these specified conditions the compound was crystallized as the free acid, barium salt and methyl ester.

Difficulty has been experienced in obtaining consistent analyses. Therefore, from combustion data no empirical formula could be derived. However, the analyses do serve to distinguish this compound from any related compound previously reported.[7,9]

The ultraviolet absorption spectrum of the fermentation *L. casei* factor is presented in Fig. 1. The compound exhibits the same absorption characteristics as the liver *L. casei* factor.[10] The extinction coefficients are somewhat lower indicating that the fermentation *L. casei* factor is a higher molecular weight compound. The extinction coefficient at 365 mμ in 0.1 *N* sodium hydroxide is 134.

The fermentation compound has the same biological activity for animals as does the liver *L. casei* factor with the proviso that increased amounts are necessary to compensate for the higher molecular weight.[11]

The fermentation *L. casei* factor differs from the liver *L. casei* factor by its relative activity for *Lactobacillus casei* and *Streptococcus faecalis* R. The fermentation compound is 60–80% as active as the liver compound for *L. casei* but only 4–6% as active for *S. faecalis* R. The amounts of the fermentation compound required per ml. for half-maximum growth of *L. casei* and *S. faecalis* R., respectively, are 0.000061 and 0.0042 microgram.

The analyses and biological activity serve to distinguish this compound from any of the com-

---

(1) Present address: Department of Agricultural Chemistry, Purdue University, Lafayette, Indiana.

(2) Present address: Department of Bacteriology, Harvard University, Boston, Massachusetts.

(3) The organism was classified as *Corynebacterium sp.* One of the criteria of classification was the absence of spores. This was determined by heating the organism at 90° for varying lengths of time. The organism was killed even with short periods of heating.

Later studies have shown that the organism is not killed by heating at 85° for periods up to thirty minutes. This evidence introduces the possibility of the presence of spores and, of necessity, questions the validity of the previous classification. Attempts to demonstrate the presence of spores by staining techniques have not been successful. Until the question of the presence or absence of spores is answered, the above classification must be designated as tentative.

Sub-cultures of the organism will be sent on request. All requests should be directed to Dr. B. L. Hutchings, Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York.

The organism can be cultured under aerobic conditions on a medium of the following composition: glucose, 20 g.; glycine, 4.0 g.; dipotassium hydrogen phosphate, 0.5 g.; potassium dihydrogen phosphate, 0.5 g.; ferrous sulfate heptahydrate, 0.04 g.; magnesium sulfate heptahydrate, 0.20 g.; thiamine, 0.40 mg., and tap water to 1 liter. A solid medium can be obtained by the addition of 20 g. of agar to the above medium.

pounds previously reported as influencing the growth of *L. casei* or *S. faecalis* R. under conditions of the test.

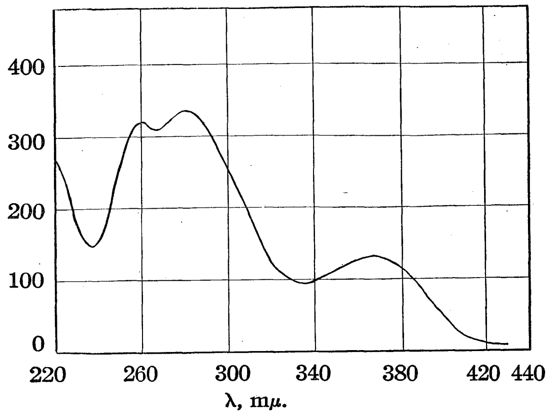

Fig. 1.—Ultraviolet absorption spectrum of fermentation *L. casei* factor in 0.1 *N* sodium hydroxide.

Experimental

Adsorption and Elution from Charcoal.—After removal of the bacterial cells the solution which contained from 3–5 γ of the active compound per ml. was adjusted to *p*H 3.0 and 6 g. of Norite A added per liter of filtrate. After thirty minutes adsorption, the charcoal was filtered off and washed well with water. The charcoal was eluted with 50% ethanol (6 liters per kg. of charcoal). This eluate was discarded. The charcoal was then eluted with 50% ethanol and 10% ammonium hydroxide (by volume) at 70° for one hour (12 liters per kg. of charcoal). The elution was repeated once. The eluates were combined. The recovery approximated 65%.

Precipitation of the Barium Salt.—The ammonia-ethanol eluates were adjusted to *p*H 8.0 with concentrated hydrochloric acid and ethanol added to a concentration of 85%. A saturated aqueous solution of barium chloride was added until complete precipitation occurred, meanwhile maintaining the *p*H at 8.0. After cooling to 0–5° the precipitate was centrifuged out and washed with methanol. The active compound was completely precipitated by this procedure.

Esterification and Extraction with Butanol.—The barium precipitate was suspended in 0.25 *N* methanol–hydrogen chloride (one-fifteenth the volume of the original filtrate) and esterified at room temperature. At the end of twenty-four hours the esterification mixture was adjusted to *p*H 4.5 by cautious addition of 5 *N* sodium hydroxide, and then concentrated to dryness under reduced pressure. The residue was suspended in a volume of water equivalent to a concentration of 15 micrograms per ml. of the active compound. The water insolubles were centrifuged out and discarded.

The aqueous solution was extracted 3 times with 2 volumes of butanol. Each butanol extract was in turn extracted with one-half volume of water. The combined butanol extracts were concentrated to one-sixth of their volume and extracted with one-half volume of water. This water wash was extracted with 2 volumes of butanol. The butanol extracts were combined and concentrated to dryness under reduced pressure. The esterification and butanol extraction gave a yield of 50–90%.

Fractionation from Methanol.—The residue after removal of the butanol was dissolved in the minimum amount of hot methanol. After thorough chilling to −5° the precipitated ester was collected. The precipitate was extracted two times (total volume was one-fifth the volume of methanol necessary to dissolve the residue after removal of butanol) with 0.1 *N* methanol–hydrogen chloride. The extracts were diluted with 2 volumes of methanol and 2 moles of sodium acetate were added per mole of hydrogen chloride. The solution was heated to 60°, centrifuged and the supernatant chilled at −10° for twenty-four hours. The precipitate which formed was centrifuged, then dissolved in hot methanol and sodium chloride was added to a concentration of 0.05 *N*. The solution was centrifuged at 60° and the insoluble fraction discarded. The supernatant was cooled at −10° for twenty-four hours and then centrifuged at 2°. The precipitated ester was obtained in yields approximating 65%.

Clarification with Florisil.—The ester was washed free of methanol, suspended in water and 0.1 *N* barium hydroxide was added until the solution was faintly alkaline to phenolphthalein. The hydrolysis of the ester was extremely rapid. The hydrolysate was centrifuged and the supernatant treated with florisil (1 g. per 100 mg. of active compound) for thirty minutes to remove extraneous pigments. The florisil was filtered off and washed with dilute barium hydroxide. The filtrate and washings were combined. Yield was 85–90%.

Crystallization of the Free Acid.—One-tenth volume of 1 *N* barium chloride was added to the above filtrate, the solution was cooled to 0–5° and ethanol was added to a concentration of 50%. The solution was chilled overnight, then centrifuged and the precipitate washed with alcohol, ether and dried.

The barium precipitate was extracted with small portions of hot water until all of the active compound was in solution. The resulting extracts were combined and 1 *N* hydrochloric acid was added to *p*H 2.8. The solution was cooled to 5° and the precipitate collected. The precipitate was dissolved in hot water previously adjusted to *p*H 2.8 and containing a small amount of calcium or sodium chloride. On cooling the acid crystallized as very short needles or long threads. The acid could be repeatedly crystallized in this manner.

Anal.[12] Found: C, 48.6, 48.0, 47.7; H, 4.8, 4.4, 4.7; N, 16.2, 15.5, 15.5.

Crystallization of the Barium Salt.—The amorphous barium salt obtained by precipitation with 50% ethanol was dissolved in hot 0.1 *N* barium chloride. On cooling the compound crystallized as small needles.

Crystallization of the Methyl Ester.—The compound was re-esterified by dissolving in 0.1 *N* methanol–hydrogen chloride and allowing to stand at 32° for twelve hours.

The ester crystallized as short needles or long threads from methanol 0.05 *N* with sodium chloride.

Table I

Solubility of the Fermentation *L. casei* Factor

Compound	Solvent	Temp., °C.	Concn. mg. per ml.
Methyl ester	Methanol	60	5.00
Methyl ester	Methanol	−5	0.30
Methyl ester	Methanol–0.05 *N*	60	2.00
Methyl ester	sodium chloride	−5	0.11
Methyl ester	Water	80	1.00
Methyl ester	Water	5	0.12
Free acid	Water	80	3.00
Free acid	Water	5	0.10

Solubility.—The methyl ester and the free acid were soluble under the conditions noted in Table I.

Microbiological Assays.—The microbiological activity of the compound was determined for *Lactobacillus casei* and *Streptococcus faecalis* R. according to established procedures.

Ultraviolet Absorption.—The ultraviolet absorption spectra of the fermentation *L. casei* factor was determined using a Beckman Spectrophotometer.

Acknowledgment.—We are indebted to the Misses E. Boggiano and B. Eames for the micro-

biological assays and the spectrophotometric determinations, and to Mr. L. Brancone and coworkers for the microanalyses.

The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work performed in the various laboratories.

Summary

An isolation procedure for the fermentation *L. casei* factor is outlined. The analyses and biological activity distinguish the fermentation *L. casei* factor from any similar compound previously reported.

[CONTRIBUTION FROM LEDERLE LABORATORIES DIVISION, AMERICAN CYANAMID COMPANY]

The Isolation of the *Lactobacillus casei* Factor from Liver

BY E. L. R. STOKSTAD, BRIAN L. HUTCHINGS AND Y. SUBBAROW

Pfiffner, *et al.*,[1] and Stokstad[2] have described compounds isolated from liver which are active in promoting the growth of *L. casei* and *S. faecalis* R. The synthesis of this compound has recently been described by Angier, *et al.*[3] It is the purpose of this communication to describe the isolation of this compound from liver.

Experimental

Assays for the *L. casei* factor were made by the method of Landy and Dicken.[4] The assay results were expressed originally in terms of an arbitrary standard Solvamin.[5] One-tenth milligram of this constituted one unit and corresponded to approximately the amount required per 10 ml. of medium to give three-fourths maximum growth. The pure liver *L. casei* factor was later found to have an activity very close to 1,000,000 units per mg.

The starting material for this isolation was a commercial preparation of a dried 85% ethanol precipitate of an aqueous extract of liver. Different preparations of liver extract contained between 20,000 and 30,000 units per gram which corresponds to 20 to 30 micrograms of the pure liver *L. casei* factor per gram.

In the isolation of this compound, four essential steps were used. They were: adsorption and elution of the free acid, esterification and extraction of the methyl ester with immiscible solvents, chromatographic adsorption of the ester, and fractional precipitation of the ester from water and methanol. The results of all these isolation steps are presented in Table I.

Eighty kg. of liver extract was dissolved in 1600 liters of water, sodium hydroxide was added to *p*H 8.5, 80 liters of 2 *N* calcium chloride added and the mixture heated to 85° to flocculate the precipitate. The mixture was filtered while hot with the aid of filter cell. The filtrate was cooled to 25° and adjusted to *p*H 3.00. The *L. casei* factor was adsorbed with 16 kg. of Norit A. This adsorbate was washed, first, with 320 liters of neutral 60% ethanol at 25° to remove inert materials and then with two 320-liter portions of 0.5 *N* ammonium hydroxide in 60% ethanol at 70° to remove the activity.

The ammoniacal eluate was concentrated to 80 liters and adjusted to *p*H 3.5 and the precipitate which formed on standing removed by centrifuging. The precipitate was redissolved in 40 liters of water with the aid of sodium hydroxide and reprecipitated at *p*H 3.5. A large amount of inert material was removed by the precipitate but almost half the activity was carried down with it.

This filtrate was adsorbed at *p*H 1.3 on Superfiltrol[6] by

Fig. 1.—Crystals of liver *L. casei* factor.

percolation through a column of the granular adsorbent. Forty liters of the filtrate, equivalent to 40 kg. of liver extract, was percolated through 100 to 200 mesh Superfiltrol in a column 5 inches deep and 8 inches in diameter. The maximum rate of flow was 100 ml. per sq. cm. of filter surface per hour. The column was then eluted by percolation with 20 liters of 1.0 *N* ammonium hydroxide in 60% ethanol. After elution the column was rewashed with 0.1 *N* hydrochloric acid and then reused several times for subsequent adsorptions and elutions. When an adsorbent is used only once a certain amount of activity is adsorbed which cannot be eluted. In subsequent adsorptions and elutions this loss apparently does not occur. After six such cycles no decrease in efficiency of the adsorbent was observed and almost complete recovery of activity was obtained. From the table it can be seen that the Superfiltrol eluate contained 3,500 units per gram equivalent of liver extract and 340 units per mg. of solids. This represents a 17-fold increase in activity with a recovery of 17%.

The barium salt was next prepared by concentrating the superfiltrol eluates and adjusting to *p*H 7.0. The *L. casei* factor was precipitated as the barium salt by adding 9 volumes of ethanol and an excess of barium chloride solution. Little or no increase in activity was achieved but it did convert the material into a form which could be dried finely ground and then esterified.

It might be noted that while the *L. casei* factor can be precipitated by heavy metals such as lead and silver, and by basic precipitants such as phosphotungstic acid, no large increases in activity could be effected at this stage by the use of these reagents.

The next step consisted in esterification and extraction of the methyl ester with *n*-butanol. Two hundred grams of the finely ground barium salt were esterified in 20 liters of 0.2 *N* hydrochloric acid in methanol for sixteen hours at 25°. Esterification proceeds very rapidly going to completion in one hour at 25° if anhydrous reagents are used. This ester is approximately 10% as active for *L. casei* as the free acid. Part of the activity of the ester may be due to partial hydrolysis of the ester during autoclaving of the sample with the medium as the ester is very rapidly hydrolyzed. Four hours hydrolysis at 100° at *p*H 8.0 produced 75% hydrolysis, and 0.1 *N* sodium hydroxide at 25° gave complete hydrolysis in half an hour. Since the ester possesses only partial activity, assays for potency were preceded by ten minutes saponification with 0.1 *N* sodium hydroxide at 100°.

The esterified mixture was neutralized and evaporated to almost dryness, redissolved in 20 liters of water and adjusted to *p*H 6 to 7. It was then extracted three times with 2 volumes of *n*-butanol. Each butanol extract was washed successively with the same portion of half a volume of water. The distribution coefficient of the *L. casei* factor methyl ester for butanol to water is 3 to 1. The final butanol extract contained 2,000 units per gram equivalent of liver and 3,450 units per mg. of solids.

While chromatographic adsorption of the free acid from aqueous solution proved ineffective, chromatographic adsorption of the ester in organic solvents was highly efficient. Superfiltrol[6] proved the best adsorbent; Brockman alumina and calcium carbonate were much less effective. The *L. casei* factor methyl ester could be adsorbed on Superfiltrol from *n*-butanol, methanol, acetone and water. The only efficient eluant was aqueous acetone. Aqueous methanol, aqueous methyl ethyl ketone, acetone–methanol mixtures, acetone–ethanol mixtures and methyl ethyl ketone–methanol mixtures were ineffective.

Chromatographic separation was carried out as follows: The butanol extract was evaporated to dryness and redissolved in methanol. An aliquot of this methanol solution, equivalent to 0.5 kg. of liver extract, was passed through a 3.5 × 13.0 cm. column containing 75 g. of 200 to 325 mesh Superfiltrol. This was eluted first with 750 ml. of 92.5% acetone and then with three portions of 750-ml. of 75% acetone. The 92.5% acetone elution removed a large amount of highly colored impurities without removing appreciable activity. The 75% acetone rapidly eluted the active factor. The first 75% acetone eluate which had an activity of 47,000 units per mg. was concentrated to 200 ml. during which most of the acetone had been removed. On cooling the aqueous solution most of the activity precipitated out. This contained 1,000 units per gram of original liver extract and 370,000 units per mg. of solids.

This precipitate which formed from aqueous solution was extracted with a small amount of cold methanol using 1 ml. of solvent per kg. of original liver. This removed very little activity but removed most of the dark brown pigment. The *L. casei* factor methyl ester was then dissolved by extraction with a larger amount of boiling methanol (4 ml. per kg. of liver extract). This hot methanol extract was almost colorless and highly active. On cooling the hot methanol extract to 2° the methyl ester separated out in a nearly pure form as a gelatinous precipitate which had an activity of 1,030,000 units per mg. Reprecipitation from hot methanol yielded a preparation whose activity could not be increased by further purification. The solubility of the methyl ester in methanol is approximately 60 micrograms per ml. at 2°. The results obtained by methanol fractionation are shown in Table I. The analysis of two preparations of the methyl ester as obtained by this method are as follows

	C	H	N (Dumas)
Sample 1	53.0	4.6	21.2
Sample 2	53.1	5.1	20.5

The free acid was prepared by saponifying 2.0 mg. of a nearly pure preparation of the ester with 5.0 ml. of 0.01 *N* sodium hydroxide. The solution was treated with 4 mg. of Darco. On acidifying the filtrate to *p*H 3.0, the free acid precipitated out, which was then redissolved by heating to 90°. On cooling slowly the free acid of the *L. casei* factor crystallized out. The solubility of the free acid at *p*H 3.0 at 2° is approximately 10 micrograms per ml. and more than 0.5 mg. per ml. at 100°. These were recrystallized once from 0.1 *n* sodium chloride and two times from water.

The crystal form of the free acid is shown in Fig. 1.

The extinction coefficients in 0.1 *N* sodium hydroxide were determined with a Beckman spectrophotometer and found to be as follows: $E^{1\%}_{1\ \text{cm.}}$ 255 mμ, 565; 282 mμ, 350; 365 mμ, 195.

The amount required per ml. of medium for half maximum growth was 0.00007 microgram for *L. casei* and 0.0003 for *S. faecalis* R. This amount required for half maximum growth is not an accurately reproducible value and varies from one experiment to another.

Acknowledgment.—The authors wish to acknowledge the assistance of Barbara Eames in making the microbiological assays and to express their thanks to Dr. T. H. Jukes for his constant interest and counsel.

Summary

The isolation of the *Lactobacillus casei* factor from liver has been described. This was accomplished by the use of adsorption and elution of the free acid on Norit, esterification and extraction of the methyl ester with *n*-butanol. The methyl ester was chromatographed on Superfiltrol using aqueous acetone as the developer. Final purification of the ester was accomplished by fractional precipitation from water and methanol. The free acid was crystallized from hot water.

The Degradation of the Fermentation *Lactobacillus casei* Factor. I

BY E. L. R. STOKSTAD, BRIAN L. HUTCHINGS, JOHN H. MOWAT, JAMES H. BOOTHE, COY W. WALLER, ROBERT B. ANGIER, JOSEPH SEMB AND Y. SUBBAROW

The isolation of two *Lactobacillus casei* factors, one from liver[1,2] and one from a fermentation product[3,4] has been described.

These two *L. casei* factors differ in biological activities and physical properties. Extinction coefficients indicated that the fermentation *L. casei* factor has the larger molecular weight. The structure and synthesis of the liver *L. casei* factor have been described in a preliminary communication.[5] The synthetic liver *L. casei* factor has been reported to be the same as vitamin B_c[6] which had previously been isolated from liver and yeast.[7,8]

The relationship of the liver *L. casei* factor to folic acid[9] has not been definitely established although available evidence indicates they are the same.[10]

The liver *L. casei* factor also appears to be the same as the factor designated as the norite eluate factor.[11]

This communication deals with the degradation of the fermentation compound by alkaline hydrolysis under aerobic and anaerobic conditions and by acid hydrolysis.

In experiments on the degradation of the *L. casei* factor from liver and fermentation sources, it was soon observed that hydrolysis with acid or alkali led to the formation of a diazotizable aromatic amine which could be estimated by the method of Bratton and Marshall.[12] The liberation of amine was most rapid in alkaline solutions and it was found that oxygen had a marked effect on the course of the reaction. When the fermentation *L. casei* factor was heated with 1.0 *N* sodium hydroxide at 100° in the presence of oxygen there was a marked change in the absorption spectrum, a diazotizable aromatic amine was produced, a fluorescent pigment was formed and rapid biological inactivation occurred. The *L. casei* factor before hydrolysis has three absorption maxima in 0.1 *N* sodium hydroxide at 257, 282 and 365 mμ. After aerobic alkaline hydrolysis it has two maxima at 263 and 365 mμ.

When the hydrolysis was carried out anaerobically with 1.0 *N* sodium hydroxide at 100° there

was no change in the absorption spectrum and very little aromatic amine or fluorescent pigment was produced. The activity for *L. casei* was only slightly decreased during anaerobic hydrolysis while the activity for *S. faecalis* R was greatly increased. After prolonged anaerobic alkaline hydrolysis the ratio of activities for *L. casei* and *S. faecalis* R was approximately the same as that for the liver *L. casei* factor. A summary of results of anaerobic and aerobic alkaline cleavage appear in Table I. It should be noted here that while *p*-aminobenzoic acid (PABA) was used as the standard in the Bratton and Marshall determination, the analytical data are reported in terms of PABA as the arbitrary standard; and that the diazotizable amine was not PABA. The aromatic amine was not extractable from aqueous solutions at *p*H 3.0 with ether, while PABA under the same conditions was extracted readily.

[a] S. faecalis activity coefficient = $\frac{\textit{S. faecalis}\text{ activity of 1.0 }\textit{L. casei}\text{ unit of unknown}}{\textit{S. faecalis}\text{ activity of 1.0 }\textit{L. casei}\text{ unit of liver }\textit{L. casei}\text{ factor}}$

[b] Results of pteridine analysis expressed as 2-amino-4-hydroxy-6-pteridine carboxylic acid.

The α-amino acid which was formed during anaerobic hydrolysis had been cleaved from the rest of the molecule because it could be separated from the biologically active fragment. This alpha amino acid could be precipitated by barium hydroxide and 75% ethanol which indicated a dicarboxylic α-amino acid.[13]

The biologically active compound obtained by anaerobic hydrolysis with 1.0 *N* sodium hydroxide at 120° for ten hours was isolated and crystallized as the magnesium salt. It could not be crystallized as the free acid by the method previously employed to yield the crystalline liver *L. casei* factor. The ultraviolet absorption spectrum of this compound was identical with that of the liver *L. casei* factor. However, it was only 57% as active biologically as the liver compound by *S. faecalis* R assay and 58% by *L. casei* assay. The low microbiological activity suggested a racemic product. The identification of this compound as racemic liver *L. casei* factor was accomplished later by comparison of its infrared absorption spectrum with that of a synthetic specimen of racemic liver *L. casei* factor. The infrared absorption spectra of the racemic and natural isomers, which were significantly different, appear in a subsequent paper of this series. It is probable that racemization occurred during the extended alkaline hydrolysis.

The fluorescent pigment which was produced by aerobic alkaline hydrolysis was isolated by the following procedure. It was precipitated by acidifying the hydrolysate to *p*H 3.0 and crystallized as the sodium salt from 2.0 *N* sodium hydroxide. It could not be crystallized from weakly alkaline solutions. The free acid prepared by precipitation at *p*H 3.0 appeared amorphous but did show a micro-crystalline structure by X-ray diffraction. The elementary analysis suggested the empirical formula $C_7H_5N_5O_3$.

The presence of a guanidine group in the fluorescent pigment was observed. Oxidation with chlorine water and subsequent hydrolysis with 0.1 *N* hydrochloric acid at 140° or three hours yielded guanidine which was estimated colorimetrically. The Weber test[14] which is given by guanidine and methyl guanidine was positive. The Sullivan test[15] which is given by guanidine but not by methylguanidine was positive. The Sakaguchi test[16] which is given by methylguanidine but not by guanidine was negative. These colorimetric tests indicated the presence of a non-substituted guanidine in the hydrolyzed chlorine oxidation product. The formation of guanidine by chlorine oxidation constitutes evidence for a pyrimidine ring with an amino group in the 2-position.[17]

A titration curve of the sodium salt showed the presence of two acid groups with *pKa* values of 3.9 and 7.7. The presence of a carboxylic acid group was demonstrated by decarboxylation at 300° for three hours with the liberation of 0.8 mole of carbon dioxide. From this decarboxylated mixture a new fluorescent monobasic compound with a *pKa* of 8.0 was obtained. This decarboxylation of a dibasic acid to a monobasic acid with a *pKa* of 8.0 showed that the original compound contained a carboxylic and an enolic group.

This decarboxylated fraction had an ultraviolet absorption spectrum in 0.1 *N* sodium hydroxide with absorption maxima at 252 and 365 mμ while the original dibasic acid had maxima at 262 and 365 mμ. The absorption spectra of these two compounds in alkaline and acid solutions are shown in Figs. 1 and 2, respectively.

The empirical formula of $C_5H_7N_5O_3$, based on elementary analysis and titration data, and the formation of guanidine suggested a 2-aminopurine or 2-aminopteridine. The absorption spectra,

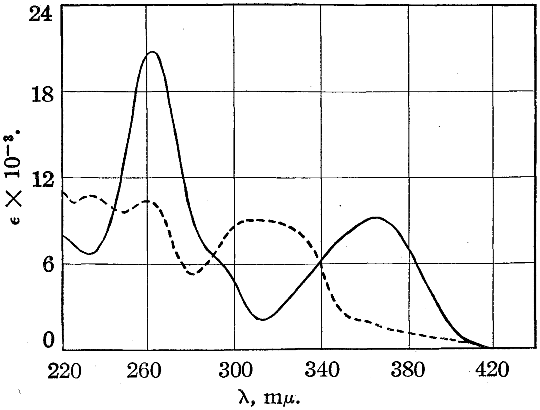

Fig. 1.—Ultraviolet absorption spectra of 2-amino-4-hydroxypteridine-6-carboxylic acid: ——, 0.1 *N* sodium hydroxide; ----, 0.1 *N* hydrochloric acid.

however, eliminated the possibility of a purine because purines do not have absorption maxima above 300 mμ. Thus the available evidence pointed toward 2-aminopteridine with an enolic and a carboxy group. Attempts were made to synthesize pteridines having these functional groups. With this objective, 2-amino-4-hydroxy-6-pteridinecarboxylic acid was synthesized and found to be identical with the fluorescent dibasic pigment. Identity was established by comparison of ultraviolet absorption spectra Fig. 1 and X-ray diffraction patterns. The synthesis and proof of structure of this compound will be given in a subsequent paper. The monobasic fluorescent pigment produced by decarboxylation was identified as 2-amino-4-hydroxypteridine.

Hydrolysis of fermentation *L. casei* factor with 1.0 *N* sulfuric acid anaerobically for eight hours at 100° yielded a fluorescent monobasic acid which was extracted from the hydrolysate with *n*-butanol at *p*H 7.0. This procedure left the dibasic pteridine in the aqueous phase. The monobasic compound was crystallized as the sodium salt from 10.0 *N* sodium hydroxide and then converted to the free acid. This was identified as 2-amino-4-hydroxy-6-methylpteridine by comparison of the ultraviolet and infrared absorption spectra of the natural and synthetic compounds. The synthesis and proof of structure of this compound will be given in a later paper.

The aromatic amine fraction was obtained by first hydrolyzing the fermentation compound anaerobically with alkali to give the racemic liver *L. caesi* factor and then further hydrolyzing aerobically to liberate the aromatic amine. After removal of pteridines the dried amine fraction was extracted as the free acid with ethanol. The aromatic amine obtained from racemic liver *L. casei* factor contained 2.1 atoms of total nitrogen for each atom of aromatic amine nitrogen as measured by the Bratton and Marshall method. On hydrolysis with 2.0 *N* sulfuric acid for sixteen hours at 100°, 45% of the total nitrogen appeared as alpha amino acid nitrogen. *p*-Aminobenzoic acid was isolated from this hydrolysate by extraction with ethyl acetate, crystallized from water and identified by mixed melting points and microbiological assay.

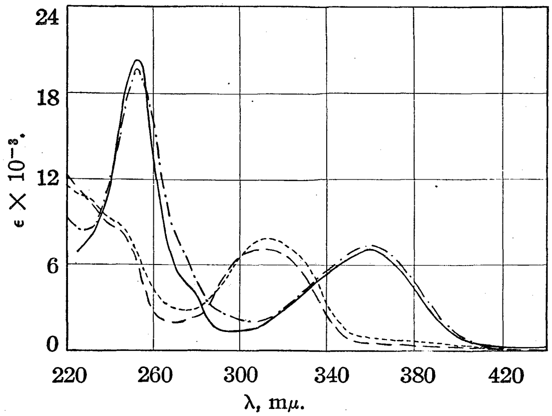

Fig. 2.—Ultraviolet absorption spectra of 2-amino-4-hydroxypteridine, synthetic: ———, in 0.1 *N* sodium hydroxide; — — —, in 0.1 *N* hydrochloric acid. Product obtained from decarboxylation of natural 2-amino-4-hydroxypteridine-6-carboxylic acid; — · — · — in 0.1 *N* sodium hydroxide; ------ in 0.1 *N* hydrochloric acid. The absorption spectra of the decarboxylated product were determined on an aliquot of a solution of an unweighed sample and the values are arbitrarily plotted on the same scale to show similarity.

This evidence indicated that the aromatic amine from the racemic liver *L. casei* factor is a dipeptide of *p*-aminobenzoic acid and an α-amino acid. This peptide linkage must involve the carboxyl group of the *p*-aminobenzoic acid, as the aromatic amine group must be free in order to react in the Bratton and Marshall test.

Some evidence regarding the mode of linkage is furnished by the results of aerobic alkaline hydrolysis. The absence of fluorescence and of free aromatic amine in the original *L. casei* factor, and the simultaneous appearance of these two during aerobic alkaline hydrolysis suggests that the pteridine is linked to the aromatic amine nitrogen. As hydrolysis proceeds, the liberation of pteridine and amine, and biological inactivation proceed at approximately the same rate. No method of cleavage has been found which will liberate the aromatic amine without forming a pteridine. A linkage which can be cleaved only by oxidative hydrolysis is also demanded. This excludes the possibility of a peptide linkage between the carboxy group of the pteridine and the aromatic amine nitrogen. It also eliminates the possibility of the aromatic amine nitrogen being attached to the 4 position of the pteridine. Cleavage of such a bond to give a 4-hydroxypteridine would be simple hydrolysis and would not require oxidation.

Experimental

Effect of Oxygen on Alkaline Hydrolysis.—A solution of 17.4 mg. of fermentation *L. casei* factor in 0.5 ml. of 1.0 *N* sodium hydroxide was hydrolyzed in a sealed 8-mm. test-tube. The tube was evacuated for anaerobic hydrolysis and filled with oxygen for aerobic hydrolysis. After hydrolysis for the times and temperatures indicated in Table I, the solutions were assayed microbiologically with *L. casei* and *S. faecalis* R, using the method of Tepley and Elvehjem.[18] α-Amino acid nitrogen was determined by the method of Van Slyke and aromatic amine by the method of Bratton and Marshall,[12] using *p*-aminobenzoic acid as the standard. The ultraviolet absorption spectra were measured in a Beckman spectrophotometer, and the fluorescence was measured in 0.05 *M* borate buffer with a fluorophotometer. The results were later recalculated in terms of 2-amino-4-hydroxypteridine-6-carboxylic acid.

Isolation of Racemic Liver *L. casei* Factor.—Fermentation *L. casei* factor, 170 mg. in 6 ml. of 1.0 *N* sodium hydroxide, was hydrolyzed for ten hours at 120° anaerobically in an evacuated sealed tube. The hydrolysate contained 39 mg. of liver *L. casei* factor. The biologically active material was precipitated twice with zinc acetate at *p*H 6.7 at 80°. The final zinc precipitate was dissolved in alkali, the zinc hydroxide removed, and the *L. casei* factor precipitated at *p*H 3.0. The precipitate was dissolved in 25 ml. of 0.025 *N* sodium hydroxide, the solution was treated with 100 mg. of activated charcoal (Darco) and the *L. casei* factor precipitated with barium chloride and 3 volumes of methanol.

The barium salts were extracted with hot water, and the extracts heated to 100° and acetic acid added to *p*H 3.0. The active material precipitated on cooling and was reprecipitated twice in a similar manner. These amorphous precipitates of the free acid, 18 mg., were converted into the crystalline magnesium salts by boiling with 5.0 mg. of magnesium oxide and 3.0 ml. of water, and separating off the excess magnesium oxide. On cooling the hot extract the magnesium salt crystallized. This was recrystallized from water. The final magnesium salt, when converted into the free acid by precipitation from a hot solution at *p*H 3, yielded spherulites which exhibited birefringence but which did not form the typical spear-shaped crystals characteristic of the natural isomer of the liver *L. casei* factor; yield of free acid, 5.0 mg. $E^{1\%}_{1\,\mathrm{cm.}}$ for free acid of racemic liver *L. casei* factor as determined in 0.1 *N* sodium hydroxide, 257 mμ, 591; 285 mμ, 575; 365 mμ, 207. Biological activity compared with natural isomer of liver *L. casei* factor: *L. casei* assay, 58.0%; *S. faecalis* R assay, 57.0%. The infrared absorption spectrum of the free acid of the isolated racemic liver *L. casei* factor matched exactly that of the synthetic racemic liver *L. casei* factor.

Isolation of Fluorescent Dibasic Pigment.—Two hundred mg. of fermentation *L. casei* factor in 10.0 ml. 1.0 *N* sodium hydroxide was hydrolyzed six hours at 100° with a stream of oxygen bubbling through the solution. The hot hydrolysate was centrifuged to remove some brown pigment. On cooling the filtrate to 2° a crystalline precipitate (10 mg.) formed which later proved to be the disodium salt of 2-amino-4-hydroxypteridine-6-carboxylic acid. The greater part of the pteridine remained in the filtrate. This filtrate was adjusted to *p*H 5.0 with sulfuric acid and diluted to 20 ml., heated to 70° and the hot solution centrifuged to remove insoluble impurities. The filtrate containing 48 mg. of pteridine was adjusted to *p*H 2.3. The pteridine which precipitated as the free acid at this *p*H was redissolved in dilute alkali and reprecipitated at *p*H 2.3. This free acid (44 mg.) was dissolved at *p*H 11 in 2.0 ml. of water plus sodium hydroxide. After standing at 2° for sixteen hours, impurities were removed by centrifuging and the filtrate brought to 1.0 *N* with sodium hydroxide. On cooling to 2° for sixteen hours the crude sodium salt crystallized. This was recrystallized three times from 1.0 *N* sodium hydroxide.

At this point the products of five such hydrolyses (1.0 g. total fermentation *L. casei* factor) were combined and precipitated twice as the free acid at *p*H 2. The final product was washed with water, methanol and finally ether and dried two hours at 60° in high vacuum over phosphorus pentoxide; yield was 69 mg.

Anal. Found: C, 40.11, 41.03, av., 40.57; H, 1.75, 3.23, av., 2.50; N Kjeldahl, 32.2, 31.8; N Dumas, 32.4, 32.75, av., 32.3. Calcd. for $C_7H_5N_5O_3$: C, 40.58; H, 2.42; N, 32.3.

Formation of Guanidine by Chlorine Oxidation.—A fine suspension of 5 mg. of the fluorescent dibasic acid was treated with 10 ml. of 0.15 *N* chlorine water at 40° for fifteen minutes. The solution was evaporated to dryness, water added, and the solution again evaporated to remove excess chlorine. The residue was dissolved in 4.0 ml. of 0.1 *N* hydrochloric acid and heated three hours at 140°. Guanidine was estimated qualitatively by the method of Sullivan[15] and quantitatively by the method of Weber.[14] Under these conditions of oxidation and hydrolysis the fluorescent dibasic acid yielded 0.24 mole of guanidine, while xanthopterin gave 0.09 mole and leucopterin gave 0.27 mole of guanidine.

Decarboxylation.—The fluorescent dibasic acid (2.562 mg.) was heated at 250–300° for three hours in a stream of nitrogen and the carbon dioxide collected in barium hydroxide solution. The barium carbonate which formed was converted into barium sulfate and weighed. The results were as follows

Wt. of sample, mg.	2.562
Loss on heating, mg.	0.448
Wt. barium sulfate, mg.	1.852
Moles carbon dioxide (based on weight loss on heating and assuming mol. wt. 207)	0.82
Moles carbon dioxide based on barium sulfate found	.64

An electrometric titration of this heated product indicated that complete decarboxylation had not occurred.

A larger sample of 6.63 mg. was decarboxylated and fractionated as follows: It was dissolved in excess alkali, adjusted to *p*H 5.0 and diluted to 10.0 ml. The solution was heated to 90° and centrifuged hot. The filtrate was chilled to 2°. The precipitate which formed had a *pKa* of 8.0 and showed no evidence of an acid group with a *pKa* of 3.7. The absorption spectrum in 0.1 *N* sodium hydroxide was determined on an aliquot of this solution and the new decarboxylated pteridine was found to have maxima at 252 and 365 mμ. As insufficient material was present to be weighed, the absorption spectrum was based on an unknown weight of material. This absorption spectrum was found to be very similar to that of 2-amino-4-hydroxypteridine. The absorption curves of these two compounds appear in Fig. 2.

Isolation of Monobasic Fluorescent Pigment.—Fermentation *L. casei* factor (227 mg.) was dissolved in 25 ml. of 1.0 *N* sulfuric acid and hydrolysed anaerobically for eight hours at 100°. A large amount of black precipitate formed which was centrifuged off. The supernatant was adjusted to *p*H 7.0 and extracted five times with 10 volumes of butanol, using one portion of water to wash each butanol extract. The butanol extract, which contained *ca.* 17.0 mg. of pteridine by spectrophotometric analysis, was evaporated to 9.0 ml. and 3.0 ml. of ether added. The precipitated pteridine was centrifuged, dried and redissolved in 10.0 ml. of water and reextracted three times with 10 volumes of butanol. The combined butanol extracts were concentrated to 5.0 ml., 5.0 ml. ether added and the solution chilled to 0°. The precipitate, containing *ca.* 8.7 mg. pteridine was dried, dissolved in 5.0 ml. of hot water, centrifuged while hot and the supernatant chilled to 0°. The pteridine, which was soluble in hot water, precipitated on cooling. The precipitate, containing *ca.* 6.7 mg. of pteridine was dissolved in 6.0 ml. of dilute sodium hydroxide and treated with 30 mg. of activated charcoal (Darco). The filtrate (3.4 mg. pteridine) was adjusted to *p*H 5.0. On cooling to 0° the pteridine precipitated out. The precipitate was dried, and crystallized two times from 0.5 ml. of 10.0 *N* sodium hydroxide. Crystallization proceeded rapidly from 10.0 *N* sodium hydroxide but not from 5.0 *N*. The final crystalline product was dissolved in

---

(18) Tepley and Elvehjem, *J. Biol. Chem.*, **157**, 303 (1945).

0.55 ml. water. The amount of material present was so small, *ca.* 0.57 mg. by spectrophometric analysis at 365 mμ, that an aliquot of the solution was used to determine the complete absorption spectrum. The absorption spectrum matched with that of 2-amino-6-hydroxy-6-methyl pteridine. The remainder was converted to the free acid, dried and its infrared absorption spectrum determined. This was found to be identical with that of a synthetic specimen of 2-amino-4-hydroxy-6-methylpteridine. The ultraviolet and infrared absorption spectra of this compound will be given in the following paper of this series.

Isolation of Amine Fractions.—Fermentation *L. casei* factor (162 mg.) was dissolved in 9.5 ml. of 1.0 *N* sodium hydroxide and hydrolyzed anaerobically for ten hours at 120°. The racemic liver *L. casei* which formed was precipitated with silver nitrate at *p*H 3.0 and the precipitate freed of silver with hydrochloric acid. The silver precipitate fraction contained 92 mg. of racemic liver *L. casei* factor on the basis of a spectrophotometric determination.

This racemic liver *L. casei* factor was then hydrolyzed aerobically for six hours in 11 ml. of 1.0 *N* sodium hydroxide at 100°. The pteridine was removed by precipitation with silver sulfate at *p*H 5.0. The filtrate, after being freed of silver with hydrochloric acid, was adjusted to *p*H 3.0 and evaporated to dryness. The residue was extracted twice with a total of 75 ml. of hot absolute ethanol to extract this amine. The ethanol extracts were evaporated to dryness and extracted twice with 25-ml. portions of hot isopropanol. This extracted the amine without removing appreciable amounts of inorganic salts. This isopropanol solution was evaporated to dryness and the residue dissolved in 10 ml. of water. This solution analysed as follows:

Aromatic amine calcd. as PABA, mg.	19.0
Aromatic amine nitrogen, mg.	1.94
Alpha amino acid nitrogen, mg.	0.42
Total nitrogen, mg.	4.50
Distribution coefficient for aromatic amine at *p*H 3.0; ethyl acetate to water	0.20

This amine could be hydrolyzed by either 2.0 *N* sulfuric acid at 100° for sixteen hours or by 5.0 *N* sodium hydroxide for thirteen hours at 120°. After hydrolysis with acid, the distribution coefficient at *p*H 3.0 for ethyl acetate to water was 8.1; after alkaline hydrolysis, it was 11.0, while that for PABA under the same conditions was 11.0. *p*-Aminobenzoic acid was isolated by hydrolyzing 7.8 mg. of the amine fraction (calcd. as PABA) in 5.0 ml. of 2.0 *N* sulfuric acid for sixteen hours at 100°. The hydrolysate contained 6.7 mg. of amine (as PABA). The solution was diluted to 50 ml. and freed of sulfuric acid with barium carbonate, the filtrate concentrated to 10 ml. and adjusted to *p*H 8.0. Extraction at this *p*H with two 10-ml. portions of ethyl acetate removed no amine. The solution was adjusted to *p*H 3.0 and again extracted with ethyl acetate in the same way. The two *p*H 3.0 ethyl acetate extracts were each washed successively with one 5-ml. portion of water.

The ethyl acetate extract and the water phase analyzed as follows:

Ethyl acetate extract.	
Aromatic amine (as PABA), mg.	4.5
Aromatic amine nitrogen, mg.	0.47
Total nitrogen, mg.	.42
Aqueous residue plus washings.	
Aromatic amine (as PABA), mg.	0.10
Aromatic amine nitrogen, mg.	.01
Total nitrogen, mg.	.70

On evaporating the ethyl acetate extract to dryness, a crystalline product was obtained which was recrystallized from 0.3 ml. of hot water: yield was 0.8 mg.; m. p. unknown (hot stage), 183.5–184.5° uncor.; m. p. *p*-aminobenzoic acid (hot stage), 185.5–186.5° uncor.; mixed melting point (hot stage), 185.5–186.5° uncor.

Microbiological assays for *p*-aminobenzoic acid were made by the methods using *Clostridium acetobutylicum*[19] and *Acetobacter suboxydans*[20] which gave values of 95 and 81%, respectively.

Acknowledgment.—The authors wish to acknowledge the assistance of Barbara Eames, Edythe Brogan and Anna Buxó for spectrophotometric determinations, Louis Brancone and coworkers for elementary analysis, and Dan McLachlan[21] for X-ray diffraction studies. The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work performed in the various laboratories.

Summary

1. Anaerobic alkaline hydrolysis of the fermentation *L. casei* factor gives racemic liver *L. casei* factor and 2 moles of a dicarboxylic alpha amino-acid.

2. Aerobic alkaline hydrolysis gives 2-amino-4-hydroxypteridine-6-carboxylic acid and an aromatic amine.

3. The aromatic amine obtained by aerobic alkaline hydrolysis of the racemic liver *L. casei* factor consists of a dipeptide of *p-aminobenzoic* acid and an α-amino acid.

4. Anaerobic acid hydrolysis of the fermentation *L. casei* factor yields 2-amino-4-hydroxy-6-methylpteridine.

5. Linkage of the pterin to the amino group of *p*-aminobenzoic acid is indicated by the rates of liberation of pteridine and amine during aerobic alkaline hydrolysis.

Degradation of the Fermentation *L. casei* Factor. II

BY BRIAN L. HUTCHINGS, E. L. R. STOKSTAD, JOHN H. MOWAT, JAMES H. BOOTHE, COY W. WALLER, ROBERT B. ANGIER, JOSEPH SEMB AND Y. SUBBAROW

In the previous paper[1] data were presented indicating that 2-amino-4-hydroxypteridine-6-carboxylic acid, 2-amino-4-hydroxy-6-methylpteridine and *p*-aminobenzoic acid were degradation products of the fermentation *L. casei* factor. In this paper further degradation products are presented and evidence for the structure of the liver *L. casei* factor is outlined.

When the fermentation *L. casei* factor was dissolved in water at *p*H 4.0 and autoclaved at 120° for six hours, the activity of the compound was destroyed. From this inactive solution a crystalline product was isolated. The analysis, chemical properties, and melting point suggested that the substance was *l*-pyrrolidonecarboxylic acid. However, a cryoscopic determination of the molecular weight offered the possibility of a diketopiperazine of glutamic acid.

Synthetic *l*-pyrrolidonecarboxylic acid caused no depression of the melting point of the unknown compound. Further corroborative evidence of the identity of the degradation product with *l*-pyrrolidonecarboxylic acid was furnished by comparison of their infrared absorption spectra (Fig. 1).

When the fermentation *L. casei* factor was dissolved in water and the resulting solution made 0.5 *N* with sulfur dioxide, the growth-promoting properties of the compound were destroyed. There was a marked increase in the fluorescence of the solution and an aromatic amine was formed that could be detected by the method of Bratton and Marshall.[2]

After removal of the sulfur dioxide, the fluorescent moiety reacted rapidly with such typical aldehyde reagents as hydroxylamine, phenylhydrazine and semicarbazide to form insoluble products. The condensation products exhibited no fluorescence. These derivatives were extremely insoluble and quite unstable but analyses indicated the condensation product with phenylhydrazine to be a hydrazone. If the fluorescent compound arising from sulfurous acid hydrolysis was allowed to stand in dilute alkali anaerobically, approximately equal amounts of 2-amino-4-hydroxypteridine-6-carboxylic acid and a compound which was identified as 2-amino-4-hydroxy-6-methylpteridine were formed. The presence of 2-amino-4-hydroxy-6-methylpteridine was unexpected and its mode of formation is obscure. The ability to form insoluble precipitates with typical aldehyde reagents and the dismutation in dilute alkali indicate the presence of an aldehyde group in the pteridine arising from sulfite cleavage of the fermentation *L. casei* factor.

By appropriate manipulations the aromatic amine fragment could be purified. The aromatic amine nitrogen as determined by the method of Bratton and Marshall was found to be approximately 25% of the total nitrogen. The remaining 75% of the nitrogen could be converted into α-amino acid nitrogen by acid or alkaline hydrolysis. From such hydrolysates the aromatic amine was isolated and identified as *p*-aminobenzoic acid. Microbiological assay of the hydrolysate indicated the presence of 3 moles of glutamic acid. Analytical figures suggested that the amino acids are joined in peptide linkage as *p*-aminobenzoyldiglutamylglutamic acid. The mode of linkage of the glutamic acids will be discussed in a subsequent communication.

After sulfurous acid hydrolysis of the fermentation *L. casei* factor no one or two carbon-containing fragments could be detected. Aerobic ultraviolet inactivation of the fermentation *L. casei* factor which cleaves the compound into a pteridine fraction and an aromatic amine fraction failed to yield any carbon dioxide. The evidence suggests that the carbon content of the fermentation *L. casei* factor is that represented by the degradation products.

The fermentation *L. casei* factor was not measurably inactivated by hydrogenation over regular Raney nickel, Raney nickel containing aluminum, or over palladium on barium sulfate if the hydrogenation was carried out at a *p*H of 7.0 or greater and at atmospheric pressure. If the compound was hydrogenated at *p*H 1.0 or 3.0 and at atmospheric pressure using a palladium–barium sulfate catalyst, there was rapid biological inactivation with the simultaneous formation of an aromatic amine. The ultraviolet absorption at 365 mμ was greatly decreased indicating the reduction of the pteridine to a compound that exhibited no absorption at this wave length. The absorption and fluorescence of the pteridine moiety could be regenerated by oxidation with manganese dioxide in acid solution.

The reductive reaction can be carried out chemically with zinc dust and either dilute hydrochloric or sulfuric acids. From chemically reduced solutions of the fermentation *L. casei* factor, 2-amino-4-hydroxy-6-methylpteridine has been isolated and characterized.

In a summation of the data presented in this and the previous paper of this series the following salient points serve as a guide to the formulation of the structure of the liver *L. casei* factor:

A. Aerobic alkaline hydrolysis, sulfite cleavage and chemical or catalytic reduction each give

[2] Bratton and Marshall, *J. Biol. Chem.*, **128**, 537 (1939).

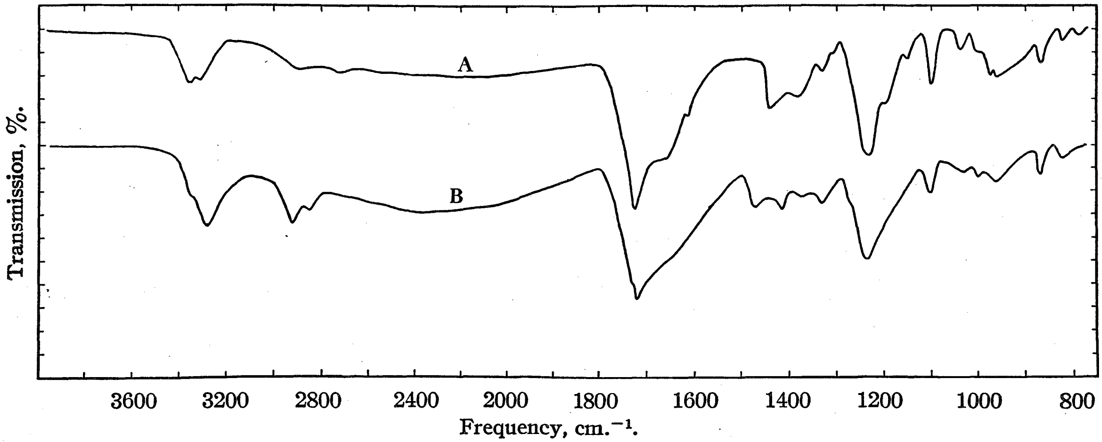

Fig. 1.—Infrared absorption spectra of *l*-pyrrolidonecarboxylic acid: A, synthetic; B, natural.

rise to a pteridine fraction and a primary aromatic amine. This indicates that the point of linkage is probably through the aromatic amine group to the pteridine.

B. A single carbon atom serves as a linkage between the pteridine and aromatic amine. This is indicated by obtaining either 2-amino-4-hydroxypteridine-6-carboxylic acid or 2-amino-4-hydroxy-6-methylpteridine or a compound that could be converted into them as degradation products in several methods of cleavage. Further indicative evidence is the inability to detect any one or two carbon-containing fragments arising from two degradative reactions. The evidence suggests that the one carbon is present as a methylene group. Thus, the necessity of oxygen for the alkaline cleavage is more rational. The reductive formation of 2-amino-4-hydroxy-6-methylpteridine is in accord with this hypothesis.

C. The aromatic amine arising from sulfite-cleavage is a tetrapeptide composed of one mole of *p*-aminobenzoic acid and three moles of glutamic acid. In the previous paper of this series it was observed that in degrading the fermentation *L. casei* factor to the *dl*-liver *L. casei* factor, two moles of α-amino acid nitrogen were liberated. Thus, the liver *L. casei* factor contains one mole of glutamic acid and the fermentation compound three moles of glutamic acid.

Experimental[3,4,5]

Aqueous Hydrolysis of the Fermentation *L. casei* Factor.—Two hundred mg. of the fermentation *L. casei* factor was dissolved in 125 ml. of water and autoclaved at 120° for six hours. The resulting clear solution was allowed to stand at 5° for twenty-four hours. The material that precipitated was centrifuged out and discarded. The water solution was concentrated to dryness and the residue extracted with 4–15 ml. portions of hot absolute ethanol. The ethanol extracts were concentrated to dryness and the residue extracted with 125 ml. of acetone. The acetone was evaporated and the residue sublimed in high vacuum at 148° for six hours. The sublimate was contaminated with a brown pigment that was removed by extracting the sublimate with several 0.1-ml. portions of ice-cold ethanol. The residue was re-sublimed at 138° for six hours. There was obtained a colorless crystalline sublimate (wt. 28 mg.) which melted at 147–148°. A cryoscopic determination of the molecular weight using camphor as the solvent gave a value of 284.

Anal. Found: C, 47.05; H, 5.14; N, 10.93.

Titration data for the compound indicated the presence of a strong carboxylic acid group. The equivalent weight calculated at *p*H 7.0 was 129.2. The compound exhibited no ultraviolet absorption. The substance gave no color with ferric chloride in aqueous or alcoholic solution. The sample adsorbed no hydrogen over Adams platinum oxide catalyst.

The compound contained no α-amino acid nitrogen. However, when 1.794 mg. of the compound was dissolved in 2 ml. of 1 *N* sodium hydroxide and heated at 100° for three hours, the following figures were obtained: total nitrogen, 0.196 mg.; α-amino acid nitrogen before hydrolysis, negative; α-amino acid nitrogen after hydrolysis, 0.174 mg. Because of the small sample used and the accuracy of the Van Slyke determination, these values are indicative of complete conversion of the nitrogen into α-amino acid nitrogen.

A semi-quantitative microbiological determination of the glutamic acid content of a 1 *N* sodium hydroxide hydrolysate of the sublimate was carried out using *Lactobacillus casei* as the test organism. A glutamic acid control was run under identical conditions to determine the extent of racemization. This factor was used in calculating the results. The sublimate analyzed for 81.5% glutamic acid.

l-Pyrrolidonecarboxylic acid was synthesized according to the procedure of Abderhalden and Kautzsch.[6] The *l*-pyrrolidonecarboxylic acid melted not sharply at 144–148°.[7] A mixture of *l*-pyrrolidonecarboxylic acid and the unknown melted at 145–147°.

A cryoscopic determination of the molecular weight of the synthetic *l*-pyrrolidonecarboxylic acid gave a value of 284 indicating polymerization of the compound.

Reaction of the Sulfite-cleaved Pteridine with Phenylhydrazine.—One hundred mg. of the fermentation *L. casei* factor was dissolved in 50 ml. of water with slight warming and a solution of sulfurous acid added. The final volume was 200 ml. and was 0.5 *N* with respect to sulfurous acid. The solution was kept at 32° for sixteen hours. The solu-

---

(3) All concentrations carried out in vacuum.

(4) All melting points are uncorrected.

(5) The ultraviolet absorption was determined with a Beckman Spectrophotometer. The fluorescence of the pteridines was determined in 0.05 *M* sodium borate buffer with a Pfaltz and Bauer Fluorophotometer.

(6) Abderhalden and Kautzsch, *Z. physiol. Chem.*, **68**, 487 (1910).

(7) On further fractional crystallization the m. p. of the synthetic compound was raised to 160–162°. A lack of material precluded further purification of the isolated *l*-pyrrolidonecarboxylic acid. Partial racemization could account for the low m. p. of the isolated compound (see ref. 3).

tion was concentrated to one-half volume under nitrogen to remove the sulfur dioxide, warmed to 80° and a solution of phenylhydrazine in dilute acetic acid was added. There was an immediate formation of a red precipitate. The solution was warmed for thirty minutes, then cooled and centrifuged. The precipitate was dissolved in a mixture of piperidine and water (0.4:10) and precipitated by the addition of acetic acid. The solution and precipitation were repeated twice.

Anal. Calcd. for $C_{13}H_{11}N_7O$: C, 55.5; H, 3.92. Calcd. for $C_{20}H_{17}N_9O$: C, 48.1; H, 3.41. Found: C, 54.2; H, 3.86.

The analyses indicate the formation of a hydrazone rather than a dihydrazone.

Effect of Alkali on the Sulfite-cleaved Pteridine.—Two hundred and fifty mg. of the fermentation *L. casei* factor was treated with sulfurous acid as described above. After hydrolysis the solution was concentrated to dryness under nitrogen and the residue dissolved in 6.0 ml. of 1 *N* sodium hydroxide. The flask was evacuated and then stored in a vacuum desiccator at 4°. After fourteen days the precipitate which had formed was centrifuged off and washed with 2 *N* sodium hydroxide. The absorption spectra of this precipitate in both 0.1 *N* sodium hydroxide and 0.1 *N* hydrochloric acid were identical with the absorption spectra of the 2-amino-4-hydroxypteridine-6-carboxylic acid. The amount of the 2-amino-4-hydroxypteridine-6-carboxylic acid as determined by ultraviolet absorption was 17 mg.

The solution after removal of the precipitated 2-amino-4-hydroxypteridine-6-carboxylic acid was adjusted to *p*H 7.0 and a volume of 30 ml. and extracted five times with ten volume portions of butanol. The total amount of pteridine extracted by the butanol as measured by fluorescence was 30 mg. The butanol was concentrated and the compound precipitated by the addition of ether. The precipitate was dissolved in 20 ml. of hot water at *p*H 7.0. A small amount of brown insoluble pigment was removed by centrifugation. The solution was cooled and the precipitate collected; yield was 25 mg. The pteridine was crystallized from 2.0 ml. of 5 *N* sodium hydroxide. The crystalline precipitate was collected and recrystallized from 1.3 ml. of 5 *N* sodium hydroxide. The crystals were suspended in water, adjusted to *p*H 7.0 and dissolved by heating. After cooling the pteridine was collected.

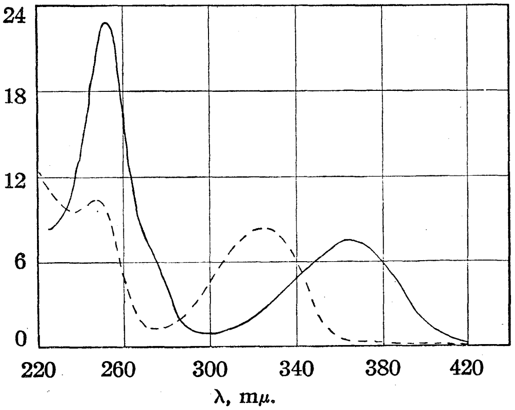

Fig. 2.—Ultraviolet absorption spectra of 2-amino-4-hydroxy-6-methylpteridine: ——, in 0.1 *N* sodium hydroxide; – – – –, in 0.1 *N* hydrochloric acid.

Anal. Calcd. for $C_7H_7N_5O_2$: C, 43.5; H, 3.63; N, 36.3. Calcd. for $C_7H_7N_5O$: C, 47.4; H, 3.95; N, 39.5. Found: C, 47.4; H, 4.43; N, 39.6.

A comparison of the ultraviolet absorption spectra of this compound with the absorption spectra of various pteridines indicated its identity with 2-amino-4-hydroxy-6-methylpteridine (Fig. 2). The synthesis of this compound will be described in the following paper of this series. The infrared absorption spectra of the natural and synthetic 2-amino-4-hydroxy-6-methylpteridine are identical (Fig. 3).

The pteridine remaining in the water layer after butanol extraction was precipitated twice by silver at *p*H 5.0 to remove it from the amine in solution. The yield was 10 mg. as determined by ultraviolet absorption. The absorption spectra of this pteridine were similar to those for the 2-amino-4-hydroxypteridine-6-carboxylic acid.

The total amount of pteridines obtained from the fermentation *L. casei* factor that had been cleaved with sulfurous acid and subsequently treated anaerobically with 1 *N* sodium hydroxide is presented in Table I.

TABLE I

PTERIDINE OBTAINED ON ALKALINE DISMUTATION

	Milligrams	Moles per mole of F. L. C. F.
Fermentation *L. casei* factor used	250	
Amine (calcd. as PABA)	48	0.98
2-Amino-4-hydroxypteridine-6-carboxylic acid		
a. Precipitated by 1.0 *N* sodium hydroxide	17	.23
b. Remaining after extraction with butyl alcohol and precipitated by silver	10	.14
Total	27	.37
2-Amino-4-hydroxy-6-methylpteridine		
a. Total amount extracted by butanol	30	.47

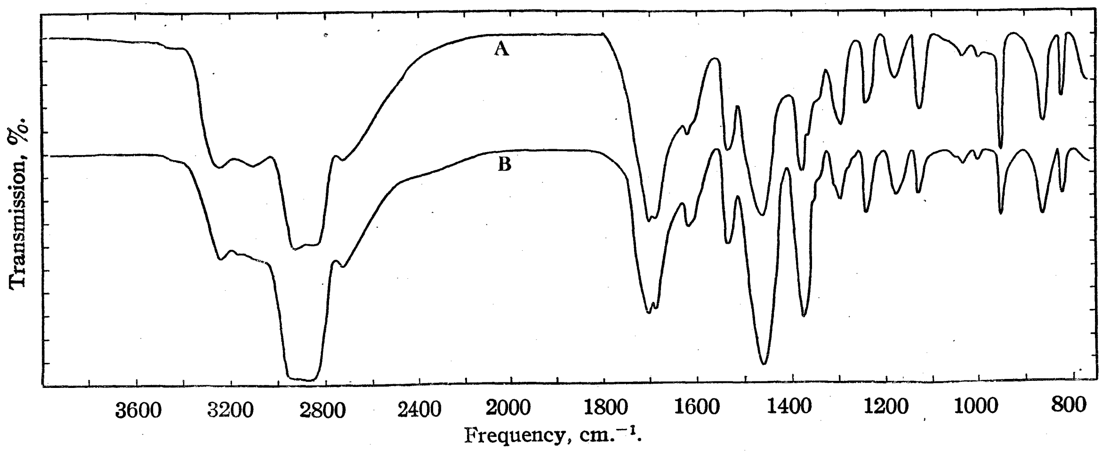

Fig. 3.—Infrared absorption spectra of 2-amino-4-hydroxy-6-methylpteridine: A, natural; B, synthetic.

Purification of the Aromatic Amine.—One gram of the fermentation *L. casei* factor was hydrolyzed with sulfurous acid. After cleavage, the solution was concentrated to one-half volume to remove the sulfur dioxide. The pteridine fraction was removed by precipitation with silver sulfate at *p*H 2.0. Excess silver and sulfate ions were removed from the filtrate; yield was 115 mg. calculated as *p*-aminobenzoic acid. The solution was adjusted to *p*H 2.0 and concentrated to dryness. The residue was dried thoroughly and the amine extracted from the solid with absolute isopropanol. The isopropanol solution was concentrated to dryness and the residue dissolved in 30 ml. of water. Excess lead acetate was added. After standing overnight at 5°, the lead precipitate was collected and washed with 5 ml. of cold water containing a little lead acetate. The precipitate was suspended in water and the lead removed as the sulfide; yield was 96.5 mg. calculated as *p*-aminobenzoic acid. The solution was adjusted to *p*H 2.0 and concentrated to dryness. The amine was extracted into absolute isopropanol. The isopropanol was evaporated and the residue dissolved in 50 ml. of water. Barium hydroxide was added to *p*H 10.0 and the slight precipitate removed. Ethanol was added to 50% concentration and the material kept at 5° overnight. The barium precipitate was collected, dissolved in water, adjusted to *p*H 2.0 and concentrated to dryness. The amine was extracted with isopropanol and then precipitated by the addition of one volume of petroleum ether. The precipitate was centrifuged off, dissolved in 35 ml. of water and concentrated slightly to remove the isopropanol and petroleum ether. Barium hydroxide was added to *p*H 10.0 and ethanol to 50% concentration. After thorough chilling the precipitate was collected, washed thoroughly with 50% ethanol, absolute ethanol and acetone; yield was 71 mg. calculated as *p*-aminobenzoic acid.

Anal. Calcd. for $C_{22}H_{28}N_4O_{11}$: C, 50.5; H, 5.35; N, 10.69. Found: C, 29.42; H, 4.20; N, 6.64; ash, 50.00. Cor. for C in ash: C, 32.46; H, 4.20; N, 6.64; Ba, 34.80. Ba-free: C, 49.8; H, 6.44; N, 10.17.

As the ash is barium carbonate, the carbon values have been corrected for the amount of carbon retained in the ash.

The free acid is extremely soluble in water or alcohol. The compound could not be crystallized from various solvents or combinations thereof.

Aromatic Amine Nitrogen.—Duplicate weighings were dissolved equivalent to 13.62 micrograms of total nitrogen per ml.; 29.1 microgram equivalents of *p*-aminobenzoic acid was found per ml., which is equivalent to 2.97 micrograms of aromatic amine nitrogen. Therefore 22.39% of the total nitrogen was present as aromatic amine nitrogen.

Effect of Acid and Alkaline Hydrolysis on the Amine Fragment.—All samples were hydrolyzed for sixteen hours at 120° in a sealed tube. One normal sodium hydroxide, 5 *N* sodium hydroxide, 1 *N* hydrochloric acid and 2.5 *N* hydrochloric acid liberated 57.6, 73.0, 72.2, and 74%, respectively, of the nitrogen as α-amino acid nitrogen. Glutamic acid analysis of the 2.5 *N* hydrochloric acid hydrolysate was carried out using *Lactobacillus arabinosus*.

Anal. Calcd. for 3 moles of glutamic acid in the amine fragment (as the free acid): 84.25. Found: 81.8, 82.5.

Isolation of *p*-Aminobenzoic Acid from the N_4 Amine.—One hundred and eighty-seven mg. of the amine fragment was dissolved in 6 ml. of 5 *N* sodium hydroxide and hydrolyzed anaerobically for thirteen hours at 120°. The resulting hydrolysate was diluted to 100 ml. and adjusted to *p*H 3.0. The solution was extracted with 100 ml. of ethyl acetate and the ethyl acetate extract washed with 25 ml. of water. The ethyl acetate was removed by distillation and the residue dissolved in 0.5 ml. of hot water. On cooling the compound crystallized as needles. The precipitate was recrystallized from 0.25 ml. of hot water, m. p. 180.5–182.5°. In admixture with an authentic specimen of *p*-aminobenzoic acid (m. p. 183.5–184.5°) it melted at 182.5–183.5°.

Anal. Calcd. for $C_7H_7O_2N$: C, 61.3; H, 5.11. Found: C, 61.5; H, 4.93.

Detection of One or Two Carbon-atom-containing Fragments.—From sulfurous acid hydrolysates of the fermentation *L. casei* factor no carbon dioxide, glyoxal, glycolic aldehyde or ethylene glycol could be detected by appropriately controlled tests. No carbon dioxide was formed on aerobic ultraviolet irradiation of the fermentation *L. casei* factor.

Reductive Cleavage of the Fermentation *L. casei* Factor.—Two hundred and sixteen mg. of the fermentation *L. casei* factor was dissolved in 250 ml. of 0.4 *N* sulfuric acid and 5 g. of zinc dust was added. After twenty-five minutes the excess zinc dust was removed by filtration and 5 g. of manganese dioxide added. After ten minutes of oxidation the solution was filtered and enough dipotassium hydrogen phosphate was added to the filtrate to raise the *p*H to 6.5. The zinc phosphate was centrifuged off, washed with water and discarded. The centrifugate and washings were combined The distribution of the pteridine between butanol and water at various *p*H values was determined. The results suggested that the compound contained no carboxylic acid group. The solution (*p*H 6.5) was extracted with three ten-volume portions of butanol. The butanol extracts were concentrated and the pteridine precipitated by the addition of ether. The compound was crystallized twice from 4 *N* sodium hydroxide, converted to the free compound and dried.

The ultraviolet absorption spectra of the isolated pteridine were identical with the spectra of an authentic sample of the 2-amino-4-hydroxy-6-methylpteridine.

Acknowledgment.—It is a pleasure to acknowledge the assistance of the Misses E. Boggiano, B. Eames, E. Brogen and A. Buxó for the microbiological assays and the spectrophotometric determinations. The authors extend their appreciation to Dr. R. C. Gore of the Stamford Research Laboratories, American Cyanamid Company, for the infrared determinations, and to Mr. L. Brancone and co-workers for the microanalyses.

The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work performed in the various laboratories.

Summary

l-Pyrrolidonecarboxylic acid, 2-amino-4-hydroxypteridine-6-carboxylic acid, 2-amino-4-hydroxy-6-methylpteridine and *p*-aminobenzoic acid have been isolated as degradation products of the fermentation *L. casei* factor. Evidence for the existence of 2-amino-4-hydroxypteridine-6-carboxaldehyde and glutamic acid has been presented.

The significance of these products in formulating the structure of the *L. casei* factors has been discussed.

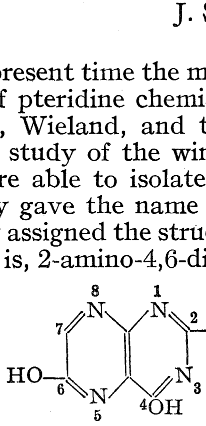
The Structure of the Liver *L. casei* Factor

BY J. H. MOWAT, J. H. BOOTHE, B. L. HUTCHINGS, E. L. R. STOKSTAD, C. W. WALLER, R. B. ANGIER, J. SEMB, D. B. COSULICH[1] AND Y. SUBBAROW

Up to the present time the major reported work in the field of pteridine chemistry has been that of Purrmann, Wieland, and their collaborators, who, in their study of the wing pigments of the butterfly, were able to isolate a yellow pigment to which they gave the name xanthopterine and to which they assigned the structure[2] shown in the formula, that is, 2-amino-4,6-dihydroxypteridine.[3]



Earlier reports[4,5,6,7] of the biological relationship between xanthopterine and the *L. casei* factors, as well as a comparison of the ultraviolet absorption spectra of these factors with the spectra of a number of known pteridines, suggested the presence of a pteridine nucleus in the *L. casei* factors. This possibility warranted more serious consideration when we were able to isolate from the fermentation *L. casei* factor a number of degradation products having pteridine-like absorption curves and having chemical properties consistent with such a hypothesis.

The first of these pteridine-like compounds (V) whose isolation and properties have been described in Paper III[8] of this series, after cleavage with chlorine water and hydrochloric acid gave a positive test for guanidine,[8] thus indicating the presence of a 2-aminopyrimidine. Furthermore, a titration curve indicated the presence of two acidic groups of *pKa* 3.9 and 7.7, probably a carboxyl group and another less acidic group of the enolic type.

Elementary analyses[9] indicated a compound having an empirical formula $C_7H_5O_3N_5$. Neither methoxyl groups nor N-methyl groups could be detected.

Decarboxylation of a few milligrams of the material gave a product which appeared to be identical with 2-amino-4-hydroxypteridine (II), prepared from 2,4,5-triamino-6-hydroxypyrimidine[10] (I) and glyoxal.

The total synthesis of (V) was then accomplished by chlorination and reduction of the previously known iso-xanthopterinecarboxylic acid (III)[11] and also by the condensation of 2,4,5-triamino-6-hydroxypyrimidine (I) and ethyl α-bromo-β,β-diethoxypropionate.[12] These syntheses established the nature of the ring skeleton and the positions of the 2-amino group and the 4-hydroxyl group, and by directly relating the position of the carboxyl group to that of iso-xanthopterinecarboxylic acid (III), showed that the carboxyl group was attached to the pyrazine ring, very probably in the 6-position. The position of the carboxyl group required further proof, however, since the structures postulated by Purrmann[2,11] for xanthopterine and iso-xanthopterinecarboxylic acid were still open to question.

A method of degrading substituted lumazines to pyrazines has been described by Weijlard, Tishler and Erickson[13] and by following this procedure, using 2-amino-4-hydroxy-7-methylpteridine (XIII) we obtained 2-amino-6-methylpyrazine. Subsequently this work was repeated, using the corresponding 2-amino-4-hydroxy-6-methylpteridine (VII), and the product was found to be identical with an authentic sample of 2-amino-5-methylpyrazine (IX) prepared from the known 2,5-dimethylpyrazine (X).

The structure of the so-called "fluorescent dibasic acid[8] obtained from the fermentation *L. casei* factor after aerobic alkaline hydrolysis was therefore conclusively proven to be 2-amino-4-hydroxypteridine-6-carboxylic acid (V).

Another pteridine-like compound[8,14] isolated from hydrolysates of the fermentation *L. casei* factor gave an analysis leading to the empirical formula $C_7H_7ON_5$, a formula which corresponded to that of 2-amino-4-hydroxy-6-methylpteridine. This assumption was proved to be correct by the synthesis of an identical compound through the following series of reactions.

(9) For some time we experienced considerable difficulty in obtaining correct and reproducible analysis of the pteridines, particularly in the case of nitrogen determinations. Wieland and Purrmann, *Ann.*, **545**, 163 (1940), have reported similar difficulties. An investigation of this problem by our microanalytical department appears to have resulted in a satisfactory procedure which may be the subject of a later communication.

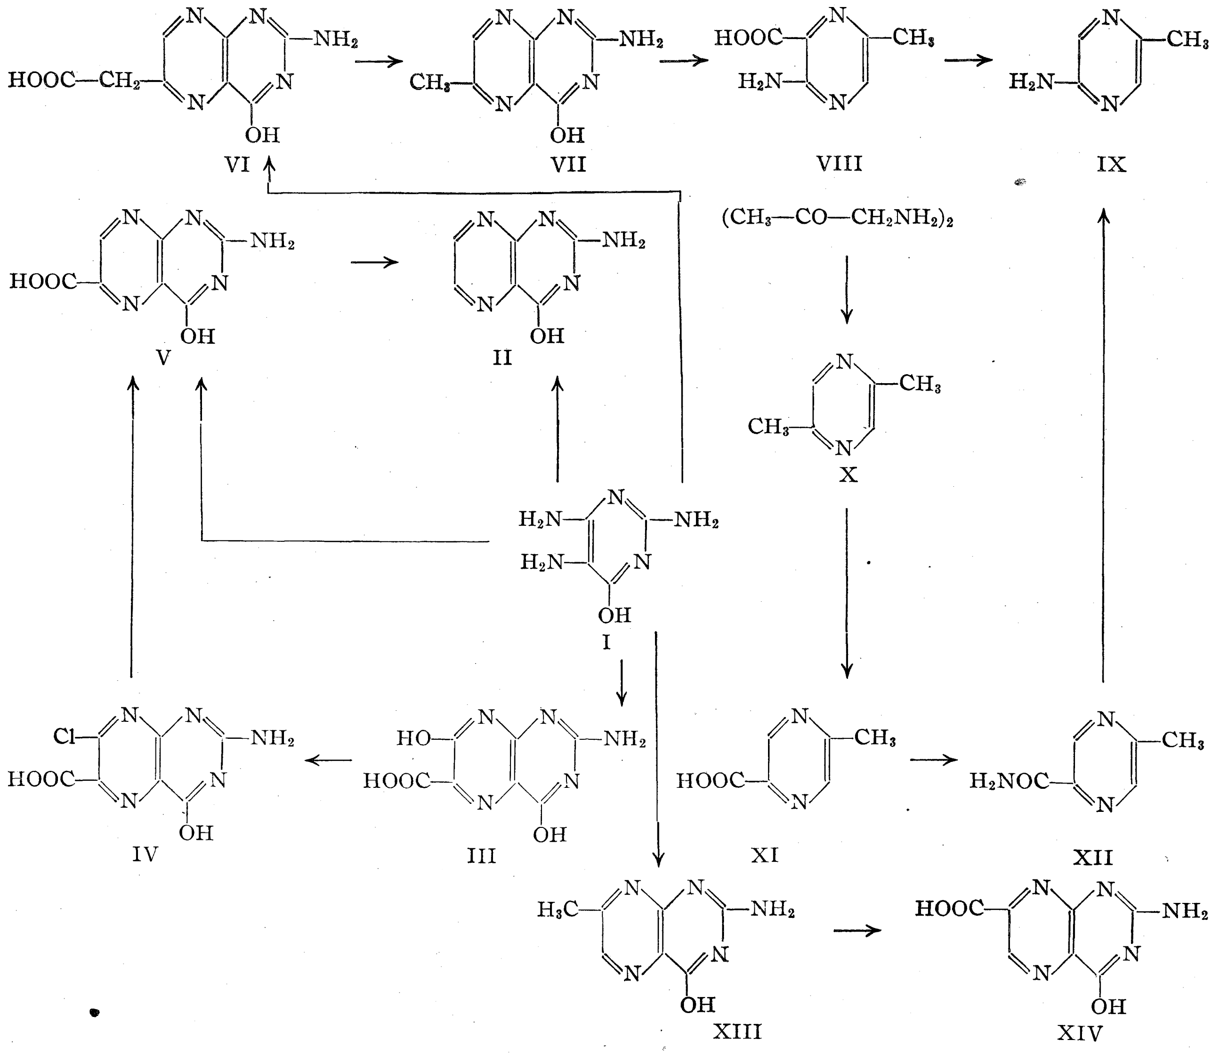
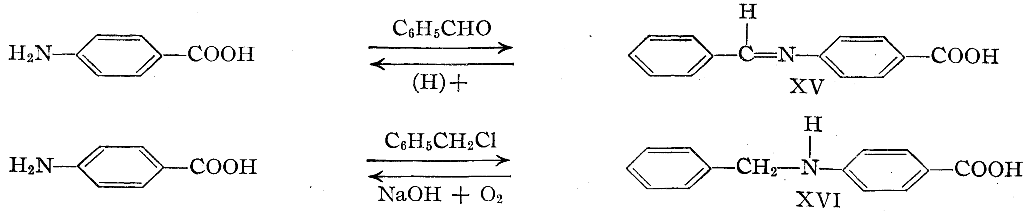
(11) Purrmann, *Ann.*, **548**, 284 (1941).

(12) Direct halogenation of ethyl-β,β-diethoxypropionate appeared to give a mixture of the mono- and di-halogen compounds which could not be readily separated, but which was satisfactory for the synthesis described. The pure mono-halogenated compound has been prepared recently by Oroshnik and Spoerri, THIS JOURNAL, **67**, 721 (1945), using another method.

(13) Weijlard, Tishler and Erickson, THIS JOURNAL, **67**, 802 (1945).

(14) Hutchings, *et al.*, *ibid.*, **70**, 1 (1948).





Methyl γ,γ-dimethoxyacetoacetate, prepared from methyl dimethoxyacetate and methyl acetate by the procedure of Johnson and Mikeska,[15] was condensed with 2,4,5-triamino-6-hydroxypyrimidine (I), to give 2-amino-4-hydroxypteridine-6-acetic acid (VI), (Fig. 5) which could be easily oxidized with alkaline potassium permanganate to 2-amino-4-hydroxypteridine-6-carboxylic acid (V). Decarboxylation of (VI) gave the desired 2-amino-4-hydroxy-6-methylpteridine (VII).

The isomeric 2-amino-4-hydroxy-7-methylpteridine (XIII) was prepared by the condensation of 2,4,5-triamino-6-hydroxypyrimidine (I) with the acetal of methyl glyoxal.[16] This 7-methylpteridine was then converted to the corresponding 2-amino-4-hydroxypteridine-7-carboxylic acid (XIV) by oxidation with alkaline potassium permanganate.

The ultraviolet absorption curves of the 6- and 7-methylpteridines are shown in Figs. 1 and 2.

Since the pteridine nucleus appears to be stable in the presence of alkaline potassium permanganate, various side chains in the 6 or 7 position may usually be oxidized to the corresponding pteridinecarboxylic acid which may then be identified by comparing its ultraviolet absorption spectrum

with that of a known sample. The ultraviolet absorption curves of these pteridinecarboxylic acids are shown in Figs. 3 and 4.

The structure of the cleavage products of the *L. casei* factors having been determined, it then became necessary to consider the linkages by which these fragments were joined. Evidence has been presented in a previous paper[14] of this series which indicates that the pteridine ring system must be joined at the 6-position to the amino group of *p*-aminobenzoylglutamic acid (or its homologs) through a one-carbon atom linkage. Two simple model compounds were prepared, namely, N-(benzylidene)-*p*-aminobenzoic acid[17] (XV), and N-(benzyl)-*p*-aminobenzoic acid (XVI). The anil linkage of (XV) was found to cleave with extreme rapidity in the presence of even traces of weak acids, whereas the methylene linkage of (XVI) was stable when subjected to acids or to anaerobic alkaline hydrolysis but was rapidly cleaved by aerobic alkaline hydrolysis, just as in the case of the *L. casei* factors. Such a linkage also appears to explain the role of oxygen in the aerobic alkaline hydrolysis, since it has been reported[18] that compounds of this type are cleaved by hydrolysis in the presence of hydrogen acceptors.

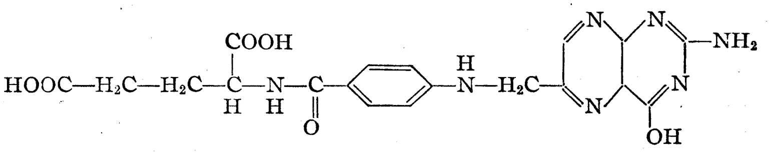
In view of these considerations the structure of the liver *L. casei* factor was therefore postulated to be N-[4-{[(2-amino-4-hydroxy-6-pteridyl)-methyl]-amino}-benzoyl]-*l*(+)-glutamic acid, that is



The validity of this formula has been proved by the synthesis of this compound by a number of methods, several of which are described in the following communications.

Experimental

2-Amino-4-hydroxypteridine (II).—A solution of 14.1 g. of 2,4,5-triamino-6-hydroxypyrimidine[10] in 200 cc. of 1 *N* hydrochloric acid was heated to 70° and treated with 22 cc. of a 26.5% solution of glyoxal. After twenty-four hours the precipitate was collected, washed with water, alcohol and ether and dried; weight was 13.4 g. This material was dissolved in a mixture of 50 cc. of water and 10 cc. of 10 *N* sodium hydroxide solution, filtered and then diluted with an equal volume of 10 *N* sodium hydroxide. The sodium salt crystallized rapidly. The sodium salt was collected, washed with alkali and again dissolved in water. Acidification to *p*H 3 precipitated the crude 2-amino-4-hydroxypteridine; weight was 13 g. A portion of this material was recrystallized several times from alkali and then precipitated at *p*H 3, thoroughly washed with hot water, alcohol and ether, and dried *in vacuo*.

Anal. Calcd. for $C_6H_5ON_5$: C, 44.10; H, 3.07; N, 42.94. Found: C, 43.65, 44.04; H, 2.82, 3.50; N, 42.88, 42.75.

2-Amino-4-hydroxy-7-chloropteridine-6-carboxylic Acid (IV).—A mixture of 0.59 g. of 2-amino-4,7-dihydroxy-pteridine-6-carboxylic acid (iso-xanthopterinecarboxylic acid),[11] (III) 3.0 g. of phosphorus pentachloride and 30 cc. of phosphorus oxychloride was heated on the steam-bath under a reflux condenser for twenty minutes. The mixture was then refluxed over a gas burner for about thirty minutes. In order to effect complete solution of the starting material, an additional 15 cc. of phosphorus oxychloride was then added and refluxing was continued for fifteen minutes. The hot solution was filtered and evaporated to dryness *in vacuo*. The residue was then triturated with 5 cc. of cold water for about forty-five minutes. The solid product was collected on a filter and washed with a little water and finally with a little ether; weight was 0.56 g.

Anal. Calcd. for $C_7H_4O_3N_5Cl$: Cl, 14.7. Found: Cl, 13.9. Attempts to further purify a portion of this material resulted in the loss of halogen.

2-Amino-4-hydroxypteridine-6-carboxylic Acid (V): A.—A mixture of 1.5 g. of 2-amino-4-hydroxy-7-chloropteridine-6-carboxylic acid, 21 cc. of glacial acetic acid and 21 cc. of hydriodic acid (sp. gr. 1.7) was heated on the steam-bath with stirring for five minutes. The cooled solution was diluted with 150 cc. of cold water. After a short time, the precipitate was collected in the centrifuge, washed with water and then with very dilute sulfurous acid. The product was then washed with water, alcohol and ether and dried; wt. 0.400 g. This material was dissolved in about 30 cc. of very dilute sodium hydroxide solution, and decolorized with charcoal. The clarified solution was acidified to *p*H 2 and the precipitate was collected and recrystallized several times from 2 *N* sodium hydroxide solution. The pure, crystalline sodium salt was then dissolved in warm water and converted to the free acid by acidification to *p*H 2. After thorough washing with water, alcohol and ether, the product was dried *in vacuo*. Weight was 0.060 g. *Anal.* Calcd. for $C_7H_5O_3N_5$: C, 40.58; H, 2.42; N, 33.82. Found: C, 40.24; H, 2.80; N, 33.37.

B.—A mixture of 100 g. of 2,4,5-triamino-6-hydroxypyrimidine, 192 g. of ethyl α-bromo-β,β-diethoxypropionate,[12] 112 g. of silver carbonate and 2500 cc. of absolute alcohol was refluxed under an atmosphere of nitrogen for five hours. After distilling off most of the alcohol the residue was suspended in a mixture of 2500 cc. of water and 250 cc. of concentrated hydrochloric acid, refluxed for one hour and then filtered while hot. To the filtrate was added a solution of 125 g. of iodine in 800 cc. of alcohol and the mixture was then adjusted to *p*H 2 by the addition of ammonium hydroxide. After thorough cooling, the precipitate was collected in the centrifuge and washed once with dilute sulfurous acid and then with water. This crude product was dissolved in 1 liter of hot water containing 16 g. of sodium hydroxide, decolorized with charcoal and then precipitated by acidification of the solution to *p*H 2. The precipitate was collected, washed with water, alcohol, and ether and dried; weight was 15.5 g. Further purification was effected by crystallization from 1 *N* sodium hydroxide. The pure, crystalline sodium salt was then converted to the free acid. *Anal.* Calcd. for $C_7H_5O_3N_5$: C, 40.58; H, 2.42; N, 33.82. Found: C, 40.54; H, 2.75; N, 33.80.

2-Amino-4-hydroxypteridine-6-acetic Acid (VI).—A stirred mixture of 7.5 g. of 2,4,5-triamino-6-hydroxypyrimidine, 50 cc. of glacial acetic acid and 9.0 g. of methyl γ,γ-dimethoxyacetoacetate[15] (b. p. 92° (5 mm.)) was heated on the steam-bath for twenty minutes; then 50 cc. of water was added and the mixture was heated for an additional thirty minutes. After cooling thoroughly, the precipitate was collected, washed with a little water and then dissolved in 250 cc. of very dilute sodium hydroxide solution. The solution was clarified with charcoal and the crude product was precipitated by the addition of acetic acid; weight was 6.1 g. A portion of this crude material (1.0 g.) was dissolved in 10 cc. of dilute sodium hydroxide solution, filtered, and then treated with an equal volume of 10 *N* sodium hydroxide solution. After cooling, the crystalline sodium salt was collected, washed with 5 *N* sodium hydroxide solution and then recrystallized twice more by the same procedure. The pure, crystalline sodium salt was then dissolved in water at *p*H 10–12, decolorized with charcoal and the free acid was precipitated by the addition of hydrochloric acid to *p*H 2. The washed and dried product weighed 0.355 g. *Anal.* Calcd. for $C_8H_7O_3N_5$: C, 43.44; H, 3.17; N, 31.67. Found: C, 43.75; H, 3.82; N, 32.05.

Oxidation of 2-Amino-4-hydroxypteridine-6-acetic Acid.—A stirred solution of 0.11 g. of 2-amino-4-hydroxypteridine-6-acetic acid, 0.25 cc. of 10 *N* sodium hydroxide solution and 10 cc. of water was heated in a water-bath to a temperature of about 75°. To this hot solution was then added 5 cc. of a 0.2 *M* solution of potassium permanganate during ninety minutes. After stirring at 75° for an additional thirty minutes, the mixture was cooled and treated with a few drops of sulfurous acid to destroy any excess permanganate. The manganese dioxide was removed by filtration and the oxidation product was precipitated by acidification to *p*H 2. The precipitate was collected, washed with water, and recrystallized from about 5 cc. of 2 *N* sodium hydroxide solution. The crystalline sodium salt was then dissolved in water and acidified. The product was collected, washed with water, alcohol and ether and dried; weight was 0.060 g. This material was identical with the previously described 2-amino-4-hydroxypteridine-6-carboxylic acid.

2-Amino-4-hydroxy-6-methylpteridine (VII).—A dry, finely powdered sample of 2-amino-4-hydroxypteridine-6-acetic acid (0.200 g.) was heated for about seven hours at 280° in an atmosphere of nitrogen. The residue was dissolved in 150 cc. of dilute sodium hydroxide solution, decolorized with charcoal and then adjusted to *p*H 7.0. The mixture was then boiled for a few minutes and filtered through a heated funnel. The filtrate was thoroughly cooled and the precipitate was collected; weight was 0.105 g. This material was again dissolved in very dilute alkali, adjusted to *p*H 7.0, heated to boiling, filtered and allowed to cool. The precipitate was collected, washed with cold water and finally recrystallized from 90 cc. of hot water; weight was 0.068 g. *Anal.* Calcd. for $C_7H_7ON_5$: C, 47.46; H, 3.96; N, 39.55. Found: C, 47.82; H, 4.75; N, 39.56.

2-Amino-4-hydroxy-7-methylpteridine (XIII).—A mixture of 0.5 g. of 2,4,5-triamino-6-hydroxypyrimidine and 0.6 g. of methylglyoxal diethyl acetal[16] was dissolved in 25 cc. of warm 4 *N* hydrochloric acid. After heating on the steam-bath for ninety minutes the solution was cooled and neutralized to *p*H 3.0. The precipitate was collected in the centrifuge, washed with water, alcohol and ether and dried; weight was 0.6 g. This crude product was dissolved in 30 cc. of dilute sodium hydroxide solution and then treated with an equal volume of 10 *N* sodium hydroxide solution. The crystalline precipitate was collected and recrystallized twice more by the same procedure. The crystalline sodium salt was then dissolved in water, decolorized with charcoal and precipitated at *p*H 3.0. *Anal.* Calcd. for $C_7H_7ON_5$: C, 47.46; H, 3.96; N, 39.55. Found: C, 47.18; H, 4.45; N, 39.42.

2-Amino-4-hydroxypteridine-7-carboxylic Acid (XIV).—A stirred solution of 0.200 g. of 2-amino-4-hydroxy-7-methylpteridine in 20 cc. of water containing 0.3 cc. of 10 *N* sodium hydroxide solution was heated in a water-bath to 90° and treated with small portions of a 0.2 molar solution of potassium permanganate until no further reaction occurred. The excess potassium permanganate was destroyed with a little sodium sulfite and the manganese dioxide was removed by filtration. The filtrate was adjusted to *p*H 2.0 and the precipitate was collected, washed with water, methanol and ether; weight was 0.195 g. This material was purified by crystallization from alkali as previously described and finally converted to the free acid. *Anal.* Calcd. for $C_7H_5O_3N_5$: C, 40.58; H, 2.42; N, 33.82. Found: C, 40.50; H, 3.11; N, 33.30, 33.49. This compound appears to be very hygroscopic and rapidly takes up water to form a very stable monohydrate.

2-Amino-5-methylpyrazine-3-carboxylic Acid (VIII).—A mixture of 7.0 g. of 2-amino-4-hydroxy-6-methylpteridine (VII), 22 cc. of water and 16 cc. of 10 *N* sodium hydroxide solution was heated in a sealed bomb at 170° for twenty hours. After being removed from the bomb, the reaction mixture was heated to effect solution and filtered while still hot. The hot filtrate was then acidified to *p*H 2.5 with hydrochloric acid, and on cooling the crude product crystallized; weight was 4.1 g. This material was recrystallized from 45 cc. of hot water after clarification with charcoal; weight was 3.2 g. An analytical sample was recrystallized twice more from hot water, m. p. 171.5–172.0°. *Anal.* Calcd. for $C_6H_7O_2N_3$: C, 47.05; H, 4.60; N, 27.45. Found: C, 46.75; H, 4.49; N, 27.40.

2-Amino-5-methylpyrazine (IX).—A solution of 1.0 g. of 2-amino-5-methylpyrazine-3-carboxylic acid (VIII) in 5 cc. of butyl cellosolve was refluxed for forty-five minutes. The solution was then clarified with charcoal, diluted with about 40 cc. of heptane and cooled. The precipitate was filtered off and discarded and the filtrate was then treated with gaseous hydrogen chloride. The precipitated hydrochloride was collected, dissolved in water and made alkaline by the addition of sodium hydroxide solution. This solution was extracted with ether several times. The ether solution was evaporated to dryness and the yellow crystalline residue (0.3 g.) was then recrystallized from a mixture of ether and petroleum ether and then sublimed twice *in vacuo* at 70° and 1–2 mm. pressure. The white sublimate melted at 116–117°. This melting point was not depressed by mixture with a sample of 2-amino-5-methylpyrazine prepared from 2-methylpyrazine-5-carboxylic acid by the method of Weijlard, Tishler and Erickson.[13] *Anal.* Calcd. for $C_5H_7N_2$: C, 55.00; H, 6.47; N, 38.53. Found: C, 55.58; H, 6.68; N, 38.40.

N-(Benzyl)-*p*-aminobenzoic Acid (XVI).—A mixture of 1.4 g. of *p*-aminobenzoic acid, 0.7 g. of potassium carbonate, 20 cc. of absolute ethanol and 1.3 cc. of benzyl chloride was refluxed on the steam-bath for several hours and then allowed to stand overnight at room temperature. The reaction mixture was diluted with water and the precipitate was collected and washed with water, then with a little cold alcohol and then again with water. The material may be recrystallized from hot, aqueous ethanol. *Anal.* Calcd. for $C_{14}H_{13}O_2N$: C, 74.00; H, 5.77; N, 6.16. Found: C, 74.10; H, 5.40; N, 6.13.

Acknowledgment.—We wish to acknowledge the technical assistance of Miss Barbara Eames and Miss Edith Brogan. The microanalyses were carried out by Mr. Louis Brancone and coworkers. The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work performed in the various laboratories.

Summary

The structure of the pteridine nucleus of the *L. casei* factors has been established and a structure for the liver *L. casei* factor consistent with all of the experimental evidence has been postulated.

Experimental methods and reference compounds of known structure have been described which allow rapid and certain distinction between pteridines which are isomeric in the 6- and the 7-positions.

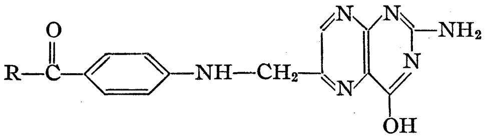
Synthesis of Pteroylglutamic Acid (Liver *L. casei* Factor) and Pteroic Acid. I

BY COY W. WALLER,[1] BRIAN L. HUTCHINGS,[1] JOHN H. MOWAT,[1] E. L. R. STOKSTAD,[1] JAMES H. BOOTHE,[1] ROBERT B. ANGIER,[1] JOSEPH SEMB,[1] Y. SUBBAROW,[1] DONNA B. COSULICH,[2] M. J. FAHRENBACH,[2] M. E. HULTQUIST,[2] ERWIN KUH,[2] E. H. NORTHEY,[2,3] DORIS R. SEEGER,[2] J. P. SICKELS[2] AND JAMES M. SMITH, JR.[2]

In a preliminary note[4] it was announced that the total synthesis of the liver *L. casei* factor had been accomplished. In a second note[5] the structure was given and the method of synthesis was outlined. The purpose of this communication is to describe in detail this method of synthesis of the liver *L. casei* factor.

The present status of the nomenclature of the *L. casei* factors and related compounds is extremely ambiguous. Mitchell, Snell and Williams[6] used the term "Folic Acid" to represent a product obtained from spinach and defined folic acid "as the material responsible for growth stimulation of *Streptococcus lactis* R on a given medium." Folic acid has become popular as a term to represent any material with such activity without regard for differences in chemical nature; this usage makes it unsuited to represent a chemical entity. The complexity of these compounds precludes the general usage of their chemical names. Therefore, it would be desirable to have a short, pseudochemical name for the basic compound from which the name of any related compound can be derived. The name suggested for the liver *L. casei* factor[5] and its structure is as represented by I. The basic compound whose synthesis is reported in detail herein is represented by II.



Compound	R—	Name
I	 $HOOC-CH(NH-)-CH_2-CH_2-COOH$	Liver *L. casei* factor, pteroylglutamic acid, N-[4-{[(2-amino-4-hydroxy-6-pteridyl)-methyl]-amino}-benzoyl]-glutamic acid
II	HO—	Pteroic acid, 4-{[(2-amino-4-hydroxy-6-pteridyl)-methyl]-amino}-benzoic acid

In Table I the compounds which have been obtained in a pure state are summarized according to their biological activities and the number of glutamic acid residues in each molecule. The number of glutamic acid residues ranges from none for pteroic acid to seven for pteroylhexaglutamylglutamic acid with one and three for pteroylglutamic acid and the fermentation *L. casei* factor, respectively. Pteroic acid has the basic structure found in all of these compounds. The exact name of the fermentation *L. casei* factor will be given when the nature of the peptide linkage is reported.

TABLE I

	No. of glutamic acid residues	Activities in micrograms per ml. for half maximum growth		Active for chicks	Refs.
		S. faecalis R	*L. casei*		
Pteroic acid	0	0.0008	0.07	No	5
Pteroylglutamic acid (liver *L. casei* factor)	1	.0003	.00007	Yes	4, 5, 7, 8, 9
Fermentation *L. casei* factor	3	.0042	.000061	Yes	5, 7, 8, 12
Pteroylhexaglutamylglutamic acid (B_c conjugate)	7	Slight[a]	Slight[a]	Yes	10, 11

[a] One microgram is equivalent to 0.003–0.006 microgram of vitamin B_c when measured with *L. casei* and 0.002 microgram when using *S. faecalis*.

In a previous publication[9] the pteridines were synthesized from 2,4,5-triamino-6-hydroxypyrimidine and a compound in which adjacent carbons contained functional groups capable of reacting with amines. By analogy a reaction should occur between the 2,4,5-triamino-6-hydroxypyrimidine and a three-carbon compound in which the *p*-aminobenzoylglutamic acid is attached to a terminal carbon atom and functional groups such as bromine or oxygen are on each of the other two carbons to give pteroylglutamic acid.

The first reaction attempted in this synthesis was to combine α,β-dibromopropionaldehyde and diethyl *p*-aminobenzoylglutamate and then to treat the product with 2,4,5-triamino-6-hydroxypyrimidine. When diethyl *p*-aminobenzoylglutamate reacted with the dibromopropionaldehyde, a crude, hygroscopic, non-crystalline product (III) was obtained. This material appeared to contain an anil structure because it hydrolyzed readily to diethyl *p*-aminobenzoylglutamate and a tar. Upon condensation of III with 2,4,5-triamino-6-hydroxypyrimidine, a very low yield of biologically active material was obtained.

[a] *Anal.* Calcd. for $C_{19}H_{19}O_6N_7 \cdot H_2O$: C, 49.6; H, 4.15; N, 21.4. Found: C, 49.5, 49.5; H, 4.36, 4.16; N, 21.40, 21.5.

In view of the failure of the first reaction to give appreciable yields of pteroylglutamic acid, the dibromopropionaldehyde was then treated with the 2,4,5-triamino-6-hydroxypyrimidine in an attempt to obtain a 6-bromomethylpteridine or a 6-hydroxymethylpteridine. From this condensation a crude product was obtained and separated into two fractions. One fraction was identified as 2-amino-4-hydroxy-7-methylpteridine. The other fraction (IV) could be characterized only to the extent that it was a 6-substituted-pteridine since it could be oxidized with alkaline permanganate to 2-amino-4-hydroxypteridine-6-carboxylic acid.

In a final attempt to obtain pteroylglutamic acid by the use of dibromopropionaldehyde, equal molecular amounts of 2,4,5-triamino-6-hydroxypyrimidine and the *p*-aminobenzoylglutamic acid were dissolved in water and treated with the dibromopropionaldehyde which was dissolved in an organic solvent. The yields were 30–50% of crude material which was shown to contain 10–25% of pteroylglutamic acid. A series of experiments at various acidities showed that the best yields were obtained when the *p*H was maintained at 4. The addition of the *p*-aminobenzoylglutamic acid to a reaction mixture of the 2,4,5-triamino-6-hydroxypyrimidine and the dibromopropionaldehyde gave much less pteroylglutamic acid than when all reactants were mixed together.

The synthesis of pteroic acid, which is reported herein, was accomplished by substituting *p*-aminobenzoic acid for *p*-aminobenzoylglutamic acid in the above reaction.

Pteroylglutamic and pteroic acids were purified in the same general way. The crude materials were dissolved in alkali, brought to *p*H 7, filtered and brought to *p*H 3 to precipitate the active compounds. The products were purified further by repeated treatments with charcoal in alkaline solution and recrystallizations from water at *p*H 3.

A comparison of pteroylglutamic acid with the liver *L. casei* factor indicated that the two compounds are identical.[13]

The crystalline structure of pteroylglutamic acid and the liver compound are identical. The ultraviolet absorption spectra for pteroic acid, pteroylglutamic acid and the liver *L. casei* factor are plotted in Fig. 1. The infrared absorption spectra for pteroylglutamic acid, the liver *L. casei* factor, racemic pteroylglutamic acid, racemic liver *L. casei* factor from the anaerobic alkaline hydrolysis of the fermentation *L. casei* factor and pteroic acid are given in Fig. 2. The infrared absorption spectrum of the liver *L. casei* factor is identical with that of pteroylglutamic acid and this spectrum of the racemic liver *L. casei* factor is identical with that of the racemic pteroylglutamic acid.

Degradation of pteroylglutamic acid and pteroic acid with alkali and oxygen gave 2-amino-4-hydroxypteridine-6-carboxylic acid which was the same acid obtained from the natural liver and fermentation *L. casei* factors.

Experimental

Materials.—The 2,4,5-triamino-6-hydroxypyrimidine was prepared by nitrosation and reduction of 2,4-diamino-6-hydroxypyrimidine.[14] The *p*-aminobenzoyl-*l*(+)-glutamic acid and the *p*-aminobenzoyl-*d,l*-glutamic acid were prepared by nitrobenzoylation and reduction of *l*(+)-glutamic acid and *d,l*-glutamic acid according to the method of Van Der Scheer and Landsteiner.[15] The dihalopropionaldehydes were prepared by direct halogenation of acrolein in carbon disulfide[16] or in carbon tetrachloride.[17] The dihalopropionaldehydes were purified by repeated fractionation; the fractions boiling at 53 to 54° at 2.5 mm. pressure and 46 to 49° at 12 to 14 mm. pressure for the dibromopropionaldehyde and dichloropropionaldehyde, respectively, were used.

Diethyl *p*-Aminobenzoyl-*l*(+)-glutamate.—The *p*-aminobenzoyl-*l*(+)-glutamic acid (25 g.) was slurried in 200 ml. of 95% ethanol which had previously been saturated with hydrogen chloride at 0°. This mixture was allowed to stand for two days during which time the *p*-aminobenzoylglutamic acid gradually dissolved. The excess hydrogen chloride and part of the ethanol were removed by evaporation under reduced pressure at room temperature. The residual solution was diluted to 1 liter with cold water and neutralized with ammonia to about *p*H 8. A slightly colored crystalline product was filtered off at once, washed and dried; yield 24 g. (75%); m. p. 139–141°.

This crude product is satisfactory for most purposes. For analytical sample it was recrystallized twice from ethanol after decolorizing the solution with charcoal; yield 16 g.; m. p. 143–144°.

---

[13] Pfiffner[11] found that pteroylglutamic acid and vitamin B_c were identical.

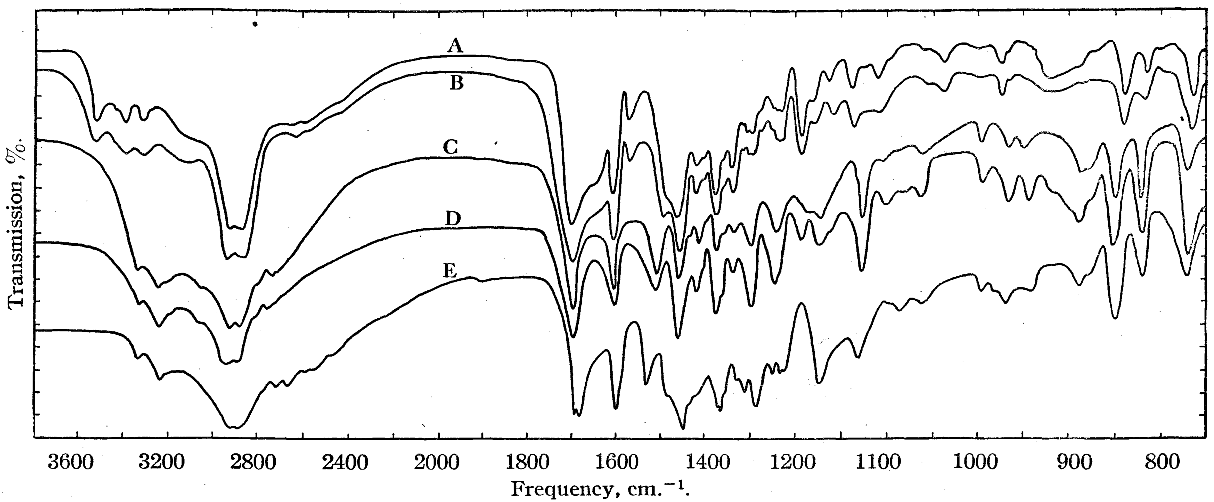

Fig. 2.—Infrared absorption spectra: A, natural liver *L. casei* factor; B, synthetic liver *L. casei* factor (pteroylglutamic acid; C, synthetic racemic liver *L. casei* factor (racemic pteroylglutamic acid); D, natural racemic liver *L. casei* factor; E, pteroic acid.

Anal. Calcd. for $C_{16}H_{22}O_5N_2$: C, 59.61; H, 6.89; N, 8.69. Found: C, 59.2; H, 6.7; N, 8.84.

Preparation of Anil (III).—A solution of 5 g. of diethyl *p*-aminobenzoyl-*l*(+)-glutamate and 3.35 g. of α,β-dibromopropionaldehyde in 200 ml. of diethyl ether was refluxed for four hours. After standing overnight the red oil was separated from the ether solution, dissolved in 15 ml. of ethanol and precipitated with 500 ml. of ether. The resulting oily product was dried to a powder.

A sample of the above anil and an equal weight of sodium bisulfite when heated in water for twenty minutes deposited a tar. This tar was collected and discarded. The solution deposited a crystalline material when cooled which melted at 138 to 140°. It was diethyl *p*-aminobenzoylglutamate.

Diethyl Pteroylglutamate from Anil (III).—To a solution of 0.5 g. of 2,4,5-triamino-6-hydroxypyrimidine and 0.88 g. of sodium acetate in 50 ml. of water was added a solution of 2.3 g. of anil (III) in 50 ml. of ethanol. After standing overnight a very small amount of precipitate was collected, washed and dried. After alkaline hydrolysis this crude product was shown to contain 1.9% of biologically active material calculated as pteroylglutamic acid.

Preparation of (IV).—To a solution of 3 g. of 2,4,5-triamino-6-hydroxypyrimidine in 300 ml. of 10% sodium acetate solution was added dropwise with stirring 4.7 g. of α,β-dibromopropionaldehyde dissolved in 150 ml. of ethanol. Fifteen minutes after completion of the addition 2 g. of the precipitated product was collected. When the acidity of this reaction was maintained at *p*H 4 by the gradual addition of sodium hydroxide solution instead of using the acetate buffer, a comparable yield of the same product was obtained.

Attempted purification and identification of this material was unsuccessful; however, when a sample was oxidized with hot alkaline permanganate solution 2-amino-4-hydroxypteridine-6-carboxylic acid[9] was obtained.

2-Amino-4-hydroxy-7-methylpteridine and (IV).—To a solution of 30 g. of 2,4,5-triamino-6-hydroxypyrimidine dihydrochloride in 300 ml. of 1 *N* hydrochloric acid was added a solution of 30 g. of α,β-dibromopropionaldehyde in 300 ml. of ethanol. After standing for one hour, 6 g. of the precipitated product was collected and identified as 2-amino-4-hydroxy-7-methylpteridine.[9] The filtrate after buffering with a slight excess of sodium acetate deposited 4 g. more of the above 7-methylpteridine.

The above filtrate on standing with the excess acetate buffer for two hours deposited 1.7 g. of material which had the properties of compound IV.

Pteroylglutamic Acid: A.—Ten grams of 2,4,5-triamino-6-hydroxypyrimidine and 19 g. of *p*-aminobenzoyl-*l*(+)-glutamic acid were dissolved in 1 liter of 10% sodium acetate solution. To this solution was added slowly with stirring a solution of 15.3 g. of α,β-dibromopropionaldehyde in 100 ml. of ethanol. After stirring for ninety minutes 4.8 g. of the precipitated product was collected. This crude product was shown to contain 10% of pteroylglutamic acid by bioassaying with *S. faecalis* R.

A reaction was run as above except the *p*-aminobenzoylglutamic acid was added five minutes after the addition of the dibromopropionaldehyde was complete. The resulting crude was found to contain only 4% of pteroylglutamic acid.

B.—Fifty grams (0.355 mole) of 2,4,5-triamino-6-hydroxypyrimidine and 95 g. (0.355 mole) of *p*-aminobenzoylglutamic acid were dissolved in 7.5 liters of water. The acidity of this solution was adjusted and maintained at *p*H 4 throughout the reaction. To this solution was added slowly with stirring over a ninety-minute period a solution of 77 g. (0.355 mole) of α,β-dibromopropionaldehyde in 7.5 liters of ethanol. The resulting mixture was then stirred for two hours more. The precipitated product was collected, washed with water and alcohol and dried. The yield of crude material was 50 g. which was shown to contain 20.8% of pteroylglutamic acid by the bioassay.

This synthesis was repeated using 0.007 mole each of 2,4,5-triamino-6-hydroxypyrimidine, *p*-aminobenzoylglutamic acid and α,β-dichloropropionaldehyde. The crude product weighed 0.8 g. and contained 14.5% pteroylglutamic acid. Further repetition of this synthesis using benzene, chloroform, carbon tetrachloride, acetic acid or acetone as solvents for the dibromopropionaldehyde instead of ethanol gave yields of the crude material ranging from 0.8 g. to 1.5 g. using 0.007 mole of each of the reactants. The pteroylglutamic acid in these crudes was about 20%.

A series of condensations was run at various acidities using 0.0035 mole of each of 2,4,5-triamino-6-hydroxypyrimidine-α,β-dibromopropionaldehyde and *p*-aminobenzoylglutamic acid. At *p*H 2, 3, 4 and 5 the yields of the crude products were 0.24, 0.30, 0.35 and 0.33 g.; and were shown by bioassay to contain 13, 24, 35 and 14%, respectively, of pteroylglutamic acid. At *p*H 6, 7, 8 and 10 there were no appreciable amounts of precipitates formed; however, pteroylglutamic acid was found by bioassay to be present in the reaction mixtures to the extent of 20 to 30% as much as the condensation usually yielded at *p*H 4.

Racemic Pteroylglutamic Acid.—This compound was prepared by the method given above for pteroylglutamic acid (method B) except that the *p*-aminobenzoyl-*l*(+)-glutamic acid was replaced by *p*-aminobenzoyl-*d,l*-glutamic acid.

Purification of Pteroylglutamic Acid.—A sample of crude material (5.85 g.) containing 0.755 g. of pteroylglutamic acid was dissolved in 3500 ml. of hot water at *p*H 10–12. This alkaline solution was brought to *p*H 7, cooled and filtered. The filtrate was adjusted to *p*H 3 and the active material was collected. This partially purified material was dissolved in 200 ml. of water at *p*H 10–12, clarified with 1 g. of activated charcoal and diluted with 800 ml. of hot water containing enough acetic acid to bring the acidity to *p*H 3–3.5. After cooling 0.61 g. of product was obtained. A bioassay showed the presence of 76.8% pteroylglutamic acid giving a 62% recovery.

Two hundred milligrams of the above 76.8% material was dissolved in 100 ml. of water at *p*H 10–12, clarified with 0.4 g. of charcoal, diluted to 700 ml. with boiling water containing enough acetic acid to bring to *p*H 3–3.5, filtered and cooled. The active material crystallized as rosets. This was collected and dried; yield, 166.2 mg.; bioassay, 92% pteroylglutamic acid. Recrystallization from water gave needle-like crystals.

Anal. As magnesium salt, calcd. for $C_{19}H_{15}O_6N_7$-$Mg_{1.5}\cdot 2H_2O$: C, 44.8; H, 3.74; N, 19.4; Mg, 7.06. Found: C, 44.8; H, 3.8; N, 19.3; Mg, 6.6.

Degradation of Synthetic Pteroylglutamic Acid.—A 0.275-g. sample of purified synthetic pteroylglutamic acid when hydrolyzed for eight hours at 100° with 10 ml. of 1 *N* solution of sodium hydroxide in a current of oxygen as described[4] for the natural *L. casei* factor, gave 0.058 g. (46%) of pure 2-amino-4-hydroxypteridine-6-carboxylic acid. No 2-amino-4-hydroxypteridine-7-carboxylic acid was detected in the hydrolysate.

Pteroylglutamic acid (0.5 g.) was cleaved with sulfite as described for the fermentation *L. casei* factor.[5] The solution when freed of sulfur dioxide and treated with phenylhydrazine gave 0.206 g. of the red phenylhydrazone. Analytical figures agree with those given for the hydrazone from the fermentation compound.

Pteroic Acid.—A vigorously stirred solution of 1 g. each of 2,4,5-triamino-6-hydroxypyrimidine and *p*-aminobenzoic acid in 150 ml. of water was adjusted and maintained at *p*H 4 throughout the reaction. A solution of 1.53 g. of α,β-dibromopropionaldehyde in 150 ml. of ethanol was then added dropwise. The resulting mixture was stirred for ninety minutes after the addition of the aldehyde was complete. The precipitated product was collected, washed with water and alcohol and dried. A yield of 0.59 g. of crude containing 19.2% of pteroic acid was obtained.

This synthesis using the same amounts of the reactants and substituting benzene for ethanol as the solvent for the dibromopropionaldehyde gave 0.9 g. of crude product containing 13.5% of pteroic acid as shown by bioassay with *S. faecalis* R.

Synthesis of Ethyl Pteroate.—A vigorously stirred solution of 1 g. of 2,4,5-triamino-6-hydroxypyrimidine and 1.2 g. of ethyl *p*-aminobenzoate in a mixture of 150 ml. of water and 100 ml. of ethanol was adjusted and maintained at *p*H 4 while 1.53 g. of α,β-dibromopropionaldehyde in 50 ml. of ethanol was added over a twenty-minute period. The mixture was stirred for an additional ninety minutes and filtered. A yield of 0.38 g. of crude was obtained. This crude after hydrolyzing with sodium hydroxide solution in the cold was shown to contain 14.3% pteroic acid.

Purification of Pteroic Acid.—The crude material containing 15% of pteroic acid was dissolved in 0.01 *N* sodium hydroxide solution at a concentration of 1 mg. of crude per ml., brought to *p*H 7, filtered and brought to *p*H 3. The precipitated material at *p*H 3 was collected and shown by bioassay to contain 60% pteroic acid. This represented a recovery of 11%. The precipitate at *p*H 7 contained the bulk of the active material which can be largely recovered by repeating the procedure several times.

Final purification was accomplished by the following procedure: The partially purified pteroic acid was clarified in 0.2 *N* sodium hydroxide solution with charcoal at a concentration of 1 mg. per ml. The resulting alkaline filtrate was diluted to 0.1 mg. per ml., heated to boiling and neutralized slowly with dilute hydrochloric acid to *p*H 3. The crystals of pteroic acid formed in the hot solution. After cooling this material was collected and recrystallized three times by dissolving in hot sodium hydroxide solution at a concentration of 0.1 mg. per ml. and bringing to *p*H 3 with dilute hydrochloric acid.

Anal. Calcd. for $C_{14}H_{12}O_3N_6$: C, 53.85; H, 3.85. Found: C, 53.3; H, 4.15.

Degradation of Pteroic Acid.—When 0.1 g. of purified pteroic acid was hydrolyzed with 5 ml. of 1 *N* solution of sodium hydroxide in the presence of oxygen at 100° for six hours, 0.0225 g. (37.5%) of pure 2-amino-4-hydroxypteridine-6-carboxylic acid was obtained. No 2-amino-4-hydroxypteridine-7-carboxylic acid was detected in the hydrolysate.

Acknowledgment.—The authors wish to thank the following for their work on this project: Dr. R. C. Gore and assistants of Stamford Research Laboratories, American Cyanamid Company, for infrared spectrographs; Dr. A. F. Kirkpatrick of Stamford Research Laboratories, American Cyanamid Company, for the microscopical examinations: Miss Edythe Brogan[1] and Miss Anna Buxó[1] for ultraviolet spectrographs; Miss Eleanora Boggiano[1] for microbiological assays; and Mr. L. Brancone[1] and Mr. O. Sundberg[2] and their assistants[1,2] for the microanalyses. The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work performed in the various laboratories.

Summary

The preparation of pteroic acid and pteroylglutamic acid is given. This method of preparation illustrates a general procedure for the synthesis of pteroyl derivatives.

Physical, chemical and biological data on pteroylglutamic acid and the liver *L. casei* factor appear to show that the two compounds are identical.

Synthesis of Pteroylglutamic Acid (Liver *L. casei* Factor) and Pteroic Acid. II

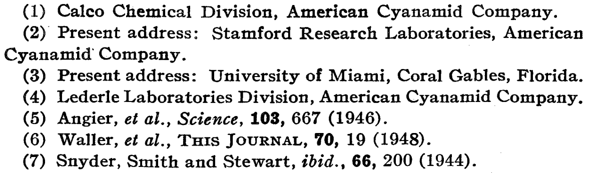
BY MARTIN E. HULTQUIST,[1] ERWIN KUH,[1] DONNA B. COSULICH,[1] MARVIN J. FAHRENBACH,[1] ELMORE H. NORTHEY,[1,2] DORIS R. SEEGER,[1] JACKSON P. SICKELS,[1,3] JAMES M. SMITH, JR.,[1] ROBERT B. ANGIER,[4] JAMES H. BOOTHE,[4] BRIAN L. HUTCHINGS,[4] JOHN H. MOWAT,[4] JOSEPH SEMB,[4] E. L. R. STOKSTAD,[4] Y. SUBBAROW[4] AND COY W. WALLER[4]

In a previous publication,[5,6] pteroylglutamic acid and pteroic acid were synthesized by reactions involving 2,4,5-triamino-6-hydroxypyrimidine, 2,3-dibromopropionaldehyde and *p*-aminobenzoylglutamic or *p*-aminobenzoic acid. It was felt that preparation of a 6-substituted pteridine capable of alkylating the above amino acids was desirable. Descriptions in the literature suggest the use of quaternary ammonium salts as alkylating agents, such as the procedure of Snyder, Smith and Stewart[7] in alkylating malonic and similar esters with benzyl trimethylammonium salts or gramine to obtain the corresponding C-benzyl malonic ester or substituted esters of β-(3-indole)-propionic acid.

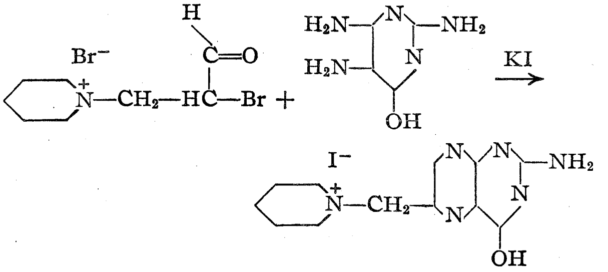
The above workers and others made use of this type of reaction in the preparation of synthetic *dl*-tryptophan[8,9,10]; and the use of simple quaternary salts in the preparation of sulfur[11] and oxygen[12,13,14,15] alkylated derivatives has also been described.

The use of a tertiary amine to alkylate another amine is reported by Howe, *et al.*[10] The effectiveness of pyridine as the tertiary base component of the quaternary ammonium salt was shown by Snyder and Speck.[11]

α,β-Dibromopropionaldehyde was condensed with pyridine to give the intermediate, N-(2-formyl-2-bromoethyl)-pyridinium bromide



and this compound was then condensed with the 2,4,5-triamino-6-hydroxypyrimidine to give the desired N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium bromide for use in alkylation.



Presumably a dihydro derivative was formed which, during the course of the reaction, was converted to the aromatic form. The product was isolated as the less soluble iodide.

Oxidation of the N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium iodide gave the corresponding 2-amino-4-hydroxypteridine-6-carboxylic acid,[16] showing the substituted methyl group to be in the 6- position. No 2-amino-4-hydroxypteridine-7-carboxylic acid was detected.

Pteroylglutamic acid or pteroic acid was then prepared by heating the N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium iodide, *p*-aminobenzoylglutamic acid or *p*-aminobenzoic acid and sodium methylate in anhydrous ethylene glycol. After isolation of the crude material, purification was carried out as described by Waller, *et al.*[6] The crystalline structure, ultraviolet absorption spectra, and bioassay of the synthetic pteroylglutamic acid were identical with those same properties of the liver *L. casei* factor. The properties of the synthetic pteroic acid were identical with those of the pteroic acid prepared by Waller, *et al.*[6]

Experimental

Materials.—The 2,4,5-triamino-6-hydroxypyrimidine, *p*-aminobenzoyl-*l*(+)-glutamic acid and dibromopropionaldehyde were prepared as described in the previous paper in this series.[6]

N-(2-Formyl-2-bromoethyl)-pyridinium Bromide.—To a solution of 21.6 g. (0.1 mole) of freshly distilled 2,3-dibromopropionaldehyde in 100 ml. of anhydrous ether at 0° was added slowly 8.8 g. (0.11 mole) of dry pyridine in 100 ml. of anhydrous ether, with stirring and cooling to keep the temperature of the reaction mixture at 0 to 10°. There was an immediate precipitation of a white product at the start of the addition, and, after allowing the mixture to stand for one or two hours, the hygroscopic solid was filtered, washed with ether and dried in a vacuum desiccator, or extracted with water for use directly in the next step. The crude material melted at 66–69°.

Anal. Calcd. for C_8H_9NBr: Br, 27.09. Found: Br, 29.8.

It was recrystallized from absolute 2-propanol, and then melted to a milky liquid at 55–65°, cleared at 80–90°, became partially crystalline again at 105–110°, and melted at 120–125°.

Anal. Calcd.: Br, 27.09. Found: Br, 27.55, 27.59.

N-[(2-Amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium Iodide.—To a solution of 14.1 g. (0.1 mole) of 2,4,5-triamino-6-hydroxypyrimidine in 150 ml. of water and 20 ml. of concd. hydrochloric acid was added the N-(2-formyl-2-bromoethyl)-pyridinium bromide prepared as above in a 0.1-mole run and extracted from the ether with 50 ml. of water. The yellowish-brown solution became almost purple. There was then added 10 g. of potassium iodide, and the solution was allowed to stand overnight. After addition of sodium hydroxide solution to bring the *p*H to 3 to 4, the mixture of brown, amorphous material and lighter crystalline product was filtered off and recrystallized from water, using activated charcoal to decolorize the hot solution. The addition of potassium iodide aided in obtaining more complete crystallization of the less soluble iodide. The purified material consisted of bright yellow, thin plates and rosets of plates.

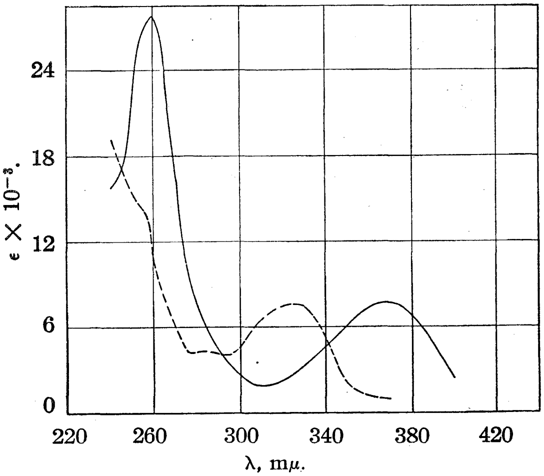

Fig. 1.—Ultraviolet absorption spectra of N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium iodide: ——— 0.1 *N* sodium hydroxide; - - - - - - - 0.1 *N* hydrochloric acid.[a]

[a] ε is the molecular extinction coefficient as defined by $I = I_0\ 10^{-\epsilon c l}$ where *c* is the concentration in moles/liter and *l* is the cell length in centimeters. Transmittancy (I/I_0) measurements of 10 mg./liter solutions were made in 1-cm. cells at 5 mμ intervals on a Model DU Beckmann Spectrophotometer using a solvent filled cell in the reference position. Additional data were obtained at 2 mμ intervals at maxima, minima and points of inflection.

Anal. Calcd. for $C_{12}H_{11}ON_6I$: N, 22.0; I, 33.2. Found: N, 21.9; I, 32.7.

The ultraviolet absorption curve for this compound is given in Fig. 1.

Oxidation of the above product with hot alkaline permanganate yielded 2-amino-4-hydroxypteridine-6-carboxylic acid.[16] An odor of pyridine was noted during the oxidation step.

Pteroylglutamic Acid.—To a solution of 10.8 g. (0.2 mole) of sodium methylate in 75 ml. of anhydrous ethylene glycol was added 26.6 g. (0.1 mole) of *p*-aminobenzoyl-*l*(+)-glutamic acid and 38.2 g. (0.1 mole) of N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium iodide. A solution of 5.4 g. (0.1 mole) of sodium methylate in 25 ml. of anhydrous ethylene glycol was added, and the resulting solution was heated at 140–145° for three hours. The brown solution obtained was poured into one liter of water at 70°, and acidified to *p*H 3 to 4 with hydrochloric acid. The precipitated product filtered from the cooled solution weighed 9 g., and was shown to contain 25% pteroylglutamic acid by bioassaying with *S. faecalis* R.

Purification of this crude material as described by Waller, *et al.*,[6] gave pteroylglutamic acid showing crystalline structure, ultraviolet absorption spectra and bioassay identical with those same properties of liver *L. casei* factor.

Pteroic Acid.—This was prepared as described under pteroylglutamic acid, substituting *p*-aminobenzoic acid for *p*-aminobenzoyl-*l*(+)-glutamic acid, and decreasing the sodium methylate usage by one mole per mole of N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium iodide.

Purification as described by Waller, *et al.*,[6] gave pteroic acid. The ultraviolet spectra in alkaline solution showed this to be identical with Waller's material.

Acknowledgment.—We are indebted to Dr. R. C. Gore of the Stamford Research Laboratories, American Cyanamid Company, for the infrared spectra; to Dr. A. F. Kirkpatrick of the same laboratories for crystallographic comparisons; to Miss Ruth Abbott for ultraviolet spectrographs; and to Mr. O. Sundberg and assistants for the microanalyses. Dr. P. F. Dreisbach assisted in the preparation of certain compounds.

The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work in the various laboratories.

Summary

1. N-[(2-Amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium iodide has been prepared by the reaction of N-(2-formyl-2-bromoethyl)-pyridinium bromide with 2,4,5-triamino-6-hydroxypyrimidine.

2. Pteroylglutamic acid and pteroic acid have been prepared by alkylating the appropriate amino acid with N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-pyridinium iodide.

Synthesis of Pteroylglutamic Acid. III

BY ROBERT B. ANGIER,[1] E. L. R. STOKSTAD,[1] JOHN H. MOWAT,[1] BRIAN L. HUTCHINGS,[1] JAMES H. BOOTHE,[1] COY W. WALLER,[1] JOSEPH SEMB,[1] Y. SUBBAROW,[1] DONNA B. COSULICH,[2] M. J. FAHRENBACH,[2] M. E. HULTQUIST,[2] ERWIN KUH,[2] E. H. NORTHEY,[2,3] DORIS R. SEEGER,[2] J. P. SICKELS,[2] AND JAMES M. SMITH, JR.[2]

Two methods of synthesizing pteroylglutamic acid have been described.[4] Another approach to the synthesis of this compound involves the reaction of N-(*p*-aminobenzoyl)-glutamic acid with a three carbon compound to form a stable intermediate which after isolation could be condensed with 2,4,5-triamino-6-hydroxypyrimidine to form the desired product.

The most satisfactory intermediate of this type was prepared from the three carbon compound, reductone (2,3-dihydroxyacrylaldehyde).[5] Euler and Martius[6] described the reaction of reductone with urea in a dilute mineral acid solution to form the two expected products, 2,3-dihydroxy-2-ene-propylideneurea and bis-(2,3-dihydroxy-2-ene-propylidene)-urea. O'Meara, *et al.*,[7] described the reaction of an impure reductone solution with *p*-aminobenzoic acid to obtain a crystalline compound but no analyses or physical data were given for the product.

In this Laboratory reductone reacted with diethyl N-(*p*-aminobenzoyl)-glutamate in a dilute hydrochloric acid solution to produce diethyl N-{*p*-(2,3-dihydroxy-2-ene-propylideneamino)-benzoyl}-glutamate (VI). In a similar way a number of other derivatives of *p*-aminobenzoic acid were treated with reductone to form compounds which might be used as intermediates in the preparation of various analogs of pteroylglutamic acid. These compounds are listed in Table I. As is evident from the formula these compounds could exist in several tautomeric forms. However, in writing the formula of the product the enediol structure of the starting compound has been retained since it is at least the initial product of the reaction. Irrespective of the tautomeric nature of the solid it was thought probable that in solution there would be present at least a small percentage of the keto-aldehyde tautomer. The fact that compounds (II) and (VI) were found to react readily with an alcoholic solution of phenylhydrazine to form the corresponding diphenylhydrazones indicated that this might be true. In contrast to these results attempts at treating the ester (VI) with 2,4,5-triamino-6-hydroxypyrimidine[8] in aqueous or methanolic solution gave little or no product. However, when hot ethylene glycol was used as a solvent the reaction proceeded satisfactorily and the product was obtained by diluting with water and filtering. As was true in the first synthesis[4a] this material was very impure and contained 10 to 30% pteroylglutamic acid (5 to 21% molal yield) as determined with *S. faecalis* R. The best yield was obtained either by using a one to three mole excess of 2,4,5-triamino-6-hydroxypyrimidine or by using a 0.5 mole excess of the pyrimidine and one equivalent of a basic condensing agent such as sodium acetate or disodium phosphate.

reacted with 2,4,5-triamino-6-hydroxypyrimidine in the manner described above. The crude product obtained from VII was active in stimulating the growth of both *S. faecalis* R and *L. casei*. The products obtained from I and II were active in stimulating the growth of *S. faecalis* R but were only very slightly active for *L. casei*. The yield of the expected pteroic acid from I and II compared favorably with the yield of pteroylglutamic acid from VI. The reaction appears to be generally applicable to intermediates of the type described.

Experimental[9]

Ethyl N-(*p*-Aminobenzoyl)-glycinate.—N-(*p*-Aminobenzoyl)-glycine[10] (4.0 g.) was suspended in a solution of 50 cc. of absolute ethanol and 3 cc. of concentrated hydrochloric acid and refluxed for two hours. The solution was evaporated to a sirup which crystallized. This was dissolved in 60 cc. of water, filtered and then neutralized with a saturated sodium carbonate solution. The material oiled out but soon crystallized. This was recrystallized once from a water–ethanol solution.

For purposes of analysis this was recrystallized twice from benzene; white crystals, m. p. 93–95°.

Anal. Calcd. for $C_{11}H_{14}O_3N_2$: C, 59.45; H, 6.35; N, 12.61. Found: C, 59.83; H, 6.71; N, 12.78.

Diethyl N-{*p*-(2,3-Dihydroxy-2-ene-propylideneamino)-benzoyl}-glutamate (VI).—Reductone (5.0 g.) (0.057 mole) prepared by the method of Euler and Martius[5] was dissolved in 100 cc. of water and added to a mixture of 16 g. (0.05 mole) of diethyl N-(*p*-aminobenzoyl)-glutamate[4a] and 7 cc. of concentrated hydrochloric acid in a solution of 1600 cc. of water and 100 cc. of ethanol. This was stirred rapidly for two hours and then stood in the refrigerator for several hours. It was then filtered, washed with ether, and dried; yield 16.7 g. (85%). This was sufficiently pure for subsequent reactions but may have contained water of crystallization since it had the rather low melting range of about 65–73°.

For analyses this was purified by dissolving it in chloroform at room temperature and then adding petroleum ether. The product oiled out but crystallized after standing. This purification was repeated once; cream colored crystals, m. p. 121–125°.

General Procedure for the Preparation of *p*-(2,3-Dihydroxy-2-ene-propylideneamino)-benzoic Acid (I) and Its Derivatives.—Compounds (I), (II), (III), (IV), (V) and (VII) were prepared by methods analogous to that described above for compound (VI) except that no ethanol was used in the solvent. With the exception of the acid (VII) these products were all crystalline and pale yellow to light orange in color. The acids (I) and (IV) and the amide (III) were rather insoluble in most solvents but they analyzed satisfactorily without purification. The esters (II) and (V) were readily recrystallized from ethanol or chloroform.

The Diphenylhydrazones of the Esters (II) and (VI).—A. Ethyl *p*-(2,3-dihydroxy-2-ene-propylideneamino)-benzoate (II) (0.2 g.) and 0.2 cc. of phenylhydrazine were dissolved in 10 cc. of ethanol containing 2 drops of acetic acid and refluxed for twenty minutes. Upon cooling the product separated; yield 0.2 g. This was recrystallized once from benzene and once from chloroform; long, yellow thread-like needles; m. p. 203–205°.

Anal. Calcd. for $C_{24}H_{25}O_2N_5$: C, 69.36; H, 6.07; N, 16.86. Found: C, 69.84; H, 5.42; N, 17.21.

B. Diethyl N-{*p*-(2,3-dihydroxy-2-ene-propylideneamino)-benzoyl}-glutamate (VI) (0.5 g.) and 0.9 cc. of phenylhydrazine were dissolved in 10 cc. of ethanol containing 3 drops of acetic acid and refluxed for twenty minutes. Upon cooling the product separated; yield 0.42 g. This was recrystallized once from benzene and once from ethanol; m. p. 157–159°.

Anal. Calcd. for $C_{31}H_{36}O_5N_6$: C, 65.01; H, 6.34; N, 14.68. Found: C, 64.79; H, 5.95; N, 15.06.

Pteroylglutamic Acid.—Seven grams (0.018 mole) of diethyl N-{*p*-(2,3-dihydroxy-2-ene-propylideneamino-benzoyl}-glutamate (VI), 5.0 g. (0.036 mole) of 2,4,5-triamino-6-hydroxypyrimidine[8] and 200 cc. of ethylene glycol were placed in a 250-cc. flask and heated to 135° for thirty minutes with continuous stirring. The solution was cooled almost to room temperature and poured into 600 cc. of water. A little concentrated hydrochloric acid was added to bring it to *p*H 3–4. The mixture was then filtered, washed with water, methanol and ether and dried; yield of crude 5.5 g. (63%). This was shown to be 20% pteroylglutamic acid by bioassay with *S. faecalis* R. Real yield was 12.6%.

This material was purified by the method of Waller, *et al.*,[4a] to obtain a crystalline product. The ultraviolet and infrared spectra, crystallography and biological activity of this compound, the previously prepared synthetic pteroylglutamic acid,[4] and the naturally occurring liver *L. casei* factor were found to be identical.

Acknowledgment.—We are indebted to Dr. R. C. Gore of the Stamford Research Laboratories, American Cyanamid Company, for infrared spectra and to Dr. A. F. Kirkpatrick of the same Laboratories for crystallographic comparisons. We also acknowledge the technical assistance of the Misses E. Boggiano and A. Buxó and the microanalytical work performed by L. Brancone and his co-workers.[1]

The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work performed in the various laboratories.

Summary

1. *p*-(2,3-Dihydroxy-2-ene-propylideneamino)-benzoic acid and six of its derivatives have been prepared by treating reductone (2,3-dihydroxyacrylaldehyde) with *p*-aminobenzoic acid or a derivative.

2. Pteroylglutamic acid has been prepared by condensing diethyl N-{*p*-(2,3-dihydroxy-2-ene-propylideneamino)-benzoyl}-glutamate with 2,4,5-triamino-6-hydroxypyrimidine.

Synthesis of Pteroylglutamic Acid. IV

BY JAMES H. BOOTHE,[1] COY W. WALLER,[1] E. L. R. STOKSTAD[1], BRIAN L. HUTCHINGS,[1] JOHN H. MOWAT,[1] ROBERT B. ANGIER,[1] JOSEPH SEMB,[1] Y. SUBBAROW,[1] DONNA B. COSULICH,[2] M. J. FAHRENBACH,[2] M. E. HULTQUIST,[2] ERWIN KUH,[2] E. H. NORTHEY,[2,3] DORIS R. SEEGER,[2] J. P. SICKELS[2] AND JAMES M. SMITH, JR.[2]

The structure of pteroylglutamic acid requires the presence of a methylene group connecting the pteridine nucleus and N-(*p*-aminobenzoyl)-glutamic acid. The methods of synthesis previously reported[4] have made use of the reaction of a three-carbon compound between 2,4,5-triamino-6-hydroxypyrimidine and N-(*p*-aminobenzoyl)-glutamic acid, or the alkylation of N-(*p*-aminobenzoyl)-glutamic acid with 2-amino-4-hydroxy-6-pteridylmethylpyridinium iodide.

This communication deals with the halogenation of 2-amino-4-hydroxy-6-methylpteridine, and the alkylation of N-(*p*-aminobenzoyl)-glutamic acid with the crude halomethylpteridine. It includes an improved method of synthesis of 2-amino-4-hydroxy-6-methylpteridine and a description of the dihydro form of this compound.

The previously described method of preparation of 2-amino-4-hydroxy-6-methylpteridine[5] was difficult to adapt to large scale preparative work. A more convenient method of preparing this pteridine was found to be by the reduction of 2-amino-4-hydroxy-6-pteridylmethylpyridinium iodide.[4b] The reduction was accomplished by dissolving the compound in 1 *N* sodium hydroxide and stirring with zinc dust. During the reduction the pteridine ring was reduced to a dihydro form which could be oxidized readily to the aromatic form with hydrogen peroxide, iodine or potassium permanganate. It was proved to be a dihydro form and not a more highly reduced form by oxidation to 2-amino-4-hydroxy-6-methylpteridine with the theoretical amount of potassium permanganate. This dihydro compound has an ultraviolet absorption spectrum quite different from the ordinary aromatic form of the pteridines (Fig. 1).

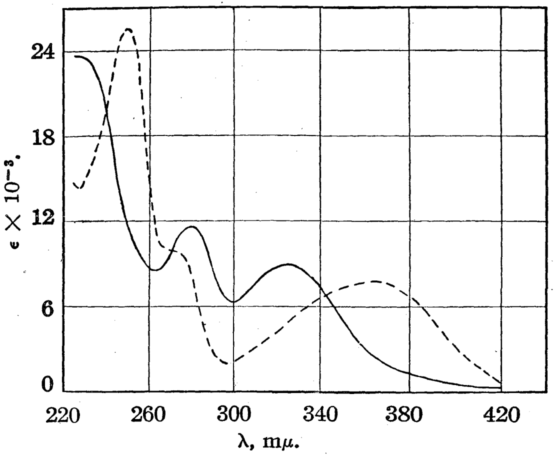

Fig. 1.—Ultraviolet absorption spectra of 2-amino-4-hydroxy-6-methyldihydropteridine hydrochloride monohydrate: ——— in 0.1 *N* sodium hydroxide; - - - - - - in 0.1 *N* hydrochloric acid.

Several methods of halogenation have been used with varying degrees of effectiveness. Bromination was accomplished by heating the 2-amino-4-hydroxy-6-methylpteridine in a sealed tube with bromine at temperatures of from 100–150°. Catalytic amounts of benzoyl peroxide and concentrated hydrochloric acid were each tried but both resulted in lowered yields. The most effective temperature seemed to be 150°. Bromination was also accomplished by heating the methylpteridine in 48% hydrobromic acid and bromine. Chlorination was effected to a very limited extent by refluxing the methylpteridine in sulfuryl chloride and benzoyl peroxide. These crude halogenation products then reacted with diethyl N-(*p*-aminobenzoyl)-glutamate[4a] by heating in ethylene glycol at 100–110°. The products of this condensation were then assayed microbiologically

against *S. faecalis* R after hydrolysis of the ester groups.

Experimental

2-Amino-4-hydroxy-6-methyldihydropteridine.—Ten grams of 2-amino-4-hydroxy-6-pteridylmethylpyridinium iodide was dissolved in 500 cc. of 1 *N* sodium hydroxide. Twenty grams of zinc dust was added and the reaction mixture was stirred twenty minutes at room temperature. The excess zinc was filtered out and the solution was adjusted to *p*H 2.7 with concentrated hydrochloric acid. The light yellow precipitate was removed by filtration and dried; weight was 6 g. This product contained some zinc oxide. It was purified by dissolving in the minimum amount of 0.5 *N* sodium hydroxide, treating with Norite, and then adding an equal volume of 10 *N* sodium hydroxide solution. On cooling, the sodium salt crystallized and was removed by filtration. The sodium salt was then dissolved in the minimum amount of warm water and enough concentrated hydrochloric acid was added to make the solution 0.5 *N*. The yellow crystalline hydrochloride separated and was filtered out. For an analytical sample this purification was repeated once more. The hydrochloride crystallizes as a monohydrate, from which water is not removed by heating at 60° *in vacuo*.

Anal. Calcd. for $C_7H_{10}ON_5 \cdot HCl \cdot H_2O$: C, 36.05; H, 5.14; N, 30.00. Found: C, 36.20; H, 5.47; N, 30.20.

2-Amino-4-hydroxy-6-methylpteridine.—(a) Two hundred mg. of 2-amino-4-hydroxy-6-methyldihydropteridine was dissolved in 10 cc. of dilute sodium hydroxide. A solution of 0.2 *M* potassium permanganate was added dropwise at room temperature until a light green color persisted when the manganese dioxide was centrifuged out. This required 3.7 cc. After discharging the green color with sodium sulfite, the manganese dioxide was filtered out and the clear yellow solution was acidified with hydrochloric acid. The precipitated product was centrifuged and washed with water. It was crystallized by dissolving in 6 cc. of dilute sodium hydroxide and adding 6 cc. of 10 *N* sodium hydroxide. The crystalline sodium salt was dissolved in water and the solution was acidified. The product was collected and dried. Weight was 130 mg. The ultraviolet absorption spectrum was identical to that of authentic samples of 2-amino-4-hydroxy-6-methylpteridine.[5]

(b) One hundred grams of 2-amino-4-hydroxy-6-pteridylmethylpyridinium iodide was dissolved in 4 liters of 1 *N* sodium hydroxide and 100 g. of zinc dust was added. The mixture was stirred twenty minutes and the excess zinc was filtered out. Sixteen cc. of 30% hydrogen peroxide was added and stirred ten minutes at room temperature. The solution was then heated on the steam-bath and treated with Norite. The clarified solution was then added dropwise to a heated, stirred solution of 600 cc. of acetic acid in 2 liters of water. After standing overnight the supernatant liquid was siphoned off and the product collected on a filter, washed and dried. Weight was 32.4 g. This material was pure enough for most work but could be crystallized from 5 *N* sodium hydroxide as described above. For an analytical sample the material was crystallized twice from boiling water.

Anal. Calcd. for $C_7H_7N_5O$: C, 47.45; H, 3.96; N, 39.6. Found: C, 47.40; H, 4.32; N, 39.45.

The ultraviolet and infrared absorption spectra were identical with authentic samples of 2-amino-4-hydroxy-6-methylpteridine.[5]

Pteroylglutamic acid.—(a) Two grams of 2-amino-4-hydroxy-6-methylpteridine was sealed in a glass tube with 2.5 g. of bromine. The tube was heated at 150–155° for five hours, cooled and opened. The contents were dried in vacuum over potassium hydroxide for twenty-four hours and then washed out of the tube with a solution of 1 g. of diethyl N-(*p*-aminobenzoyl)-glutamate in 100 cc. of hot ethylene glycol. This mixture was heated one hour at 100–110°, cooled, and diluted with 300 cc. of ethanol. The insoluble product was removed by centrifuging, washed with alcohol and ether, and dried. Weight was 1.75 g. After hydrolysis of the ester groups by standing in 0.1 *N* sodium hydroxide for twelve hours, the crude material was shown to contain 14% pteroylglutamic acid by microbiological assay against *S. faecalis* R. The active material was isolated by the method previously described[6] and found to be identical with pteroylglutamic acid by comparison of the microbiological assay, the ultraviolet and infrared absorption spectra.

(b) Twelve grams of 2-amino-4-hydroxy-6-methylpteridine was suspended in 500 cc. of 48% hydrobromic acid and 12 cc. of bromine was added. The suspension was heated on a steam-bath under a reflux condenser with occasional stirring for five hours. The methylpteridine was nearly all in solution at this point. After standing overnight at room temperature, the solution was concentrated in vacuum until all the excess bromine had been removed. The solution was then treated with Norite, filtered, and concentrated in vacuum until the product began to crystallize (30–40 cc.). To this concentrated solution was added 2.5 liters of cold water which precipitated the product. It was filtered and dried; weight was 14 g. One hundred mg. of this material was heated three hours at 100° with 400 mg. of diethyl N-(*p*-aminobenzoyl)-glutamate in 8 cc. of ethylene glycol. The solution was cooled and diluted with 30 cc. of acetone. The insoluble product was centrifuged, washed and dried. Weight was 60 mg. After hydrolysis of the ester groups in 0.1 *N* sodium hydroxide at room temperature for twelve hours, the material was bioassayed with *S. faecalis* R and found to contain 14.8% pteroylglutamic acid.

(c) Five hundred mg. of 2-amino-4-hydroxy-6-methylpteridine was suspended in 10 cc. of sulfuryl chloride and a small amount of benzoyl peroxide was added. The mixture was refluxed five hours, evaporated to dryness and dry benzene was added and evaporated to dryness again. One gram of diethyl N-(*p*-aminobenzoyl)-glutamate in 10 cc. of hot ethylene glycol was added and heated one hour at 100–110°. The mixture was cooled and diluted with 30 cc. of ethanol and the product centrifuged, washed, and dried. Weight was 500 mg. This product after hydrolysis was shown to contain 0.5–1.0% pteroylglutamic acid by bioassay against *S. faecalis* R.

Acknowledgment.—The authors wish to acknowledge the technical assistance of E. Boggiano, and A. Buxó in obtaining ultraviolet absorption data and microbiological assays. Infrared absorption comparisons were made by R. C. Gore, Stamford Research Laboratories, American Cyanamid Company. Microanalyses were done by Louis Brancone and co-workers.

The authors are especially indebted to Dr. J. H. Williams for his constant interest and counsel and for his efforts in coördinating the work performed in the various laboratories.

Summary

A new synthesis of 2-amino-4-hydroxy-6-methylpteridine is described which includes a description of the dihydro form of this compound as an intermediate.

A synthesis of pteroylglutamic acid from 2-amino-4-hydroxy-6-methylpteridine by halogenation and reaction with diethyl N-(*p*-aminobenzoyl) glutamate is described.

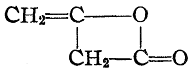
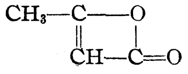
Studies Relating to the Structure of Ketene Dimer[1]

BY A. T. BLOMQUIST AND FRANKLIN H. BALDWIN

Ziegler's[2] development of specific reagents for halogenation of the allyl position suggested a useful application in securing additional chemical evidence for the structure of ketene dimer. Consideration of the most reliable evidence to date indicates structures I and II as being the most likely ones for ketene dimer.[3]

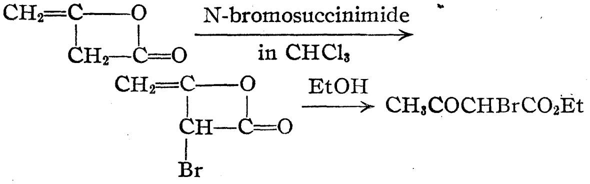


I

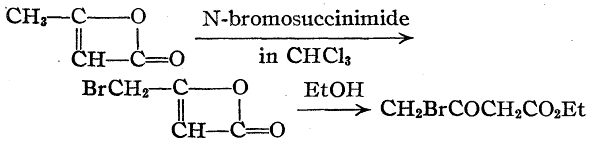


II

If structure I is the correct representation of ketene dimer, halogenation with Ziegler's reagents should afford halogen derivatives directly convertible to α-haloacetoacetic esters



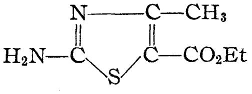
However, should structure II be the true one for ketene dimer, a similar series of reactions would lead to γ-haloacetoacetic esters



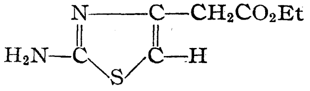
These formulations are, of course, also based on the assumption that Ziegler's reagents halogenate the allyl position in oxygenated unsaturated compounds as in unsaturated hydrocarbons.

Treatment of ketene dimer in chloroform solution with N-bromosuccinimide gave a highly unstable bromo derivative which reacted smoothly with ethyl alcohol to yield exclusively α-bromoacetoacetic ester. Similarly, chlorination with N,2,4-trichloroacetanilide followed by reaction with ethyl alcohol gave only α-chloroacetoacetic ester.

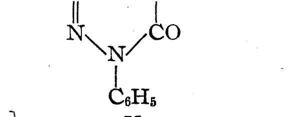
The two α-haloacetoacetic esters were characterized by conversion to two known solid derivatives. Reaction with thiourea gave, in each case, ethyl 2-amino-4-methylthiazole-5-carboxylate (III)[4] and none of the ethyl-2-aminothiazolyl-4-acetate (IV) derivable from γ-haloacetoacetic esters.[5] Phenylhydrazine converted both α-halogen esters into 3-methyl-1-phenyl-4-phenylhydrazono-5-pyrazolone (V).[6]



III



IV



V

It is significant that there was no evidence for the presence of γ-haloacetoacetic esters in the reaction products. Although it has been demonstrated that there is no tendency for α-chloroacetoacetic ester to rearrange to its γ-isomer, α-bromoacetoacetic ester may rearrange to γ-bromoacetoacetic ester under certain conditions. The rearrangement of γ-haloacetoacetic esters to the α-isomers has not been observed.[7]

The isolation of the direct products of halogenation of ketene dimer in pure form has not been realized as yet but work along this line is being continued.

Experimental[8]

Materials.—Ketene dimer was prepared as described in "Organic Syntheses."[9] N-Bromosuccinimide, m. p. 160–161°, was prepared by the method of Lengfeld and Stieglitz.[10] N,2,4-Trichloroacetanilide was prepared as described by Orton and Reed.[11]

Bromination of Ketene Dimer.—To a solution of 8.4 g. (0.1 mole) of freshly distilled ketene dimer in 200 cc. of chloroform there was added, at room temperature with vigorous stirring, a solution of 17.8 g. (0.1 mole) of N-bromosuccinimide in 700 cc. of chloroform. The volume of the mixture was reduced to 400 cc. by distillation at atmospheric pressure from a steam-bath. The succinimide which precipitated was removed by filtration and to the filtrate there was added 10 cc. of absolute alcohol and 2 drops of triethylamine. After refluxing for one hour the reaction mixture was fractionated under reduced pressure. α-Bromoacetoacetic ester (9 g., 43% based on ketene dimer) was obtained as a fraction boiling at 125–127° at 25 mm. It was characterized by the following two derivatives:

Ethyl 2-Amino-4-methylthiazole-5-carboxylate.—Using the method of Epprecht[4] 0.5 g. of α-bromoacetoacetic ester gave 0.5 g. (80%) of the thiazole derivative: m. p. 171–172° (Epprecht[4] gave the m. p. as 175–176°).

3-Methyl-1-phenyl-4-phenylhydrazono-5-pyrazolone. Following the procedure of Buchka and Sprague,[6] 1.3 g. of α-bromoacetoacetic ester gave 1.5 g. (50%) of the pyrazolone derivative: m. p. 154° (Buchka and Sprague[6] reported the m. p. at 157°).

Chlorination of Ketene Dimer.—In a flask protected against atmospheric moisture there was placed a solution of 8.4 g. (0.1 mole) of ketene dimer in 100 cc. of chloroform, a solution of 23.8 g. (0.1 mole) of N,2,4-trichloroacetanilide in 200 cc. of chloroform was added, and the mixture refluxed for twenty hours. The reaction mixture was then reduced to a volume of 150 cc., cooled in an ice–salt-bath, the precipitated 2,4-dichloroacetanilide filtered, and 4.6 cc. of absolute alcohol added to the chloroform solution. This mixture was then refluxed for six hours, concentrated to 50 cc., and again cooled to precipitate additional dichloroacetanilide. The liquid residue was then fractionated under reduced pressure giving 6.0 g. (35% based on ketene dimer) of α-chloroacetoacetic ester: b. p. 100–110° (25 mm.).

This chloroester was characterized in the same manner as described for α-bromoacetoacetic ester: ethyl 2-amino-4-methylthiazole-5-carboxylate, m. p. 172–173°; 3-methyl-1-phenyl-4-phenylhydrazono-5-pyrazolone, m. p. 155–157°.

Summary

Chemical evidence, based on halogenation of the allyl position, is presented in support of that lactone structure for ketene dimer which has the exocyclic carbon–carbon double bond.

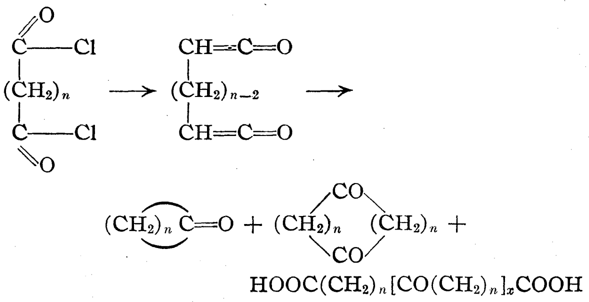
Many-membered Carbon Rings. I. Cyclization of Some Bifunctional Ketenes[1]

BY A. T. BLOMQUIST AND R. D. SPENCER[2]

In the course of investigations in this Laboratory with respect to certain derivatives of many-membered carbon rings it was decided to investigate the possibilities of a new method of cyclization involving bifunctional ketenes. Sauer[3] in his investigation of ketene dimers from acid halides observed that the bifunctional ketene derived from adipyl chloride gave a 40% yield of α-carbethoxycyclopentanone when treated with ethyl alcohol while sebacyl chloride yielded only a polymeric ketene derivative with no evidence of the formation of cyclic compounds. In these experiments no attempt was made to achieve significantly greater dilution than that employed in the preparation of monofunctional ketene dimers. Ziegler[4] and subsequently Hunsdiecker[5] have shown that high dilution is essential for the formation of many-membered rings in satisfactory yields by their methods. Ruzicka's method[6] was not adaptable to the application of the dilution principle and, consequently, the yields of the larger rings formed by his method were quite low.

We reported in a recent communication[7] the results obtained when the dilution principle was applied to the formation of the bifunctional ketene prepared from sebacyl chloride by dehydrohalogenation with triethylamine. There was some evidence for the formation of traces of cyclononanone as a product of the reaction, but none was isolated. A 16% yield of crude 1,10-cycloöctadecanedione was obtained. We have now prepared cycloheptanone and 1,8-cyclotetradecanedione from suberic acid as well as cyclopentadecanone and 1,16-cyclotriacontanedione from thapsic acid.

The following general equation indicates the products obtained upon hydrolysis and decarboxylation of the ketene derivatives without making any attempt to show the structure of these intermediates themselves. The structure of ketene dimer and the aldoketene dimers is still a controversial issue.[8,9]



In the course of the cyclization reaction much ketene polymer is formed. Part of this is ether insoluble and remains with the triethylamine hydrochloride. The ether soluble polymeric material is easily separable from the desired cyclic products after the mixture has been hydrated and decarboxylated with alcoholic potassium hydroxide. Presumably the polymers afford polyketodibasic acids which are soluble in aqueous alkali.

The original experimental procedure has been

$$\begin{array}{l}CH_2{=}C{-}CH_3\\ \;\;\;\;\;\;|\;\;\;\;\;|\\ \;\;\;\;\;\;O{-}C{=}O\end{array}$$

simplified by using crude acid chlorides.[10] Traces of thionyl chloride have no apparent effect on the reaction but the presence of larger amounts are undesirable.

Three tertiary amines have been tried as the dehydrohalogenating and condensing agents. Triethylamine gave the best yields, even though it was possible to achieve considerably greater dilution with N-ethylpiperidine by using apparatus (B) (see Experimental). Tributylamine of uncertain purity gave negative results in a cyclization of sebacyl chloride. However, even with carefully purified tributylamine, low yields of the desired product were obtained with pelargonyl chloride and with the crude acid chloride from lauric acid and thionyl chloride.

A second approach to the problem of formation of macrocyclic ketene dimers is under study at the present time. It is known that several keto- and aldoketene dimers can be reconverted to the monomers by heat.[11] On the other hand, Sauer has reported[3] that the ketene derivative obtained from adipyl chloride resinified when its distillation was attempted. An analogous observation was made by Hill and Carothers,[12] when they attempted to depolymerize a linear polyanhydride (sebacic "α-anhydride") by heating it under greatly diminished pressure in a Claisen flask; but, by molecular distillation at 200°, they obtained a twenty-two-membered cyclic dimer. Preliminary experiments in this Laboratory on the ketene polymer from sebacyl chloride indicate that it does indeed depolymerize on heating. The results of these investigations will be the subject of a future communication. In addition to the high temperature depolymerization there is some evidence that the "dimerization" reaction is reversible or, possibly, that a further condensation of some sort occurs even at the temperature of refluxing ether.

Comparison to Other Methods of Formation of Large Ring Ketones

In the cyclization step the yields of large ring ketones by the ketene method are generally superior to those of Ruzicka, but inferior to those of Ziegler and Hunsdiecker. The discrepancy is not so great, however, when the over-all yields are compared, since the synthesis of dibasic acids generally involves fewer steps than do the syntheses of the corresponding nitriles and ω-iodo-β-keto-esters. The lower yields obtained by the ketene method are probably due very largely to the lower dilution employed. It is shown in the experimental section that an increase in the reaction time during the cyclization step has the effect of materially reducing the yield. This phenomenon could be caused either by reversibility of the ketene dimerization reaction in the presence of the catalyst or by a further condensation of the dimer. The authors favor the first explanation and experiments are under way to test this theory. It can readily be seen that if the dimerization reaction is appreciably reversible under the conditions of the cyclization, a point of diminishing returns may be reached. At this point the cyclic dimers open up and react with the linear ketene polymer (present in solution in ever-increasing concentration) more rapidly than they are formed by the intramolecular condensation of the monomer. Consequently, with this in mind, it was necessary to avoid prolonging the reaction time. This was accomplished partly by making small runs, but, nevertheless, the advantages of extremely high dilution had to be sacrificed.

The ketene method is surpassed in convenience only by that of Ruzicka. The necessity of maintaining rigorously anhydrous conditions makes the ketene method somewhat more tedious. However, this inconvenience is offset by the greater ease of separating the cyclic ketones from the accompanying by-products. In this respect the ketene method far surpasses the other three. Although the cyclic diketones have been somewhat difficult to purify (possibly because of the presence of small amounts of the cyclic tri- and polyketones), the cyclic monoketones have been obtained in a relatively high state of purity after simple vacuum distillation.

Experimental[13]

Materials.—The thionyl chloride used in the cyclization step was carefully purified.[14] Commercial anhydrous ether was further purified by distillation from an ether solution of *n*-butylmagnesium bromide. A good grade of commercial triethylamine was purified by drying over potassium hydroxide pellets, refluxing over successive portions of sodium wire until a fresh portion retained its luster and, finally, fractioning it from the sodium wire through a 50-cm., vacuum-jacketed column packed with glass helices. The main fraction boiled at constant temperature. It was stored in a glass-stoppered bottle over sodium wire. N-Ethylpiperidine was prepared from piperidine by alkylation with ethyl iodide, and freed from the secondary amine by treatment with benzoyl chloride followed by fractional distillation. It was stored over sodium wire in the dark, but after about a month it had become light yellow in color.

The sebacyl chloride used in these experiments was prepared from commercial acid which had been purified through the ethyl ester. The suberic acid was from old Kahlbaum stock, m. p. 139.5–141°. The thapsic acid was prepared by the saponification of dimethyl thapsate.[15]

Apparatus.—(A) The apparatus which gave the most satisfactory results was very unpretentious. A one-liter, three-necked flask with ground joints was used. When in operation one neck was stoppered with a glass stopper. In the center neck was an efficient, all-glass stirrer equipped with a small condenser which effectively prevented the ether from distilling up into the mercury seal during the long periods of continuous operation. To the third neck was attached, by means of a bent adapter tube, a 30-cm. bulb condenser. The adapter was used simply to place the

condenser and the dropping funnel at a convenient distance from the stirring motor. At the top of the condenser, by means of a well-rolled cork, was attached a U-tube bearing a calcium chloride drying tube and a Hershberg–Hinman dropping funnel.[16] The dropping funnel was protected with a calcium chloride tube.

(B) A more complicated cyclization apparatus was devised in which ether was distilled from the reaction flask through a short fractionating column and condensed into a second flask where it was used to further dilute the solution of the acid chloride before eventually returning to the reaction flask. It was estimated that fifty-fold dilution was easily realized by this arrangement. However, triethylamine distilled too readily with the ether despite the fractionation employed and, consequently, could not be used successfully as the condensing agent with this apparatus. A condensing agent of higher molecular weight, N-ethylpiperidine, although it did not distil appreciably with the ether (of the order of one part of amine per one hundred thousand parts of ether)[17] gave a much lower yield than that obtained when triethylamine was used in apparatus (A).

(C) When the simplified Ziegler apparatus[18] was used, with triethylamine and three times as much ether in the reaction flask, there was troublesome clogging of the dropping funnel and the yield was not improved over (A). The clogging was probably due to the greater ease of diffusion of triethylamine vapor to the funnel tip, with consequent formation of the hydrochloride in the capillary.

General Procedure.—A cyclization run is conveniently made with from 3–5 g. of dibasic acid or a correspondingly larger amount of the bifunctional acid chloride. If the acid is used it is first converted to the crude acid chloride by the following procedure. To the acid is added one and one-half to two times the theoretical amount of purified thionyl chloride.[19] The mixture is heated in a water-bath maintained at about 55° for two hours and is then heated on the steam-bath until evolution of hydrogen chloride and sulfur dioxide has ceased. This usually requires from one to three hours longer. When the reaction is complete the excess thionyl chloride is removed as completely as possible without subjecting the acid chloride to excessive heating. This is best accomplished by applying cautiously the direct suction of a good glass aspirator (10–15 mm.) shaking and swirling gently for three to four minutes at room temperature and for four to five minutes more on the steam-bath. The flask must be swirled constantly in order to prevent bumping and should be protected with a small Kjeldahl safety trap. If a sufficiently efficient aspirator is not available, addition of a small amount of anhydrous ether and repetition of the above evacuation is suggested. As previously mentioned, a large excess of thionyl chloride present in the crude acid chloride causes the cyclization mixture to become orange or brown in color and seems to reduce the yield materially. If the removal of thionyl chloride has been essentially complete, the cyclization mixture is almost colorless or is a very light yellow. The crude acid chloride which is usually a light yellow color, is transferred by means of a pipet to a carefully dried Hershberg–Hinman dropping funnel to which 200–300 cc. of dry ether has previously been added. The two liquids must be thoroughly mixed before the addition is started.

While the acid chloride is being prepared, the apparatus for the cyclization is assembled and thoroughly dried for one to two hours with air or nitrogen which has previously passed through an efficient drying tower. To the flask is added 500–600 cc. of dry ether and 10–20 cc. (three to four times the calculated amount) of pure triethylamine. Stirring is started and the "glass-col" heating mantle adjusted to a temperature which causes the ether to reflux gently. Addition is started at such a rate that it is usually complete at the end of twenty–forty hours. (Longer periods were sometimes required because of the occasional clogging of the dropping funnel.) The dropping funnel is rinsed with 50 cc. of dry ether and this is run in rapidly and is used to rinse down the sides of the condenser. Refluxing is continued for an hour longer. The subsequent operations differ somewhat and will be discussed under the individual cases.

Cyclization of Thapsic Acid.—The apparatus used were those described under (A), (B) and (C). The procedure for working up the reaction product was essentially the same in all three cases. In each run 4.00 g. (0.014 mole) of thapsic acid was used. The addition time varied from thirty-eight hours for (A) to forty-eight and fifty-three hours for (B) and (C), respectively. The reaction mixture was distilled until about 300 cc. of solution remained. This was decanted from the precipitated amine salt and ketene polymer and shaken with a slight excess of dilute hydrochloric acid in a separatory funnel to remove the excess amine. The ether solution was washed with water, dried and distilled on the steam-bath. The viscous orange or amber oil was refluxed for three hours with a solution of 1.5 g. (0.027 mole) of potassium hydroxide in 25 cc. of alcohol. During the first hour, an incrustation, presumably potassium carbonate, formed around the sides of

---

(16) "Organic Syntheses," Coll. Vol. 2, John Wiley and Sons, Inc., New York, 1943, p. 129. The capillary stem of Hershberg's funnel was modified by L. Hinman as follows. A tungsten wire (about 0.5–0.6 mm. in diameter) with a sharpened tip was placed in a lathe and used as the grinding tool to enlarge a capillary of smaller diameter. The stem was 7 cm. long and the wire, when completely seated, extended slightly beyond the glass tip, thus making it possible to clear the capillary when it became clogged. This modification permitted a very fine adjustment of flow ranging from complete stoppage to a steady stream.

(17) This was determined by a simple test. A 1-cc. portion of the ether solution of N-ethylpiperidine is placed in a small test-tube containing a piece of red litmus paper about 5 mm. square. One drop of boiled, distilled water is allowed to fall through the ether solution onto the litmus paper. The tube is shaken gently and the time required for the paper to become perceptibly blue (as compared with a blank) serves as a rough indication of the concentration of N-ethylpiperidine in the solution. The test was sensitive enough to detect one part by volume of the amine in at least two hundred thousand parts of ether.

(18) Schroeder, Ph.D. Dissertation, Harvard University, 1938.

(19) An equal volume of anhydrous ether may also be added to accelerate the solution of the acid and thereby speed the reaction. If this is done the ether is allowed to distil slowly through the uncooled condenser during the first hour.

the flask. The reaction mixture was diluted with 50 cc. of water and thoroughly extracted with ether. The ether extract was washed with water, dried over magnesium sulfate and distilled. Removal of the ether left an aqueous-alcoholic residue which deposited 1,16-cyclotriacontanedione in needles. The yield ranged from 1.3% of tan crystals sintering at 68° and melting at 74–76° when apparatus (C) was used, to 5.3% of white crystals melting at 76–77° when apparatus (B) was used. Apparatus (A) gave 2.9% m. p. 76.5–78°. Recrystallization from alcohol did not appreciably raise the melting points, 77–78° (Ruzicka reports 74–75°[20]). The yield of diketone obtained seemed to bear no relation at all to the yield of monoketone.

The cyclopentadecanone (Exaltone) was isolated by distillation of the filtrate from the diketone in a 5-cc. flask provided with a sausage side arm. The white, waxy ketone distilled at 107–108° (0.25 mm.). The yields ranged from 14 (B) to 20% (C) and (A). The ketone was converted directly to the semicarbazone, which, after one crystallization from methanol melted at 190.5–191.5° (Ruzicka gives 187–188°).[21]

Cyclization of Suberic Acid.—The apparatus was that described under (A). The addition of the solution of crude acid chloride from 3.00 g. of suberic acid required twenty-six hours. The ether solution from the cyclization was decanted from the precipitated triethylamine hydrochloride and trace of insoluble polymer into a separatory funnel. After shaking with a slight excess of dilute hydrochloric acid, it was washed with water until the washings were neutral to congo red. The solution was dried over magnesium sulfate and then fractionally distilled through a 50-cm., vacuum-jacketed column packed with glass helices. To the residual light yellow oil was added 5 cc. of alcohol, and, *very slowly*,[22] with cooling, a solution of 1.8 g. (0.032 mole) of potassium hydroxide in 20 cc. of alcohol. The solution was allowed to stand at room temperature for ten hours and was then refluxed for two hours more. A precipitate, presumably potassium carbonate, started to form shortly after addition of the alcoholic potassium hydroxide. The mixture was worked up in the same manner as the thapsic acid cyclization product with the exception that the ether solution was fractionally distilled through the above-mentioned fractionating column. From the alcoholic solution which remained was isolated 93 mg. of shining white plates, m. p. 144–145.5°. Distillation of the filtrate gave 642 mg. (33.3%) of cycloheptanone, b. p. 176° (735 mm.). An additional 100 mg. of slightly yellow crystals, m. p. 143–146.5°, was isolated by crystallization from alcohol of the residue from the distillation of the cycloheptanone. The two crops represent a yield of 10% of 1,8-cyclotetradecanedione. Crystallization from alcohol raised the melting point to 147.5–148° and this was not changed by a vacuum sublimation.

Anal. Calcd. for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78; mol. wt., 224.34. Found: C, 74.89; H, 10.89; mol. wt., 231 (micro Rast).

The disemicarbazone of 1,8-cyclotetradecanedione was prepared by treating 50 mg. of the diketone in 3 cc. of warm methanol with semicarbazide reagent. A yield of 75 mg. of fine, white powder was obtained (the theoretical yield on the basis of disemicarbazone). This, being very insoluble in the common solvents, was purified by extraction with two portions of boiling alcohol, m. p. 261° dec. in a copper block with rapid heating (about five degrees per minute).

Anal. Calcd. for $C_{16}H_{30}O_2N_6$: N, 24.83. Found: N, 23.73, 23.84.

The dioxime of 1,8-cyclotetradecanedione was prepared by the pyridine method.[23] The white material was crystallized from a large volume of alcohol, m. p. 234–235° dec.

Anal. Calcd. for $C_{14}H_{26}O_2N_2$: N, 11.01. Found: N, 11.10, 10.93.

Evidence for Reversibility of the Dimerization Reaction.—The stability of the cyclic ketene derivatives was tested in the following manner. To a solution of 50 cc. (36.5 g., 0.36 mole) of triethylamine in 100 cc. of dry ether was added over a period of fifty-seven hours a solution of 11.90 g. (0.0498 mole) of sebacyl chloride in 600 cc. of dry ether. The apparatus described under (A) was used. The funnel was rinsed with dry ether and the mixture allowed to stand overnight at room temperature. The ether was siphoned into a one-liter graduated cylinder through a glass tube in the end of which was placed a plug of fine glass wool. Care was taken to minimize the exposure of the ether solution to the atmosphere. Half of the ether was returned to the flask by means of a pipet and refluxed for three more days. The other half was worked up as follows.

Most of the ether was distilled on the steam-bath. When the volume became small the remainder of the ether and most of the excess triethylamine was removed with suction at room temperature and finally for a short period at 50–60°. A solution of 3 g. (0.053 mole) of potassium hydroxide in 50 cc. of alcohol was added and the resulting solution was refluxed on the steam-bath for three hours. A precipitate, presumably potassium carbonate, started to come down at once. Upon the addition of 50 cc. of water the potassium carbonate readily dissolved, but the 1,10-cycloöctadecanedione was precipitated. This solution was steam distilled until 200 cc. of liquid had been collected in the distillate. This was acidified to congo red. A pronounced sweetish odor was detected, but extraction with ether and fractionation through a 12-cm., helix-packed column, followed by treatment with semicarbazide reagent, failed to yield any cyclononanone semicarbazone. Filtration of the residue from the steam distillation gave 783 mg. (22.5%) of crude, faintly brown 1,10-cycloöctadecanedione, m. p. 80–90° with sintering at about 75°. One crystallization from ether gave 446 mg. of almost white cubes, m. p. 93–96°. Concentration of the mother liquor yielded an additional 117 mg., m. p. 92.5–95°. This represents a yield of 16% of relatively pure diketone. The melting point can be raised to 96–97° by sublimation at 110° (0.45 mm.).

The ether solution which had been returned to the flask for further refluxing was worked up the same way as the first half. The crude diketone weighed 478 mg. (13.7%) and melted at 75–85° with previous sintering at about 70°.

Summary

Acid chlorides of suberic, sebacic and thapsic acids have been dehydrohalogenated by tertiary aliphatic amines to form the bifunctional ketene derivatives. These condense linearly to give ketene polymers, but under conditions of high dilution, moderate yields of macrocyclic compounds are obtained. Hydrolysis and decarboxylation of these cyclic ketene derivatives gives the large ring ketones and diketones.

Many-membered Carbon Rings. II. A New Synthesis of Civetone and *dl*-Muscone

BY A. T. BLOMQUIST, ROBERT W. HOLLEY[1] AND R. D. SPENCER[2]

The only recorded synthesis of civetone is that of Hunsdiecker in which intramolecular alkylation of an ω-iodoacylacetic ester was effected to form the appropriate many-membered carbon ring.[3] Ruzicka, Plattner and Widmer[4] as well as Hunsdiecker[5] reported the preparation of suitable intermediates for the synthesis of civetone by Ziegler's method[6] but have not described cyclization experiments leading to the complete synthesis.

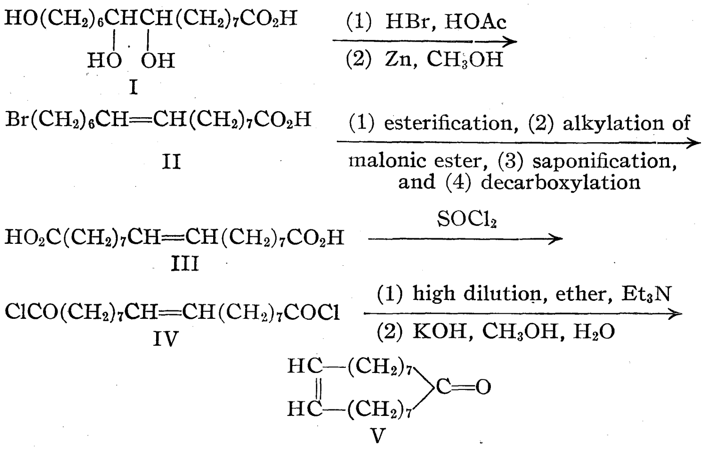
Ziegler and Weber[7] and Ruzicka and Stoll[8] announced, practically simultaneously, the synthesis of *dl*-muscone by the Ziegler method although the two groups used different syntheses for the requisite ω,ω′-dinitrile used in the cyclization. Hunsdiecker also has synthesized *dl*-muscone through his intramolecular alkylation method.[9]

It was of interest to attempt the synthesis of civetone and *dl*-muscone through the intramolecular condensation, under conditions of high dilution, of suitable bifunctional ketenes. This synthetic method for many-membered rings is described in preceding articles.[10]

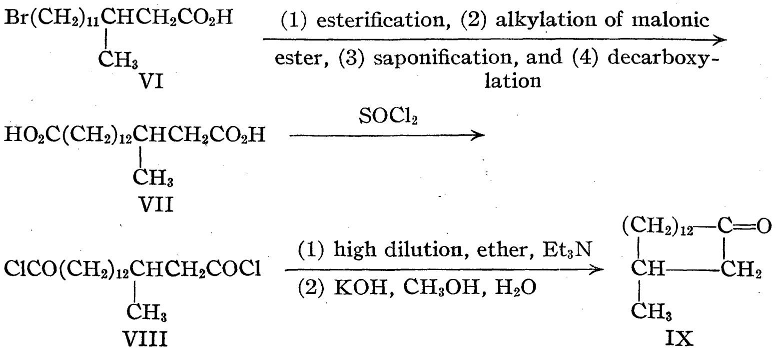
The reactions employed in the syntheses here reported are indicated in the accompanying diagram. Using aleuritic acid (I) as the starting material for the civetone synthesis, 9-octadecene-1,18-dioic acid (III) was prepared essentially by Hunsdiecker's procedure.[5] The crude acid chloride (IV) derived therefrom was cyclized through the bifunctional ketene. Civetone (V) was obtained in 33% yield from 9-octadecene-1,18-dioic acid (III).

The starting material for the synthesis of *dl*-muscone was 14-bromo-3-methyltetradecanoic acid (VI).[11] It was converted to 3-methyl-1,16-hexadecanedioic acid (VII) as indicated and the corresponding crude acid chloride (VIII) cyclized through the bifunctional ketene. *dl*-Muscone (IX) was obtained in 22% yield from 3-methyl-1,16-hexadecanedioic acid.

SYNTHESIS OF CIVETONE



SYNTHESIS OF *dl*-MUSCONE



In the present study the yields of civetone and *dl*-muscone from the appropriate dicarboxylic acids are lower than those reported by Hunsdiecker[3] and by Ziegler and Weber[7] for the cyclization steps of their respective syntheses. However, a consideration of such factors as ease of synthesis of necessary intermediates, convenience in laboratory manipulation, and over-all yield from the starting materials may favor the new syntheses somewhat. In repeating Hunsdiecker's synthesis of civetone we effected certain simplifications and improvements in yield in some of the steps and realized an 8.5% over-all yield of civetone, as its semicarbazone, from aleuritic acid. By the present method a 9.8% yield of civetone, as its semicarbazone, from aleuritic acid was obtained. Nicely crystalline inter-

mediates were encountered in the present syntheses.

Experimental

Preparation of Civetone

16-Bromo-9-hexadecenoic Acid (II).—This acid was prepared from aleuritic acid according to Hunsdiecker's procedure.[3] The 9,10,16-tribromopalmitic acid was treated, in methanol solution, with zinc dust at reflux temperature for five and a half hours. The yield of crude acid from aleuritic acid was 62%; the yield of acid m. p. 40.5–42° was 39%.

Methyl 16-Bromo-9-hexadecenoate.—The acid described above on treatment with an excess of an ethereal solution of diazomethane gave a quantitative yield of the liquid methyl ester.

8-Hexadecene-1,1,16-tricarboxylic Acid.—The procedure was that of Hunsdiecker.[5] The tricarboxylic acid, m. p. 67–69°, was used without purification.

9-Octadecene-1,18-dioic Acid (III).—The tricarboxylic acid described above was decarboxylated by heating *in vacuo* to 200°, as described by Hunsdiecker.[5] The unpurified acid, m. p. 95.5–98°,[12] was recrystallized from ethyl acetate, m. p. unchanged, yield 82% from 16-bromo-9-hexadecenoic acid. The acid was used without further purification in the cyclization step. Neutral equivalent was 163 (calcd. 156).

Civetone (V). Cyclization of 9-Octadecene-1,18-dioic Acid.—A mixture of 1.8 g. (5.8 millimoles) of 9-octadecene-1,18-dioic acid, 2 cc. (3.3 g., 28 millimoles) of thionyl chloride and 5 cc. of absolute ether was warmed gently. Sulfur dioxide and hydrogen chloride distilled gradually. After half an hour the temperature was raised to *ca.* 70° and kept there for one hour. Removal of excess thionyl chloride *in vacuo* at 50–60° gave 2.03 g. of the crude acid chloride which still had an odor of thionyl chloride.

A solution of the crude acid chloride in 200 cc. of absolute ether (Grignard-dried) was added over a period of fifteen hours from a Hershberg[13] dropping funnel down the condenser into a stirred, refluxing mixture of 500 cc. of absolute ether (Grignard-dried) and 10 cc. of triethylamine. At the end of this time the dropping funnel and condenser were rinsed with absolute ether and 500 cc. of ether was removed by distillation of the combined ethereal solution. The remaining ethereal solution, triethylamine hydrochloride, and polymer was washed with 50-cc. and 30-cc. portions of 3 *N* hydrochloric acid and finally with water until the washes were neutral to congo red. The ethereal solution was dried over anhydrous magnesium sulfate.

The ether was distilled and the residue weighed 1.72 g. In order to hydrolyze ketene dimers, this material was dissolved in a solution of 2.0 g. of potassium hydroxide in 2.0 cc. of water and 30 cc. of methanol. The solution was kept at room temperature for forty hours and then was refluxed one and one-half hours. The saponification mixture was cooled, diluted with water to about 200 cc., and the neutral organic material extracted repeatedly with ether. The ethereal solution was washed with water and dried over anhydrous magnesium sulfate. The ether was distilled and 545 mg. of residue, crude civetone, was obtained. The material remaining in the aqueous layer was investigated sufficiently to insure that no civetone was being lost as α-civetonecarboxylic acid.

The civetone was distilled at 0.2 mm. pressure with a bath temperature of about 160°. A nearly colorless distillate was obtained; yield, 476 mg. (33% from 9-octadecene-1,18-dioic acid).

Civetone Semicarbazone.—The distilled civetone (476 mg.) was dissolved in 5 cc. of acetone-free methanol and a solution of 700 mg. of semicarbazide hydrochloride and 1.05 g. of sodium acetate trihydrate in 2.1 cc. of water was added dropwise. The semicarbazone started to crystallize after 15 to 20% of the semicarbazide solution had been added. The mixture was allowed to stand at room temperature overnight.

The semicarbazone was collected, washed with water and was dried four hours in the air and finally *in vacuo;* yield, 575 mg. It was recrystallized from 35 cc. of methanol. The recrystallized semicarbazone, shining leaflets, weighed 497 mg.; m. p. 189.5–191.5° (Ruzicka[14] reported 185–186°, Hunsdiecker[3] reported 190–191°). The melting point was not changed when this semicarbazone was mixed with the semicarbazone of civetone obtained according to Hunsdiecker's[3] procedure.

Anal. Calcd. for $C_{18}H_{33}ON_3$: N, 13.67. Found: N, 13.64; 13.71.

The mother liquors were concentrated to about 5 cc. and the second crop of semicarbazone was recrystallized; 48 mg. were obtained; m. p. 190–192°. The total yield of civetone semicarbazone was 31% from 9-octadecene-1,18-dioic acid. This was a 25% yield from 16-bromo-8-hexadecenoic acid and a 9.8% yield from aleuritic acid.

Civetone may be regenerated from its semicarbazone in quantitative yield by heating the semicarbazone with an oxalic acid solution as described by Ruzicka.[14]

Preparation of *dl*-Muscone

14-Bromo-3-methyltetradecanoic Acid (VI).—This acid was prepared in the Cornell laboratories by Miss M. Burg[15] according to the procedure described by Hunsdiecker.[9]

Methyl 14-Bromo-3-methyltetradecanoate.—The liquid ester was obtained in quantitative yield by treatment of the acid described above with an excess of diazomethane.

2-Methyl-1,14,14-tetradecanetricarboxylic Acid.—The alkylation of diethyl malonate was carried out in exactly the same way as in the preparation of 8-hexadecene-1,1,16-tricarboxylic acid from methyl 16-bromo-9-hexadecenoate, the procedure described by Hunsdiecker.[5] The crude 2-methyl-1,14,14-tetradecanetricarboxylic acid was an oil, and no attempt was made to purify it.

3-Methyl-1,16-hexadecanedioic Acid (VII).—The tricarboxylic acid described above was decarboxylated at 200°. The resulting dicarboxylic acid was recrystallized from ethyl acetate and from a mixture of ethyl acetate and 60–70° petroleum ether. The yield from 14-bromo-3-methyltetradecanoic acid was 46%; m. p. 74–76° (Chuit, *et al.*,[16] reported the melting point as 77.2–77.4°). Neutral equivalent was 152 (calcd. 150).

***dl*-Muscone (IX). Cyclization of 3-Methyl-1,16-hexadecanedioic Acid.**—The di-acid chloride was prepared from 1.8 g. (6.0 millimoles) of 3-methyl-1,16-hexadecanedioic acid exactly as the corresponding di-acid chloride was prepared in the synthesis of civetone. The cyclization procedure was exactly the same except that the solution of di-acid chloride was added over twenty-three hours. The product was isolated as before. The saponification mixture was allowed to stand at room temperature for five and one-half days.

The saponification mixture was diluted with 250 cc. of water and the *dl*-muscone was extracted into ether; 450 mg. was obtained. The *dl*-muscone was distilled at 0.2 mm. pressure with a bath temperature of about 140°. The colorless *dl*-muscone weighed 315 mg. (22% from 3-methyl-1,16-hexadecanedioic acid).

***dl*-Muscone Semicarbazone.**—The distilled *dl*-muscone (315 mg.) was dissolved in 4 cc. of acetone-free methanol and a solution of 500 mg. of semicarbazide hydrochloride and 750 mg. of sodium acetate trihydrate in 1.5 cc. of water was added over ten minutes. The solution was maintained at 65° for fifteen minutes, at which time the semicarbazone began to precipitate. The mixture was allowed to stand at room temperature for twenty-four hours.

The semicarbazone was collected and was allowed to dry in air; yield 400 mg. It was recrystallized from 5 cc. of

boiling methanol. The recrystallized semicarbazone weighed 319 mg.; m. p. 131.5–132.5°. (Hunsdiecker[9] reported 133–133.5°; Ruzicka[8] reported 136–137°.)

Anal. Calcd. for $C_{17}H_{33}ON_3$: N, 14.22. Found: N, 14.38, 14.39.

A second crop of semicarbazone (54 mg.) was obtained from the mother liquors; m. p. 127–128.5°. The total yield of *dl*-muscone semicarbazone from 14-bromo-3-methyltetradecanoic acid was 9.7%.

dl-Muscone may be regenerated from its semicarbazone by heating the semicarbazone with an oxalic acid solution, as in the regeneration of civetone from its semicarbazone.

Summary

A new synthesis for civetone and *dl*-muscone is described in which the appropriate many-membered carbon rings are formed by the intramolecular condensation of bifunctional ketenes.

Many-membered Carbon Rings. III.[1] Carboxylic Acid Derivatives of Cycloheptadecane[2]

BY A. T. BLOMQUIST AND ROBERT W. HOLLEY[3]

The extensive researches in the chemistry of higher fatty acids have resulted in the discovery of therapeutic agents of some promise against tuberculosis and leprosy.[4] Recently, activity in the field has been stimulated by the interesting study of phthioic acid, isolated from the tubercle bacillus.[5] Accordingly, it seemed of interest to undertake an investigation of the properties of carboxylic acids containing many-membered carbon rings.

The present paper records exploratory studies on synthetic methods for the preparation of large-ring carboxylic acids of the type A and B.

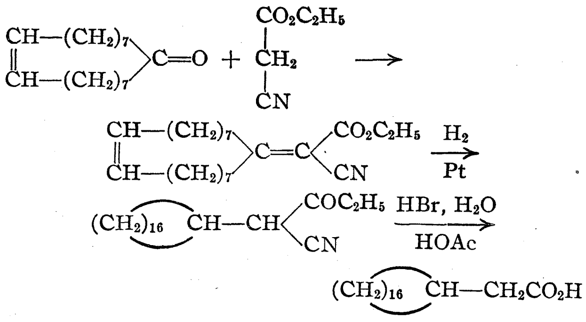
A

B

The relative availability of the seventeen-carbon cyclic ketone, civetone, suggested its use in developing synthetic methods for the type of acids described above. These methods should be applicable to the synthesis of higher homologs with the carbon ring containing from twenty to thirty members.

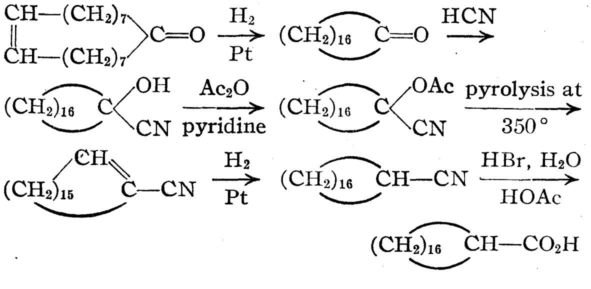
Hunsdiecker's synthesis of civetone from aleuritic acid[6] was selected as a suitable method for obtaining the C_{17} ring. Unfortunately, his published procedure is incomplete and considerable experimentation was necessary before a useful synthesis was developed. A number of modifications were worked out and these are described in the experimental section. Through the use of unpurified intermediates in many of the steps it was possible not only to achieve a considerable saving of labor but also to improve the over-all yield of civetone from aleuritic acid, 8.5% as compared with 5.3% obtained by Hunsdiecker.

Cycloheptadecaneacetic acid was readily obtained from the condensation product of civetone with ethyl cyanoacetate as indicated by the equations



The over-all yield of purified cycloheptadecaneacetic acid from civetone was 57%.

The preparation of cycloheptadecanecarboxylic acid presented more difficulties. It was eventually obtained by way of cycloheptadecanone cyanohydrin as indicated below.



The over-all yield of cycloheptadecanecarboxylic acid was 40%.

Attempts to obtain the above acid by carbonation of the appropriate Grignard reagent or

organolithium compound were unsuccessful as the chief products were neutral, halogen-free oils. Degradation of cycloheptadecaneacetic acid according to the Barbier–Wieland procedure[7] gave a low yield of the carboxylic acid. Although 1-hydroxycycloheptadecanecarboxamide was obtained in excellent yield from cycloheptadecanone cyanohydrin its conversion to the carboxylic acid did not appear promising. Further, since methyl α-civetonecarboxylate, an intermediate in the civetone synthesis, could not be readily purified, it was not used as a starting material for the synthesis of the carboxylic acid.

Civetol, characterized as its acid phthalate ester, was obtained in 95% yield by reduction of civetone with aluminum isopropoxide and was converted quantitatively into cycloheptadecanol by hydrogenation over platinum.

Civetone was converted smoothly into an hydantoin derivative by treatment with sodium cyanide and ammonium carbonate.

Experimental[7a]

Preparation of Civetone

16-Bromo-9-hexadecenoic Acid.—A mixture of 190 g. (2.9 moles) of commercial zinc dust, 1800 cc. of methanol and 5 cc. of 14.5% hydrogen bromide solution in acetic acid was placed in a 5-liter, three-necked flask equipped with a stirrer, reflux condenser, and a thermometer which dipped below the surface of the liquid. The mixture was heated to gentle reflux and then was cooled to about 55°. A solution of 286 g. of crude 9,10,16-tribromopalmitic acid (prepared from 182 g. of aleuritic acid exactly as described by Hunsdiecker[6]) in 300 cc. of methanol was added slowly. The mixture was warmed and refluxed for 5.5 hours during which time additional 10-g. portions of zinc dust were added at one-hour intervals. The hot solution was decanted from unreacted zinc and cooled.

The zinc salt was collected, recrystallized from 6400 cc. of boiling methanol (heated on a steam-bath to avoid overheating the solid zinc salt) and dried in air: yield 136 g., 62% from aleuritic acid.

The acid was liberated by shaking the zinc salt with a mixture of 6 *N* hydrochloric acid and ether. The 16-bromo-9-hexadecenoic acid weighed 125 g., m. p. 38–41° (62% from aleuritic acid). It was recrystallized from 160 cc. of pure methanol: first crop 72 g., m. p. 40.5–42°, second crop 7 g., m. p. 40–42°. The second crop was recrystallized from 25 cc. of methanol by cooling the solution first in the refrigerator and then in Dry Ice: weight 6.6 g., m. p. 40.5–42°. The total yield was 39% from aleuritic acid.

Methyl 18-Bromo-3-oxo-11-octadecenoate.—The acylation of ethyl acetoacetate was carried out in a three-necked, 500-cc. flask equipped with a stirrer, reflux condenser and dropping funnel. The sodium enolate was prepared from 38 g. (0.29 mole) of freshly distilled ethyl acetoacetate by adding small pieces of sodium totalling 5.75 g. (0.25 mole) to a solution of ethyl acetoacetate in 40 cc. of absolute ether. About three-quarters of the sodium dissolved before the sodium enolate began to precipitate. The remainder of the sodium was added, the mixture diluted with 100 cc. of absolute ether, and stirring was continued for three hours.

While the above mixture was being stirred, 72 g. (0.22 mole) of 16-bromo-9-hexadecenoic acid was mixed with 18.5 cc. (30.3 g., 0.25 mole) of pure thionyl chloride and 30 cc. of absolute ether was added. The mixture was warmed very slightly on a steam-bath until the rapid evolution of sulfur dioxide and hydrogen chloride had slowed. The remaining ether was distilled and the temperature raised to approximately 80° over an additional hour. The excess thionyl chloride was removed at water pump pressure, finally at 80°. The acid chloride, 76 g., was dissolved in 75 cc. of absolute ether.

The suspension of sodium enolate of ethyl acetoacetate was diluted to give a total volume of 200 cc. A few small pieces of unreacted sodium remained. The solution of acid chloride in ether was added to this suspension through the dropping funnel over a period of about five minutes. The mixture was refluxed for two hours and then was allowed to stand at room temperature overnight.

The reaction mixture was added to a mixture of 30 cc. of concentrated sulfuric acid and 250 cc. of ice and water. An additional 100 cc. of ether was added. The last traces of solid dissolved with some difficulty. The ether layer was separated and the aqueous layer was extracted with two additional 50-cc. portions of ether. The combined ether extracts were washed with water until the washes were neutral to congo red. The ethereal solution was dried over anhydrous magnesium sulfate. The ether was distilled and volatile material remaining was removed *in vacuo*, first at water pump pressure with a bath temperature of 120° and finally by heating at 120° for fifteen minutes at a pressure of 0.2 mm. The residue of crude ethyl 2-acetyl-18-bromo-3-oxo-11-octadecenoate, 90 g., was dissolved in a solution of sodium methylate prepared from 5.75 g. of sodium and 250 cc. of methanol (dried by distillation from magnesium methylate). The solution was left at room temperature for five hours.

The solution was added to a mixture of 30 cc. of concentrated sulfuric acid and 500 cc. of ice and water. The gummy solid which precipitated was extracted into ether (400-cc. total). The ethereal solution was washed with water, until the washes were neutral to congo red, and was dried over anhydrous magnesium sulfate. After removal of the ether, 82 g. of crude methyl 18-bromo-3-oxo-11-octadecenoate was obtained (97.5% from 16-bromo-9-hexadecenoic acid).

Methyl 18-Iodo-3-oxo-11-octadecenoate.—The crude methyl 18-bromo-3-oxo-11-octadecenoate (82 g., 0.21 mole) was dissolved in a solution of 37.5 g. (0.25 mole) of sodium iodide in 250 cc. of reagent grade acetone. The mixture was left at room temperature overnight.

About two-thirds of the acetone was distilled *in vacuo*. A mixture of 100 cc. of water and 200 cc. of ether was added to the residue. The ether layer was separated and the aqueous layer was extracted twice with additional ether. The combined ether extracts were dried over anhydrous magnesium sulfate. The ether was distilled *in vacuo*. The residue was taken up in methanol and this was removed *in vacuo* (for comparison of the m. p. with samples recrystallized from methanol). The crude methyl 18-iodo-3-oxo-11-octadecenoate was a mushy solid at 25° and liquified completely at 30°, weight 86 g. (93.5% from methyl 18-bromo-3-oxo-11-octadecenoate).

Civetone.—A solution of 25 g. (0.057 mole) of crude methyl 18-iodo-3-oxo-11-octadecenoate in 300 cc. of methyl ethyl ketone was added over sixty hours from a Hershberg dropping funnel[8] into the returning stream of condensate from a stirred, refluxing mixture of 3300 cc. of methyl ethyl ketone and 500 g. of potassium carbonate. After the addition was complete, the mixture was stirred and refluxed an additional twenty-four hours.

The mixture was cooled and the potassium carbonate was removed by filtration and washed several times with methyl ethyl ketone. The methyl ethyl ketone was distilled: the last 50 cc. was removed *in vacuo*, weight of residue 33 g. This material was shaken with 100 cc. of 15% formic acid as described by Hunsdiecker[6] to remove products of the condensation of methyl ethyl ketone with itself. The insoluble material weighed 27.5 g. The more volatile fraction of this crude cyclization product was distilled by heating at 70° at 0.2 mm. pressure for ten min-

[7] Hoehn and Mason, THIS JOURNAL, **60**, 1493 (1938).

[7a] All melting points and boiling points are uncorrected unless otherwise specified.

[8] "Organic Syntheses," **18**, 16 (1938).

utes. The residue, crude methyl α-civetonecarboxylate, weighed 19 g. It was dissolved in a solution prepared from 30 g. of potassium hydroxide, 30 cc. of water and 450 cc. of methanol. The solution was allowed to stand at room temperature (about 25°) for five days.

The saponification mixture was added to 1200 cc. of 10% sulfuric acid and the organic material was extracted with portions of ether totalling 500 cc. The ether extracts were washed with water, and then 100 cc. of 3% potassium hydroxide solution was poured through the ether solution in a fine stream. The aqueous layer became orange. The separatory funnel was tipped on its side and rotated slowly in order to expose most of the ether layer to the alkali. Care was taken not to shake the mixture since a very stable emulsion formed if this was done. Considerable acidic material went into the alkaline extract. Investigation indicated that no α-civetonecarboxylic acid was present at this point. The alkaline layer was drawn off and the ether layer was washed twice with water, pouring the water through the ether and down the sides of the funnel. The ethereal solution was dried over anhydrous magnesium sulfate. The ether was distilled and the residue, crude civetone, weighed 8 g.

The civetone was distilled, weight 4.58 g., boiling chiefly at 144–150° at 0.2 mm. (probably superheated). The vapor temperature was allowed to rise to 175° because of the large amount of residue.

Civetone Semicarbazone.—The civetone (4.58 g.) was converted to its semicarbazone by the method described by Ruzicka.[9] It was recrystallized from 250 cc. of boiling methanol, weight 4.16 g., m. p. 189–191°. (Ruzicka[9] reported 185–186°; Hunsdiecker[9] reported 190–191°.) The yield was 74% from the distilled civetone, 23.8% from methyl 18-iodo-3-oxo-11-octadecenoate, and 8.5% over-all from aleuritic acid. Civetone, m. p. 35–36.5°, was obtained in quantitative yield from the semicarbazone by the method described by Ruzicka.[9]

Cycloheptadecanone.—Civetone was reduced catalytically using ethanol as the solvent and 3% by weight of platinum oxide catalyst. Reduction was complete in one hour at 20° and atmospheric pressure. Only 90% of the theoretical amount of hydrogen was absorbed. This low value was also obtained in the catalytic reduction of civetol. The cycloheptadecanone (quantitative yield) was used in subsequent reactions without purification. Recrystallized from methanol, it melted at 64–65°. (Hunsdiecker[6] reported 64–64.5°.)

Preparation of Cycloheptadecaneacetic Acid

Condensation of Civetone with Ethyl Cyanoacetate.—The procedure was essentially the same as that described by Cope, *et al.*[10]

A mixture of 3.4 g. (13.5 millimoles) of civetone, 1.6 g. (14 millimoles) of ethyl cyanoacetate, 155 mg. (2 millimoles) of ammonium acetate, 1.7 cc. of glacial acetic acid and 14 cc. of dry benzene was heated in an oil-bath at 125–130°. The benzene was distilled slowly to remove water; 8 cc. were distilled during nine hours of heating. The reaction mixture was cooled, diluted with ether, and the solution was washed three times with water. The washes were extracted once with ether and this was washed again with water. The ethereal solutions were dried over anhydrous magnesium sulfate. The ether was distilled and the residue, weight 4.65 g., crystallized. The product was recrystallized once from 15 cc. of methanol. The once recrystallized product weighed 3.49 g. (74% from civetone) and melted on the microscope hot stage at 65–68° (cor.).

Anal. Calcd. for $C_{22}H_{35}O_2N$: N, 4.06. Found: N, 4.26.

The condensation product was reduced catalytically in ethanol solution using 4% by weight of platinum oxide catalyst. The theoretical amount of hydrogen (for two double bonds) was absorbed in four hours at room temperature and atmospheric pressure, and practically no more hydrogen was absorbed during two additional hours. The reduced product was an oil (quantitative yield) and was used without purification.

Cycloheptadecaneacetic Acid.—A solution of 253 mg. of reduced condensation product in 3 cc. of glacial acetic acid and 1 cc. of 48% hydrobromic acid was refluxed for forty-eight hours. The mixture was cooled, diluted with water and extracted with ether. The ethereal solution was washed with water and then was extracted with 3% potassium hydroxide solution. The cycloheptadecaneacetic acid, weight 196 mg., was a light brown oil which crystallized within a few days when stored at 5°. The unpurified acid melted at 20–25°. It was recrystallized from acetone by cooling the solution with Dry Ice, first crop, 147 mg., m. p. 27–28° (Calcd. neut. equiv., 296.5. Found: 289; second crop, 20 mg., m. p. 26.5–28°, neut. equiv., found, 294). The yield (167 mg.) was 77% from the civetone–ethyl cyanoacetate condensation product, and 57% from civetone.

Cycloheptadecaneacetamide.—Unpurified cycloheptadecaneacetic acid was converted to the acid chloride using purified thionyl chloride. The crude acid chloride was treated with cold concentrated aqueous ammonia. The amide was extracted with a small volume of petroleum ether and was recrystallized from ether. The yield of once recrystallized amide was 62%; micro m. p. 134–134.8° (cor.).

Anal. Calcd. for $C_{19}H_{37}ON$: N, 4.74. Found: N, 4.68, 4.72.

Preparation of Cycloheptadecanecarboxylic Acid

Acetate of Cycloheptadecanone Cyanohydrin.—The entire reaction was carried out in the hood.

Excess anhydrous hydrogen cyanide[11] (from 600 mg., 12.2 millimoles, of sodium cyanide) was condensed on top of 700 mg. (2.78 millimoles) of cycloheptadecanone at 0° to give a clear solution. A tiny droplet of piperidine was added as a catalyst[12] and the reaction mixture soon became viscous. The temperature was allowed to rise to room temperature during half an hour and was kept there three hours.

A solution of 1 cc. of acetic anhydride in 2.5 cc. of pyridine was added to the reaction mixture and the solution was heated at 125° for four hours. The reaction mixture was diluted with 20 cc. of water and the insoluble material was extracted into ether. The ether solution was washed successively with 1.5 *N* hydrochloric acid, water, 10% sodium carbonate solution and finally with water. The ethereal solution was dried over anhydrous magnesium sulfate and the ether was distilled. The crude acetate of cycloheptadecanone cyanohydrin, 825 mg. (92% from cycloheptadecanone), was used in the subsequent pyrolysis without purification. It reduced potassium permanganate in acetone solution only slightly and very slowly. In a micro hydrogenation apparatus, it took up only 10% of one mole of hydrogen during five hours.

Pyrolysis of the Acetate of Cycloheptadecanone Cyanohydrin.—The pyrolysis was similar to those carried out by Burns, Jones and Ritchie.[13]

The acetate (500 mg.) was refluxed at atmospheric pressure for ten minutes (Wood's metal bath at 360°). The pyrolyzed product gave a strong unsaturation test with potassium permanganate in acetone solution. It was reduced in a micro hydrogenation apparatus using 50 mg. of platinum oxide as the catalyst and 10 cc. of ethanol as the solvent. About 5% more than the theoretical amount of hydrogen (1 mole) was absorbed in 1.7 hours. The catalyst was removed by filtration and the crude cycloheptadecyl cyanide was isolated, yield 418 mg.

Cycloheptadecanecarboxylic Acid. Hydrolysis of Cycloheptadecyl Cyanide.—A solution of 316 mg. of crude cycloheptadecyl cyanide in 6 cc. of glacial acetic acid and

1.2 cc. of 48% hydrobromic acid was refluxed seventy hours. A small amount of insoluble oil separated during the hydrolysis. The mixture was diluted with water and the insoluble material was extracted into ether. The ethereal solution was washed thoroughly with water and then was diluted with more ether to about 50 cc. A total of 50 cc. of 3% potassium hydroxide solution was used to extract acidic material. This alkaline solution was washed once with ether and then was acidified to congo red. The acidic material was extracted into ether and the ethereal solution was washed thoroughly with water and was dried over anhydrous magnesium sulfate. The cycloheptadecanecarboxylic acid was isolated, yield 144 mg. (40% of the theoretical amount from cycloheptadecanone).

The unpurified liquid cycloheptadecanecarboxylic acid gave a neutral equivalent of 295; calcd., 282.5.

Cycloheptadecanecarboxamide.—Unpurified cycloheptadecanecarboxylic acid was converted to the acid chloride using an excess of purified thionyl chloride. The crude acid chloride reacted with cold concentrated aqueous ammonia. The brown amide was extracted with a small volume of petroleum ether and then was dissolved in hot 85% ethanol and insoluble tar was separated. The amide was precipitated by the addition of water and was dried. It was dissolved in ethanol and treated with charcoal. The amide, re-isolated, was colorless; yield 48% from the acid; micro m. p. 158–163°. It was recrystallized from ether; yield 25% from the acid; micro m. p. 165–167°.

Anal. Calcd. for $C_{18}H_{35}ON$: N, 4.98; Found, N, 4.78, 4.92.

1-Hydroxycycloheptadecanecarboxamide.—The procedure was essentially the same as that described by Stoughton.[12] The entire reaction was carried out in a hood.

Anhydrous hydrogen cyanide (from 300 mg. of sodium cyanide) was condensed on top of 95 mg. (0.38 millimole) of cycloheptadecanone at 0°. A tiny droplet of piperidine was added and the mixture was kept at 0° for one and a half hours. The mixture was cooled in an ice–salt-bath and 0.4 cc. of 90% sulfuric acid was added. The mushy solid was stirred occasionally at 0° for one and a half hours and then was allowed to stand at room temperature overnight.

Cracked ice was added to the somewhat mushy mixture until the total volume was about 3 cc. The precipitated solid was extracted into ether: a total of 8 cc. of ether was used. The ether solution was washed with water until the washes were neutral to congo red and then the solution was dried over anhydrous magnesium sulfate. The ether was distilled until about 1 cc. remained. Beautiful white needles separated and, after the mixture was kept at 5° for two hours, the crystals were collected, weight 70 mg., micro m. p. 146–147° (cor.). A second crop of 9 mg. of less pure material was obtained by concentrating the mother liquors to 0.3 cc. and cooling again. The second crop was recrystallized and 7 mg. of fine crystals was obtained. The total yield (72 mg.) was 64% from cycloheptadecanone.

For analysis, part of the first crop was recrystallized from ether, micro m. p. 147–147.7° (cor.).

Anal. Calcd. for $C_{18}H_{35}O_2N$: N, 4.71; Found: N, 4.72.

Reaction of Cycloheptadecanone with Sodium Cyanide and Ammonium Carbonate. 5,5-Hexadecamethylenehydantoin.—The procedure was essentially that of Bucherer and Lieb.[14]

A solution of 100 mg. of cycloheptadecanone in 2 cc. of 95% ethanol was mixed with a solution of 50 mg. of sodium cyanide and 200 mg. of ammonium carbonate in 1 cc. of water. The mixture was warmed at 50–55° for twelve hours. The mixture was cooled and then was extracted with a mixture of ether and 60–70° petroleum ether. The ether–petroleum ether layer was washed with water and was dried over anhydrous magnesium sulfate. The ether was distilled and the petroleum ether-insoluble needles, presumably hydantoin, were collected and washed with petroleum ether, yield 46 mg. The petroleum ether-soluble material, presumably unchanged cycloheptadecanone, weighed 64 mg.

For analysis, the hydantoin was recrystallized from absolute ether, micro m. p. 251–252°, dec. (cor.).

Anal. Calcd. for $C_{19}H_{34}O_2N_2$: N, 8.69. Found: N, 8.61, 8.73.

Civetol. Reduction of Civetone with Aluminum Isopropoxide.—The procedure was similar to those described in "Organic Reactions."[15]

A mixture of 1.2 g. (4.8 millimoles) of civetone, 10 cc. of dry isopropanol, and 10 g. of distilled aluminum isopropoxide was placed in a 25-cc. distilling flask and was heated in an oil-bath at 125°. The aluminum isopropoxide dissolved and the opalescent solution was refluxed at such a rate that 1 to 2 cc. of isopropanol distilled per hour. A total of 20 cc. of isopropanol was added during the reaction and about 25 cc. was distilled. The test for acetone in the distillate was negative after about eight hours and heating was discontinued at fifteen hours.

The reaction mixture was added to 20 cc. of 10% sulfuric acid and the civetol was extracted with a total of 50 cc. of ether. The ethereal solution was washed with water until the washes were neutral to congo red. The washes were extracted with a little more ether and this was washed free of acid. The ethereal solution of civetol was dried over anhydrous magnesium sulfate. The ether was distilled, finally *in vacuo* at 60°; 1.22 g. of crude, solid civetol was obtained.

The civetol was recrystallized from 10 cc. of 60–70° petroleum ether by cooling the solution slowly with Dry Ice. A second crop of crystals was obtained by concentrating the mother liquors and cooling again with Dry Ice. The first crop weighed 1.00 g.; m.p. 64–65° with sintering at 62°; the second crop weighed 165 mg.; m. p. 62–65° (Rusicka, *et al.*,[16] reported the melting point of civetol at 65°). The yield of recrystallized civetol was 95% of the theoretical from civetone.

The half-ester of phthalic acid was prepared by heating phthalic anhydride with civetol at 125° for sixteen hours. The product was recrystalized from methanol–water and then from 60–70° petroleum ether; yield 53%, beautiful needles; micro m. p. 117.5–119° (cor.); neut. equiv. cald., 400.5; found, 397.

Cycloheptadecanol. Catalytic Reduction of Civetol.—Civetol was hydrogenated, using ethanol as the solvent and 1% by weight of platinum oxide catalyst. The reduction was complete in two hours at room temperature and atmospheric pressure; only 86% of the theoretical amount of hydrogen was absorbed. The crude cycloheptadecanol was isolated and solidified immediately. The yield was quantitative, m. p. 79–81° (Ruzicka, *et al.*,[16] reported the m. p. as 80°).

Summary

Procedures have been developed for the synthesis of carboxylic acids containing many-membered carbon rings. The acids prepared have the general formulas RCH_2CO_2H and RCO_2H, where R is a seventeen-membered carbon ring.

The synthesis of civetone by Hunsdiecker's procedure has been improved.

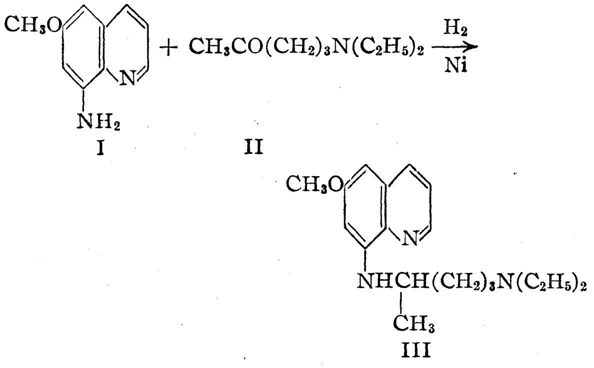
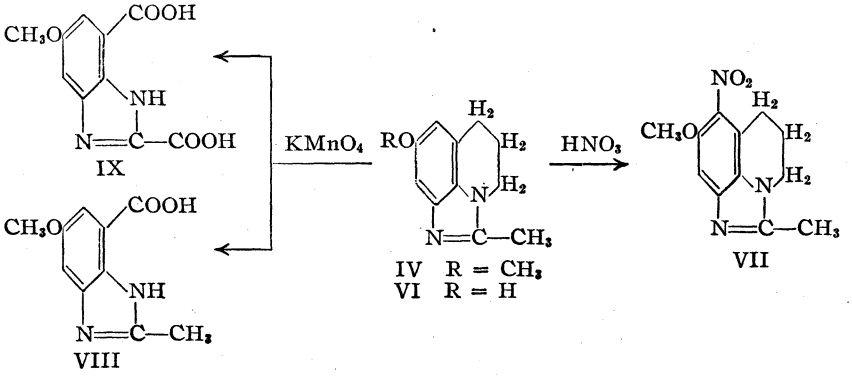
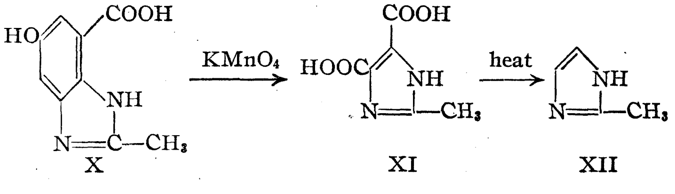
A Study of the Synthesis of Plasmochin by the Reductive Amination Method with Raney Nickel[1]

BY ROBERT C. ELDERFIELD, FRANK J. KREYSA, JAMES H. DUNN AND DAVID D. HUMPHREYS

Commercial Plasmochin (6-methoxy-8-[4-diethylamino-1-methylbutylamino]-quinoline) (III) as commonly manufactured contains significant amounts of an isomeric substance[2] to which the name Isoplasmochin and the tentative structure of 6-methoxy-8-(3-diethylamino-1-ethylpropylamino)-quinoline have been given.[2] The source of this isomer apparently may be found in the relatively large amounts of 1-diethylamino-3-bromopentane with which commercial 1-diethylamino-4-bromopentane, the intermediate for Plasmochin, is contaminated. Pure 1-diethylamino-4-bromopentane, from which pure Plasmochin may be prepared, can be made by the action of thionyl bromide on the corresponding alcohol[2,3] rather than by the action of hydrobromic acid on the alcohol as has been the commercial practice.







The use of the reductive amination reaction involving 6-methoxy-8-aminoquinoline and 1-diethylaminopentanone-4 (I–III) for the synthesis of Plasmochin presents attractive possibilities from the viewpoint of relatively accessible materials, simplicity of operation and potential formation of a product which should be free from isomers. Accordingly the reactions I–III have been the subject of intensive investigation.

Three general methods which are described in detail later were used in carrying out the reaction between I and II; *viz.*, (A) the ketone, II, was pumped into a solution of I at a specified pressure and temperature in the presence of hydrogen and Raney nickel; (b) I and II were refluxed with a substance such as ethylbenzene for azeotropic removal of water eliminated in the formation of the pertinent Schiff base and the latter was then hydrogenated; (c) I and II were heated with stirring in the presence of a dehydrating agent such as magnesium methoxide and the resulting crude product was hydrogenated. Although several variations of the above procedures were investigated, the high boiling products from all runs were roughly similar in composition. On fractionation, the material boiling in the Plasmochin range consisted of a yellow semi-solid which melted at about 104–109° and darkened rapidly on exposure to the air. Investigation of this in a typical case showed the presence of 4–5% of I, 26–29% of III and 50% of a substance which was subsequently shown to be 2-methyl-8-methoxy-5,6-dihydro-4-imidazo-[ij]-quinoline (IV). Material from other runs was of the same general composition.

After IV had been chemically identified, the substance was described by Price and Herbrandson[4] and by Barber and Wragg.[5] Although compounds of the type of IV have been previously reported[4,6] from the reaction of 8-amino-derivatives of 1,2,3,4-tetrahydroquinoline with acetic acid

---

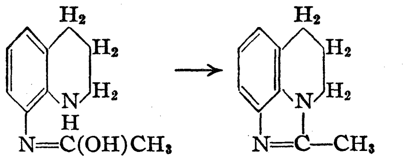
under mild dehydrating conditions in accordance with XIII–XIV it seemed improbable that such a reaction would occur when a ketone was substituted for acetic acid. In the latter case rupture of a carbon–carbon linkage under relatively mild conditions must occur. Therefore, prior to the appearance of Price and Herbrandson's note,[4] the constitution of IV was established by a study of its chemical reactions.



XIII XIV

The presence of the methoxyl group was shown by its cleavage to the corresponding phenol VI. Attempted oxidation with 35% nitric acid resulted in the formation of a mononitro derivative for which the most likely structure is VII by analogy with the behavior of other quinoline compounds on nitration. Oxidation of IV with potassium permanganate in pyridine resulted in cleavage of the reduced pyridine ring with the formation of 2-methyl-5-methoxybenzimidazole-7-carboxylic acid (VIII) as the major product together with a small amount of 5-methoxybenzimidazole-2,7-dicarboxylic acid (IX). Attempted decarboxylation of the acid, VIII, did not lead to the isolation of any definite compound. However, when 2-methyl-5-hydroxybenzimidazole-7-carboxylic acid (X), obtained from VIII by cleavage of the ether, was oxidized further with potassium permanganate, 2-methylimidazole-4,5-dicarboxylic acid (XI) was obtained. XI, on decarboxylation, gave 2-methylimidazole XII. The identities of XI and XII were established by comparison with known samples synthesized by the methods of Fargher and Pyman[7] and Dedichen,[8] respectively.

On the basis of the above degradation, the structure IV must be assigned to the major product arising from the reductive amination reaction with I and II. This was confirmed by comparison of the substance with a sample prepared by known methods.[4,6]

It is obvious that the elements of N,N-diethylpropylamine must have been eliminated during the course of the formation of the imidazole from I and II. Therefore the solvent removed from the crude hydrogenation reaction mixture was examined. From this it was indeed possible to isolate the above amine which was identified by comparison with a sample synthesized by known methods. Thus, the at first seemingly unlikely formation of the imidazole IV from I and II has been definitely confirmed. A further study of the formation of such imidazoles is reported in the succeeding paper.

Since the empirical formula of the imidazole IV is the same as that of 6-methoxy-8-ethylaminoquinoline (XV) and since formation of the latter was conceivable by a transethylation during the reaction of I and II, we have prepared XV which has not been reported previously. Ethylation of 6-methoxy-8-(*p*-toluenesulfonylamino)-quinoline according to the general method of Gawron and Spoerri[9] for the amination of aminoquinoxalines followed by hydrolysis of the tosyl group readily yielded XV.

Experimental[10,11]

Reaction of 6-Methoxy-8-aminoquinoline with 1-Diethylaminopentanone-4 in the Presence of Nickel and Hydrogen.—Three general methods have been used.

Procedure A.—A 2-gallon hydrogenation autoclave was charged with 800 ml. of methanol, 60 g. of Raney nickel and 348 g. (2 moles) of 6-methoxy-8-aminoquinoline (I). After heating to 130° at 600 lb. hydrogen pressure, 628 g. (4 moles) of 1-diethylaminopentanone-4 (II) was pumped in. A pressure drop of about 150 lb. took place over about two and one-half hours. The reaction mixture, after filtration from the catalyst was distilled up to a temperature of 135° (1 mm.) for removal of excess amino ketone and alcohol derived from it by reduction. An intermediate fraction (about 200 g.) consisting of unreacted 6-methoxy-8-aminoquinoline, and probably some of its tetrahydroderivative, followed. The so-called "Plasmochin fraction[11] (96 g.) was collected at 182–194° (1 mm.). It consisted of a mush of crystalline material in an oil which rapidly discolored on exposure to the air. The residue in the flask was a hard brittle resin and was not investigated further. The 182–194° fraction was redistilled under nitrogen and examined spectrographically in the ultraviolet using a Beckman quartz spectrophotometer. The curves obtained are shown in Figs. 1 and 2 in which it has been necessary to depart from the conventional manner of plotting to secure the information desired.[12]

At 390 mμ neither the pure imidazole, IV, nor 6-methoxy-8-aminoquinoline (I) has an appreciable extinction coefficient. The amount of Plasmochin (III) present calculated by the extinction coefficient at this wave length is 29%. At about 360 mμ, 6-methoxy-8-aminoquinoline and Plasmochin have the same extinction coefficient whereas the imidazole, IV, has a coefficient of O. Calculations at this wave length indicate a total of 34% 8-aminoquinolines, assuming Plasmochin and 6-methoxy-8-aminoquinoline to be the only 8-aminoquinolines present. At 295 mμ the imidazole, IV, has a sharp maximum. By correcting for the absorption of the 8-aminoquinolines at this wave length, calculations show the presence of about 50% of the imidazole on the assumption that no other compound present absorbs at this wave length.

Colorimetric analysis of the crude reaction product substantiated the above results. Direct coupling of the material with diazotized sulfanilic acid indicated a total of 30% 8-aminoquinolines in terms of Plasmochin. Direct diazotization and coupling indicated the presence of about 4% of 6-methoxy-8-aminoquinoline. The difference is about 26% of Plasmochin.

That there is still another substance or substances present in the crude reaction product is indicated by the fact that the absorption curve is falling at 320 to 330 mμ whereas at these wave lengths the pure imidazole, IV, has an extinction coefficient of zero while the curves for the 8-

[10] All melting points are corrected.

[11] The microanalyses reported in this paper were done by Miss Lois May of the Columbia laboratories.

[12] We wish to acknowledge our indebtedness to Dr. Bernard Brodie of the Goldwater Memorial Hospital for carrying out the spectrographic and colorimetric analyses here reported and for permission to incorporate them in this paper.

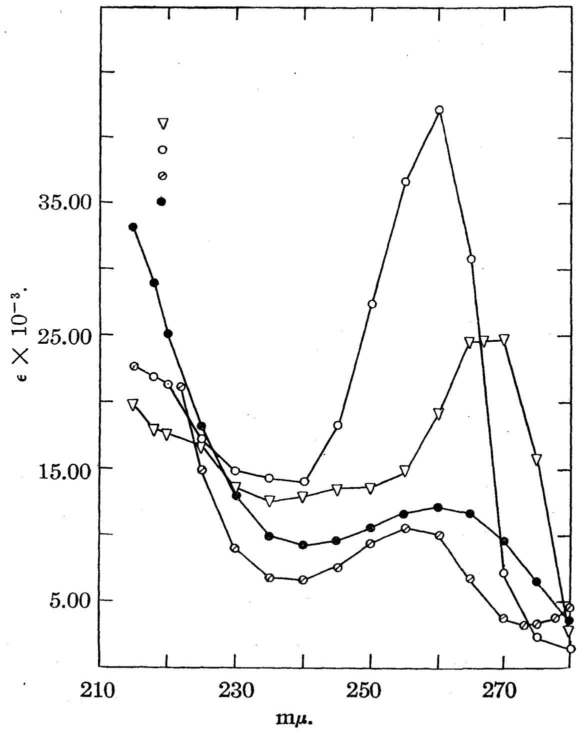

Fig. 1.—Ultraviolet absorption spectra: ▽, Plasmochin; O, 6-methoxy-8-aminoquinoline; ⊘, pure imidazole, IV; ●, twice distilled plasmochin fraction; solvent, heptane; concentration, 10 γ per ml.

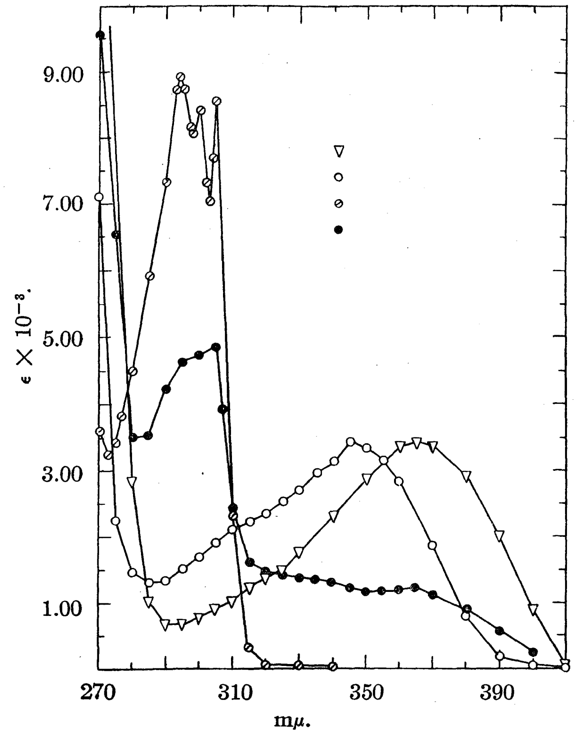

Fig. 2.—Ultraviolet absorption spectra: ▽, Plasmochin; O, 6-methoxy-8-aminoquinoline; ⊘, pure imidazole, IV; ●, twice distilled plasmochin fraction; solvent, heptane; concentration, 100 γ per ml.

aminoquinolines are rising. No attempt was made to isolate other substances which may have been present.

Procedure B.—A 2-gallon autoclave was charged with 348 g. (2 moles) of 6-methoxy-8-aminoquinoline, 60 g. of Raney nickel and a solution of magnesium methylate prepared by dissolving 24 g. of magnesium turnings in 1600 ml. of boiling absolute methanol. At 130° and 780 lb. hydrogen pressure, 628 g. (4 moles) of 1-diethylaminopentanone-4 was pumped in. The temperature was raised to 150° where a pressure drop of 250 lb. was noted. After cooling, water was added to the reaction mixture and the magnesium hydroxide was filtered off with considerable difficulty and some loss of material. Distillation of the product gave a "Plasmochin fraction" of 83 g. which was of the same character as that obtained above.

Procedure C.—The Schiff base (see below) prepared by refluxing 174 g. (1 mole) of 6-methoxy-8-aminoquinoline and 314 g. (2 moles) of 1-diethylaminopentanone-4 with 200 ml. of ethylbenzene for seventy-two hours was reduced at 90–95° and 600 lb. hydrogen pressure with 40 g. of Raney nickel for two and one-half hours. After working up as before 40 g. of a "Plasmochin fraction" having the same characteristics as that described above was obtained.

Several runs by each of the above procedures were made. Temperature limits were from 95 to 180°. In all of the runs the product was essentially the same.

Isolation of N,N-Diethylpropylamine from the Products of the Above Reaction.—The Dry Ice traps in the apparatus in which the crude product from a run similar to that given under Procedure A was distilled contained 30 ml. of liquid. This was fractionated through a small Podbielniak column. The carefully purified material boiled at 111.9–112.2°.

Anal. Calcd. for $C_7H_{17}N$: C, 73.0; H, 14.9; neutral equiv., 115. Found: C, 73.2; H, 15.1; neutral equiv., 115.7.

The amine was definitely identified by mixed melting points of the hydrochloride and methiodide with an authentic sample synthesized as below.

N,N-Diethyl-*n*-propylamine has been described as the chloroplatinate by LeBel[13] but the base has not been described. It was therefore synthesized by the general method described by Caspe[14] for the preparation of the corresponding isopropyl compound.

A mixture of 50 g. of glycerol, 123 g. of *n*-propyl bromide and 95 g. of diethylamine was heated under reflux for sixty hours. The melt was dissolved in 50 ml. of water and the solution was made strongly alkaline with 200 ml. of 50% potassium hydroxide solution, the temperature being kept below 25°. The amine layer was separated and the aqueous layer was repeatedly extracted with ether. The combined amine and ether layers were dried over potassium hydroxide and fractionated yielding 58 g. (50%) of the amine.

Anal. Calcd. for $C_7H_{17}N$: C, 73.0; H, 14.9. Found: C, 73.1; H, 14.7.

N,N-Diethyl-*n*-propylamine hydrochloride formed hygroscopic white needles from ethyl acetate and melted at 205.5–206.5°.

Anal. Calcd. for $C_7H_{17}N \cdot HCl$: C, 55.4; H, 12.0. Found: C, 55.5; H, 12.2.

N,N-Diethyl-*n*-propylamine methiodide formed hygroscopic plates from isopropanol or acetone and melted at 243–244°.

Anal. Calcd. for $C_7H_{17}N \cdot CH_3I$: C, 37.4; H, 7.8. Found: C, 37.6; H, 8.1.

Isolation of 2-methyl-8-methoxy-5,6-dihydro-4-imidazo-[ij]-quinoline, IV, from the "Plasmochin fraction."—The crystalline mush of twice distilled "Plasmochin fraction" obtained by any of the above procedures was washed with cold heptane and the insoluble crystalline material was

[14] Caspe, This Journal, **54**, 4457 (1932).

further recrystallized from heptane yielding plates which melted at 119.5–120°.

Anal. Calcd. for $C_{12}H_{14}ON_2$: C, 71.3; H, 7.0; N, 13.9; OCH_3, 15.3. Found: C, 71.2; H, 6.8; N, 14.0; OCH_3, 15.0.

The hydrochloride of the imidazole formed hygroscopic needles from absolute alcohol–carbon tetrachloride (1:1) which melted at 233–233.5°.

Anal. Calcd. for $C_{12}H_{14}ON_2{\cdot}HCl$: C, 60.4; H, 6.3; N, 11.7; Cl, 14.9. Found: C, 60.1; H, 6.2; N, 11.7; Cl, 14.8.

The hydrobromide, from absolute alcohol, was hygroscopic and melted at 242°.

Anal. Calcd. for $C_{12}H_{14}ON{\cdot}HBr$: C, 50.9; H, 5.3; N, 9.9; Br, 28.2. Found: C, 51.0; H, 5.4; N, 9.7; Br, 28.1.

The picrate, from alcohol or dioxane, softened at 243° and decomposed at 248–253°.

Anal. Calcd. for $C_{18}H_{17}O_8N_5$: C, 50.1; H, 4.0. Found: C, 50.2; H, 4.0.

The methiodide, from methanol, darkened at 280° and decomposed at 285–290°.

Anal. Calcd. for $C_{12}H_{14}ON_2{\cdot}CH_3I$: C, 45.4; H, 5.0. Found: C, 45.4; H, 4.9.

The *p*-toluenesulfonic acid salt, from isopropyl ether, alcohol or carbon tetrachloride, melted at 139.5–140.5°.

Anal. Calcd. for $C_{19}H_{22}N_2O_4S$: C, 60.9; H, 5.9; N, 7.5. Found: C, 61.1; H, 5.7; N, 7.4.

The imidazole was identified by mixed melting points of the base and the above derivatives with samples prepared according to the known method of Hazlewood, Hughes and Lions.[6]

Perbromide of the Imidazole, IV.—To a solution of 0.2 g. of the imidazole in 10 ml. of carbon tetrachloride, 5 ml. of a 5% solution of bromine in carbon tetrachloride was added dropwise. Orange crystals separated but no evolution of hydrogen bromide occurred. After recrystallization from methanol, the substance darkened at 265° and decomposed about 285°.

Anal. Calcd. for $C_{12}H_{14}Br_2ON_2$: C, 39.8; H, 3.9. Found: C, 39.8; H, 3.8.

2-Methyl-7(?)-nitro-8-methoxy-5,6-dihydro-4-imidazo[ij]quinoline.—The imidazole, IV, was unattacked when oxidation with 35% nitric acid was attempted. Rather a mononitro derivative was formed during the working up of the reaction mixture.

A solution of 1 g. of the imidazole in 10 ml. of 35% nitric acid was boiled under reflux for five hours. The mixture was transferred to an evaporating dish and 10 ml. of 70% nitric acid was added. It was then evaporated to dryness on the steam-bath after which 10 ml. of water was added and the evaporation was repeated. After triturating with 5 ml. of ice water the crystalline nitro compound was collected and recrystallized from ethyl acetate or alcohol. The substance is soluble in aqueous acid (*p*H 3) and is reprecipitated at *p*H 10. It melted at 238–240° (dec.). Assignment of the nitro group to the 7-position is preferred although the 9-position cannot be excluded.

Anal. Calcd. for $C_{12}H_{13}O_3N_3$: C, 58.3; H, 5.3. Found: C, 58.3; H, 5.2.

2-Methyl-8-hydroxy-5,6-dihydro-4-imidazo[ij]-quinoline.—A solution of 5 g. of the imidazole, IV, in 75 ml. of 48% hydrobromic acid was refluxed for ten hours. On refrigeration a crystalline precipitate separated. This was dissolved in 75 ml. of warm water (*p*H 4) and the solution was adjusted to *p*H 10 with sodium hydroxide during which the hydroxy compound first precipitated and then dissolved. The filtered alkaline solution was saturated with carbon dioxide and the precipitate was recrystallized from isopropanol. It darkened at 285° and decomposed at 295–305° (copper block).

Anal. Calcd. for $C_{11}H_{12}ON_2$: C, 70.2; H, 6.4. Found: C, 70.2; H, 6.4.

Oxidation of the Imidazole, IV, with Potassium Permanganate.—To a boiling well-stirred solution of 6 g. of the imidazole, IV, in 900 ml. of 33% aqueous pyridine was added 1200 ml. of 3% aqueous potassium permanganate solution over two hours. The mixture was boiled and stirred for an additional hour. After cooling, the manganese dioxide was filtered and extracted by boiling it with 500 ml. of 10% aqueous pyridine for half an hour. The combined filtrates from the manganese dioxide were evaporated to dryness on the steam-bath. The residue was dissolved in 200 ml. of warm water (*p*H 10) and the *p*H of the filtered solution was adjusted to 5–6 with hydrochloric acid. After refrigerating, the precipitate was collected and recrystallized from dioxane, water or alcohol. The yield was 70%. On air drying 2-methyl-5-methoxybenzimidazole-7-carboxylic acid was thus obtained as the dihydrate which darkened at 295° and decomposed at 300–305°.

Anal. Calcd. for $C_{10}H_{10}O_3N_2{\cdot}2H_2O$: C, 49.6; H, 5.8; N, 11.6. Found: C, 49.8; H, 5.7; N, 11.6.

On drying at 175° and 15 mm. over calcium chloride for one hour the substance lost 14.72% of water; calcd. 14.87%. The anhydrous acid decomposed at 295–305°.

Anal. Calcd. for $C_{10}H_{10}O_3N_2$: C, 58.3; H, 4.9; N, 13.6. Found: C, 58.5; H, 4.7; N, 13.6.

The aqueous filtrate from the above acid at *p*H 5–6 was acidified to *p*H 2 with hydrochloric acid. After refrigerating, the precipitate was purified by acidification of its hot filtered solution in 10% sodium hydroxide with hydrochloric acid and finally by recrystallization from glacial acetic acid. The yield of 5-methoxybenzimidazole-2,7-dicarboxylic acid monohydrate which darkened about 270° and decomposed at 290–295° was 0.1 g. The air-dried acid, for which analytical figures are given, lost 7.1% of water on drying at 175° and 15 mm. over calcium chloride; calcd. 7.1%.

Anal. Calcd. for $C_{10}H_8O_5N_2{\cdot}H_2O$: C, 47.3; H, 4.0; N, 11.0. Found: C, 47.3; H, 4.0; N, 11.3.

2-Methyl-5-hydroxybenzimidazole-7-carboxylic Acid.—A solution of 5 g. of the methoxy acid, VIII, in 50 ml. of 48% hydrobromic acid was refluxed for forty-five minutes at which time bumping caused by separated crystalline material necessitated stopping the reaction. After cooling, the hydroxy acid was filtered off and dissolved in 50 ml. of warm water (*p*H 2). The *p*H was adjusted to 5 with sodium hydroxide at which point the acid, X, precipitated. It was recrystallized from 900 ml. of boiling water yielding 3 g. of white needles which slowly decomposed without melting at 300–350° (copper block).

Anal. Calcd. for $C_9H_8O_3N_2$: C, 56.3; H, 4.2; N, 14.6. Found: C, 56.2; H, 4.0; N, 14.7.

Oxidation of the Acid, X, to 2-Methylimidazole-4,5-dicarboxylic Acid, XI.—To a stirred suspension of 1 g. of the acid, X, in 200 ml. of water cooled to 5° was added 80 ml. of 4% potassium permanganate solution during the course of one hour. Oxidation was prompt and the temperature was kept below 10° by external cooling. The mixture was then refrigerated for twelve hours and any unreacted permanganate was destroyed with methanol. The filtrate from the manganese dioxide was acidified to *p*H 2–3 with hydrochloric acid and then evaporated to dryness. The residue was dissolved in 40 ml. of 7% ammonium hydroxide solution, and the solution was treated with 0.1 g. of decolorizing carbon (Norit A) in the cold, filtered and evaporated to dryness. If too much Norit is used or if the solution is boiled at this point the ammonium salt of the acid is completely absorbed on the Norit. The solution of the residue in 10 ml. of warm water was acidified to *p*H 2–3 and the crystalline precipitate was collected and recrystallized several times from a small amount of water. The fine white needles decomposed at 275–285°. After drying at atmospheric pressure over calcium chloride, the acid still retained a molecule of water.

Anal. Calcd. for $C_6H_6N_2O_4{\cdot}H_2O$: C, 38.3; H, 4.3. Found: C, 38.3; H, 4.0.

A sample of 2-methylimidazole-4,5-dicarboxylic acid monohydrate prepared according to Fargher and Pyman[7] by condensation of tartaric acid dinitrate with acetaldehyde, and recrystallized in the same manner decomposed at 275–285°.

The acid was decarboxylated by heating it over a small free flame according to Dedichen[8] and the resulting 2-methylimidazole was recrystallized from benzene. The latter compound prepared from the acid from both sources melted at 134–136° and the mixed melting point was not depressed. Dedichen[8] reports the m. p. of 2-methylimidazole as 139°.

6-Methoxy-8-(4-diethylamino-1-methylbutylideneamino)-quinoline.—The Schiff base was used by Barber and Wragg in the preparation of tetrahydropamaquine but neither the method of synthesis nor physical constants of the compound are given by the British workers. A mixture of 157 g. (1 mole) of 1-diethylaminopentanone-4, 87 g. (0.5 mole) of 6-methoxy-8-aminoquinoline and 150 ml. of ethylbenzene was refluxed for one hundred hours in an apparatus equipped with a liquid separator from which the condensed reflux of ethylbenzene was returned to the reaction flask after passing through anhydrous potassium carbonate for removal of water. The bulk of the solvent was distilled off at atmospheric pressure in an atmosphere of nitrogen and 80 g. of the amino-ketone was then removed at water pump vacuum followed by 45 g. of unreacted 6-methoxy-8-aminoquinoline boiling at 175–185° (4 mm.). The crude Schiff base (85 g.) then distilled at 230–240° (4 mm.). Redistillation yielded 55 g. (35%) of orange oil boiling at 184–186° (0.4 mm.).

Anal. Calcd. for $C_{19}H_{27}ON_3$: C, 72.8; H, 8.7. Found: C, 72.8; H, 8.5.

6-Methoxy-8-(*p*-toluenesulfonylamido)-quinoline.—A mixture of 17.5 g. of 6-methoxy-8-aminoquinoline, 19 g. of *p*-toluenesulfonyl chloride and 100 ml. of 10% sodium hydroxide was shaken at room temperature until the acid chloride was all gone. The sulfonamide was recrystallized from isopropanol and melted at 133.5°.

Anal. Calcd. for $C_{17}H_{16}O_3N_2S$: C, 62.2; H, 4.9. Found: C, 62.0; H, 4.8.

6-Methoxy-8-(*p*-toluenesulfonylethylamido)-quinoline. To a stirred solution of 32.8 g. of the above tosyl compound in 350 ml. of absolute alcohol at 75–80° in a flask protected from atmospheric moisture was added a solution of 6.7 g. of potassium hydroxide in 150 ml. of absolute alcohol. After stirring the mixture for thirty minutes at 70–80° and then cooling, the crystalline potassium salt (90%) was filtered off and washed with absolute alcohol.

A stirred mixture of 18.3 g. of the above potassium salt, 8.3 g. of ethyl bromide (no reaction occurred when ethyl iodide was used) and 250 ml. of absolute alcohol was heated under reflux for twenty-four hours. After cooling the filtrate from the potassium bromide was evaporated to dryness. To the residue was added 250 ml. of 5% potassium hydroxide solution and this mixture was extracted with ether. After washing and drying the extract, evaporation of the ether left a yellow residue which was recrystallized from isopropanol or acetone. The substance melted at 125–126°.

Anal. Calcd. for $C_{19}H_{20}O_3NS$: C, 64.0; H, 5.7. Found: C, 64.0; H, 5.6.

6-Methoxy-8-ethylaminoquinoline.—A mixture of 1 g. of the above compound and 3 ml. of 96% sulfuric acid was heated with occasional stirring at 100° for ten minutes. After cooling and standing at room temperature for three hours, 20 ml. of 40% sodium hydroxide solution was added very cautiously. The mixture was extracted with benzene, yielding a yellow oil which gradually solidified. After recrystallization from *n*-heptane, the ethylaminoquinoline melted at 38–40°.

Anal. Calcd. for $C_{12}H_{14}ON_2$: C, 71.3; H, 7.0. Found: C, 71.0; H, 6.9.

Summary

1. Reductive amination of 1-diethylaminopentanone-4 with 6-methoxy-8-aminoquinoline with Raney nickel under various conditions leads to a mixture consisting of Plasmochin and 2-methyl-8-methoxy-5,6-dihydro-4-imidazo[ij]quinoline as principal components.
2. A study of the oxidative degradation of 2-methyl-8-methoxy-5,6-dihydro-4-imidazo[ij]quinoline has been made.
3. N,N-Diethylpropylamine and 6-methoxy-8-ethylaminoquinoline have been prepared.

The Reaction of *o*-Phenylenediamine and of 8-Amino-1,2,3,4-tetrahydroquinoline Derivatives with Carbonyl Compounds

BY ROBERT C. ELDERFIELD AND FRANK J. KREYSA

In the preceding paper[1] a study of the reductive amination of 1-diethylamino-pentanone-4 with 6-methoxy-8-aminoquinoline has been described. The major product of the reaction was 2-methyl-8-methoxy-5,6-dihydro-4-imidazo[ij]quinoline (I) and N,N-diethyl-*n*-propylamine was isolated from the products of the reaction. Since the formation of I obviously involves cleavage of a carbon–carbon bond under relatively mild conditions the reaction conditions under which imidazoles of the general type of I are formed from ketones have been the subject of further investigation.

As pointed out by Hazlewood, Hughes and Lions[2] 8-amino-1,2,3,4-tetrahydroquinoline (II) can be regarded as a mono-N-alkyl-*o*-phenylenediamine and the same authors prepared imidazoles of the type of I by the action of acids on II under mild dehydrating conditions. Formation of the imidazole ring in this fashion is easily understood and obviously proceeds by intramolecular elimination of water from an enolic form of an N-acyl derivative of II (III) in accordance with the observations of Phillips[3] on the behavior of *o*-phenylenediamine itself under similar conditions. Whether the acyl derivatives of II involve the ring nitrogen or that of the primary amino group is irrelevant and cannot be stated with certainty at this time. As far as we are aware only three cases of the formation of a 2-substituted benzimidazole

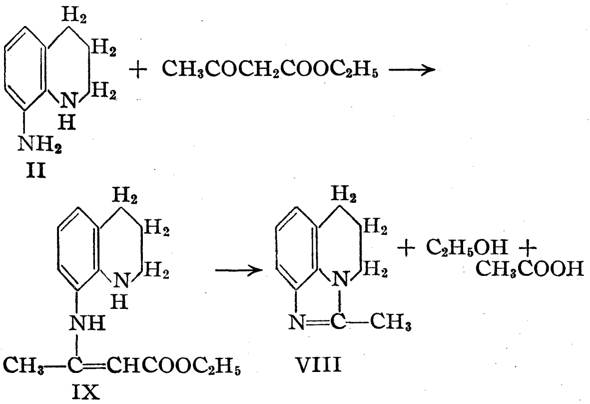
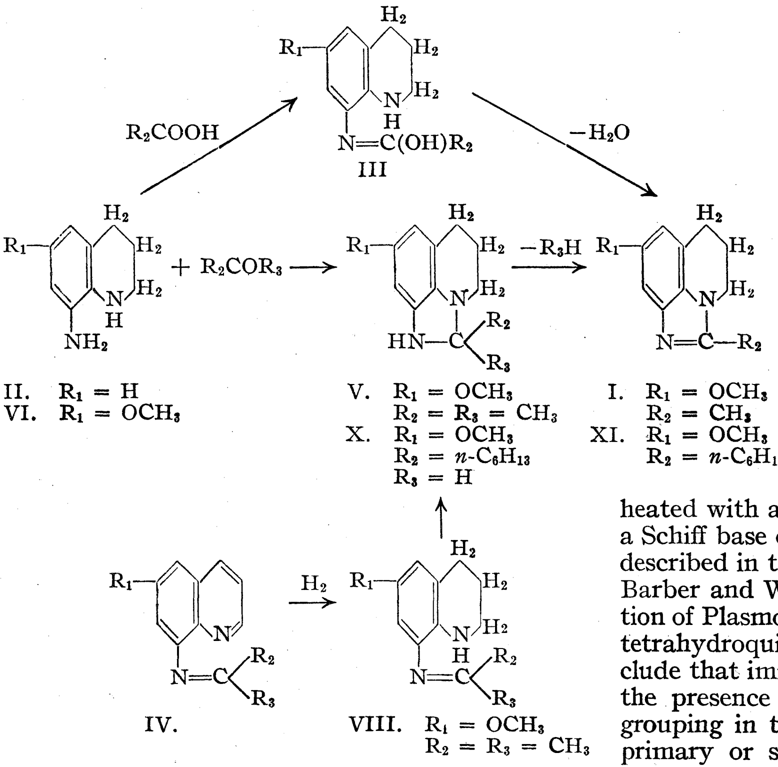
from the action of a ketone on *o*-phenylenediamine or its derivatives have been reported.[4] Hazlewood, Hughes and Lions[2] describe the formation of the imidazole, VIII, from II and ethyl acetoacetate and suggest the following sequence of reactions for the observed facts.





The formation of IX took place when a mixture of II and ethyl acetoacetate was allowed to stand at room temperature in the presence of a trace of hydrochloric acid and the crotonic ester, IX, on dropping into hot paraffin lost the elements of ethyl acetate to yield VIII. A similar reaction has been noted by Baxter and Spring,[5] who obtained 2-methylbenzimidazole instead of the expected 2-methyl-3-carbethoxyquinoxaline by merely warming *o*-phenylenediamine with ethyl α-chloroacetoacetate in alcoholic solution. Finally, Weil and Marcinkowska[6] describe the formation of 2-phenylbenzimidazole by heating *o*-phenylenediamine with dibenzoylphenylmethane in the presence of hydrochloric acid. Desoxybenzoin must have been eliminated at some stage of this reaction, although its isolation was not reported.

TABLE I

PRODUCTS FROM THE REACTION OF *o*-PHENYLENEDIAMINES WITH CARBONYL COMPOUNDS

Diamine	Carbonyl compd.	R_2 in the 2-position of the resulting imidazole
6-Methoxy-8-amino-tetrahydroquinoline	$CH_3CO(CH_2)_3N(C_2H_5)_2$	CH_3
	$CH_3COCH_2C_6H_5$	CH_3
	$CH_3CO(CH_2)_5CH_3$	CH_3
	$OCCH_2CH_2CH_2CH_2$	$CH_2CH_2CH_2CH_3$
	CH_3COCH_3	CH_3
	$n\text{-}C_6H_{13}CHO$	$n\text{-}C_6H_{13}$
o-Phenylenediamine	$CH_3COCH_2C_6H_5$	CH_3 and $CH_2C_6H_5$
	$CH_3CO(CH_2)_3N(C_2H_5)_2$	Product not isolated

Accordingly the action of representative simple ketones on 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline and on *o*-phenylenediamine has been investigated. The results are summarized in Table I. We suggest the sequence of reactions shown in formulas VI to I or IV to I as a tentative explanation for the observed results. Imidazole formation occurs when an 8-amino-1,2,3,4-tetrahydroquinoline is heated with a ketone (formulas VI to I), or where a Schiff base of an 8-aminoquinoline is reduced as described in the preceding paper (IV to I). Since Barber and Wragg[7] have shown that hydrogenation of Plasmochin yields an 8-alkylamino-1,2,3,4-tetrahydroquinoline and not an imidazole, we conclude that imidazole formation is contingent upon the presence in the molecule of an azomethine grouping in the proper spatial relationship to a primary or secondary amino group. This conclusion implies that on reduction of IV, the pyridine ring is saturated before any substantial reduction of the azomethine grouping has occurred.

Both reaction paths involve an intermediate for which we propose an imidazoline structure of the type of V. Barber and Wragg[7] have assigned structure V to the product arising from condensation of VI with acetone, and we have now shown that this condensation product does indeed give I

---

(4) An excellent review of the modes of formation of 2-substituted benzimidazoles is given by Wiedenhagen, *Ber.*, **69**, 2263 (1936).

(5) Baxter and Spring, *J. Chem. Soc.*, 229 (1945).

(6) Weil and Marcinkowska, *Roczniki Chem.*, **14**, 1312 (1934); *C. A.*, **29**, 6233 (1935).

(7) Barber and Wragg, *J. Chem. Soc.*, 610 (1946).

in good yield on heating at 250–300° for six hours. Structure V for the condensation product is confirmed by the close similarity of its ultraviolet absorption spectrum to that of VI. If the condensation product possessed the Schiff base structure, VII, the azomethine double bond in conjugation with the benzene ring should have caused a more profound change in absorption characteristics. Furthermore, the instability of the condensation product—alcoholic picric acid cleaves it to the picrate of VI–argues against the Schiff base structure.

The ready conversion of the imidazoline into the imidazole type is noteworthy. We assume that the gain in resonance stabilization[8] accompanying this aromatization provides the driving force for the direct elimination of the alkyl group and a hydrogen atom from the molecule. It is of interest that the benzothiazolines resulting from the reaction of *o*-aminothiophenol and aldehydes or ketones, are relatively stable.[9] The principle of molecular symmetry suggests that the benzothiazoles conceivably can possess a lower level of resonance stabilization than the imidazoles, which would account for the greater reported stability of the thiazolines.

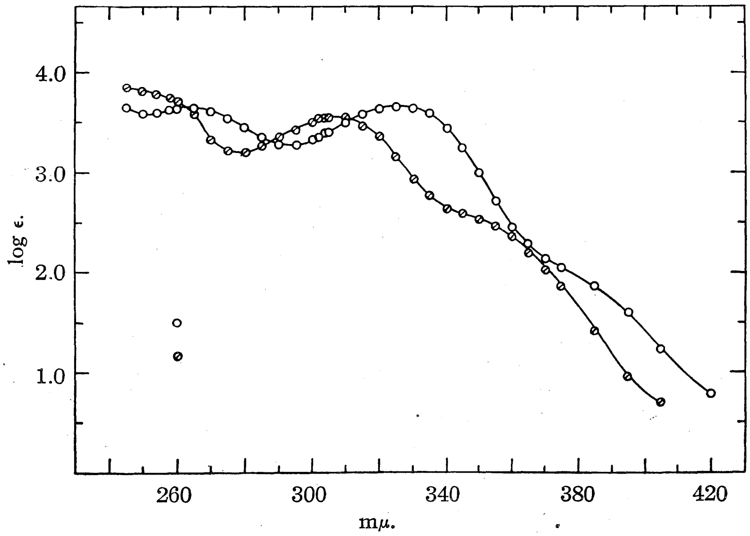


Fig. 1.—Ultraviolet absorption spectra: ○, 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline; ⊖, the imidazoline, V; solvent, cyclohexane.

The factor determining which of the two substituents in structure V is eliminated, in the formation of the benzimidazole ring, appears to be connected with the degree of substitution on one of the nitrogens of the *o*-phenylenediamine derivative entering into the reaction. Thus in all cases examined in which an N-alkyl-*o*-phenylenediamine, typified by a tetrahydroquinoline derivative (VI), was one of the reactants, the other being a methyl ketone, the only imidazole emerging was the 2-methyl derivative, I, although the results obtained with acetophenone were obscure in the sense that a poor yield of I was obtained. On the other hand, in the reaction of *o*-phenylenediamine with methyl benzyl ketone and, presumably, with 1-diethylaminopentanone-4, elimination of the methyl group of the ketone occurred to a major extent. While it would be attractive to generalize on this point, no such generalization can be more than suggested at this time pending the outcome of further experiments currently in progress in these laboratories.

We have also investigated the reaction of a typical aliphatic aldehyde, *n*-heptaldehyde, on 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline (VI) and find that hydrogen is eliminated from the proposed intermediate, X, as readily as is a hydrocarbon residue when a ketone is employed with the formation of XI. The use of aldehydes in the synthesis of benzimidazoles from *o*-phenylenediamine has been recorded in the literature. Hinsberg and Koller[10] and Weil and Marcinkowska[6] obtained 2-phenylbenzimidazole from the action of benzaldehyde on *o*-phenylenediamine. As far as we are aware the only instance whereby a 2-substituted imidazole carrying an alkyl substituent has been obtained by this general method using an aliphatic aldehyde as one reactant is that reported by Weidenhagen.[4] In this case cupric salts were added to the reaction mixture which raises the possibility that the aldehyde used might be oxidized to the corresponding acid prior to condensation with *o*-phenylenediamine. Production of imidazoles from acids is a well known reaction. In the present work, such oxidation of the aldehyde to the acid was avoided by working in an atmosphere of nitrogen, a fact which would appear to establish beyond doubt that the imidazole results from the intermediate imidazoline by direct expulsion of hydrogen.

Experimental[11,12]

6-Methoxy-8-amino-1,2,3,4-tetrahydroquinoline.—The preparation of this compound has been described by Price and Herbrandson[13] by the reduction of 6-methoxy-8-aminoquinoline with stannous chloride (62%) or catalytically with copper chromium oxide (78%) and by Barber and Wragg[7] by reduction of the corresponding quinoline derivative catalytically with Raney nickel in dioxane (80%). None of the above workers report a yield or analysis of the free amine, but rather converted it directly into a suitable salt, on which the yield was based, because of the instability of the free amine. In the present work,

we have avoided catalytic reduction with nickel in dioxane, because of the inherent danger involved, and have used the sodium and alcohol method first used in the reduction of 8-aminoquinoline by Hazlewood, Hughes and Lions.[2]

To a refluxing solution of 30 g. of 6-methoxy-8-aminoquinoline (m. p. 48.5–49.5°) in 750 ml. of absolute alcohol (distilled from sodium and diethyl phthalate) protected with a calcium chloride tube was added, with stirring, 60 g. of sodium during the course of ninety minutes. Refluxing and stirring was continued for an additional ninety minutes. The flask was then equipped with a condenser set downward and about 250 ml. of alcohol was distilled off. To the contents of the flask 400 ml. of cold water was added and the alkaline solution was extracted with four 100-ml. portions of benzene. The combined extracts were dried with anhydrous potassium carbonate and concentrated in an atmosphere of nitrogen to about 200 ml. The resulting solution was washed with three 20-ml. portions of water and dried with potassium carbonate. After removal of the solvent, the dark, viscous red oil was distilled in an atmosphere of nitrogen at 0.65 mm. pressure. The main fraction, boiling at 148–150°, amounted to 28 g. (90%), of pure 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline and slowly crystallized as plates which melted at 44–45°. Barber and Wragg[7] give the melting point as 43–45°.

Reaction of 6-Methoxy-8-amino-1,2,3,4-tetrahydroquinoline (VI) with 1-Diethylaminopentanone-4.—A mixture of 18 g. of freshly distilled VI and 31 g. of 1-diethylaminopentanone-4 was heated in a flask equipped with an inside thermometer and a condenser set downward for distillation through the contents of which a stream of dry nitrogen furnished agitation. At an inside temperature of 200° a colorless distillate appeared. The inside temperature was slowly raised during six hours to 265° at which point the heating was interrupted.

The distillate (15–20 g.) was redistilled in an atmosphere of nitrogen. The fraction boiling at 105–115° (5–6 g.) was collected, followed by a second fraction boiling at about 200° which consisted of unreacted 4-diethylamino-1-methylbutylamine. The lower boiling fractions, which separated into two layers, were taken up in 75 ml. of ether and dried over anhydrous potassium carbonate. After removal of the solvent, the main fraction was distilled twice, with drying over potassium hydroxide after the first distillation, yielding 4 g. of material boiling at 111–112°.

Anal. Calcd. for $C_7H_{17}N$: C, 73.0; H, 14.9. Found: C, 73.2; H, 15.1.

The amine was identified as N,N-diethyl-*n*-propylamine by mixed melting points of its hydrochloride and methiodide with authentic samples.[1]

The residue in the original reaction flask solidified on cooling. It was triturated with 50 ml. of cold ether and the insoluble portion was recrystallized from heptane. The product was identified as 2-methyl-8-methoxy-5,6-dihydro-4-imidazo[ij]quinoline by mixed melting point with an authentic sample.[1]

Reaction of 6-Methoxy-8-amino-1,2,3,4-tetrahydroquinoline with Octanone-2.—A mixture of 5 g. of the tetrahydroquinoline and 5 g. of octanone-2 (b. p. 173–174°) was heated in an atmosphere of nitrogen for three hours at 150–250°. The distillate was discarded and the residue in the reaction flask was distilled *in vacuo* under nitrogen, the fraction boiling at 170–175° (0.6 mm.) being collected. This crystallized in the receiver and was identified as the imidazole, I, as in the preceding cases.

Reaction of 6-Methoxy-8-amino-1,2,3,4-tetrahydroquinoline with Methyl Benzyl Ketone.—A mixture of 18 g. of the tetrahydroquinoline and 27 g. of methyl benzyl ketone [b. p. 75° (3 mm.)] was heated in a flask equipped with a thermometer and a condenser set downward in an atmosphere of nitrogen from 150 to 250° during six hours. At 150° water separated in the reaction mixture and the color changed from dark red to a light orange red. During the course of the reaction about 10 ml. of distillate was collected. This was taken up in 20 ml. of ether, dried over anhydrous magnesium sulfate and again distilled. The fraction boiling at 110–111° (3 g.) was identified as toluene by oxidation to benzoic acid with potassium permanganate.[14]

The orange-red residue in the reaction flask was seeded with a crystal of the imidazole, I, and after refrigeration it crystallized for the most part. The crystalline material was isolated and identified as the imidazole, I, as previously described.

Thermal Decomposition of 2,2-Dimethyl-8-methoxy-1,2,5,6-tetrahydro-4-imidazo[ij]quinoline.—This compound was prepared according to Barber and Wragg,[7] whose results were duplicated. Although the substance melts at approximately the same temperature as the imidazole, I, it differs from the imidazole in its easy decomposition to 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline when warmed with an alcoholic solution of picric acid. The mixed melting point of the two substances is likewise depressed. The British authors report the m. p. of the picrate of the latter substance as 163–164°, whereas Price and Herbrandson[13] give 151.5–152°. This discrepancy has now been found to be due to the rate of heating. On rapid heating of the capillary, the m. p. of 163–164° is observed, whereas on slow heating (several minutes per degree) the decomposition point of 150–152° is observed.

When the acetone condensation product of the tetrahydroquinoline was heated at 250–300° for six hours in a stream of nitrogen, the residue, on distillation at 0.6 mm. yielded 78% of the imidazole, I, which was identified as in the preceding cases.

Reaction of 6-Methoxy-8-amino-1,2,3,4-tetrahydroquinoline with Cyclopentanone.—A mixture of 9 g. of the tetrahydroquinoline and 8.5 g. of cyclopentanone (b. p. 129–130°) was heated under nitrogen in a sealed tube for twenty-four hours at 265°. The black mixture was distilled *in vacuo* under nitrogen and a main fraction of 4 g. boiling at 210–220° (1.5 mm.) was collected. To the solution of this in hot absolute alcohol, 250 ml. of an alcoholic solution of picric acid was added. The yellow needles were recrystallized from alcohol and melted at 171.5–173°.

The picrate was then decomposed with warm potassium hydroxide solution and the liberated imidazole was extracted with ether and benzene. The free imidazole obtained on evaporation of the combined extracts was recrystallized first from ether and then from pentane and formed needles which melted at 60–61°.

Both the 2-*n*-butyl-8-methoxy-5,6-dihydro-4-imidazo-[ij]quinoline and its picrate obtained above were identified by mixed melting points with samples of the same substance prepared according to the general method of Hazlewood, Hughes and Lions[2] as follows.

A mixture of 1 g. of 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline and 5 ml. of *n*-valeric acid was refluxed in an atmosphere of nitrogen for two hours, after which 25 ml. of water and 25 ml. of ammonium hydroxide (d. 0.9) was added to the red mixture. The ammoniacal mixture was extracted with benzene. The crude imidazole from the extracts was purified by sublimation at 150–175° (0.3 mm.) and then was recrystallized twice from pentane. It melted at 60–61°.

Anal. Calcd. for $C_{15}H_{20}ON_2$: C, 73.7; H, 8.2. Found: C, 73.5; H, 8.0.

The picrate melted at 172–173° after crystallization from absolute alcohol.

Anal. Calcd. for $C_{21}H_{23}O_8N_5$: C, 53.3; H, 4.9. Found: C, 53.4; H, 4.8.

Reaction of 6-Methoxy-8-amino-1,2,3,4-tetrahydroquinoline with Acetophenone.—A mixture of 10 g. of 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline and 24 g. of acetophenone was heated in a distilling flask in an atmosphere of nitrogen for seven hours during which the temperature was raised from 150 to 265°. From the distillate from this reaction no benzene could be isolated. The reaction mixture was fractionally distilled under re-

---

(14) Shriner and Fuson, "The Systematic Identification of Organic Compounds," 2nd ed., John Wiley and Sons, Inc., New York, N. Y., 1940, p. 164.

duced pressure in an atmosphere of nitrogen. Unreacted acetophenone came over at 60–70° (3 mm.) followed by a fraction, a heavy red oil, (4 g.) boiling at 210–225° (1.5–2 mm.). A third fraction (4 g.) boiling at 225–250° (1.5–2 mm.) was a heavy red tar. The second fraction was dissolved in alcohol and treated with a saturated alcoholic solution of picric acid. The red picrate was recrystallized from boiling dioxane, washed with benzene and decomposed with 50% potassium hydroxide solution. The alkaline solution was extracted with benzene and the extract, after drying yielded a semi-solid which was sublimed at 185–235° (0.2 mm.). The sublimate was recrystallized from heptane and again converted to the picrate (0.1 g.). The picrate melted at 248–253° and did not depress the melting point of a known sample of the picrate of the imidazole, I.

Condensation of *n*-Heptaldehyde with 6-Methoxy-8-amino-1,2,3,4-tetrahydroquinoline.—A mixture of 18 g. of 6-methoxy-8-amino-1,2,3,4-tetrahydroquinoline and 23 g. of pure *n*-heptaldehyde was heated in an atmosphere of nitrogen at 150–250° for eight hours. The residue was distilled under reduced pressure, a main fraction (22 g.) boiling at 180–220° (0.3 mm.) being collected. After redistillation, the fraction boiling at 190–210° (0.35 mm.) (19 g.) consisting of a viscous yellow oil was treated with a saturated absolute alcoholic solution of an equal weight of picric acid. The yellow needles of the imidazole picrate were recrystallized from alcohol yielding 20 g. of material melting at 127°.

Anal. Calcd. for $C_{23}H_{27}O_8N_5$: C, 55.1; H, 5.4. Found: C, 55.1; H, 5.4.

The picrate was decomposed with 50% potassium hydroxide as before and the *n*-hexylimidazole derivative crystallized on refrigerating. It melted at 27°. The free base was very hygroscopic which prevented securing satisfactory analytical data. Both the above imidazole and its picrate were identified by mixed melting point with an authentic sample prepared from I and oenanthic acid.

Reaction of *o*-Phenylenediamine with Methylbenzyl Ketone.—A mixture of 10.8 g. of *o*-phenylenediamine and 27 g. of methyl benzyl ketone was heated in an atmosphere of nitrogen in a distilling flask at 200–250°. The distillate was dried over anhydrous magnesium sulfate and redistilled yielding a fraction (1.5 g.) boiling at 110–111° which was identified as toluene by oxidation to benzoic acid. The residue in the distilling flask was poured out while still molten and, after cooling, was rubbed up under ether. The ether insoluble portion was repeatedly recrystallized from 60% methanol–water yielding 8 g. of 2 benzylbenzimidazole melting at 186.5–187.5°. The picrate melted at 214–215° (dec.). Both substances were identified by mixed melting point with an authentic sample synthesized for the purpose. 2-Benzylbenzimidazole is reported as melting at 187° and its picrate at 214°.[15]

From the combined mother liquors of the above 2-benzylbenzimidazole about 1 g. of 2-methylbenzimidazole was obtained by taking advantage of the ready solubility of the latter as compared to the benzyl derivative in hot water. The methyl derivative melted at 175–176° after final recrystallization from benzene and was identified by mixed melting point with an authentic sample. It is reported as melting at 176° by Phillips[3] among other workers.

Reaction of *o*-Phenylenediamine with 1-Diethylaminopentanone-4.—When the reaction was carried out as in the preceding case, no 2-methylbenzimidazole could be isolated from the reaction mixture. On attempted distillation substantially complete decomposition occurred. The reaction was not investigated further.

Summary

1. Direct heating of *o*-phenylenediamine and a mono-N-alkyl derivative with representative aldehydes and ketones leads to 2-substituted benzimidazoles by elimination of one of the atoms or radicals of the carbonyl compound from the intermediate imidazoline.

2. A mechanism for the reaction is suggested.

The Preparation and Rearrangements of 1,2-Dimethylaminochloropropanes

BY EVERETT M. SCHULTZ AND JAMES M. SPRAGUE

Recent work has shown that the chloroamine obtained from 1-dimethylamino-2-propanol reacts with diphenylacetonitrile in the presence of basic condensing agents to yield two isomeric nitriles, I and II.[1] The structures of these nitriles showed that a rearrangement had occurred, otherwise only the nitrile I should have resulted. In view of recent work dealing with the chemistry of chloroethylamines,[2] it seemed probable that, under the influence of the basic condensing agents, the chloroamine gave rise to an ethylenimonium ion which led to the isomeric nitriles on further reaction with diphenylacetonitrile. However, the possibility that the rearrangement occurred during the conversion of the aminoalcohol to the chloroamine was not excluded. More recently, Brode and Hill[3] have raised the question of the identity of the chloroamine employed in this reaction. These investigators failed to obtain different and distinct isomeric chloroamine bases from the treatment of 1-dimethylamino-2-propanol and 2-dimethylamino-1-propanol with thionyl chloride although apparently two distinct hydrochlorides were obtained. They conclude that the chloroamines rearranged, under the conditions used to isolate the bases from their salts,

[1] Schultz, Robb and Sprague, THIS JOURNAL, **69**, 188 (1947); **69**, 2454 (1947).

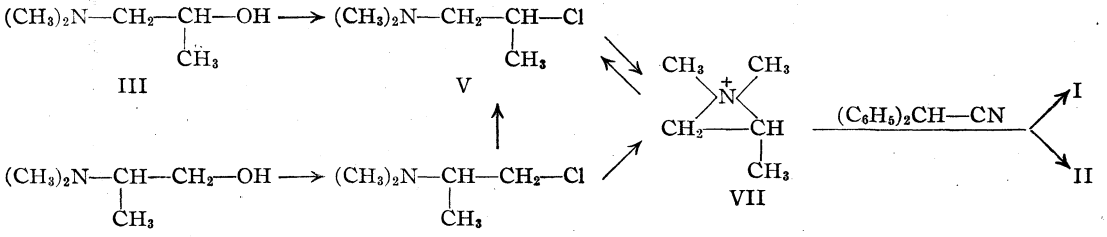
[2] Golumbic, Fruton, Bergmann, *et al.*, *J. Org. Chem.*, **11**, 518–591 (1947).

[3] Brode and Hill, THIS JOURNAL, **69**, 724 (1947).

to yield the same product and suggest that this product may be either of the two isomeric chloroamines or an equilibrium mixture of the two.

The results of work in this Laboratory are not in agreement with the observations and conclusions of Brode and Hill. It has been possible to prepare both of the isomeric chloroamines from the respective aminoalcohols and to show that 2-dimethylamino-1-chloropropane is rearranged by heat into 1-dimethylamino-2-chloropropane, whereas the latter is thermally stable and that both chloroamines give rise to the same mixture of aminonitriles on reaction with diphenylacetonitrile.

1-Dimethylamino-2-propanol (III) was converted by the action of thionyl chloride into a chloroamine hydrochloride, m. p. 185–186°, that is relatively insoluble in chloroform. The chloroamine base (V) obtained from this hydrochloride was characterized both before and after distillation by conversion to the picrate, hydrochloride and methiodide. The properties of these derivatives and of the picrate prepared directly from the original hydrochloride indicated that no rearrangement had occurred either during the liberation of the chloroamine from the hydrochloride or during the distillation. The action of thionyl chloride on the isomeric alcohol IV, or its hydrochloride, gave a chloroamine hydrochloride, m. p. 104°, that is very soluble in chloroform. The properties of the picrate prepared from this hydrochloride or from the undistilled chloroamine as well as the properties of the methiodide of the undistilled base showed this chloroamine to be different from V. After distillation, however, it was identical with V as shown by a comparison of the hydrochloride, picrate and methiodide. Furthermore, the hydrochloride, m. p. 104°, on heating rearranged into the isomer, m. p. 185–186°.

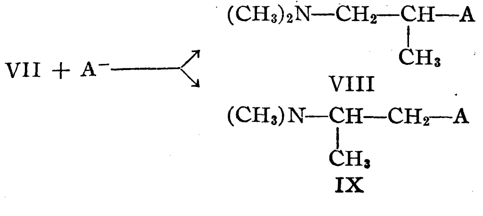


Although no irrefutable evidence is available concerning the structure of these isomeric chloroamines, it seems improbable that a rearrangement also occurred during the treatment of both of the isomeric dimethylaminopropanols with thionyl chloride or during the isolation of the resulting chloroamine hydrochlorides. Therefore, it must be concluded that 1-dimethylamino-2-chloropropane (V) and 2-dimethylamino-1-chloropropane (VI) are obtained from the respective alcohols, III and IV, and, furthermore, that VI, either as the hydrochloride or the free base, rearranges on heating to the more stable isomer, V.

Although a number of runs with IV, as well as its hydrochloride, yielded the hydrochloride of VI, m. p. 104°, one run gave only the hydrochloride of V, m. p. 185–186°. It is evident that some undetermined condition was responsible for the rearrangement in this experiment. When the chloroamine hydrochloride, m. p. 104°, was subjected to conditions comparable to the thionyl chloride reaction, it was recovered unchanged. It seems likely that the results of Brode and Hill may be similar to this anomalous experiment in our series.

In the earlier work, the stable chloroamine, V, was employed in the condensation with diphenylacetonitrile.[1] Therefore, it seems probable that the unexpected nitrile II arose through the intermediate formation of the ethylenimonium ion VII under the influence of the strong alkaline condensing agents. However, the expected nitrile I could arise either directly by replacement of the chlorine of V, or indirectly by the opening of the cyclic imonium ion in a manner opposite to that resulting in nitrile II. Under the conditions of this reaction, VI should yield the same imonium ion VII either directly or by first rearranging to V. In either event this chloroamine would give rise to the same mixture of nitriles on condensation with diphenylacetonitrile. This was found to be the case. The hydrochloride of VI was converted to the base at a low temperature. The dried undistilled base, VI, was condensed with diphenylacetonitrile to yield a mixture of equal amounts of the two isomeric nitriles, I and II.

All of the foregoing results suggest that the rearrangement of 2-dimethylamino-1-chloropropane (VI) into its isomer (V) as well as the reaction of either chloroamine, V or VI, with diphenylacetonitrile proceeds through the cyclic ion VII. The behavior of VII is governed, no doubt, by steric as well as polar factors, both within the cyclic ion and in the anion (A^-) with which it reacts. The rearrangement which involves the reaction of the ethylenimonium ion with a chloride ion leads predominately, if not exclusively, to structure VIII



(A = Cl). However, the reaction of VII with the relatively large anion of diphenylacetonitrile results in virtually equal amounts of the two possible isomers VIII and IX (*cf.* I and II).

Experimental[4,5]

1-Dimethylamino-2-propanol (III) was prepared in two ways: (A) from 1-chloro-2-propanol and dimethylamine in aqueous alkali by the German procedure[6] and (B) by the methylation of 1-amino-2-propanol with formaldehyde and formic acid by the method of Clarke, Gillespie and Weisshaus.[7] The physical constants were: b. p. 120–125°, d^{26}_{26} 0.855, n^{20}_D 1.4210, n^{26}_D 1.4182; molecular refraction: calcd., 30.75; found, 30.37.

The **methiodide** was prepared in ether; m. p. 153–154° after recrystallization from isopropyl alcohol.

Anal. Calcd. for $C_6H_{16}INO$: N, 5.75. Found: N, 5.68.

1-Dimethylamino-2-chloropropane Hydrochloride. A. In Chloroform.—Dry chloroform (200 ml.) and purified thionyl chloride (68 g., 0.58 mole) were placed in a round-bottomed flask equipped with a stirrer, reflux condenser and dropping funnel. The flask was placed in an ice-bath and 1-dimethylamino-2-propanol (50 g., 0.49 mole) added to the cooled, stirred mixture over a period of one hour. Near the end of the addition, the reaction mixture became semisolid due to the separation of a white precipitate. The mixture then was heated to gentle boiling whereupon the white solid dissolved gradually. After boiling for one-half hour, the whole reaction mixture solidified suddenly. The mixture was cooled at once, the solid collected by filtration and recrystallized from isopropyl alcohol. The product was washed with ether and dried in air at about 60°; yield 47 g. (61.5%) m. p. 185–186°.

B. In Benzene.—The German procedure[6] was followed. From 75 g. (0.56 mole) of thionyl chloride and 50 g. (0.48 mole) of III in 190 ml. of dry benzene there was obtained 51.5 g. (67.5%) of pure white needles, m. p. 185–186° after crystallization from chloroform (Norit) and then from isopropyl alcohol.

This salt is quite soluble in isopropyl alcohol, sparingly soluble in acetone and dissolves in chloroform to the extent of about one gram in 40 ml. at 26°. It is only slightly hygroscopic and sublimes readily without change at temperatures below its melting point.

Anal. Calcd. for $C_5H_{12}NCl{\cdot}HCl$: N, 8.85. Found: N, 8.87.

The **picrate** was prepared from the hydrochloride in water solution. After crystallization from benzene and from water, it melted at 101–103°.

1-Dimethylamino-2-chloropropane (V).—The hydrochloride (30 g.) was dissolved in 40–50 ml. of water and made strongly basic with 20% sodium hydroxide. The chloroamine layer was separated, dried over solid potassium hydroxide and distilled, b. p. 62–63° (100–110 mm.); yield, 19 g., n^{20}_D 1.4250. The recorded boiling point[6] is 60° (110 mm.). On addition of this chloroamine to an acidified solution of silver nitrate, no silver chloride precipitated even after several days at room temperature. Precipitation was rapid when the solution was heated.

The distilled base (2.7 g.) in ether was converted to the **hydrochloride**, (3.35 g., m. p. 181–183°). After crystallization from isopropyl alcohol and from chloroform, it melted at 185–186° (1.6 g.).

Anal. Calcd. for $C_5H_{12}NCl{\cdot}HCl$: C, 37.97; H, 8.24; N, 8.85; Cl (ionic), 22.47. Found: C, 38.0; H, 8.34; N, 8.87; Cl (ionic), 22.45.

The distilled base (2 g.) in chloroform was converted to its hydrochloride, m. p. 185–186°, yield 2.28 g., 97%, after correcting for the solubility in chloroform. Therefore, little, if any, of the isomer, VI, was present since its hydrochloride is very soluble in chloroform, 1 g./2 ml.

The **picrate** was prepared from the distilled base in ether. The melting point was 101–103° and was not changed by crystallization from benzene. The picrate was prepared from the undistilled base as follows: 1-dimethylamino-2-chloropropane hydrochloride (1.0 g.) (m. p. 185–186°) was taken up in a little water, the solution chilled to 0° in an ice-bath and made basic with 20% sodium hydroxide. The oil was removed and the picrate was prepared in alcohol; yellow needles, m. p. 101–103°, 0.84 g. The picrate is very soluble in alcohol and hot water but less soluble in benzene. Crystallization from alcohol or benzene did not change the melting point.

Anal. Calcd. for $C_{11}H_{15}ClN_4O_7$: C, 37.66; H, 4.31; N, 15.97. Found: C, 37.7; H, 4.28; N, 16.00.

The **methiodide** of V was prepared from the undistilled base in the following manner: the hydrochloride was dissolved in water and the cold solution made basic with 20% sodium hydroxide solution. The organic material was taken up in ether and dried over anhydrous sodium sulfate. An excess of methyl iodide was added to the ether solution. After a few hours at room temperature, a white precipitate separated, m. p. 180–181°. After crystallizing once from absolute alcohol and three times from acetone, the rectangular prisms melted at 184–185°. (The melting point depends upon the manner in which it is taken but did not change between the last two crystallizations.) This methiodide was prepared also from the distilled base in ether solution. After crystallization from acetone, it melted at 185–186° with decomposition and a mixed melting point with the previous sample showed no depression.

Anal. Calcd. for $C_6H_{15}ClIN$: C, 27.34; H, 5.73; N, 5.32. Found: C, 27.25; H, 5.76; N, 5.31.

2-Dimethylamino-1-hydroxypropane (IV) was prepared from ethyl α-dimethylaminopropionate[8] by reduction with sodium according to the method of Stoll[9] and also from the reductive methylation[7] of 2-amino-1-propanol that was obtained by the reduction of 2-nitro-1-propanol according to the method of Gakenheimer and Hartung[10]: b. p. 145–148° (765 mm.), n^{20}_D 1.4365, d^{26}_{26} 0.889, molecular refraction, calcd., 30.75; found, 30.16.

The **methiodide** was prepared in absolute alcohol and precipitated with ether,[11] m. p. 293°. The melting point depends upon the rate of heating.

2-Dimethylamino-1-chloropropane Hydrochloride. A. In Benzene.—Dry benzene (200 ml.) and thionyl chloride (63 g., 0.53 mole), were placed in a round-bottomed flask fitted with a reflux condenser, a dropping funnel and a mechanical stirrer. The flask was cooled in an ice-bath and 2-dimethylamino-1-propanol (46 g., 0.448 mole) in dry benzene (100 ml.) was added to the vigorously stirred mixture during a period of thirty minutes. A gummy yellow precipitate formed. The flask was allowed to warm to room temperature and then placed in a water-bath that was heated slowly to 60°. At 60–70° sulfur dioxide was evolved. After heating at 60–70° for one hour, the mixture was refluxed for two hours. During the heating, the original yellow precipitate was converted to a black tarry oil. Upon allowing the reaction mixture to cool, the oil solidified. The solid was collected by filtration and dried *in vacuo* over solid potassium hydroxide and concentrated sulfuric acid. The dark-brown product was taken up in 300 ml. of boiling acetone, the solution filtered and decolorized with charcoal. Upon cooling, pure white crystals separated, 29 g. (41%), m. p. 103–104°. Further recrystallization from acetone did not change the melting point. When the temperature was raised slowly above 104°, the

[11] Karrer, *et al.*, *Helv. Chim. Acta*, **5**, 477 (1922), reports m. p. 296°.

melt resolidified at 140–150° and then remelted with decomposition at 175–177°. This hydrochloride is exceedingly hygroscopic and it is difficult to obtain a reproducible melting point.

Anal. Calcd. for $C_5H_{12}NCl \cdot HCl$: N, 8.85; Cl, 44.86; Cl (ionic), 22.47. Found: N, 8.90; Cl, 44.35; Cl (ionic), 22.77.

The above salt (0.5 g.) m. p. 104° was sublimed at a pressure of 18 mm. and a bath temperature of 150°. The compound first melted and then resolidified. Sublimation was rapid. The sublimate melted at 185–186° after one crystallization from isopropyl alcohol. A mixed melting point with the chloroamine hydrochloride prepared from 1-dimethylamino-2-propanol showed no depression.

The **picrate** was prepared from the hydrochloride (m. p. 103–104°) in a cold aqueous solution. The solid that separated melted at 153°. After one crystallization from alcohol, it melted at 166–167°, and further recrystallization did not change the melting point.

B. In Chloroform.—Dry chloroform (200 ml.) and purified thionyl chloride (68 g., 0.575 mole) were placed in the apparatus described in A. The flask was placed in an ice-bath and 2-dimethylamino-1-propanol (50 g., 0.485 mole) in chloroform (100 ml.) was added with stirring during one-half hour. A clear, amber, homogeneous solution resulted. The solution was boiled for two and one-half hours. No solid appeared at any time. The reaction mixture was divided into two equal parts.

(a) To the clear solution 500 ml. of dry benzene and 200 ml. of absolute ether were added. A white solid, 36 g., m. p. 98–100°, separated. After crystallization from acetone, using decolorizing charcoal, the product melted at 102–104° (29 g.). The picrate prepared from the hydrochloride melted at 166–167° after purification.

(b) The chloroform was distilled by heating on a steam-bath leaving a dark oil that solidified on cooling. Trituration of the residue with dry benzene gave a tan solid (30 g.) m. p. 95°. After purification as described in a, the product (20 g.) was identical with that obtained in **a**. Total yield from **a** and **b** was 49 g. (64%).

In one run, chlorination of 2-dimethylamino-1-propanol (50 g.) with thionyl chloride (68 g.) in chloroform (300 ml.) gave an anomalous result. The isolation was carried out as in **b**. No difference was observed during the reaction. Upon distillation of the chloroform, the hot mixture solidified when the volume became small. The product (54 g.) melted at 180° and, after crystallization from isopropyl alcohol, using decolorizing charcoal, a pure white product was obtained, 37 g. (52%), m. p. 185–186°. The picrate prepared from the hydrochloride melted at 101–103°. The mother liquors from the reaction mixture and recrystallization were evaporated. The only substances obtained were tar and about 5 g. of hydrochloride melting at 178–180°.

C. In sym-Tetrachloroethane.—2-Dimethylamino-1-propanol (25 g.) was added slowly to *sym*-tetrachloroethane (50 ml.) at 80°. At this temperature the amino-alcohol reacted with the tetrachloroethane to yield the hydrochloride and trichloroethylene. The flask then was placed in an ice-bath and thionyl chloride (34 g.) in *sym*-tetrachloroethane (100 ml.) was added during a period of fifteen minutes. The mixture then was heated to boiling for two hours. The solvent was removed by vacuum distillation and the residual dark sirup solidified on adding dry benzene. After one crystallization from acetone, 26.6 g. (69.5%) of product, m.p. 102–103°, was obtained.

2-Dimethylamino-1-chloropropane (VI).—The picrate and methiodide were prepared from this chloroamine immediately after liberation from the hydrochloride as follows:

A. Picrate.—The hydrochloride (1 g.) was taken up in water (5–6 ml.). The solution was cooled in an ice-bath and made basic by addition of 20% sodium hydroxide. The oil that separated was removed and added to 3 ml. of ethanol. To the resulting solution was added 20 ml. of saturated ethanolic picric acid solution. After the mixture had stood at room temperature for four hours, the product was removed by filtration; yield, 1.1 g., m. p., 162–163°. After one crystallization from alcohol, the m. p. was 166–167° and was not changed by subsequent recrystallizations.

Anal. Calcd. for $C_{11}H_{15}ClN_4O_7$: C, 37.66; H, 4.31; N, 15.97. Found: C, 37.90; H, 4.27; N, 15.89.

B. Methiodide.—The hydrochloride (1 g.) was taken up in 5–6 ml. of water. The solution was cooled in ice and made basic with 20% sodium hydroxide solution. The oil that separated was removed, taken up in ether and the solution dried over anhydrous magnesium sulfate at 0–5°. To the dried solution was added 2 ml. of methyl iodide. After standing at 25–30° for sixteen hours, the white precipitate (1.1 g.) was collected by filtration. It decomposed at 190–191°, with evolution of gas, after extensive darkening at about 170°. The melting behavior was not changed by four crystallizations from absolute alcohol. A mixture with an equal amount of its isomer (m. p. 185–186°) melted at 181–184°.

Anal. Calcd. for $C_6H_{15}ClIN$: C, 27.34; H, 5.73; N, 5.32. Found: C, 27.27; H, 5.63; N, 5.23.

Distillation of 2-Dimethylamino-1-chloropropane (VI).—The hydrochloride (20 g.) was converted to the base and distilled in the manner described for V, b. p. 64–67° (97–100 mm.), $n^{20}D$ 1.4252. The yield of distilled free base was about 10 g. There was some mechanical loss in drying and a few ml. of high boiling, sirupy residue remained in the distilling flask. This chloroamine base, before or after distillation, did not give an immediate precipitate with acidified silver nitrate solution. After long standing or upon heating silver chloride formed.

The **hydrochloride** was prepared from the distilled base (2 ml.) in ether (2.1 g., m. p. 173–175°). After recrystallization from isopropyl alcohol, it melted at 186–187°. The **picrate** of the distilled base (0.8 ml.) was prepared in ether; yield, 1.0 g., m. p. 96–99°. After crystallization from water and from benzene it melted at 101–103°. The **methiodide** was prepared from 0.8 ml. of the distilled base and 3 ml. of methyl iodide in ether solution; yield 1.17 g., m. p. 172°. After crystallization from absolute alcohol and from acetone, the m. p. was 185–186°.

As shown by melting points and mixed melting points, all three derivatives, the hydrochloride, the picrate and the methiodide, of the distilled base were different from the derivatives that were prepared before distillation and were identical with the derivatives of 1-dimethylamino-2-chloropropane, V.

Reaction of 2-Dimethylamino-1-chloropropane with Diphenylacetonitrile.—In a 500-ml. flask equipped with a sealed stirrer, a gas inlet tube and air condenser, potassium metal (4 g., 0.1 mole) was dissolved in hot *t*-butyl alcohol (135 ml.) under an atmosphere of nitrogen. Diphenylacetonitrile (19.3 g., 0.1 mole) was added to the hot solution. The mixture was heated to boiling and undistilled 2-dimethylamino-1-chloropropane (15 g., 0.124 mole) in xylene (12 ml.) was added during a period of twenty-five minutes. After boiling for six hours, the alcohol was distilled and water and ether were added to the residue. The basic substances were extracted from the ether layer with dilute hydrochloric acid. The acid solution was made basic with dilute sodium hydroxide solution and the semisolid organic material was taken up in ether. The ether solution was washed with water, dried over anhydrous sodium sulfate and the ether evaporated. The semisolid residue was triturated with hexane (35 ml.) and cooled in an ice-bath. White crystals of 2,2-diphenyl-4-dimethylaminopentanenitrile were obtained by filtration. After crystallization from benzine, the product was obtained as long needles, m. p. 90–91° (11.05 g., 40%). The evaporation of the hexane filtrate yielded a thick oil that was distilled, b. p. 165° (1–2 mm.). The distillate soon solidified, and was identified as 2,2-diphenyl-3-methyl-4-dimethylaminobutanenitrile by means of its picrate,[1] m. p. 204–205°.

The chloroamine used in this preparation was obtained from 2-dimethylamino-1-chloropropane hydrochloride, m. p. 103–104°. The salt (45 g.) was dissolved in water (20–30 ml.) and, while cooling in an ice-bath, the solution was made basic with 20% sodium hydroxide solution. The base was taken up in ether and the solution was dried over anhydrous magnesium sulfate. The solvent was removed by vacuum distillation at 30–35°. Immediately before using the residual oil in the condensation reaction, a sample was withdrawn and converted to the picrate, (m. p. 158–160°). After crystallization from alcohol, the melting point was 166–167°. Therefore, the chloroamine added to the reaction was 2-dimethylamino-1-chloropropane.

Summary

1-Dimethylamino-2-chloropropane and 2-dimethylamino-1-chloropropane were prepared from the corresponding dimethylaminopropanols by the action of thionyl chloride.

2-Dimethylamino-1-chloropropane, either as the free base or as the hydrochloride, rearranges on heating into 1-dimethylamino-2-chloropropane which is thermally stable.

Both chloroamines reacted with diphenylacetonitrile to give the same mixture of isomeric aminonitriles.

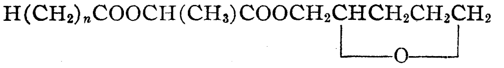
n-Alkanoyl Derivatives of *n*-Butyl and Tetrahydrofurfuryl Lactates

By M. L. Fein and C. H. Fisher

Several alkyl lactates have been acylated[2] with the lower acid anhydrides and chlorides, but little is known about acylated lactic esters of relatively high molecular weight. The present paper describes several homologous acyl derivatives (I and II, *n*-1, 2, 3, 6, 8 and 11) of *n*-butyl lactate and tetrahydrofurfuryl lactate, prepared in high yields by treating the corresponding lactic esters with various aliphatic acid chlorides or anhydrides.

$$H(CH_2)_nCOOCH(CH_3)COO(CH_2)_4H$$

I



$$H(CH_2)_nCOOCH(CH_3)COOCH_2\underbrace{CHCH_2CH_2CH_2}_{O}$$

II

The *n*-alkanoyl derivatives (I and II) were purified carefully by fractional distillation. The resulting colorless liquids were used in the determination of density (*d*), refractive index (*n*), viscosity (η), and boiling points (T) under different pressures. These physical properties of the two homologous series (I and II) were related to the number of carbon atoms, *x* (or molecular weight) by plotting certain functions of the physical properties (x/d, x/n, log η, and T^2) against *x*. The resulting straight line relationships are useful in estimating properties of other homologous members of I and II by interpolation and extrapolation, comparing the properties of I and II with those of other homologous series, and correlating x/d, x/n, log η and T^2 with one another (within a homologous series, *i.e.*, I or II).

Experimental

Materials.—Redistilled *n*-butyl lactate (b.r. 79–80° at 12.4 mm.) from a commercial source and tetrahydrofurfuryl lactate[3] (b.p. 92° at 1 mm.) prepared by alcoholysis of methyl lactate were used. Commercial grades of acetic, propionic, and butyric anhydrides and pelargonyl chloride were used; the *n*-heptanoyl and *n*-dodecanoyl chlorides were Eastman Kodak Co. White Label grade.

Acylation: Acid Anhydrides.—The previously described[2b] method was used to acylate the lactic esters.

Acid Chlorides.—The acid chloride (1 mole per mole of lactic ester) was added slowly with stirring to a mixture of the lactic ester, reagent-grade pyridine (10% excess), and benzene (100 ml. per mole of lactic ester) contained in a 3-necked flask fitted with a condenser, mechanical stirrer, and glass-stoppered funnel. In most instances, the temperature of the reaction mixture was kept at 10 to 20° by external cooling. Cooling is recommended, although it was omitted in some experiments (temperature rose to 80°). When the reaction was complete (shortly after the addition of all the acid chloride), a small quantity of water was added to dissolve the pyridine hydrochloride. The oil layer was separated and washed in succession with dilute hydrochloric acid, saturated brine, and dilute sodium bicarbonate. In some instances, water was removed by drying over anhydrous sulfate; in others this treatment was omitted, and the water was distilled azeotropically with the benzene already present. The low- and high-boiling materials were then distilled under reduced pressures with a water aspirator and oil pump, respectively. Vigreux columns approximately 50 cm. high were used for most of the distillations. Yields and properties of the products are given in Tables I and II.

Determination of Physical Constants.—The boiling points used for the construction of Fig. 1 were determined, as in a previous study,[4] by carefully distilling narrow-boiling fractions either through a 60-cm. Vigreux column or with an alembic flask[5]; pressures were read from a Dubrovin gage.[6] When the same equipment and technique were used to determine boiling points of butyl phthalate at several pressures between 2 and 10 mm., data agreeing with those of Hickman[7] were obtained. The boiling points of the acylated lactic esters (I and II) were plotted on a Cox chart[8]; boiling points at 10 mm. were taken from the chart (Fig. 1).

Refractive indices and specific gravities (Table I) were determined with an Abbe type refractometer and a 10-ml.

[a] A.S.T.M. procedure using modified Ostwald tubes. [b] Souders' viscosity function, I (M. Souders, Jr., THIS JOURNAL, 60, 154 (1938); A. N. Planovskii and V. V. Kafarov, *Khimicheskaya Prom.*, No. 8, 19 (1944)(*C.A.*, 40, 2048 (1946))). [c] According to R. T. Lagemann (THIS JOURNAL, 67, 498 (1945)), I/M should be approximately 12. [d] In calculating I from group and structural values, −24 (recommended by Souders for 5-membered carbon rings) was used for the 5-membered tetrahydrofuran ring.

specific gravity bottle (fitted with a ground glass thermometer and cap), respectively. Viscosities (Table II) were determined by A.S.T.M. procedure,[9] using modified Ostwald tubes and a constant temperature bath[10] capable of maintaining the temperature within ± 0.02° at 20°.

Determination of Boiling Water Stability.—A mixture of 5 g. of ester and 100 ml. of distilled water was refluxed for twenty-four hours and allowed to cool. Approximately 200 ml. of acetone and several drops of cresol red–thymol blue mixed indicator[11] were added, and the resulting solution was titrated with 0.1 *N* sodium hydroxide. This method appeared to have certain advantages (one-phase system and less fading of end-point) over the similar method of Fordyce and Meyer.[12] Water solubilities were determined by a method similar to that of Fordyce and Meyer[12], using Sudan Red No. III dye.

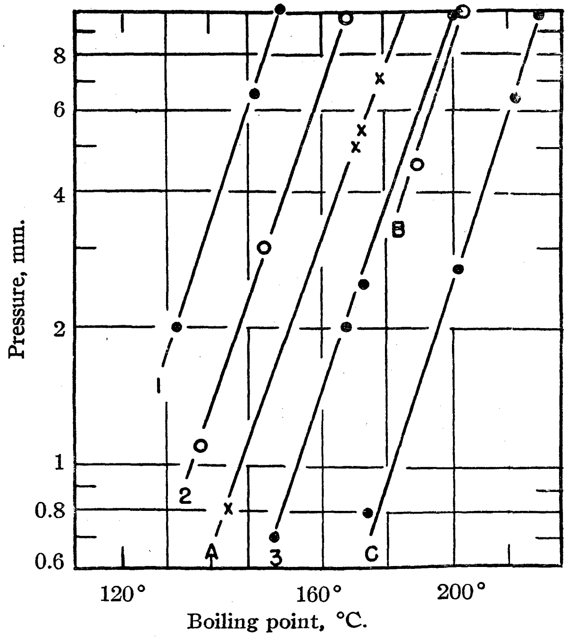

Fig. 1.—Boiling points at various pressures of acyl derivatives of *n*-butyl and tetrahydrofurfuryl lactates: acyl derivatives of *n*-butyl lactate: 1, heptanoate; 2, nonanoate; 3, dodecanoate; acyl derivatives of tetrahydrofurfuryl lactate: A, heptanoate; B, nonanoate; C, dodecanoate.

n-Dodecanoyl	< .1	.04	5.0	C	I	C	C

[a] Estimated from Fig. 1 by extrapolation; vapor pressure of butyl phthalate at 120° = 0.26 mm. (ref. 7). [b] Volume 0.1 *N* sodium hydroxide (ml.) to neutralize sample (5 g. in 100 ml. of water) that had been refluxed for twenty-four hours; values obtained by this method with methyl and butyl phthalate, respectively, were 1.0 and 0.2 ml. [c] C, compatible; I, incompatible; and CI borderline compatibility (commercially available plastics used for tests). [d] Ratio of polymer to plasticizer.

Compatibilities.—The acylated lactic ester and certain commercially available resins (Table III) were dissolved in a suitable solvent (acetone for ethyl cellulose, cellulose acetate, and cellulose acetate butyrate and dioxane for polyvinyl chloride). The solution was placed in a Petri dish and covered with a watch glass, and the solvent was allowed to evaporate. The resulting film was examined to determine compatibility. The esters were recorded as being compatible (Table III) only when transparent and dry films were obtained.

Correlation of Properties with Number of Carbon Atoms

The experimental data of the present work (Tables I to III) characterize many members of two homologous series (α-carbobutoxyethyl *n*-alkanoates, I, and α-carbotetrahydrofurfuryloxyethyl *n*-alkanoates, II), but several members of both series were not prepared or examined. To provide methods for estimating the properties of the missing members and to facilitate comparison of the *n*-alkanoyllactic esters (Table I) with certain previously-described homologous series, relationships between physical properties and number of carbon atoms (or molecular weight) of the homologous *n*-alkanoyl lactates were developed. Instead of plotting the physical constants as such against the number of carbon atoms and obtaining curved lines, certain functions of the properties that gave straight lines were selected. In agreement with earlier work, it was found that the straight line relationships usually were unsatisfactory for the first two or three members of the homologous series.

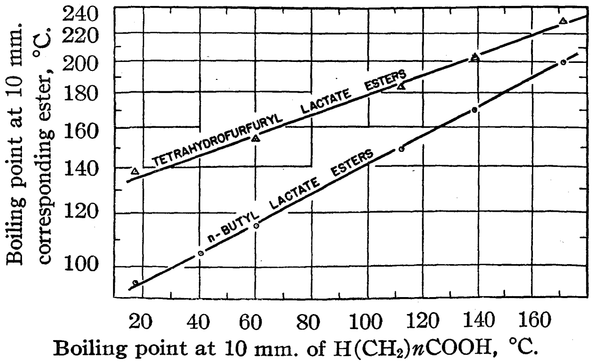

Fig. 2.—Relation of boiling points at 10 mm. of aliphatic acids and the corresponding acyl derivatives of tetrahydrofurfuryl and *n*-butyl lactates.

Boiling points at 10 mm. were taken from Fig. 1 and related[13] to the number of carbon atoms (x) and molecular weight (M) by equations 1, 2, 3 and 4 (T = b.p. at 10 mm., °K.). Observed boiling points vary 2° or less from the values calculated by equations 1 and 3. In the case of equations 2 and 4, the variation is 1° or less.

Butyl esters: $T^2 10^{-4} = 0.061M + 1.96$ (1)

$T^2 10^{-4} = 0.85x + 5.8$ (2)

Tetrahydrofurfuryl esters:

$T^2 10^{-4} = 0.061M + 3.42$ (3)

$T^2 10^{-4} = 0.85x + 8.2$ (4)

Figure 2, constructed by plotting boiling points at 10 mm. of aliphatic acids[14] against the boiling points of the corresponding carbobutoxyethyl (I) and carbotetrahydrofurfuryloxyethyl esters (II) on semilog paper, also can be used to estimate boiling points of the missing homologous esters. Boiling points (°K.) of the acids ($H(CH_2)_{x-1}COOH$) at 10 mm.[14] were used also to derive equations 5 and 6. Boiling points reported[14] in the literature vary 1 degree or less from the values calculated by equations 5 and 6.

$H(CH_2)_{x-1}COOH$: $T^2 10^{-4} = 1.28x + 6.06$ (x = 1 to 7, inclusive) (5)

$T^2 10^{-4} = 0.93x + 8.60$ (x = 8 to 18, inclusive) (6)

The boiling points of the lactic esters (1 and II) are compared with those of other homologous

---

[13] This method for relating the boiling point at 760 mm. and number of carbon atoms or molecular weight has been used by E. Boggia-Lera, *Gazz. chim. ital.*, **29**, 441 (1899); A. H. W. Aten, *J. Chem. Phys.*, **5**, 260 (1937); and F. Klages, *Ber.*, **76**, 788 (1943).

[14] Boiling points were estimated from the vapor pressure data of W. O. Pool and A. W. Ralston (*Ind. Eng. Chem.*, **34**, 1104 (1942)) by the use of Cox charts.[8]

series in Fig. 3, in which boiling points at 10-mm. pressure (°C.) are plotted against the square root of the number of carbon atoms. The *n*-butyl (I) and tetrahydrofurfuryl esters (II) boil lower and higher, respectively, than the diethyl esters[15] ($(CH_2)_n(COOC_2H_5)_2$) having the same number of carbon atoms. The lateral methyl group of the lactic esters and the tetrahydrofurfuryl group are relatively ineffective and effective, respectively, in raising the boiling point.[16] Both homologous series of lactic esters boil higher than the methyl alkanoates ($H(CH_2)_nCOOCH_3$) having an equal number of carbon atoms (with the exception of some of the higher *n*-alkanoyl derivatives of *n*-butyl lactate). The lines in Fig. 3 representing the homologous series having two or more functional groups have less slope than the *n*-paraffin[17] and methyl alkanoate lines.

The boiling points at 760 mm. of the *n*-butyl lactate derivatives (I) were calculated (Table IV) by the methods of Kinney,[16a] Burnop[16b] and Klages.[18] Boiling points at 760 mm. computed by Kinney's method[16a] were used to estimate[19] boiling points at 10 mm. Some of the calculated boiling points at 10 mm. (Table IV) are in close agreement with the experimental values.

The densities ($d^{20}{}_4$) and refractive indices ($n^{20}{}_D$) of the *n*-alkanoyl derivatives of *n*-butyl lactate (I) are given in Table I. They are related to the number of carbon atoms (x) by equations 7 and 8. Observed densities differ 0.0009 or less from the values calculated by equation 7. With the exception of the first member of the series, the observed refractive indices vary 0.0009 or less from the values calculated by equation 8.

$$\text{Butyl esters: } x/d = 1.164x - 1.509 \qquad (7)$$
$$x/n = 0.6845x + 0.2082 \qquad (8)$$

Similarly, equations 9 and 10 may be used to calculate $d^{20}{}_4$ and $n^{20}{}_D$ of the tetrahydrofurfuryl esters (II) from the number of carbon atoms (x). With the exception of the first member of the series, the average deviation of the observed densities from those calculated by equation 9 was 0.002. The average deviation for the refractive indices (equation 10) was 0.0004.

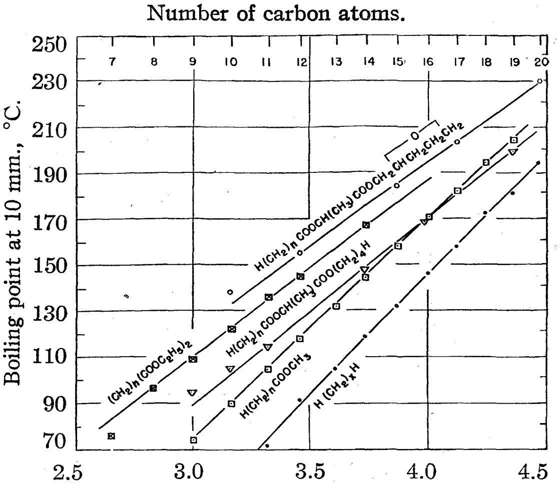

Fig. 3.—Relation between boiling point at 10 mm. and carbon atoms (X) of homologous compounds.

TABLE IV

CALCULATED BOILING POINTS OF THE ACYL DERIVATIVES OF *n*-BUTYL LACTATE

No. of carbon atoms	9	10	11	14	19
Boiling point (760 mm.), °C.					
Kinney's method[a]	222	235	254	304	377
Burnop's method[b]	232	249	266	312	375
Klages' method[c]	230	250	269	323	404
Boiling point (10 mm.), °C.					
Found[d]	95	105	115	148	201
Calcd.[e]	97	107	122	161	219

[a] Ref. 16a. [b] Ref. 16b. [c] Ref. 18. [d] From Fig. 1 or similar charts. [e] On the assumption[19] that esters have the temperature–vapor pressure relationship of group 3 compounds, using the equation: b. p. 10 mm. = (0.786) (b. p. 760 mm.) − 77.6.

$$\text{Tetrahydrofurfuryl esters: } x/d = 1.142x - 2.563 \qquad (9)$$
$$x/n = 0.6845x + 0.0892 \qquad (10)$$

The butyl acyloxypropionates (I) and tetrahydrofurfuryl acyloxypropionates (II) are similar to other homologous series,[20] in that linear relationships (Fig. 4) exist (excluding the first few members) between the logarithm of viscosity and the number of carbon atoms (Table II). The *n*-butyl (I) and tetrahydrofurfuryl esters (II) had lower and higher viscosities, respectively, than the diethyl esters[21] ($(CH_2)_n(COOC_2H_5)_2$) having an

---

[15] Boiling points of the diethyl esters ($(CH_2)_n(COOC_2H_5)_2$) at 10-mm. were estimated from boiling point data of A. I. Vogel, *J. Chem. Soc.*, 333 (1934).

[16] These conclusions are in agreement with the boiling points of somewhat related compounds at 760 mm. (a) C. R. Kinney, This Journal, **60**, 3032 (1938); Lange's "Handbook of Chemistry," 5th ed., 1944, Handbook Publishers, Inc., Sandusky, Ohio, p. 853, (b) V. C. E. Burnop, *J. Chem. Soc.*, 826 (1938).

[17] Boiling points of $H(CH_2)_nCOOCH_3$ and $H(CH_2)_nH$ at 10 mm. may be calculated by the equations: (esters) $T^2 10^{-4} = 1.09x + 2.23$; (*n*-paraffins) $T^2 10^{-4} = 1.19x - 1.0$ (x = 1 to 12, inclusive), and $T^2 10^{-4} = 1.07x + 0.35$ (x = 12 to 20, inclusive); where T = °K., and x = number of carbon atoms. Boiling point data used in deriving these equations were taken from (esters) P. M. Althouse and H. O. Triebold, *Ind. Eng. Chem., Anal. Ed.*, **16,** 605 (1944); F. A. Norris and D. E. Terry, *Oil & Soap*, **22,** 41 (1945); A. W. Weitkamp, This Journal, **67,** 447 (1945); "International Critical Tables," Vol. III, p. 217, and (*n*-paraffins) C. B. Willingham, W. J. Taylor, J. M. Pignocco and F. D. Rossini, *J. Research Natl. Bur. Standards*, **35** (31) 219 (1945); M. P. Doss, "Physical Constants of the Principal Hydrocarbons," 4th ed., The Texas Co., New York, N. Y., 1943. Boiling points reported in the literature differ 2° or less from the values calculated by the *n*-paraffin equations.

[18] F. Klages, *Ber.*, **76,** 788 (1943).

[19] In estimating the boiling points at 10 mm., it was assumed (following the suggestion of C. Bordenca, *Ind. Eng. Chem., Anal. Ed.* **18,** 99 (1946), and S. B. Lippincott and M. M. Lyman, *Ind. Eng. Chem.*, **38,** 320 (1946)) that esters fall into Group 3 with respect to temperature–vapor pressure properties.

[20] A. E. Dunstan and F. B. Thole, *J. Chem. Soc.*, **103,** 127 (1913).

[21] Viscosity data of the diethyl esters were taken from R. Cedar, *Ann. Univ. Fennicae Aboensis Series*, **A2,** No. 4, 14 pp. (1926) (*C. A.*, **22,** 3137 (1928)).

equal number of carbon atoms. The lactic esters (I and II) were more viscous than the corresponding ethyl alkanoates[22] and *n*-paraffins[23] (Fig. 4).

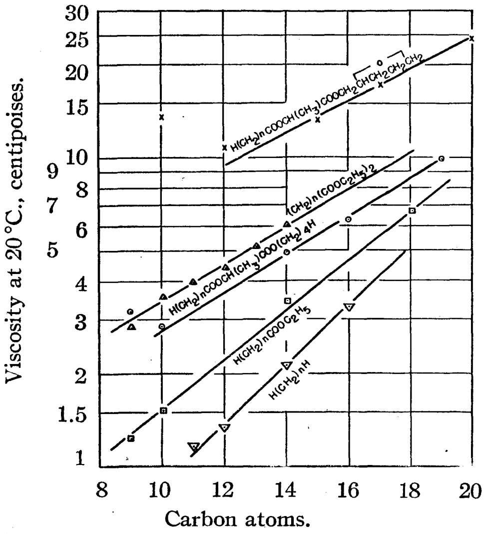

Fig. 4.—Relation between viscosity and carbon atoms of homologous compounds.

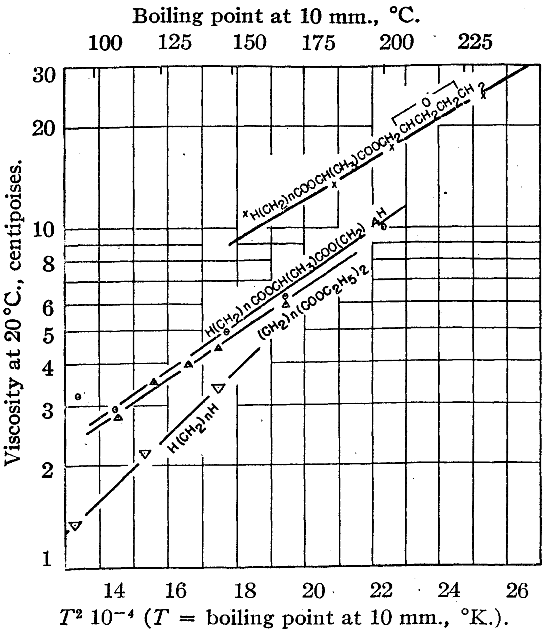
The viscosities of the *n*-butyl lactate (I) and tetrahydrofurfuryl lactate (II) derivatives are plotted in Fig. 5 as a function of the boiling points at 10 mm. The viscosities of the higher *n*-alkanoyl derivatives of butyl lactate were similar to those of the diethyl esters ($(CH_2)_n(COOC_2H_5)_2$) and *n*-paraffins of the same boiling point, but the tetrahydrofurfuryl esters (II) had viscosities considerably higher than those of the corresponding linear compounds (Fig. 5).

The values of Souders' viscosity function[24] were calculated (Table II) for the esters (I and II) of lactic acid; the I values calculated from the formula

$$I = \frac{M}{d}\log_{10}(\log_{10}n) + 2.9$$

where M = molecular weight, d = density and n = viscosity agreed moderately well with those estimated from the atomic and group increments.[24] In agreement with Lagemann,[25] the ratios between the I values and molecular refraction were approximately 12.



T^2 10^{-4} (T = boiling point at 10 mm., °K.).

Fig. 5.—Relation between boiling points at 10 mm. and viscosity of homologous compounds.

Several of the compounds of Table I had vapor pressures (Table III and Fig. 1) sufficiently low for use as plasticizers.[26] The suggestion that some of the esters of the present work should be suitable as plasticizers is supported by their relatively low viscosity, moderate stability in the presence of boiling water, and compatibility with certain commercially important plastics (Table III).

Acknowledgment.—W. P. Ratchford demonstrated that the alembic type still is suitable for determining boiling points at relatively low pressures and verified the boiling points of Figure 1. The authors are grateful for this major contribution.

Summary

Several homologous *n*-alkanoyl derivatives of *n*-butyl lactate ($H(CH_2)_nCOOCH(CH_3)COO(CH_2)_4H$) and of tetrahydrofurfuryl lactate ($H(CH_2)_nCOOCH(CH_3)COOCH_2\underbrace{CHCH_2CH_2CH_2}_{O}$) were prepared in high yields by treating the corresponding lactic esters with acid chlorides or anhydrides. Relationships between physical properties and molecular weight are given, from which the density, refractive index, viscosity and boiling point at 10 mm. of the missing members can be calculated.

Studies on Lignin and Related Compounds. LXXXIV. The High Pressure Hydrogenation of Maple Wood: Hydrol Lignin[1]

BY CHARLES P. BREWER,[2] LLOYD M. COOKE[3] AND HAROLD HIBBERT[4]

In the investigation of the structure of lignin, the techniques of oxidation[5,6] and ethanolysis have been extensively employed. Oxidation of spruce and maple woodmeal gave yields of aldehydes of 25 and 46%, respectively, based on the lignin originally present, but as these compounds are only lignin degradation products, they give no clue to the structure of the side-chains existing in the original lignin unit. On the other hand, while the yields of identifiable lignin products isolated from the ethanolysis procedure are low, they possess a marked significance with respect to the structure of lignin inasmuch as they evidently represent stabilized end-products of the more reactive, true lignin progenitors.[7]

Previous to this investigation, the products of high pressure catalytic hydrogenation of wood and lignin have been isolated mainly in the form of propylcyclohexane derivatives.[8a,b,c,9] This paper describes a method for isolating lignin from wood under hydrogenation conditions in a form believed to be essentially unchanged from that in the wood. In addition, several new products of lignin degradation have been isolated and identified.

This method consists in hydrogenating maple woodmeal over Raney nickel catalyst[10] in a neutral solution of ethanol–water (1:1) under mild conditions (165–170° for four hours) and separating the lignin from the cellulose degradation products by extraction with chloroform. In this way 75–85% of the original lignin is removed from the wood under such conditions that little or no condensation should occur. This new lignin product has been named "hydrol" lignin.

Preliminary investigations show that hydrol lignin contains phenol and methoxyl groups, but no carbonyl groups or ethylenic linkages. It is not degraded when subjected to ethanolysis, and thus appears to be more stable than lignin isolated by ethanolysis.[11] Hydrogenation of hydrol lignin at 205° results in only partial saturation, as indicated by the high yield of phenolic material in the reaction mixture. Since most aromatic derivatives are completely reduced under the conditions of this hydrogenation, this result is considered unusual.

Hydrogenation of hydrol lignin over Raney nickel and copper chromium oxide at 225° yielded a water-soluble fraction containing 4-ethylcyclohexanol to the extent of 9.7% of the original weight of lignin. This product probably resulted from the hydrogenation of 3-(4-hydroxycyclohexyl)-1-propanol, as does ethylcyclohexane from 3-cyclohexyl-1-propanol in 80% yield.[12] No identifiable products were isolated from the water-insoluble portion.

At 250°, hydrogenation of hydrol lignin over copper chromium oxide produced 4-*n*-propylcyclohexanol (I), 3-cyclohexyl-1-propanol (II), and 3-(4-hydroxycyclohexyl)-1-propanol (III), in yields of 3.1, 3.4, and 5.5%, respectively, based on the original Klason lignin. These products have been isolated in previous investigations[8,9] and thus indicate a marked similarity of behavior between hydrol lignin, other isolated lignins and protolignin.

Hydrol lignin was solvent-fractionated by precipitation into 30–50° petroleum ether, yielding 10–15% of a soluble fraction. This product was distilled through a 28-plate column,[13] but the variations in refractive indices and methoxyl contents of the distillate indicated preliminary separation was necessary. Accordingly, a separation into acid-soluble, alkali-soluble and neutral portions was made, and the large, alkali-soluble portion was fractionally distilled. The following products were thereby isolated: 3-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol, (IV), 3-(4-hydroxy-3-methoxyphenyl)-1-propanol, (V) and 3-(4-hydroxy-3,5-dimethoxyphenyl)-propane (VI) in yields of 1.4, 0.84 and 0.83%, respectively, based on the original lignin.

An additional quantity of IV amounting to 7.4% of the lignin, was obtained by precipitating the petroleum ether-insoluble hydrol lignin into diethyl ether, and fractionally distilling the alkali-soluble portion of the ether-soluble lignin.

Synthesis of IV (not previously reported), was carried out by the following series of reactions

$$\text{Maple wood} \xrightarrow[\text{Nitrobenzene}]{\text{NaOH}} \text{RCHO} \xrightarrow{CH_2(COOH)_2}$$

(R = 4-hydroxy-3,5-dimethoxyphenyl)

The isolation of the previously known saturated compounds, I, II, III, by the hydrogenation of hydrol lignin indicated the similar behavior of this material, wood, and isolated lignins when subjected to the same conditions of hydrogenation. The structure of these isolated products pointed to their derivation from propylphenol derivatives containing terminal oxygen atoms on the side chains, probably in the form of ether or acetal linkages.

Isolation of the aromatic derivatives (IV, V and VI) provides valuable support for the above theory, since 92% of these products contain terminal carbinol groups on the side chain. Furthermore, the methoxyl groups are left intact, thus permitting the isolation of guaiacyl (4-hydroxy-3-methoxyphenyl) and syringyl (4-hydroxy-3,5-dimethoxyphenyl) derivatives as wood hydrogenation–hydrogenolysis products for the first time.

Moreover, the difference in yields between the guaiacyl- and syringyl- containing propylphenol derivatives points to a marked difference in the mode of linkage by which these are united to similar units in protolignin, and supports the theory that in the former we are concerned largely with —C—C— linkages, and in the latter with —C—O—C— linkages between propylphenol units.

Experimental

Preparation of Hydrol Lignin.—Maple woodmeal (22 g. 20.3% Klason lignin, 6.1% $\mathrm{OCH_3}$ and 4–6% water) was mixed with 1:1 ethanol:water (220 cc.) and moist Raney nickel catalyst (16.5 g.) and hydrogenated for four hours at 165–170° with an initial hydrogen pressure of 3000 lb./sq. in. The pulp yield was 65% of the dry wood and the lignin removal was 75–85%, based on the original lignin in the wood. The pulp was filtered from the reaction medium, the solution concentrated to incipient precipitation, and then extracted three times with an equal volume of chloroform. The chloroform solution was dried and concentrated to a clear, red-brown viscous oil containing 24–25% $\mathrm{OCH_3}$ and representing 70–80% of the lignin in the wood. Hydrol lignin prepared in this way was used in all further experiments.

Hydrogenation of Hydrol Lignin. I. At 250°.—Hydrol lignin (7 g.) was hydrogenated in dioxane (150 cc.) for five hours at 250° over copper–chromium oxide catalyst[12] (10 g.) with an initial hydrogen pressure of 3000 lb./sq. in. The catalyst was removed by centrifugation, and the dioxane and lower boiling compounds by distillation. The residual colorless oil was dissolved in ether (20 cc.) and the solution extracted five times with 10-cc. portions of water. The extracted ether solution contained 3.1 g. water-insoluble oils, while the water extract contained 1.4 g.

(a) **Isolation and Identification of 4-*n*-Propylcyclohexanol and 3-Cyclohexyl-1-propanol.**—The water-insoluble oils (3.1 g.) were fractionated through a Podbielniak column[15] at 0.1 mm. pressure and bath temperatures up to 250° to yield two identifiable fractions, 4-*n*-propylcyclohexanol (n^{25}_{D} 1.4640–1.4648) and 3-cyclohexyl-1-propanol (n^{25}_{D} 1.4650–1.4679), identified as their phenylurethans, m. p. 126–127° and 84–85°, respectively. Yields were 0.4 and 0.43 g., respectively.

(b) **Isolation and Identification of 3-(4-Hydroxycyclohexyl)-1-propanol.**—The water-soluble oils (1.4 g.) were fractionated in a semi-micro column[13] to give 0.7 g. of a semi-crystalline fraction n^{53}_{D} 1.4768–1.4786 identified as 3-(4-hydroxycyclohexyl)-1-propanol by oxidation to β-(4-ketocyclohexyl)-propionic acid and preparation of the semicarbazone.[9]

II. **At 225°.**—Hydrol lignin (10.9 g.) was hydrogenated in dioxane (180 cc.) for seven and one-half hours at 225° over Raney nickel (10 g.) and copper–chromium oxide (8 g.) with an initial hydrogen pressure of 3100 lb./sq. in. The products were separated into water-soluble (0.5 g.) and -insoluble (3.9 g.) fractions as described above, and the latter fractionally distilled through a 28-plate column.[13] From the products a fraction with n^{25}_{D} 1.4600–1.4615 was isolated and identified as 4-ethylcyclohexanol by a mixed melting point of the phenylurethan with an authentic sample. Melting point of urethan 113.5–114.5°; yield 1.25 g.

The water-soluble portion (0.5 g.) was not identified.

Fractionation of Hydrol Lignin.—(1) Hydrol lignin (9.5 g.) was dissolved in chloroform (100 cc.) and precipitated by pouring into two liters of 30–50° petroleum ether with stirring. The oily precipitate was allowed to separate, the clear supernatant liquor was decanted, and the residual solvent removed by evaporation, leaving the petroleum ether-soluble fraction as a viscous oil (1.0 g.). The petroleum ether-insoluble material (8.4 g.) was further fractionated by dissolving in chloroform (80 cc.) and extracting four times with 20 cc. of saturated sodium bicarbonate solution. The extracts were combined, neutralized with 10% sulfuric acid and back-extracted with four 20-cc. portions of chloroform, which were then combined, dried over sodium sulfate and the solvent removed; yield of acid fraction 0.6 g. A similar treatment of the residual chloroform solution with 5% sodium hydroxide solution yielded an alkali-soluble fraction of 6.4 g. and left a neutral fraction of 0.8 g. in the residual chloroform solution.

(2) A quantity (17.4 g.) of the petroleum ether-insoluble hydrol lignin obtained according to the above procedure was dissolved in chloroform (100 cc.) and precipitated into 1 liter of diethyl ether. A light buff-colored amorphous precipitate (6.4 g.) was removed by filtration, and evaporation of the filtrate left a reddish oil, 11 g. (42% of Klason lignin). An aliquot (9.6 g.) of this oil was separated into acid (0.95 g.), alkali-soluble (6.6 g.), and neutral fractions (0.7 g.) by the procedure described above in I.

Isolation and Identification of 3-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanol, IV.—The alkali-soluble fraction (6.4 g.) of petroleum ether-soluble hydrol lignin (from 108 g. of Klason lignin) was fractionated through a 28-plate column[13] (270–290° bath temp. at 0.25 mm. pressure) and yielded a white, crystalline product, m. p. 75.5–76.5° after recrystallization from benzene. A mixed m. p. with a synthetic sample described below showed no depression; yield 1.5 g. (1.4% of lignin).

The alkali-soluble portion (6.6 g.) of the petroleum ether-insoluble, diethyl ether-soluble hydrol lignin was fractionated in the same column to yield an additional quantity of the same crystalline product; yield 1.72 g. (7.4% of the Klason lignin).

Isolation and Identification of 3-(4-Hydroxy-3-methoxyphenyl)-1-propanol (V).—Fractions (1.35 g., n^{50}_{D} 1.5200–1.5380) obtained in the fractionation of the alkali-soluble portion of petroleum ether-soluble hydrol lignin described in the previous section were combined and refractionated in a smaller column,[13] (bath temp. 170° at 0.2 mm. pressure) to yield a clear, colorless oil, n^{50}_{D} 1.5360–1.5380, identified as 3-(4-hydroxy-3-methoxyphenyl)-1-propanol

---

[13a] Sinapic acid melted at 178–183° (reported 191–192°[14]) and could not be further purified by recrystallization.

[14] Graebe and Martz, *Ber.*, **36**, 1031 (1903).

[15] Podbielniak, *Ind. Eng. Chem. Anal. Ed.*, **3**, 177 (1931); **5**, 119 (1933).

by a mixed melting point of the bis-*p*-nitrobenzoate with that of the synthetic derivative; yield was 0.9 g. (0.84% of Klason lignin).

Isolation and Identification of 3-(4-Hydroxy-3,5-dimethoxyphenyl)-propane (VI).—Fractions (1.45 g., n^{50}D 1.5000–1.5150), also obtained from the fractionation of alkali-soluble, petroleum ether-soluble hydrol lignin, were combined and refractionated to yield a clear, colorless oil identified as 3-(4-hydroxy-3,5-dimethoxyphenyl)-propane by a mixed m. p. of the acetate with that of the synthetic product; yield was 0.89 g. (0.83% of Klason lignin).

Synthesis of Products Isolated from Hydrol Lignin. I. 3-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanol (IV) Syringaldehyde.—A mixture of vanillin and syringaldehyde was prepared by the oxidation of maple woodmeal, using the method of Creighton.[16] The syringaldehyde was separated from the vanillin by the method of Hunter and Hibbert.[17] A total of 400 g. of maple woodmeal was treated to yield 18 g. of syringaldehyde, m. p. 110–112°.

β-(4-Hydroxy-3,5-dimethoxyphenyl)-acrylic Acid (Sinapic Acid).[18]—A mixture of syringaldehyde (11.1 g.), malonic acid (14.5 g.), pyridine (33 cc.) and piperidine (0.7 cc.) was heated together at 80–85° for four hours, cooled, and dilute hydrochloric acid added (125 cc.). The product crystallized out immediately in fine, pale-yellow needles; m. p., 178–183°; yield was 8.2 g. (60%).

β-(4-Hydroxy-3,5-dimethoxyphenyl)-propionic Acid (Hydrosinapic Acid).—Sinapic acid (7.2 g.), ethanol (155 cc.), water (50 cc.) and Raney nickel catalyst (3 g.) were hydrogenated at an initial hydrogen pressure of 2200 lb./sq. in. The charge was heated to 110–115° in fifteen minutes, then allowed to cool for one hour with agitation. Removal of the solvent left a grey-white solid which was recrystallized from water and then from ether–petroleum ether, m. p. 102–103°, yield 6.7 g. (92%). The product crystallized in white needles, readily soluble in ethanol and ether.

Anal. Calcd. for $C_{11}H_{14}O_5$: C, 58.4; H, 6.25; OCH_3, 27.5. Found: C, 58.4; H, 6.4; OCH_3, 27.6.

Ethyl Hydrosinapate.—Hydrosinapic acid (5.2 g.) was esterified by the method of Nomura and Hotta.[19] A clear, colorless oil was obtained, b. p. 178–179° (1 mm.), n^{25}D 1.5250; yield was 5.4 g. (93%).

Anal. Calcd. for $C_{13}H_{18}O_5$: C, 61.4; H, 7.14; OR, 36.6. Found: C, 61.5; H, 7.2; OR, 36.6.

3-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanol, IV.—To sodium (0.96 g.), in small pieces, was added rapidly with stirring a solution of the ester (1.76 g.) in absolute ethanol (10.6 g.). The mixture was refluxed for four hours, 15 cc. of water added and the refluxing continued for one hour. The ethanol was then removed, the residual solution neutralized with 10% sulfuric acid and extracted with four 10-cc. portions of ether. The latter were combined, extracted with five 5-cc. portions of sodium bicarbonate solution, dried and evaporated to dryness. The residue was recrystallized from ether–petroleum ether, from which, on cooling, fine white needles separated, m. p. 75.5–76.5°; yield was 15–20%. No further change in melting point was found on repeated recrystallization.

Anal. Calcd. for $C_{11}H_{16}O_4$: C, 62.2; H, 7.61; OCH_3, 29.3. Found: C, 62.3; H, 7.8; OCH_3, 29.1.

II. 3-(4-Hydroxy-3-methoxyphenyl)-1-propanol, V.—This was synthesized by the same method as used above, save that vanillin was used as a starting material. The alcohol was a colorless, slightly cloudy oil, b. p. 197° (15 mm.), n^{25}D 1.5545.

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.95; H, 7.7; OCH_3, 17.05. Found: C, 65.95; H, 7.95; OCH_3, 17.0.

The **bis-*p*-nitrobenzoate** was prepared by the method of Kawai and Sugiyama,[20] m. p. 119.5–120.5°, yield 30%.

III. Acetate of 3-(4-Hydroxy-3,5-dimethoxyphenyl)-propane.—A sample (0.112 g.) of 3-(4-hydroxy-3,5-dimethoxyphenyl)-propane[17] (b. p. 123–126° (0.1 mm.), n^{25}D 1.5285), glacial acetic acid (0.1 cc.) and acetyl chloride (0.065 cc.) were refluxed for one hour and then poured over ice (2 cc.), whereupon a brown oil separated. The oil and aqueous mixture was extracted with ether, the ether solution dried over sodium sulfate and the solvent removed, leaving a white crystalline solid. Recrystallization from ethanol yielded 0.09 g. of a pure product, m. p. 87–88°.

IV. 4-Ethylcyclohexanol.—Acetovanillone (5 g.), dioxane (60 cc.) and copper–chromium oxide catalyst (3 g.) were hydrogenated for 1.3 hr. at 273–278° at an initial hydrogen pressure of 2930 lb./sq. in. The residual oil was distilled to yield 2.7 g. of a clear colorless oil (b. p. 83–84° (10 mm.), n^{25}D 1.4607) identified as the phenylurethan, m. p. 114–115°.[21]

Summary

1. A new method has been developed for the extraction of lignin from maple wood by a hydrogenation–hydrogenolysis procedure. A separation of this extracted lignin from carbohydrate material has been achieved, and the purified product has been designated as "hydrol" lignin.

2. Hydrogenation studies of hydrol lignin have indicated a marked similarity of behavior to other isolated lignins and to wood under the same conditions of hydrogenation.

3. From hydrol lignin three new propylphenol derivatives have been isolated, *viz.*, 3-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol, 3-(4-hydroxy-3-methoxyphenyl)-1-propanol and 3-(4-hydroxy-3,5-dimethoxyphenyl)-propane in yields of 8.8, 0.84 and 0.83%, respectively, based on the original Klason lignin. The structural significance of these derivatives to the lignin nucleus rests on the fact that they are the first propylphenol derivatives, isolated from wood or lignin by hydrogenation, in which a terminal —CH_2OH group is present in the side chain.

4. The synthesis and properties of a new compound, 3-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol, are reported.

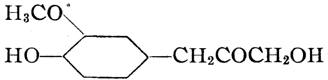
Studies on Lignin and Related Compounds. LXXXV. Synthesis and Properties of Dimers Related to Lignin[1]

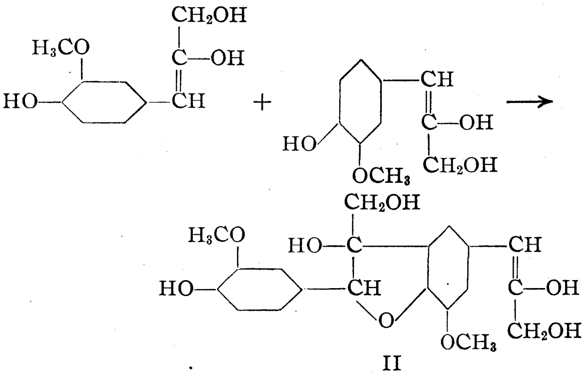
BY SAMUEL B. BAKER,[2] TAYLOR H. EVANS[3] AND HAROLD HIBBERT[4]

A considerable number of previous investigations[5–9] carried out in these laboratories have given clear experimental support to Hibbert's assumption that protolignin consists of a mixture of different substances derived from relatively simple propylphenol units. Although considerable uncertainty still exists regarding the nature of the C_3 side chain and the mode of its linkage in the complex protolignin structure, several experimental facts have been established. The aromatic portion of spruce protolignin is always the guaiacyl (4-hydroxy-3-methoxyphenyl) nucleus,[10] the side chain is an oxygenated radical[7,8,9] without terminal methyl groups[11] and it contains primary hydroxyl groups.[5,6]

According to Hibbert,[12] the experimental results seem to indicate that a large portion of native lignin consists of a polymer or polymers of the dehydrodiisoeugenol type, in which the isoeugenol unit is replaced by β-oxyconiferyl alcohol (I). Dimerization of the enol modification of (I) to yield dehydrodi-(β-oxyconiferyl)-alcohol (II) is highly probable since this has been shown by Erdtman[13] and by Haworth[14] to be typical of the dimeric plant resins or lignins.

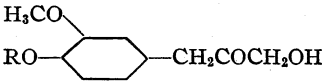


I

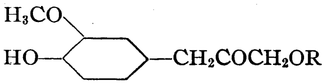


II

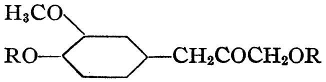
Inasmuch as the ethanolysis reaction indicates that some of the native lignin is present in a much less complex form (water-soluble) than the remainder (water-insoluble fractions),[15] it has been suggested that the ethanolysis products result from the decomposition of the less complex form. Hibbert suggests three general types of relatively simple units that could yield the ethanolysis products. These are assumed to be the glycosides (III), (IV), (V), the hemiketals (VI), (VII) and the ether (VIII).



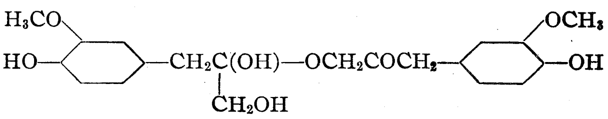
III



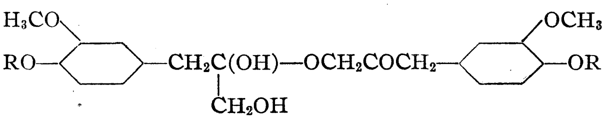
IV



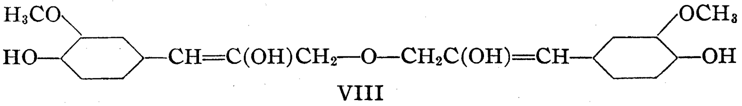
V



VI



VII



VIII

(R is carbohydrate unit)

These (III, IV, V, VI, VII, VIII) could yield β-oxyconiferyl alcohol (I) on ethanolysis and the latter could undergo dismutation and rearrangement[12] to yield the ethyl ethers of (IX) and (XII) and also (X) and (XI), actually obtained by ethanolysis of spruce wood.

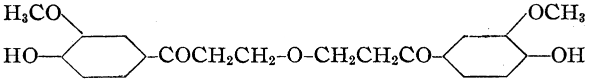
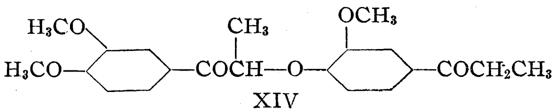
(R is 4-hydroxy-3-methoxyphenyl)

Experimental support for this mechanism recently has been obtained.[16]

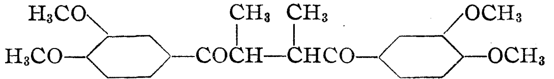
It was desirable to synthesize compounds of structures similar to (II) and (VIII) in order to test the validity of Hibbert's[11] suggestions regarding the probable structures of the simple and more complex portions of spruce protolignin. Three dimeric compounds have been synthesized, 2,2′-divanilloyl diethyl ether (XIII), 1-veratroyl-1-(2-methoxy-4-(propanone-1)-phenoxy)-ethane (XIV), and 2,3-diveratroylbutane (XV). The first (XIII) was synthesized by the iodine dehydration[17] of 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone. The second (XIV) was prepared by a Williamson reaction between the sodium phenolate of 1-(4-hydroxy-3-methoxyphenyl)-1-propanone and 2-bromo-1-(3,4-dimethoxyphenyl)-1-propanone. The third (XV) was prepared by means of an acetoacetic ester synthesis.



XIII



XIV



XV

The first dimer (XIII) is characterized by the presence of a dialkyl ether linkage between the two propylphenol units, each of which has a carbonyl group in the γ-position to the ether linkage and adjacent to the ring. The second dimer (XIV) differs from the first (XIII) in that it contains (a) an alkaryl ether linkage and (b) the carbonyl group in the β-position to the ether linkage and adjacent to the ring. The third dimer (XV) is characterized by (a) a carbon–carbon linkage between carbon atoms β- to the ring and (b) carbonyl groups adjacent to the rings.

Each of these dimers (XIII), (XIV), (XV) was heated with 2% ethanolic hydrogen chloride. The first (XIII) yielded about 15% of an amorphous lignin-like product, the balance about 80% being recovered unchanged. Chain fission probably did occur to a small extent and the fission products underwent immediate polymerization. The second (XIV) was unaffected by this treatment; no monomolecular fission products were isolable. The third (XV) treated similarly, with 2% ethanolic hydrogen chloride, gave a high yield (80%) of an amorphous lignin-like product with no indication of chain fission to stable monomolecular units. Hydrogenation[18] of this carbon–carbon linked dimer (XV) did not result in cleavage into monomolecular products. Therefore it may be that polymerization of (XV) during ethanolysis occurred not due to primary cleavage into reactive monomolecular units but due to the inherent reactivity of the 1,4-diketonic grouping.

Experimental

Synthesis of 2,2′-Divanilloyl Diethyl Ether (XIII)

3-Bromo-1-(4-hydroxy-3-methoxyphenyl)-1-propanone. Powdered anhydrous aluminum chloride (10 g.) was suspended in anhydrous carbon disulfide (40 cc.) in a three-necked round-bottomed flask equipped with a mercury-sealed stirrer, a reflux condenser with drying tube and a dropping funnel. The reaction flask was cooled by immersion in ice-water and β-bromopropionyl chloride (13.0 g.) added rapidly to the well-stirred suspension. Veratrole (10.0 g.) was added gradually during one hour with vigorous stirring, then two more 10-g. portions of aluminum chloride were added, the second portion fifteen minutes after the first. The reaction mixture was heated at 50° for one hour, allowed to stand overnight at room temperature and the carbon disulfide decanted. The Perrier complex was decomposed in a mixture of ice and concentrated hydrochloric acid. The product was filtered, washed on the filter with 10% hydrochloric acid and finally with water. The crude, dried product was dissolved in ether and decolorizing charcoal added. The suspension was heated under reflux for one hour, filtered and petroleum ether (30–50°) added until a permanent turbidity was formed. A crystalline product separated from the cooled solution and was recrystallized from ether–petroleum ether yielding 11.1 g. (60%), m. p. 103–104°.

Anal. Calcd. for $C_{10}H_{11}O_3Br$: OCH_3, 11.9; Br, 30.9. Found: OCH_3, 11.8; Br, 30.7.

The product was further characterized by conversion into the known[19] 3-acetoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone.

3-Hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone.—Aqueous sodium hydroxide (1%, 100 cc.) was added to 3-bromo-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (2 g.) in a round-bottomed flask. The reaction mixture was heated at 50° for four hours, cooled and then acidified with dilute hydrochloric acid. The acidified solution was extracted with eight portions of chloroform (60 cc.) and the combined chloroform solutions were dried over anhydrous sodium sulfate. The solvent was removed and the resulting product twice recrystallized from hot benzene (30 cc.) yielding 1.32 g. (88%), m. p. 109–110°. A mixed melting point determination with an authentic sample of 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone showed no depression.

2,2′-Divanilloyl Diethyl Ether (XIII).—3-Hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (3.0 g.) was dissolved in hot anhydrous benzene (25 cc.) in a small Claisen flask fitted with a reflux condenser. A crystal of

re-sublimed iodine (0.05 g.) was added and the solution was refluxed for one hour on the steam-bath. The benzene was removed by distillation at atmospheric pressure. The resulting product, a viscous oil, was dissolved in hot methanol (5 cc.) and on cooling, crystals separated rapidly. The crude product was recrystallized from anhydrous methanol yield 1.0 g. (36%), m. p. 153–154°.

Anal. Calcd. for $C_{20}H_{22}O_7$: C, 64.17; H, 5.88; OCH_3, 16.6; mol. wt., 374. Found: C, 64.2; H, 5.9; OCH_3, 16.6; Rast mol. wt., 380.

The bis-2,4-dinitrophenylhydrazone was prepared by the usual method.

Anal. Calcd. for $C_{32}H_{30}O_{13}N_8$: C, 52.31; H, 4.08; OCH_3, 8.4. Found: C, 52.4; H, 4.1; OCH_3, 8.4.

Diazomethane Methylation of XIII.—2,2′-Divanilloyl diethyl ether (0.16 g.) was dissolved in benzene and a solution of diazomethane in benzene was added. The solvent was removed after twenty-four hours and the unmethylated portion was removed by washing with 2% alkali. The remaining portion was dissolved in hot ethanol. Crystals separated rapidly when the solution was cooled yielding 0.15 g. (89%), m. p. 139–140°.

Anal. Calcd. for $C_{22}H_{26}O_7$: C, 65.69; H, 6.47; OCH_3, 30.8; mol. wt., 402. Found: C, 65.6; H, 6.6; OCH_3, 30.6; Rast mol. wt., 395.

Oxidation of 2,2′-Diveratroyl Diethyl Ether.—The methylated ether (0.13 g.) was suspended in 3% aqueous sodium hydroxide (50 cc.) in a small three-necked flask fitted with a reflux condenser, stirrer, and a dropping funnel. Aqueous potassium permanganate (9%, 25 cc.) was added dropwise to the hot (100°) stirred alkaline suspension during one hour. The precipitated manganese dioxide was removed by filtration and the clear filtrate acidified with dilute hydrochloric acid. A crystalline substance separated and was recrystallized from methanol–water (3:1) yielding 0.09 g. (77%), m. p. 180–181°. A mixed melting point determination with an authentic sample of veratric acid showed no depression.

Synthesis of 1-Veratroyl-1-[2-methoxy-4-(propanone-1)-phenoxy]-ethane (XIV)

2-Methoxyphenyl Propionate.—A solution of guaiacol (25 g.), pyridine (20 g.) and propionyl chloride (19 g.) was heated on the steam-bath during one hour. The reaction mixture was cooled and then poured into 2% aqueous hydrochloric acid. The aqueous solution was extracted with two portions (50 cc.) of ether and the combined solutions dried over anhydrous sodium sulfate. The solvent was removed and the resulting oil distilled from a Claisen flask at 140–143° (20 mm.) yielding 34.5 g. (95%).

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.67; H, 6.67; OCH_3, 17.2. Found: C, 66.6; H, 6.9; OCH_3, 17.0.

1-(4-Hydroxy-3-methoxyphenyl)-1-propanone.—Powdered anhydrous aluminum chloride (30 g.) was dissolved in anhydrous nitrobenzene (75 cc.) at 100°. The solution was cooled and added to a three-necked round-bottomed flask, equipped with a mercury-sealed stirrer, a reflux condenser with drying tube, and a thermometer. Stirring was started and 2-methoxyphenyl propionate (20 g.) was added rapidly. The reaction mixture was heated at 60° for one hour, then allowed to stand overnight at room temperature. The mixture was filtered with the exclusion of air and moisture and the Perrier complex washed well with a mixture of benzene and ligroin (2:1). The complex was decomposed in ice–hydrochloric acid and the oily layer extracted with chloroform. The chloroform solution was refluxed for one hour with activated charcoal and after filtration the solvent was removed under reduced pressure. The oily product crystallized and it was recrystallized from ether–petroleum ether (30–50°) yielding 13 g. (65%), m. p. 62–63°.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.67; H, 6.67; OCH_3, 17.2. Found: C, 66.6; H, 6.9; OCH_3, 17.2.

1-Veratroyl-1-[2-methoxy-4-(propanone-1)-phenoxy]-ethane.[20]—The sodium phenolate, prepared from sodium (2.0 g.) and 1-(4-hydroxy-3-methoxyphenyl)-1-propanone (14.7 g.) was dissolved in anhydrous ethanol (300 cc.) in a round-bottomed flask. 2-Bromo-1-(3,4-dimethoxyphenyl)-1-propanone[21] (22.3 g.) was added and the solution heated under reflux for four hours. The hot solution was poured into cold water and the microcrystalline precipitate removed by filtration. The crude product was recrystallized twice from methanol yielding 23.8 g. (78%), m. p. 148–149°.

Anal. Calcd. for $C_{21}H_{24}O_6$: C, 67.74; H, 6.45; OCH_3, 25.0; mol. wt., 372. Found: C, 67.7; H, 6.5; OCH_3, 24.9; Rast mol. wt., 387.

The bis-2,4-dinitrophenylhydrazone was prepared by the usual method.

Anal. Calcd. for $C_{33}H_{32}O_{12}N_8$: C, 54.09; H, 4.37; OCH_3, 12.7; mol. wt., 732. Found: C, 54.0; H, 4.4; OCH_3, 12.6; Rast mol. wt., 724.

Synthesis of 2,3-Diveratroylbutane (XV)

Ethyl Veratrate.—The ester was prepared by refluxing during four hours veratric acid (80 g.), anhydrous ethanol (500 cc.) and sulfuric acid (15 cc.). The product was isolated in the usual manner yielding 82 g. (89%) which after one recrystallization from ether–petroleum ether (30–50°) melted sharply at 43.5–44.5°.

Anal. Calcd. for $C_{11}H_{14}O_4$: OCH_3, 44.3. Found: OCH_3, 43.9.

Ethyl Veratroylacetate.—Ethyl veratrate (50 g.) was added to a three-necked flask equipped with a reflux condenser, a dropping funnel and a glycerol-sealed stirrer. Granulated sodium (4 g.) was added, the stirrer started and the mixture heated at 80°. A pasty mass was obtained to which ethyl acetate (15 g.) was added dropwise, and the temperature raised to 90°. An additional quantity of sodium (4 g.) and ethyl acetate (15 g.) was added to the reaction mixture. This addition of sodium and ethyl acetate was continued until a total of 20 g. of sodium and 75 g. of ethyl acetate had been added. Stirring and heating were continued for sixteen hours. The mixture was cooled, added with stirring to ice–hydrochloric acid, and the acidic solution extracted with three portions of ether (250 cc.). The combined ethereal solutions were dried over anhydrous sodium sulfate and the solvent removed. The resulting oil was distilled under reduced pressure. The first fraction, boiling up to 120° (0.01 mm.), consisting mainly of ethyl acetoacetate and ethyl veratrate was discarded. The required product distilled as a viscous oil at 150–160° (0.01 mm.) yielding 24.1 g. (40%).

Anal. Calcd. for $C_{13}H_{16}O_5$: OCH_3, 36.9. Found: OCH_3, 37.3.

Methyl Ethyl Veratroylacetate.—Ethyl veratroylacetate (24 g.) was dissolved in anhydrous benzene (150 cc.) in a three-necked round-bottomed flask equipped with a reflux condenser, dropping funnel, and a glycerol-sealed stirrer. Granulated sodium (2.2 g.) was added in small portions during four hours and the mixture heated with stirring during twelve hours. Methyl iodide (15 g.), dissolved in anhydrous benzene (200 cc.), was added dropwise to the cooled mixture. Stirring was continued until the reaction mixture became transparent. The mixture was heated on the steam-bath during one hour, then cooled and added in a fine stream to cold water (500 cc.). The benzene layer was decanted and the aqueous solution extracted with ether (100 cc.). The combined benzene and ether solutions were dried over anhydrous sodium sulfate and the solvent removed under reduced pressure. The resulting oil was distilled and the fraction boiling at 155–167° (0.01 mm.) collected yielding 25 g. (98%).

Anal. Calcd. for $C_{14}H_{18}O_5$: OCH_3, 34.9. Found: OCH_3, 34.3.

bis-(Methyl Ethyl Veratroylacetate).—Methyl ethyl veratroylacetate (25 g.) was dissolved in anhydrous benzene (300 cc.) in a three-necked flask equipped with a dropping funnel, a glycerol-sealed stirrer and a reflux con-

denser with a drying tube. The solution was heated on a steam-bath and granulated sodium (2.2 g.) added in small portions during two hours, with vigorous stirring. The reaction mixture became very viscous and another portion of benzene (300 cc.) was added. Iodine (13 g.) dissolved in anhydrous benzene (250 cc.), was added dropwise to the hot, well-stirred mixture during four hours. Stirring was continued for one hour longer and the solution added in a fine stream to water (one liter). The benzene layer was decanted, washed with 5% aqueous sodium thiosulfate (100 cc.) and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure and the resulting oil distilled at 210–216° (0.01 mm.), yielding 23.3 g. (93%).

Anal. Calcd. for $C_{28}H_{34}O_{10}$: OCH_3, 35.1. Found: OCH_3, 34.6.

2,3-Diveratroylbutane (XV).—bis-(Methyl ethyl veratroylacetate) (23 g.) was dissolved in anhydrous ethanol (375 cc.) containing sodium hydroxide (8.5 g.) and the mixture allowed to stand at room temperature during twenty-four hours with occasional stirring. The reaction mixture was cooled and concentrated hydrochloric acid added dropwise until the evolution of carbon dioxide ceased. The mixture was immediately added to cold water (450 cc.), the solution filtered, the oily product dissolved in chloroform–ethanol (1:2, 200 cc.) and charcoal added. The mixture was heated under reflux on the steam-bath during two hours and filtered while hot. The solvent was removed under reduced pressure and the tan-colored crystalline substance which separated was twice recrystallized from hot methanol yielding 8.4 g. (48%), m. p. 189–190°.

Anal. Calcd. for $C_{22}H_{26}O_6$: C, 68.39; H, 6.76; OCH_3, 32.1; mol. wt., 386. Found: C, 68.3; H, 6.9; OCH_3, 31.9; Rast mol. wt., 395.

The bis-2,4-dinitrophenylhydrazone was prepared by the usual method.

Anal. Calcd. for $C_{34}H_{34}O_{12}N_8$: OCH_3, 16.6. Found: OCH_3, 16.6.

Action of 2% Ethanolic Hydrogen Chloride on XIII.—2,2′-Divanilloyl diethyl ether (1.00 g.) was heated under reflux with 2% ethanolic hydrogen chloride (50 cc.) for forty-eight hours in an atmosphere of carbon dioxide. A small amount (0.15 g.) of an amorphous lignin-like substance which separated was removed by filtration. The filtrate was neutralized with sodium ethylate and the precipitated sodium chloride removed by filtration. The solvent was removed under reduced pressure and the product recrystallized from methanol yielding 0.75 g., m. p. 153–154°. A mixed melting point determination with an authentic sample of XIII showed no depression.

Action of 2% Ethanolic Hydrogen Chloride on XIV.—The effect of 2% ethanolic hydrogen chloride on this dimer (XIV) (1.00 g.) was determined as above. The starting material was recovered unchanged in a yield of 0.91 g.

Action of 2% Ethanolic Hydrogen Chloride on XV.—In this reaction 1.00 g. of dimer (XV) was used and the amorphous product weighed 0.79 g.

Acknowledgment.—The authors gratefully acknowledge the kind financial assistance of the Canadian Pulp and Paper Association and the Spruce Falls Power and Paper Company.

Summary

1. Several propylphenol monomolecular compounds related to lignin progenitors were prepared. Some of these were new compounds, while others were prepared by new and better methods.

2. The synthesis of three dimers from these propylphenol units has been carried out.

3. Ethanolysis of the three dimers did not yield the customary monomolecular fission products, obtained by the ethanolysis of wood. This indicates that these synthetic dimers differ from those materials forming the readily hydrolyzable portion of native lignin.

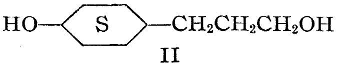
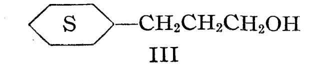
Studies on Lignin and Related Compounds. LXXXVI. Hydrogenation of Dimers Related to Lignin[1]

BY SAMUEL B. BAKER[2] AND HAROLD HIBBERT[3]

Complete liquefaction of spruce wood has been achieved by means of high-pressure catalytic hydrogenation.[4] The protolignin is converted in part to 4-*n*-propylcyclohexanol (I), 3-(4-hydroxycyclohexyl)-1-propanol (II) and 3-cyclohexyl-1-propanol (III) in yields of 9.9, 5.8 and 12.6%, respectively (based on the Klason lignin content of the wood).[4,5,6] These isolated products (I, II, III) serve to establish the propylphenol units in lignin. Further investigations[7,8] have shown that a relatively high proportion of the cyclohexylpropane units contains oxygen atoms attached to the terminal carbon atoms in the side chains.



I



II

III

According to Hibbert, the experimental results seem to indicate that a large portion of native lig-

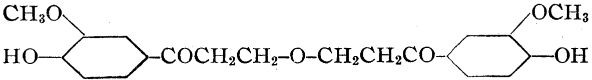
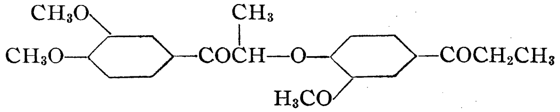
nin could conceivably consist of complex polymers of the dehydrodiisoeugenol type.[9] This similarity in structure between lignin and the lignans has been noted by Erdtman[10] and Haworth.[11]

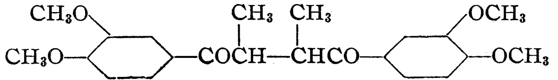
The three dimers, 2,2′-divanilloyl diethyl ether (IV), 1-veratroyl-1-[2-methoxy-4-(propanone-1)-phenoxy]-ethane (V), and 2,3-diveratroylbutane (VI) whose syntheses have been reported previously[9] have been hydrogenated using conditions developed in these Laboratories for the hydrogenation of spruce wood.



IV



V



VI

Hydrogenation of IV.—Hydrogenation of IV[12] over Raney nickel in aqueous ethanol (1:1), containing 3% alkali, for four hours at 165°, at an initial pressure of 3020 p.s.i., resulted in the hydrogenolysis of the ether linkage to the extent of 60%. Both carbonyl groups were reduced while the aromatic rings remained intact. The remaining 30% consisted of the original dimer in which the only change taking place was that of a reduction of the carbonyl to methylene groups. The products were identified as 4-hydroxy-3-methoxyphenylpropane (VII), 3-(4-hydroxy-3-methoxyphenyl)-1-propanol (VIII) and 2,2′-divanillyl diethyl ether (IX), in yields of 30, 30 and 33%, respectively.

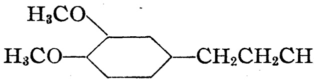
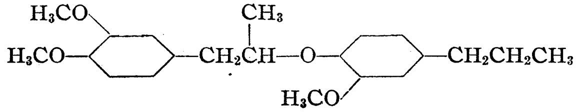
Hydrogenation with the same type of catalyst and medium at 185° for eighteen hours yielded the following cyclohexane derivatives: 4-*n*-propylcyclohexanol (I), and 3-(4-hydroxycyclohexyl)-1-propanol (II), in yields of 46 and 50%, respectively. Evidently chain fission occurred at the ether linkage followed by reduction of the aromatic rings. This type of reaction probably occurs in the hydrogenation of native lignin when spruce and maple woods are hydrogenated.[5,6]

Using copper–chromium oxide as catalyst, hydrogenation of the first dimer (IV) in aqueous ethanol at 150–160° for one hour at an initial pressure of 2980 p.s.i., but in the absence of alkali, gave only one product, 2,2′-divanillyl diethyl ether (IX) in a yield of 95%. Chain fission did not occur under these conditions.

Hydrogen of V.—Treatment[12] of the second dimer (V) under the same conditions using Raney nickel, ethanol–water (1:1), 3% alkali at 165° for four hours and at an initial pressure of 3030 p.s.i. brought about both cleavage of the ether linkage and reduction of the carbonyl groups. The products isolated were 4-hydroxy-3-methoxyphenylpropane (VII), 3,4-dimethoxyphenylpropane (X) and the carbonyl-reduced dimer (XI) in yields of 30% each. The same result was obtained under similar conditions as above but in the absence of alkali.



X



XI

Substitution of copper–chromium oxide catalyst for the Raney nickel, at 150–160° in ethanol for one hour yielded the same products (VII), (X) and (XI) in yields of 40, 40 and 15%, respectively. Hydrogenation of the carbonyl-reduced dimer (XI), under the same conditions of time, temperature and pressure but with copper–chromium oxide catalyst left the product unchanged. The presence of alkali brought about a partial cleavage (15%), the remainder of the saturated dimer (XI) being recovered unchanged. On the other hand, hydrogenation of the latter (XI) over Raney nickel at 160–165° for four hours brought about a cleavage, the reaction products comprising (VII), (X) and (XI) in yields of 25, 25 and 50%, respectively. The presence of the two carbonyl groups appeared to exert a marked effect in the hydrogenation of the dimer over copper–chromium oxide catalyst since cleavage did not occur when the saturated dimer (XI) was hydrogenated, while fission did occur when the unreduced dimer (V) was hydrogenated under the same conditions. When the hydrogenation over Raney nickel was carried out at 185° for eighteen hours, only one product was obtained, namely, 4-*n*-propylcyclohexanol (I) in a yield of 85%. Under these conditions both ether cleavage and reduction of the aromatic rings apparently occurred.

Hydrogenation[12] of VI.—Using Raney nickel catalyst, ethanol–water (1:1), 3% alkali, a

temperature of 165°, time of four hours, and at an initial hydrogen pressure of 2950 p.s.i., the only reaction product obtained was the dimer with the side chain saturated, namely, 2,3-diveratrylbutane (XII). The same result was obtained using copper–chromium oxide catalyst at 150–160° for one hour. This reduced dimer (XII) when hydrogenated over the latter catalyst at 185–190° for twelve hours underwent reduction of the aromatic rings, but no fission occurred. The product isolated was 2,3-bis-(hexahydroveratryl)-butane (XIII). Substitution of the copper–chromium oxide catalyst in the last reduction by Raney nickel gave, under the same conditions, only the one product, namely, 1,4-bis-(4-hydroxycyclohexyl)-2,3-dimethylbutane (XIV). The latter, on hydrogenation at 225–230° over Raney nickel and at 260 and 280° over copper–chromium oxide catalyst, was recovered unchanged with gasification to the extent of 10, 20 and 38%, respectively.

These experimental results apparently substantiate Hibbert's theories regarding the types of linkages found in native lignin. It would appear that a portion of the lignin contains easily cleaved linkages, in all probability, ether linkages. The greater portion of the hydrogenated native lignin consists of a complex mixture of dimeric, trimeric, etc., type of substances since hydrogenolysis of a carbon–carbon linkage does not occur even at 280° over copper–chromium oxide catalyst, it seems that the dimers obtained from the hydrogenation of spruce wood do not arise by the cleavage of more complex polymers.

Experimental

Hydrogenation of IV.—2,2′-Divanilloyl diethyl ether (IV) was hydrogenated in a small Parr bomb of 500-cc. capacity under the various conditions given in Table I.

The product (A) (0.85 g.) obtained in the first hydrogenation was dissolved in ethereal diazomethane solution (200 cc.) and the solution allowed to stand overnight at 0°. The solvent and excess diazomethane were removed under reduced pressure and the resulting product re-methylated to completion, as shown by a negative ferric chloride–phenol test. This methylated product was distilled under reduced pressure yielding two fractions (i) and (ii).

(i) **Low-boiling Fraction.**—Bath temperature at 80–90° (0.1 mm.); yield, 0.51 g. The oily product was analyzed to determine whether cleavage of the dialkyl ether linkage occurred. The methods used were methoxyl and Smith–Bryant[13] hydroxyl determinations.

Anal. Calcd. for cleavage mixture: OH, 4.54; OCH_3, 32.9. Found: OH, 4.5; OCH_3, 32.8.

(ii) **High-boiling Fraction.**—Bath temperature at 150–153° (0.01 mm.); yield, 0.28 g.

Anal. Calcd. for $C_{22}H_{30}O_5$: OCH_3, 33.1. Found: OCH_3, 33.1.

The product (B) from the second hydrogenation of 2,2′-divanilloyl diethyl ether was distilled under reduced pressure yielding the two fractions (i) and (ii).

(i) **First Fraction.**—Bath temperature at 115–119° (15 mm.); yield, 0.31 g. The phenyl urethan of this distillate was prepared (m. p. 127–128°) and a mixed melting point determination with the phenyl urethan of 4-*n*-propylcyclohexanol showed no depression.

(ii) **Second Fraction.**—Bath temperature at 119–123° (0.1 mm.); yield, 0.35 g. The product (0.35 g.) was dissolved in a mixture containing chromic oxide (1.1 g.), glacial acetic acid (10 cc.), water (5.5 cc.) and benzene (20 cc.) in a small Erlenmeyer flask. The reaction mixture was shaken at room temperature during nineteen hours, the benzene layer removed and the dark green acid mixture extracted with three portions (10 cc.) of benzene. The combined benzene solutions were washed once with water (15 cc.) to remove suspended chromic acid, then extracted with four portions (10-cc. each) of sodium carbonate solution (10%). The carbonate solution was cautiously acidified with dilute hydrochloric acid and the milky solution extracted with five portions (10 cc. each) of benzene. The combined benzene solutions were dried over anhydrous sodium sulfate and the solvent removed under reduced pressure. The yield of the resulting oil was 0.17 g. This oil was dissolved in aqueous ethanol (50%, 1 cc.) and added to a solution consisting of semicarbazide hydrochloride (0.2 g.), potassium acetate (0.25 g.) and water (5 cc.). The solution was heated at 60° for ten minutes and the crystalline product which separated was removed by filtration and recrystallized twice from hot water; yield, 0.09 g., m. p. 200–202°. A mixed melting point determination with an authentic sample of the semicarbazone of 3-(4-cyclohexanone)-1-propanoic acid showed no depression, thereby indicating that the original product, prior to the chromic acid oxidation, was 3-(4-hydroxycyclohexyl)-1-propanol (II).

The copper–chromium oxide catalytic hydrogenation of 2,2′-divanilloyl diethyl ether (1.0 g.) resulted in a product (C) which after complete methylation with diazomethane, was distilled at a bath temperature of 150–154° (0.01 mm.); yield, 0.88 g.

Anal. Calcd. for $C_{22}H_{30}O_5$: OCH_3, 33.1. Found: OCH_3, 33.0.

Hydrogenation of V.—The second dimer (V) was hydrogenated under the various conditions indicated in Table II. The resulting products were isolated by alkaline separation into phenolic and non-phenolic fractions, dis-

[b] Products 1, 4 are identical 
[c] Products 2, 3, 6, 7, 8 are identical 
[d] Product 5 is 
tilled under reduced pressure and finally identified by ultimate analysis. In each case the low-boiling phenolic fractions were shown to be 4-hydroxy-3-methoxyphenylpropane by the formation of the *p*-nitrobenzoate (m. p. 73.5–74.5°). A mixed melting point determination with an authentic sample of the *p*-nitrobenzoate of 4-hydroxy-3-methoxyphenylpropane showed no depression.

The final hydrogenation over Raney nickel resulted in one product only, 4-*n*-propylcyclohexanol. The phenyl urethan (m. p. 127–128°) was prepared and a mixed melting point determination with an authentic sample of the phenyl urethan of 4-*n*-propylcyclohexanol showed no depression.

Hydrogenation of VI.—The third dimer (VI) was hydrogenated and the products rehydrogenated under the various conditions given in Table III. Examination of the products indicated reduction of the carbonyl groups, demethylation, demethoxylation and/or ring reduction. However, cleavage of the carbon-to-carbon linkage in the side chain did not occur even at 280°.

Acknowledgment.—The authors gratefully acknowledge the kind financial assistance of the Canadian Pulp and Paper Association and the Spruce Falls Power and Paper Company.

Summary

1. Three dimeric compounds, containing linkages similar to those in the complex structure of

native lignin, have been hydrogenated under similar conditions to those used in the hydrogenation of spruce wood.

2. The ether-linked dimers cleaved at the ether linkage, yielding products similar to those found in the reaction mixture after hydrogenation of spruce wood.

3. The carbon-to-carbon linked dimer did not yield fission products although nuclear reduction occurred. This apparently substantiates the opinions of Hibbert that dimeric, trimeric, etc., substances obtained by the hydrogenation of wood do not arise through the carbon-to-carbon cleavage of similar but more complex polymers. It would therefore appear that these complex substances exist as such in the wood prior to the hydrogenation reaction.

Studies on Lignin and Related Compounds. LXXXVII. High Pressure Hydrogenation of Maple Wood[1]

BY JAMES M. PEPPER[2] AND HAROLD HIBBERT[3]

Although abundant evidence is available[4] which points to the now well-recognized essentially aromatic character of native lignin, the actual yield, to date, of identified products, is in no case very large. By means of the ethanolysis procedure[5] all of the identified lignin products obtained from maple wood are *propylphenol* derivatives but amount to only 9.75% of the original lignin (Klason basis).[6] From nitrobenzene oxidation studies[7] much larger amounts of aromatic compounds are obtained, the total mixed aldehydes (vanillin and syringaldehyde) have been isolated in yields of 43% of the lignin, but in this case it must be remembered that these derivatives have only a C_6–C skeleton and as such cannot be used as positive evidence for the presence of a C_6–C–C–C lignin monomer. Much higher yields of C_6–C–C–C compounds have been obtained by means of the high pressure hydrogenation technique[4] but in every such case these have been *propylcyclohexyl* derivatives, and, although it is improbable that these could arise from any source except a propylphenyl unit, it still remained necessary to isolate the *aromatic* C_6–C–C–C units in high yields to justify the several formulas for native lignin that have been proposed.[4,8]

In a previous communication[9] a new technique has been described by which, under greatly milder conditions of hydrogenation and hydrogenolysis, propylphenol lignin derivatives have been isolated and identified. The apparent advantages of such a method include, apart from the value of the results obtained, the use of a starting material containing *all* of the lignin *in situ* and the stabilization, by reduction, of any reactive groups formed during the pressure cook thereby preventing any subsequent polymerization which might otherwise occur. It was thought that if it were possible to remove the entire lignin fraction from the wood by this means greatly increased yields of aromatic lignin products could be obtained. To effect this a detailed study of the conditions of isolation was undertaken and subsequently when it was found possible to isolate all the lignin as a chloroform-soluble product, characterization of this material was commenced in an attempt to increase the yield of aromatic derivatives.

Preliminary Experiments.—A concurrent investigation[9] had shown that for the hydrogenation of maple wood in a neutral medium (ethanol–water (1:1)), the optimum conditions for lignin removal were 165–170° for four hours at an initial pressure of 3000 lb./sq. in. Such a medium, after the cooking procedure, had a *p*H of 5.5, and this slight acidity may have been sufficient to bring about an effective hydrolysis of any existent lignin–carbohydrate complex. This fact initiated a series of experiments[10] to study the effect of *p*H on the lignin removal by this newly developed technique. Complete solution of the lignin was obtained in both acidic and basic media. The extensive use of an acid medium (hydrochloric acid) was not favored for the following reasons: (a) poisoning of the catalyst (Raney nickel) which does not take place in alkali; (b) the tendency toward increased polymerization which is minimized in alkali due to the blocking of the phenolic hydroxyl groups, and (c) the increased tendency toward formation of hydroaromatic derivatives at a lower temperature.[11]

Dioxane was chosen to replace ethanol in the final large-scale hydrogenation experiments in

order to prevent any ethoxylation occurring at the elevated temperatures. Duplicate hydrogenation experiments using, on the one hand, a dioxane–water (1:1) solvent and on the other, an ethanol–water (1:1) solvent, showed that in the latter case and not in the former ethoxyl groups (as determined by the method of Cooke and Hibbert)[12] were present to the extent of 5.6%.

Large-scale Hydrogenation Experiments.—In order to obtain the reaction products in amounts sufficient to permit of a detailed study, two 500-g. portions (Series A and B) of extracted wood meal were suspended in dioxane–water (1:1) containing sodium hydroxide (3%) and hydrogenated over Raney nickel catalyst[13] at 173° (initial pressure of hydrogen of 3000 lb./sq. in.) for six hours and the combined products, in each case, treated in the following manner.

After separation of the catalyst and residual wood meal, the filtrate was acidified (congo red) in the presence of chloroform and then thoroughly extracted with chloroform. The residual meal was similarly extracted in a Soxhlet extractor and the two chloroform extracts combined. This process effected an almost complete separation of the extracted lignin from carbohydrate contaminants. From Series A the total chloroform-soluble fraction was distilled from a Claisen flask thus separating it into the fractions: A1, distilling below 150° (bath temperature) (1 mm.); A2, distilling below 250° (1 mm.), and A3, a non-distillable resin. The low-boiling fraction, A1, was divided into water-insoluble (A1x) and water-soluble (A1y) portions and the former (A1x) fractionally distilled through the recently developed spiral screen packed laboratory column[14] (twenty-one theoretical plates) to yield (4-hydroxy-3-methoxyphenyl)-ethane and (4-hydroxy-3,5-dimethoxy-phenyl)-ethane, identified by the preparation of their *p*-nitrobenzoates and comparison with the *p*-nitrobenzoates of authentic samples.

The preparation of Series B was necessary in order to replace the fraction A2 from Series A which was not studied completely. By a treatment similar to that given for Series A, the total chloroform-soluble fraction from Series B, after distillation through a Claisen flask, was divided into four portions according to their boiling ranges: B1, distilling below 180° (bath temperature) (1.2 mm.); B2, at 180–215° (1 mm.); B3, at 215–280° (0.1 mm.) and B4, a non-distillable resin. Distillates B2 and B3 were combined, divided into a water-soluble portion (Bx) and a water-insoluble portion (By) and each of these fractions then fractionally distilled through the spiral screen packed column. From the former portion (Bx) was isolated the crystalline material 2-(4-hydroxy-3,5-dimethoxyphenyl)-ethanol, identified by formation of the phenyl urethan of its 4-methoxy derivative. The fractionation of the latter portion (By) yielded (4-hydroxy-3,5-dimethoxyphenyl)-ethane, and a fraction which crystallized in the condenser, subsequently identified as 2-(4-hydroxy-3,5-dimethoxyphenyl)-ethanol by a mixed melting point determination with the previously identified material.

In order to obtain the maximum amount of the isolated lignin as identified products, all the non-distillable (resin) fractions as well as the distilled fractions which were not identified from the various fractionation procedures were combined and rehydrogenated under the conditions (at 280° for twelve hours, initial pressure 3000 lb./sq. in.) used previously.[15] The object was to convert them, if possible, into the known cyclohexyl derivatives: 4-*n*-propylcyclohexanol, 3-cyclohexyl-1-propanol, 3-(4-hydroxycyclohexyl)-propanol-1 and 4-*n*-propylcyclohexane-diol-1,2. Rehydrogenation of the resins followed by fractional distillation of the product yielded three "flats"[15a] whose empirical analyses and molecular weights showed them to be derivatives of the "dimeric" type. Further study on these fractions was not carried out. Similar retreatment of the unidentified fractions and fractionation of the product yielded a distillation curve showing three "flats" which were identified, by means of their phenylurethans, as 4-ethylcyclohexanol, 4-*n*-propylcyclohexanol and 3-cyclohexyl-1-propanol.

Discussion

Although the entire native lignin has been obtained as a chloroform-soluble material, only a minor part (27.4% on a Klason lignin basis) has been characterized as combined alkylphenolic and alkylcyclohexyl derivatives. However during the various fractionation treatments, a total of 66% (by weight) of the isolated lignin products were distilled through the twenty-one or twenty-eight plate columns[14]: a convincing indication of their relatively simple (low molecular weight) nature and thermal stability. Of the distillable products from 500 g. of maple wood, 45.4 g. of lignin products (42.7% of the Klason lignin) existed either as identifiable "flats" or as crystalline material. A summary of the identified products, from 500 g. of maple wood, their yields, refractive indices and melting points of their characterizing derivatives is given in Table I.

The previously observed more readily extractable syringyl components of the native lignin from maple wood, as compared with those of the guaiacyl type, finds confirmation in these results: the guaiacyl and syringyl components being isolated in a ratio of 1 to 10. Significant, too, is the fact that after removal of the more easily distillable portion of the hydrogenation products,

rehydrogenation of the resins at elevated temperatures (280° instead of 173°) yielded products polymeric in type and having the same general characteristics (empirical analyses, refractive indices, boiling points and molecular weights) as those obtained from the analogous spruce resins which are in all probability polymers having the guaiacyl-type nucleus. Also it may be noted that since rehydrogenation of the resins under the conditions used for direct hydrogenation of wood did *not* give any propylcyclohexyl derivatives, the source of these compounds was the more easily isolated aromatic units obtained by the initial milder treatment.

Comparison of these results with those of Brewer, Cooke and Hibbert[9] shows the pronounced and somewhat drastic effect of the alkali (other conditions being similar) in the isolation of C_6–C–C units and not C_6–C–C–C units as was the case with the neutral medium. The isolation of these C_6–C–C units and most especially the 2-(4-hydroxy-3,5-dimethoxyphenyl)-ethanol, would seem to indicate their derivation from a polymeric form in which the side chains of the building units are united through an oxygen linkage in the beta position. The presence of this type of linkage in all plant resins (lignans) has been repeatedly emphasized by Erdtman[17] and Haworth.[18]

Experimental

Preparation of Maple Wood Meal.—Maple wood meal (40-mesh) was extracted continuously with a mixture of ethanol and benzene (4:1) for forty-eight hours, then with ethanol for twenty-four hours, washed overnight with hot water, air-dried for three days and finally dried in a vacuum oven at 50–55° (15 mm.) for thirty-six hours.

Anal. Moisture, 3.5; OCH_3, 5.95; Klason lignin, 20.6.

Hydrogenation of Maple Wood (Series A and B).—Seven portions of solvent extracted maple wood meal together totaling 500 g. (Series A) were hydrogenated in an Aminco hydrogenator (2500 cc. capacity). A typical run is described as follows: wood meal (75.5 g.) was suspended in dioxane–water (1:1) (900 cc.) containing sodium hydroxide (27 g.) and hydrogenated over Raney nickel catalyst (55 g.) (wet with ethanol) at 173° (initial hydrogen pressure, cold, 3000 lb./sq. in.) for six hours. At the end of this time hydrogen absorption had ceased, the total hydrogen used being 0.38 mole per 100 g. of wood. A further seven portions of similar wood meal together weighing 500 g. (Series B) were hydrogenated under the same conditions. For each series the bomb contents were examined initially by the procedure outlined previously. For Series A, from the 500 g. wood meal there was obtained 364 g. of dried pulp and catalyst (equivalent approximately to 130 g. of residual pulp), and a chloroform soluble fraction containing 107.3 g. of hydrogenation products.

Examination of the Hydrogenation Products (Series A).—The total chloroform soluble fraction (107.3 g.) was distilled from a Claisen flask, thus dividing it into three portions; fraction A1 (36.7 g.) distilling below 150° (bath temperature) (1 mm.), fraction A2 (26.5 g.) distilling 150 to 250° (1 mm.) and a non-distillable resin A3 (26.0 g.). Distillate A1 (36.7 g.) was dissolved in chloroform (300 cc.) and extracted successively with five portions of saturated sodium bicarbonate solution giving a bicarbonate- and water-insoluble fraction A1x (25.9 g.) and a bicarbonate-soluble fraction A1y.

Fractional Distillation of Bicarbonate- and Water-Insoluble Fraction A1x.—Fraction A1x (24.6 g.) was fractionated through the Cooke–Bower spiral screen type fractionating column (14) (twenty-one plates). Two distinct "flats" were obtained, one in the $n^{25}D$ 1.5230–1.5251 range and the second in the $n^{25}D$ 1.5323–1.5344 range. Conversion of test samples from the first "flat" into their *p*-nitrobenzoates showed the former to be 4-hydroxy-3-methoxyphenylethane (m. p. of the *p*-nitrobenzoate 98–99°, mixed m. p. with an authentic sample showed no depression).

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.0; H, 7.9; OCH_3, 20.4. Found: C, 70.4; H, 7.8; OCH_3, 20.5.

The second "flat" upon similar treatment proved to be 4-hydroxy-3,5-dimethoxyphenylethane (m. p. of the *p*-nitrobenzoate 153.5–154.5°, mixed m. p. with an authentic sample gave no depression).

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.9; H, 7.8; OCH_3, 34.1. Found: C, 65.2; H, 7.; OCH_3, 33.6.

Examination of the Hydrogenation Products (Series B).—The total chloroform-soluble fraction (123.1 g.) was distilled from a Claisen flask thus dividing it into four portions; fraction B1 (33.8 g.) distilling below 180° (bath temperature) (1.2 mm.), fraction B2 (23.4 g.) distilling 180 to 215° (1 mm.), fraction B3 (15.2 g.) distilling 215 to 280° (0.1 mm.) and a non-distillable resin B4 (48.6 g.). Distillates B2 and B3 were combined (38.7 g.), dissolved in chloroform (150 cc.) and extracted with water (4 × 30 cc.) and the aqueous extract back-extracted once with chloroform (20 cc.). This yielded a water-soluble fraction Bx (5.0 g.) and a water-insoluble fraction By (33.3 g.).

Fractional Distillation of Water-soluble Fraction Bx.—The water-soluble fraction Bx (5.0 g.) was fractionated through the twenty-one plate column. Distillation was discontinued when a white crystalline material accumulated in the take-off condenser. The combined distillates (2.71 g.) contained no identifiable "flats" but the crude crystalline material (1.15 g.) was partially identified as 2-(4-hydroxy-3,5-dimethoxyphenylethanol (0.82 g.) (see below). The non-distillable resin (0.76 g.) was rehydrogenated (see below).

Fractional Distillation of Water-insoluble Fraction By.—The water-insoluble fraction By (33.3 g.) was fractionated as before (28-plate column). The distillation was discontinued when, as before, a crystalline material accumulated in the condenser. This effected a separation into a distilled portion (17.12 g.), an undistilled portion (14.3 g.) and the residue (crystalline) remaining in the condenser and column (0.94 g.). The fractionation curve of the distilled portion showed one pronounced "flat" in the $n^{25}D$

---

(16) Reported by Reichstein (*Helv. Chim. Acta*, **15**, 1450 (1932)) to be 100°.

(17) Erdtman, *Svensk Papperstidn.*, **44**, 243–253 (1941).

(18) Haworth, *J. Chem. Soc.*, 448 (1942).

1.5320–1.5339 range. Conversion of test samples of this "flat" into their *p*-nitrobenzoates showed this product to be 4-hydroxy-3,5-dimethoxyphenylethane (m. p. of the *p*-nitrobenzoate 153.5–154.5°, mixed m. p. with an authentic sample showed no depression).

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.9; H, 7.8; OCH_3, 34.1. Found: C, 65.3; H, 7.8; OCH_3, 33.8.

Isolation and Identification of 2-(4-Hydroxy-3,5-dimethoxyphenyl)-ethanol. Isolation.—The undistilled portion (14.3 g.) of the water-insoluble fraction By was distilled through a "goose-neck,"[19] thus separating it into a distillate (13.0 g.) and a non-distillable resin (1.2 g.). Washing of the distillate, which had become partially crystalline on standing, with ether removed the occluded non-crystalline fraction (8.2 g.) and left a non-ether-soluble crystalline portion (4.8 g.). Added to this was the material obtained from the column holdups in the fractionation of the water-insoluble fraction By (0.94 g.) and in the fractionation of the water-soluble portion Bx (0.82 g.) to give a total recovery of the pure material of 6.6 g. A sample of this crystalline product was recrystallized from ether-petroleum ether and from ethanol–petroleum ether and melted 116–117°.

Anal. Calcd. for $C_{10}H_{14}O_4$: C, 60.6; H, 7.1; OCH_3, 31.1. Found: C, 60.7; H, 6.9; OCH_3, 31.3.

Identification.—2-(4-Hydroxy-3,5-dimethoxyphenyl)-ethanol (0.6 g.) was methylated with diazomethane (three times), the methylated product dissolved in acetone–water (1:1) (20 cc.) and oxidized by boiling for one hour with a 3% solution of potassium permanganate (40 cc.). The reaction mixture was extracted with ether, then acidified and again extracted with ether. The second extract contained 3,4,5-trimethoxy-benzoic acid (0.12 g.); recrystallized from ether–petroleum ether, m. p. 167–168°; no m. p. depression when mixed with an authentic sample of 3,4,5-trimethoxybenzoic acid. This gave strong evidence that the compound had a syringyl type nucleus. 2-(4-Hydroxy-3,5-dimethoxyphenyl)-ethanol (1.0 g.) was methylated (four times) with diazomethane (400% excess). The methylated product was distilled at 220–235° (bath temperature) (0.02 mm.); yield 0.44 g.

Anal. Calcd. for $C_{11}H_{16}O_4$: OCH_3, 43.8. Found: OCH_3, 43.6.

The 2-(3,4,5-trimethoxyphenyl)-ethanol was identified by preparation of the α-naphthyl urethan derivative, m. p. 132–133°; mixed m. p. with an authentic sample showing no depression.

Rehydrogenation of Resins from Claisen and Fractional Distillations of the Hydrogenation Products from Series B.—Part (42.0 g.) of the non-distillable resins (50.5 g.) obtained during the fractionation of the hydrogenation products of Series B were dissolved in dioxane (645 cc.) and hydrogenated over copper chromium oxide (18 g.) at 255° (initial hydrogen pressure, cold, 3000 lb./sq. in.) for six hours. Total hydrogen absorption was 3.4 moles per 100 g. of resin. Half of the product from this hydrogenation (14.9 g.) (4.2% methoxyl) was dissolved in dioxane (200 cc.) and rehydrogenated over copper chromium oxide (6.0 g.) at 280° (initial hydrogen pressure, 3000 lb./sq. in.) for six hours. Total absorption was 1.81 moles per 100 g. starting material.

The colorless, methoxyl-free product (12.5 g.) was fractionated through the previously described column (28-plates) to yield a distillable fraction (9.39 g.) and a non-distillable fraction (2.81 g.). The fractionation curve showed three "flats" in the $n^{25}\mathrm{D}$ 1.4882–1.4900 (I), 1.4909–4910 (II) and 1.4992–1.5007 (III) ranges.

Anal. Found for "flat" I: C, 79.9; H, 11.9; mol. wt. (Rast), 235. II: C, 81.3; H, 12.7; mol. wt. (Rast), 215. III: C, 82.5; H, 12.6; mol. wt. (Rast), 288.

Rehydrogenation of Non-identified Portions from Fractional Distillations of Hydrogenated Products, Series A and B.—All the non-identified portions, representing 7.57 g. from Series A and 16.43 g. from Series B, were combined (24.0 g.), dissolved in dioxane (200 cc.) and rehydrogenated over copper chromium oxide (9.29 g.) at 280–290° (initial hydrogen pressure, 3000 lb./sq. in.) for eighteen hours. The product (10.1 g.) was fractionated through the 28-plate column, yielding a distillable portion (7.63 g.) and a non-distillable resin (2.37 g.). The distillation curve showed three "flats," in the $n^{25}\mathrm{D}$ 1.4582–1.4611, 1.4616–1.4629 and 1.4650–1.4664 ranges. Conversion of test samples from these "flats" into their phenyl urethans showed these products to be 4-ethylcyclohexanol, m. p. of phenyl urethan 113.5–114.5°; 4-*n*-propylcyclohexanol, m. p. of phenyl urethan 124–125°; and 3-cyclohexyl-1-propanol, m. p. of phenyl urethan 83–84°, respectively; mixed melting points with authentic samples of their phenylurethanes showing no depression.

Syntheses of Reference Compounds

(1) **Synthesis of 4-Hydroxy-3-methoxyphenylethane.**—4-Hydroxy-3-methoxyphenyl methyl ketone (10.0 g.) was dissolved in ethanol (100 cc.) and hydrogenated (initial hydrogen pressure, cold, 2950 lb./sq. in.) over Raney nickel (4.0 g.) at 180–190° for thirty-five minutes. The product (7.8 g.) on distillation gave a fraction b. p. 90–100° (15 mm.), $n^{25}\mathrm{D}$ 1.5281, whose *p*-nitrobenzoate derivative, recrystallized from ethanol–water, melted at 98–99°. Reported m. p. of this compound is 100°.[16]

(2) **Synthesis of 4-Hydroxy-3,5-dimethoxyphenylethane.**[20] **A. Preparation of 1-Acetyl-2,6-dimethylpyrogallol.**—2,6-Dimethylpyrogallol (5.0 g.) was dissolved in anhydrous benzene (5.0 cc.) containing anhydrous pyridine (3.3 g.) and acetyl chloride (3.0 g.) added dropwise to the vigorously stirred solution. The mixture was then heated at 60° for two hours, cooled and filtered. Removal of the solvent from the filtrate and distillation of the residual oil at 120–130° (bath temperature) (0.01 mm.) gave the required product: yield, 5.7 g.

Anal. Calcd. for $C_{10}H_{12}O_3$: OCH_3, 31.6. Found: OCH_3, 31.0.

B. Preparation of 4-Hydroxy-3,5-dimethoxyphenyl Methyl Ketone.—1-Acetyl-2,6-dimethylpyrogallol (5.7 g.) and powdered anhydrous aluminum chloride (7.7 g.) were added to nitrobenzene (35 cc.) in a three-necked flask fitted with a mercury-sealed stirrer and a reflux condenser. The solution was stirred for two hours at 2–5°, allowed to stand at room temperature for twenty-two hours and then poured into a mixture of ice (250 g.) and concentrated hydrochloric acid (25 cc.). The resultant product, after solvent removal, was distilled at 160–175° (bath temperature) (0.01 mm.) to yield a crystalline product (0.80 g.); recrystallized from ether, m. p. 121–122°. A mixed m. p. with an authentic sample showed no depression.

C. Reduction of 4-Hydroxy-3,5-dimethoxyacetophenone.—4-Hydroxy-3,5-dimethoxyacetophenone (0.4 g.), zinc amalgam (amalgamated prior to use) (20 g.) and 50% hydrochloric acid (100 cc.) were refluxed for six hours. The resultant product was distilled at 160–170° (bath temperature) (0.02 mm.): yield, 0.17 g.

Anal. Calcd. for $C_{10}H_{14}O_3$: OCH_3, 34.1. Found: OCH_3, 33.8. The *p*-nitrobenzoate derivative of this oil, recrystallized from ethanol–water and ether–petroleum ether, melted at 151–152°.

(3) **Synthesis of 2-(3,4,5-Trimethoxyphenyl)-ethanol.**[21] **A. Preparation of 3,4,5-Trimethoxybenzoyl Chloride.**—Trimethylgallic acid (2.0 g.) and purified thionyl chloride (7 cc.) were heated under reflux in an all-glass apparatus for one hour. The reaction mixture was then transferred to a small Claisen flask and the excess thionyl chloride removed by co-distillation with anhydrous benzene. The resulting product was used directly in the next procedure.

B. Preparation of 3,4,5-Trimethoxyphenyl Diazomethyl Ketone.—The 3,4,5-trimethoxybenzoyl chloride

---

(19) A "goose-neck" consists of a piece of 6 mm. (i. d.) tubing, 12.5-cm. in length bent at the middle to an angle of 60° and connected to the distillation pot through a ground joint.

(20) Synthesized by Samuel B. Baker.

(21) Synthesized by Samuel B. Baker and James M. Pepper.

(see above) was dissolved in benzene and the solution added slowly to an ethereal solution of diazomethane prepared from nitrosomethylurea (7.0 g.) and allowed to stand at 0° for sixteen hours. The solvent, together with the excess diazomethane, were removed under reduced pressure. The crude product (2.1 g.) was used directly in the following procedure.

C. Hydrolysis of 3,4,5-Trimethoxyphenyl Diazomethyl Ketone.—The 3,4,5-trimethoxyphenyl diazomethyl ketone (2.1 g.) (see above) was hydrolyzed by heating at 70° for three hours with aqueous 2% sulfuric acid (100 cc.). The solution, after cooling, was extracted with chloroform, the chloroform solution dried and the solvent removed. The resulting product was recrystallized from ether: yield, 1.5 g., m. p. 77–78°.

Anal. Calcd. for $C_{11}H_{14}O_5$: OCH_3, 41.1. Found: OCH_3, 40.85.

D. Reduction of 3,4,5-Trimethoxyphenyl Hydroxymethyl Ketone.—3,4,5-Trimethoxyphenyl hydroxymethyl ketone (1.0 g.) was dissolved in ethanol (100 cc.) and hydrogenated over copper chromium oxide (0.5 g.) at 150–160° for one hour. The bomb contents were filtered, the filtrate concentrated under reduced pressure and the resulting yellow oil distilled at 220–240° (bath temperature) (0.02 mm.): yield, 0.8 g.

Anal. Calcd. for $C_{11}H_{16}O_4$: OCH_3, 43.8. Found: OCH_3, 43.5.

The α-naphthyl urethan derivative of this oil melted at 131–133°.

Acknowledgment.—The authors wish to thank the National Research Council of Canada for the award of two studentships to one of them (J. M. P.) and also the Canadian Pulp and Paper Association for their kind financial assistance. The authors also wish to thank Dr. R. F. Patterson who so kindly assisted in the lengthy continuous fractionation procedures.

Summary

1. Maple wood meal has been suspended in dioxane containing 3% sodium hydroxide and hydrogenated over Raney nickel catalyst using an initial pressure of 3000 lb./sq. in. and a temperature of 170° and complete conversion of the lignin portion of the wood into chloroform-soluble products has been effected.

2. From the reaction mixture three new lignin aromatic degradation products were isolated: 4-hydroxy-3-methoxyphenylethane, 4-hydroxy-3,5-dimethoxyphenylethane and 2-(4-hydroxy-3,5-dimethoxyphenyl)-ethanol in yields of 2.2, 15.4 and 6.2% (based on the Klason lignin content of the wood), respectively.

3. The syntheses of 4-hydroxy-3-methoxyphenylethane, 4-hydroxy-3,5-dimethoxyphenylethane and 2-(3,4,5-trimethoxyphenyl)-ethanol were accomplished.

4. The isolation of these lignin derivatives thus provides further confirmatory evidence for the essentially aromatic (alkylphenolic) nature of lignin; and for the belief that the lignin of hardwoods is composed of units of both the guaiacyl and syringyl types, compounds containing the latter type being the more readily isolated.

5. The isolation of 2-(4-hydroxy-3,5-dimethoxyphenyl)-ethanol as a lignin degradation product provides some evidence for a carbon–oxygen linkage through the β-carbon atom of the alkyl side chain.

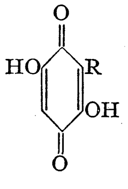
Synthesis of Embelin, Rapanone and Related Quinones by Peroxide Alkylation[1]

BY LOUIS F. FIESER AND EARL M. CHAMBERLIN

Embelin, an orange pigment isolated from the berries of the Indian shrub *Embelia ribes*, is of interest because of early reports that the substance, like the fruit from which it is derived, possesses valuable properties as an anthelmintic agent, particularly against tapeworm.[2] Degradative studies of the substance led to varying conclusions[3]; then Hasan and Stedman[4] synthesized 2,5-dihydroxy-3-lauryl-1,4-benzoquinone (II) and an isomer and concluded from the results of their comparisons that embelin is identical with synthetic II. More recently Asano and Yamaguti[5] obtained analytical data pointing to a structure with one less methylene group. The latter investigators synthesized both II and the lower homolog I and found that both quinones have very nearly the same melting point as embelin and give no depression when mixed with the natural pigment. However, they observed that although the three hydroquinone tetraacetates likewise had very similar melting points, the derivative of II gave a definite, slight depression when mixed with the embelin derivative (Hasan and Stedman indeed reported a mixed melting point 1–2° below that of either component). We have not found in the Japanese paper any statement of a comparison of the derivatives of I and of embelin.



I, R = $-(CH_2)_{10}CH_3$
II, R = $-(CH_2)_{11}CH_3$
III, R = $-(CH_2)_{12}CH_3$

Asano and Yamaguti[6] further characterized a pigment rapanone isolated (by Kawamura, 1937) from the bark and woody portion of *Rapanea maximowiczii* and assigned to it the structure II on the basis of degradation and synthesis. They synthesized III and the next higher homolog and showed that these quinones likewise give no melting point depressions when mixed with the natural pigment, but that a differentiation can again be made by comparison of the hydroquinone tetraacetates.

We have now synthesized the homologs I, II and III by causing the appropriate diacyl peroxide to decompose in an acetic acid solution containing 2,5-dihydroxybenzoquinone.[7] The yields were low and in the first instance the dialkyl derivative was isolated as a by-product, but small amounts of the pure pigments can be prepared readily by this method. Our comparison of natural embelin with the synthetic substances and their derivatives confirms the conclusion of Asano and Yamaguti[5] that embelin has the structure I (see table).

TABLE I

MELTING POINTS, °C.

Substance	Hasan and Stedman	Asano and Yamaguti	Fieser and Chamberlin
		Quinones	
Embelin	143	142	142–143
I	...	143–144	145–146
II	143	142	142–143
Embelin + I	...	143–144	.....
Embelin + II	143	142	.....
I + II	...	.....	144–145
		Hydroquinone Tetraacetates	
Embelin	121	123.5	125–126
I	...	124	124.5–125.5
II	121	120	120–121
Embelin + I	...	.....	125–126
Embelin + II	119	118	.....
I + II	...	.....	118–119

The depressions observed with mixtures of homologous hydroquinone tetraacetates are very evident to the experimenter even though they amount to only a degree or two.

Some two years after the synthetic work of this paper had been completed, one of us received from O. Fernandez of Madrid a supply of orange pigment melting at 141–142° that had been extracted from *Oxalis purpurata*, Jacq.[8] Analyses indicate the formula $C_{19}H_{30}O_4$, which is that of rapanone (III), and the color, solubilities, melting point, and formation of a hydroquinone tetraacetate, m. p. 116.5–117.5°, all suggested strongly that the substance is a member of the embelin–rapanone series. Mixtures of the pigment with the quinones I–III melted the same as the components or at intermediate temperatures, which definitely places the substance in this series. The hydroquinone tetraacetate did not depress the melting point of the derivative of synthetic III, whereas mixtures with the derivatives of I and II melted at 110.5–111.5° and 114–115.5°, respectively. From these observations we conclude that the pigment isolated from the Spanish plant is identical with rapanone, III.

The orange-red pigment maesaquinone[9] may be another member of the same or a related series, for it has been characterized as a dihydroxybenzoquinone with a C_{20} side chain (or chains) with one double bond. Fieser and Gates[10] noted that the side chain may be a phytyl group, and as a test of this hypothesis we initially planned to try to synthesize 2,5-dihydroxy-3-dihydrophytyl-1,4-benzoquinone for comparison with dihydromaesaquinone. The required acid intermediate was prepared from dihydrophytol through the bromide and the nitrile and found to be a liquid at ordinary temperatures: $CH_3CH(CH_3)CH_2CH_2[CH_2CH(CH_3)CH_2CH_2]_3COOH$ (homophytanic acid). An acid of the same composition was isolated by Hiramoto as a product of the oxidation of dihydromaesaquinone and stated, without supporting evidence, to be heneicosanoic acid (m. p. 75–76°). Since the acid is a solid, the side chain of the saturated quinone can hardly be the dihydrophytyl group. If the side chain is normal, it is possible that maesaquinone is related to one of two known naturally occurring eicosenoic acids, namely, the Δ^{11}-derivative found in the liquid seed wax of *Californica simmondsia;* hence the structure may be IV. The acid intermediate required for the synthesis of IV was prepared from oleyl alcohol by the steps indicated (X = Br or $SO_2C_6H_4CH_3$-*p*)

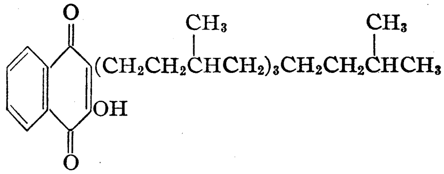
Δ^{12}-Heneicosenoic acid (XII) was obtained as a crystalline solid melting at 56–57°. However, in a trial alkylation of 2,5-dihydroxybenzoquinone with the peroxide from erucic acid, the next higher homolog V was produced (along with the dialkyl derivative) with such difficulty and in so low yield (0.3%) that the synthesis of IV has not yet been attempted. The quinone V melts at 112.5–113.5°; maesaquinone melts at 122°.

Because of the interest in naphthoquinone antimalarials in this Laboratory, the intermediate homophytanic acid was utilized for the synthesis of 2-hydroxy-3-dihydrophytyl-1,4-naphthoquinone. The substance was isolated with difficulty by high vacuum distillation as a yellow oil; it possesses no antirespiratory activity.



XIII

Tests of synthetic embelin and rapanone for their effects on dog helminths kindly conducted at the American University at Beirut by Dr. D. A. Berberian and E. Rajm through the courtesy of Dr. S. E. Kerr were negative (method of M. C. Hall).[11]

Experimental

1. 2,5-Dihydroxy-3-undecyl-1,4-benzoquinone (Embelin), I

Peroxide.—Redistilled lauric acid (44.1 g.) was heated with phosphorus trichloride (11 g.) at 50° for one hour, the upper layer was decanted, treated with a current of dry air to remove excess reagent, and the lauroyl chloride distilled; b.p. 138–142° (15 mm.), yield 45.9 g. (95%). A solution of 45 g. of the acid chloride in 100 cc. of 20–40° petroleum ether was added to a mixture of 100 cc. of petroleum ether, cracked ice, and 20 g. of sodium peroxide. The mixture was shaken vigorously for two minutes and then, after the addition of 15 g. more sodium peroxide and more ice, for ten minutes. The mixture was transferred to a separatory funnel, enough diethyl ether was added to keep the dilauroyl peroxide in solution, and the organic layer was separated, washed, dried, and the solvent removed in vacuum at room temperature. The yield of waxy white solid, dried over potassium hydroxide in vacuum, was 35.5 g. (85%).

Alkylation.—A suspension of 11.2 g. of 2,5-dihydroxybenzoquinone[12] and 35.5 g. of dilauroyl peroxide in 550 cc. of acetic acid was warmed to the point where gas began to be evolved (92°), maintained at that temperature for one-half hour and the solution allowed to stand overnight. A crystallizate that separated proved to be the dialkylated derivative (see below); the filtered solution was concentrated to a small volume in vacuum at steam-bath temperature. Some product separated during the evaporation and was collected after cooling and crystallized in turn from alcohol, benzene and acetic acid. **2,5-Dihydroxy-3-undecyl-1,4-benzoquinone** was thus obtained as glistening orange plates, m.p. 145–146°; yield 1.7 g. (7.2%).

Anal. Calcd. for $C_{18}H_{26}O_4$: C, 69.35; H, 9.19. Found: C, 69.53; H, 8.90.

The **hydroquinone tetraacetate** when recrystallized from alcohol melted at 124.5–125.5° (Asano and Yamaguti,[5] 124°).

Anal. Calcd. for $C_{25}H_{36}O_8$: C, 64.70; H, 7.77 Found: C, 64.36, H, 8.21.

2,5-Dihydroxy-3,6-diundecyl-1,4-benzoquinone.—The material that separated from the cooled alkylation mixture was crystallized from alcohol and found to contain unchanged dihydroxybenzoquinone. The dialkyl derivative could be extracted from the mixture with hot benzene, and it separated from the benzene filtrate as orange crystals. Recrystallization from alcohol gave glistening orange plates, m.p. 129–130°.

Anal. Calcd. for $C_{28}H_{48}O_4$: C, 74.95; H, 10.78. Found: C, 74.99; H, 10.84.

Natural embelin was obtained by extracting dried powdered berries of *Embelia Ribes* (22.4 g.) with ether in a Soxhlet apparatus and digesting the extracted product with petroleum ether. The residue (340 mg.) melted at 141–144.5°, and the material crystallized from absolute alcohol formed glistening orange plates, m.p. 142–143° (Heffter and Feuerstein,[3] 142°). The **hydroquinone tetraacetate**[13] melted at 125–126° (A. and Y.,[6] 123.5°). A mixture of the synthetic and natural tetraacetates showed no depression; m.p. 125–126°.

2. 2,5-Dihydroxy-3-dodecyl-1,4-benzoquinone, II

Tridecylic acid was prepared by a known method[14] as follows. Technical lauryl alcohol was distilled through a Widmer column and a fraction boiling at 168–175° (43 mm.) converted according to Kamm and Marvel[15] into the bromide, b.p. 178–180° (48 mm.), in 91% yield. The nitrile (76% yield) boiled at 153–158° (12 mm.), and the acid (97% yield) boiled at 155–160° (3 mm.) and melted at 44.5–45.5°; the melting point is the same as that reported for tridecylic acid prepared by another synthesis.[16] The conversion to the acid chloride (97%) and the crystalline peroxide (65%) was conducted as in the first section, as was the alkylation of 2,5-dihydroxy-1,4-benzoquinone (2 g.). A precipitate separated from the reaction mixture but was removed and not investigated; the filtrate in the course of several days deposited orange crystals of **2,5-dihydroxy-3-dodecyl-1,4-benzoquinone**. Recrystallized from acetic acid, the substance melted at 142–143° (A. and Y.,[5] 142°). The **hydroquinone tetraacetate** melted at 120–121° (A. and Y.,[5] 120°).

Anal. Calcd. for $C_{18}H_{28}O_4$: C, 70.10; H, 9.15. Found: C, 70.31; H, 9.24.

3. 2,5-Dihydroxy-3-tridecyl-1,4-benzoquinone (Rapanone), III

Synthesis.—By the procedures described above myristic acid was converted into the chloride (97%) and the

peroxide (crystalline solid, 42%) and the latter (6 g.) used for the alkylation of 2,5-dihydroxybenzoquinone (1.7 g.). The material that precipitated from the reaction mixture was recrystallized in turn from methanol, benzene and 95% alcohol and obtained as glistening golden-orange plates, m.p. 141–142° (A. and Y.,[6] 139–140°). The **hydroquinone tetraacetate** melted at 116–117° (A. and Y.,[6] 118°).

From *Oxalis Purpurata*, **Jacq.**—The material as supplied by O. Fernandez was in the form of orange crystals melting at 141–142°. Three further crystallizations from toluene gave lustrous orange plates of the same melting point.

Anal. Calcd. for $C_{19}H_{30}O_4$: C, 70.77; H, 9.38. Found: C, 71.07, 70.86; H, 9.64, 9.43.

A mixture of this substance with the synthetic rapanone described above melted at 141–142°; a mixture with synthetic embelin melted at an intermediate temperature: 142–144°.

The **hydroquinone tetraacetate** formed small colorless needles, m.p. 116.5–117.5°.

Anal. Calcd. for $C_{27}H_{40}O_8$: C, 65.83; H, 8.19. Found: C, 66.13; H, 8.33.

A mixture of this substance and the corresponding derivative of synthetic rapanone melted at 116–117°; the melt readily solidified and remelted at the same temperature.

4. Experiments with Unsaturated Acids

Alkylation of 2,5-Dihydroxybenzoquinone with Dierucoyl Peroxide.—A mixture of 10.9 g. of erucic acid and 8.3 g. of purified thionyl chloride was allowed to stand overnight and then heated on the steam-bath for one-half hour. The excess reagent was removed by evaporation in vacuum with dry benzene and the erucoyl chloride was then distilled by the "unobstructed path" technique of Hickman[17] at a bath temperature of 180–190° (0.08 mm.); the yield of colorless product was 9.4 g. (81%). The peroxide was prepared from 8 g. of the acid chloride as in the other instances but was not isolated from the ether–petroleum ether solution; titration of an aliquot indicated a yield of 56% of peroxide. The solution was then run slowly into a solution at 65° of 0.89 g. of the benzoquinone in 70 cc. of acetic acid and at the rate of evaporation of the low-boiling solvents. The reaction mixture was then refluxed for one-half hour and allowed to stand overnight, when an orange precipitate containing the disubstituted product had separated (see below). The mother liquor was evaporated in vacuum and the residue extracted with petroleum ether. The extract was evaporated in a stream of dry air to a point where a small amount of oily dark solid separated and this was removed by centrifugation. After considerable further processing, the clarified petroleum ether solution, when cooled in Dry Ice, yielded a solid product, and this on spontaneous evaporation of an acetone solution afforded orange crystals of **2,5-dihydroxy-3-(Δ^{12}-heneicosenyl)-1,4-benzoquinone (V)**, m.p. 109–114°. When recrystallized from alcohol–water and from absolute alcohol the substance was obtained in glistening orange plates, m.p. 112.5–113.5°; the yield was only 8 mg. (0.3%).

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.95; H, 10.25. Found: C, 74.98; H, 10.39.

Purification of the less soluble reaction product that separated from the reaction mixture by repeated slow evaporation of a petroleum ether solution afforded 15 mg. (0.6%) of **2,5-dihydroxy-3,5-di-(Δ^{12}-heneicosenyl)-1,4-benzoquinone**, m.p. 84–85°.

Anal. Calcd. for $C_{48}H_{84}O_4$: C, 79.38; H, 11.80. Found: C, 79.43; H, 11.85.

Δ^{12}-Heneicosenoic Acid, XII

Oleyl alcohol was prepared according to Reid and Cockerille[18] except that methyl oleate was employed for reduction with sodium and butyl alcohol; the yield from 1333 g. of methyl oleate, b.p. 140–145° (0.3 mm.) of twice distilled, colorless oleyl alcohol, b.p. 132–142° (0.2 mm.) was 804 g. (67%).

The preparation of **oleyl bromide** by the method of Deatherage and Olcott[19] proved tedious because of the troublesome emulsions encountered, and in batches of 1 mole each the yield was never better than 43% of colorless, fractionated product, b. p. 175–178° (0.6 mm.).

Oleyl *p*-toluenesulfonate was investigated as a possible alternate intermediate and was obtained readily by the method of Tabern and Volwiler[20] by interaction of the alcohol and acid chloride in pyridine and benzene; the crude product was obtained in 94% yield as an oil that failed to crystallize and that decomposed on attempted distillation, but it could be employed satisfactorily in place of the bromide in the malonic acid synthesis.

Methyl Δ^{11}-eicosenoate (VIII) was the next intermediate isolated in a pure form. Oleylmalonic ester proved to be undistillable at 0.1 mm. but on saponification afforded a solid dibasic acid; this was decarboxylated at 160–180° and the product esterified with methanol and sulfuric acid. After an initial rough distillation, the ester was fractionated through a Vigreux column and obtained as a colorless liquid boiling at 164–174 (0.02 mm.). The yield from 100.8 g. of oleyl bromide was 52 g. (53.5%), which represents an over-all yield from oleyl alcohol of 23%. The over-all yield from 588 g. of oleyl alcohol through the tosylate was 189 g. (26%).

Anal. Calcd. for $C_{21}H_{40}O_2$: C, 77.72; H, 12.42. Found: C, 77.76; H, 12.27.

A sample of free **Δ^{11}-eicosenoic acid** (VII) obtained by hydrolysis of the ester, purified through the lead salt, and crystallized from acetone melted at 49–51° (Bodenstein,[21] m.p. 50°).

Butyl Δ^{11}-eicosenate was prepared from 20 g. of the acid, 300 cc. of *n*-butyl alcohol and 4 g. of acetyl chloride at room temperature.[22] After six days the ester was recovered and distilled, b.p. 190–193° at 0.7 mm. (11.5 g.).

Anal. Calcd. for $C_{24}H_{46}O_2$: C, 78.62; H, 12.65. Found: C, 78.70; H, 12.80.

Δ^{11}-Eicosenyl alcohol (IX) was prepared by reduction of 188 g. of methyl Δ^{11}-eicosenate with sodium (66 g.) and *n*-butyl alcohol (1200 cc.) in the usual manner; the yield was 77.3 g. (45%); b.p. 134–146° (0.1 mm.), m.p. 25–26°.

Anal. Calcd. for $C_{20}H_{40}O$: C, 81.01; H, 13.60. Found: C, 80.88, 81.23; H, 13.89, 13.73.

Δ^{12}-Heneicosenoic Acid (XII) A. Through the Bromide.—Δ^{11}-Eicosenyl bromide was obtained by the action of phosphorus tribromide on the alcohol (50 g.) and distilled: b.p. 175–180° (0.7 mm.), yield 27.7 g. (46%). The product was refluxed for thirty hours in 300 cc. of alcohol with 10.7 g. of potassium cyanide dissolved in the minimum amount of water; 120 cc. of 50% sodium hydroxide was then added and refluxing continued for twelve hours. The bulk of the alcohol was distilled, the mixture diluted with water and the white curd of soap collected. The soap was digested with hot acetone and heated with hydrochloric acid until a clear oily layer formed, and the free acid was taken up in ether and the solution clarified with charcoal and evaporated. The residue (dried in vacuum) was a white crystalline solid, m.p. 56–57°; yield 5.5 g. (22% from the bromide, 10% from the alcohol).

B. Through the Tosylate.—The crude tosylate (15.2 g.) from 10 g. of Δ^{11}-eicosenyl alcohol was converted through the nitrile to the acid exactly as in (a) and afforded 5.0 g. of crude acid (46% from the alcohol).

For purification, boiling solutions of 5 g. of the crude acid and 3.5 g. of lead acetate trihydrate, each in 25 cc. of alcohol, were mixed and the lead salt that crystallized was recrystallized from 70 cc. of alcohol and then shaken with

ether and dilute sulfuric acid. The acid recovered from the ether layer on recrystallization from acetone afforded 0.2 g. of pure acid, m.p. 56–57°.

Anal. Calcd. for $C_{21}H_{40}O_2$: C, 77.72; H, 12.43; mol. wt., 324. Found: C, 77.54; H, 12.61; neut. equiv., 322.

5. 2-Hydroxy-3-dihydrophytyl-1,4-naphthoquinone, XIII

Dihydrophytyl Bromide.—Commercial phytol was shaken with catalyst and redistilled and the product (101 g.) was hydrogenated[23] in absolute alcohol (200 cc.) in the presence of Adams catalyst (0.5 g.) and gave 101 g. of **dihydrophytol**, b.p. 157–159° (0.8 mm.). This was converted to the bromide with phosphorus tribromide (92 g.) in carbon tetrachloride (30 cc.) according to Deatherage and Olcott[19] and the product extracted with ligroin. The solution was washed with saturated calcium chloride solution and with 30% methanol, dried and evaporated, and the bromide distilled. The yield of colorless liquid, b.p. 154–156° (0.1 mm.), was 68.3 g. (55%).

Anal. Calcd. for $C_{20}H_{41}Br$: C, 66.46; H, 11.43. Found: C, 66.67; H, 11.52.

Homophytanic Acid (4,8,12,16-Tetramethylheptadecanoic Acid).—Dihydrophytyl bromide (68g.) was refluxed with 15.5 g. of potassium cyanide in 625 cc. of alcohol for twenty-four hours, a solution of 25 g. of sodium hydroxide in 200 cc. of alcohol was added and refluxing continued for another thirty hours. The solution was concentrated to a small volume on the steam-bath, acidified and extracted with ether. For purification, the crude acid (58 g.) was converted to the acid chloride with thionyl chloride (44 g.) and the product refluxed with methanol (500 cc.); the **methyl ester** when twice distilled was a colorless liquid (44.5 g.), b.p. 145–147° (0.1 mm.).

Anal. Calcd. for $C_{22}H_{42}O_2$: C, 77.58; H, 13.02. Found: C, 77.90; H, 13.17.

A solution of the pure ester (44.5 g.) in 300 cc. of methanol was refluxed with 35 g. of potassium hydroxide in 200 cc. of 45% methanol for sixteen hours and the solution was concentrated on the steam-bath to the point of frothing, acidified and diluted. Extraction with ether and distillation afforded 35.2 g. (57% from the bromide) of acid as a clear liquid b.p. 184–188° (1.2 mm.).

Anal. Calcd. for $C_{21}H_{42}O_2$: C, 77.24; H, 12.96. Found: C, 77.48; H, 13.04.

Peroxide.—The acid (10 g.) was converted to the acid chloride with purified thionyl chloride and the excess reagent removed by evaporation in vacuum with benzene. Distillation by the Hickman technique[17] gave 9.9 g. (93%) of the acid chloride, b.p. 150–155° (0.08 mm.). The acid chloride was treated with sodium peroxide, petroleum ether and ice, as above, and the peroxide collected in dried petroleum ether solution and titrated: yield 60%.

Alkylation.—The alkylation was conducted by running the solution of the peroxide into a solution of hydroxynaphthoquinone in acetic acid maintained at 65°. In one experiment the peroxide from 24 g. of acid chloride was caused to react with 3.6 g. of hydroxynaphthoquinone and the material recovered by evaporation of the acetic acid solution in vacuum and the residue was digested with several portions of 70–90° ligroin. The combined extract was cooled in Dry Ice, filtered from hydroxynaphthoquinone and evaporated. The residue was a reddish oil weighing 15.8 g. This was then processed by a procedure used with success for the isolation of vitamin K_1,[24] namely, by extraction of the hydroquinone from petroleum ether with Claisen alkali and oxidation with silver oxide. A small amount (50 mg.) of a viscous red oil was obtained of composition not far from that of the expected product (C, 78.38; H, 11.55).

In a second experiment the crude material resulting from the alkylation of 1 g. of hydroxynaphthoquinone was distilled in high vacuum. At a pressure of 5×10^{-5} mm., 2.63 g. of light yellow oil distilled at a bath temperature of 100°, and then 0.63 g. (24%) of a dark reddish oil distilled at 140–150° that appeared to be substantially pure **2-hydroxy-3-dihydrophytyl-1,4-naphthoquinone**. The substance did not crystallize when an acetone solution was chilled in Dry Ice, but the oil itself solidified in the ice box to waxy orange plates that melted at room temperature.

Anal. Calcd. for $C_{30}H_{46}O_3$: C, 79.24; H, 10.20. Found: C, 79.52; H, 10.54.

The **hydroquinone triacetate** was obtained by crystallization from alcohol as a waxy white solid melting at 79–80°.

Anal. Calcd. for $C_{36}H_{54}O_6$: C, 74.19; H, 9.34. Found: C, 74.40; H, 9.54.

Summary

1. The peroxide alkylation reaction has been applied to the synthesis of the 3-undecyl (I), 3-dodecyl (II) and 3-tridecyl (III) derivatives of 2,5-dihydroxy-1,4-benzoquinone. A comparison with natural embelin confirms the structure I assigned to the pigment by Asano and Yamaguti.

2. A pigment isolated by Fernandez from a plant in Spain has been found identical with synthetic rapanone, III.

3. A structure is suggested for maesaquinone on the basis of certain model experiments.

4. The synthesis of 2-hydroxy-3-dihydrophytyl-1,4-naphthoquinone is described.

Some Isomers of Amidone and Related Compounds

BY NELSON R. EASTON, JOHN H. GARDNER, MARY L. EVANICK AND JOSEPH R. STEVENS

In a recent Communication to the Editor[1] from this Laboratory, it was stated that 4-dimethylamino-2,2-diphenyl-3-methylbutanenitrile, the lower melting nitrile formed in the original Amidone synthesis,[2] reacts with ethylmagnesium bromide to give a ketimine (I), salts of which are readily isolated in a pure state. This ketimine hydrolyzes with difficulty to the corresponding ketone (II), which has been given the trivial name, Isoamidone II. After the ketimine had been boiled with 20% hydrochloric acid for five hours, some unreacted ketimine was isolated from the crude mixture in the form of its sesquioxalate. Its identity was confirmed by the preparation of the dipicrate.

On working up the product obtained from the reaction of ethylmagnesium bromide with the crude mixture prepared by the condensation of diphenylacetonitrile and 1-dimethylamino-2-chloropropane, another isomer of Amidone, designated as Isoamidone I, has been found in addition to Amidone and Isoamidone II ketimine. The details of this work are now described in the Experimental Part of this paper. The structure of Isoamidone I has not yet been determined, but is being studied at the present time.

In this connection, 7-dimethylamino-4,4-diphenyl-3-heptanone (III) was prepared and characterized as the hydrochloride, picrate and methiodide. All of these salts were markedly different from the corresponding salts of Isoamidone I. Also, the ketimine of III was isolated as the picrate.

As further members of this series of compounds, the acetyl ketimine related to Amidone has been prepared as the base (IV) and hydrochloride. The acetyl ketimine (V) related to Isoamidone II was found to be an oil which was converted into the hydrochloride without purification. Also, the dipicrate of Amidone ketimine has been prepared.

V

Experimental

6-Dimethylamino-4,4-diphenyl-5-methyl-3-hexanoneimine (I).—To an ethereal solution of ethylmagnesium bromide prepared from 26.4 g. (1.08 moles) of magnesium turnings and 132 g. (1.21 moles) of ethyl bromide in 180 ml. of ether, there was added during a half hour, with stirring, a solution of 150 g. (0.53 mole) of 4-dimethylamino-2,2-diphenyl-3-methylbutanenitrile[2] in 150 ml. of xylene. The mixture was heated on a water-bath for three hours. The mixture was then poured into a solution of 170 ml. of concentrated hydrochloric acid in 300 ml. of water. A vigorous reaction resulted, evaporating the xylene and ether. The acid solution was made alkaline with 50% sodium hydroxide. Celite 503 was added and the mixture filtered. Both the precipitate and filtrate were extracted with ether. The ether solution was dried over magnesium sulfate, filtered and evaporated to dryness, leaving 147 g. of the crude ketimine as an oily residue.

For the preparation of the sesquioxalate, the oil was treated with an equal weight of oxalic acid dissolved in alcohol. On cooling and scratching, the sesquioxalate crystallized. After crystallization from a mixture of alcohol and ether, it melted at 145–146°.

Anal. Calcd. for $2C_{21}H_{28}N_2 \cdot 3H_2C_2O_4$: C, 64.99; H, 7.05; N, 6.32; $H_2C_2O_4$, 30.45. Found: C, 65.15; H, 6.96; N, 6.36; $H_2C_2O_4$, 30.50.

The dihydrochloride was prepared by treating an alcoholic solution of the ketimine with the theoretical amount of 30% alcoholic hydrogen chloride. On standing, an oil separated which eventually crystallized. After crystallization from a mixture of alcohol and ether, the white crystals melted at 200–202° dec.

Anal. Calcd. for $C_{21}H_{28}N_2 \cdot 2HCl$: C, 66.13; H, 7.93; N, 7.35; Cl, 18.59. Found: C, 66.00; H, 7.75; N, 7.30; Cl, 18.43.

For the preparation of the dipicrate, the oily ketimine was dissolved in alcohol and a hot alcoholic solution of picric acid was added. The mixture was heated on the steam-bath and crystals formed. The solid material was separated and recrystallized successively from acetone, acetone containing a little picric acid and from ethyl acetate. The yellow product melted at 140–141°, and could be converted into a more stable form, m. p. 166.5–168° by crushing on a porous plate or by boiling for some time in alcohol. *Anal.* Calcd. for $C_{21}H_{28}N_2 \cdot 2C_6H_3O_7N_3$: C, 51.69; H, 4.47; N, 14.62. Found: C, 51.65, 51.75; H, 4.54, 4.38; N, 14.41, 14.58.

6-Dimethylamino-4,4-diphenyl-5-methyl-3-hexanone [Isoamidone II (II)] Oxalate.—A solution of 17.4 g. of the ketimine dihydrochloride in 150 ml. of 20% hydrochloric acid was refluxed for five hours, cooled and made alkaline with 50% sodium hydroxide. After cooling, it was extracted twice with ether. The ether solution was concentrated to about 50 ml. and a solution of 17.5 g. of oxalic acid in 75 ml. of alcohol was added. On cooling and scratching, crystals were deposited. After crystallization from a mixture of acetone and alcohol, the yield was 9.7 g. (47%), m. p. 163–164°.

Anal. Calcd. for $2C_{21}H_{27}ON \cdot 3H_2C_2O_4$: C, 64.86; H, 6.76; N, 3.15; $H_2C_2O_4$, 30.41; neut. equiv., 148. Found: C, 65.2; H, 6.66; N, 3.43, 3.39; $H_2C_2O_4$, 30.40; neut. equiv., 149.

On diluting the original mother liquor with ether to complete precipitation, an oil was deposited which slowly

[2] Office of the Publication Board, Department of Commerce, Report PB 981, p. 96; E. M. Schultz, C. M. Robb and J. M. Sprague, THIS JOURNAL, **69**, 188 (1947); W. R. Brode and M. W. Hill, *ibid.*, **69**, 724 (1947).

crystallized on standing in the refrigerator. The liquid was decanted and the residue recrystallized twice from a mixture of acetone and alcohol, giving white crystals, m. p. 145–146°. A mixed melting point with Isoamidone II ketimine sesquioxalate showed no depression. For confirmation, the base from 0.5 g. of the oxalate was dissolved in 5 ml. of alcohol and treated with a solution of 0.5 g. of picric acid in 8 ml. of alcohol. The picrate came down as an oil. The alcoholic mother liquor was decanted and the oil was dissolved in about 75 ml. of hot alcohol. On cooling, the picrate formed yellow crystals, m. p. 166–167°, mixed with Isoamidone II ketimine dipicrate, m. p. 167–169°.

6-Dimethylamino-4,4-diphenyl-5-methyl-3-hexanone [Isoamidone II Base (II)].—An aqueous solution of 7.8 g. of Isoamidone II oxalate was made alkaline with sodium hydroxide. The base was extracted with ether and the ether extract was dried over potassium carbonate. The ether was distilled. The residue was dried by heating in a water aspirator vacuum on a steam-bath and distilled in vacuum. The yield was 3.9 g. (72%) of a clear, slightly yellow, very viscous liquid, b. p. 215° under 12 mm.

Anal. Calcd. for $C_{21}H_{27}ON$: C, 81.55; H, 8.74; N, 4.53. Found: C, 81.50; H, 8.90; N, 4.54, 4.52.

6-Dimethylamino-4,4-diphenyl-5-methyl-3-hexanone [Isoamidone II (II)] Hydrochloride, Picrate and Methiodide.—For the preparation of the hydrochloride, 16 g. of the oxalate was converted to the base as above. The crude base was treated with 8 ml. of 20% hydrochloric acid in an evaporating dish and the mixture was evaporated to dryness on a steam-bath, and finally dried at 70° in a vacuum oven. The yield of crude product was 12.5 g., m. p. 187–188°, after softening at 139°. After crystallization from isopropyl alcohol, there were obtained 5.7 g. of white crystals, m. p. 145–149°, rising to m. p. 190–193° after drying in a vacuum at 100°. Working up the mother liquors gave an additional 4.3 g. of the same m. p. after drying. The total yield was 10.0 g. (80%).

Anal. Calcd. for $C_{21}H_{27}ON{\cdot}HCl$: C, 72.92; H, 8.16; N, 4.05; Cl, 10.25. Found: C, 72.90; H, 8.13; N, 4.02, 4.01; Cl, 10.20.

The picrate was prepared by treating a solution of 0.4 g. of the base in 2 ml. of alcohol with a solution of 0.6 g. of picric acid in 5 ml. of hot alcohol. The solution was cooled and the yellow crystals were filtered out and after recrystallization from alcohol, the yield was 0.45 g. (64.5%), m. p. 149–150°.

Anal. Calcd. for $C_{21}H_{27}ON{\cdot}C_6H_3O_7N_3$: C, 60.21; H, 5.62; N, 10.40. Found: C, 59.95; H, 5.54; N, 10.55, 10.52.

For the preparation of the methiodide, the base from 2 g. of the oxalate was dissolved in ether. The ether solution was dried over magnesium sulfate, filtered and an excess of methyl iodide was added. On standing crystals, m. p. 263–264°, unchanged by recrystallization from methanol, separated.

Anal. Calcd. for $C_{22}H_{30}ONI$: C, 58.54; H, 6.70; N, 3.10; I, 28.11. Found: C, 58.45; H, 6.78; N, 3.06; I, 28.25, 28.35.

Isolation of Isoamidone I.—Diphenylacetonitrile (213.5 g.) was condensed with 133 g. of 1-dimethylamino-2-chloropropane by the procedure described in the Report PB 981.[2] The crude mixture of nitriles was treated with ethylmagnesium bromide and the resulting complex decomposed as described in the Report. The three layers which formed were separated. The middle layer was made alkaline with 50% sodium hydroxide and extracted with ether. The ether extract was dried over magnesium sulfate and concentrated to a thick oil. The oil was dissolved in absolute alcohol and the calculated amount of absolute alcoholic hydrogen chloride was added. Amidone hydrochloride crystallized and was recrystallized from absolute alcohol. The yield was 54 g., m. p. 229–231°.

The mother liquor was concentrated, neutralized with 50% sodium hydroxide and extracted with ether. The ether extract was dried over magnesium sulfate and evaporated to dryness, leaving an oil. An equal weight of oxalic acid dissolved in alcohol was added to the oil. On adding anhydrous ether and scratching, 13 g. of Isoamidone I oxalate, m. p. 158–160°, crystallized. A sample for analysis was recrystallized from acetone, with no change in melting point.

Anal. Calcd. for $C_{21}H_{27}ON{\cdot}H_2C_2O_4$: C, 69.15; H, 7.32. Found: C, 69.20; H, 7.06.

The base was liberated by the addition of sodium hydroxide to an aqueous solution of the oxalate and was extracted with ether. The ether solution was washed with water and dilute ammonium hydroxide and dried over magnesium sulfate. The ether was distilled and the residue dried by heating under reduced pressure.

Anal. Calcd. for $C_{21}H_{27}ON$: C, 81.50; H, 8.80; N, 4.53. Found: C, 81.34; H, 8.84; N, 4.76, 4.73.

A sample, when distilled under 3 mm. pressure, boiled at 164–167°.

The hydrochloride was prepared by the addition of alcoholic hydrogen chloride and anhydrous ether to the base. After crystallization from acetone, it melted at 172–173°.

Anal. Calcd. for $C_{21}H_{27}ON{\cdot}HCl$: C, 72.92; H, 8.16; N, 4.05; Cl, 10.25. Found: C, 73.05; H, 8.21; N, 4.25, 4.22; Cl, 10.25.

The methiodide was prepared by adding methyl iodide to an ethereal solution of the crude base. After crystallization from a mixture of acetone and di-isopropyl ether, it melted at 195–196°.

Anal. Calcd. for $C_{22}H_{30}ONI$: C, 58.53; H, 6.70; I, 28.11. Found: C, 58.65; H, 6.85; I, 28.40, 28.50.

For the preparation of the picrate, a sample of the base liberated from the hydrochloride was dissolved in alcohol and treated with a solution of an equal weight of picric acid in alcohol. After crystallization twice from alcohol and drying in vacuum at 77°, it melted at 131–133°.

Anal. Calcd. for $C_{21}H_{27}ON{\cdot}C_6H_3O_7N_3$: C, 60.21; H, 5.62; N, 10.40. Found: C, 60.05; H, 5.54; N, 10.61, 10.62.

For the isolation of Isoamidone II ketimine, the bottom layer from the decomposition of the original complex was neutralized with 50% sodium hydroxide and extracted with ether. The ether extract was dried over magnesium sulfate and evaporated to dryness. The residue was dissolved in alcohol and absolute alcoholic hydrogen chloride was added. After adding anhydrous ether and scratching, 12 g. of crystals, m. p. 195–200°, separated. A sample was recrystallized from absolute alcohol and then melted at 200–202°. A mixture with an authentic sample of Isoamidone II ketimine dihydrochloride melted at 199–201°.

To determine whether Isoamidone I might be a molecular compound between Amidone and Isoamidone II, the melting point ranges of several mixtures of the hydrochlorides of the last two compounds were determined. Each mixture melted over a wide range with an upper limit of 190° or higher and the melting range of no mixture approached that of Isoamidone I hydrochloride. The data are shown in Table I.

TABLE I

Hydrochlorides of Amidone, %	 Isoamidone II, %	Softened, °C.	Completely melted, °C.
76	24	175	218
55	45	176	211
28	72	145	190

A mixture made up of approximately equal amounts of the hydrochlorides of Amidone and Isoamidone II was dissolved in alcohol and precipitated by the addition of ether. The resulting granular precipitate softened at 157° and was completely melted at 200°.

5-Dimethylamino-2,2-diphenylpentanenitrile.—To a well-stirred suspension of 9 g. of sodamide in 50 ml. of dry benzene, warmed to 45–50°, there was added, during a fifteen-minute period, 39 g. of diphenylacetonitrile. The temperature of the reaction mixture was maintained at 40–45° for one and one-half hours. The mixture was cooled to 20–25° and 25 g. of 3-dimethylaminopropyl chloride was added during thirty minutes. The mixture was refluxed for five hours. After standing overnight, the mixture was poured into water. The water layer was separated and discarded. The benzene layer was extracted with 20% hydrochloric acid. The acid layer was neutralized with 10% sodium hydroxide and extracted with ethyl ether. The ether solution was dried over magnesium sulfate, filtered and evaporated to dryness. The product was recrystallized from petroleum ether and from Skellysolve C. The yield of white crystals melting at 64–65° was 19.4 g.

Anal. Calcd. for $C_{19}H_{22}N_2$: C, 81.97; H, 7.97; N, 10.06. Found: C, 81.95, 81.90; H, 7.82, 7.98; N, 10.09, 10.02.

7-Dimethylamino-4,4-diphenyl-3-heptanone (III) Hydrochloride, Picrate and Methiodide.—A solution of 25.4 g. of 5-dimethylamino-2,2-diphenylpentanenitrile in 20 ml. of xylene was added to a Grignard reagent prepared from 4.4 g. of magnesium and 22 g. of ethyl bromide in 20 ml. of ether. The reaction mixture was heated on a steam-bath for five and one-half hours. After standing overnight, it was poured into a solution of 40 ml. of concentrated hydrochloric acid in 100 ml. of water. Two layers were formed. The water layer was separated, made alkaline with 10% sodium hydroxide and extracted with ether. The ether solution was dried over magnesium sulfate, filtered and evaporated to dryness, leaving 28 g. of an oil.

A small portion of the oil was converted into a picrate, m. p. 181–182°, in the usual way. Analysis showed it to be the dipicrate of the ketimine.

Anal. Calcd. for $C_{21}H_{28}N_2 \cdot 2C_6H_3O_7N_3$: C, 51.69; H, 4.47; N, 14.62. Found: C, 51.50; H, 4.59; N, 14.50, 14.51.

The remaining oil was boiled with concd. hydrochloric acid for five hours. The mixture was cooled, made alkaline with 10% sodium hydroxide and extracted with ether. After being dried over magnesium sulfate, the ether solution was treated with dry hydrogen chloride. The oil which separated gradually crystallized. The solid was dissolved in ethyl acetate, treated with Nuchar C, filtered and the resulting solution was cooled. The white crystals which separated melted at 139–140°.

Anal. Calcd. for $C_{21}H_{27}ON \cdot HCl$: C, 72.92; H, 8.16; N, 4.05. Found: C, 73.00; H, 8.30; N, 4.06.

The picrate was prepared by treating the base liberated from the hydrochloride with picric acid in alcohol. After crystallizing from the same solvent, it melted at 118–119°.

Anal. Calcd. for $C_{21}H_{27}ON \cdot C_6H_3O_7N_3$: C, 60.21; H, 5.62; N, 10.40. Found: C, 60.30; H, 5.85; N, 10.32.

The methiodide was prepared by treating the base with methyl iodide in ether. After crystallizing from methanol, it melted at 250–252°.

Anal. Calcd. for $C_{22}H_{30}ONI$: C, 58.54; H, 6.70; N, 3.10; I, 28.11. Found: C, 58.25; H, 6.98; N, 3.16; I, 28.55.

6-Dimethylamino-4,4-diphenyl-3-heptanone-acetylimine (IV).—4-Dimethylamino-2,2-diphenylpentanenitrile was treated with ethylmagnesium bromide according to the procedure for the preparation of Amidone by the original method.[2] The resulting mixture was poured into acetic anhydride with cooling in an ice-bath. Ethyl alcohol was added and most of the solid precipitate dissolved. The mixture was concentrated under reduced pressure and the residue dissolved in water. After making alkaline with sodium hydroxide, the base was extracted with ether. The ether solution was dried over magnesium sulfate and evaporated to dryness. The residue crystallized on standing and was recrystallized from Skellysolve C, m. p. 130–131°.

Anal. Calcd. for $C_{23}H_{30}ON_2$: C, 78.82; H, 8.63; N, 7.99. Found: C, 78.90; H, 8.70; N, 8.08.

The hydrochloride was prepared by passing dry hydrogen chloride into a solution of the base in di-isopropyl ether. After recrystallizing from acetone, it melted at 219–221°.

Anal. Calcd. for $C_{23}H_{30}ON_2 \cdot HCl$: C, 71.38; H, 8.08; N, 7.24; Cl, 9.16. Found: C, 71.30; H, 8.17; N, 7.23; Cl, 9.14.

6-Dimethylamino-4,4-diphenyl-5-methyl-3-hexanone-acetylimine (V) Hydrochloride.—A mixture of 25 g. of the ketimine and 50 g. of acetic anhydride was heated on the steam-bath for about three hours, and then concentrated under reduced pressure. The residue was dissolved in water and the solution made alkaline with sodium hydroxide. The base was extracted with ether, the ether solution dried over magnesium sulfate and evaporated to dryness. On attempting to prepare the oxalate in the usual way, an oil which did not crystallize was formed. The base was regenerated and converted into the hydrochloride by adding an alcoholic solution of hydrogen chloride and then ether. The hydrochloride crystallized on scratching; m. p. 213–215°.

Anal. Calcd. for $C_{23}H_{30}ON \cdot HCl$: C, 71.38; H, 8.08; N, 7.24; Cl, 9.16. Found: C, 71.45; H, 8.12; N, 7.23, 7.23; Cl, 9.15.

6-Dimethylamino-4,4-diphenyl-3-heptanoneimine (Amidone Ketimine) Dipicrate.—Ethylmagnesium bromide was brought into reaction with 4-dimethylamino-2,2-diphenylpentanenitrile as in the original preparation of Amidone.[2] On completion of the reaction, the reaction mixture was poured into a mixture of ice and 30% acetic acid. After neutralization with 10% sodium hydroxide, the mixture was extracted with ether. The ether solution was dried over magnesium sulfate, filtered and concentrated. A portion of the residue was dissolved in alcohol and treated with an alcoholic solution of picric acid. The solid which precipitated was recrystallized from a mixture of ethyl acetate and acetone. The yellow product melted at 182–184°.

Anal. Calcd. for $C_{21}H_{28}N_2 \cdot 2C_6H_3O_7N_3$: C, 51.69; H, 4.47; N, 14.62. Found: C, 51.60; H, 4.28; N, 14.68, 14.65.

Acknowledgment.—We are indebted to Dr. V. B. Fish of this Laboratory for the analyses reported in this paper.

Summary

1. Three isomers of Amidone have been described.

2. Four ketimine derivatives related to Amidone have been prepared.

Thiophene Analogs of DDT

BY PRICE TRUITT, MARJORIE MATTISON[1] AND EUGENE RICHARDSON[1]

Since thiophene very often yields compounds that are analogous to benzene derivatives in general physiological properties,[2] it was decided to prepare a number of compounds derived from thiophene and halogenated thiophenes that would be analogous to DDT, 1,1,1-trichloro-2,2-bis-(*p*-chlorophenyl)-ethane.[3]

1,1,1-Trichloro-2,2-bis-(thienyl)-ethane had been previously prepared by the action of phosphorus pentoxide on a mixture of thiophene and chloral, and in a similar fashion 1,1,1-tribromo-2,2-bis-(thienyl)-ethane has been prepared from bromal and thiophene with sulfuric acid as a condensing agent.[4] However, it seemed desirable to again prepare these compounds and test their insecticidal properties along with the new compounds.

In our hands, the use of sulfuric acid with thiophene and substituted thiophene without a diluent gave very little of the desired product and a large amount of orange-colored material which was soluble in alkali.

The use of phosphorus pentoxide was very unsatisfactory since the material became very lumpy and difficult to stir. However, when acetic acid was used as a diluent with sulfuric acid,[5] the amount of sulfonation was materially reduced, and the desired products obtained. None of the above methods was satisfactory for the preparation of 1,1,1-tribromo-2,2-bis-(thienyl)-ethane.

Experimental

Thiophene used in this work was obtained from Socony-Vacuum and was used without further purification.

2-Chlorothiophene.—This compound was prepared by the action of sulfuryl chloride on thiophene in ether with aluminum chloride as a catalyst according to the directions of Thol and Eberhard.[6] 200 g. of thiophene gave 145 g. of 2-chlorothiophene, b. p. 127–128°, n^{20}D 1.5510.

2-Bromothiophene.—This compound was donated by Michigan Chemical Corporation, St. Louis, Michigan, and was used without further purification.

2-Iodothiophene.—This compound was prepared according to the procedure given in "Organic Syntheses."[7]

2-Methylthiophene.—This compound was donated by Socony–Vacuum and was used without further purification.

Chloral.—This compound was donated by Westvaco Chlorine Products Company, New York, N. Y.

1,1,1-Trichloro-2,2-bis-(chlorothienyl)-ethane.—To a well-stirred mixture of 34.0 g. (0.29 mole) chlorothiophene and 14.7 g. (0.1 mole) of chloral in 150 ml. of glacial acetic acid, 67 g. of concentrated sulfuric acid were added dropwise over a period of one hour. The temperature was kept below 5° during addition, and the reaction mixture was stirred in an ice-bath for several hours. The reaction mixture was neutralized with 10% potassium hydroxide solution, and the crystals which separated were filtered. The product was recrystallized from 95% ethanol, and when pure melted at 63.7–63.8°.

Anal. Calcd. for $C_{10}H_5S_2Cl_5$: Cl, 48.38. Found: Cl, 48.21.

1,1-Dichloro-2,2-bis-(chlorothienyl)-ethylene.—A solution of 6.73 g. of 1,1,1-trichloro-2,2-bis-(chlorothienyl)-ethane and 3.2 g. of potassium hydroxide in 100 ml. of ethanol was refluxed for two hours. Some of the alcohol was removed *in vacuo*, and the remainder of the alcoholic solution was poured over ice. The oil which separated was extracted with ether. The ethereal solution was dried over sodium sulfate. The ether was removed under reduced pressure, and the residue was distilled *in vacuo*. The product boiled at 208–210° (6 mm.), n^{21}D 1.6833.

Anal. Calcd. for $C_{10}H_4S_2Cl_4$: Cl, 42.97. Found: Cl, 42.64.

1,1,1-Trichloro-2,2-bis-(bromothienyl)-ethane.—To a well-stirred mixture of 24 g. (0.15 mole) of bromothiophene and 8.85 g. (0.06 mole) of chloral in 150 ml. of glacial acetic acid, 54 g. of fuming sulfuric acid were added dropwise over a period of two hours. The temperature was kept below 15° during addition, but the reaction was heated to 55° after addition was complete and was stirred for twenty-four hours. The product mixture was poured into ice-water, and the organic fraction which separated as an oil was extracted with ether. The ether solution was washed with water, bicarbonate solution, and dried over anhydrous calcium chloride. The ether was evaporated, and the crude crystalline product obtained. The product was recrystallized from a mixture of petroleum ether and *n*-hexane, and when pure melted at 93.7°.

Anal. Calcd. for $C_{10}H_5S_2Cl_3Br_2$: Cl, 23.35; Br, 35.09; Found: Cl, 23.32; Br, 35.03.

1,1,1-Trichloro-2,2-bis-(iodothienyl)-ethane.—To a well-stirred mixture of 63.8 g. (0.31 mole) iodothiophene and 19.1 g. (0.13 mole) of chloral in 50 ml. of glacial acetic acid, 100 g. of concentrated sulfuric acid was added dropwise over a period of two hours. The temperature was kept below 20° during addition, and the reaction mixture was stirred in an ice-bath for two hours and at room temperature for twenty-four hours. The product mixture was poured into ice-water, and the organic fraction, a black oily mass, was extracted with ether. The ether solution was washed with water, bicarbonate solution, and dried over sodium sulfate. The ether was evaporated, and petroleum ether was added to the residue. The mixture was cooled overnight, and the brown crystals which separated were filtered and washed with *n*-hexane. The crude product was recrystallized from *n*-hexane and when pure melted at 94.8–95.1°.

Anal. Calcd. for $C_{10}H_5S_2Cl_3I_2$: Cl, 19.36; I, 46.20. Found: Cl, 19.36; I, 46.27.

1,1,1-Trichloro-2,2-bis-(methylthienyl)-ethane.—To a well-stirred mixture of 75 g. (0.75 mole) of 2-methylthiophene and 49.5 g. (0.30 mole) of chloral hydrate in 100 ml. of glacial acetic acid, 184 g. of concentrated sulfuric acid were added dropwise with stirring while the temperature was kept at 15°. The reaction mixture was stirred at room temperature for twenty-four hours. The product mixture was poured into ice water, and the aqueous layer decanted. The crystalline product was dissolved in ether. The ether solution was washed with water, bicarbonate solution, and dried over anhydrous calcium chloride. The ether was evaporated, and the product recrystallized from an alcohol–acetone mixture. When pure it melted at 72.2°.

Discussion of Results

1,1,1-Trichloro-2,2-bis-(thienyl)-ethane was previously reported melting at 76.0°. Using the same procedure in preparation of this compound, we obtained a compound, when pure, melting at 78.4°.[8] However, analysis of this product proves it to be the desired product.

Attempts to determine the structure of 1,1,1-trichloro-2,2-bis-(chlorothienyl)-ethane were carried out by the method of Cristol and Haller.[9]

This method failed to give the product anticipated. Treatment of 1,1-dichloro-2,2-bis-(chlorothienyl)-ethylene with chromic oxide in boiling glacial acetic acid gave a yellow oil which failed to crystallize. Since the bis-chlorothienyl ketone was expected to be a solid, it was concluded the susceptibility of the thiophene nucleus to oxidation led to decomposition.

When the olefin was refluxed with alkaline and neutral potassium permanganate, the original product was recovered. Hydrolysis of the olefin with barium hydroxide[10] in ethylene glycol gave a neutral oil and a trace of acidic material. The yield of neutral product was insufficient for characterization, but a qualitative test showed the presence of sulfur and a trace of halogen. A halogen analysis indicated approximately 1.0% chlorine. Evidently the chlorine in the thiophene nucleus was removed by barium hydroxide as well as that attached to the ethylenic chain. No definite structure has been assigned to these compounds, but on the basis of analysis and the known high reactivity of the 2,5-positions of thiophene, it is suspected that the thiophene nucleus is joined at the 5-position.

Laboratory tests of the insecticidal properties indicate that 1,1,1-trichloro-2,2-bis-(chlorothienyl)-ethane is the most effective compound against cockroaches; however, the derivatives of 2-bromothiophene and 2-iodothiophene show some activity. The derivative of 2-methylthiophene shows no insecticidal activities. 1-Trichloro-2,2-bis-(chlorothienyl)-ethane seems to be as active as DDT against cockroaches.

Summary

A series of thiophene analogs of DDT have been prepared. The ones not previously reported are: 1-trichloro-2,2-bis-(chlorothienyl)-ethane, 1-dichloro-2,2-bis-(chlorothienyl)-ethylene, 1-trichloro-2,2-bis-(bromothienyl)-ethane, 1-trichloro-2,2-bis-(iodothienyl)-ethane, 1-trichloro-2,2-bis-(methylthienyl)-ethane.

Biophysical Studies of Blood Plasma Proteins. VII. Separation of γ-Globulin from the Sera of Various Animals[1]

BY J. CHARLES NICHOL AND H. F. DEUTSCH

The separation of the components of biological tissues and fluids by ethanol fractionation as carried out by Cohn, *et al.*,[2] is directed to the isolation and recovery of all recognizable entities of the system in question. Often, however, in the interests of expediting the recovery or of increasing the yield of a given component it may be desirable to separate such an entity with immediate (but not necessarily eventual) disregard for other constituents. The antibodies of various animal species immunized to different antigens are known to possess the gross physical–chemical characteristics of the γ-globulins and to separate from solution with them. The scientific and technical importance of these antibody-rich fractions is the incentive which has led us to the development of a simple and effective procedure for removal of the normal γ-globulins from the sera of human beings and of the goat, dog, rabbit, rat, chicken and guinea pig.

It is found that in the individual species the chemical treatment may vary somewhat, but in all cases there is an initial and important step in which the antibody-rich γ-globulins are precipitated from a diluted serum which may be followed by a purification treatment to remove certain small amounts of contaminant β-globulins. In this way the γ-globulins are obtained in relatively pure form. The methods used involve variations in ethanol and salt concentrations and *p*H such as were used previously in studies on human γ-globulin.[3,4,5]

The general scheme, based in part upon our previous work,[3,4] consists in diluting one volume of serum with three volumes of water, adjusting the

*p*H to 7.6–7.7, and adding 50% ethanol to give a final ethanol concentration of 20%. Temperatures are maintained to within one degree of the freezing point at all times. The precipitate which forms (ppt. A) contains most of the serum γ-globulins in admixture with some β-globulins. After removal by centrifugation, this precipitate is suspended in cold distilled water at a concentration of 0.5–1.0% and the suspension is adjusted to a *p*H ranging from 5.0 to 5.2. Various concentrations of ethanol and salt are used at this point, depending upon the species from which the original serum was obtained, to effect removal of the β-globulin (ppt. B), while maintaining the major portion of the γ-globulins in solution. The ppt. A from all the sera which were studied contains two families of γ-globulins, γ_1- and γ_2-globulins in our nomenclature.[4]

To effect the separation of the globulin of higher electrophoretic mobility (γ_1) when it was not removed entirely in ppt. B, the supernatant in this precipitation is brought to *p*H 5.6–6.0, the ethanol concentration to 10% and the ionic strength to 0.01, giving ppt. C-1. This precipitate consists predominantly of γ_1-globulin, along with some γ_2-globulin. The proteins remaining in solution at this point are essentially pure γ_2-globulins. Supernatants to ppt. B or ppt. C-1 are adjusted to *p*H 7.2–7.4 and the ethanol concentration is brought to 25% to effect precipitation. The γ_2-globulins, ppt. C-2, obtained in this manner are removed by centrifugation, suspended in distilled water, frozen and dried *in vacuo*.

A general scheme for the fractionation of an animal serum for γ_2-globulin is shown in Fig. 1. The conditions found suitable for that step of the fractionation process involving the separation of the beta from the gamma globulins for the various sera are shown in Table I. In the case of dog and rat sera it was necessary to introduce an additional step at *p*H 5.6–6.0 to remove γ_1-globulin (ppt. C-1) prior to the precipitation of the γ_2-globulin (ppt. C-2). An alternative procedure designed to remove γ_1-globulins with ppt. B is to raise the alcohol concentration above the values shown in Table I for the rat and dog systems.

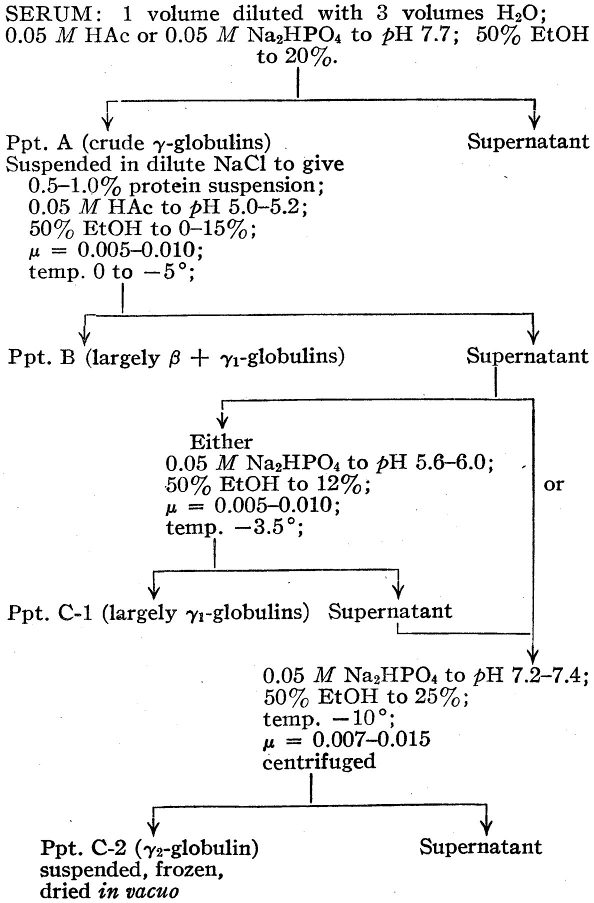

Fig. 1.—Fractionation scheme for isolation of γ_2-globulin from animal sera.

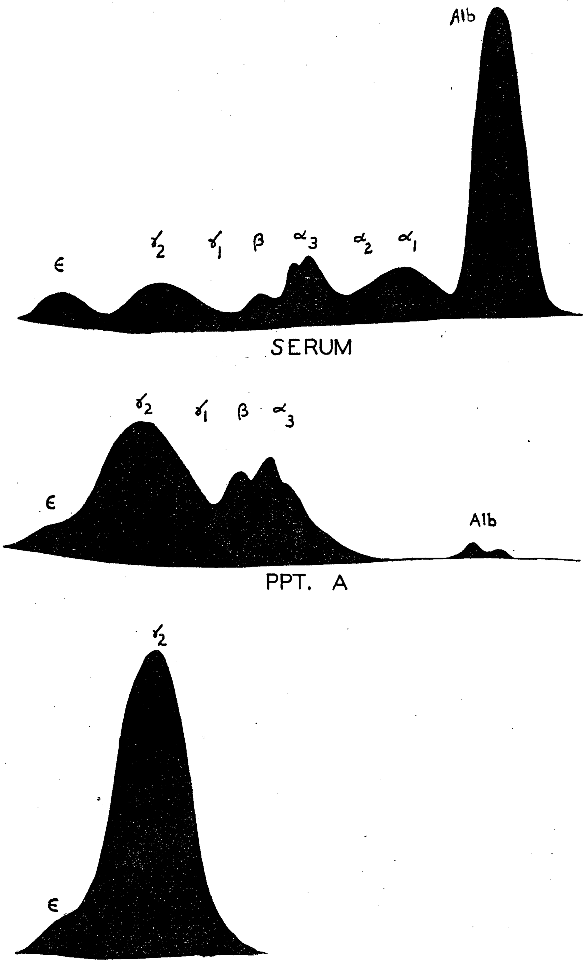

Fig. 2.—Descending electrophoretic patterns showing the course of fractionation of goat serum. Electrophoretic experiments were performed using barbiturate–citrate buffer, μ = 0.088, *p*H 8.6; duration of experiments 7800 sec. at potential gradient of 8.5 volts per cm.

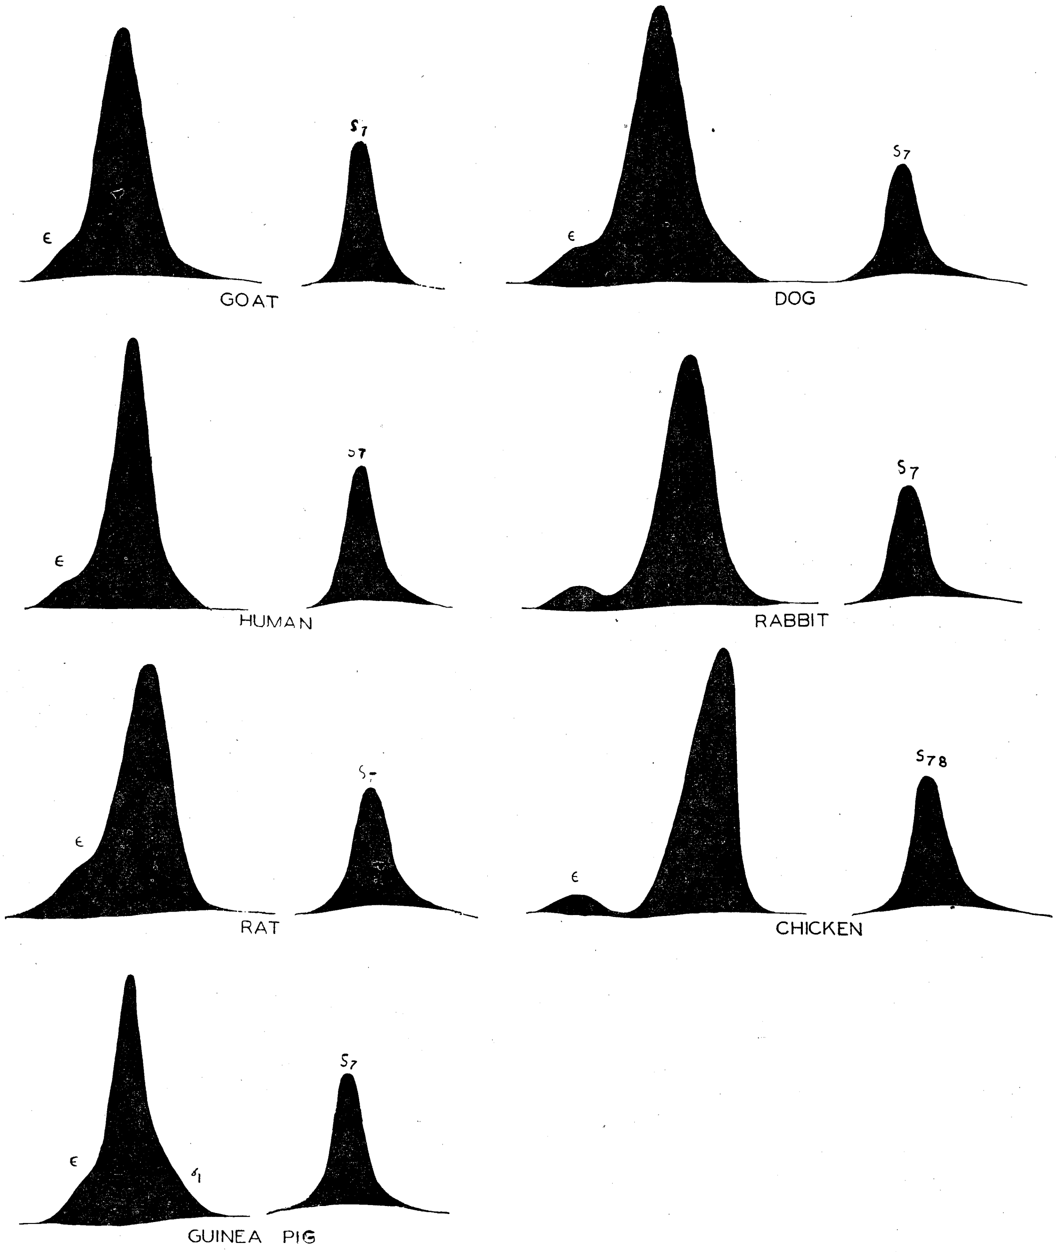

Fig. 3.—Descending electrophoretic patterns and sedimentation pictures of the γ_2-globulin of various animals (electrophoretic diagrams on left). Electrophoretic experiments were performed using barbiturate buffer, $\mu = 0.1$, pH 8.6 at a potential gradient of 6.5 volts per cm.; duration of experiments in seconds, goat 7800; human 8400; dog 11,000; rabbit 12,000; rat 7200; chicken 7800; and guinea pig 7200. Sedimentation pictures were taken after sixty minutes in the ultracentrifuge at 50,400 r. p. m.

However, by carrying out the precipitation step C-1 (Fig. 1) one can also obtain concentrates of γ_1-globulins whereas by the above procedure they are carried down into a precipitate consisting largely of β-globulins.

The electrophoretic patterns following the course of the fractionation of goat serum as outlined in Fig. 1 are shown in Fig. 2.

The fractionations were evaluated in terms of yield (recovery) and electrophoretic "purity" of product. The latter analyses were carried out in a pH 8.6 diethylbarbiturate buffer of ionic strength 0.1 at a constant potential gradient of approximately 6.5 volts per cm. The duration of experiments was from 7200 to 12000 seconds. Mobilities were determined by using the center of the initial boundary as the reference point.

Sedimentation analyses were carried out with γ-globulin solution in the high-velocity oil-turbine ultracentrifuge at 50,400 r.p.m., using a

schlieren method to record the position of the boundaries as a function of time.

Diffusion studies performed in this Laboratory by Polson[6] with solutions of our rabbit γ_2-globulin gave normal scale line displacement-distance curves to give $D_{20\text{w}} = 4.1 \times 10^{-7}$ sq. cm./sec. The method of moments was used in the computation. From this value and our sedimentation constant $s_{20\text{w}} = 7.05\ S$ a molecular weight of 160,000 is calculated. It is of interest that this value is in agreement with data of Kabat[7] for immune rabbit globulin.

The γ_2-globulins of the various animals are quite similar as regards their electrophoretic and sedimentation behavior (Table II, Fig. 3). However, it is apparent that chicken γ-globulin deviates somewhat in its properties, because it can be seen from Fig. 3 that two closely related electrophoretic components are present. The average mobility of this fraction is considerably higher than that of the γ_2-globulins of the other species studied. The sedimentation experiments show a single, somewhat broadened, peak but the sedimentation constant is somewhat higher than that of the other γ_2-globulins and heterogeneity is indicated. This fraction is free of lipid and was designated as a γ_2-globulin since it represented the component of lowest electrophoretic mobility in chicken serum. We have found this protein fraction to contain antibody.

Except as just noted, all γ_2-globulins sedimented as relatively homogeneous proteins with $s_{20\text{w}} = 7S$. Ppt. B of dog serum, consisting largely of γ_1-globulin, contained a component of high molecular weight ($s_{20\text{w}} = 18S$). γ_1-Globulins from other species were not separated from the main γ-globulin fraction for study, although electrophoretic analyses of the various fractions indicated their presence. From the point of view of their physical properties, the several animal γ_2-globulins appear to be quite similar to those found in human plasma. In addition, the γ_1-globulin of the dog shows similar molecular and electrokinetic behavior as compared to that of the corresponding fraction in human plasma.

TABLE II

PHYSICAL CONSTANTS AND YIELDS OF γ_2-GLOBULIN

[a] Mobilities measured from center of the initial boundary. [b] Based on per cent. of γ_2-globulin in original serum as determined by electrophoresis. [c] Source material was old reconstituted dried plasma. [d] $s_{20\text{w}} = 7.8$ for the chicken γ_2-globulin. [e] Electrophoretic pattern suggests the presence of two closely related proteins. Lipoproteins having the same electrophoretic mobility as those of the gamma globulins in chicken sera make it impossible to give an exact estimate of the γ-globulin yield.

After being shell-frozen and dried, the final products (γ_2-globulins) of the fractionation are recovered as white powders which are readily soluble in 0.15 M sodium chloride to give clear and stable solutions. Cruder products which are contaminated with γ_1- and β-globulins may give solutions showing considerable amounts of suspended material and turbidity.

Acknowledgments.—The authors wish to acknowledge the many helpful suggestions of Dr. J. W. Williams during the course of these investigations. The valuable technical assistance of Mr. E. M. Hanson and Mrs. Alice McGilvery is gratefully recognized.

Summary

A method for the separation of γ_2-globulins from normal animal sera has been developed. It has been applied successfully to human, goat, dog, rabbit, guinea pig, rat and chicken sera.

Biophysical Studies of Blood Plasma Proteins. VIII. Separation and Properties of the γ-Globulins of the Sera of Normal Cows[1]

By E. L. Hess and H. F. Deutsch

By applying the latest methods of Cohn, *et al.*,[2] for the separation of γ-globulins from human plasma, two immune globulins have been fractionated from the plasma of hyperimmunized cows by Smith.[3] Prior to this time Cohn and associates[4] had described the fractionation of the bovine plasma proteins by equilibration across membranes with ethanol–water mixtures of controlled *p*H, ionic strength and temperature. Work in this Laboratory on the recovery of the γ-globulins of animal sera indicates that increased yields and sharper fractionations may be obtained by determining methods more or less specific for the removal of a given component in the plasma of a particular species of animal.[5] There has been evolved what is believed to be the optimum *combination* of conditions for the separation and recovery of the γ-globulins of normal bovine sera. Under these conditions two closely related γ-globulin fractions differing in electrophoretic mobility and in solubility have been separated in good yield from normal bovine serum.[5a] The conditions of separation, yield, and some of the physical properties of these normal bovine serum γ-globulins constitute the subject of this report.

Fractionation Studies

Pooled sera of Holstein cows served as a source of starting material. The experimental conditions used to separate the γ-globulins in crude form are consistent with those previously reported.[5] In this way there was obtained a fraction of composition 85% γ-globulins and 15% β-globulins. The electrophoretic patterns in Figure 1 follow the course of the fractionation. Figures 1A and 1B represent the serum and the first crude fraction (hereafter called precipitate A), respectively. The conditions necessary to precipitate the beta globulins from precipitate A, while maintaining the major portion of the γ-globulins in solution, were then studied in detail. These experiments were carried out on 1-g. samples of precipitate A. As shown in Fig. 2, the conditions *p*H 4.95 ($\pm$0.05), $\mu = 0.01$, and ethanol concentration = zero, represented suitable conditions for this separation. The γ-globulin resulting after the removal of β-globulin is indicated by the electrophoretic pattern shown in Fig. 1C.

This γ-globulin fraction (Fig. 1C) which is heterogeneous on electrophoresis, was separated into two sub-fractions in a manner similar to that employed previously in the analogous system of human γ-globulin.[6] The effect of variation of ethanol concentration at *p*H 5.65 ($\pm$0.05) was first studied on 2-g. samples of precipitate C since the γ-globulins of higher electrophoretic mobility should be isoelectric near this *p*H. The effect of *p*H variation in the sub-fractionation of the γ-globulins was likewise investigated, starting with 2-g. samples of precipitate C, with the results shown in Fig. 3. A *p*H of 5.8 and an ethanol concentration of 10% was selected as suitable for a separation of the γ_1- and γ_2-globulins.

The effect of variation of ionic strength, at *p*H 5.80 ($\pm$0.05) and 10% ethanol concentration was then studied, with the result shown in Fig. 4. The electrophoretic patterns of the γ_1- and γ_2-globulin sub-fractions obtained by precipitating the γ_1 fraction at *p*H 5.8 ($\pm$0.05) ethanol concentration of 10%, and $\mu = 0.01$, under which conditions approximately equal amounts of γ_1- and γ_2-globulins result, are shown in Fig. 1 for precipitates C-1 and C-2, respectively.

The complete fractionation procedure, with yield data for the gamma globulins, is indicated schematically in Fig. 5.

Characterization Studies

Diffusion and Sedimentation.—Diffusion studies of Kahn and Polson,[7] which were carried out in this Laboratory, indicate the same diffusion constant for both γ_1- and γ_2 fractions (precipitates C-1 and C-2), giving $D_{20\mathrm{w}} = 4.1 \times 10^{-7}$ sq. cm./sec. at a protein concentration of 1%. The normalized curves indicate traces of polydispersity.

The two fractions were analyzed in the standard Svedberg oil turbine ultracentrifuge for their molecular mass spectra. Observations of the change of position of the boundaries were made by using a schlieren optical system. Within the limits of experimental error, the same sedimentation content is observed for the γ_1- and γ_2-globulin sub-fractions. At a protein concentration of 1%

[5a] In accordance with our terminology for the immune globulins of humans, we have called the fraction of higher electrophoretic mobility, γ_1-globulins, and the fraction of lower mobility, γ_2-globulins. Thus the γ_1-globulin fraction is comparable to the "T" component of Smith[3].

the sedimentation constant is $s_{20w} = 7.4S$. The sedimentation diagrams themselves are shown in Figs. 6B and 6D. An analysis of Fig. 6B indicates the presence of approximately 4% of heavier constituents with $s_{20w} \cong 9S$ (but no component with $s_{20w} = 20S$) in the γ_1-globulin sub-fraction. An examination of Fig. 6D shows that all the γ_2-

globulins have sedimentation constant $s_{20w} = 7.4S$ within the limits of experimental error.

In order to apply a criterion of homogeneity to the sedimentation diagrams an apparent diffusion constant was calculated from the sedimentation diagram 6B. An apparent diffusion constant of $D_{20w} = 5.4 \times 10^{-7}$ sq. cm./sec. was obtained, indicating that, as regards sedimentation behavior, the γ_1 sub-fraction is essentially monodisperse. Similar analysis applied to the sedimentation diagram for the γ_2-globulin leads one to the same conclusion.

The γ_1- and γ_2-globulins have a molecular weight of approximately 175,000 based upon the sedimentation velocity and independent diffusion measurements. The frictional ratio $f/f_0 = 1.4$ may be computed from diffusion data. This molecular weight agrees well with values which have been previously reported for some animal serum globulins.[3,8,9,10]

Electrophoresis.—The electrophoretic mobilities of the γ_1- and γ_2-globulin fractions were observed in a buffer system at a *p*H of 8.6 with the aid of the conventional Tiselius assembly. The medium was either a veronal buffer at $\mu = 0.1$ or a veronal–citrate buffer at $\mu = 0.088$. The veronal system was used when mobilities were measured. The patterns for the two gamma globulins are shown in Figs. 6A and 6C. The mobility of the γ_1-globulin fraction under these conditions is 2.1×10^{-5} sq. cm./sec./volt, the same value as that reported for the "T" component by Smith. The mobility of the γ_2-globulin fraction as observed, 1.25×10^{-5} sq. cm./sec./volt, is slightly higher than that reported by Smith for his component which corresponds. Mobilities were determined from the rate of movement of the maximum ordinate, which involves negligible error because of the essential symmetry of the refractive index gradient.[11]

An apparent diffusion constant $D_{20w} = 245 \times 10^{-7}$ sq. cm./sec. was calculated from the electrophoretic pattern for γ_1-globulin (by using the diagram, Fig. 6A). A value $D_{20w} = 135 \times 10^{-7}$ sq. cm./sec. was obtained for γ_2-globulin by using Fig. 6C. These apparent diffusion constant data indicate boundary spreading of far greater magnitude than can be attributed to normal diffusion. In these studies, the ascending and descending patterns were virtually mirror images of one another. A reversal of the current and a calculation of the diffusion constant, after the spreading due to electrophoretic inhomogeneity had been eliminated, gave an apparent value for the diffusion constant of $D_{20w} = 11 \times 10^{-7}$ sq. cm./sec. for the γ_2-globulins. These data indicate that although there is some irreversible boundary spreading, the major part of the spreading is reversible and therefore most probably due to electrical inhomogeneity. The γ_1-globulin fraction is less homogeneous than the γ_2-globulin fraction.

The reversible boundary spread exhibited by the gamma globulin sub-fractions is similar to that observed by Sharp, Cooper and Neurath[7] for pseudoglobulin from horse serum. As a measure of heterogeneity Sharp, Taylor, Beard and Beard[12] have proposed a heterogeneity constant $H = \Delta\sigma/E\Delta t$ where $\Delta\sigma$ is the change in the standard deviation σ during the time interval Δt, and E is the potential gradient. An average value of $H = 5 \times 10^{-6}$ sq. cm./sec./volt was computed for γ_2-globulins from electrophoretic patterns obtained in veronal buffer at $\mu = 0.1$, *p*H = 8.6, which is slightly lower than the heterogeneity values obtained by Sharp, Hebb, Taylor and Beard[13] for pseudoglobulin from horse serum. Quite possibly a whole series of γ-globulins varying only slightly in their chemical and physical behavior is present in the serum of normal animals. In studies of hyperimmune bovine plasma, which are now in progress, we hope to obtain more information concerning this matter.

By reference to Fig. 1C it will be seen that there is no real resolution of the γ_1- and γ_2-globulins in veronal–citrate buffer of $\mu = 0.088$ and *p*H 8.6. Consequently, it is impossible to estimate from the pattern in the conventional way the relative amounts of the two families of γ-globulins which are present. However, a study was made of the electrophoretic behavior in the same buffer solution of synthetic mixtures of the γ_1- and γ_2-globu-

Discussion

There has been described a method for the recovery, with subsequent separation into two fractions, of the γ-globulin constituents of bovine serum. The application of these procedures is important in that a considerable increase in yield of the proteins concerned with antibody production results. At the same time, "purity" of the fractions, as judged by electrophoretic analysis has not been sacrificed. Comparison may be made with the experiments of Smith[3] whose yields of the γ-globulins were approximately one-half those obtained in our experiments, in spite of the fact that hyperimmune serum was available to him and not to us.

In the earlier publications[3,6] the starting material has been the Fraction II + III of the Cohn framework.[2a] In the present instance the γ-

globulins are precipitated directly from the blood serum for such later purification or separation into sub-fractions as may be desired. The important differences in conditions of separation are the immediate adjustment of the serum to *p*H 7.7 and the use of a considerably greater dilution of the serum as fractionation begins. The new conditions serve several very useful purposes. The sharpness of cleavage between β- and γ-globulins is markedly increased. The removal of the gamma globulin is simple and direct. Tendencies toward denaturation are reduced. Actual yields of γ-globulin are now in excess of 85%.

As a result of the work described in this report and in the companion article[5] it may be predicted that practical and economical ethanol fractionation methods for the removal of antibody from hyperimmune sera will be soon in operation.

Acknowledgments.—The authors wish to thank Dr. J. W. Williams and Dr. Gerson Kegeles for their many helpful suggestions during the course of this work. It is a pleasure as well to thank Mr. E. M. Hanson and Mrs. Alice McGilvery for their technical assistance.

Summary

A procedure for the fractionation of bovine serum, which recovers approximately 85% of the gamma globulins in normal serum, has been outlined. These γ-globulins can be further separated into fractions with varying electrophoretic mobilities. The γ_1 and γ_2 sub-fractions are essentially monodisperse as regards molecular kinetic behavior, but there are marked indications of electrophoretic inhomogeneity.

Decompositions of Di-*t*-Alkyl Peroxides. I. Kinetics

BY JOHN H. RALEY, FREDERICK F. RUST AND WILLIAM E. VAUGHAN

The di-*t*-alkyl peroxides have been reported, almost simultaneously by Milas and Surgenor[1] and George and Walsh,[2] to undergo clean-cut decompositions in the vapor phase to ketone and hydrocarbon which, for the di-*t*-butyl compound, can be represented by

$$(CH_3)_3COOC(CH_3)_3 \xrightarrow{k_1} 2(CH_3)_3CO \quad (1)$$

$$(CH_3)_3CO \longrightarrow (CH_3)_2CO + CH_3 \quad (2)$$

$$CH_3 + CH_3 \longrightarrow C_2H_6 \quad (3)$$

During the past few years we have investigated the preparation and properties of these compounds in some detail,[3] and in this paper we present the results of a kinetic study of the pyrolyses of the di-*t*-butyl and di-*t*-amyl derivatives. The reactions of the free radicals produced in these decompositions with various compounds are reported in a following paper.[4]

In the studies of Milas and co-workers the vaporous peroxides were decomposed in the presence of a large amount of glass surface. Under such conditions, reactions of the alkyl radicals are essentially limited to combinations with one another and, in the case of di-*t*-butyl peroxide, ethane and acetone are the sole products. However, if the decompositions are carried out in a large diameter, unpacked vessel, interaction of the alkyl radicals and the ketone becomes important. Thus, methyl, ethyl and higher ketones and methane can also be formed

$$CH_3 + CH_3COCH_3 \longrightarrow CH_4 + CH_3COCH_2 \quad (4)$$

$$CH_3 + CH_3COCH_2 \longrightarrow CH_3COCH_2CH_3 \quad (5)$$

In the kinetic experiments to be described the fraction of released methyl radicals which reacts substitutively (5–10%) is dependent on the acetone concentration as well as the surface. Somewhat higher values (20%) are observed if the decomposition proceeds to completion or if acetone is added.

The reality of the *t*-butoxy radical is demonstrated by the formation of *t*-butyl alcohol when the decomposition is carried out in isopropylbenzene solution. The solvent is converted to 2,3-dimethyl-2,3-diphenylbutane.[5]

Experimental

1. **Materials.**—The di-*t*-butyl peroxide[3] ($n^{20}D$ 1.3890), redistilled under high vacuum, assayed at least 98% (reduction by hydriodic acid[3]) and gave negative tests for *t*-butyl alcohol and hydroperoxide. Steam-distilled di-*t*-amyl peroxide[3] was treated with bromine and vacuum distilled to remove olefin. The resultant material ($n^{20}D$ 1.4086) was also redistilled on the high vacuum line. The nitrogen, oxygen and propylene were taken directly from commercial cylinders and the carbon dioxide sublimed from Dry Ice. Nitric oxide was prepared according to the method of Noyes.[6]

2. **Rate Measurements.**—The apparatus used for all rate measurements is shown in Figs. 1 and 2. The temperature of the oil-bath was measured by a thermometer which was calibrated in position by comparison with a platinum resistance thermometer. The accuracy of the temperature readings is estimated as 0.04°. The quartz spiral gage[7] and leads from the reaction vessel were heated electrically to prevent condensation. The degassed liquid

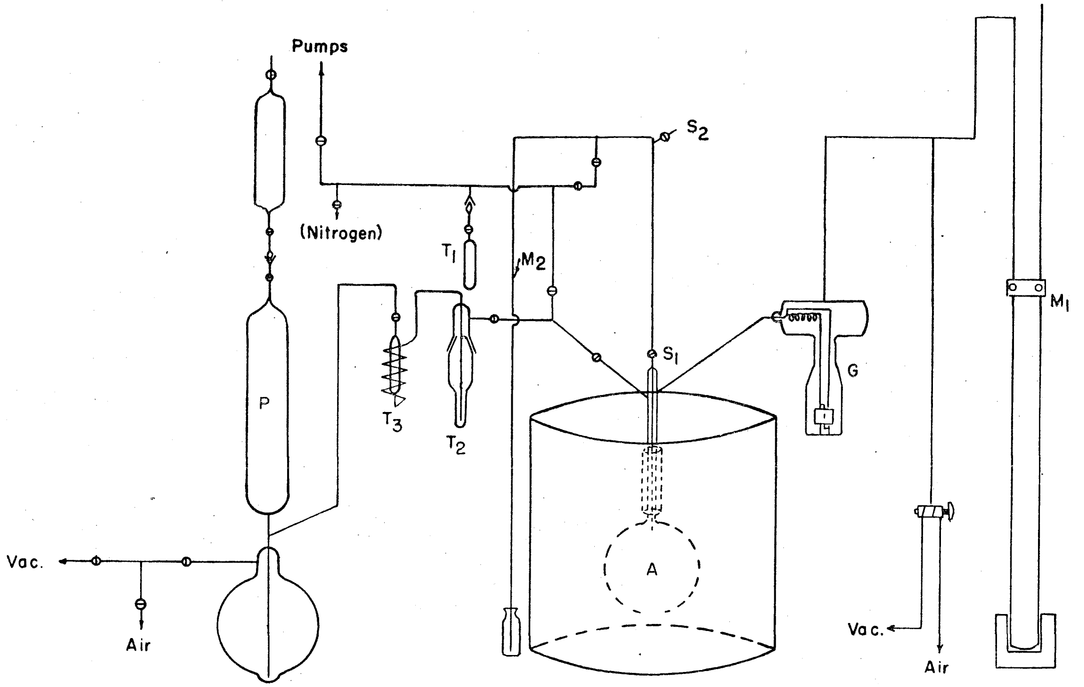

Fig. 1.—Apparatus for peroxide decompositions. Legend (see text): A, reaction vessel; G, quartz spiral pressure gage; M_1, gage manometer (equipped with vernier); M_2, input manometer; P, Toepler pump; S_1, input stopcock for peroxide and nitrogen; S_2, stopcock for admitting di-*t*-amyl peroxide; T_1, storage trap for di-*t*-butyl peroxide; T_2, T_3, product condensing traps.

peroxide was admitted to the capillary above S_1 (either by distillation or through S_2) and nitrogen added, the pressure of which was registered by M_2. The nitrogen served to force the peroxide into the reaction vessel when S_1 was opened. The pressure increase during the decomposition was followed by using the gage as a null point instrument in conjunction with M_1. The reaction was halted by freezing the vapors into T_2 and pumping the residual gases into a sample bulb for analysis with a mass spectrometer. Ketone was determined by adding an excess of hydroxylamine hydrochloride solution to the contents of T_2 and titrating the liberated acid.

3. **Flow Experiments.**—The technique for these experiments is described in the following paper.[4] In the subsequent paragraphs "cc./min." refers to cc. of vapor (N.T.P.) per minute.

Ketone Products of Di-*t*-butyl Peroxide.—Di-*t*-butyl peroxide (165 cc./min.) and nitrogen (25 cc./min.) were passed through the unpacked Pyrex tube at 225°. The liquid product was collected in a Dry Ice-cooled trap and fractionated. The distillation cuts obtained were (1) 56° (acetone), (2) 79° (methyl ethyl ketone), (3) higher boiling carbonylic compounds.

TABLE I

KETONE PRODUCTS FORM DI-*t*-BUTYL PEROXIDE

Ketone	Cc./min. N. T. P.	$n^{20}D$ Found	$n^{20}D$ Lit.	Deriv.	M. p., °C. Deriv.	M. p., °C. Mixed
Acetone	274	1.3589	1.3589	....	..	...
Methyl ethyl	21	1.3790	1.3788	*p*-Nitrophenylhydrazone	128[a]	128

[a] Literature value (Huntress and Mulliken, "Identification of Pure Organic Compounds") was 128–129°.

Di-*t*-butyl Peroxide and Nitric Oxide.—A mixture of the peroxide (67 cc./min.), nitric oxide (175 cc./min.), and nitrogen (50 cc./min.) was passed through the tube at 225° for one hundred and forty minutes, the liquid product being collected in ether cooled with Dry Ice. Distillation (after addition of Cellosolve to furnish a high boiling residue) gave a fraction of b. p. 83–85° which was collected in ether. Treatment of one third of the distillate with hydrogen chloride gas according to the method of Dunston and Bossi[8] yielded one gram of the hydrochloride [m. p. 136–137°, lit.[8] 136°; % Cl (Volhard) 20.8, calcd. for $(CH_2NOH)_3{\cdot}HCl$, 20.66]. A second portion of the distillate was converted to the benzoate derivative [m. p. 168–168.5° (decomp.), lit.[8] 168.5° (decomp.); % N (Dumas) 9.29, 9.30; % C 64.40, 64.67; % H 4.80, 5.02; theory 9.39, 64.42, 4.73, respectively]. Characteristic behaviors of formaldoxime—condensation to a white, insoluble solid upon standing, and violet coloration with cupric sulfate–potassium hydroxide solution—were also observed with the crude product.

Decomposition of Di-*t*-amyl Peroxide.—Di-*t*-amyl peroxide and nitrogen (*ca.* 100 cc./min. of each) were passed through the tube at 235°. The liquid product contained 87–88% acetone, 4–5% methyl ethyl ketone (aqueous azeotrope, b. p. 73°), and higher boiling ketones. The gaseous products, separated by low temperature distillation, were as in Table II.

TABLE II

GASEOUS DECOMPOSITION PRODUCTS OF DI-*t*-AMYL PEROXIDE

Gas	Cc./min.
n-C_4H_{10}	66.6

isopropylbenzene (1.44 moles) was heated in an oil-bath at 130° for thirty hours. The following products were obtained: *t*-butyl alcohol (0.24 mole), methane (0.06 mole), 2,3-dimethyl-2,3-diphenylbutane (0.07 mole) (C, 90.65; H, 9.3; mol. wt., 242; theory C, 90.75; H, 9.25; mol. wt., 238).

Decomposition of Di-*t*-butyl Peroxide

Kinetic Order.—If the pyrolysis follows the over-all stoichiometries

$$(CH_3)_3COOC(CH_3)_3 \longrightarrow 2(CH_3)_2CO + C_2H_6 \quad (6)$$

or

$$\longrightarrow CH_3COCH_3 + CH_3COC_2H_5 + CH_4$$

the peroxide pressure, $(A - x)$, is related to P, the total pressure, by

$$(A - x) = A - (P - P_0)/2 \quad (7)^9$$

where P_0 is the initial total pressure, obtained by a short extrapolation. The initial peroxide pressure, A, is obtained from

$$A = P_0 - P_{N_2} \quad (8)$$

where P_{N_2} is the nitrogen pressure, obtained by analysis of the product gases. log $(A - x)$ as a function of time is illustrated in Fig. 3 from which it is clear that, at least in the first 30–40%, the decomposition follows a first order expression. Data for typical runs are given in Table III. As the reaction approaches completion, a slight curvature is noticeable (Fig. 4) and upon complete decomposition, the total pressure of the products is found to be slightly less than three times the initial peroxide pressure. If the experimental ratio (2.88) is used to calculate values for $(A - x)$, adherence to the first order expression is indicated for virtually the entire reaction.[10] We have preferred, however, to use equation (7) since during the early stages of the reaction, where all rate measurements were made, the discrepancy between assumed and observed stoichiometries is within experimental error (Table IV). The initial rate constant calculated in this manner is essentially independent of pressure over the range 50–380 mm. (Table V).

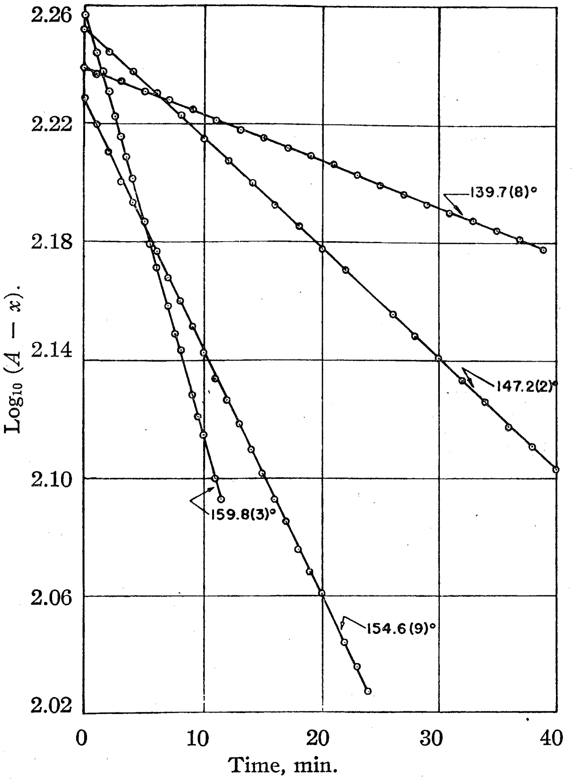

Fig. 3.—Decomposition of di-*t*-butyl peroxide, 140–160°.

Homogeneity.—Although the fate of methyl radicals produced during the reaction is modified by the surface of the confining vessel, the decomposition itself is apparently homogeneous. As shown in Table VI, the rate constant is not affected by the presence of Pyrex rod packing (2 mm. diameter) sufficient to produce an elevenfold change in surface–volume ratio of the vessel.

Tests for a Chain Reaction.—A number of well recognized chain inhibiting reagents have

---

[9] Since the higher ketones are also probably formed by substitutive methylation, their production should not alter the pressure change during decomposition.

[10] It should be mentioned that the apparent decrease in rate is not traceable to interaction with reaction products since addition of a spent mixture does not influence the decomposition of a fresh peroxide charge.

been added in attempts to detect chain processes in the di-*t*-butyl peroxide decomposition. In the first of these tests the peroxide and additive were passed through a heated tube[4] and the unreacted peroxide collected and measured. From the results, summarized in Table VII, it is clear that neither nitric oxide nor propylene appreciably affects the decomposition velocity. That methyl radicals react readily under the experimental conditions with both additives is shown by the isolation of products derivable only from these sources. The formation of formaldoxime has been postulated previously[11] but apparently this is the first report of its isolation from a methyl radical–

Propylene	95	C_4H_8, C_4H_{10}, C_5H_{12}, etc.

In a closed system oxygen causes a slight acceleration in the rate of pressure increase, but apparently the velocity of decomposition is not affected since the production of ketone is virtually unchanged (Table VIII).

TABLE VIII

DECOMPOSITION OF DI-*t*-BUTYL PEROXIDE. EFFECT OF OXYGEN

Temperature, 147.2(2)°; reaction time, 47 min.

Peroxide, mm.	Oxygen, mm.	Oxygen consumed, mm.	Ketone produced, mm. Found	Calcd.[a]
170.1	41.4	37.2	113	112

[a] Assuming the rate constant (1.41×10^{-4} sec.$^{-1}$) at this temperature for an oxygen-free system.

It should be noted that the major gaseous oxidation product of methyl radicals at this temperature is carbon monoxide, in contrast to the formaldehyde and methanol reported for the reaction at 0°.[12] A test for aldehyde with Schiff reagent on the liquid product was negative.

Mechanism and Activation Energy.—A summary of all data presented above leads to the conclusion that the decomposition of di-*t*-butyl peroxide is a homogeneous, first order, nonchain process. The suggested mechanism (equations (1), (2) and (3)) yields the rate equation

$$-\frac{d[(CH_3)_3COOC(CH_3)_3]}{dt} = \frac{d[C_2H_6]}{dt} = \frac{{}^1/_2 d[(CH_3)_2CO]}{dt} = k_1[(CH_3)_3COOC(CH_3)_3]$$

from which it is seen that k_1 and the experimentally determined rate constant should be identical. In support of this, the calculated energy of activation, E_1, for (1) is in close agreement with the experimental value. Since (1) is postulated as a unimolecular dissociation reaction, E_1 may be taken equal to the energy of dissociation.[13] The latter value has been calculated from the heat of combustion of the peroxide and other thermochemical data.[14]

The combustion heats for the peroxide and *t*-butyl alcohol lead to the equation

$$\underset{1282.6}{C_4H_9O_2C_4H_9(g)} + \underset{68.4}{H_2(g)} \longrightarrow \underset{2(640.7)}{2C_4H_9OH(g)}; \quad \Delta H_{298} = -69.6; \ \Delta E = \Delta H.$$

$$D_{O-O} \text{ (in peroxide)} = 2D_{O-H} - D_{H-H} - 69.6$$

The value of D_{O-H} in *t*-butyl alcohol is computed from

$$\underset{686.3}{C_4H_{10}(g)} + {}^1/_2O_2(g) \longrightarrow \underset{640.7}{C_4H_9OH(g)}; \quad \Delta H_{298} = -45{,}6; \ \Delta E = -45.3.$$

$$D_{O-H} = D_{C-H} + {}^1/_2 D_{O-O} \text{ (in oxygen)} - D_{C-O} + 45.3 = 105.2 \text{ kcal./mole}$$

Hence $E_1 = D_{O-O}$ (in peroxide) = 39 kcal./mole.[15]

The data of Table IV, plotted in the conventional manner in Fig. 5, yield an experimental activation energy of 39.1 ± 0.5 kcal./mole.

Calculation of the pre-exponential factor gives, for the rate constant $k = 3.2 \times 10^{16}(e^{-39{,}100/RT})$.

The entropy of activation is the abnormally high[16] value + 14.5 E.U. at 160°.

Decomposition of Di-*t*-amyl Peroxide

Milas and Surgenor[1] have shown that the decomposition of di-*t*-amyl peroxide over glass wool yields, mainly, *n*-butane and acetone with small amounts of ethane, propane and methyl ethyl ke-

(13) Glasstone, Laidler and Eyring, "The Theory of Rate Processes," McGraw-Hill Book Co., New York, N. Y., 1941.

(14) (a) Data from this Laboratory: Di-*t*-butyl peroxide: heat of combustion = 1273 kcal./mole for (1) 25°; heat of vaporization = 9.6 kcal./mole. *t*-Butyl alcohol: heat of combustion = 629.4 kcal./mole for (s) 25°; heat of fusion = 1.6 kcal./mole; heat of vaporization = 9.7 kcal./mole; (b) Rossini, *J. Research Natl. Bur. Standards*, **15**, 357 (1935): Isobutane; heat of combustion = 686.3 kcal./mole for (g) 25°; (c) Baughan and Polanyi, *Trans. Faraday Soc.*, **39**, 19 (1943): D_{C-O} in *t*-butyl alcohol = 85.0 kcal./mole. D_{C-H} in isobutane (for the *t*-hydrogen) = 86.0 kcal./mole; (d) W. A. Noyes, Jr., and P. A. Leighton, "The Photochemistry of Gases," Reinhold Publishing Corp., New York, N. Y., 1941, pp. 134–135: D_{H-H} in hydrogen = 4.454 e. v./mole. D_{O-O} in oxygen (normal atoms) = 5.11 e. v./mole.

(15) Pauling ("The Nature of the Chemical Bond," Cornell University Press (1939)) estimated D_{O-O} in hydrogen peroxide as 34.9 kcal./mole while Skinner (*Trans. Faraday Soc.*, **41**, 645–662 (1945)) gives the much higher value 52 kcal./mole. However, recently Glockler and Matlack, (*J. Chem. Phys.*, **14**, 504 (1946)) using methods similar to those of Skinner, reported that the latter's value is much too high and that 34.9 is the better figure.

(16) For example, the activation entropies for the decomposition of nitrogen pentoxide and dimethyl ether are, respectively, −2.5 and +2.5 E. U.

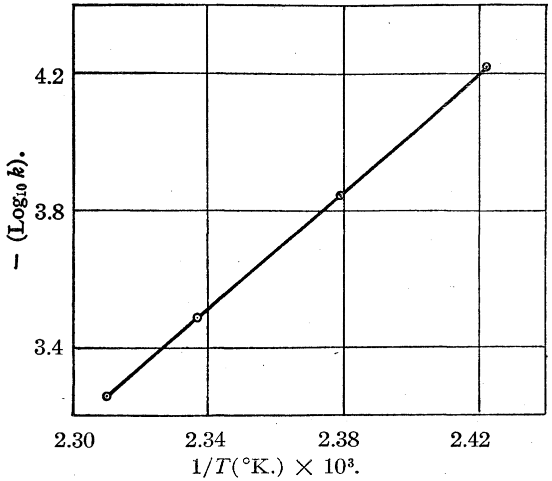

Fig. 5.—Decomposition of di-*t*-butyl peroxide, effect of temperature.

tone. With a larger bore, unpacked tube we find, in addition, small amounts of ethylene, methane and unidentified higher ketones. These additional products are attributed to free radical processes in the gas phase, the ethylene (and perhaps some methane) being ascribed to disproportionation reactions and the rest to alkyl radical attack on the primary ketone products.

Kinetic Order.—Since all products except ethylene are derivable from processes which should give rise to a three-fold pressure increase, the instantaneous values of the di-*t*-amyl peroxide pressure were also calculated from equation (7). A typical experiment is illustrated in Table IX and the summarized data for the decomposition at 132–150° are given in Table X and Fig. 6. (As before, the rate constants and ketone yields were computed from measurements taken during the first third of the reaction. No hydrocarbon yields are given because of difficulty in recovering the butane quantitatively.)

	184 + 257 CO_2	5.12	
	339	5.61	

Furthermore, in the higher pressure runs, a definite falling off of the rate is noticeable before the decomposition is 30% complete. These results probably indicate that the principal mode of decomposition is first order but that a higher order process is also occurring.

Homogeneity.—No appreciable difference in rate was observed when the pyrolysis was carried out in the packed vessel (Table XII). It is concluded, therefore, that the decomposition takes place only in the gas phase.

Activation Energy.—Since the decomposition of di-*t*-amyl peroxide is not strictly first order, the over-all activation energy, 37 kg.-cal./mole (Fig. 7), does not represent the energy requirements of any single process. Presumably, however, a closer approximation to the activation energy for scission of the oxygen–oxygen bond could be obtained from low pressure data where effects of higher order processes would be minimized. Extrapolation to zero pressure of the values (for $n = 3$) in Table XI yields $E = 41$ kcal./mole. Hence, it is probable that the true value of E_1 is between 37 and 41 kcal./mole.

Acknowledgment.—The authors wish to thank Messrs. F. H. Seubold and E. R. Bell for their assistance in performing the flow experiments. They also are indebted to Dr. D. P. Stevenson of the Physics Department and to Messrs. W. R. Keeler and V. Lantz of the Analytical Department of this Company for supplying the mass spectrometric and calorimetric data.

Summary

1. The vapor phase decomposition of di-*t*-butyl peroxide at 140–160° is a homogeneous, first order, non-chain reaction, the rate constant for which is given by $k = 3.2 \times 10^{16}(e^{-39{,}100/RT})$. The rate-determining step is the scission of the oxygen–oxygen bond and the experimental activation energy closely approximates the calculated strength of this bond.

2. The decomposition proceeds through the formation of *t*-butoxy and methyl radicals. The primary reaction product of the latter and nitric oxide has been identified as formaldoxime.

3. The principal decomposition products are ethane and acetone. However, some methyl radicals react with acetone to yield methane and methyl ethyl and higher ketones. A small fraction of the peroxide may decompose in another manner.

4. The pyrolysis of di-*t*-amyl peroxide at 130–150° is a homogeneous, approximately first order reaction. The over-all activation energy is 37 kcal./mole and that for the initial step is estimated as 37–41 kcal./mole. The predominant products are n-butane and acetone, but methane, ethane, ethylene, propane and methyl ethyl and higher ketones are also found in small amounts. All products can be accounted for by the intermediate formation of *t*-amyloxy, ethyl and methyl radicals.

Decompositions of Di-*t*-Alkyl Peroxides. II. Reactions of the Resultant Free Radicals

BY FREDERICK F. RUST, FRANK H. SEUBOLD AND WILLIAM E. VAUGHAN

In the previous paper[1] evidence was presented that free methyl radicals derived from decomposing di-*t*-butyl peroxide reacted with and converted a part of the acetone—also a product of the decomposition—to methyl ethyl ketone and higher ketones. The inclusion of other compounds with the decomposing di-*t*-butyl and di-*t*-amyl peroxides has now made possible a study of other gas phase reactions of free methyl and free ethyl in the temperature region of 200–235°. Although possibilities for organic syntheses will suggest themselves—such as the addition of two methyl or ethyl groups to a double bond or the replacement of hydrogen atoms by methyls, it is not the intent of the present paper to present optimum conditions for such syntheses. Instead, it is hoped that the present study will demonstrate the usefulness of the di-*t*-alkyl peroxides as tools in the study of free radical phenomena. The fate of the various peroxide-derived free radicals in different hydrocarbon atmospheres is revealed by the components which have been separated from fairly complex reaction mixtures.

Thus, the abstraction of a hydrogen atom from a molecule by methyl and the combination of the resulting radical with another methyl is shown by the formation of ethylbenzene from toluene and triptane from 2,3-dimethylbutane.

$$(CH_3)_3COOC(CH_3)_3 \longrightarrow [2(CH_3)_3CO-] \longrightarrow 2CH_3 + 2CH_3COCH_3 \qquad (1)$$

$$RH + CH_3 \longrightarrow CH_4 + R \qquad (2)$$

$$R + CH_3 \longrightarrow RCH_3 \qquad (3)$$

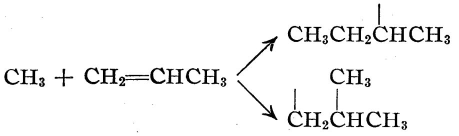
When olefins become the objects of radical attack the transformations are more complex, but the results are in general agreement with current concepts of chain initiation, transfer, and termination in polymerization reactions. Thus, as suggested by other workers,[2] *methyl addition to ethylene* gives a propyl radical which adds to other ethylene molecules unless or until the chain is terminated by collision with another methyl.

$$CH_3 + nC_2H_4 \longrightarrow CH_3(C_2H_4)_n \qquad (4)$$

$$CH_3(C_2H_4)_n + CH_3 \longrightarrow CH_3(C_2H_4)_nCH_3 \qquad (5)$$

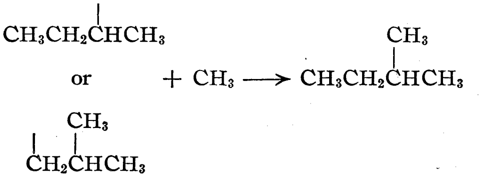
At these low temperatures, however, the polymerization is relatively uncomplicated by disproportionation reactions. *n*-Butane, *n*-hexane and *n*-octane were isolated and no odd carbon-numbered hydrocarbons or unsaturates were found.

The reaction of *methyl and propylene* has been more extensively studied. Addition of free methyl to the double bond



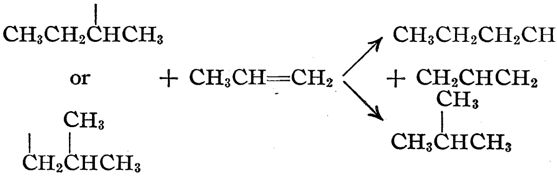
$$CH_3 + CH_2{=}CHCH_3 \begin{array}{l} \nearrow CH_3CH_2\overset{|}{C}HCH_3 \\ \searrow \overset{|}{C}H_2\overset{\overset{CH_3}{|}}{C}HCH_3 \end{array} \qquad (6)$$

is followed either by (a) combination with another methyl to give isopentane



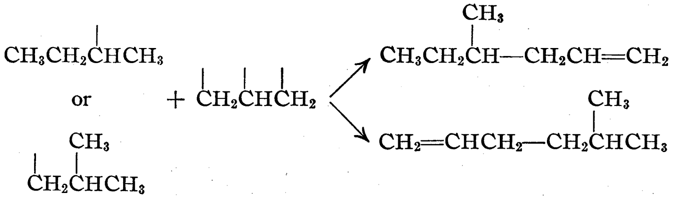
$$\begin{array}{c} CH_3CH_2\overset{|}{C}HCH_3 \\ \text{or} \\ \overset{|}{C}H_2\overset{\overset{CH_3}{|}}{C}HCH_3 \end{array} + CH_3 \longrightarrow CH_3CH_2\overset{\overset{CH_3}{|}}{C}HCH_3 \qquad (7)$$

(b) abstraction of a hydrogen atom from propylene to yield butanes



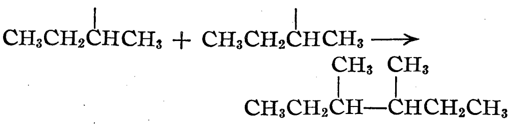
$$\begin{array}{c} CH_3CH_2\overset{|}{C}HCH_3 \\ \text{or} \\ \overset{|}{C}H_2\overset{\overset{CH_3}{|}}{C}HCH_3 \end{array} + CH_3CH{=}CH_2 \begin{array}{l} \nearrow CH_3CH_2CH_2CH_3 \\ \quad + CH_2CHCH_2 \\ \searrow CH_3\overset{\overset{CH_3}{|}}{C}HCH_3 \end{array} \qquad (8)$$

(c) combination with allyl to form a heptene

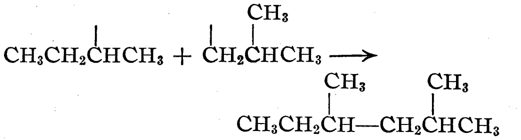


$$\begin{array}{c} CH_3CH_2\overset{|}{C}HCH_3 \\ \text{or} \\ \overset{|}{C}H_2\overset{\overset{CH_3}{|}}{C}HCH_3 \end{array} + \overset{|}{C}H_2\overset{|}{C}H\overset{|}{C}H_2 \begin{array}{l} \nearrow CH_3CH_2\overset{\overset{CH_3}{|}}{C}H{-}CH_2CH{=}CH_2 \\ \searrow CH_2{=}CHCH_2{-}CH_2\overset{\overset{CH_3}{|}}{C}HCH_3 \end{array} \qquad (9)$$

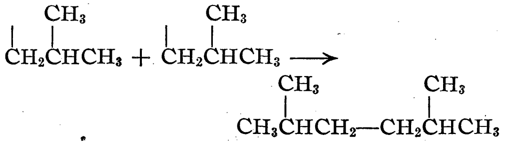
(d) addition to other radicals to form, for example, octanes



$$CH_3CH_2\overset{|}{C}HCH_3 + CH_3CH_2\overset{|}{C}HCH_3 \longrightarrow CH_3CH_2\overset{\overset{CH_3}{|}}{C}H{-}\overset{\overset{CH_3}{|}}{C}HCH_2CH_3 \qquad 10)$$



$$CH_3CH_2\overset{|}{C}HCH_3 + \overset{|}{C}H_2\overset{\overset{CH_3}{|}}{C}HCH_3 \longrightarrow CH_3CH_2\overset{\overset{CH_3}{|}}{C}H{-}CH_2\overset{\overset{CH_3}{|}}{C}HCH_3 \qquad (11)$$



$$\overset{|}{C}H_2\overset{\overset{CH_3}{|}}{C}HCH_3 + \overset{|}{C}H_2\overset{\overset{CH_3}{|}}{C}HCH_3 \longrightarrow CH_3\overset{\overset{CH_3}{|}}{C}HCH_2{-}CH_2\overset{\overset{CH_3}{|}}{C}HCH_3 \qquad (12)$$

(e) addition to propylene in a manner analogous

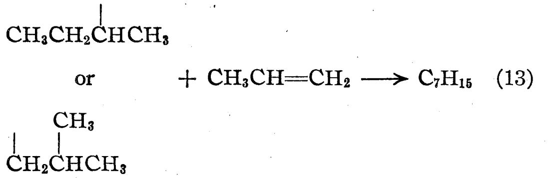
TABLE I

ISOLATED PRODUCTS FROM REACTION OF METHYL WITH 2-BUTENE AND ISOBUTENE, 235°

Products from 2-butene	Products from isobutene	Mechanism of formation, equation
$CH_3\overset{CH_3}{\overset{\vert}{C}}H\overset{H}{\overset{\vert}{C}}HCH_3$	$(CH_3)_2\overset{H}{\overset{\vert}{C}}CH_2—CH_3$	6 and 8
$CH_3—CH_2CH{=}CHCH_3$	$CH_2{=}C(CH_3)CH_2—CH_3$	14 and 15
$CH_3\overset{CH_3}{\overset{\vert}{C}}{=}CHCH_3$	$(CH_3)_2C{=}CH—CH_3$	14 and 15
$CH_3\overset{CH_3}{\overset{\vert}{C}}H\overset{CH_3}{\overset{\vert}{C}}HCH_3$	$(CH_3)_2\overset{CH_3}{\overset{\vert}{C}}CH_2—CH_3$	6 and 7
Nonenes	Nonenes	6 and 9
$CH_3\overset{CH_3}{\overset{\vert}{C}}HCH(CH_3)—(CH_3)CH\overset{CH_3}{\overset{\vert}{C}}HCH_3$	Decanes	6 and 10
Higher boiling	Higher boiling	....

to the addition of methyl with eventual formation of octanes and higher products



$$CH_3CH_2\overset{\vert}{C}HCH_3 \text{ or } \overset{\vert}{C}H_2\overset{CH_3}{\overset{\vert}{C}}HCH_3 + CH_3CH{=}CH_2 \longrightarrow C_7H_{15} \quad (13)$$

When methyl abstracts a hydrogen atom from propylene

$$CH_3 + CH_3CH{=}CH_2 \longrightarrow CH_4 + CH_2CHCH_2 \quad (14)$$

the resulting allyl can be found in the C_7 olefin (equation 9) or as butene.

$$CH_3 + CH_2CHCH_2 \longrightarrow CH_3CH_2CH{=}CH_2 \quad (15)$$

Each of these hydrocarbons has been identified in the reaction products and, perhaps equally important, no others of different carbon structure have been found.

Evidence for initial addition of methyl to either end of the propylene double bond is indicated by the presence of both normal and isobutane among the reaction products (equation 8). That ethyl behaves similarly is shown by isolation of *n*- and isopentane from the reaction of propylene and di-*t*-amyl peroxide (*cf.* Beeck and Rust[3]).

One unexplained phenomenon is the shift in the double bond of the olefinic products which probably occurs at the time of formation. Thus, both 1- and 2-butene are found and, although a terminal double bond would be predicted for the heptenes, actually a shift to an internal position has occurred in a part of the product. The expected carbon structure is, however, borne out by infrared analysis of the hydrogenated C_7 fraction.

The attack of methyl on 2-butene or isobutylene gives the products which would be predicted from the analogous reactions of methyl with propylene. These products are listed in Table I, together with references to the equations representing the mode of formation of the analogous compounds derived from propylene. Thus, 2,3-dimethylbutane which is derived by dimethylation of the double bond of 2-butene is analogous to isopentane which is formed by dimethylation of the propylene double bond. The mechanism is illustrated by equations 6 and 7. The exaggerated bonds shown in the table are the ones newly formed as a consequence of radical attack.

When di-*t*-amyl peroxide is decomposed at 235°, the products prove that ethyl radicals are released and when propylene is mixed with the decomposing peroxide, the expected compounds are formed. 3-Methylhexane, from the addition of two ethyl groups to the double bond; iso- and normal pentane, from internal and external addition, respectively, of ethyl radical to the double bonds (equation 6 and 8); and straight chain pentenes, from the replacement of a hydrogen atom by an ethyl group (equation 14 and 15), have all been isolated.

Effect of Surface

Extensive investigation by previous workers[2] has provided ample evidence for the combination of methyl radicals at the wall. So important is this wall effect that virtually no olefin could be involved in reactions with methyl if 15-mm. Pyrex tubing were used as the reactor. Successful results were obtained in 70-mm.-tubes. The obvious implication is that methyl addition to double bonds and methane formation by hydrogen abstraction are largely gas phase reactions. The conditions of combination for larger radicals are not suggested by the present work.

Materials and Procedure

The ethylene was a product of the Ohio Chemical Company and assayed 99.5%. Propylene was prepared by dehydration of isopropyl alcohol and, after being purified by distillation, analyzed 98.2%, the remainder being air and saturates. The 2-butene was analyzed by infrared absorption to be as follows: 1-butene, 5.5%; 2-butene, 94.2%; butadiene, 0.2%; and *n*-butane, 0.1%. The isobutene was a refinery product which analyzed 99.7%. The liquid hydrocarbons were all carefully distilled and checked for purity by refractive indices.

---

[3] Beeck and Rust, *J. Chem. Phys.*, **9**, 480 (1941).

The di-*t*-butyl and di-*t*-amyl peroxides were synthesized in accordance with the procedures given by Vaughan and Rust.[4] The di-*t*-butyl peroxide had an index $n^{20}\mathrm{D}$ 1.3890 and was 98+% pure. The di-*t*-amyl peroxide distilled at 54.5–55° at 17–18 mm.; its refractive index was $n^{20}\mathrm{D}$ 1.4083.

In general, experiments were conducted by metering the gaseous hydrocarbons or carrier nitrogen through flowmeters and the liquid peroxide through a rotameter. The peroxide was vaporized and mixed with the gaseous materials in a glass tubular coil surrounded usually by boiling water. The reaction mixture then passed directly into the top of the reactor tube (1250 cc., 70 mm. i.d.), which was heated by a thermostated oil-bath. The liquid product was collected in a water wash-bottle and an ice-cooled trap while the effluent gas was passed into an aspirator bottle. The gases and vapors were analyzed by low temperature distillation except where otherwise specified.

Experimental

Toluene and Di-*t*-butyl Peroxide. 2,3-Dimethylbutane and Di-*t*-butyl Peroxide.—Mixtures of hydrocarbon and peroxide in a molar ratio of 2:1 were metered into the reaction system at a rate calculated to give a total vapor flow of 300 cc./minute[5] N.T.P. Carrier nitrogen (50 cc./minute) was added. The reaction temperature was 235°.

From toluene, ethylbenzene (b. p. 136°, $n^{20}\mathrm{D}$ 1.4937) was produced in a 6.25% yield based on the input peroxide. Higher boiling product, 50% greater in amount than the ethylbenzene, was also collected; this material had a molecular weight of 199 which compares with 182 for diphenylethane.

Under comparable conditions triptane was produced from the dimethylbutane in a yield of 7.7%. The analysis of the triptane fraction was made by infrared absorption. Higher boiling products in comparable volume were not investigated.

Ethylene and Di-*t*-butyl Peroxide.—Experiments were carried out as follows: A mixture of ethylene plus peroxide was introduced at a rate of 200 cc./min. vapor volume into a Pyrex tube heated to 225 or 235°. Ratios of ethylene to peroxide between 1:1 and 9:1 were used. The data are given in Table II.

TABLE II

REACTION OF DI-*t*-BUTYL PEROXIDE AND ETHYLENE

Temp., °C.	210	225	225	225	225	235
Ratio C_2H_4:peroxide	1:1	1:1	2:1	4:1	9:1	9:1
% Peroxide reacted	56.8	89.6	94.2	80.4	59.2	63.5
% Reacted peroxide converted to						
Ethane	66.9	82.3	68.2	62.1	40.7	61.6
n-Butane	9.7	6.8	14.2	15.1	28.8	13.6
n-Hexane	4.4	1.6	4.6	13.4	10.2	16.0
n-Octane	...	...	...	...	...	4.0

In every case higher boiling products were produced but the amounts were too small to permit identification. The hexane had a boiling point of 69° and $n^{20}\mathrm{D}$ 1.3750 (lit.[6] 68.7° and 1.3750). Respective values for the octane isolated are b. p. 124.2° and $n^{20}\mathrm{D}$ 1.3986 (lit., 125.6° and 1.3976). The above estimates of conversions are based on the actual amounts of materials isolated and on the amount of decomposed peroxide as given by the ketone formed. Unreacted peroxide in the high boiling fractions was removed by boiling with concentrated hydrogen iodide in acetic acid; the resulting iodine was destroyed with thiosulfate solution and the alkyl iodides with alcoholic potassium hydroxide. The residue was then washed and fractionated.

Propylene and Di-*t*-butyl Peroxide.—Propylene and di-*t*-butyl peroxide vapor reacted at 235° with input flow rates of propylene and peroxide of 200 cc./min. and 100 cc./min. The effluent vapors, after passing through a water bubbler and ice-cooled trap, were collected in an aspirator bottle and later fractionated by low temperature distillation. The gaseous fractions were analyzed subsequently in an Orsat-type apparatus with the exception of the C_4 cut which was analyzed by infrared spectrophotometry. The composition of these light fractions is shown in Table III.

TABLE III

Product	Per cent.
Propylene	60.6
Methane	13.7
Ethane	9.8
Isopentane	6.3
n-Butane	2.4
1-Butene	2.0
2-Butene	0.8
Isobutane	0.4
Others	4.0

The liquid product was washed with water and hydroxylamine to remove as much ketone as possible and then fractionated. Besides the low boiling cuts (C_5) this distillation showed fractions in the C_7, C_8 and C_9 ranges and a very substantial amount of still higher boiling material. The 107 to 113.5° cut after washing with concentrated sulfuric acid and distilling, had a refractive index of $n^{20}\mathrm{D}$ 1.3970. According to infrared analysis this fraction was *ca.* 95% 2,4-dimethylhexane, and 5% 2,5-dimethylhexane. These two octanes have reported boiling points of 109.8 and 109.3° and indices $n^{20}\mathrm{D}$ 1.3958 and 1.3929, respectively. The 113.5 to 119.5° fraction had an index $n^{20}\mathrm{D}$ 1.4044 before and after washing with concentrated sulfuric acid. Infrared analysis showed it to be 98% 3,4-dimethylhexane (lit. b. p. 117.85°, $n^{20}\mathrm{D}$ 1.40436). The next higher fraction boiling around 135° appears to be a nonane, but has not been identified. Figure 1 is a line diagram of the infrared absorption spectra of the heptene and octane fractions.

In order to determine the carbon skeleton of the small heptene fraction, propylene and peroxide were passed through the reactor at 235° for twenty-five hours. The resulting product, after being washed free of acetone, was hydrogenated at 80° in isopropyl alcohol with Ruffert nickel. The product was filtered, water-washed, dried

TABLE IV

YIELD OF HIGHER HYDROCARBONS DERIVED FROM PROPYLENE (BASED ON INPUT PEROXIDE)

Product	Per cent.
n-Butane	4.5
1- and 2-butene	5.0

(5) Hereinafter, "cc./min." means cc. vapor/minute N.T.P.

(6) The literature values for the physical constants for the hydrocarbons cited herein are taken from M. P. Doss, "Physical Constants of the Principal Hydrocarbons," The Texas Company, New York, N. Y., 1942.

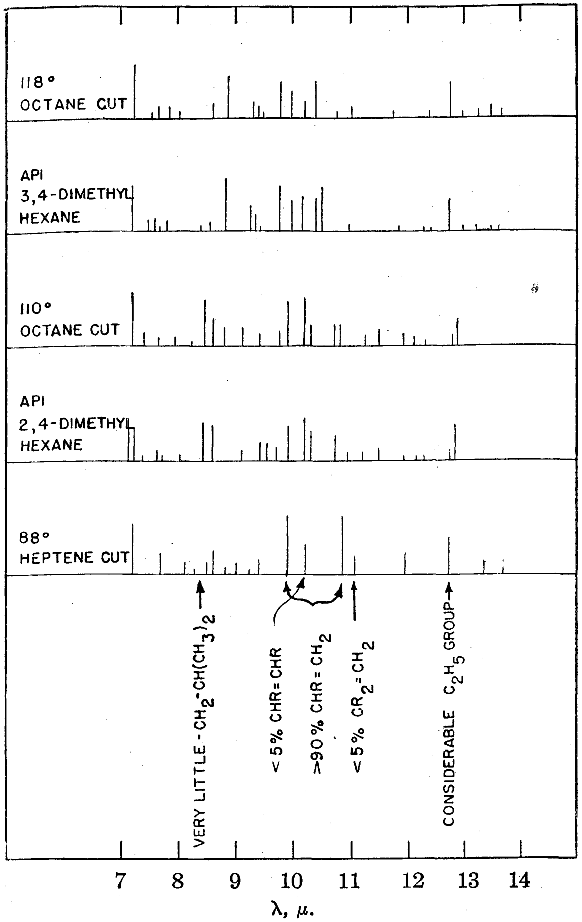

Fig. 1.—Infrared spectra of di-*t*-butyl peroxide–propylene reaction products.

and fractionated. The heptane fraction was separated and by infrared analysis was found to be 85–95% 3-methylhexane and 5–15% 2-methylhexane. The yields of some products are given in Table IV.

2-Butene and Di-*t*-butyl Peroxide.—Di-*t*-butyl peroxide (100 cc./min.) and 2-butene (200 cc./min.) were mixed and passed into the reactor at 235°. Analysis of the effluent gaseous products gave

	Per cent.
Butenes	60.0
Methane	17.5
Ethane	9.3
Pentenes	4.2
Isopentane	1.2
Other	7.8

The fraction containing dimethylbutane was washed with water and concentrated sulfuric acid to remove acetone and olefins. The material was then distilled and found to have an index $n^{20}D$ 1.3750 and a boiling point of 58.2° (lit., 1.3749 and 57.99°). The dibromide derivative was prepared (2,3-dibromo-2,3-dimethylbutane); this had a melting point of 163–164°, and a mixed melting point of 163.5–164.0°.

The higher boiling product was carefully water-washed and then steam distilled. The hydrocarbons were separated from the water in the distillate and refractionated. The material that boiled between 128 and 142° had a molecular weight (by vapor density) of 122.6 to 122.7, and a molecular weight on the basis of bromine number of 126; the molecular weight of nonene is 126. A narrow boiling fraction between 153.5 and 155.0° had a molecular weight of 139, while the theoretical value for decane is 142. Based on the probable reaction mechanism this decane must be the heretofore unreported 2,3,4,5-tetramethylhexane. The boiling point, as given by the distillation flat, was 155° and the index, $n^{20}D$, 1.426. A substantial amount of still higher boiling material remained. The yields are given in Table V.

TABLE V

YIELD OF HIGHER HYDROCARBONS DERIVED FROM 2-BUTENE (BASED ON INPUT PEROXIDE)

Product	Per cent.
Pentenes	10.0
Isopentane	3.5
Dimethylbutane	8.0
Nonenes	2.0
Decane	1.5

Isobutene and Di-*t*-butyl Peroxide.—Isobutene (200 cc./min.) and di-*t*-butyl peroxide (100 cc./min.) were passed into the reactor at 235°. The reaction products were analyzed essentially as described for propylene and 2-butene. Dimethylation of the double bond gives neohexane. The boiling point of the isolated fraction was 49–50° and its index $n^{20}D$ 1.3686 (lit., 49.7° and 1.3686, respectively). However, the principal products are *t*-amylenes. The predicted compound would be $CH_2{=}\overset{CH_3}{\overset{|}{C}}CH_2CH_3$ but the usual accompanying isomerization, in this case to trimethylethylene, seems to be rapid. Infrared analysis of the amylene fraction shows 60% 2-methyl-1-butene and 40% trimethylethylene. Isopentane is formed in an appreciable quantity ($n^{20}D$ 1.3530, b. p. 28.0°; lit., $n^{20}D$ 1.3540, b. p. 27.9°).

The low temperature distillation of the gaseous effluent gave results as follows

	Per cent.
Isobutene	56.0
Methane	21.3
Ethane	8.0
t-Pentenes	5.1
Isopentane	4.7
Others	4.9

A fraction boiling in the nonene range, 128–136°, had a molecular weight of 121.5 and bromine number of 115.5; for nonene the molecular weight and theoretical bromine number are both 126.

A fraction distilling between 162 and 172° was found to have a molecular weight of 141 and a bromine number of 2.6, which compares well with 142 and zero for decane. By analogy with propylene the decanes expected and probably present are 2,2,4,4-, 2,2,5,5- and 3,3,4,4-tetramethylhexanes. Inclusion of additional isobutene units in the reaction chain gives higher molecular weight hydrocarbons. Yields are shown in Table VI.

TABLE VI

YIELD OF HIGHER HYDROCARBONS DERIVED FROM ISOBUTENE (BASED ON INPUT PEROXIDE)

Product	Per cent.
t-Amylenes	8.5
Isopentane	7.5
Neohexane	6.0
Nonenes	2.0
Decanes	2.0

Propylene and Di-*t*-amyl Peroxide.—Propylene 200 cc./min. and di-*t*-amyl peroxide vapor 100 cc./min. were passed through the reactor at 235°. The effluent gaseous products of the reaction were found to be as follows

	Per cent.
Propylene	61.3
n-Butane	17.3
Ethane	8.5
Ethylene	2.0
Propane	2.0
Straight chain pentenes	1.3
n-Pentane	1.1
Methane	0.9
Isopentane	0.7
Others	4.9

The liquid products collected were water-washed and fractionated. Cut I (20–54°) was water-washed to remove some acetone and analyzed by infrared absorption. Its hydrocarbon composition was 50% isopentane, 25% *n*-pentane, 10% 1-pentene and 5% each of 2-pentene, 2-methyl-1-butene and 2-methyl-2-butene. The 54–57° fraction was almost entirely acetone, and the very small amount of water-insoluble organic material (b. p. 70–71°) was not analyzed further. A small intermediate fraction (57–91°) was washed with hydroxylamine hydrochloride solution and dried; infrared analysis showed 5% of a 1-olefin, 60% 3-methylhexane and 30% 2-methylhexane. The remaining 5% was ketone which was not completely removed by water-washing. Cut IV (b. p. 91–94) was washed with concentrated sulfuric acid with virtually no change in volume or the refractive index of 1.3890. Infrared analysis identified the material as 3-methylhexane and a vapor density measurement gave the molecular weight as 100 (theory 100.2). The decane fraction (153–161°) after being washed with concentrated sulfuric acid and 6 *N* sodium hydroxide analyzed as follows: carbon 84.4%, hydrogen 15.4%, mol. wt. 149; calcd., 84.5, 15.5 and 142, respectively.

TABLE VII

YIELD OF HIGHER HYDROCARBONS DERIVED FROM PROPYLENE (BASED ON DI-*t*-AMYL PEROXIDE)

Product	Per cent.
Amylenes	2.7
n-Pentane	2.5
Isopentane	1.6
3-Methylhexane	8.0
Nonenes and decanes	3.0

Acknowledgment.—The authors are indebted to the members of the Spectroscopic Department of This Company, and in particular to Dr. R. S. Rasmussen, for the infrared analyses.

Summary

1. The di-*t*-alkyl peroxides are especially useful tools for the study of free radical processes.

2. Some of the products from the interaction of free methyl and ethyl with various saturated and unsaturated hydrocarbons have been isolated and identified. Mechanisms of formation of these compounds are suggested.

The Structures of the Carbides, Nitrides and Oxides of Uranium[1]

BY R. E. RUNDLE, N. C. BAENZIGER, A. S. WILSON AND R. A. MCDONALD

Introduction

The systems uranium–carbon, uranium–nitrogen and uranium–oxygen have been given thorough X-ray study in the course of work carried out for the Metallurgical Project. In this paper this work will be summarized rather briefly, giving pertinent structural information and necessary details concerning the methods used in carrying out the work.

In general, little discussion of the structures will be presented here. The nature of the metal-like monocarbide, mononitride and monoxide are discussed elsewhere along with other similar compounds.[2] Since the structures of nearly all the phases examined have been simple, parameterless structures of types described thoroughly in "Strukturbericht," it has seemed unnecessary to present lengthy accounts of the structural determinations, together with tables of calculated and observed intensities. In every case not otherwise indicated a careful comparison of observed and calculated intensities for the assigned structure has been made.

Though this paper is intended primarily as a summary of X-ray structures, many of the compounds whose structures are reported here were discovered and their compositions first obtained either solely by X-ray study or jointly with chemical investigations. It seems well to point out, therefore, that X-ray study of the carbides, nitrides and oxides of uranium has required extensive revision of formulas in these systems. The monocarbide and the mononitride were discovered, with chemical and metallographic aid, by X-ray diffraction; the monoxide was found solely by X-ray diffraction. Not a single nitride of uranium had been assigned a correct formula before these X-ray studies were made.[3] Even among the higher oxides new phases were found, and the relationships among the higher oxides

[3] Gmelin's "Handbuch der anorganischen Chemie," system Number 55, Verlag Chemie, Berlin, 1936, p. 107 ff.

and nitrides turned out to be more complex than hitherto suspected.

Most of the compounds reported here are prepared by the reaction of solids to form solid products which are difficult to handle chemically. The fact that X-ray study has required extensive revision of formulas in the systems provides an example of the serious errors which can arise in the interpretation of solid–solid reactions by purely chemical examination.

The authors do not wish to imply that unaided X-ray study is a substitute for unaided chemical study. The authors have had the full coöperation of metallographic, inorganic and analytical chemists in preparing and determining the compositions of the compounds reported here. Indeed, much of this work originated with metallographic or inorganic studies of uranium systems.

It must be pointed out that determination of compositions of phases involving light elements and uranium is generally possible only in the case of relatively simple structures. It is, of course, nearly impossible to locate light elements in the presence of uranium, particularly in structures involving parameters. Consequently, even in those cases where X-ray study gave a clear indication of composition, confirmation by analytical chemists was sought.

Uranium Carbides

Uranium Monocarbide.[4]—The lowest carbide of uranium is the monocarbide, UC. Dendritic material of this composition can be separated even from uranium metal of very low carbon content by dissolving the metal preferentially with dilute acids. X-Ray diagrams of dendritic material were identical with diagrams of material prepared from metal and carbon at the stoichiometric ratio, UC. Other methods of preparation are described below.

Uranium monocarbide is face-centered cubic, $a = 4.951 \pm 0.001$ Å., with four "molecules" per unit cell. The X-ray density is, then, 13.63 g./cc.

The possible structures are the sodium chloride- and zinc-blende-types, which differ only in the positions of the carbon atoms. Although relative to uranium the X-ray scattering power of carbon is very slight, it appears possible to differentiate between these two structures by examining the pair of reflections (331) and (420). These reflections have the same multiplicity factor and are separated by only three degrees on X-ray diagrams made with CuKα radiation. The intensity factors dependent upon scattering angle only may, therefore, be considered essentially identical, particularly in the neighborhood $2\theta = 90°$, where these reflections occur.

For the sodium chloride-type structure the structure factors for (331) and (420) are $(4f_u - 4f_c)$ and $(4f_u + 4f_c)$, respectively, where f represents the atom form factor. For the zinkblende-type structure the corresponding structure factors are $(4f_u - 4if_c)$ and $(4f_u - 4f_c)$. For the sodium chloride-type structure $I_{(420)} > I_{(331)}$ by about 14%, while for the zinkblende-type structure, $I_{(331)} > I_{(420)}$ by about 7%. (The values of the atom form factor used in these calculations, $f_u = 54.3$, $f_c = 1.8$, are those for uranium and carbon atoms. Actually this is the most unfavorable case, since there may be some transfer of electrons from the electropositive to the electronegative element. Similar intensity comparisons have been made for uranium mononitride and monoxide, where the intensity ratios are greater, due to larger scattering of nitrogen and oxygen.) On X-ray powder diagrams made using cylindrical, well-powdered samples (420) was clearly more intense than (331). Other intensity comparisons, while not as critical as the above, also support the sodium chloride-type structure.

Range of Composition of the Monocarbide Phase.—Precise values of the lattice constant of the monocarbide have been obtained for samples containing excess carbon and for others containing excess metal. In a large group of samples of various compositions, lattice constants ranging from 4.947 to 4.951 Å. have been observed, but these varied at random and were in no way related to composition. Dendritic samples, which probably contain all the oxygen and nitrogen impurities of the metal, have spacings of about 4.948 Å. The isomorphous monoxide and mononitride of uranium are known to have smaller lattice constants than the carbide (see below). We presume, therefore, that the composition of the monocarbide is quite definite in the absence of nitrogen and oxygen, and that the largest spacing observed, 4.951 Å., represents the best value of the lattice constant of the monocarbide. The solubility of both carbon and uranium in the monocarbide is negligible at room temperature.

Solubility of Nitrogen and Oxygen in the Monocarbide.—A striking example of the interchange of nitrogen atoms for carbon atoms in the uranium monocarbide lattice is shown by by the following experiment. Mr. P. Chiotti of this Laboratory has heated uranium monocarbide and uranium mononitride at 1950° for fifteen minutes. Precision X-ray diagrams of the sample showed that the spacing of the uranium monocarbide had changed from $a = 4.947$ to 4.921 Å., and that of uranium mononitride from 4.883 to 4.917 Å. After longer heating the sample would undoubtedly come to equilibrium with just one spacing of approximately 4.92 Å.

Similar experiments with the isomorphous uranium monoxide are more difficult to carry out since uranium monoxide cannot be prepared in pure form. However, in systems in which oxygen was the principle contaminant, the monocarbide spacing was considerably lowered.

In the case of mononitride and monocarbide, complete solid miscibility has been demonstrated.

---

[4] Mostly from Metallurgical Project Report CT-686, May (1943).

It appears likely that monoxide and monocarbide are also completely miscible. In view of the very similar lattice spacings of carbide (4.951), oxide (4.91) and nitride (4.880) this is not surprising.

Uranium Sesquicarbide.[5]—U_2C_3 is the next phase of higher carbon content. This phase, which exists only at very high temperatures, has resisted all attempts to quench it to room temperature. Samples of the composition U_2C_3 quenched from well above 2000° are two-phase, uranium monocarbide and uranium dicarbide, as shown by powder diagrams and by microscopic examination. The microscopic and X-ray investigations do indicate, however, that at very high temperatures (probably above 2000°) uranium sesquicarbide must indeed exist. At the composition U_2C_3 what appear superficially to be single crystals are formed in the melt. At room temperature these "single crystals" give broad but definite, single-crystal X-ray reflections, but the reflections are due to both uranium monocarbide and dicarbide arranged so that their crystal axes are mutually parallel to the main edges of the apparently single crystal. Microscopic examination reveals a Widmanstatten structure. Quite apparently the sesquicarbide forms at high temperatures but decomposes to the mono- and dicarbides at lower temperatures.

Uranium Dicarbide.—Uranium dicarbide is the only carbide whose X-ray structure had been reported previously in the literature.[6] Its structure then was established as isomorphous with calcium dicarbide. Since purer uranium was available to this laboratory than to earlier workers, the lattice constants of the dicarbide were re-examined.

The lattice constants of the body-centered, tetragonal dicarbide vary with the previous heat treatment of the sample; all samples which were cooled slowly to room temperature had lattice constants independent of carbon content, a = 3.517 ± 0.001 Å., c = 5.987 ± 0.001 Å. Samples which contained an excess of carbon (about 10–11 weight per cent. carbon) and which were quenched from 2400 and 2700° had much smaller lattice constants: a = 3.504 ± 0.001 Å., c = 5.951 ± 0.001 Å. and a = 3.507 ± 0.001 Å., c = 5.962 ± 0.001 Å. for samples quenched from the two temperatures. X-Ray diagrams of the samples allowed to cool slowly to room temperature contained maxima of the monocarbide and carbon as well as that of uranium dicarbide. The lattice constants of the dicarbide had increased to that for slowly cooled samples.

Apparently carbon dissolves in the dicarbide at higher temperatures and may be maintained in solution by quenching. Samples which are not quenched not only precipitate carbon, but also apparently yield monocarbide and more carbon through decomposition of the dicarbide at some intermediate temperature. Unlike the sesquicarbide, however, the dicarbide is easily quenched.

The decrease in lattice constants with increased carbon solubility may be explained in several ways. Either an uranium atom is occasionally replaced by a carbon atom or C_2 group, or the structure containing excess carbon must be thought of as a uranium dicarbide lattice deficient in uranium, allowing cell dimensions to shrink slightly.

Previously the carbon positions in uranium dicarbide had been assumed to be like those in calcium carbide. Because of the different chemical properties of calcium and uranium dicarbides, it does not appear that the uranium dicarbide can be regarded as a salt of acetylene. Accordingly, we have tried to see if anything can be said about the carbon positions from intensity considerations.

Reflections differing only in carbon contributions and close enough together to be compared with reliability are rare for powder diagrams of uranium dicarbide. However, reflections (204) and (310) meet these requirements. M. von Stackelberg has discussed the possible structures,[7] and we have considered these for uranium dicarbide.

With U at 000 and $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ there are five possible sets of body-centered positions for the carbon atoms. These are

A $000, \frac{1}{2}\frac{1}{2}\frac{1}{2} + 00z, 00\bar{z}$
B $000, \frac{1}{2}\frac{1}{2}\frac{1}{2} + 0\frac{1}{2}z, \frac{1}{2}0\bar{z}$
C $000, \frac{1}{2}\frac{1}{2}\frac{1}{2} + 0\frac{1}{2}0, \frac{1}{2}00$
D $000, \frac{1}{2}\frac{1}{2}\frac{1}{2} + 0\frac{1}{2}\frac{1}{4}, \frac{1}{2}0\frac{1}{4}$
E $000, \frac{1}{2}\frac{1}{2}\frac{1}{2} + 0\frac{1}{2}z, \frac{1}{2}0z$

Structures A and B permit C_2 groups. A is the calcium carbide structure, and B is related to the zinkblende structure, with C_2 groups parallel to the c axis replacing a monatomic ion.

If C_2 groups with a C–C distance equal to that in acetylene are assumed, then z in structures A and B becomes approximately 0.4 and 0.15, respectively. One then finds that for structure A, $I_{(204)}/I_{(310)} = 26/34$, while for B, $I_{(204)}/I_{(310)} = 26/26$. (Atom form factors were chosen in the same manner as for the monocarbide.) On powder diagrams (310) is clearly more intense than (204), so that if there are C_2 groups, the calcium carbide-type structure must be chosen.

Structures C and D make $I_{(204)} > I_{(310)}$ and can be eliminated Structure E with $z = 1/8$ or $3/8$ is satisfactory as far as the intensity comparisons are concerned, but it does not seem to be a reasonable structure, in that there are four carbon atoms bonded very closely to uranium at about 1.90 Å. This bond is shorter than the sum of the covalent radii of uranium and carbon (2.17 Å.). Moreover, all four carbons would lie on one side of uranium, with no good bonds on the other side. We consider that these intensity considerations, while fragmentary, support C_2 groups and the calcium carbide-type structure for uranium dicarbide.

Uranium Nitrides

Uranium Mononitride.[8]—Uranium mononitride, UN, is the lowest nitride of uranium. Its face-centered cubic lattice constant is $a = 4.880$ Å.; its X-ray density, $\rho = 14.32$ g./cc. It is entirely isomorphous with uranium monocarbide. Here again a comparison of the intensities of reflections (420) and (331) shows (420) as the stronger reflection, indicating the sodium chloride-type structure.

Uranium mononitride heated with uranium to high temperatures does not change its lattice constant beyond the limit of error. If the mononitride is treated with more nitrogen, a second phase with the composition U_2N_3 appears, but the lattice constant of the mononitride remains unchanged. Thus, the solubility of either nitrogen or uranium in the mononitride is vanishingly small.

Uranium Sesquinitride.[8]—Uranium sesquinitride, U_2N_3, is body-centered cubic, $a = 10.678 \pm 0.005$ Å., $Z = 16$, $\rho = 11.24$ g./cc. The structure of this phase is isomorphous with manganese sesquioxide (Type $D5_3$ in the "Strukturbericht" designation). The location of the uranium atoms requires one parameter, which has been found to be -0.018 at the ideal composition.[9] Nitrogen positions presumably are similar to those of oxygen in manganese sesquioxide. Since the structure is a well known type, the structure determination will not be reproduced here, nor will atomic positions be listed.

The lattice constant of uranium sesquinitride has been studied as a function of composition by heating uranium sesquinitride with uranium mononitride and uranium. Detectable changes in the constant cannot be produced on the low nitrogen side of the composition U_2N_3, so the phase must not exist below this ideal composition.

Uranium Dinitride and the Phase Between the Sesquinitride and Dinitride.[8]—The sesquinitride structure is very similar to the fluorite-type structure. Indeed, if the weak reflections from uranium sesquinitride were ignored a face-centered cubic pseudo-lattice, $a = 5.339$ Å. (half the true lattice constant), could be chosen. This is nearly identical with that of the dinitride which has the fluorite structure.

The sesquinitride structure is essentially a distorted fluorite-type structure with nitrogen missing in a regular way from the lattice.[10] As nitrogen is added to the sesquinitride the distortion in the structure from that of the fluorite-type decreases and the system remains one phase. This is shown by the gradual decrease in intensity of the weak lines of the uranium sesquinitride structure, corresponding to a change of the uranium parameter from -0.018 toward zero.

At a nitrogen pressure of one atmosphere the maximum obtainable nitrogen–uranium ratio seems to be about 1.75, which probably accounts for the fact that U_4N_7 and other unusual formulas for uranium nitrides have been reported in the literature. Compositions in this range at ordinary pressures are determined by the pressure and temperature of preparation of the nitride, and, since the system remains one phase throughout the region from uranium sesquinitride to dinitride, only the extreme ends of the phase need be considered as distinct compounds.

In the one-phase region between uranium sesquinitride and dinitride the lattice constant decreases with increasing nitrogen content, at least up to the composition $UN_{1.75}$. At $UN_{1.5}$, $a = 10.678 \pm 0.005$ Å., while at $UN_{1.75}$, $a = 10.580 \pm 0.005$ Å. At $UN_{1.75}$ the maxima requiring the doubled unit are just barely visible. Presumably this decrease in lattice constant is due to a shift toward a more closely packed structure as the distortion, occasioned by nitrogen missing from the fluorite-type structure, is removed.

Samples prepared at high nitrogen pressures (126 atm. nitrogen) in the composition range UN to UN_2 are two-phase, consisting of UN and UN_2. Here the UN_2 phase has the ideal fluorite structure and a lattice constant, $a = 5.31 \pm 0.01$ Å. Apparently at high pressures U_2N_3 disproportionates into the mono- and dinitrides. This is to be expected from the change in volume in the reaction

$$U_2N_3 = UN + UN_2$$

The unit volume of U_2N_3 is 1217.5 Å.^{3} and the corresponding volume for UN plus UN_2 is 1057 Å.^{3} The volume decrease is thus about 13%.

It is to be noted, however, that between $UN_{1.75}$ and UN_2 the lattice expands, since at $UN_{1.75}$ the lattice constant is 10.58 ± 0.01 Å. and twice the lattice constant of UN_2 is 10.62 ± 0.02 Å. Pure UN_2 seems to be difficult to prepare, as most samples of nitrides prepared at high pressures contained some UN, but in a few cases the UN_2 phase was pure, at least to the extent that UN reflections could no longer be detected on X-ray diagrams.

Uranium Oxides

Uranium Monoxide.[11]—Uranium monoxide is face-centered cubic, $a = 4.92 \pm 0.02$ Å. with the sodium chloride-type structure. (The evidence for the sodium chloride structure is again the comparison of reflections (331) and (420).) Since uranium monoxide has never been prepared in any quantity and is known only from X-ray data, it seems necessary to describe its preparation and the nature of the evidence for the compound.

The monoxide was discovered during attempts to make X-ray diagrams of uranium metal in the beta and gamma temperature ranges. The diagrams, in almost all cases, consisted chiefly of a

[9] Parameter as listed in "Strukturbericht," Vol. II, 38 (1937).

[10] For a more complete description of the relation between these structures see "Strukturbericht," ref. 9.

[11] Metallurgical Project Reports CN-1495, April (1944), and CC-1984, Dec. (1944). British workers found this oxide independently at a later date.

face-centered cubic phase, a = 49.1 Å. The metal had been previously cleaned, and was contained in carefully evacuated, quartz capillaries which had been cleaned up with a zirconium getter. The metal was kept away from the quartz with columbium metal spacers. The chief contaminant in these samples was known to be oxygen.

Later it was found that a uranium metal surface which has become badly discolored due to "oxidation" continues to give a powder diagram characteristic of the metal until heated. The gold or even black coating disappears on heating, producing a metallic-looking surface somewhat whiter in appearance than uranium itself. The surface after heating produces an X-ray diagram of a face-centered cubic phase, a = 4.91 Å. The chief impurity in the surface is oxygen, though small amounts of nitrogen and carbon also are present.

Attempts to prepare the monoxide by heating UO_2 or a higher oxide with metal have usually been disappointing. Generally the high temperature necessary has caused considerable contamination by carbon (from graphite heating elements in some cases). Where carbon and nitrogen have been very carefully excluded little or no reaction has resulted. In cases of considerable carbon contamination the face-centered phase was produced. In these instances oxygen was the chief light element of the UX phase. Though it seems probable that carbon is necessary only to promote the reaction of a higher oxide with uranium to form UO, the possibility cannot be excluded that some UC or UN must be present for the phase to form. It may be possible that UO should be described as a UX phase, where X is carbon, nitrogen and oxygen, but that the amount of oxygen in the phase can be made to predominate.

Due to the fact that UO has never been prepared with great purity, the spacing is not known precisely. The spacing lies between that of the carbide and the nitride. Spacings between 4.93 and 4.91 Å. have been observed. Since carbon contamination has generally exceeded nitrogen contamination, the lower spacing is probably more nearly correct.

Uranium Dioxide.—Uranium dioxide has been investigated by many early workers in the field of X-ray diffraction.[12] Various values of the cubic spacing have been reported, so it was thought well to check the values with a sample of the very pure oxide available on this project. The lattice constant of such a sample is a = 5.4581 ± 0.0005 Å.

Subsequent investigation showed that a wide variation in spacing is possible due to solubility in uranium dioxide. When the oxide is heated with uranium above 2000°, as in making the monoxide, the dioxide spacing is increased to a = 5.4610 ± 0.0007 Å. Presumably in this region uranium is introduced into the vacant set of cubic interstices in the uranium dioxide structure. As one increases the oxygen content by heating uranium dioxide with U_3O_8 in a sealed quartz system, the lattice constant of the dioxide decreases in magnitude, finally reaching a = 5.4297 ± 0.0008 Å. as a limit. A new phase appears in a sample of composition $UO_{2.3}$, so the limit of the solubility region must lie between $UO_{2.2}$ and $UO_{2.3}$.

Uranium dioxide has the fluorite structure. This may be considered as a simple cubic lattice of oxygen ions with U^{+4} ions in one half of the cubic interstices. If the oxygen ion lattice remains fixed but U^{+4} ions are occasionally missing at random from the lattice, the oxygen lattice would be allowed to shrink slightly giving the lower lattice constants. If the density is calculated on this assumption, using $UO_{2.25}$ as the limiting composition, the density would change from 10.96 g./cc. for pure uranium dioxide to 10.04 g./cc. for $UO_{2.25}$.

Biltz and Müller have examined the uranium–oxygen system and have found a discontinuity in both vapor pressure and molecular volume at $UO_{2.25}$ in agreement with the X-ray data.[13] They have reported an increase in densities with composition in this region for samples prepared above 1000° and a decrease in density for samples prepared below 1000°. The reliability of these observations is open to question since by a different choice of their densities, the opposite trend may be shown. Moreover, their experimental value for the density of UO_2 is 10.73 to 10.82 g./cc., well below the calculated X-ray density, and the highest density reported in the whole region above uranium dioxide (with one exception) is less than the calculated X-ray density of uranium dioxide. Since densities measured by liquid displacement methods are subject to errors due to micro cracks and fissures, the data of Biltz and Müller cannot finally decide the type of solubility.

It is difficult to reconcile the decrease in lattice constant with the type of solubility requiring the introduction of additional oxygen ions into an already close-packed arrangement of oxygen ions. Accordingly, we feel that the solubility is due to the absence of U^{+4} ions rather than the presence of interstitial oxygen ions. Calculating the density on the alternative assumption that oxygen ions are being introduced into interstices in the UO_2 structure, the density would increase to 11.30 g./cc.

Higher Uranium Oxides.[14]—The oxides U_2O_5, U_3O_8, several forms of UO_3 and a hydrate of UO_4 are known. W. H. Zachariasen first examined the structures of U_3O_8, UO_3 and the hydrated UO_4. These will, presumably, be reported by him.

Biltz and Müller found that a one phase area extended from UO_3 to $UO_{2.62}$. X-Ray diagrams

(14) Largely from Metallurgical Project Report CC-1980, Nov. (1944).

of the samples in this range show that this one phase area is based on the "ideal" UO_3 phase. U_3O_8 has been shown to be very similar to UO_3 by W. H. Zachariasen; this has been confirmed by our data. Our X-ray evidence also indicates that this one phase area may extend to the composition $UO_{2.5}$.

X-Ray diagrams of an equimolar mixture of U_3O_8 and UO_2 were made both before and after heating to 1100°. Before heating the sample the uranium dioxide maxima were the strongest maxima in the diagram due to the higher symmetry of the phase. After heating the sample the $UO_{2.25}$ maxima, although present, were weak and the U_3O_8 maxima had shifted in position and intensity. By examination of known mixtures of U_3O_8 and UO_2 it was possible to estimate the relative amounts of the phases present in the $UO_{2.5}$ sample. The upper bound on the lower limit of the composition of the UO_3-like phase was found to be $UO_{2.52}$.

By chance single crystals of $UO_{2.5}$ have been obtained by thermal decomposition of UO_2Cl_2. Powder diagrams of these needles were identical with those of $UO_{2.5}$ as described above. A detailed structure of U_2O_5 will be given later. However, the unit cell can be reported as orthorhombic, $a = 8.27 \pm 0.02$ Å., $b = 31.65 \pm 0.1$ Å., $c = 6.72 \pm 0.02$ Å., with 16 U_2O_5 per unit cell. There is a pseudo cell with $a = 4.135$ Å., $b = 3.956$ Å., $c = 6.72$ Å. The X-ray density is 8.35 g./cc.

Experimental

Methods.—X-Ray diagrams were made using Debye–Scherrer powder cameras of 5.73 and 5 cm. radius with the exception of the oxide samples in the composition range uranium dioxide to trioxide. These diagrams were obtained using an unsymmetrical self-focusing powder camera of 10 cm. radius manufactured by the Wyland Company. This camera gave very high dispersion and was ideally suited for the examination of the complex phases between uranium dioxide and trioxide. Nickel filtered CuK radiation was used in all but precision diagrams. Precision diagrams were prepared using a symmetrical self-focusing, back-reflection camera manufactured by the Wyland Co. Unfiltered CuK radiation and the mixed radiations of a copper–nickel alloy target were used to obtain more lines in the back reflection region. The data were evaluated using Cohen's method. The limit of error, when reported, is the standard error as determined from the measurement of one film.

X-Ray densities were calculated according to the suggestion of Jette and Foote using the formula $\rho = 1.65023\ MN/V$, where M is the molecular weight, N is the number of molecules per unit cell, and V is the volume of the unit cell calculated in terms of Siegbahn wave lengths.[15]

Preparation of Samples.—Most of the samples were prepared by other members of the Ames laboratory of the Manhattan Project. The general methods of preparation are given below.

Uranium Carbides.—Messrs. A. Daane, A. Snow, P. Chiotti and H. Carter prepared the carbide samples. The carbides were prepared by the direct reaction of appropriate amounts of uranium or uranium oxide and carbon in graphite crucibles at elevated temperatures obtained by induction heating. Samples were subsequently analyzed for carbon, since some carbon was dissolved from the crucibles. A. Tevebaugh separated uranium monocarbide dendrites from uranium by using dilute hydrochloric acid containing some hydrogen peroxide.

Metallographic study of the uranium carbon system by the above members of the Ames metallographic group is reported elsewhere. The metallographic reports contain additional information on the uranium–carbon system.[16]

Uranium Nitrides.—A. Newton prepared most of the nitride samples except those at high pressure. A. Daane first prepared uranium mononitride by the thermal decomposition of higher nitrides of uranium in a vacuum. It may also be prepared by heating uranium and the higher nitrides at elevated temperatures, the reduction of higher nitrides with hydrogen, the direct reaction of ammonia or nitrogen with uranium hydride and the direct reaction of nitrogen and uranium. Higher nitrides were prepared by the direct reaction of either nitrogen or ammonia with the hydride or the metal and by the reduction of still higher nitrides with hydrogen. The dinitride was prepared only at high pressures (about 126 atm.) of nitrogen on uranium metal. W. Tucker and P. Figard prepared the high pressure samples.

Chemical investigation of the uranium–nitrogen system has been reported by the above members of the Ames inorganic group.[17]

Uranium Oxides.—P. Chiotti, R. Raeuchle and J. Warf prepared the uranium–oxygen samples in the composition ranges between uranium and uranium dioxide by heating to over 2000° powdered metal and oxide which had been pressed into a billet. Samples of higher oxygen content than the dioxide were prepared by heating to about 1100° calculated amounts of UO_2 plus U_3O_8 or U_3O_8 plus UO_3 in sealed evacuated quartz capillaries. R. Raeuchle prepared the first U_2O_5. O. Johnson prepared single crystals of U_2O_5 by thermal decomposition of UO_2Cl_2 at 900°. The UO_2, U_3O_8, and UO_3 used were the pure materials available on the Manhattan Project.

Acknowledgments.—The authors wish to acknowledge gratefully the help of the above members of the Metallurgical Project, together with the analytical group at Ames.

Summary

1. Uranium monocarbide is face-centered cubic, $a = 4.951$ Å., and has the sodium chloride-type structure. Uranium dicarbide is body-centered tetragonal, $a = 3.517$ Å., $c = 5.987$ Å., and has the calcium carbide structure. Carbon is soluble in the dicarbide at high temperatures, and the dicarbide decomposes into the monocarbide and carbon at intermediate temperatures. Uranium sesquicarbide probably exists at temperatures above 2000°. It does not exist at room temperature.

2. Uranium mononitride is face-centered cubic, $a = 4.880$ Å., and has the sodium chloride-type structure. Uranium sesquinitride is body-centered cubic, $a = 10.678$ Å., and has the manganese sesquioxide structure. The uranium sesquinitride structure gradually changes toward the ideal dinitride structure in a one phase region extending to the composition $UN_{1.75}$. High pressure is needed to form the dinitride which is face-centered cubic, $a = 5.31$ Å., and has the fluorite structure.

3. Uranium monoxide is face-centered cubic, $a = 4.92$ Å., and has the sodium chloride-type

(17) Work to be reviewed in Div. VIII of the Manhattan Project Technical Series.

structure. It is very difficult to prepare free from carbon or nitrogen. Uranium dioxide has the fluorite structure, a = 5.4581 Å. Oxygen is soluble in the fluorite structure up to approximately the composition $UO_{2.25}$ at which point the lattice constant is a = 5.4297 Å. U_2O_5 is orthorhombic, a = 8.27 Å., b = 31.65 Å., c = 6.72 Å. The structure is related to those of U_3O_8 and UO_3. A one phase region exists from U_2O_5 to UO_3 in which the various structures continuously transform from one to another.

Basic Fluorides of Aluminum

BY J. M. COWLEY AND T. R. SCOTT

Introduction

The readiness with which aluminum and fluorine form complex ions in solution has been demonstrated by Brosset,[1] who determined the proportions of ions of the type AlF_n (where n = 1 to 6) in dilute solutions at constant activity. In solutions containing both aluminum fluoride and sulfate, the complex cations AlF^{2+} and $AlF_2{}^+$ appear to predominate, and the former may well be present in the salt $AlF_3 \cdot Al_2(SO_4)_3$ or $(AlF)SO_4$, discovered by Ehret and Frere.[2] Various Russian workers, *e.g.*, Nikolaev,[3] have described the preparation of aluminum fluosulfate, $(AlF_2)_2SO_4$ or $4AlF_3 \cdot Al_2(SO_4)_3$, although Ehret and Frere found no evidence for the formation of this compound in the system AlF_3–$Al_2(SO_4)_3$–H_2O at 25°. It is thus conceivable that aluminum might form hydroxy- (or oxy-) fluorides having the compositions $AlF(OH)_2$ and $AlF_2(OH)$: methods for the preparation of the latter compound (or the oxyfluoride $(AlF_2)_2O$) have indeed been given in several Russian patents.[4,5] Apart from the work of Schober and Thilo,[6] who described the diffraction pattern of $Al_7O_{10}F$ (prepared by the thermal hydrolysis of aluminum fluoride), no X-ray diffraction studies of these compounds have been made. The present paper describes the preparation of basic fluorides with compositions varying within the limits AlF_3 and $Al(OH)_3$, and gives details of their crystallographic structures.

Experimental

The basic fluorides may be precipitated from solutions of aluminum fluosulfate by treatment with ammonia[3] or by hydrolysis at temperatures ranging from 100–180°.[4] Aluminum fluonitrate solution may also be neutralized with calcium carbonate, leaving calcium nitrate in solution and precipitating basic aluminum fluoride.[5] Solutions of aluminum fluoride undergo slight hydrolysis on boiling, but the precipitate is very gelatinous and difficult to manipulate. While it is probable that hydrolysis at 150–200° would produce basic fluorides in better yield and in more satisfactory physical form, suitable corrosion-resistant equipment for this method was not available.

For the present study, samples were prepared by the addition of ammonia to solutions of aluminum sulfate containing varied proportions of aluminum fluoride. The aluminum sulfate was of A.R. grade, while solutions of aluminum fluoride were prepared by dissolving Laboratory Reagent grade aluminum metal in A.R. hydrofluoric acid. The general reaction was

$$6NH_4OH + Al_2(SO_4)_3 + xAlF_3 \longrightarrow 3(NH_4)_2SO_4 + Al_{2+x}(OH)_6F_{3x}$$

where x was varied from 0.4 to 14.0. Nikolaev[3] used this method for the production of AlF_2OH and his directions for the use of 20% more than the theoretical quantity of ammonia and for subsequent boiling of the gelatinous suspension of basic fluoride were carefully followed. (With a greater excess of ammonia, the fluorine content of the basic fluoride is considerably reduced.) After boiling for two hours, the suspensions were filtered and the basic fluorides thoroughly washed with water. The products were dried at 130°, again washed with water to remove entrained ammonium sulfate, and dried for a further four to six hours at 130°. No sulfate could be detected in the final products, though in all instances combined ammonia was present. Attempts to prepare uncontaminated basic fluorides by other methods were no more successful. The compound obtained by hydrolysis of aluminum fluosulfate solution at 100° contained 5% of sulfate, and it is highly probable that the treatment of aluminum fluonitrate with calcium carbonate would also yield an impure product. A further sample was obtained by adding ammonia to molar aluminum fluoride solution until the pH reached 6.4, and consisted of a mixture of almost equal parts by weight of aluminum basic fluoride and ammonium tetrafluoaluminate.

All specimens were analyzed for aluminum, fluorine, silica and ammonia, the oxygen content being calculated from the atomic ratio Al:F and the water content being obtained by difference. Aluminum was precipitated and weighed as the hydroxyquinolate, after fusion of the sample with potassium pyrosulfate or digestion with concentrated sulfuric acid. Fluorine was determined by the Willard–Winter distillation followed by titration of an aliquot of the distillate with thorium nitrate solution. Silica was estimated by a distillation method[7] devised by one of the authors.

X-Ray diffraction patterns were obtained from all samples with the 14.3 cm. powder-camera of the General Electric XRD unit, using filtered cobalt Kα radiation. The powder was packed into a wedge using a dilute solution of collodion in amyl acetate as binder and rocked through an angle of 20° during the exposure. To obtain the relative intensities of the lines, a key pattern, that from sample 4 (Table II), was microphotometered and used as an intensity standard. In the powder-wedge method, the reflections at small angles are weakened by absorption. The extent of this effect was estimated by comparison of the intensities of the key pattern with those given by a fine cylindrical sample, and the appropriate correction was made to the observed intensities of the diffraction lines.

Results

Composition of Basic Fluorides.—Empirical formulas for the compounds prepared are given in Table I. It is interesting to compare the formula of sample 6 with the compound $Al_2OF_4 \cdot 3.5H_2O$ (*i. e.*, $Al(OH)F_2 \cdot 1.25H_2O$) described by Kashcheev and Lazarev.[4] The samples contained silica (0.2–1.8%) and ammonium hexafluoaluminate (2.3–7.3%) as impurities, but neither of these was found to produce lines in the X-ray powder photographs. With "amorphous" ammonium hexafluoaluminate, it is quite possible that the diffuse lines caused by 7% of the material would not be apparent in the diffraction patterns.

TABLE I

COMPOSITION OF BASIC FLUORIDES

Sample no.	Al	Empirical formula[a] OH	F	H_2O	Percentage of ammonium hexafluo-aluminate
1	1	2.60	0.40	0.25	2.3
2	1	2.30	.70	.31	4.1
3	1	1.98	1.02	.58	7.0
4	1	1.35	1.65	1.09	6.0
5	1	1.25	1.75	1.14	7.2
6	1	1.04	1.96	0.90	7.3
7	1	0.93	2.07	0.91	4.4

[a] Corrected for presence of $(NH_4)_3AlF_6$.

Ammonium hexafluoaluminate was distinguished by the fact that at 300°, in air, it decomposes almost completely to aluminum fluoride and volatile ammonium fluoride. By contrast, ammonium tetrafluoaluminate is relatively stable and retains the greater part of its ammonia until higher temperatures are reached. The latter compound was identified by its diffraction pattern in the precipitate obtained by the treatment of aluminum fluoride solution with ammonia, but was only present in minor quantities, if at all, in the samples listed in Table I. It is noteworthy that the ammonium hexafluoaluminate inferred to be present could not be removed from the basic fluorides by leaching with water, despite its appreciable solubility (0.76 at 25°). Nevertheless, the ignition behavior of the contaminated oxyfluorides, with respect to their ammonia contents, was so closely parallel to that of ammonium hexafluoaluminate, that no doubt is felt as to the presence of the latter compound.

Although only a small excess of ammonia was used in the preparation of the basic fluorides, a portion of the fluorine was lost by reactions of the type $NH_4OH + AlF_2OH \rightarrow NH_4F + AlF(OH)_2$. When the atomic ratio F:Al did not exceed 2:1 in the solutions used, the ratio in the resulting basic fluorides was, on the average, about 10% smaller, but increase of the ratio beyond 2:1 did not result in a proportional increase in the basic fluoride obtained. Sample 7, for example, with a F:Al ratio of 2.07:1, was prepared from solution of aluminum sulfate and fluoride in which the ratio was 2.63:1, and the former ratio was not exceeded even in basic fluorides prepared from aluminum fluoride solutions alone.

X-Ray Diffraction Studies.—Except for sample 1, all samples gave the same line-pattern, and in no case were any lines due to aluminum oxides, fluorides or any other impurities observed. Sample 1 gave only diffuse haloes such as are obtained from "amorphous" aluminum hydroxide. These diffuse haloes were present faintly with the line-patterns from 2 and 3. Samples 4 and 5 gave good patterns of sharp lines. For 6 and 7 the lines were broadened, indicating smaller crystal size.

The pattern from no. 4 was measured and analyzed in detail. The lattice spacings and intensities are set out in Table II. Spacings agree with those for a cubic structure with unit cell dimension $a_0 = 9.829 \pm 0.010$ Å. The missing reflections indicate the space group $O_h^7 - Fd3m$.

[a] Sample 4, containing 6 molecules of water per unit cell.

[b] Sample 6, containing no molecules of water per unit cell after dehydration.

The measured density is 2.25. Assuming that only one third of the water is in the lattice, this gives 16 $AlX_3 \cdot 6H_2O$ per unit cell, where X may be (OH) or F. (The remaining water is less firmly held and is apparently absorbed physically.)

This group may be fitted into the unit cell as follows

$48X$ in $O_h^7(f)$, general position $(u00)$
16 Al in $O_h^7(c)$, general position $(\frac{1}{8}\frac{1}{8}\frac{1}{8})$
$6H_2O$ in $O_h^7(b)$, general position $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$

the six molecules of water being distributed among the eight sites.

Agreement between calculated and observed intensities is obtained for $u = 3/16$. With this value of u, the hydroxyl and fluorine ions lie at the corners of regular octahedra with aluminum ions arranged tetrahedrally, as centers, and form part of a hexagonal close-packed lattice. Each hydroxyl or fluorine ion is shared by two octahedra. The water molecules lie at the mid-points of the edges, at the body center, and at the centers of the unfilled segments of the unit cube (Fig. 1). This arrangement gives the distances between neighboring atoms as

Al—F, O_{OH}	1.84 Å.
F, O_{OH}—F, O_{OH}	2.61 Å.
F, O_{OH}—O_{H_2O}	3.07 Å.

These values are consistent with those for similar groups in other compounds. The observed intensities and those calculated for this structure are compared in Table II. Intensities calculated for more or less than six molecules of water in the lattice give less satisfactory agreement. The intensity of the *222* line does not vary with the number of water molecules present, and has been taken as the standard for the comparison of intensities.

The line patterns from the other samples had the same relative intensities, but the unit cell dimension was found to vary. Corresponding to the progressive replacement of hydroxyl by fluorine ions, which have smaller ionic radius, the lattice constant decreased regularly with increasing fluorine content as shown in Table III.

TABLE III

VARIATION OF LATTICE CONSTANT WITH FLUORINE CONTENT

Sample	Ratio F:Al	Lattice constant	
1	0.40	..	Diffuse haloes only
2	0.70	9.85	Diffuse haloes present
3	1.02	9.84	Diffuse haloes present
4	1.65	9.83	
5	1.75	9.81	
6	1.96	9.77	Lines broader
7	2.07	9.77	Lines broader

Effect of Ignition on Basic Fluorides.—Samples were weighed into platinum crucibles and heated for three hours in an electric furnace at temperatures ranging from 200 to 600°. Material ignited at 300° or more was gritty and hygroscopic, sample 6 regaining more than half the weight lost at 300°, when exposed to the air for three days. The hygroscopicity was less marked in samples ignited at 500–600°.

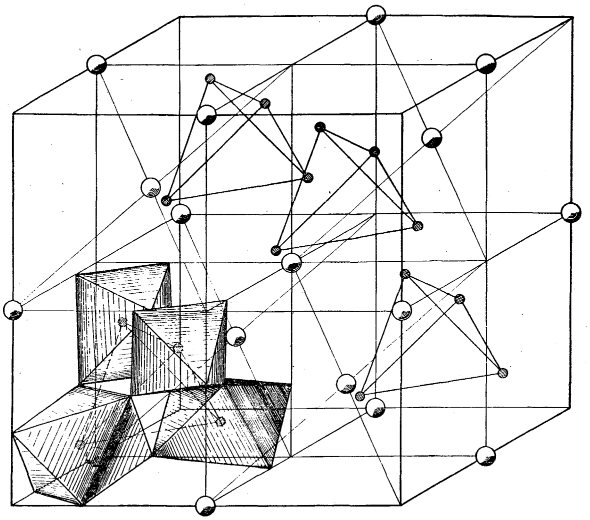

Fig. 1.—Unit cell of aluminum hydroxyfluoride containing 16 $Al(F,OH)_3 \cdot 6H_2O$: ●, aluminum; ◒, water (only 6 of the 8 sites per unit cell shown are occupied by water molecules); fluorine or hydroxyl ions occupy the corners of the octahedra surrounding the aluminium ions, as shown in only one octant of the unit cube.

At 600°, the basic fluoride pattern of sample 6 was replaced by lines due to fluorides and oxides of aluminum. Ignition at 300, 400 and 500° gave basic fluoride patterns showing a progressive decrease in lattice constant (Table IV) and a progressive variation in relative intensities of the lines. In particular the *220* line became visible and increased in intensity. The observed intensity variations follow closely those of the intensities calculated for the removal of the six water molecules from the lattice. The observed intensities for sample 6 heated to 500° are compared in Table II with those calculated for a structure in which no water molecules remain. The number of molecules of water remaining, corresponding to the intensity distribution at each stage of the heating, is given in the third column of Table IV.

TABLE IV

PROPERTIES OF IGNITED BASIC FLUORIDES

Sample	Lattice constant	Molecules of water/ unit cell	Ignition loss Calcd., %	Ignition loss Actual %
3 unheated	9.84	6		
3 heated 400°	9.65	0	14.7	28.9
6 unheated	9.77	6		
6 heated 300°	9.72	5	14.6	19.6
6 heated 400°	9.65	2	18.0	23.7
6 heated 500°	9.63	0	20.2	25.5

Discussion

In the introductory remarks, it was stated that aluminum might form either the hydroxyfluorides $AlF(OH)_2$ and $AlF_2(OH)$, or the corresponding oxyfluorides AlFO and $(AlF_2)_2O$, when solutions containing the complex cations AlF^{++} and AlF_2^+ were treated with ammonia. X-Ray diffraction studies support this view, but the ionic radii of fluorine and hydroxyl ions are so similar that the same crystal structure serves for the range of composition from $AlF(OH)_2$ to AlF_2OH. The small decrease in lattice constant, as the proportion of fluorine increases, is not only incompatible with an oxyfluoride structure but also shows that the samples do not merely consist of mixtures of aluminum hydroxide or fluoride with a single hydroxyfluoride of constant composition. Assuming that the ionic radii of the oxygen and fluorine ions in the hydroxyfluoride structure are in the same ratio as those given by Pauling[8] for a sodium chloride-type structure, the decrease in unit cell dimension is calculated as 0.7% for a change in composition from $AlF(OH)_2$ to $AlF_2(OH)$. The observed decrease of 0.8% is in good agreement with this figure. (The ionic radius of hydroxyl ion is only slightly greater than that of oxygen ion.[9])

It is improbable that cations containing more fluorine than AlF_2^+, or less than AlF^{++}, exist in solution to any important extent, and the range of hydroxyfluoride compositions is consequently confined to the limits given above. Despite numerous attempts to prepare samples with a F:Al ratio significantly greater than 2:1, the highest value obtained was 2.07:1 (sample 7) and this is almost certainly due to the presence of small quantities of aluminum fluoride. Samples 1 and 2 contain a smaller proportion of fluorine than $AlF(OH)_2$, but are contaminated with considerable amounts of aluminum hydroxide, the presence of which is revealed not only by the X-ray diffraction data (Table III) but also by the much smaller water content of these samples when compared with purer basic fluorides (nos. 4–7).

Dehydration of the hydroxyfluorides might be expected to yield oxyfluorides which would obviously differ in structure with variation in their fluorine content. Samples 3 and 6 were chosen for investigation because simple dehydration would produce AlFO and $(AlF_2)_2O$, respectively, but, even at 500°, the hydroxyfluoride structure was retained. At higher temperatures, decomposition to aluminum fluoride and oxide occurred and no evidence was obtained for the formation of distinct oxyfluoride structures. It is of interest to note that fluorine may be completely removed from ignited hydroxyfluorides by the Willard–Winter distillation, using 55% sulfuric acid, but that, once decomposition has occurred, only a small fraction of the fluorine can be released by this method.

The loss of weight of hydroxyfluorides was found to increase smoothly with temperature up to 500° and no distinction could be made between loss of loosely-combined water, crystal water (*i. e.*, 6 moles per unit cell) and water derived from the conversion of hydroxyl to oxygen ions. The latter process might be expected to result in the formation of oxyfluorides, but the hydroxyfluoride structure was retained in sample 3 when slightly more than 50% of the hydroxyl groups were thus decomposed. Table IV shows the actual ignition losses at various temperatures, compared with the losses calculated on the basis that hydroxyl ions were undisturbed and that crystal water was lost in amounts determined from the change in intensities of the lines of the diffraction patterns. It is evident that conversion of hydroxyl to oxygen ions must occur simultaneously with loss of crystal water at all temperatures from 300–500°. This would not have any great effect upon the X-ray line intensities.

Two factors combine to increase the calculated ignition losses given in Table IV. As with most hydrated fluorides, thermal hydrolysis occurs during ignition, resulting in loss of hydrogen fluoride instead of water, but it is unlikely that more than 10% of the fluorine is lost in this fashion, even at 500°. The corresponding increase in the calculated ignition loss is 1 to 2%. The second factor depends on the presence of aluminum hydroxide in samples 1, 2 and 3, as demonstrated by the diffraction patterns. Assuming that this contaminant is present to the extent of 25% and decomposes to γ-Al_2O_3 at 400°, the calculated ignition loss of sample 3 would be increased by a further 8%. Consideration of these two factors makes it possible to substitute a figure of 24% for that of 14.7% for the calculated ignition loss of sample 3 at 400° as given in Table IV. This brings the behavior of sample 3 more into line with that of sample 6, but still requires the destruction of at least 50% of the hydroxyl groups.

In the hydroxyfluoride structure derived above it was shown that the hydroxyl or fluorine ions formed regular octahedra about the aluminum ions. In both the fluoride and hydroxide there is a similar arrangement of ions except that the octahedra in these two cases are distorted. It may be concluded that the value of the radius of the negative ion which allows the six negative ions to surround the aluminum ion so that they just touch each other, lies between the values for the hydroxyl and fluorine ions. Thus groups of four hydroxyl and two fluorine, or two hydroxyl and four fluorine could be fitted about aluminum ions to give very nearly regular octahedra, whereas groups of either six fluorine or six hydroxyl would lead to deformation of the octahedra.

From the Al–F distance of 1.84 Å., the ionic radii are found to be 0.54 Å. for Al^{3+} and 1.30 Å. for the negative ions. This value for Al^{3+} lies between the values 0.57 Å., given by Goldschmidt,[10] and 0.50 Å., given by Pauling,[8] for coördination number 6. For oxygen and fluorine ions with the same coördination number, Goldschmidt gave 1.32 and 1.33 Å., and Pauling 1.40 and 1.36 Å., respectively, for the ionic radii.

---

[8] Pauling, THIS JOURNAL, **49**, 765 (1927).

[10] Goldschmidt, *Trans. Faraday Soc.*, **25**, 253 (1929).

The above value for the negative ions is lower than these, as would be expected from the lower value of the coördination number occurring in this structure.

Conclusions

The treatment of mixed solutions of aluminum fluoride and sulfate with ammonia produces hydroxyfluorides falling within the range of composition $AlF(OH)_2$ to $AlF_2(OH)$. These compounds are cubic with space group O_h^7-Fd3m. The lattice constant decreases with increasing fluorine content from 9.85 to 9.77 Å. The unit cell contains sixteen formula-groups plus six water molecules.

The hydroxyfluoride structure is stable up to 500°, the gradual loss of water being reflected by a corresponding contraction of the lattice. The remarkable stability of the lattice is demonstrated by the retention of the structure despite the destruction of more than half the hydroxyl groups at high temperatures. At 600°, the hydroxyfluoride structure is no longer evident. No oxyfluorides are formed, the hydroxyfluorides decomposing directly to aluminum oxide and fluoride.

The Aqueous Ionization Constants of Inorganic Oxygen Acids

BY JOHN E. RICCI

It is presumably possible to determine independently the formulas, structures and aqueous ionization constants of inorganic acids. The data so obtained may then be correlated either empirically or on the basis of theories of molecular structure and of the process of ionization in solution, in which case the results of the comparison may serve as a test of the theories. A remarkably successful correlation has been obtained by Kossiakoff and Harker, in a paper on "The Calculation of Ionization Constants of Inorganic Oxygen Acids from their Structures,"[1] and the results have been interpreted as supporting the mechanism proposed as the basis of the calculation.[2] The purpose of this paper is to examine critically the treatment and results of Kossiakoff and Harker, and to determine which of their assumptions are supported by their calculations.

Kossiakoff and Harker assume (1) that the ionization constant of an oxygen acid is defined by the free energy of transfer of a proton from a hydroxyl group to the surrounding water structure, and (2) that this energy, in electrostatic terms, depends on (a) the formal charge of the central atom of the acid, (b) the number of non-hydroxyl oxygen atoms in the acid ion available for attachment of a proton, (c) the number of equivalent hydrogens available for "dissociation," and (d) the structure of the acid as determined by crystallographic data on its salts.[3]

We shall see that the first and main assumption is not effectively tested by the treatment of Kossiakoff and Harker, and that the test of 2(c) and 2(d) is entirely inconclusive, but that the assumptions 2(a) and 2(b) are effective and lead to very enlightening empirical correlations.

I. Calculations of Kossiakoff and Harker

The general expression used by Kossiakoff and Harker for the free energy change fixing a particular ionization constant is

$$\Delta F = \sum W_i - C + RT \ln n_O/n_H \qquad (1)$$

Here C is a solvent constant, n_O is the number of equivalent non-hydroxyl oxygens in the ion being formed, n_H is the number of equivalent (transferable) hydrogens in the acid, and W_i is the electrostatic energy of a single transfer. Furthermore

$$W_i = \sum_j \frac{m_j e}{\epsilon}\left(\frac{1}{r_j} - \frac{1}{r_j'}\right) \qquad (2)$$

in which $r_j' - r_j$ is the displacement of the proton relative to the j'th atom of the solute particle, whose formal charge is m_j; e is the charge of the electron and ϵ the dielectric constant of the medium. The formal charge of an atom is its group number in the periodic table minus the number of electrons in its valence shell, a shared pair being counted as one.

For the evaluation of C, Kossiakoff and Harker chose K_1 of orthophosphoric acid H_3PO_4(pK_1 = 2.1, ΔF = 2.9) as reference; from structural data they calculated ΣW_i = 46.1. For this calculation, the first term of ΣW_i, or the term for the first transfer, from hydroxyl to adjacent water molecule, was taken as

$$W_1 = \frac{e^2}{\epsilon}\left[\left(\frac{1}{R} - \frac{1}{R'}\right) - \left(\frac{1}{\rho} - \frac{1}{\rho'}\right) + \left(\frac{1}{d} - \frac{1}{d'}\right)\right] \qquad (3)$$

in which $R' - R$ is the absolute displacement of the proton (R being the original O—H distance), ρ'-ρ its displacement relative to the central atom, phosphorus (with m = +1), and d'-d its displace-

---

[1] A. Kossiakoff and D. Harker, THIS JOURNAL, **60**, 2047 (1938).

[2] For a discussion of their method and results, see O. K. Rice, "Electronic Structure and Chemical Binding," McGraw-Hill Book Co., New York, N. Y., 1940, pp. 429–438.

[3] "Structure" refers not to the formula but to the physical quantities of bond angles and interatomic distances. A formula such as $Ge(OH)_4$, graphical or otherwise, is the result of chemical and analytical reasoning, independent of the physical determination of the structure of the substance.

ment relative to each (here only 1) non-hydroxyl oxygen (with $m = -1$) of the acid.

The distances R and R' are assumed to be constant for all oxygen acids in water, in all subsequent calculations. It will therefore be useful at this point to re-write equation (3) in the form

$$W_1 = W_0 + mf(\rho) + nf(\mathrm{d}) \qquad (4)$$

in which m is the formal charge of the central atom and n the number of non-hydroxyl oxygens of the acid. In the case of orthophosphoric acid, the values of these terms were

$$W_1 = 52.4 - 12.4 + 4.9 = 44.9 \text{ kcal.} \qquad (5)$$

The remaining terms of ΣW_i amounted to only 1.2, giving $\Sigma W_i = 46.1$. Now with $RT \ln n_0/n_\mathrm{H} = -0.2$, $C = 46.1 - 2.9 - 0.2 = 43.0$ kcal. This value of C was then used in equation (1) to calculate the twenty-six other ionization constants, for acids with "non-resonating" structures (this excludes those of the first row elements: B,C,N). For the purpose of the calculation, the authors furthermore pointed out that since the difference, $\Sigma W_i - W_1$, ($\cong 1.2$ for orthophosphoric acid) is expected to be equally small and nearly constant for all the other acids to be considered, this quantity may be combined with the constant C, so that C_1 (to be used with W_1 alone) $= C - 1.2 = 41.9$. In other words, instead of equation (1) we may write, with negligible error

$$\Delta F = W_1 - C_1 + RT \ln n_0/n_\mathrm{H} \qquad (6)$$

The over-all average deviation between observed and calculated log K, for these twenty-six calculations, was 0.89.[4] According to Kossiakoff and Harker, "The quantities calculated represent differences between large numbers (presumably meaning ΣW_i and C, or W_1 and C_1), making the resulting agreement all the more encouraging." The agreement is then taken as supporting the assumptions involved in calculating ΣW_i and through it C, and specifically the electrostatic theory of the work of separating a proton from the hydroxyl group to the first water molecule through the immediate distance R'-R.[5]

II. Criticism and Discussion

Since R and R' are assumed to be the same for all oxygen acids in water, and since C_1 is a solvent constant, then writing k for $W_0 - C_1$, and combining (4) and (6), we have

$$\Delta F = k + mf(\rho) + nf(\mathrm{d}) + RT \ln n_0/n_\mathrm{H} \qquad (7)$$

With orthophosphoric acid as reference (*i.e.*, using its K_1), k has the value 10.5. The calculation of the other twenty-six ionization constants then involves this reference constant k, or the constant difference $W_0 - C_1$, but never the supposed actual values of W_0 and C_1 separately. For the purpose of the calculation of the other twenty-six constants it was in fact not necessary at all to derive or state separate values of the quantities $W_0 - C$. The actual "solvent constant" is the difference $W_0 - C$, and at no point do the subsequent calculations and comparisons test the separate values of W_0 and C. The whole set of calculations is then practically, if not completely, independent of the assumptions concerning the distances R and R', once it is assumed that W_0 and C are constants for all oxygen acids in water. Perhaps it should be pointed out, too, that even if the comparisons had succeeded in verifying the separate values of W_0 and C, the result would probably be equally explainable either as a transfer of proton from solute to solvent (according to the modern or Brönsted picture) or as a transfer of hydroxyl from solvent to solute, (as suggested some time ago by Werner[6]), giving rise in either case to a negative solute ion.

Furthermore, W_0 is by far the largest term in equations (4) and (5). When it is realized that the difference between the two largest quantities of equation (6), namely, $W_0 - C_1$, is a constant in all the calculations, the final agreement between calculated and observed ionization constants is perhaps no longer very impressive. The over-all agreement is nevertheless sufficient to suggest that at least the difference, $W_0 - C_1$, has been verified, as a fundamental constant for oxygen acids in water. But even this conclusion may be questioned. As a purely mathematical problem, it would seem that the best determination of the solvent constant, k (or $W_0 - C_1$), from equation (7), would be through the known first ionization constant (and hence ΔF) of what may be called a "true ortho-acid," for which both m and $n = 0$.[7] For an acid of this class, with the formula H_aMO_a, in other words, we have

$$k = (W_0 - C_1) = \Delta F + RT \ln \mathrm{a} \qquad (8)$$

presumably requiring no information about structure, but only knowledge of its formula. In the list of acids considered by Kossiakoff and Harker, hypochlorous acid is the only acid believed beforehand to be a true ortho-acid; it gives $k = 10.0$,[8] in close agreement with the value 10.5 from ortho phosphoric acid. Three other acids, of doubtful formula beforehand, are classified as true ortho-acids on the basis of the calculated constants; these are H_3AsO_3, H_4GeO_4 and H_6TeO_6. But these give $k = 13.3$, 12.7 and 11.0, respectively.

---

(4) Based on observed values as listed in ref. 2 itself; relative to values listed below (Table I), the deviation is hardly changed, being 0.91.

(5) In ref. 2, O. K. Rice states that the calculations give a "remarkable check" and discusses the "reasonableness" of the value of C (and hence by implication, of W_0 and of the distances R and R') given by the method.

(6) Alfred Werner's ideas on this subject, in "Neuere Anschauungen auf dem Gebiete der anorganischen Chemie," and *Z. anorg. Chem.*, **3**, 267 (1893), and **15**, 1 (1897), are rarely mentioned. They are presented (but with disapproval) in P. Walden's book, "Salts, Acids and Bases," McGraw-Hill Book Company, New York, N. Y., 1929, p. 118–120.

(7) A true ortho-acid has the formula $M(OH)_a$, or H_aMO_a; as a result the formal charge on the central atom is always zero, and n, the number of non-hydroxyl oxygens, is also zero.

(8) Ionization constants used in the present discussion are listed below, in Table I, where sources are also stated.

Hypobromous and hypoiodous acids, not mentioned by Kossiakoff and Harker, give $k = 12.0$ and 15.2, respectively. Altogether this is a rather large range for what is presumably a fundamental constant not involving the functions $f(\rho)$ and $f(d)$ of equation (7) at all for its determination; this is so even if we disregard hypoiodous acid, here and later, because of the uncertainty about its ionization constant.[9]

It must be noted clearly that in the case of true ortho-acids, the calculation of Kossiakoff and Harker does not involve their structures at all. Despite the title of their paper, the calculations for HClO, H_3AsO_3, H_4GeO_4 and H_6TeO_6, as ortho-acids, involved nothing more than their written formulas.[10] If the fundamental assumptions for the application of equation (7) are correct, and $W_0 - C_1$ is a constant, then according to equation (8) all these ortho-acids should have values of K_1 identical except for the small differences due to the term $-RT \ln a$. The actual great variation, even in so close a series as the hypohalous acids, which should on this basis have identical ionization constants, suggests that the equation is overlooking some fundamental difference in the properties (perhaps in what may be called the property of "acidity," or the electronegativity) of the central atom. The nature of the central atom, M, presumably affects the calculation through the effect on the M–O distances (and the angles between the oxygens) in the structure of the acid, and hence through the second and third terms of equation (7). But even this effect is assumed to disappear entirely in the ortho-acids, since there is no formal charge on either the M or the oxygens of the acid. While the calculated K_1 for H_4GeO_4, in other words, agrees with the observed value, the identical value would be calculated for any other acid of the general formula H_4MO_4 or H_aMO_a, which is probably not to be expected in reality.

One may of course attribute the variation among these ortho-acids to incorrect assignment of their formulas in some cases, although this is hardly likely for hypobromous acid (and hypoiodous acid). Moreover, the agreement for the four ortho-acids in Kossiakoff and Harker's list already involves a choice of formula for all but hypochlorous acid, to give the agreement.

This insensitivity to the nature of the central atom in the case of true ortho-acids suggests that an equation like (7) is essentially only a semi-empirical equation concerned with the relative effects of the formal charge on the central atom (m) and of the number of oxygens, in a given series of acids. Most of the examples in Kossiakoff and Harker's list are acids with $m = 1$. For higher values of m the strengths become so high that reliable data are not in general available. At any rate there are hardly two acids in the list with $m > 1$, having formulas and structures similar enough for a clear check on the effect of the secondary variables (n and $f(d)$). Of the twenty-seven acids: four are ortho ($m = 0$); seventeen are the molecules and ions of seven acids with $m = +1$ and n varying from 1 to 3 depending on the charge on the acid; four are the molecule and ions of $H_4P_2O_7$, a special case with two central atoms each having $m = 1$; and the remaining two are HIO_3 ($m = 2$, $n = 2$) and the bisulfate ion ($m = 2$, $n = 3$).

Now the remarkable thing, despite "the wide variation found in the ionization constants of acids" noted by Kossiakoff and Harker, is the striking simplicity and repetition of the values for the inorganic oxygen acids in water; this simplicity or grouping becomes apparent when the acids are classified according to their values of m and n. The actual pK's are then seen to be grouped in such a way as to suggest a (rough) linear dependence upon m and n without detailed dependence upon the structure (angles, M–O distances, etc.) of the acid. Nor is there, in fact, any systematic correlation between the deviations found by Kossiakoff and Harker (between observed and calculated constants) and relative changes of structure, to suggest, within the precision of the comparison, any dependence upon this structure (see Table II, below). This may be entirely the fault of the inaccuracy and uncertainty of the observed values. But the fact remains that we may assume the functions, $f(\rho)$ and $f(d)$, of equation (7) to be constants for all the acids, and still obtain as good an over-all average agreement between calculated and observed constants, as was obtained by the laborious calculations of Kossiakoff and Harker. The precision of their comparison is so low, for example, (and with no trend) that the average error is greater than the average value of the term, $RT \ln n_O/n_H$, so that even the sign of this particular effect is not being tested.

Assuming then that (whatever the length and angles of the M–O bonds) the effect of the formal charge, m, of the central atom is uniform and constant, and similarly that the effect of each non-hydroxyl oxygen is also constant, and incorporating in the constant k the term $RT \ln n_O/n_H$, we may test the following empirical expression

$$pK = 8.0 - m(9.0) + n(4.0) \qquad (9)$$

Here K is the acid ionization constant of the species H_aMO_b, whatever its net or total charge; m is the formal charge of M; $n = b - a$. The equation has been used to calculate not only the ionization constants of the twenty-seven species listed by Kossiakoff and Harker, but nine more in addition: $HGeO_3^-$ (or $H_3GeO_4^-$), $H_4IO_6^-$, H_3PO_2, $HSeO_4^-$, HBrO, $H_2S_2O_4$, $HS_2O_4^-$, $H_2P_2O_6^=$, $HP_2O_6^≡$. In applying equation (9) the acids

---

[9] See W. M. Latimer, "Oxidation Potentials," Prentice-Hall, Inc., New York, N. Y., 1938, p. 57.

[10] The calculated values of ΔF for HClO, H_3AsO_3, H_4GeO_4, H_6TeO_6, were 10.7, 10.1, 9.9, 9.6; corrected for the statistical factors of 0, −0.6, −0.8, −1.1, respectively, these are all 10.7. The M–O distances listed in Kossiakoff and Harker's paper for these acids (1.59, 1.66, 1.97 and 1.54 Å., respectively) do not enter the calculation at all.

$H_4P_2O_7$, $H_2S_2O_4$ and $H_4P_2O_6$, with $m = +1$ for each of the two central atoms, are treated as though the central complex were a single atom with $m = +2$. Phosphorous acid (dibasic) and hypophosphoric acid (monobasic) are treated as $H_2(PH)O_3$ and $H(PH_2)O_2$, respectively, the central complex having in each case the formal charge of $+1$. These assignments of total formal charge will be found to be in accord with the definition of formal charge already given. For the twenty-seven constants of Kossiakoff and Harker's list, the average deviation between observed and calculated values of log K (according to equation 9), is 0.93, while for the entire thirty-six constants the average deviation is 0.91.[11] Since this is as good as the result of the application of equation (1), using the structure of the acids, the implication is that either the data (ionization constants and structural information) or the assumptions required in the application of equation (1) are not fine enough for a significant test of the assumptions themselves.

It has already been pointed out that the first term of this equation, here the empirical constant 8.0, corresponding to $W_0 - C_1$, was likewise essentially an empirical constant in Kossiakoff and Harker's treatment. Their treatment, however, does apparently succeed in calculating the coefficients of the m and n terms of this expression, as determined, presumably, by the structural data. But since the resulting agreement was not better than that obtained through equation (9), it may be concluded that the theory can predict the rough value of these coefficients but not their detailed dependence upon structure, and that the most that may be deduced is a roughly constant dependence merely on the values of the parameters m and n.

III. Similarity of Ionization Constants for Inorganic Oxygen Acids

Equation (9), although tested indiscriminately on all the thirty-six available (and presumably dependable) ionization constants, is of course not to be suggested as an actual formula for the ionization constant of any oxygen acid in water. It is useful primarily because it suggests certain regularities in the values of the ionization constants. According to such a formula the values of the ionization constants of oxygen acids should fall into groups represented by the various possible combinations of m and n. These classes are listed in Table I, which shows the individual acids and their ionization constants, falling in various classifications.

TABLE I

CLASSIFICATION OF THE CONSTANTS[a]

Class	Example	pK_1	pK_2	pK_3	pK_4
$m = 0$		$(n = 0)$	$(n = 1)$		
	H_4GeO_4	8.6	12.7		
	H_3AsO_3	9.2			
	H_6TeO_6	(6.2; 8.8)[b]	10.4[c]		
	$HClO$	7.2			
	$HBrO$	8.7			
	(HIO)	(11.0)			
$m = 1$		$(n = 1)$	$(n = 2)$	$(n = 3)$	
	H_3PO_4	2.1	7.2	12.0	
	H_3PO_3	1.8	6.2		
	H_3PO_2	2.0			
	H_3AsO_4	2.3	7.0	13.0	
	H_2SO_3	1.9	7.0		
	H_2SeO_3	2.6[d]	8.3[d]		
	H_2TeO_3	2.7	8.0		
	$HClO_2$	2.0			
	H_5IO_6	1.6	6.0		
$m = 2$		$(n = 2)$	$(n = 3)$	$(n = 4)$	$(n = 5)$
	H_2SO_4		1.9		
	H_2SeO_4		2.0		
	HIO_3	0.8[e]			
	$H_4P_2O_7$[f]	.9	2.0	6.7	9.4
	$H_4P_2O_6$[g]	(2.2)[g]	(2.8)	7.3	10.0
	$H_2S_2O_4$	0.3	2.5		

[a] With the exceptions noted, these values are taken from Latimer, ref. 9. [b] D. M. Yost and H. Russell, "Systematic Inorganic Chemistry," Prentice-Hall, Inc., New York, N. Y., 1944, p. 351. The value 6.2, from Blanc, *J. chim. phys.*, 18, 28 (1920); the value 8.8, from Rosenhaim and Janders, *Kolloid Z.*, 22, 23 (1918). [c] From Blanc, referred to in [b]. [d] Yost and Russell, p. 331. [e] Ricci and Naidich, THIS JOURNAL, 61, 3268 (1939). [f] Yost and Russell, p. 228. [g] Yost and Russell, p. 206. The first and second constants of $H_4P_2O_6$, like that of HIO, were not included in testing equation 9. About hypophosphoric acid, Yost and Russell state (p. 207) that the data are unsatisfactory, and that "no definite statement about the ionization constants K_1 and K_2 can be safely made yet."

The group with $m = 1$ is the most complete and most uniform. The un-ionized forms of these acids are all assigned the formula $H_aMO_{(a+1)}$, and all have approximately the same values of the ionization constants, given by the expression, $pK = 2.1 + (n - 1)(4.9)$, with $n = 1, 2, 3$ for K_1, K_2, K_3, respectively. In other words, the experimental values of the pK's for this class, if they are significant, show a surprising independence from structural characteristics, despite a range, in fact, of M–O distance, from 1.50–1.54 for H_2SO_3, H_3PO_4, H_3PO_3, $HClO_2$, through 1.66 for H_3AsO_4, 1.73 for H_2SeO_3, 1.84 for H_2TeO_3 to 1.93 Å. for H_5IO_6.[12] The calculations of Kossiakoff and Harker, involving the structures, do not even reproduce the order of the slight differences between each acid and the reference acid, orthophosphoric acid; this is shown in Table II. (The acids listed

TABLE II

COMPARISON WITH H_3PO_4

Acid	($pK_1 = 2.1$) Obs.	($pK_1 = 2.1$) Calcd., K. and H.	($pK_2 = 7.2$) Obs.	($pK_2 = 7.2$) Calcd., K. and H.
H_3PO_3	−0.3	+0.2	−0.7	−0.5
H_3AsO_4	+ .2	+ .4	− .2	−1.0
H_2SO_3	− .2	+ .2	− .4	− .2
H_2SeO_3	+ .4	+ .8	+1.0	− .9

$HClO_2$	− .1	+0.5		
H_5IO_6	− .5	+ .8		

---

(11) In terms of root mean square deviation, or $\sqrt{\Sigma\Delta^2/N}$, the deviation is 1.03 in the calculations of Kossiakoff and Harker's paper (relative to their own listed observed values, and 1.11 relative to the observed values listed here in Table I (26 constants). For the 36 constants tested through equation 9, the root mean square deviation is 1.16.

(12) Quoted from ref. 1.

with $m = 2$ are not so comparable among themselves; they furthermore involve much more uncertainty both as to structures and as to values of ionization constants.)

The similarities in Table I are both surprising and instructive. The acids here listed in the class $m = 1$, for example, are usually considered as unrelated, and if related, they are usually thought of as having widely different ionization constants, for the reason that they have never (to the writer's knowledge)[13] been grouped together in this fashion to bring out both the uniformity of their strengths and the similarity of constitution underlying this uniformity. The similarity is simply that the formal charge on the central atom is the same, and this seems to be the controlling factor for the aqueous ionization constant despite the variety of the elements represented, of their oxidation states and of the (analytical) formulas of the acids. The similarity of the first ionization constants of H_3PO_4, H_3PO_3 and H_3PO_2 has been noted by Yost and Russell (Table I, ref. [b], p. 193), who remark that these are "unlike other series of acids (H_2SO_3, H_2SO_4, for example)." But H_2SO_4 (with $m = 2$, $n = 2$) and H_2SO_3 (with $m = 1$, $n = 1$) would not be expected to have similar values of K_1 at all, while the three phosphorus acids would, from this point of view, which may therefore be a useful one for correlation and systematization in general.

At any rate there may be a significant suggestion in the simplicity and uniformity of the ionization constants as arranged in Table I, that whatever the process of ionization may be in water solution, it is much less dependent upon the structure and constitution of the acid—as these are currently pictured, at least—than one would have expected. One wonders to what extent our ideas of these "structures" may be at fault, being possibly preconceived upon the assumption that the structure of the acid is the same as that of its salt, an apparently necessary consequence of the customary but arbitrary definition that an "acid" is something which "dissociates" in water solution to "give off" a proton; that an oxygen acid, in other words, is of necessity a hydrogen compound to begin with, whether we use the Arrhenius or the thermodynamically equivalent Brönsted point of view.

It is possible that a concept of ionization through coördination, more or less as originally suggested by Werner,[6] amounting to capture of hydroxyl ion and capture of proton as the acid and base ionization processes, respectively, might be developed, in which the emphasis would be laid upon the coördination requirements of the actual solute itself (SO_3) and not upon the structure of its ion ($SO_4^{=}$ or HSO_4^-) in its salts, as the determining factor for the ionization constant.

Summary

Critical examination of theoretical calculations of the aqueous ionization constants of inorganic oxygen acids shows that the treatment does not constitute a test of the fundamental assumption of a proton transfer from solute to solvent. An empirical correlation and grouping of these ionization constants based on the formal charge of the central atom and the number of non-hydroxyl oxygens in the acid, is presented. This grouping, apparently independent of the supposed "structures" of the acids, may indicate the need of a different picture of the process of ionization.

NEW YORK, N. Y. RECEIVED JANUARY 18, 194

[13] The referee examining this paper kindly brought to the author's attention a book entitled "General Chemistry," by Linus Pauling (Edward Bros., Inc., Ann Arbor, Michigan, 1944), presenting a classification of ionization constants, based on coördination, which is in several respects similar to that in Table I.

The Influence of Dipolar Ions on the Solubility of Some Sparingly Soluble Salts

BY FANG-HSUIN LEE AND LI-KWON LUH

The interionic attraction theory applied to dipolar ions and real ions in solution has been formulated by Scatchard and Kirkwood.[1,2] This theory has been supported chiefly by experiments of Cohn.[3] Although much work has been done in finding the effect of varying the concentration of salts on the activity of amino acids, only few experiments have been done on influence of amino acids on the activity of salts. Solubility, f. p. and e. m. f. were the method chiefly used for the latter purpose. Among the amino acids glycine was the one most commonly used. The salts studied by previous workers are $NaCl$,[4,5] KCl,[6] $TlCl$,[4,7] $CaCl_2$,[4] $AgIO_3$,[8] $TlIO_3$,[9] $Ba(BrO_3)_2$,[8] $ZnCl_2$,[4] $Ca(IO_3)_2$[8] and $Pb(IO_3)_2$.[8]

According to Kirkwood, the solubility, S, of a sparingly soluble salt is related to the molality, m, of amino acid by the simplified experimental equation

$$\log S/S_0 = K(Z_+ \cdot Z_-/2)m \qquad (1)$$

where Z_+ and Z_- are the valences of the ions and K is a constant which is a function of radius of the dipolar ion and the sum of the mean radius of real ions and that of the dipolar ion. Although K varies to some degree from salt to salt, the slope of (log S) against m of salts of different valence types should bear approximately a relation with their valence. The above-mentioned list indicates that the salts are limited to 1-1 and 2-1 types only. In this present work, study was extended to 2-2 type salt with 1-1 type salt as reference. Thallium chloride and calcium sulfate were thus chosen and their solubilities determined in presence of glycine ranging from 0-1 molal.

Experimental

As to the chemicals used in this experiment, glycine was from Paul Lewis Laboratories and calcium sulfate from Merck Co. Thallium chloride was prepared from pure thallium sulfate. They were recrystallized twice.

For each solubility determination, a glycine solution of a certain known concentration was prepared. The solution was put in a Pyrex container to which an excess of salt was added. The solutions were shaken mechanically for six hours in a thermostat kept at 25.0 ± 0.1°. It has been found that saturation was reached during the time. The solution was then analyzed gravimetrically.

Discussion

The results collected in Table I are plotted in Fig. 1. It is seen that log S bears a linear relationship with m up to 1 m. The slope, $(\log S/S_0)/m$, represents $K(Z_+ \cdot Z_-/2)$ in the equation (1). These are 0.11 and 0.47 for thallium chloride and calcium sulfate, respectively. The constant K calculated from these values comes out to be 0.22 and 0.24 in the respective order. Although values of K in the literature vary somewhat in a considerable range, our values of K for thallium chloride and calcium sulfate (0.22 and 0.24) check very closely to that of thallium chloride by e. m. f. method (0.22) and of sodium chloride by both e. m. f. and f. p. methods (0.24).

Acknowledgment.—The authors are very grateful to Mrs. Dorothy M. Needham of the British Council Cultural Scientific Office for her interest in this work and kindness in supplying the chemicals during the war period while these experiments were performed. They wish also to express their thanks to Professor J. G. Kirkwood for discussing this problem.

Summary

1. The solubilities, S, of thallium chloride and calcium sulfate in glycine ranging from 0–1 m have been determined at 25°.

2. The slope of $(\log S)/m$ for thallium chloride and calcium sulfate are 0.11 and 0.47 bearing out an approximate ratio, 1:4, as required by theoretical equation.

The Structures of the Hydrides of Boron. VIII. Decaborane

BY GLORIA SILBIGER AND S. H. BAUER

In this paper we shall present an analysis of old and new electron diffraction data obtained on several hydrides of boron. The visual procedure will be used. Since the validity of the method has been questioned in the particular case of the hydrides of boron, we wish to state at the outset that although the various subjective factors have been discussed by several investigators,[1] differences of opinion regarding the "interpretations" of detailed features still remain. In any special case, judgment of these details ultimately lies with the individual. However, it is generally agreed that no spurious peaks or shoulders appear visually unless there are definite inflections in the computed curve.

Since it is so often overlooked, one other point needs emphasis. In equation (1) for the diffraction pattern produced by an assembly of atoms, atom form factors (which are a measure of their relative scattering power) and the distances between atomic centers appear. Were the data of high precision, sufficient to resolve these parameters perfectly, the deduced values would be uniquely interpretable, in most cases, in terms of a molecular structure. Unfortunately, that is far from being the case. Hence a statement to the effect that a model is excluded by the data means that within the limits of error imposed by the visual procedure, that particular location of atoms and closely similar configurations are excluded. To eliminate a given structure (wherein only the connexity between atoms is specified) one must eliminate individually models covering the entire range of interatomic distances and bond angles which seem at all plausible.

Decaborane

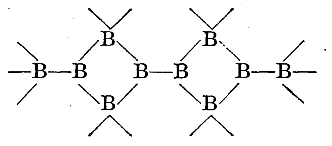
Decaborane, $B_{10}H_{14}$, is one of the most stable of the hydrides of boron. It is a colorless, well-crystallized solid at room temperature, and is formed as a product of decomposition of various boranes standing at room or elevated temperatures. It can be heated for considerable periods at 150° without observable change, but decomposition becomes noticeable at 170°.

A variety of structures have been proposed for decaborane. Möller[2] (1931) concluded from X-ray diffraction studies of single crystals that the space group is V_h^{21} with 8 molecules of $B_{10}H_{14}$ in the unit of dimensions

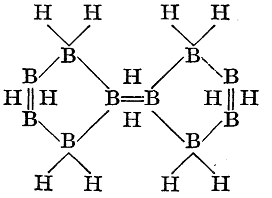
$$a = 14.46\ \text{Å}.;\qquad b = 20.85\ \text{Å}.;\qquad c = 5.69\ \text{Å}.$$

Assuming that in the solid the molecules are undissociated and similar in structure, he concludes that each molecule must have a minimum symmetry at C_2 or C_s. Möller states that C_i is also possible. However, if C_i is a minimum symmetry, the molecule must actually possess C_{2v} which is much higher than the minimum requirement of the space group. Much less reliable appear his conclusions that sub-units containing two molecules, with the dimensions $10.43 \times 7.23 \times 5.69$ Å. and possessing the symmetry V, C_{2h} or C_{2v}, are present in the crystal. Formally, it is possible to arrange the eight $B_{10}H_{14}$ units in four groups of two, each pair being disposed about a point in the lattice in such a manner that this pair exhibits the symmetry V, C_{2h} or C_{2v}. However, Möller's conclusion that these pairs are contiguous and that the envelope circumscribing each pair is a rhombohedron with the dimensions 7.23, 10.43 and 5.69 Å. is unwarranted. If the latter is accepted, $B_{10}H_{14}$ must have a naphthalene-like or similar type of structure.

On the basis of the analogy in chemical stability of decaborane with the pentaborane B_5H_9 Pauling and Bauer[3] (1936) suggested the configuration for the former



In extending his theory of the "protonated double bond" to the various higher hydrides of boron, Pitzer[4] (1945) suggested the structure



In this Laboratory we diffracted electrons on the vapor of decaborane in the hope of eliminating some of the possibilities which have been suggested. In this we were only partly successful.

This electron diffraction study was performed on the equivalent of 8 cc. (STP) of the material, kindly furnished to us by Professor A. B. Burg, to whom we wish to express our sincerest appreciation. The sample, contaminated with mercury, was distilled under vacuum (all joints of the magnetic breaker kind) into a high temperature nozzle. Some fluffy brown material was left in the tube after distillation. The photographs were ob-

Final B-B$_{\text{av}}$, 1.80 ± 0.03 Å. Average 1.016
B-H$_{\text{av}}$, 1.29 ± 0.04 Å. Average deviation 0.011

Figure 1 shows the radial distribution curve calculated after Walter and Beach.[5] The maxima at 1.28 and 1.78 Å. are very likely due to the B–H and B–B bonded distance, respectively, while the one at 2.88 Å. can be attributed to the distance between boron atoms separated by another boron atom as in a chain or ring; the ratio (2.88/1.78) corresponds to a B–B–B bond angle of 108°. Due to the sharpness and intensity of the peak at 2.88 Å., we are able to eliminate models which do not have tetrahedrally bonded $_{\text{B}}\diagup^{\text{B}}\diagdown_{\text{B}}$ atoms or those which do not contain a pentagon structure with angles of 108°. Therefore the configuration including two-four membered rings of boron suggested by Bauer and Pauling[3] is eliminated. For the same reason we were able to eliminate the planar hexagon configurations proposed by Nekrasov[6] and later by Pitzer[4] as an alternate possibility. All other models considered involved enough angles near 108° to necessitate the computation of diffracted intensity curves. The following structures were considered

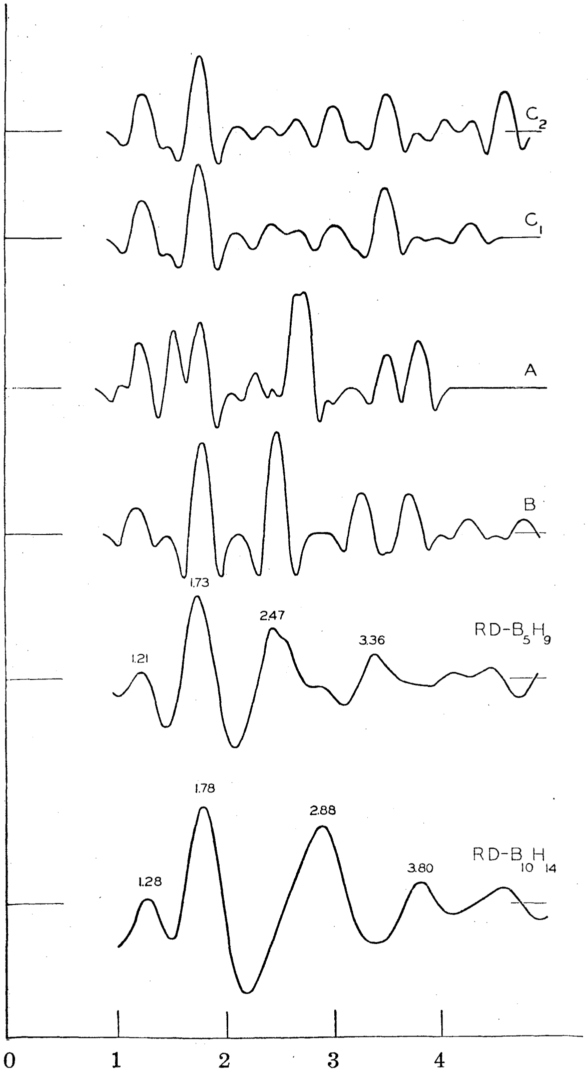

Fig. 1.—Radial distribution curves for B_5H_9 and $B_{10}H_{14}$. R. D. B_5H_9 and R. D. $B_{10}H_{14}$ were computed from diffraction data; A, B, C_1 and C_2 are "synthetic" for B_5H_9.

In selecting the above models, we considered as many diverse types as we could picture; we assumed interatomic distances and disposed the hydrogen atoms in such a manner as to get "synthetic" R.D. curves which agree best with the

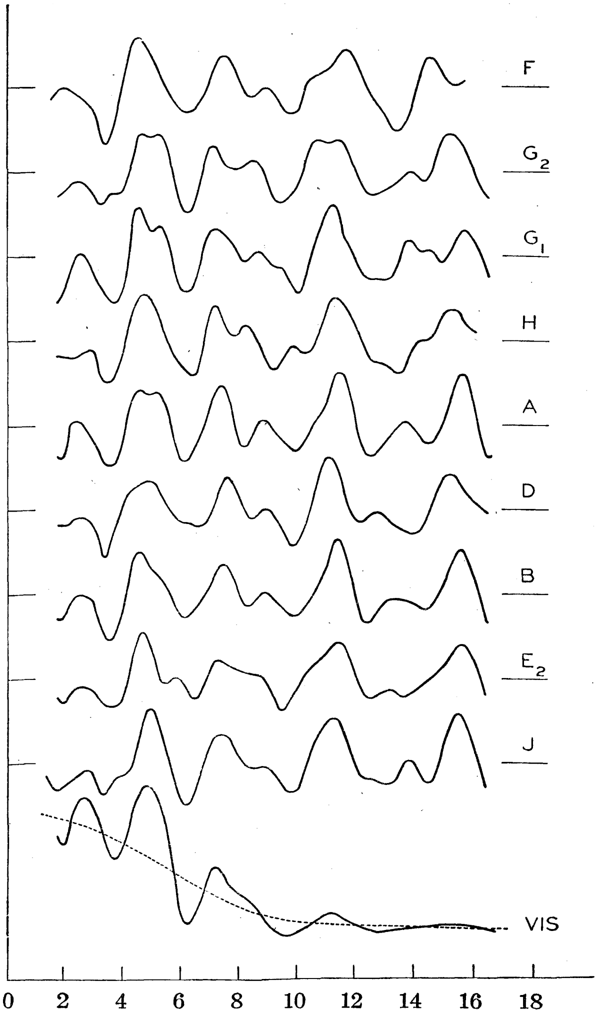

Fig. 2.—Intensity curves for $B_{10}H_{14}$.

R.D. computed from the data. After comparing the visually estimated diffraction pattern with those computed from the models (Fig. 2) using the equation

$$I(s) = \sum_{i}{}' \sum_{j}{}' (Z-F)_i (Z-F)_j \frac{\sin l_{ij}s}{l_{ij}s}{}^{7} \qquad (1)$$

we divided the group into three classes,

DEFINITELY ELIMINATED: A, F, G_1, G_2 and H
POSSIBLE: J, B, C, D and E
MOST PROBABLE: J

It is clear that G_1 and G_2 are eliminated because of the assymmetry introduced in the pentagons by the protonated double bonds. Of the structures considered "possible," we have been able to group only J, C, and D in pairs about a point so that each pair exhibits a symmetry V, C_{2h} or C_{2v} (Fig. 3). Apparently the bent chains, B and E, do not permit such symmetrical arrangements. The planar pentagon configurations (G_1, G_2, H) which were eliminated on the basis of the electron diffraction data could also be arranged to form a unit with V, C_{2h} or C_{2v} symmetry. Finally, although a coplanar pentagon configuration similar to J was not considered, it would fit the X-ray data and probably the E.D. data as well as does model J.

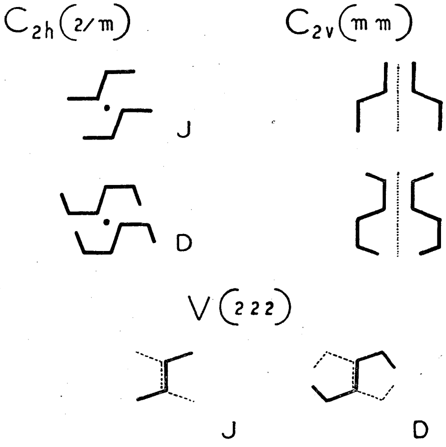

Fig. 3.—Arrangement of two molecules of the J and D configurations for decaborane so as to satisfy the symmetries suggested by Möller: C_{2h} (2/m)-plane of symmetry in plane of page; C_{2v} (m m)-planes of symmetry in plane of page and perpendicular to page at the dotted lines; V(222)-dotted line in plane parallel to that of page.

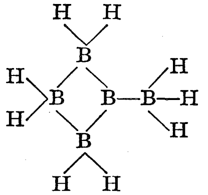
A careful study of the X-ray data and computations leading to a Fourier projection should permit the elimination of those structures at present considered possible. Were larger amounts of decaborane available for this investigation so that more fully developed electron diffraction photographs could be obtained, a definite structure assignment might have resulted.

Pentaborane, B_5H_9

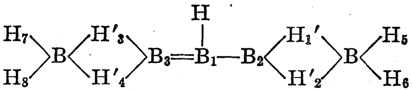
Since hydrogen bridge structures[4,8] were not considered in the original electron diffraction study of B_5H_9,[3] we reconsidered these data with the view of testing the acceptability of a bridge type configuration. The radial distribution curve, recalculated after the method of Walter and Beach[5] (Fig. 1), shows a slightly different ratio of BH/BB distances than was presented in the original report. The slight shift in maxima suggests an increase in the length of the BH distance and permits an even better match between the Bauer–Pauling structure (B, Fig. 1) and the observed data.



BB = 1.76 Å.
BH = 1.17 Å.

Maxima appeared at 1.21, 1.73 and 2.47 Å. These we interpreted as being due to the BH, BB and the $\overset{\diagup \mathrm{B} \diagdown}{\mathrm{B} \leftarrow\!\!\rightarrow \mathrm{B}}$ interactions in the ring, respectively. Because of the intensity of the peak at 2.47 Å. it cannot be assigned to BH interactions only. Since the combination 1.73 and 2.47 Å. leads to a BBB angle of approximately 90°, no model without this 90° angle can be made to agree with the observed pattern. The two suggested models, involving hydrogen bridges contain no BBB angles of 90°. The synthetic R.D. patterns C_1 and C_2 (Fig. 1) were calculated following the suggestion of Longuet-Higgins and Bell.

C_1.



$B_1B_2 = B_1B_3 = 1.70$ Å.
$BH = 1.18$
$BH' = 1.24$
$B_3B_4 = 1.76$

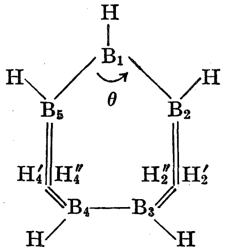
Due to resonance, B_1B_2 equals B_1B_3; H'_1, H'_2, H'_3 and H'_4 determine a plane perpendicular to the plane of H_5, H_6, H_7 and H_8; C_2 is identical with C_1 except that $\angle B_2B_1B_3 = \angle HB_1B_2 = \angle HB_1B_3 = 120°$. As can be seen from a comparison of the synthetic and calculated radial distribution curves, there is no way of varying bond distances or angles for C_1 or C_2 to obtain a suitable fit, since there is no way of obtaining a sufficiently high maximum at 2.47 Å. Thus this bridge structure is definitely eliminated.

---

(7) This equation, rather than $\sum Z_i Z_j \frac{\sin l_{ij}s}{l_{ij}s}$ was used because in taking the photographs a stop was inserted to remove the main beam about 1 cm. from the nozzle. This served not only to clear up the inner region of the photographs, but also acted as a selective mask for small angles, so that the pattern was in effect multiplied by some low power of s. Equation (1) satisfactorily accounts for this change.

(8) (a) H. C. Longuet-Higgins and R. P. Bell, *J. Chem. Soc.*, 250 (1943); (b) *Proc. Roy. Soc.* (*London*), **A183**, 357 (1944–1945).

When Pitzer first presented the protonated double bond structures he claimed that the following angles and bond lengths for B_5H_9 fitted the electron diffraction data.



$B_3B_4 = 1.70$ Å.
$B_1B_2 = B_1B_5 = 1.50$ Å.
$B_2B_3 = B_4B_5 = 1.75$ Å.
BH (protonated double bond) = 1.25 Å.
BH = 1.10 Å.
$\theta = 113°$

H_2' and H_2'' (also H_4' and H_4'') were placed 0.86 Å. above and below the plane of the B atoms and displaced outward from the line B_2B_3 (B_4B_5) by 0.25 Å.

That appeared doubtful, since there are no BBB angles of approximately 90° in this configuration. There are other discrepancies in the R.D. curve (A, Fig. 1) which argue against it. Nevertheless, we calculated intensity curves using the distances and angles proposed (Fig. 4A). This should be compared with the curve computed for the methylene cyclobutane model (Fig. 4B) and with the visually estimated pattern. Since the relative intensities and shapes of the maxima are as important as their positions, the curve computed assuming the protonated double bond structure is definitely eliminated.

It is worthwhile to emphasize that for this compound it is the location of the boron atoms and not of the hydrogen atoms which determine the essential features of the pattern. Thus the intensity curves computed for models of the type  wherein BB = 1.76 Å.; B–H = 1.17 Å.; and $90 < \theta < 100°$, will be generally satisfactory. The characteristic features are not specially sensitive to the location of atom B'; and one really cannot specify the type of bonding suggested by the - - - links. This is evident from inspection of the curves plotted in Fig. 5, ref. 3.

Diborane

A recently reported infrared study of diborane[9] argues very strongly in favor of the bridge structure, whereas the original electron diffraction data[10] were interpreted to favor the ethane type configuration. Since that conclusion depends on whether a faint inner ring is present or absent in the region of $s = 3$, the electron diffraction work is being repeated, employing an apparatus with a rotating sector, with the hope of obtaining objective microphotometer traces of the pattern.

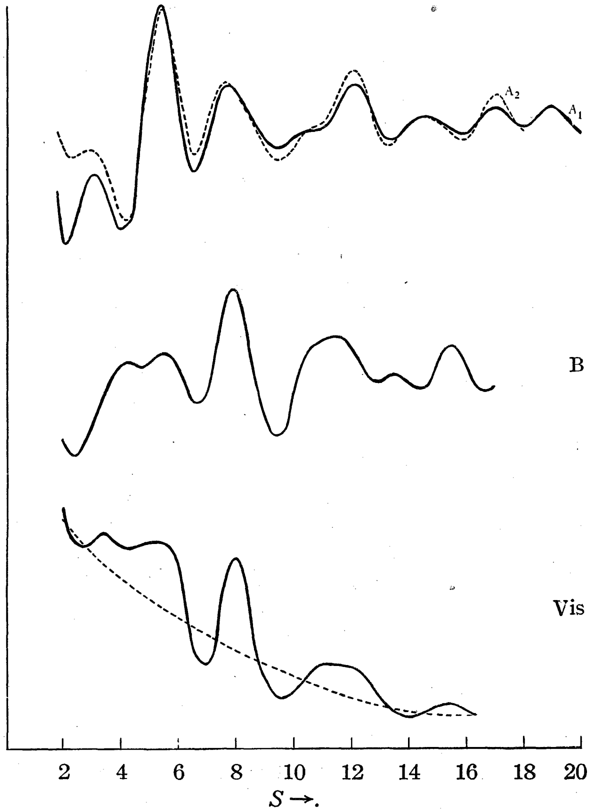


Fig. 4.—Intensity curves for B_5H_9: A_1 was computed using $\Sigma Z_iZ_j \sin(sl_{ij}/sl_{ij})$ for Pitzer's model; A_2 was computed using eq. (1) for the same model; B methylene cyclobutane model, and visual curve from reference 3.

Summary

New electron diffraction data on decaborane are reported. Using the visual procedure we found that

$$B\text{—}B_{av.} = 1.80 \pm 0.03 \text{ Å.}$$
$$B\text{—}H_{av.} = 1.29 \pm 0.04 \text{ Å.}$$
$$\angle B\text{—}B\text{—}B\ 109 \pm 3°$$

Although a unique structure assignment is not possible, the data can best be interpreted on the assumption that $B_{10}H_{14}$ consists of two symmetrical pentagons held together by a B–B bond. Furthermore, we consider the data sufficient to eliminate the H-bridge type configurations which were tested.

Previously published electron diffraction data on B_5H_9 were reviewed, and it is demonstrated that Pitzer's model for this compound is definitely not acceptable.

NOTE ADDED IN PROOF.—I am grateful to Drs. Kasper, Lucht and Harker for kindly communicating to me the conclusion which they reached regarding the structure of decaborane, based on their X-ray diffraction studies of single crystals. Due to its unexpected form, their configuration had not been considered in the above electron diffraction study. It may be obtained by folding model H along the B–B bond shared by the two pentagons upward until the angle between the planes is about 75°; then by bending each of the terminal boron atoms downward until its bond makes an angle of about 50° with the plane of the ring; finally, by redistributing some of the hydrogen atoms. Preliminary computations indicate that this model could be brought into excellent agreement with the electron diffraction data.—S. H. BAUER.

Carbonyl Chloride. Entropy. Heat Capacity. Vapor Pressure. Heats of Fusion and Vaporization. Comments on Solid Sulfur Dioxide Structure

BY W. F. GIAUQUE AND W. M. JONES

This paper presents the results of a calorimetric investigation of carbonyl chloride covering the range from 15° K. to its boiling point. A comparison of the entropy calculated from molecular data with the entropy change obtained from the $\int_0^T C_p \, d\ln T$ leads to the conclusion that the planar phosgene molecule shows a nearly complete lack of discrimination between the positions of oxygen and chlorine in the crystal lattice.

Apparatus and Method.—The measurements were made in a vacuum calorimeter which has the laboratory designation Gold Calorimeter IV. A description has been given by Kemp and Giauque,[1] and a more detailed description of this type of calorimeter has been given by Giauque and Egan.[2] One calorie was taken equal to 4.1833 international joules.

The measurements on carbonyl chloride were made immediately after an investigation on nitromethane[3] and temperature scale comparisons presented in that connection apply to the present work. After the completion of all of the heat capacity and heat of fusion measurements, the resistance thermometer was broken due to a very unusual expansion of phosgene which occurred in the region extending some 25° below its melting point. A discussion of this expansion will be given below. A new resistance thermometer was installed prior to the measurements of the vapor pressure and heat of vaporization.

Preparation and Purity of Carbonyl Chloride.—About 500 cc. of Kahlbaum phosgene was fractionated in a vacuum jacketed column filled with glass helices for a length of approximately 75 cm. About three-fourths of the material was discarded. The sample employed weighed 185.5194 g. *in vacuo*, corresponding to 1.87537 moles. The molecular weight was taken as 98.924.

The change of melting point with the fraction melted was used to estimate the liquid soluble–solid insoluble impurity as 7 moles in 100,000 moles.

practicable to use the resistance thermometer-heater as a thermometer in this region. The heat capacity results are given in Table I. The five points immediately below the melting point are marked with asterisks because the temperature rise was obtained by means of the standard thermocouple on account of the thermometer strain mentioned above. These five points are of decreased accuracy and may be in error by as much as 1%.

The values given in Table II were obtained from a smooth curve through the data. They are believed to be accurate to 0.2% except at 20° K. where the error may be 1% and at 15° K. where it may be 5%.

TABLE II

HEAT CAPACITY OF CARBONYL CHLORIDE. VALUES TAKEN FROM SMOOTH CURVES THROUGH THE DATA

0°C. = 273.10°K.

T, °K.	C_p, cal. deg.$^{-1}$ mole^{-1}	T, °K.	C_p, cal. deg.$^{-1}$ mole^{-1}

Accepted value 145.34 ± 0.05° K.

The Melting Point of Carbonyl Chloride.—The equilibrium melting point temperature was observed as a function of the fraction of the phosgene melted. A summary of the observations is given in Table III. The strain in the resistance thermometer which developed in the region below the melting point disappeared as soon as the melting point was reached, as might be expected.

Heat of Fusion of Carbonyl Chloride.—The data relating to the two determinations of the heat of fusion of carbonyl chloride are given in Table IV. The measurements were started somewhat below the melting point and ended somewhat above, and a correction for $\int C_p dT$ was applied.

TABLE IV

HEAT OF FUSION OF CARBONYL CHLORIDE

Melting point, 145.34°K.

Temperature interval, °K.	Corrected heat input	Pre-melting	Cal./mole $\int C_p dT$	ΔH fusion
144.360–146.263	1405.4	3.2	38.6	1370.0
143.046–147.110	1450.6	1.3	80.4	1371.5

Mean 1371 ± 2

Vapor Pressure of Carbonyl Chloride.—The vapor pressure was measured by means of a mercury manometer, 1.6 cm. i. d., which could be attached to the glass line leading to the calorimeter. After each determination, the calorimeter was shut off from the manometer. The material in the manometer and connecting lines was then condensed, and the lines were pumped out. This was done as a precaution against error which would result if some phosgene reacted with the mercury, although a preliminary experiment did not detect this reaction.

The data of Cawood and Patterson[5] were used for correcting for capillary depression. The standard acceleration of gravity was taken as 980.665

Heat of Vaporization of Carbonyl Chloride.—The heat of vaporization of carbonyl chloride was measured directly by adding heat to the calorimeter and removing the gas at constant pressure. By means of a capillary system the pressure could be held at approximately one atmosphere while the gas was condensed in small weighed bulbs by cooling them with liquid air. Heat capacity corrections were made to take into account the small difference in the initial and final temperatures which were measured before and after energy input. Corrections were also applied for heat leak and for the evaporation required to fill the space previously occupied by evaporated liquid.

The heat of vaporization was also calculated from the vapor pressure data by means of the equation $\mathrm{d}P/\mathrm{d}T = \Delta H/T\Delta V$ and Berthelot's equation of state.

$$\Delta H = \frac{RT^2 \mathrm{d}\ln P}{\mathrm{d}T}\left[1 - \frac{9\,PT_c}{128\,P_cT}\left(1 - \frac{6\,T_c^2}{T^2}\right) - \frac{PV_{\text{liq.}}}{RT}\right]$$

The critical constants were taken from Germann and Taylor[12]: $T_c = 455°$ K. and $P_c = 56$ atm. The molal volume of the liquid at the boiling point was taken at 69.2 cc. from the "I.C.T." The use of Berthelot's equation introduced a correction of 192 cal. mole^{-1} for gas imperfection.

The heat of vaporization data are summarized in Table VII.

TABLE VII

HEAT OF VAPORIZATION OF CARBONYL CHLORIDE AT ITS BOILING POINT 280.66°K.

Moles vaporized	Time of energy input, minutes	ΔH vaporization cal. mole^{-1}
0.15098	40	5831
.15261	40	5834
.15916	40	5836
.13241	35	5825
		Mean 5832 ± 6
From the vapor pressure equation assuming a Berthelot gas		5825

The value for the heat of vaporization obtained from the vapor pressure data agrees very well with the direct determinations but can be given no weight in comparison with these more reliable values. However the agreement is evidence in support of the use of Berthelot's equation in correcting for the effect of gas imperfection on the entropy of the carbonyl chloride gas as will be done below.

The Entropy of Carbonyl Chloride.—The calculation of the entropy of carbonyl chloride from the calorimetric measurements is summarized in Table VIII.

Correction for gas imperfection	0.13
S (ideal gas at 280.66° K.) − S (solid at 0° K.) =	66.63

The structure of the carbonyl chloride molecule has been determined by Brockway, Beach and Pauling[13] by electron diffraction measurements. They give the following results; C–O = 1.28 × 10^{-8} cm., C–Cl = 1.68 × 10^{-8} cm. and the Cl–C–Cl angle = 117°. From these values the moments of inertia may be calculated as 105.4 × 10^{-40}, 240.1 × 10^{-40} and 345.5 × 10^{-40} g. cm.^{2}.

The spectrum of phosgene has been investigated by Marton[14] (infrared), Henri and Howell[15] (ultraviolet), Dadieu and Kohlrausch[16] (Raman),

Ananthakrishnan[17] (Raman), Bailey and Hale[18] (infrared).

The most important work is that of Ananthakrishnan since the polarization estimates on his Raman lines are important in assigning the observed frequencies to the several modes of motion. Only five of the six fundamental frequencies were observed in the Raman spectrum, although all were expected. Thompson[19] has reviewed the data and compared it with that on thiophosgene which he has measured, and in which case he found all six fundamental frequencies. As the two phosgenes are very similar he was able to make a good estimate of the unobserved nonplanar deformation frequency as 230 cm.$^{-1}$. Thompson estimates that the error involved in the uncertainty of his choice would be less than 0.1 cal. deg.$^{-1}$ mole^{-1} in a statistical entropy calculation. The fundamentals are given by Thompson as 1827, 845, 570, 444, 302 and (230) cm.$^{-1}$. The symmetry number of the molecule is two.

The calculation of the entropy of carbonyl chloride gas from molecular data is given below. The physical constants used are taken from the "I.C.T." The calculations are in essential agreement with results derived from equations given by Thompson.[19]

	280.66° K.	298.10° K.
S translation	39.39	39.69
S rotation	24.45	24.63
S vibration	4.42	4.81
S ideal gas, 1 atmos. cal. deg.$^{-1}$ mole^{-1}	68.26	69.13

$$S \text{ (molecular data)} - \int_0^{280.66} C_p \,\mathrm{d}\ln T = 68.26 - 66.63 = 1.63$$

The only appreciable uncertainty in the above calculation is the 230 cm.$^{-1}$ frequency. In order to eliminate the discrepancy it would be necessary to assume a value of about 900 cm.$^{-1}$ instead of 230 cm.$^{-1}$. Not only does this appear unreasonable but the polarization analysis of Ananthakrishnan[17] appears to eliminate possible reassignment of the observed frequencies so as to permit the inclusion of a 900 cm.$^{-1}$ value with the five observed frequencies.

We believe that the explanation of the discrepancy lies in the random orientation of the carbonyl chloride molecules in the crystal lattice. This planar molecule does not differ greatly from an equilateral triangle, with the carbon atom off center, and despite its appreciable electric moment it appears necessary to assume that the oxygen can occupy any of three positions. Complete randomness in this respect would correspond to R ln3 = 2.18 cal. deg.$^{-1}$ mole^{-1} of residual entropy, instead of the value 1.63 given above, but some approach to order has been noted in cases of random orientation in CO and NNO and it is reasonable to assume that some regularity may be attained in the present case.

We have mentioned the abnormal expansion which occurred in solid phosgene in the region below its melting point and it seems probable that this is related to the partial attainment of molecular orientation equilibrium in the solid.

In the some two score condensed gases which have been investigated in this Laboratory with similar calorimeters the only one we can recall which caused a disturbance of this kind was sulfur dioxide. To quote from Giauque and Stephenson[20]: "At 175° K., about 20° below the melting point of sulfur dioxide, the resistance thermometer began to give slightly high values, and just below the melting point the abnormal increase in resistance reached 0.1% of the total resistance. As soon as a portion of the sulfur dioxide was melted, the resistance returned to its normal value. No completely satisfactory explanation of this stretching effect can be offered; none of the many other condensed gases investigated in this calorimeter have caused such a disturbance."

It would seem to be more than a coincidence that the above behavior should occur in these two molecules, since, among all those investigated, only sulfur dioxide like carbonyl chloride is a triangular molecule with elements of the first and second rows of the periodic system at the apexes of the triangle. Accordingly we suggest that when carbonyl chloride and sulfur dioxide are first solidified the amount of random orientation present at the freezing point is reduced by subsequent cooling. This causes dimensional changes in the solid which are not reversed in macroscopic detail when the substance is slowly warmed, thus producing the strain observed in the calorimeter.

In the case of sulfur dioxide the electron diffraction investigation of Schomaker and Stevenson[21] combined with the entropy measurements of Giauque and Stephenson[20] make it certain that perfect order is attained at low temperatures. However the characteristics of sulfur dioxide in the region below its melting point give some basis for the suspicion that it has disorder of the molecular orientation type.

The sulfur dioxide molecule is too far from an equilateral triangle to make it appear probable that simple orientation of the triangle would be the explanation in this case. The crystal structure of sulfur dioxide is unknown; however, it is of interest to speculate about a type of plausible crystalline arrangement which would be in accord with the experimental observations.

If adjacent sulfur dioxide molecules are paired, with their molecular planes 90° apart, and with the O–O sides of the triangles together, the two sulfur and four oxygen atoms would approximate a sphere. If the oxygen atoms were at the corners of a square there would be three orientation

positions exchanging oxygen and sulfur atoms for each pair of sulfur dioxide molecules. It is also of interest that, if the oxygen atoms in such an arrangement were located on a staggered square, which is more probable, orientation disorder could result due to rotation of oxygen atoms alone with two possibilities per pair of sulfur dioxide molecules. It is also possible that both types of disorder could occur simultaneously.

In any of the above cases it is reasonable, not only that a good deal of orientation disorder should be present at the freezing point, but also that potential barriers between the several positions should be small enough to permit the attainment of perfect order as the solid is cooled, as was shown by the entropy determination.

It is obviously of interest to have a crystal structure investigation of solid sulfur dioxide. The observations should be made on the solid cooled to at least the temperature liquid air since, if the above explanation of the abnormal expansion of solid sulfur dioxide is correct, disorder near the freezing point may complicate structural observations.

It is not our intention to place too much emphasis on the particular structure suggested to explain possible random orientation in solid sulfur dioxide but rather to illustrate the possiblity of orientation disorder in such a substance.

Kemp and Giauque[22] found very slow thermal equilibrium in their measurements on carbonyl sulfide. In the 75° interval below the melting point, 134.31° K., it took about ten times the usual period to obtain temperature equilibrium after an energy input. The entropy calculations show that the substance attains perfect order at very low temperatures but they expressed the opinion that random orientation of the sulfur and oxygen ends of the molecule characterizes thermodynamic equilibrium at the higher temperatures. The difficulty of such a molecular rotation within the solid was believed to be responsible for the slow thermal equilibrium.

In the case of carbonyl chloride it is probable that a somewhat greater approach to order would be possible with excessively slow cooling, extending over months or years, but the attainment of order in cases of this type often involves coöperation of molecules sufficiently to make the rate drop off rather sharply with temperature. The phenomenon is much the same as the decrease in entropy, and thus the increased order, which accompanies the annealing of a glass. A glass must be annealed above a rather definite temperature or the process will not occur at an appreciable rate. The entropy associated with structural randomness, corresponding to thermodynamic equilibrium in the annealing region of a system, which is non-crystalline in certain respects, will remain when the substance is cooled to very low temperatures.

The solids of carbon monoxide, nitric oxide, nitrous oxide, water and evidently carbonyl chloride, are those known to remain amorphous or glass-like with respect to molecular orientation within their semi-crystalline frameworks, even when considerable time is allowed for thermal equilibrium.

The molecule thiocarbonyl chloride is so nearly an equilateral triangle, with the carbon atom near the center, that it seems safe to predict that it would have a residual entropy of $R \ln 3$ and the same situation should exist with carbonyl fluoride.

Summary

The heat capacity of solid and liquid carbonyl chloride (phosgene) has been determined from 15 to 280° K.

The melting point is 145.34° K. (0° C. = 273.10° K.). The heat of fusion is 1371 cal. mole^{-1}.

The vapor pressure of liquid carbonyl chloride has been measured from 215 to 281° K. The data are represented by the equation, $\log_{10} P_{(\text{int cm.})} = -(1690.3/T) + 9.68020 - 0.0078981T + 5.5847 \times 10^{-6}T^2$.

The boiling point is 280.66° K., and the heat of vaporization at this temperature is 5832 cal. mole^{-1}.

The calorimetric measurements have been used to calculate the increase in entropy between 0° and 280.66° K. as 66.63 cal. deg.$^{-1}$ mole^{-1}.

A calculation of the entropy of carbonyl chloride gas at 280.66° K. from molecular data leads to a value of 68.26 cal. deg.$^{-1}$ mole^{-1}.

The 1.63 cal. deg.$^{-1}$ mole^{-1} discrepancy between the above results is interpreted as due to random orientation of the planar triangular carbonyl chloride molecule in the solid at low temperatures. The maximum value for this effect would be $R \ln 3 = 2.18$ cal. deg.$^{-1}$ mole^{-1} so that some approach to order is indicated.

The entropy of carbonyl chloride is calculated from molecular data to be 69.13 cal. deg.$^{-1}$ mole^{-1} at 298.1° K. and this value, which does not include the entropy due to nuclear spin or the isotope effect, is the most reliable value to use in thermodynamic calculations.

A comparison of the similar anomalous behavior of carbonyl chloride and sulfur dioxide, in the region below their melting points, leads us to infer that sulfur dioxide also has some random orientation in the solid although the data on this substance indicate that it becomes perfectly ordered at very low temperatures. These two molecules each have atoms of the first and second rows of the periodic system at the apexes of their triangular structures.

The Dielectric Polarization and Molecular Association of Hydrogen Fluoride Vapor[1]

By Richard A. Oriani and Charles P. Smyth

The polymerization or molecular association of hydrogen fluoride has been known for a long time. Simons and Hildebrand[2] analyzed the data[3] of Thorpe and Hambly on its vapor density and concluded that the gaseous substance was composed mainly of cyclic hexamers $(HF)_6$. A very careful redetermination of vapor densities led Long, Hildebrand and Morrell[4] also to the conclusion that the data could be represented by an equilibrium existing between the monomer and the cyclic hexamer, except at low pressures, where there was some indication of lower polymers. Fredenhagen[5] also made vapor density measurements, and concluded that forms other than H_2F_2 existed and also that the theory that only HF and $(HF)_6$ existed was untenable. His data were further analyzed by Briegleb,[6,7] who assumed an equilibrium distribution of polymers according to the equation $HF + (HF)_n \rightleftarrows (HF)_{n+1}$, and calculated that the dimer had the largest energy of association, but that values of n up to 8 were significant. Briegleb considered the configurations of the polymers to be chains in which adjacent HF units were anti-parallel to one another (Fig. 1B). The electron diffraction data of Bauer, Beach and Simons[8] indicated that under the conditions obtaining in their experiments at least, the principal configuration existing in gaseous hydrogen fluoride was a chain-like arrangement in which the fluorines occupied the corners of a zig-zag structure, with the hydrogens lying on a line connecting two consecutive fluorines and with a chain angle of about 140° as in Fig. 1C. The same structure with a chain of almost infinite length and angles of 135° was indicated by the X-ray analysis of solid hydrogen fluoride.[9] On the other hand, Pauling[10] calculated that, for a degree of polymerization of 6 or more, the cyclic polymer would be more stable than its chain analog by virtue of the additional bond, that the partial covalent character of the hydrogen bonds tended to stabilize bond angles of about 110 or 120° for fluorine, and that as a consequence the cyclic hexamer was somewhat more stable than other polymers.

Because of the large difference in dipole moment to be expected between a cyclic structure and a zig-zag chain, it has been considered advisable to investigate the molecular association of hydrogen fluoride by measurement of the dielectric polarization of the vapor as a function of temperature and pressure. A preliminary note describing work along these lines has already been published.[11]

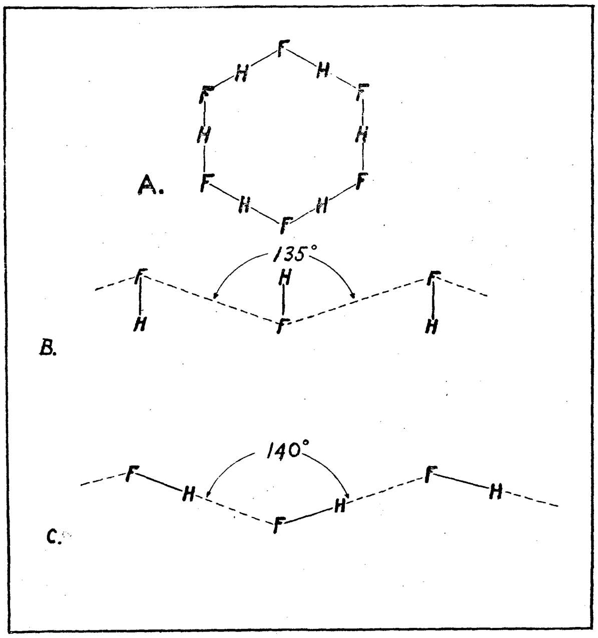

Fig. 1.—A, cyclic hexamer with zero dipole moment; B, linear model with consecutively antiparallel HF molecules; dipole moment either zero or 1.91; C, linear model deduced from electron diffraction data; dipole moment increases with chain length.

Apparatus and Method of Measurement

While the electrical measuring circuit has been previously described,[12] no account has been published of the cell and vacuum system, which were identical, except for some minor modifications, with the apparatus employed by Hannay and Smyth[13] in the determination of the dipole moment of unassociated hydrogen fluoride. The cell was constructed of three concentric nickel cylinders, of which the outer and the inner were silver-soldered to the same nickel disc, while the middle one was insulated from the other two by a gasket of "Teflon."[14] Electrical contact was made to the middle cylinder by a nickel rod passing through a bushing tightly packed with "Teflon." The capacitance of the empty cell was 250 micromicro-

farads, exclusive of lead capacitance; this latter was determined separately and was checked by measurements of the dielectric constant of air. The apparatus for handling the hydrogen fluoride was constructed of copper tubing and nickel with silver-soldered joints, except for the "Kerotest" valves, the brass bodies of which gave some trouble because of jamming due to corrosion. Two valved containers were provided for the purification of the hydrogen fluoride by distillation from one to the other, and for the storage of the purified material. A Bourdon gage, calibrated with air against a mercury manometer and readable to 1 mm., was used to measure the pressure. A commercial tank of hydrogen fluoride from the Matheson Company, East Rutherford, N. J., was permanently connected to the system, as was also a tank of fluorine. The leads to the cell were suitably shielded, and the cell was immersed in a thermostated oil-bath able to hold the temperature constant within 0.02°. The temperature was read by a calibrated platinum resistance thermometer immersed in the bath. The gas system was connected to an oil vacuum pump through a long tube filled with soda-lime. In order to prevent the occurrence of corrosion during the course of a measurement, the system was given a prolonged exposure to fluorine from the attached cylinder, and the fluorination was repeated whenever the inside of the system had been exposed to the atmosphere. The importance of this operation may be gaged by the observation that, when the system was inadequately conditioned, a gas pressure slightly larger than one atmosphere was developed over a period of time apparently by reaction of hydrogen fluoride with the metal.

In order to purify the hydrogen fluoride, a quantity was distilled from the commercial tank into a reservoir by chilling the latter (b. p. of hydrogen fluoride, 19.4°). This material was then distilled back and forth from one reservoir to the other by alternately chilling and warming the containers. After each distillation the apparatus was evacuated, while the condensate was chilled with liquid nitrogen. At least one of these distillations was performed through an atmosphere of fluorine to aid in the removal of moisture. The procedure was repeated until the vapor pressure of the hydrogen fluoride at 0° was close to the literature value of 357 mm.[15] (358.2 mm.[16]). In these purifications, the vapor pressure at 0° always decreased as the purification proceeded to assume values from 354 to 356 mm. Another criterion of purity was the consistency and reproducibility of the dielectric measurements in the low pressure regions at all the temperatures studied, and their agreement with the results of Hannay and Smyth.[13]

In order to carry out a determination of polarization, the system was evacuated of the fluorine left in it, and flushed out repeatedly with hydrogen fluoride. After another evacuation, and after the cell had attained temperature equilibrium, simultaneous readings of pressure and capacitance were made after admittance of successive small portions of hydrogen fluoride, and also after successive withdrawals of the vapor by recondensation into the storage container. Enough time had to be allowed before making readings after each admission or withdrawal of hydrogen fluoride to permit adsorption of the vapor to attain equilibrium. Adsorption was evidenced in a lag in the attainment of constant capacitance and pressure readings at the higher pressures when the temperature was not far above the boiling point. Repeated measurements of capacitance and pressure as functions of time showed that, in typical experiments where adsorption was a maximum when the pressure was raised to 700 mm., the adsorbed layer raised the capacitance by about 50 scale divisions while the total increase of capacitance produced by the hydrogen fluoride was about 1600 scale divisions. The maximum error thereby produced in the dipole moment value, which is proportional to the square root of the capacitance, was, therefore, about 1.6%.

It was believed that the treatment of the hydrogen fluoride with fluorine had removed any last traces of moisture. As moisture has been supposed to affect the association of hydrogen fluoride materially, a considerable quantity of water vapor was introduced into the cell after the completion of the measurements reported in Tables I and II. A very slight apparent increase in the dipole moment at low pressures was observed and, at higher pressures, adsorption or condensation of the water so affected the capacity measurement as to render the experiment valueless. Indeed, the slight increase in apparent moment at low pressures was probably the effect of adsorption.

Experimental Results

The molar polarizations P were computed from the condenser readings C by the relation

$$P = \frac{RT}{3p} \cdot \frac{C - C_0}{fC'_0} \qquad (1)$$

in which f is a condenser calibration factor, C_0 is the condenser reading at zero pressure, C'_0 is the vacuum capacitance in micromicrofarads, R is the gas constant per mole, T is the absolute temperature, and p is the pressure in mm. The dipole moments were computed by the Debye equation

$$\mu = 0.01281\,[(P - MR_\mathrm{D})T]^{1/2} \qquad (2)$$

in which MR_D, the molar refraction, was taken[17] as 2.0.

Table I gives the values of the polarization P in cu. cm. per mole and of the dipole moments in e.s.u. × cm. for the linear portions of the capacitance–pressure isothermal curves, that is, for

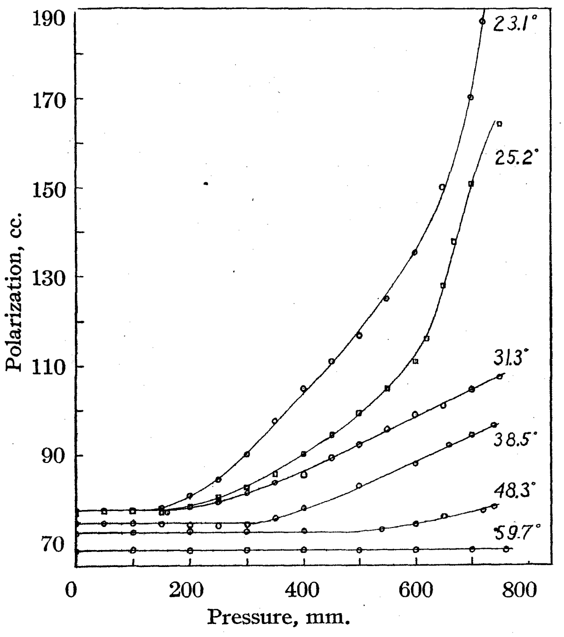

Fig. 2.—Polarization of hydrogen fluoride vapor.

Discussion of Results

Without close analysis, it is evident that the $6HF \rightleftarrows (HF)_6$ (cyclic) equilibrium postulated by some investigators[2,4] cannot be the whole story; such an equilibrium would predict lower polarizations as the ratio of hexamer to monomer increased with increasing pressure, since the dipole moment of a plane ring (Fig. 1A) or of any ring formed by joining the ends of the chain shown in Fig. 1C would be zero. Also, these results invalidate Briegleb's model (Fig. 1B) of a polymeric chain in which the units are consecutively antiparallel, since this structure would have a moment 0 or 1.91 according as the number of HF units was even or odd.

For associated hydrogen fluoride, the polarization is the sum of the contributions from the molecules of each of the several species present, so that the Debye equation becomes

$$P = \frac{4\pi}{3}\sum_{i=1}^{n} N_i\alpha_i = \frac{4\pi}{3}\left(\sum_{i=1}^{n} N_i\alpha_{0i} + \sum_{i=1}^{n} N_i\frac{\mu_i^2}{3kT}\right) \qquad (3)$$

in which α_i, α_{0i} and μ_i are, respectively, the total polarizability, distortion polarizability and dipole moment of the i^{th} species; N_i is the number of molecules of the i^{th} species, and $\sum_{i=1}^{n} N_i = N_A$, the Avogadro number. The index i has integral values from 1 to n corresponding to monomer, dimer, etc., to the n^{th}-mer. The application of equation (2) to the polarization data gives an average dipole moment, which, in terms of the quantities used in equation (3) is

$$\mu = \left(\frac{1}{N_A}\sum_{i=1}^{n} N_i\mu_i^2\right)^{1/2} \tag{4}$$

Similarly, the average distortion polarizability is

$$\alpha_0 = \left(\frac{1}{N_A}\sum_{i=1}^{n} iN_i\right)\alpha_{0_1} \tag{5}$$

Although the distortion polarizabilities of the polymers are larger than that of the monomer, the value 2.0 has been used for MR_D throughout since, in the range of these measurements, the molar refraction should never increase above 2.0 by more than 2, an amount negligible in its effect upon the calculations.

The dipole moments given in Table II are the average values represented by equation (4). In order to obtain values of the degree of association from these average dipole moments, a molecular model is necessary. The most probable structure would seem to be the chain with bond angles of 140° (see Fig. 1C), as indicated by X-ray[9] and electron diffraction[8] studies. As a basis for calculation, it may be assumed, as an approximation, that the moment of each monomeric unit remains unchanged at 1.91 when it forms part of a polymeric chain, and that each such unit is free to rotate with respect to the HF unit to which it is linked by a hydrogen bond, the bond angle being maintained at 140°. Such a polymeric chain would have a dipole moment dependent upon the degree of association, the relationship being obtainable from an equation[18] which, for this particular case, assumes the form

$$\mu = \mu_1(n + 2[(n-1)\cos 40° + (n-2)\cos^2 40° + \ldots + (n-(n-1))\cos^{n-1} 40°])^{1/2} \tag{6}$$

in which n is the degree of association, and μ_1 is the moment of one HF, 1.91. In Fig. 3, a smooth curve is drawn through the values of μ calculated for $n = 1, 2, 3, \ldots, 8$ by means of equation (6). For a mixture of monomer and dimer, dimer and trimer, or any pair of successive polymers, the value of μ calculated from equations (2) and (3) could be used to calculate an average value of n by means of equation (6). This average value of n is a special case of the association factor, z, which may be defined as the ratio of the total number of HF units to the total number of molecules. In view of the small departure of the curve in Fig. 3 from linearity, its abscissas may be treated as giving the approximate values of an association factor, z_m, for the polar molecules of average moment μ.

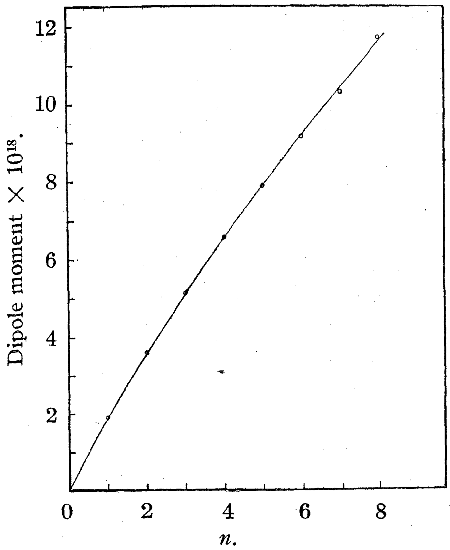

Fig. 3.—Calculated moment of polymeric chain of n units.

Table III gives the values of the association factor z_m estimated by means of the curve in Fig. 3 from the average dipole moment values, and Fig. 4 represents z_m as a function of pressure at the indicated temperatures.

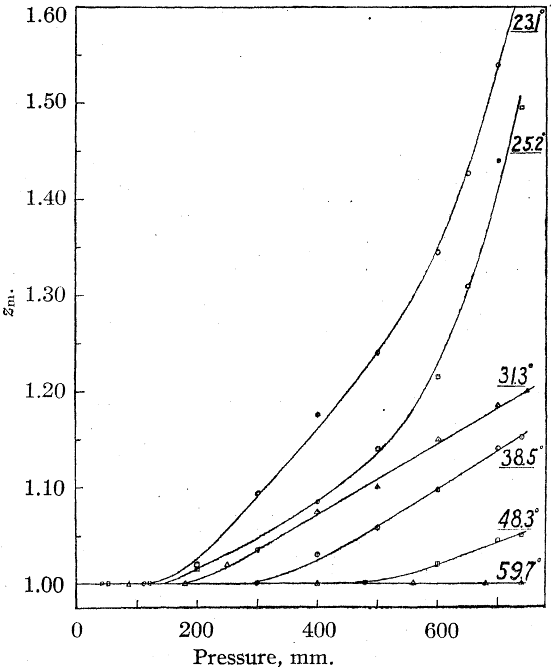

Fig. 4.—Variation of association factor, z_m, with pressure.

It must be kept in mind that since equation (6) postulates random orientation of the units of the chain because of complete freedom of rotation around the bonds, this method of evaluating the degree of association will give low results if any ring formation occurs and slightly high results if the chain is an extended, rigid structure. It will also tend to give high results if the hydrogen bonding raises the hydrogen–fluorine moment above that found for the monomer and assumed to be unchanged in the polymer. On the other hand,

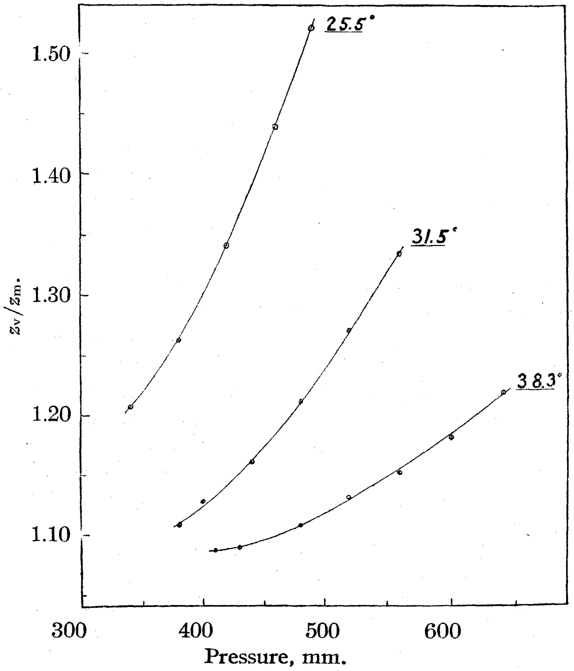

Fig. 5.—Variation of z_v/z_m with pressure.

association factors calculated from vapor density measurements are unaffected by the configuration of the polymers. Consequently, a comparison of the values estimated from the dipole moments with those obtained from vapor density data should make possible a rough estimate of the relative proportion of cyclic structures among the polymers. In Fig. 5 the ratios of the values of the association factor z_v obtained from vapor density measurements[4] to those of z_m are plotted against pressure at different temperatures for the whole range within which the two sets of data overlap. This graph shows that, as association increases, z_v becomes increasingly larger than z_m, by an amount greater than one would expect to be occasioned by any difference in the two methods of averaging. Actual computations for many equilibria assumed between two or more linear molecular species show that the discrepancy between z_v and z_m should be small. That these two association factors are different must then be attributable to the presence of cyclic structures which contribute to z_v but not to z_m. Stabilization of coiled-chain structures in which the dipole moments would largely cancel one another and give small resultant moment to the molecule as a whole would give the same effect as the presence of cyclic structures. Since, however, these coiled-chain structures do not possess the stabilizing factor of the extra bond possessed by the cyclic structures, there appears to be no reason to expect a proportion of coiled-chain structures greater than that corresponding to the random distribution assumed in the calculation of z_m. Contributory evidence along these lines is obtained from the work of Briegleb,[7] who, by assuming that only monomer and dimer were present at low pressures and that successively larger polymers made their appearances at successively higher pressures used vapor density data[5] to calculate the dependence of the concentrations of the individual polymers upon pressure at 28 and at 38°. The average dipole moments calculated by means of equation (6) from these extremely approximate concentrations are considerably higher than those in Table II, just as the values of z_v are higher than those of z_m. The presence of cyclic structures without dipole moment accounts for one discrepancy as well as for the other.

If the angle of 140° in the zig-zag chain indicated by electron diffraction were larger than the actual value, the error introduced in equation (6) would result in too low values for z_m. However, lowering of the angle to 90°, thereby replacing 40° by 90° in equation (6), still leaves the z_m values well below those of z_v.

Conclusions

The dielectric constant measurements and dipole moment calculations established the fact that hydrogen fluoride forms polar and, therefore, more or less linear polymers as indicated by X-ray and electron diffraction measurements. The discrepancy between the association factor calculated from dipole moment and that calculated from vapor density indicates the presence of cyclic polymers, the relative proportion of which increases with increasing association. The adsorption of hydrogen fluoride molecules on the metal surface of the condenser produces no significant error and the dielectric behavior of the adsorbed layer evidences the freedom of molecular orientation found in a liquid. The dipole moment results are consistent with the successive equilibria $HF + (HF)_n \rightleftarrows (HF)_{n+1}$ postulated by Briegleb[6,7] in the interpretation of the vapor densities, but show the incorrectness of the linear model with anti-parallel units which he adopted for the polymer structure. The existence of but one equilibrium, $6HF \rightleftarrows (HF)_6$, with the hexamer a ring, which was found[4] capable of representing the vapor density data, is quite inconsistent with the dipole moment results. The infinitely extended zig-zag chain shown by X-ray analysis[9] to exist in the crystal would, of course, be broken into fragments in the vapor. In the molecular beam indicated by electron diffraction[8] as consisting of these fragments, an appreciable proportion of cyclic structures might have escaped detection and the proportion may actually have been much lower than that existing under the conditions of the dielectric measurements. It is interesting to note that the zigzag structure indicated for the polymeric chain as compared to a rectilinear structure involves an attractive force between the proton of one hydrogen fluoride unit and negative charge localized as by an orbital in the fluorine of the adjacent hydrogen fluoride unit. In other words, the hydrogen bonding, in this case, though electrostatic, is not merely the undirected electrostatic attraction between the charges of a proton and an anion, as often implied in hydrogen bonding. The existence of both linear and cyclic structures in hydrogen fluoride is consistent with the belief of Bernal and Fowler[19] that both should exist in the liquid and with the conclusion of Pauling[10] that the additional bond obtained by ring formation should increase the stabilities of ring structures over open-chain structures when the degree of polymerization is greater than 5.

The work described in this paper was carried out as part of a research project supported by the Office of Naval Research.

Summary

The dielectric polarization of hydrogen fluoride vapor has been measured as a function of pressure at various temperatures above the normal boiling point of 19.4°. The apparatus employed has been described, and the errors due to adsorption of the hydrogen fluoride on the condenser walls have been shown to be unimportant. In the region of temperature and pressure where no molecular association occurs, a dipole moment value identical with that previously found in this laboratory has been obtained. At lower temperatures and higher pressures the experimental results show conclusively that a very considerable fraction of the associated molecules in the vapor state exists in various linear structures of large dipole moment, and that the average degree of association increases rapidly with increasing pressure or decreasing temperature. Further analysis of the data indicates that cyclic structures also exist in equilibrium with the chains, and that the former tend to increase in relative proportion with increase in pressure and decrease in temperature.

Perfluorinated Olefins

BY ALBERT L. HENNE AND THOS. H. NEWBY

The synthesis of perfluorinated ethylene and its polymerization to commercial TEFLON, $(CF_2)_n$, have become industrial processes; efforts are now directed at the synthesis of other fully fluorinated olefins in order to study their polymerization characteristics and their ability to copolymerize with $CF_2{=}CF_2$. We report here experiments toward the preparation of $CF_3CF{=}CF_2$, $CF_3CF{=}CFCF_3$, and $CF_3CF_2CF{=}CF_2$.

Synthesis of $CF_3CF{=}CF_2$

Perfluorinated propylene has been prepared by us before, but by a sequence which has too many steps for industrialization.[1] To simplify, we have subjected the easily available[2] $CCl_3CClFCCl_3$ to fluorination with antimony fluoride in the standard way, and have obtained in one step a 70% yield of $CF_2ClCFClCF_2Cl$, from which zinc in alcohol yielded $CF_2ClCF{=}CF_2$ almost quantitatively. From this olefin, it was expected that "allylic" fluorination[3] would easily yield the desired perfluorinated propylene, but this did not appreciably succeed because an allylic rearrangement took place which gave $CF_3CF{=}CClF$ instead of the desired product. The course of the rearrangement was evident from the facts that the rearranged olefin differed from the known[3] $CF_3CCl{=}CF_2$, and that its alkaline oxidation[4] yielded nothing but trifluoroacetic acid.

The desired synthesis was, however, completed as follows. The rearranged compound accepted a mole of chlorine to give the known[1] $CF_3CFClCFCl_2$, which antimony fluoride transformed into the known[1] $CF_3CFClCF_2Cl$. Dechlorination with zinc gave the desired perfluorinated propylene. The sequence is thus a simplified laboratory preparation, but is still too complex for industrial application.

The rearrangement reminded us of a similar case which could not be explained at the time. A

sample of $CF_2{=}CFCFCl_2$ had been supplied by Dr. W. T. Miller of Cornell University with a request that it be "allylically" fluorinated to $CF_2{=}CFCF_3$. The operation failed to go further than C_3F_7Cl. The physical properties of this heptafluoride were the same as those of $CFCl{=}CFCF_3$ made by chlorine removal from $CFCl_2CFClCF_3$, as well as those of the rearranged product mentioned above.

Preparation of $CCl_3CFClCCl_3$.—Chlorine was bubbled through 250 ml. of $CH_3CFClCH_2Cl$ in ultraviolet light until the refractive index no longer increased (one week). After washing, neutralizing and drying, vacuum distillation gave 53% of good $CCl_3CFClCCl_3$, b. p. 95° at 9 mm., n_D 1.5194 at 20°, and 47% of incompletely chlorinated material which was successfully rechlorinated.

Preparation of $CF_2ClCFClCF_2Cl$.—In a steel vessel, 216 g. (1.2 mole) of antimony trifluoride was combined under pressure with 44 g. (0.62 mole) of chlorine. This was then heated with 160 g. (0.53 mole) of $CCl_3CClFCCl_3$ at 225° for two hours, then at 150° overnight. The organic material was distilled from the bomb then steamed, to give 110 g. of material n_D 1.358 at 20°. Fractional distillation gave 98 g. (70%) of $C_3F_5Cl_3$, b. p. 72–73°, n_D 1.350 at 22° and a small amount of less fluorinated product.

Anal. Calcd.: Cl, 44.8; mol. wt., 238. Found: Cl, 44.9; mol. wt., 240.

Preparation of $CF_2ClCF{=}CF_2$.—$C_3F_5Cl_3$ (168 g. or 0.706 mole) in 150 ml. of absolute alcohol was refluxed with 65 g. (1 mole) of mossy zinc for two days. The reaction product which distilled through the reflux condenser was liquefied in an ampule cooled with Dry Ice. After washing through water and drying, fractional distillation gave 102 g. (86%) of $CF_2ClCF{=}CF_2$, b. p. 7.6°, and a small amount of unreacted material. Dilution of the reaction mixture with water precipitated an additional 6% of unreacted material. Titration of the chlorine ion in the solution indicated the correct molecular weight for the olefin.

Rearrangement to $CF_3CFC{=}FCl$.—In a steel vessel, 82 g. (0.46 mole) of antimony fluoride was combined with 13 g. (0.18 mole) of chlorine. After cooling, 102 g. (0.16 mole) of $CF_2ClCF{=}CF_2$ was added. The vessel was closed, heated in steam for eighteen hours, then at 125° for nine hours. Distillation gave a small amount of low boiling material, then 84 g. (82%) of a substance, b. p. 7.7 to 7.9° (uncor.), f. p. −156.8 to −159.6°. These properties come close to those reported[1] for the *cis–trans* mixture of $CF_3CF{=}CFCl$, b. p. 7.9°, f. p. −158°.

Synthesis of $CF_3CF{=}CFCF_3$

By means of the lead oxide–hydrogen fluoride procedure,[5] the previously reported[6] $CF_3CCl{=}CClCF_3$ was transformed into $CF_3CFClCFClCF_3$, from which zinc gave an excellent yield of the desired perfluorinated 2-butene. Later, the starting $CF_3CCl{=}CClCF_3$ was prepared in a single, standardized operation[7] from commercial C_4Cl_6, and this improvement made the sequence adaptable to commercial production.

Preparation of $CF_3CClFCClFCF_3$.—In a steel vessel cooled with Dry Ice were placed 239 g. (1 mole) of lead dioxide, 400 g. (20 moles) of liquefied hydrogen fluoride and 240 g. (1.03 mole) of $C_4H_6Cl_2$. After closing, the system was allowed to warm up, while being mechanically rocked. A reaction took place which temporarily raised the pressure to six atmospheres. The reaction mixture was poured onto ice, neutralized while cold, then steamed. The distillate contained 229 g. of a product n_D 1.337 at 25°. This is a mixture of $C_4F_8Cl_2$, b. p. 63°, and $C_4F_6Cl_2$, b. p. 65°, which it is impractical to separate by distillation. In general this mixture accounted for 26% of the desired reaction product and 63% of recovered olefin. To prepare pure $C_4F_8Cl_2$, the mixture was fractionally distilled, and the head fractions treated with permanganate to destroy the olefin. *Anal.* Calcd.: Cl, 26.2. Found: Cl, 24.2.

Preparation of $CF_3CF{=}CFCF_3$.—The mixture of $C_4F_8Cl_2$ and $C_4F_6Cl_2$ was treated with zinc in alcohol. A heating period of sixty hours was needed to complete the reaction. The expected amount of C_4F_8 distilled through the reflux condenser and was received in a Dry Ice cooled ampule. It was purified by fractional distillation; its molecular weight was computed as 270 from the chlorine ion concentration in the reaction mixture (calcd. 271). Its boiling and freezing characteristics indicate a *cis–trans* mixture. From the reaction mixture, C_4F_6Cl was recovered by precipitation with water.

Attempted Synthesis of $C_2F_5CF{=}CF_2$

Several schemes were tried, all of which deviated from the expected paths for the reasons stated.

First Attempt.—$CF_3CCl_2CCl_2CCl_3$ was prepared by extensive chlorination of $CF_3CH{=}CClCCl_3$[6] for reaction with zinc, in the hope that $CF_3CCl_2CCl{=}CCl_2$ would be preferentially obtained. From this derivative, the preparation of $C_2F_5CF{=}CF_2$ would have been the same problem as the synthesis of $CF_3CF{=}CF_2$ from $CCl_3CCl{=}CCl_2$. The zinc reaction could not be mastered, and only small amounts of $CF_3CCl_2CCl{=}CCl_2$ were obtained. This compound was transformed by a conventional fluorination into a pentafluoride presumed to be $C_2F_5CCl{=}CCl_2$ (calcd.: Cl, 42.8; found: 43). Oxidation of the latter gave a fluorinated acid which was not CF_3CO_2H, an indication that the double bond had not shifted to the center of the molecule. This fluorinated acid was not further identified.

Second Attempt.—The starting point was the easily obtained $CCl_3CF_2C_2Cl_5$.[8] Actuated by the observation that perchlorocyclopentene is easily transformed into a hexafluoride rather than a tetrafluoride,[9] we tried to transform the starting material with zinc into $CCl_3CF_2CCl{=}CCl_2$, in order to attempt fluorination of CCl_3 group located just beyond the allylic position. The zinc reaction could not be mastered, but this difficulty was skirted by subjecting the starting material to conventional fluorination, and obtaining thereby a tetra-, a penta- and a hexafluoride formulated as $CCl_3CF_2CCl_2CClF_2$, $CCl_2FCF_2CCl_2CClF_2$ and $CClF_2CF_2CCl_2CClF_2$ on the basis of the known[10] ease of fluorination. Dechlorination of the first two compounds with zinc proceeded quite well and gave the expected olefins $CCl_3CF_2CCl{=}CF_2$ and $CCl_2FCF_2CCl{=}CF_2$, respectively. Both were subjected to fluorination to see whether they would give $CF_3CF_2CCl{=}CF_2$. The reaction proceeded only at high temperature and gave a ma-

[a] Different *cis–trans* isomer ratio than that obtained by Henne, Hinkamp, and Zimmerschied[6] (m. p. −67.3°).

terial which analysis showed to be $C_4F_7Cl_3$ (calcd.: Cl, 37.2; found: Cl, 37.4). The first interpretation was that this was the dichloride of the desired $CF_3CF_2CCl=CF_2$. The two extra chlorine atoms were easily removed with zinc, and the olefin subjected to oxidation to ascertain whether it was the desired one. Instead of giving $C_2F_5CO_2H$, the oxidation yielded nothing but CF_3CO_2H, showing that the double bond had shifted to the center of the molecule. We were therefore forced to admit that an allylic shift had taken place, probably from $CClF_2CF_2CCl=CF_2$ to $CF_2ClCF=CClCF_3$ and that the latter had then been fluorinated to $CF_3CF=CClCF_3$.

Preparation of $CCl_3CF_2CCl=CCl_2$.—In a steel container were placed 211 g. (0.57 mole) of $CCl_3CF_2C_2Cl_5$, 40 g. (0.6 mole) of freshly cut zinc and 665 cc. of absolute alcohol. After closing, heating in a steam-bath was allowed for three days, which brought the pressure to about 4 atm. On pouring out after cooling, 126 g. of organic material and 70 g. of tar were obtained. Distillation at 2 to 3 mm. gave 92 g. of crude $C_4F_2Cl_6$, b. r. 44 to 50°, representing at 31% yield. Redistillation gave a pure material.

Fluorination of $CCl_3CF_2C_2Cl_5$.—The customary procedure was followed. With SbF_3Cl_2 as fluorinating agent, average yields were 6% of $C_4F_6Cl_4$, 23% of $C_4F_5Cl_5$, 40% of $C_4F_4Cl_6$ and 27% of a high polymer.

Dehalogenation of $C_4F_5Cl_5$ and $C_4F_4Cl_6$.—The customary zinc reaction in absolute alcohol proceeded very smoothly and quantitatively.

Fluorination of $C_4F_5Cl_3$ and $C_4F_4Cl_4$.—A mixture of these fluorides, (0.86 mole) was heated with SbF_3Cl_2 (1 mole) in a steel vessel at 200° for sixteen hours. The pressure reached 18 atmospheres. After bleeding off the gases, without obtaining $C_2F_5CCl=CF_2$, an additional heating period of twenty hours was permitted. On working up the reaction products, 143 g. of $C_4F_7Cl_3$ (53% yield) was found boiling at 97°. This material underwent the customary zinc dechlorination to yield C_4F_7Cl easily and quantitatively. The latter on standard oxidation gave exclusively trifluoroacetic acid, the sodium salt of which was analyzed to give 17.6% Na found (16.9 calcd.) and 41.8% F (41.9 calcd.). A search for a chlorofluoro acid gave negative results.

Summary

A synthesis sequence for $CF_3CF=CF_2$ was complicated by a rearrangement. A practical, simple sequence gave $CF_3CF=CFCF_3$. The preparation of $C_2F_5CF=CF_2$ was defeated by rearrangements.

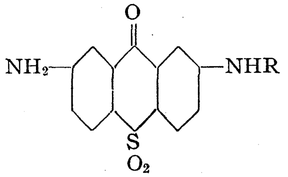
Studies in the Sulfone Series. IV.[1] Certain Heterocyclic Derivatives of 2,8-Diaminothiaxanthone-5-dioxide

BY E. D. AMSTUTZ, E. A. FEHNEL[2] AND I. M. HUNSBERGER[3]

In a continuation of the work on antitubercular compounds described in the preceding paper of this series,[1] the synthesis of various monosubstituted N-heterocyclic derivatives of 2,8-diaminothiaxanthone-5-dioxide (I–IV) has been attempted to determine if these substances exhibit chemotherapeutically interesting properties in view of their relationships to the simpler materials reported earlier.[4]



I (R = 2-pyridyl)
II (R = 2-pyrimidyl)
III (R = 2-thiazolyl)
IV (R = 2-quinolyl)

The reactions involved in the synthesis of the desired materials are outlined in the accompanying diagram.

For the preparation of the intermediate derivatives, the older route through the 2-thiophenoxybenzoic acids (VI)[5] and the more recently described route through the corresponding aldehydes (VII)[6] both were studied, and the latter method was found to be greatly superior to the former. The condensation of the sodium salts of *p*-iodo- and *p*-bromothiophenol with 2-chloro-5-nitrobenzaldehyde took place readily and in good yields, while with 2-chloro-5-nitrobenzoic acid low yields were obtained even after prolonged refluxing. On oxidation with excess 30% hydrogen peroxide in glacial acetic acid, both the aldehyde (VII) and the acid (VI) gave the identical 5-nitro-2-(*p*-halobenzenesulfonyl)-benzoic acid (VIII).

The ring-closure of the 2-thiophenoxybenzaldehyde (VII) to an equimolecular mixture of the thiaxanthene (IX) and thiaxanthone (X) proceeded readily in cold concentrated sulfuric acid solution. In one experiment the solution was diluted with water as soon as all the aldehyde (VII, Y = I) had dissolved, and the resultant precipitate was separated into its components by repeated fractional crystallization from acetone to yield 83% of the theoretical amount of 2-iodo-8-nitrothiaxanthene (IX, Y = I) and 91% of 2-iodo-8-nitrothiaxanthone (X, Y = I). Similar results were obtained in the bromo series. The same 2-halo-8-nitrothiaxanthones (X) also were obtained by the cyclodehydration of the 5-nitro-2-(*p*-halothiophenoxy)-benzoic acids (VI) in hot concentrated sulfuric acid.

In the present investigation chromium trioxide readily oxidized both IX and X, as well as the equimolecular mixture of these compounds from the aldehyde cyclization, to the desired thiaxanthone-5-dioxide (XIII) in excellent yields.[7]

Reduction of the nitro groups to an amino group was carried out as in the previous paper.[1] Attempts to bring about the simultaneous reduction of the nitro and carbonyl groups of XIII by means of metal–acid combinations were unsuccessful, since reductive dehalogenation led to intractable mixtures which apparently contained large proportions of 2-aminothiaxanthene-5-dioxide.

At 200° 2-iodo-8-aminothiaxanthone-5-dioxide (V, Y = I)[8] reacted smoothly with excess 2-aminopyrimidine in the presence of potassium carbonate and copper powder to give good yields of II, but the reaction with 2-aminopyridine appeared to take a somewhat different course. Since this prod-

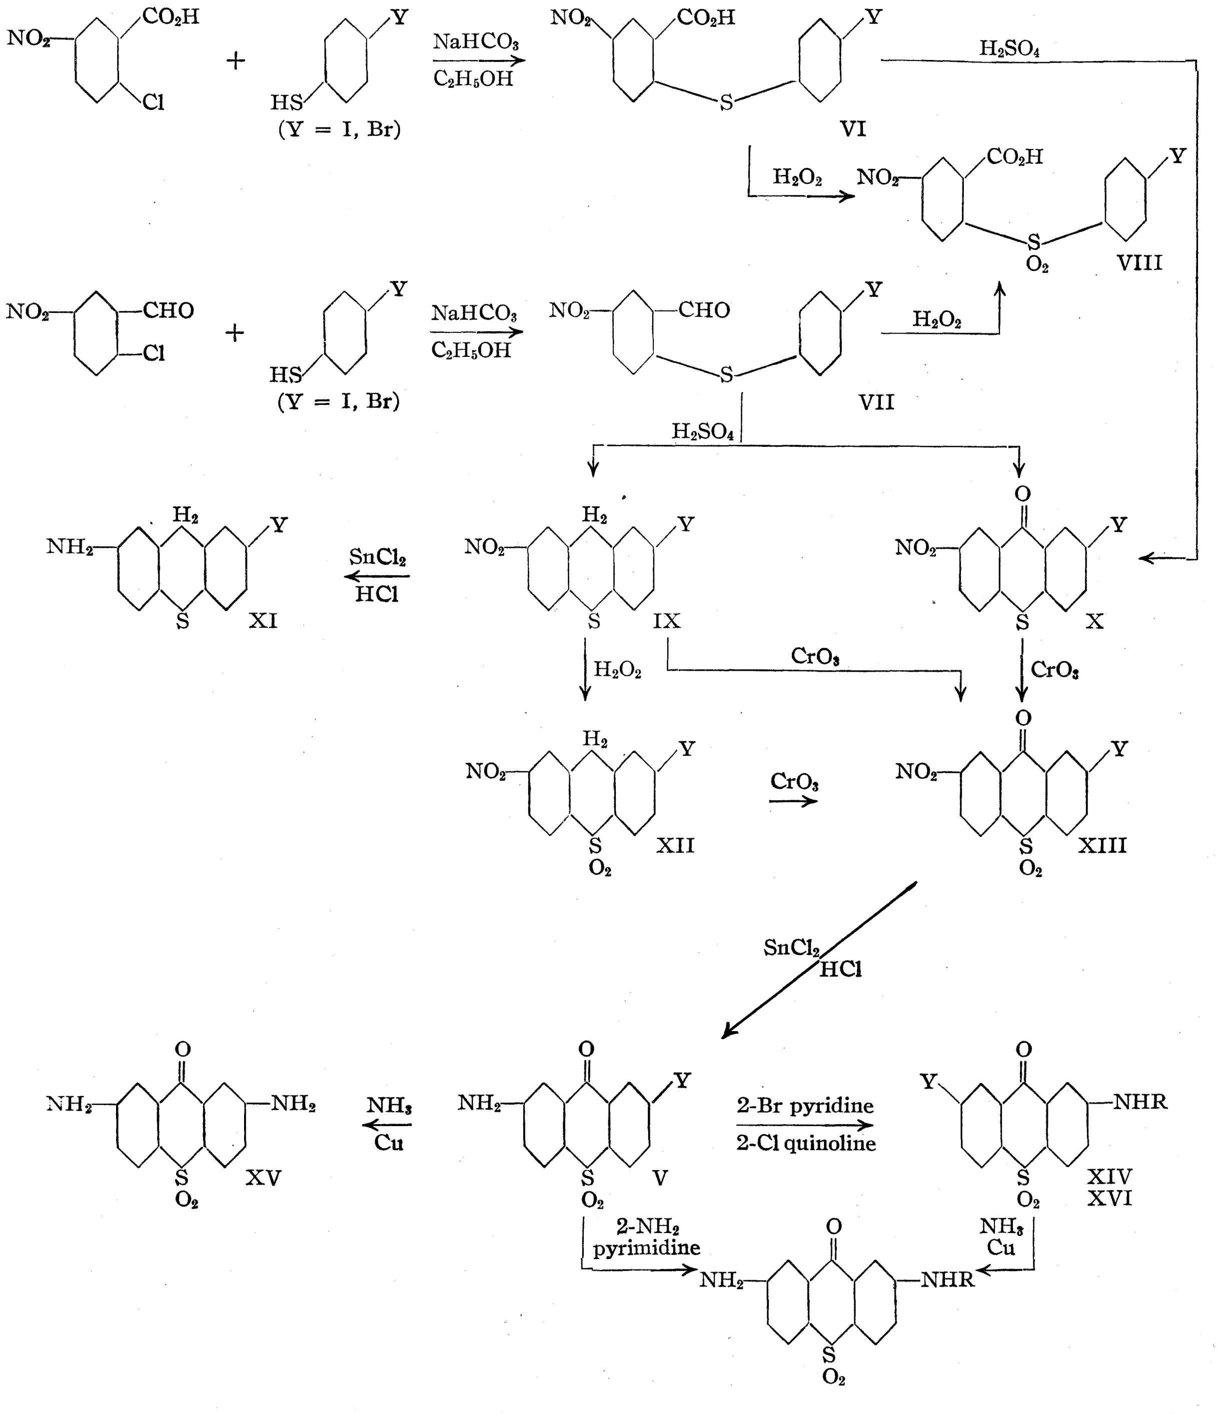
[6] Ref. (1) and Campbell, Dick, Ferguson and Loudon, *J. Chem. Soc.* 747 (1941).

[7] In contrast to the outstanding success reported by Campbell and his associates (6) in oxidizing the thiaxanthene–thiaxanthone mixture to the corresponding thiaxanthone-5-dioxide with 30% hydrogen peroxide, this reagent was found to be completely unsatisfactory for the oxidation of the 2-iodo-8-nitro-(thiaxanthene–thiaxanthone) mixture (IX + X, Y = I), and it gave only moderately good results with the corresponding bromo-(thiaxanthene–thiaxanthone) mixture. It was found that IX (Y = I) and X (Y = I) each rapidly catalyzed the decomposition of hydrogen peroxide and that the methylene group of IX (Y = I) remained unattacked even after repeated treatments with large excesses of fresh hydrogen peroxide in acetic acid. The only product isolated from the hydrogen peroxide oxidation of IX (Y = I) was 2-iodo-8-nitrothiaxanthene-5-dioxide (XII, Y = I), which was obtained in 92% yield. Similar but less clear-cut results were obtained with the corresponding bromo compound (IX, Y = Br), which was not so effective a catalyst for the decomposition of the peroxide. These results may be related to some peculiar observations of Hilditch and Smiles (*J. Chem. Soc.*, **99**, 145 (1911)), who reported that the action of a large excess of 30% hydrogen peroxide on thiaxanthene in boiling acetic acid affords thiaxanthene-5-dioxide in good yield, while the addition of the same reagent to a cold acetic acid solution of thiaxanthene with subsequent refluxing gives thiaxanthone as the sole product.

[8] It was originally hoped that access to the mono-N-heterocyclic compounds of type I–III could be gained by condensation of 2-bromo-8-aminothiaxanthone-5-dioxide (V, Y = Br) with 2-aminoheterocycles, since the yield of the *p*-bromothiophenol intermediate greatly exceeds that of the corresponding iodo compound. Although amination to the diamino compound occurred on heating the bromo compound (V, Y = Br) with ammonia in the presence of copper powder in a sealed tube, various attempts to carry out a similar reaction with several representative amines were uniformly unsuccessful. The recovery of large amounts of unchanged V indicated that the expected activation of the bromine atom by the para sulfonyl group, ((a) Todd and Shriner, THIS JOURNAL, **56**, 1382 (1934); (b) Loudon, *J. Chem. Soc.*, 902 (1939); (c) Loudon and Shulman, *ibid.*, 1618 (1938); (d) Loudon and Robson, *ibid.*, 242 (1937)), was not sufficient to permit its replacement by a substituted amino group.



uct evolved considerable ammonia on treatment with alcoholic potassium hydroxide, it was concluded that the 2-aminopyridine had reacted, at least in part, in the 2-aminopyridone form. This difficulty was circumvented by condensing 2-bromopyridine with the amino group of V (Y = I or Br), thus attaching a N-2-pyridylamino group in the desired position on the thiaxanthone dioxide nucleus.[9] The halogen atom then was replaced with an amino group by treatment of the 2-halo-8-(N-2-pyridyl)-aminothiaxanthone-5-dioxide (XIV) with concentrated aqueous ammonia in the presence of copper powder in a sealed tube at 210–220°. The same product, I, was obtained from both the iodo and bromo intermediates.

---

[9] *Cf.* Gray, *J. Chem. Soc.*, 1202 (1939). The use of 2-chlorothiazole was attempted but with little success, a very complex mixture being obtained in every run. 2-Chloroquinoline behaved more satisfactorily, and eventually the desired product was obtained in small yield.

All of the thiaxanthone dioxide derivatives prepared in this investigation gave characteristic colors, ranging from green to violet, on treatment with zinc dust in warm aqueous-alcoholic alkali.[10] The thiaxanthene dioxides gave similar colors *directly* on treatment with cold dilute aqueous-alcoholic alkali. These colors disappear quickly on exposure to air, especially on shaking, and in the case of the thiaxanthene dioxides can be made to reappear only by the addition of a suitable reducing agent such as zinc dust. These color reactions may involve the formation of semiquinone-type free radicals, but direct evidence on this point is lacking.

Acknowledgment.—The authors wish to express their appreciation to The Wm. S. Merrell Company for defraying a portion of the expenses of this investigation and to Dr. C. R. Neumoyer for his interest and assistance in part of the experimental work.

Experimental

5-Nitro-2-(*p*-iodothiophenoxy)-benzoic Acid (VI, Y = I).—To a warm (50–60°) solution of 85.0 g. (0.42 mole) of 2-chloro-5-nitrobenzoic acid[1] in 800 ml. of 95% ethanol, 400 ml. of water was added slowly followed by 103 g. (0.436 mole) of *p*-iodothiophenol[11] and 73.2 g. (0.87 mole) of sodium bicarbonate. The mixture was refluxed for twenty-two hours, and about two-thirds of the solvent then was removed by distillation. The residue was diluted with a large volume of water to precipitate the product, which was recrystallized from ethanol to yield 37.0 g. of a high-melting acid fraction and 40.0 g. (39%) of a lower-melting neutral fraction, m. p. 120–125°, which appeared to be 4,4′-diiododiphenyl disulfide. The acid fraction was purified by dissolution in hot aqueous sodium carbonate solution and reprecipitation with hydrochloric acid. Repeated crystallization from glacial acetic acid and from ethanol yielded bright yellow crystals, m. p. 244–247°.

Anal. Calcd. for $C_{13}H_8O_4NSI$: S, 7.99; I, 31.6; neut. equiv., 401. Found: S, 8.14; I, 31.6; neut. equiv., 397.

5-Nitro-2-(*p*-bromothiophenoxy)-benzoic Acid (VI, Y = Br).—A mixture of 1.7 g. (0.009 mole) of *p*-bromothiophenol,[12] 1.6 g. (0.008 mole) of 2-chloro-5-nitrobenzoic acid, 1.2 g. (0.021 mole) of potassium hydroxide, and a trace of copper powder in 90 ml. of 95% ethanol was refluxed for twenty-two hours under nitrogen. After about two-thirds of the solvent had been removed by distillation, 100 ml. of water was added to the residue, and the resultant mixture was made acid to congo red by addition of hydrochloric acid. The yellow precipitate was recrystallized from aqueous ethanol to yield 1.0 g. (36%) of yellow microcrystalline powder, m. p. 224–226°. Calcd. for $C_{13}H_8O_4NSBr$: neut. equiv., 354. Found: 357.[13]

5-Nitro-2-(*p*-iodothiophenoxy)-benzaldehyde (VII, Y = I).—A mixture of 98.4 g. (0.416 mole) of *p*-iodothiophenol, 74.2 g. (0.40 mole) of 2-chloro-5-nitrobenzaldehyde,[1] 35.0 g. (0.416 mole) of sodium bicarbonate, 850 ml. of 95% ethanol and 450 ml. of water was refluxed for two hours. The yellow curdy precipitate was washed, dried, and recrystallized from glacial acetic acid to yield 128.6 g. (84%) of yellow needles, m. p. 131–133°.

Anal. Calcd. for $C_{13}H_8O_3NSI$: S, 8.33; I, 33.0. Found: S, 8.21; I, 33.1.

5-Nitro-2-(*p*-bromothiophenoxy)-benzaldehyde (VII, Y = Br).—This compound was prepared by condensing 28.4 g. (0.15 mole) of *p*-bromothiophenol with 26.0 g. (0.14 mole) of 2-chloro-5-nitrobenzaldehyde in the presence of 12.6 g. (0.15 mole) of sodium bicarbonate in 300 ml. of ethanol and 150 ml. of water as in the case of the corresponding iodo compound above; yield, 46.2 g. (98%) of yellow needles, m. p. 123–125°.

Anal. Calcd. for $C_{13}H_8O_3NSBr$: S, 9.49; Br, 23.7. Found: S, 9.50; Br, 23.5.

5-Nitro-2-(*p*-iodobenzenesulfonyl)-benzoic Acid (VIII, Y = I).—A solution of 1.6 g. (0.004 mole) of VI (Y = I) and 2.8 ml. (0.025 mole) of 30% hydrogen peroxide in 35 ml. of glacial acetic acid was refluxed for three hours. Addition of a large volume of water to the cooled mixture precipitated a crude product which was washed with water and recrystallized from ethanol to yield 1.4 g. (81%) of white powder, m. p. 242–246° dec.

Anal. Calcd. for $C_{13}H_8O_6NSI$: S, 7.40; I, 29.3. Found: S, 7.48; I, 29.5.

5-Nitro-2-(*p*-bromobenzenesulfonyl)-benzoic Acid (VIII, Y = Br).—A mixture of 1.0 g. (0.003 mole) of VII (Y = Br), 3.0 ml. (0.027 mole) of 30% hydrogen peroxide, and 20 ml. of glacial acetic acid was refluxed for two hours, cooled and poured into a large volume of water. The precipitate was washed with water and dried; yield, 1.0 g. (90%) of white powder, m. p. 190.5–192°.

Anal. Calcd. for $C_{13}H_8O_6NSBr$: S, 8.31; Br, 20.7; neut. equiv., 386. Found: S, 8.32; Br, 20.5; neut. equiv., 379.

2-Iodo-8-nitrothiaxanthene (IX, Y = I) and 2-Iodo-8-nitrothiaxanthone (X, Y = I).—Ten grams (0.026 mole) of VII (Y = I) was dissolved in 100 ml. of cold concentrated sulfuric acid, and the dark red solution was poured onto 150 g. of cracked ice. The yellow precipitate was washed and dried at 100°. By alternate digestion and recrystallization with hot acetone, this mixture was separated into its components, yielding 4.0 g. (83%) of 2-iodo-8-nitrothiaxanthene as yellow crystals, m. p. 155.5–157.5°, and 4.5 g. (91%) of 2-iodo-8-nitrothiaxanthone as a yellow powder, m. p. 300–303° dec.

Anal. Calcd. for $C_{13}H_8O_2NSI$ (thiaxanth*ene*): S, 8.69. Found: S, 8.54. Calcd. for $C_{13}H_6O_3NSI$ (thiaxanth*one*): S, 8.37. Found: S, 8.22.

2-Iodo-8-nitrothiaxanthone (X, Y = I) also was obtained by the following cyclodehydration of VI (Y = I). Twenty grams (0.050 mole) of VI (Y = I) was dissolved in 180 ml. of concentrated sulfuric acid at 100°. The solution was maintained at this temperature for ninety minutes, allowed to cool to room temperature, and poured onto 600 g. of cracked ice. The resultant precipitate was washed, dried, and recrystallized from acetic anhydride to yield 16.2 g. (84%) of yellow microcrystalline powder, m. p. 295–300° dec. Another recrystallization raised the melting point to 297–301° dec.; a mixed melting point with the corresponding compound obtained from the aldehyde cyclization showed no depression.

2-Bromo-8-nitrothiaxanthene (IX, Y = Br) and 2-Bromo-8-nitrothiaxanthone (X, Y = Br).—The aldehyde (VII, Y = Br) (16.2 g., 0.048 mole) was cyclized in 150 ml. of cold concentrated sulfuric acid as in the case of the corresponding iodo compound above. The yellow thiaxanthene–thiaxanthone mixture was separated into its components by alternate digestion and recrystallization with hot acetic acid, yielding 5.2 g. (67%) of 2-bromo-8-nitrothiaxanthene as yellow crystals, m. p. 162–164.5°, and 7.4 g. (92%) of 2-bromo-8-nitrothiaxanthone as a bright yellow powder, m. p. 282–285° dec.

(11) Prepared in 59% yield by the reduction of *p*-iodobenzenesulfonyl chloride with tin and hydrochloric acid; *cf.* Hubner and Alsberg, *Ann.*, **156**, 325 (1870).

(12) Prepared in 98% yield from *p*-bromobenzenesulfonyl chloride by an adaptation of the method for thiophenol given in "Organic Syntheses," Coll. Vol. I, 2d ed., p. 504 (1941).

(13) This compound was not analyzed, but its formula may be considered established because the product obtained on ring-closure with sulfuric acid was identical with authentic 2-nitro-8-bromothiaxanthone (X, Y = Br) prepared from 5-nitro-2-(*p*-bromothiophenoxy)-benzaldehyde (VII, Y = Br).

Anal. Calcd. for $C_{13}H_8O_2NSBr$ (thiaxanth*ene*): S, 9.95. Found: S, 10.03. Calcd. for $C_{13}H_6O_3NSBr$ (thiaxanth*one*): S, 9.56. Found: S, 9.66.

The cyclodehydration of 1.0 g. (0.003 mole) of VI (Y = Br) in 9 ml. of hot concentrated sulfuric acid by the method used above for the corresponding iodo compound afforded 0.9 g. (95%) of 2-bromo-8-nitrothiaxanthone, m. p. 283–286° dec.; this material did not depress the melting point of the corresponding compound obtained from the aldehyde ring-closure.

2-Bromo-8-aminothiaxanthene (XI, Y = Br).—The solution obtained by passing dry hydrogen chloride into a suspension of 4.1 g. (0.018 mole) of stannous chloride dihydrate in 22 ml. of glacial acetic acid was added to a suspension of 1.6 g. (0.005 mole) of IX (Y = Br) in 6 ml. of glacial acetic acid heated to 80–85°, after which stirring was continued at this temperature for two hours. The white tin complex which precipitated on cooling was removed, treated with cold 10% aqueous sodium hydroxide, thoroughly washed with water, and dried at 100°; yield, 1.4 g. (96%) of yellow powder, m. p. 177–181°. Recrystallization from ethanol then afforded brownish-yellow plates, m. p. 183–184°.

Anal. Calcd. for $C_{13}H_{10}NSBr$: S, 10.99. Found: S, 11.12.

2-Iodo-8-nitrothiaxanthene-5-dioxide (XII, Y = I).—One gram (0.0027 mole) of IX (Y = I) was refluxed for three hours with 3.0 ml. of 30% hydrogen peroxide in 30 ml. of glacial acetic acid, after which the supernatant liquid gave a negative test for hydrogen peroxide (no color with aqueous potassium iodide solution). Another 8.0 ml. of 30% hydrogen peroxide was added in 2-ml. portions at intervals during the next four hours, and the mixture then was allowed to cool to room temperature. The pale yellow precipitate was crystallized from acetic anhydride to yield 1.0 g. (92%) of almost colorless needles, m. p. 229–231°, which gave a deep green color on treatment with aqueous-alcoholic alkali.

Anal. Calcd. for $C_{13}H_8O_4NSI$: S, 7.97. Found: S, 8.11.

2-Bromo-8-nitrothiaxanthene-5-dioxide (XII, Y = Br).—This compound was formed along with the corresponding thiaxanthone dioxide (XIII, Y = Br) when IX (Y = Br) was treated with a slight excess of hydrogen peroxide in boiling acetic acid. When 1.8 g. (0.0056 mole) of the thiaxanthene was refluxed for two hours with 1.5 ml. (0.015 mole) of 30% hydrogen peroxide in 30 ml. of glacial acetic acid, repeated fractional crystallization from acetic acid produced 0.5 g. (28%) of unreacted IX (Y = Br), 0.3 g. (15%) of XIII (Y = Br) melting at 265–268° with previous sintering, and 0.8 g. (41%) of pale yellow crystals of XII (Y = Br), m. p. 205–207°. The last compound gave a deep green color on treatment with aqueous-alcoholic alkali.

Anal. Calcd. for $C_{13}H_8O_4NSBr$: S, 9.07. Found: S, 9.17.

2-Iodo-8-nitrothiaxanthone-5-dioxide (XIII, Y = I).—This compound may be prepared by the chromium trioxide oxidation of the corresponding thiaxanthene (IX) or its dioxide (XII), the thiaxanthone (X), or the thiaxanthene–thiaxanthone mixture (IX + X) from the aldehyde ring-closure.

(a) **From 2-Iodo-8-nitrothiaxanthene-5-dioxide (XII, Y = I).**—A mixture of 0.8 g. of XII (Y = I), 0.5 g. of chromium trioxide, 20 ml. of glacial acetic acid, and a few drops of concentrated sulfuric acid (added as a catalyst) was refluxed for ninety minutes. Filtration of the cooled dark green solution yielded 0.8 g. of tan microcrystalline powder, m. p. 303–305° dec. Recrystallization from acetic anhydride then afforded 0.7 g. of almost colorless crystals, m. p. 303–306° dec.

Anal. Calcd. for $C_{13}H_6O_5NSI$: S, 7.73. Found: S, 7.80.

(b) **From 2-Iodo-8-nitrothiaxanthone (X, Y = I).**—This compound remained unattacked when refluxed for prolonged periods with large excesses of 30% hydrogen peroxide in acetic acid, although the oxidizing agent rapidly disappeared from the reaction mixture (potassium iodide test). Complete oxidation was effected with chromium trioxide as follows: To a suspension of 1.0 g. of X (Y = I) in refluxing glacial acetic acid enough chromium trioxide was added in small portions over a two-hour period to produce a brownish color. Filtration of the cooled mixture afforded 1.1 g. of pale yellow crystals, m. p. 296–298° dec. Recrystallization from a large volume of acetic anhydride yielded 1.0 g. (92%) of almost colorless crystals, m. p. 296–300° dec.

(c) **From the 2-Iodo-8-nitro-(thiaxanthene–thiaxanthone) Mixture (IX + X, Y = I).**—Oxidation of the thiaxanthene–thiaxanthone mixture with excess 30% hydrogen peroxide in boiling acetic acid afforded only low-melting mixtures consisting principally of partially oxidized compounds. Satisfactory results readily were obtained, however, using chromium trioxide as the oxidizing agent. The product from the ring-closure of 114 g. (0.296 mole) of VII (Y = I) with 1140 ml. of sulfuric acid according to the method previously described was sucked as dry as possible on the filter and then transferred directly to a large flask with 1500 ml. of glacial acetic acid. To this mixture was added 125 g. (1.25 moles) of chromium trioxide, and heat was applied cautiously until refluxing began. After the initially exothermic reaction had subsided, refluxing was continued for another two hours by the application of external heat. The white precipitate obtained from the cooled mixture was washed with water and dried. Since no suitable solvent for the recrystallization of this large amount of product could be found, purification was effected by digesting several times with fresh quantities of acetic anhydride. 2-Iodo-8-nitrothiaxanthone-5-dioxide was obtained as a colorless microcrystalline powder, m. p. 300–305° dec.; yield, 116 g. (95%, based on the aldehyde used).

The identity of the products obtained by these different routes was established by the method of mixed melting points. On treatment with zinc dust and warm aqueous-alcoholic alkali all these products gave a green color which was discharged on exposure to air.

2-Bromo-8-nitrothiaxanthone-5-dioxide (XIII, Y = Br).—The thiaxanthene–thiaxanthone mixture obtained from the ring-closure of 43.2 g. (0.128 mole) of VII (Y = Br) with 430 ml. of sulfuric acid was oxidized in 950 ml. of glacial acetic acid by refluxing for four hours with Superoxol (130 ml., 1.28 moles). After cooling to room temperature the mixture was filtered, and the precipitate was washed with sodium bicarbonate solution and water, and dried at 100°. The crude product melted at 244–251° with previous sintering; yield, 41.2 g. (88%). Recrystallization from acetic anhydride then afforded pale yellow crystals, m. p. 270–271° with previous sintering; over-all yield, based on the aldehyde, 79%. This compound did not depress the melting point of the analytically pure material obtained below by chromium trioxide oxidation of the aldehyde-cyclization mixture.

The same compound, m. p. 266–268°, also was obtained by the oxidation of X (Y = Br) with excess 30% hydrogen peroxide in boiling acetic acid.

The analytical sample of XIII (Y = Br) was prepared by the oxidation of a small sample of the aldehyde-cyclization mixture (IX + X, Y = Br) with excess chromium trioxide in acetic acid exactly as in the case of the corresponding iodo compound described above. Recrystallization from acetic anhydride gave almost colorless needles, m. p. 273–275° with previous sintering.

Anal. Calcd. for $C_{13}H_6O_5NSBr$: S, 8.71 Found: S, 8.70.

Like the corresponding iodo compound, XIII (Y = Br) gave a transient green color on treatment with zinc dust and aqueous-alcoholic alkali.

2-Iodo-8-aminothiaxanthone-5-dioxide (V, Y = I).—The reduction of 116 g. (0.28 mole) of XIII (Y = I) with 241 g. (1.07 moles) of stannous chloride dihydrate was effected as described for compound IX. Purification with 15% potassium hydroxide solution yielded 93.9 g

(87%) of bright yellow powder, m. p. 301–304° dec.[14]

Anal. Calcd. for $C_{13}H_8O_3NSI$: S, 8.33. Found: S, 8.26.

This compound (0.5 g.) was aminated by heating with 5 ml. of 12 *N* ammonium hydroxide and a trace of copper powder in a sealed tube for twenty-two hours at 220°. The product was taken up in 6 *N* hydrochloric acid (Darco) and reprecipitated with ammonium hydroxide to yield 0.3 g. of a bright yellow powder, m. p. 286–291° dec.; no depression when mixed with an authentic sample of 2,8-diaminothiaxanthone-5-dioxide (XV)[1] melting at 289–293° dec.

On treatment with zinc dust and aqueous-alcoholic alkali V (Y = I) gave a deep violet color which was discharged on exposure to air.

2-Bromo-8-aminothiaxanthone-5-dioxide (V, Y = Br).—The nitro compound XIII (Y = Br) was reduced as above with stannous chloride (0.076 mole) and hydrogen chloride in acetic acid. A quantitative yield (6.8 g.) of yellow-orange powder, m. p. 310–311°, was obtained. Recrystallization of a small sample from acetone caused no change in the melting point.

Anal. Calcd. for $C_{13}H_8O_3NSBr$: S, 9.49. Found: S, 9.48.

The same peculiar color reaction with zinc dust and alkali was shown by this compound as by its iodo analog.

2-Amino-8-(N-2-pyrimidyl)-aminothiaxanthone-5-dioxide (II).—A mixture of 5.0 g. (0.013 mole) of V (Y = I), 15.0 g. (0.158 mole) of 2-aminopyrimidine,[15] 2.0 g. (0.015 mole) of finely powdered anhydrous potassium carbonate, and a trace of copper powder was heated with stirring at 195–205° for eighty minutes under nitrogen. The dark-colored mixture was cooled slightly and triturated with hot water to remove excess 2-aminopyrimidine and potassium iodide. The finely ground residue was extracted repeatedly with cold 5 *N* nitric acid, treated with decolorizing charcoal, and finally reprecipitated from the combined acid extracts by addition of excess ammonium hydroxide; yield, 4.1 g. (90%) of a bright yellow powder, m. p. 327–335° dec. Digestion of a small sample with hot acetone, in which it is only very slightly soluble, raised the melting point to 335–338° dec.

Anal. Calcd. for $C_{17}H_{12}O_3N_4S$: S, 9.10; N, 15.9. Found: S, 9.04, 9.09; N, 15.7.

The diacetyl derivative of II was prepared by refluxing 1.6 g. (0.0045 mole) with 3.0 g. (0.029 mole) of acetic anhydride in 25 ml. of glacial acetic acid for three hours, cooling to room temperature and diluting with a large volume of water. The gelatinous yellow precipitate was recrystallized from aqueous acetic acid to yield 1.3 g. (66%) of yellow-orange crystals, m. p. 318–321° dec.

Anal. Calcd. for $C_{21}H_{16}O_5N_4S$: S, 7.34; N, 12.84. Found: S, 7.48; N, 12.96.

Condensation of V (Y = I) with 2-Aminopyridine.—In a typical experiment a mixture of 2.0 g. (0.0052 mole) of V (Y = I), 6.0 g. (0.064 mole) of 2-aminopyridine (Reilly Tar and Chemical Co., redistilled), 0.8 g. (0.0058 mole) of finely powdered anhydrous potassium carbonate, and a trace of copper powder was heated and stirred under nitrogen at 190–195° for ninety minutes. The dark-colored melt was cooled and the tarry mass extracted with warm water to remove the excess 2-aminopyridine and inorganic salts. After repeated extractions of the water-insoluble residue with 6 *N* hydrochloric acid, addition of excess ammonium hydroxide to the combined acid extracts precipitated 1.3 g. of yellow-orange powder, m. p *ca.* 150–190° dec. Repeated recrystallization from aqueous ethanol (Norit) afforded 0.4 g. of orange microcrystalline powder, m. p. 233–237° dec. with previous sintering. Digestion with boiling acetone raised the melting point to 235–240° dec. with previous sintering.

Anal. Calcd for $C_{18}H_{13}O_3N_3S$: S, 9.13. Found: S, 8.97.

When this product was refluxed with aqueous-alcoholic alkali for two hours, the evolution of considerable ammonia was observed (olfactory evidence, litmus and hydrogen chloride tests). No ammonia could be detected after three hours of similar treatment of II.

2-Iodo-8-(N-2-pyridyl)-aminothiaxanthone-5-dioxide (XIV, Y = I).—A mixture of 1.0 g. (0.0026 mole) of V (Y = I) and 3.0 g. (0.019 mole) of 2-bromopyridine[16] was stirred and heated on an oil-bath at 155–160° for eight hours. The cooled reaction mixture was diluted with several times its volume of ethanol, and the brownish-yellow precipitate was washed with ethanol, dissolved in a small amount of hot pyridine (Norit), and finally reprecipitated by the addition of four volumes of ethanol; yield, 1.0 g. (83%) of orange microcrystalline powder, m. p. 285–288°. Repeated reprecipitation from pyridine solution then yielded the pure product, m. p. 294–295°.

Anal. Calcd. for $C_{18}H_{11}O_3N_2SI$: S, 6.93. Found: S, 7.06.

2-Bromo-8-(N-2-pyridyl)-aminothiaxanthone-5-dioxide (XIV, Y = Br).—This compound was prepared by the method described above for the corresponding iodo compound, using 3.0 g. (0.0089 mole) of V (Y = Br) and 12.0 g. (0.081 mole) of 2-bromopyridine. After one reprecipitation from pyridine the product melted at 293–297°; yield 3.4 g. (92%). Another reprecipitation afforded the pure compound as an orange microcrystalline powder, m. p. 297–298°.

Anal. Calcd. for $C_{18}H_{11}O_3N_2SBr$: S, 7.72. Found: S, 7.59.

2-Amino-8-(N-2-pyridyl)-aminothiaxanthone-5-dioxide (I).—A mixture of 2.6 g. (0.0063 mole) of XIV (Y = Br), 12 ml. of 12 *N* ammonium hydroxide and a trace of copper powder was heated at 210–220° in a sealed tube for twenty hours. The contents of the tube were diluted with water and filtered, the insoluble residue being taken up in 3 *N* hydrochloric acid, treated with Norit, and reprecipitated with ammonium hydroxide. A second reprecipitation from acid solution yielded 1.5 g. (68%) of yellow-orange powder, m. p. 245–260° dec. Pure 2-amino-8-(N-2-pyridyl)-aminothiaxanthone-5-dioxide was obtained as an orange microcrystalline powder, m. p. 280–282° dec., by recrystallization from aqueous ethanol. The same product (m. p. 279–281° dec., no depression when mixed with the above material) was obtained by the action of ammonium hydroxide on XIV (Y = I) under similar conditions.

Anal. Calcd. for $C_{18}H_{13}O_3N_3S$: S, 9.12; N, 11.97. Found: S, 9.02; N, 11.84.

2-Iodo-8-(N-2-quinolyl)-aminothiaxanthone-5-dioxide (XVI).—A mixture of 1.0 g. (0.0026 mole) of 2-iodo-8-aminothiaxanthone-5-dioxide (V, Y = I) and 2.6 g. (0.016 mole) of 2-chloroquinoline,[17] m. p. 37.5–39° (uncor.), was stirred in a test-tube (reflux condenser) for fifteen and one-half hours at 150–154° (oil-bath temperature), fifty-four hours at 155–165°, and eighteen and one-half hours at 160–170°. The temperature then gradually was raised to 185° during the last hour of heating (total reaction time, eighty-nine hours). After the first twenty-four hours white crystals appeared on the walls of the test-tube, but the main reaction mixture gave a positive test for halogen only after about sixty hours, at which time a catalytic amount of copper powder was added. The cooled mixture was diluted with ether, and from the brown solid obtained on filtration 1.0 g. (79%) of crude 2-iodo-8-(N-2-quinolyl)-aminothiaxanthone-5-dioxide, m. p. 320–321° (uncor., dec.), was obtained by reprecipitation from a pyridine solution with ethanol. This product was used for the amination despite its low sulfur content.

Anal. Calcd. for $C_{22}H_{13}O_3N_2SI$: S, 6.26. Found: S, 5.18.

2-Amino-8-(N-2-quinolyl)-aminothiaxanthone-5-dioxide (IV).—A mixture of 0.32 g. (0.00062 mole) of XVI, 10 ml. of concentrated ammonium hydroxide, and a trace of copper powder was heated fifteen hours at 205° in a sealed tube. Water (90 ml.) was added and the insoluble dark-brown solid filtered off. Upon heating this material three times with 10 ml. of approximately 4 *N* hydrochloric acid, removing insoluble material by filtration, and reprecipitating from the cooled filtrate with ammonium hydroxide three impure brown-yellow fractions were obtained from which 8 mg. (3%) of pure 2-amino-8-(N-2-quinolyl)-aminothiaxanthone-5-dioxide was isolated by fractional extractions with boiling dioxane followed by reprecipitation from the cooled solutions with water.

Anal. Calcd. for $C_{22}H_{15}O_3N_3S$: S, 7.99. Found: S, 7.70.[18]

Summary

2-Amino-8-(N-2-pyridyl)-aminothiaxanthone-5-dioxide, 2-amino-8-(N-2-pyrimidyl)-aminothiaxanthone-5-dioxide and 2-amino-8-(N-2-quinolyl)-aminothiaxanthone-5-dioxide have been synthesized for study as possible new antibacterial agents.

The Allergenic Principles of Poison Ivy. VII. Absorption Spectra of 3-*n*-Pentadecylcatechol and Related Compounds[1]

BY HOWARD S. MASON

In this study the absorption spectra of 3-*n*-pentadecylcatechol and a group of other substituted catechols, catechol derivatives and *o*-quinones have been determined. The feasibility of direct spectrophotometric assay of poison ivy allergens was also investigated.

Experimental

Unless otherwise noted, all substances examined were analytically pure samples previously described[1].

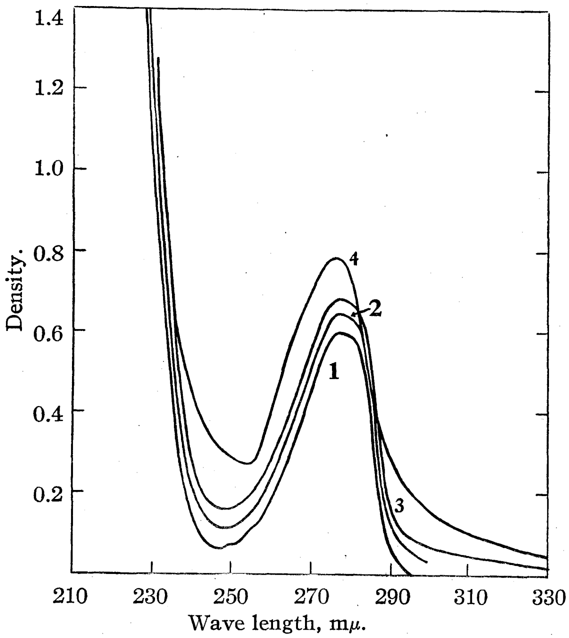

Fig. 1.—Spectrum of 3-*n*-pentadecylcatechol in ethanol. The solution contained 0.102 mg. per ml. The measurements were made at intervals of (1) zero days, (2) fourteen days, (3) thirty days and (4) ninety-one days.

3-*n*-Pentadecyl-*o*-benzoquinone.—This compound was prepared and purified by following the procedure of Willstätter[2] for the preparation of *o*-benzoquinone. It was recrystallized from a mixture of ether and hexane, from which it separated as orange rhomboids sintering and decomposing between 63–67°. The colorless modification could also be obtained by following the procedure of Willstätter and Müller[3] for the preparation of colorless *o*-benzoquinone.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.0; H, 11.0.

***o*-Benzoquinone.**—This compound was readily prepared and recrystallized by the procedures of Willstätter[2] and Goldschmidt.[4] The product consisted of bright red crystals melting and decomposing between 60–70°.

3-*n*-Pentadecylcatechol Diphenylmethylene Ether.—This compound was synthesized by a general method already described[1]. It crystallized as white prisms from methanol and melted at 42°.

Anal. Calcd. for $C_{34}H_{44}O_2$: C, 84.3; H, 9.16. Found: C, 84.0; H, 9.14.

Spectral curves were determined with a Beckman quartz spectrophotometer. The solvent used was ethanol unless otherwise specified. The quartz cells employed were 10 mm. in thickness.

Results

Fresh solutions of 3-*n*-pentadecylcatechol in ethanol displayed maximum absorption at 277 mμ, $\log \epsilon = 3.28$. On standing for several months absorption became more intense, the spectral curve shifting to slightly shorter wave lengths (Fig. 1). The effect of solvent upon the rate of this process was determined by following simultaneously the absorption spectra of identical concentrations of 3-*n*-pentadecylcatechol in ethanol, acetone and hexane. Over a period of forty-five days at 21–24° the spectral changes took place most markedly in acetone and least markedly in hexane (Table I).

Crude extracts of poison ivy also displayed

TABLE I

SPECTRAL STABILITY OF SOLUTIONS OF 3-*n*-PENTADECYLCATECHOL

Solvent	Concn. mole/liter	Density at 0 days (mμ)	Density at 45 days (mμ)
Ethanol	0.000156	0.300 (277)	0.384 (277)
Acetone[a]	.000156	.303 (277)	.407 (275)
Hexane[b]	.000156	.326 (273)	.372 (272)

[a] Aliquots of the acetone solution were evaporated in vacuum at room temperature. Spectral curves were determined with ethanolic solutions of the residues. [b] Determination upon hexane solution.

maximum absorption at 277 mμ, and underwent optical transformations upon standing (Fig. 2).

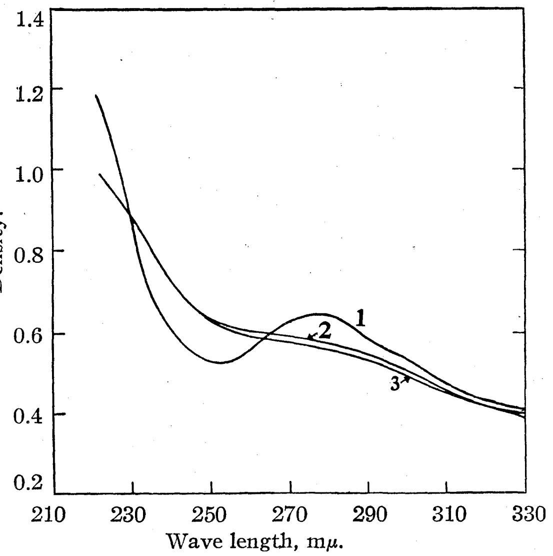

Fig. 2.—Crude poison ivy extract containing 0.0542 mg. of resin per ml. of ethanol at (1) zero days, (2) eighteen days and (3) thirty-two days.

o-Benzoquinone and 3-*n*-pentadecyl-*o*-benzoquinone were unstable in ethanol, chloroform, ether and hexane. The spectral curve of 3-*n*-pentadecyl-*o*-benzoquinone in ethanol (Fig. 3B) developed a maximum at 273 mμ over a period of six days. In hexane solution this substance possessed an initial maximum at 388 mμ, log ε = 3.36 (Fig. 3A). During a period of six days this specific absorption disappeared and only general absorption could be observed. The changing spectral curve of *o*-benzoquinone in ethanol (Fig. 4B) developed a maximum at 282 mμ in twenty-four hours. The chloroform solution displayed an initial maximum at 368 mμ, log ε = 3.23 (Fig. 4A). In three days this shifted to 372 mμ and a new maximum appeared at 273 mμ.

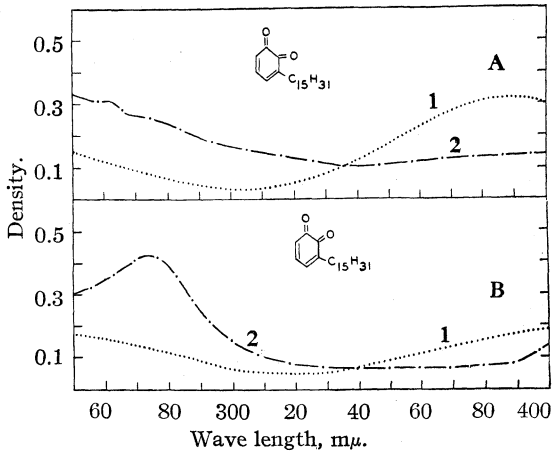

Fig. 3.—A, 3-*n*-pentadecyl-*o*-benzoquinone in hexane, 0.044 mg. per ml. at (1), twenty-five minutes and (2) six days; B, in ethanol, 0.032 mg. per ml. at (1) twenty minutes and (2) six days.

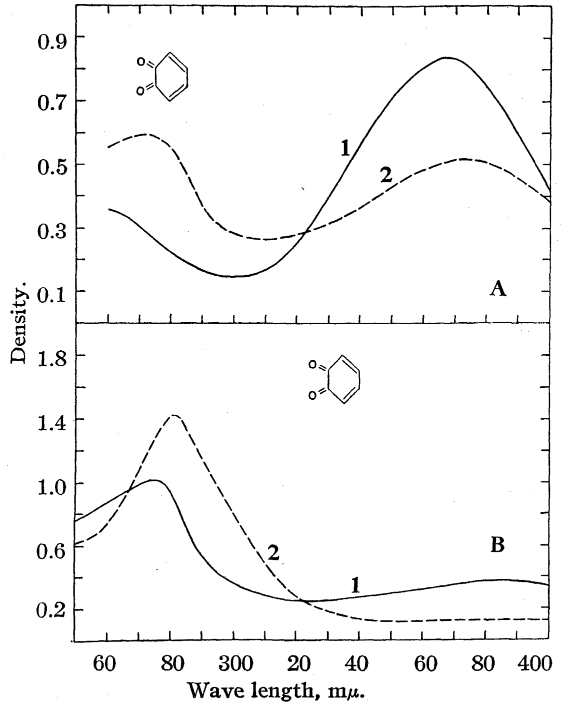

Fig. 4.—A, *o*-benzoquinone in chloroform, 0.053 mg. per ml. at (1) zero days and (2) three days; B, in ethanol, 0.0364 mg. per ml. at (1) twenty minutes and (2) twenty-four hours.

In the following summary of additional spectral curves the principal maxima are given in millimicra and the corresponding log molecular extinction coefficients are enclosed in parentheses.

Catechol	277 (3.36)
3-*n*-Pentadecylcatechol (hexane)	273 (3.32), 280 (3.31)
3-*n*-Propylcatechol	276 (3.35)
4-*t*-Butylcatechol	281 (3.48)
3-Bromocatechol	279.5 (3.41)
Bhilawanol[5]	276.5 (3.32)
Catechol diphenyl	283 (3.68)
methylene ether	279 (3.66), 282 (3.67),
(hexane)	284 (3.70), 290 (3.60)
3-*n*-Pentadecylcatechol diphenylmethylene ether	281 (3.55), 284 (3.55)
3-*n*-Propylcatechol diphenylmethylene ether	281 (3.52)

---

[5] Mason, THIS JOURNAL, **67**, 418 (1945).

3-Bromocatechol diphenylmethylene ether	287 (3.61)
4-*t*-Butylcatechol diphenylmethylene ether	287 (3.73)
Bhilawanol diphenylmethylene ether[5]	280 (3.60)
2,3-Dimethoxy-*n*-pentadecylbenzene	271 (3.18), 277 (3.16)
2,3-Dimethoxy-*n*-pentadecen-1-ylbenzene	271 (3.07), 277 (3.05)

Discussion

Adams and co-workers[6] observed that substitution of alkyl groups in the 4 position of catechol resulted in bathochromic spectral shifts of approximately 5 mμ. This phenomenon has been generalized by Jones[7] as the B-effect, and it has been shown that "the magnitude of the shift depends upon the position of the substituent in the ring system." The absorption spectrum of 4-*t*-butylcatechol, determined in the present study, is consistent with the observation of Adams.[6] However, it has been found that catechol, 3-*n*-propylcatechol, and 3-*n*-pentadecylcatechol display principal absorption (in ethanol) at 277, 276 and 277 mμ, respectively, and that the corresponding diphenylmethylene ethers show principal absorption at 283 281 and 281–284 mμ. The B-effect therefore does not obtain when alkyl groups are attached to the 3 position of catechol.

The increase in intensity of absorption at 277 mμ characteristic of solutions of 3-*n*-pentadecylcatechol and the changes with time in the spectrum of solutions of crude poison ivy extracts limit the applicability of spectrophotometric assay of the poison ivy allergens. However, the results indicate that standard solutions of these allergens are best prepared, from the point of view of chemical stability, in hydrocarbon solvents.

Goldschmidt and Graef[4] have found that, in hexane, *o*-benzoquinone and 4-methyl-*o*-benzoquinone display principal maxima at 363 and 365 mμ, respectively. 3-*n*-Pentadecyl-*o*-benzoquinone shows maximum absorption in the same solvent at 388 mμ. The substitution of an alkyl group in the 3 position of *o*-benzoquinone thus results in a bathochromic shift of unexpected magnitude, suggesting that the α-methylene group may be bonded through hydrogen to the adjacent carbonyl group.[8,9] The major shift of the spectral curves of *o*-benzoquinone and 3-*n*-pentadecyl-*o*-benzoquinone solutions, from initial absorption in the region of 368–388 mμ to final absorption between 273 and 282 mμ indicates that in the solvents investigated benzenoid molecules form from the quinones originally present. In the case of 3-*n*-pentadecyl-*o*-benzoquinone both the position and intensity of the final absorption are consistent with the hypothesis that the changes in the spectrum of aging solutions of 3-*n*-pentadecylcatechol are autoxidative and proceed through the formation of the corresponding *o*-quinone. This in turn is transformed into a benzenoid molecule. In order to characterize this substance attempts at isolation were made using *o*-benzoquinone as a starting material. From ethanolic solutions only catechol and an intractable black polymer were obtained. Upon zinc dust distillation, the polymer yielded biphenyl in small amounts. Some of the absorption in the 273–282 mμ region must therefore be due to the catechols themselves, but no decision with respect to the structures of the remaining solutes can yet be made.

Acknowledgments.—I wish to acknowledge the assistance of Mrs. Dorothy Peterson of the Industrial Hygiene Laboratory, National Institute of Health, in the determination of some of the spectral curves. I am indebted to Mr. Charles A. Kinser for the microchemical analyses.

Summary

1. The spectral curves of 3-*n*-pentadecylcatechol, related substituted catechols, catechol derivatives and *o*-quinones, have been determined.

2. The effects upon absorption spectra of changes in structure and autoxidation of the catechols, and of instability of quinonoid solutes, were observed.

3. The syntheses of 3-*n*-pentadecyl-*o*-benzoquinone and 3-*n*-pentadecylcatechol diphenylmethylene ether are reported.

Isomerism in the Diels–Alder Reaction

BY H. L. HOLMES, R. M. HUSBAND[1] AND IN PART BY C. C. LEE[1] AND P. KAWULKA[1]

Several cases of isomerism, the nature of which is not yet apparent, have been encountered in the addition of certain dienophiles to conjugated diene systems (diacetylethylene + 1-vinyl-6-methoxy 3,4-dihydronaphthalene,[2] cinnamic acid + dicyclohexenyl,[6] benzalacetophenone + dicyclohexenyl,[6] β-benzoylacrylic acid (and its 2,4-dimethyl derivative) + 2,3-dimethylbutadiene-1,3[3]). The reaction of an ethanol solution of β-benzoylacrylic with 2,3-dimethylbutadiene-1,3[3] gave a good yield of an acid adduct (m. p. 143°) as well as some ester resulting from interaction with the solvent. Saponification of the ester adduct with alcoholic alkali gave not only the above adduct but 1% of a high-melting (189°) isomer. A similar pair of isomers were obtained when the dienophile in the above reaction was β-[2′,4′-dimethylbenzoyl]-acrylic acid.

If the isomerism of the β-benzoylacrylic acid-2,3-dimethylbutadiene adduct is of a steric nature then the normal adduct (m. p. 143°) must have the *cis* configuration, for alcoholic alkali is known to promote the conversion of *cis* esters, bearing an alpha hydrogen, to the *trans* acid.[4] This is not in accord with experimental fact for saponification of the ethyl ester of the normal acid adduct with ethanolic potassium hydroxide regenerated only the normal acid (no trace of an isomeric acid could be detected). Furthermore, the high melting (m. p. 189°) acid adduct has been prepared directly, if in small yield, by heating a toluene solution of β-benzoylacrylic acid with 2,3-dimethylbutadiene (the analogous product was not obtained when β-[2,4-dimethylbenzoyl]-acrylic acid was the dienophile). Finally, *cis*-2-benzoyl-4,5-dimethyl-Δ^4-tetrahydrobenzoic acid, which differed from both of the above isomeric adducts, was prepared by condensing (*cis*) 4,5-dimethyl-Δ^4-tetrahydrophthalic anhydride with benzene. The failure of the *cis* acid to react with an ethereal solution of diazomethane is suggestive of a lactol structure for this adduct, an observation lending further support to the configuration assigned to this adduct. Dimethyl sulfate and alkali were required to effect this esterification. Saponification of the methyl ester of the *cis* acid with ethanolic sodium ethylate gave the normal acid adduct.

From these observations it must be concluded that the normal adduct has the *trans* configuration and that the high melting isomer probably results from the migration of the double bond from the normal position in the adduct to one of conjugation with either the ketone or carboxyl group or with both of these functional groups.

This work combined with the generalization of Bergmann and Eschinazi[5] that in Diels–Alder reactions "the relative position of the substituents in the olefinic component is retained in the adduct" adds further confirmation to Lutz's[6] characterization of the yellow β-benzoylacrylic acid as the *trans* form.

Experimental Part[7]

β-Benzoylacrylic Acid and its 4-Methoxy- and 2,4-Dimethyl Derivatives.—The β-benzoylacrylic acid (m. p. 95–96°) was prepared by the method of Fieser and Fieser[3]; however, a modification[8] of this reaction improved the yield of the 4-methoxy- and 2,4-dimethyl- derivatives to 80 and 75%, respectively. The β-anisoylacrylic acid melted at 133–134°,[9] while the β-[2,4-dimethylbenzoyl]-acrylic acid, previously prepared by Kozniewski and Marchlewski,[10] melted at 112–113°. Ethyl β-anisoylacrylate boiled at 184–187° (3 mm.).

The Diels–Alder Reactions.—The conditions for the addition of β-benzoylacrylic acid, its 4-methoxy- and 2,4-dimethyl derivatives to 2,3-dimethylbutadiene were the same.

A suspension of 12.00 g. of β-benzoylacrylic acid in 10 cc. of sodium-dry toluene was heated in a sealed tube with 6.2 g. of 2,3-dimethylbutadiene-1,3 for one hundred and twenty hours at 125°. A yield of 15.31 g. of the crude adduct (m. p. 120–140°) was recovered. Recrystallization from ether and petroleum ether raised the melting point to 141–142°. No depression of the melting point was observed when mixed with that prepared by Fieser and Fieser. After removal of the last traces of the product, melting at 141–142°, from the mother liquors, a second product (0.12 g.) crystallized which showed a somewhat indefinite melting point. When the sample, alone or mixed with the high melting isomer of Fieser and Fieser, was introduced into the melting point apparatus at 160° and the bath temperature increased at a rapid rate, it melted at 189° with some previous softening. This high melting isomer is unsaturated toward aqueous permanganate solution and bromine in carbon tetrachloride.

In contrast to the results of the previous workers only the product melting at 150–150.5° was recovered (80%) from the addition of β-[2,4-dimethylbenzoyl]-acrylic acid to 2,3-dimethylbutadiene. The addition product (80%), melting at 149–149.5°, was isolated from the analogous reaction with β-anisoylacrylic acid.

These dienophiles were not affected by these conditions, for, when they were heated in toluene under conditions obtaining in the above reactions, they were quantitatively recovered except in the case of β-benzoylacrylic acid. In the latter case 5% of a white crystalline solid melting at 176–177° was formed. The same product resulted from crystallization of β-benzoylacrylic acid from benzene.

Esterification of the Diene Adducts.—The ester adducts were obtained by boiling the acid adducts for four hours

[a] In every case there was a small fraction which boiled slightly higher but on saponification only the starting acid was recovered.

with four times their weight of a solution of absolute ethanol containing sulfuric acid (15% by weight). The reaction mixtures were poured into water, extracted in ether and after washing the ether extracts with water were dried over anhydrous sodium sulfate. After removal of the solvent the esters were distilled under reduced pressure. The analyses and physical constants for these esters are listed in Table I.

Saponification of the ester adducts with ethanolic potassium hydroxide (10% by weight) gave almost quantitative yields of the original acid adducts and no isomeric products could be detected.

***cis*-2-Benzoyl-4,5-dimethyl-Δ⁴-tetrahydrobenzoic Acid.**—A solution of 14.0 g. of 4,5-dimethyl-Δ⁴-tetrahydrophthalic anhydride (m. p. 78–78.5°) in 300 cc. of sodium-dry benzene was added dropwise over a period of 3 hours to a well-stirred and cooled (7–8°) suspension of 23.0 g. of aluminum chloride in 200 cc. of dry benzene. The reaction mixture was allowed to stand seven days at 10–12° and then decomposed in ice and water containing 50 cc. of concentrated hydrochloric acid. The organic layer was separated, the benzene removed by steam distillation and the residual oil dissolved in sodium bicarbonate solution, decolorized (Norit) and acidified. The resulting solid (m. p. 70–80°) was predominantly 4,5-dimethyl-Δ⁴-tetrahydrophthalic anhydride. The major portion of this unchanged starting material was removed in boiling petroleum ether. Several crystallizations of the residual oil from ether and petroleum ether gave 1.0 g. of the acid, melting at 147–148°. When mixed with the low melting adduct (m. p. 141–142°) it melted at 126–127° with previous softening.

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02. Found: C, 74.61, 74.42; H, 7.17, 6.99.

The above solid was recovered unchanged from the action of a 100% excess of an ethereal solution of diazomethane. The methyl ester (m. p. 108–110°) was obtained by the portionwise addition of methyl sulfate and sodium hydroxide to this product at 80°.

Conversion of the *cis* Ester to the *trans* Acid (m. p. 141–142°).—The methyl ester (0.5 g.) was refluxed with ethanolic sodium ethylate (0.1 g. of sodium and 2.0 cc. of absolute ethanol) for four hours. The reaction mixture, when cold, was diluted with water and acidified. The resulting solid when crystallized from ether–petroleum ether mixture gave 0.1 g. of cubic crystals, which melted alone or on admixture with *trans*-2-benzoyl-4,5-dimethyl-Δ⁴-tetrahydrobenzoic acid at 139–141°.

Acknowledgments.—We wish to acknowledge our indebtedness to Professor L. F. Fieser for the use of his analytical samples which made a direct comparison with our products possible.

Summary

An examination of the isomeric adducts resulting from the reaction of β-benzoylacrylic acid with 2,3-dimethylbutadiene has revealed that the isomer melting at 141–142° is *trans*-2-benzoyl-4,5-dimethyl-Δ⁴-tetrahydrobenzoic acid. The *cis* isomer (m. p. 147–148°) has been prepared and isomerized, through its methyl ester, to the *trans* form (m. p. 141–142°). The isomer, melting at 189°, probably results from the migration of the double bond from the normal position in the adduct to one of conjugation with some other center of unsaturation.

SASKATOON, SASKATCHEWAN RECEIVED MARCH 21, 1947

2-Hydroxyacetylfuran

BY FRANK KIPNIS, HAROLD SOLOWAY AND JOHN ORNFELT

The preparation of 5-nitro-2-hydroxyacetylfuran has been reported by Stillman and Scott.[1] During work in progress at this Laboratory, we have been interested in the preparation of furan ketols, and, in view of the appearance of the above patent, we wish to announce the synthesis of 2-hydroxyacetylfuran and the furoic acid ester thereof.

Diazoacetylfuran has been prepared[2] by the interaction of furoyl chloride with diazomethane. On treatment of the diazoketone with 2 *N* sulfuric acid, nitrogen was evolved, and, by working up the mixture in the usual manner, hydroxyacetylfuran was obtained in good yield. When the diazoketone was heated with furoic acid in benzene, 2-furoyloxyacetylfuran was produced.

Experimental

2-Hydroxyacetylfuran.—Ten and one-half grams (0.077 mole) of diazoacetylfuran[2] was mixed with 150 ml. of 2 *N* sulfuric acid and 60 ml. of dioxane. A vigorous evolution of nitrogen occurred, and the temperature rose spontaneously to 45°. The mixture was stirred and maintained at that temperature (water-bath) for four hours, at the end of which time the temperature was allowed to drop to 25°. After neutralization with solid potassium carbonate, the solution was filtered and distilled from the steam-bath at reduced pressure, removing all of the dioxane and some of the water. The residue was cooled, salted with sodium chloride and extracted six times with 30 ml. of ether. The solvent layer was dried with calcium sulfate, filtered and stripped, finally under reduced pressure, leaving a crystalline residue. This material was recrystallized three times

from hexane to give 7.2 g. (74% yield) of material melting at 81–82°.[3] Fehling solution was reduced by the ketol.

Anal.[4] Calcd. for $C_6H_6O_3$: C, 57.14; H, 4.80. Found: C, 57.23; H, 4.88.

2-Furoyloxyacetylfuran.—Eleven grams (0.081 mole) of diazoacetylfuran was refluxed for four hours with 11 g. (0.099 mole) of furoic acid in 40 ml. of anhydrous, thiophene-free benzene. The solvent was removed under reduced pressure, and the crystalline residue was triturated with saturated sodium bicarbonate solution, and then with water, and finally recrystallized from aqueous methanol (Darco) and then from much hexane to give 8.1 g. (50% yield) of a product melting at 95°.

Anal. Calcd. for $C_{11}H_8O_5$: C, 59.73; H, 3.85. Found: C, 60.00; H, 3.66.

Summary

2-Hydroxyacetylfuran and 2-furoyloxyacetylfuran have been prepared by the interaction of 2-diazoacetylfuran with dilute sulfuric acid and furoic acid, respectively.

Aliphatic Ketones and Amines Containing the Trifluoromethyl Group

BY REUBEN G. JONES

It is well known that the introduction of fluorine atoms into aliphatic molecules has a profound effect upon the physical and chemical properties. In order to ascertain the effect of fluorine on the pharmacological properties of typical aliphatic compounds, it was of particular interest to prepare some ketones, amines, and alcohols containing the trifluoromethyl group. The compounds reported at this time were derived from trifluoroacetic acid.

Two methods were examined for the preparation of trifluoromethyl benzyl ketone. Trifluoroacetonitrile was allowed to react with benzylmagnesium chloride to produce the desired ketone in 38% yield.

$$CF_3CN + C_6H_5CH_2MgCl \xrightarrow{H_2O} CF_3COCH_2C_6H_5$$

The more convenient reaction of trifluoroacetyl chloride with benzyl zinc chloride gave a 54% yield of the ketone.

$$CF_3COCl + C_6H_5CH_2ZnCl \longrightarrow CF_3COCH_2C_6H_5$$

Both methods would appear to be quite generally applicable to the preparation of trifluoromethyl ketones. Trifluoromethyl phenyl ketone (trifluoroacetophenone[1]) was obtained readily in a yield of 61% by the reaction of trifluoroacetyl chloride with diphenylcadmium.

The pharmacology of these trifluoromethyl compounds will be reported elsewhere. However, it is of interest to note at this time that the acute toxicities were relatively low.

Experimental

Trifluoromethyl Benzyl Ketone.—A. Trifluoroacetonitrile was prepared from 56 g. (0.5 mole) of trifluoroacetamide by the method of Gilman and Jones.[2] The gaseous nitrile was led from the generating flask through glass tubing and introduced below the surface of a stirred solution of benzylmagnesium chloride prepared from 80 g. (0.63 mole) of benzyl chloride and 17 g. of magnesium in a total of 300 ml. of dry ether. When the reaction was complete, the brown ether solution was poured into a mixture of 150 g. of ice and 100 ml. of concentrated hydrochloric acid. The ether layer was separated, washed with water and dilute sodium bicarbonate solution and dried over magnesium sulfate. After evaporation of the ether the residual liquid was distilled through an eighteen-inch packed column under reduced pressure, and 36 g. (38.4% yield) of trifluoromethyl benzyl ketone was obtained as a colorless liquid; b. p. 73–73.5° (20 mm.), 163–163.5° (741 mm.): $n^{25}D$ 1.4625.

Anal. Calcd. for $C_9H_7F_3O$: C, 57.45; H, 3.75. Found: C, 57.05; H, 3.92.

B. Trifluoroacetyl chloride was prepared by the method of Tinker[3] from 57 g. (0.5 mole) of trifluoroacetic acid and 200 ml. of benzoyl chloride. The gaseous trifluoroacetyl chloride was led through a glass tube into a reaction flask containing benzylzinc chloride which was made by adding slowly, with the exclusion of air, 800 ml. of ether solution containing 1.0 mole of benzylmagnesium chloride to 136 g. (1.0 mole) of freshly fused, powdered zinc chloride. The reaction flask was provided with a Dry Ice condenser and the mixture was rapidly stirred. After several hours, the mixture was decomposed with ice and dilute hydrochloric acid. The ether layer was separated, the aqueous layer was washed with three 100-ml. portions of ether, and the combined ether solution was dried over magnesium sulfate. The ether was removed by distillation through a small packed column. From the mid fractions, distilling between 36 and 105°, was obtained 8 g. (14%) of trifluoroacetic acid (isolated as the ammonium salt), and 51 g. (54.3% yield) of trifluoromethyl benzyl ketone was collected at 160–165° (740 mm.); $n^{25}D$ 1.4621.

Trifluoromethylbenzylcarbinol.—A solution of 23.5 g. (0.125 mole) of trifluoromethyl benzyl ketone in 50 ml. of anhydrous ether with 5 g. of 5% palladium–charcoal catalyst was hydrogenated under 60 lb. pressure. The theoretical quantity of hydrogen was taken up in about twenty minutes with evolution of heat. The solution was filtered and distilled to yield 23.0 g. (98%) of trifluoromethylbenzylcarbinol; b. p. 204–204.5° (740 mm.); $n^{25}D$ 1.4678.

Anal. Calcd. for $C_9H_9F_3O$: C, 56.84; H, 4.75. Found: C, 56.74; H, 4.76.

Trifluoromethyl Benzyl Ketoxime.—A solution of 23.5 g. (0.125 mole) of trifluoromethyl benzyl ketone in 100 ml. of methanol was treated with 28 g. (0.4 mole) of powdered hydroxylamine hydrochloride followed by 30

ml. of 12 *N* sodium hydroxide solution. The mixture was refluxed for sixteen hours and then most of the methanol was removed by distillation. To the residue was added 100 ml. of water, and the mixture was extracted with three 50-ml. portions of ether. The ether solution was dried over magnesium sulfate, the ether was removed, and the oxime was distilled in vacuum to yield 25.0 g. (98%) of product, b. p. 118–119° (20 mm.).

Anal. Calcd. for $C_9H_8F_3NO$: C, 53.20; H, 3.97; N, 6.89. Found: C, 53.87; H, 4.40; N, 6.44.

1,1,1-Trifluoro-2-amino-3-phenylpropane.—A solution of 41 g. (0.20 mole) of trifluoromethyl benzyl ketoxime in 150 ml. of anhydrous ether with 8 g. of 5% palladium-charcoal catalyst was placed in a steel hydrogenation bomb under a pressure of 1450 lb./sq. in. of hydrogen, heated to 150° and agitated. The theoretical quantity of hydrogen was taken up in one hour. The bomb was cooled and opened and the ether solution, after filtration, was extracted with cold dilute hydrochloric acid solution. The aqueous layer was separated, made basic with sodium hydroxide and extracted with ether. After the ether extract had been dried over magnesium sulfate, the ether was evaporated and the amine was distilled at atmospheric pressure; b. p. 189–191° (739 mm.). The yield of clear colorless liquid was 33 g. (87%); n^{25}_D 1.4470.

Anal. Calcd. for $C_9H_{10}F_3N$: N, 7.40. Found: N, 7.56.

The amine hydrochloride, prepared by passing dry hydrogen chloride into a solution of the amine in anhydrous ether, melted at 231–233°.

Anal. Calcd. for $C_9H_{10}F_3N \cdot HCl$: C, 47.95; H, 4.92. Found: C, 47.47; H, 4.89.

Ethyl 3-Hydroxy-4,4,4-trifluorobutyrate.—Ethyl trifluoroacetoacetate was prepared in 83.5% yield from ethyl acetate and ethyl trifluoroacetate according to the directions of Swarts.[4]

To a solution of 27.6 g. (0.15 mole) of ethyl trifluoroacetoacetate in 50 ml. of anhydrous ether was added 0.15 g. of platinum oxide catalyst and the mixture was shaken under an initial hydrogen pressure of 60 lb. Hydrogenation was complete in seven hours. The solution was filtered and distilled, and, after the forerun of ether, the ethyl 3-hydroxy-4,4,4-trifluorobutyrate, 24.8 g. (90% yield), boiled at 177–178° (750 mm.). When 55.2 g. (0.30 mole) of ethyl trifluoroacetoacetate was shaken under 60 lb. hydrogen pressure using 2 g. of 5% palladium-charcoal catalyst, the theoretical quantity of hydrogen was absorbed in three hours. Under high pressure (1200 lb.), 50 g. (0.27 mole) of ethyl trifluoroacetoacetate in 100 cc. of anhydrous ether with 15 g. of 5% palladium-charcoal catalyst absorbed the theoretical quantity of hydrogen in two to three minutes, and no more hydrogen was taken up even when the bomb was heated to 100° and agitated for five hours.

The ester isolated directly from the hydrogenation reaction could not be obtained analytically pure even after several distillations. A pure sample of ethyl 3-hydroxy-4,4,4-trifluorobutyrate was prepared in 90% yield by esterification of 3-hydroxy-4,4,4-trifluorobutyric acid (see below) with ethanol and hydrogen chloride. It has the following properties: b. p. 180–180.2° (748 mm.); m. p. 26.9–27.0°; n^{30}_D 1.3707; d^{30}_{30} 1.275.

Anal. Calcd. for $C_6H_9F_3O_3$: C, 38.71; H, 4.87. Found: C, 38.25; H, 5.09.

3-Hydroxy-4,4,4-trifluorobutyric Acid.—A solution of 35 g. (0.223 mole) of 3-hydroxy-4,4,4-trifluorobutyramide (see below) in 40 ml. of 12 *N* sodium hydroxide solution was heated on the steam-bath for fifteen minutes. The clear solution was cooled in an ice-bath and treated with 60 ml. of 12 *N* hydrochloric acid. The salt was collected on a filter, washed with ether, and the filtrate was extracted with three 100-ml. portions of ether. The combined ether solution was dried over magnesium sulfate and evaporated on the steam-bath. To the residual liquid was added 100 ml. of petroleum ether (b. p. 60–68°) whereupon crystallization quickly took place. The acid was collected and dried in vacuum over calcium chloride. The yield was 34.1 g. (97.2%); m. p. 69.5–70°.

Anal. Calcd. for $C_4H_5F_3O_3$: C, 30.39; H, 3.19. Found: C, 30.43; H, 3.28.

The pure acid was also readily obtained by saponification of the crude ester. It was sparingly soluble in petroleum ether, very soluble in ether, alcohol and water but apparently not hygroscopic.

3-Hydroxy-4,4,4-trifluorobutyramide.—A solution of 4.6 g. (0.025 mole) of crude ethyl 3-hydroxy-4,4,4-trifluorobutyrate in 25 ml. of methanol was saturated with dry ammonia and allowed to stand for three days. The methanol was evaporated, finally under vacuum leaving a mass of colorless prismatic crystals. The product was washed with 10 ml. of dry ether and air dried. It weighed 3.5 g. (90% yield) and melted at 124–125°.

Anal. Calcd. for $C_4H_6F_3NO_2$: N, 8.92. Found: N, 8.73.

The compound was soluble to the extent of about 1 g. per 100 ml. of dry ether, very sparingly soluble in petroleum ether, highly soluble in alcohol or water and not hygroscopic.

N-2′-Hydroxyethyl-3-hydroxy-4,4,4-trifluorobutyramide.—A mixture of 9.3 g. (0.05 mole) of ethyl 3-hydroxy-4,4,4-trifluorobutyrate and 3.5 g. (0.058 mole) of ethanolamine was heated at 140° for four hours. The mixture was distilled in vacuum and, after a small forerun, 9.5 g. (95% yield) of viscous colorless liquid distilled at 186–188° (2 mm.). It crystallized after standing; m. p. 59–61°.

Anal. Calcd. for $C_6H_{10}F_3NO_3$: N, 6.96. Found: N, 7.10.

2-Hydroxy-3,3,3-trifluoropropylamine Hydrochloride.—To a mixture of 150 g. of ice and potassium hypochlorite solution made by dissolving 11.0 g. (0.153 mole) of chlorine in a solution of 33.6 g. of potassium hydroxide in 90 ml. of ice water was added 23.6 (0.15 mole) of 3-hydroxy-4,4,4-trifluorobutyramide. The solution was kept at 0° for twenty minutes, then allowed to warm slowly to room temperature and finally heated on the steam-bath for thirty minutes. The solution was cooled and extracted with ten 100-ml. portions of ether. The ether solution was dried over magnesium sulfate, filtered and saturated with dry hydrogen chloride to yield 13.9 g. (56%) of white crystalline amine hydrochloride; m. p. 147–148°.

Anal. Calcd. for $C_3H_6F_3NO \cdot HCl$: C, 21.76; H, 4.26; N, 8.46. Found: C, 21.93; H, 4.31; N, 8.32.

To 3 ml. of 15% aqueous sodium hydroxide was added 0.5 g. of 2-hydroxy-3,3,3-trifluoropropylamine hydrochloride followed by 0.5 ml. of benzoyl chloride added dropwise with shaking. The resulting white, crystalline dibenzoyl compound, 0.9 g., was collected on a filter and recrystallized from petroleum ether containing a little ethyl acetate; m. p. 126.5–127.5°.

Anal. Calcd. for $C_{17}H_{14}F_3NO_3$: C, 60.53; H, 4.18. Found: C, 60.33; H, 4.11.

Summary

Two general methods for the synthesis of ketones have been applied successfully to the preparation of trifluoromethyl benzyl ketone.

1,1,1-Trifluoro-2-amino-3-phenylpropane has been obtained by hydrogenation of the ketoxime.

Trifluoromethyl benzyl ketone has been hydrogenated to yield trifluoromethylbenzylcarbinol.

3-Hydroxy-4,4,4-trifluorobutyric acid, its ethyl ester, amide, and N-2′-hydroxyethyl amide, and 2-hydroxy-3,3,3-trifluoropropylamine have been made starting from ethyl trifluoroacetoacetate.

N-Bromosuccinimide as a Dehydrogenating Agent[1]

BY RODERICK A. BARNES

The structure proof for most hydroaromatic compounds rests upon the fact that treatment with a dehydrogenating agent such as selenium, sulfur, platinum or palladium at temperatures of 250–450°, converts them to known aromatic substances. A large number of cases has accumulated in the literature in which the usual dehydrogenation process has been accompanied by rearrangements, migrations and ring closures. These render the use of such reagents of questionable value in an absolute structure proof.[2]

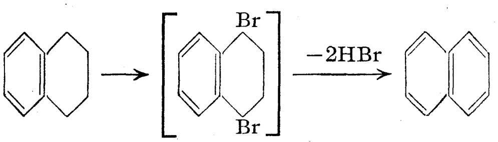
This investigation was undertaken in order to demonstrate the use of a low temperature bromination–dehydrobromination process for achieving dehydrogenation, with N-bromosuccinimide as a selective brominating agent.[3] A procedure has been developed which is satisfactory especially for compounds of the tetralin type which have one hydroaromatic ring attached to a benzenoid ring.

TABLE I

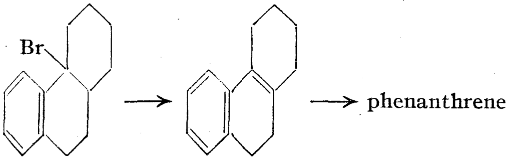
Compound	Product	Yield, %
Tetralin	Naphthalene	74
sym-Octahydroanthracene	Anthracene	69
Tetrahydrophenanthrene	Phenanthrene	79
sym-Octahydrophenanthrene	Phenanthrene	63
as-Octahydrophenanthrene	Phenanthrene	21
	1-Bromophenanthrene[a]	12
Dibenzyl	Stilbene	56
	Stilbene dibromide	10
Acenaphthene	Acenaphthylene	20
	Dihydroxyacenaphthene[b]	8
Decalin	1,5-Dibromonaphthalene	9
	x-Tetrabromo-9,10-octalin	14
Cyclohexene	*m*-Dibromobenzene *p*-Dibromobenzene	58

[a] This product was isolated in only one experiment, phenanthrene being the only pure product in four subsequent experiments. [b] This substance must have resulted by reaction of the dibromide with water and alkali when the mixture was processed as for tetralin.

The preliminary bromination of tetralin can be completed before any appreciable dehydrobromination takes place, which indicates that a fairly stable dibromotetralin must be the intermediate.



In the case of *as*-octahydrophenanthrene, an immediate and exothermic reaction took place with evolution of large amounts of hydrogen bromide. This fact is in agreement with the properties to be expected of the tertiary bromide (I).



I II

The relatively lower yield of phenanthrene in this case is probably due to the many possibilities for further reaction of the hexahydrophenanthrene (II). The fact that 1-bromophenanthrene was isolated in one experiment is in harmony with the results obtained with decalin. The structure of the brominated phenanthrene was proved by comparison with an authentic sample[4]; both samples were oxidized with chromic anhydride to yield 1-bromo-9,10-phenanthrenequinone[5] (m. p. 238–240°).

Equimolar amounts of decalin and N-bromosuccinimide reacted in the presence of benzoyl peroxide to form a tetrabromoöctalin as the major product. With 3.5–4.0 moles of N-bromosuccinimide a mixture of substances resulted from which there was isolated in addition to the tetrabromide, 1,5-dibromonaphthalene and a small amount of an isomer which melted at 76–78°.[6] The only evidence as to the structure of the tetrabromide was furnished by the observation that 9,10-octalin reacted readily with 4 moles of N-bromosuccinimide to yield the same tetrabromide; no hydrogen bromide was evolved in this reaction.

The formation of the tetrabromide from decalin is consistent with the idea that the N-bromosuccinimide bromination proceeds by way of a free radical intermediate.[7] Thus the intermediate (III) in the initial attack is stable only by virtue of its tertiary character, while the further reaction of 9,10-octalin in which the intermediate (IV) is a resonance-stabilized free radical, proceeds at a very much greater rate with resultant formation

(2) Linstead, *Ann. Repts. Chem. Soc.*, **33**, 294 (1936).

(3) Further work is in progress to test this method in cases where the usual dehydrogenations cause rearrangements.

(4) This sample was kindly furnished by Professor W. E. Bachmann; see Bachmann and Boatner, THIS JOURNAL, **58**, 2194 (1936).

(5) This is probably the same substance previously reported by Sandqvist, *Ber.*, **48**, 1149 (1915), m. p. 233–234°, and proved by him to be either 4- or 1-bromophenanthrenequinone. The bromophenanthrenequinone which melts at 126° must therefore be the 4-isomer.

(6) Although analytically pure this substance was never obtained in sufficiently large amounts to permit recrystallization to a pure isomer. 1,4-Dibromonaphthalene melts at 82°.

(7) Hey, *Ann. Repts. Chem. Soc.*, **41**, 191 (1944).

of a tetrabromide even with equimolar quantities of reactants.

Early attempts to aromatize cyclohexene by reaction with 2–3 moles of N-bromosuccinimide failed; however, 6 moles of the reagent produced a mixture of dibromobenzenes in 58% yield. The liquid mixture was found to be largely the meta isomer containing about one third of the solid para isomer. Since benzene does not react with N-bromosuccinimide at an appreciable rate, the dibromobenzenes must have resulted by aromatization of a dibromocyclohexene or dibromocyclohexadiene intermediate.[8]

Experimental[9]

sym-Octahydroanthracene and *sym*-octahydrophenanthrene were prepared by reaction of aluminum chloride with tetralin; they were separated and purified by the method of Schroeter.[10] *as*-Octahydrophenanthrene was prepared by cyclization of 1-β-phenylethyl-1-cyclohexanol with sulfuric acid[11] and 9,10-octalin was prepared according to the direction of Bartlett, Condon and Schneider.[12] The other hydrocarbons used in this work were purified commercial products.

The procedures used in carrying out the dehydrogenations are illustrated by the following examples.

Dehydrogenation of Tetralin.—A mixture of tetralin (250 mg.), N-bromosuccinimide (680 mg.), benzoyl peroxide (10 mg.) and carbon tetrachloride (15 ml.) was refluxed for thirty minutes. No hydrogen bromide was liberated during this time.[13] Potassium acetate (3 g.) and acetic acid (1 ml.) were added and the mixture refluxed for an additional half hour. The reaction mixture was poured onto ice and sodium hydroxide (2 g.). The product was isolated by ether extraction and evaporation of the solvents. The crude crystalline product was sublimed at atmospheric pressure to yield 180 mg. (74%) of pure naphthalene, m. p. and mixed m. p. 79–80°.

Dehydrogenation of *as*-Octahydrophenanthrene.—A solution of the hydrocarbon (0.93 g., $n^{25}\text{D}$ 1.5519) in carbon tetrachloride was refluxed with N-bromosuccinimide (3.56 g.), benzoyl peroxide (200 mg.), potassium acetate (4 g.) and acetic acid (5 ml.) for four hours. The reaction mixture was poured into water and extracted with benzene. The residue after evaporation of the solvents was sublimed at 20 mm. to give 445 mg. of a sticky solid which after two recrystallizations from methanol melted at 96.5–98°; yield 187 mg. (21%). A mixture of this sample and phenanthrene melted at 97–99°; both samples formed picrates which melted at 143–144° separately or when mixed.

The mother liquors from the crystallization contained an oil which gave a positive qualitative test for bromine, however, in all but one experiment no brominated compounds were isolated in pure form. This experiment differed from the others only in that the N-bromosuccinimide used (5.5 moles) was a finely powdered mixture containing 0.1 mole per cent of benzoyl peroxide which had been allowed to stand for several days before use. After sublimation and recrystallization from methanol there was isolated 320 mg. (12% based on 1.48 g. of hydrocarbon) of a substance which melted at 109–110°. A mixed melting point of this sample with an authentic sample of 1-bromophenanthrene[4] showed no depression. Both of the samples were oxidized with chromic anhydride in acetic acid to yield the same 1-bromophenanthrenequinone which melted at 238–240°.

Anal. Calcd. for $C_{14}H_7O_2Br$: C, 58.56; H, 2.46. Found: C, 58.98; H, 2.71. The melting point of a mixture of this substance with 2-bromophenanthrenequinone (m. p. 233–234°) prepared by bromination of phenanthrene[14] was 190–208°.

Reaction of Decalin with N-Bromosuccinimide.—A mixture of decalin (2.76 g.), N-bromosuccinimide (3.56 g.), benzoyl peroxide (200 mg.) and carbon tetrachloride (40 ml.) was refluxed until the solution became colorless (twenty minutes). The reaction mixture was washed with water and the carbon tetrachloride removed. The unchanged decalin was distilled on the water-pump, leaving a residue which crystallized on cooling. Two recrystallizations from ethyl acetate yielded *x*-tetrabromooöctalin which melted at 188–189°.

Anal: Calcd. for $C_{10}H_{12}Br_4$: C, 26.58; H, 2.68; Br, 70.74. Found: C, 25.97; H, 2.81; Br, 71.00.

x-Tetrabromoöctalin (1.35 g.) was the only product isolated from the reaction of 9,10-octalin (1.36 g.) with N-bromosuccinimide (7.12 g.). No hydrogen bromide was evolved in this reaction.

By reaction of decalin (5.0 g.) with 4 moles of N-bromosuccinimide there resulted a semi-solid product which was fractionally crystallized from ethyl acetate and ethanol to yield 2.3 g. (14%) of *x*-tetrabromoöctalin, 1.0 g. (9%) of 1,5-dibromonaphthalene (m. p. 127–129°) and 20 mg. of a substance which melted at 76–78°.

Anal. Calcd. for $C_{10}H_6Br_2$: C, 41.99; H, 2.11. Found: C, 41.54; H, 1.96.

The structure of 1,5-dibromonaphthalene was proved by comparison with an authentic sample prepared from 5-bromo-1-naphthylamine[15] by the method of Hodgson and Whitehurst.[16]

Reaction of Cyclohexene with N-Bromosuccinimide.—Cyclohexene (6.15 g.) was dissolved in carbon tetrachloride (75 ml.) and refluxed for twelve hours with N-bromosuccinimide (80 g.); benzoyl peroxide (3 g.) was added in several portions during this time. The carbon tetrachloride was removed and the residue washed with water, dried and distilled to yield 10 g. (58%) of crude dibromobenzenes which boiled at 215–225°. This material was redistilled at 22 mm. through a 45-cm. Podbielniak column, b. p. 102–103°.

Anal. Calcd. for $C_6H_4Br_2$: C, 30.55; H, 1.70. Found: C, 30.74; H, 1.68.

The redistilled product solidified at −15° and the last trace of solid had melted at 10°. A solution of the mixture (1.0 g.) in petroleum ether (20 ml.) was cooled to −30° and filtered quickly; this procedure was repeated to yield 185 mg. of *p*-dibromobenzene, m. p. and mixed m. p. 86–87°. The petroleum ether was removed from the filtrate and the residue treated with fuming nitric acid (8 ml.) at 0°. The reaction mixture was poured into water and the solid product was filtered and pressed dry on a porous plate, m. p. 55–57°. Crystallization from dilute methanol yielded 640 mg. of 2,4-dibromonitrobenzene which melted at 61.5–62°. This substance and 3,4-dibromonitrobenzene[17] (m. p. 58.5–59°) liquified when mixed at room temperature.

Summary

A procedure has been described for the conversion of hydroaromatic to aromatic compounds at a lower temperature than by the usual methods.

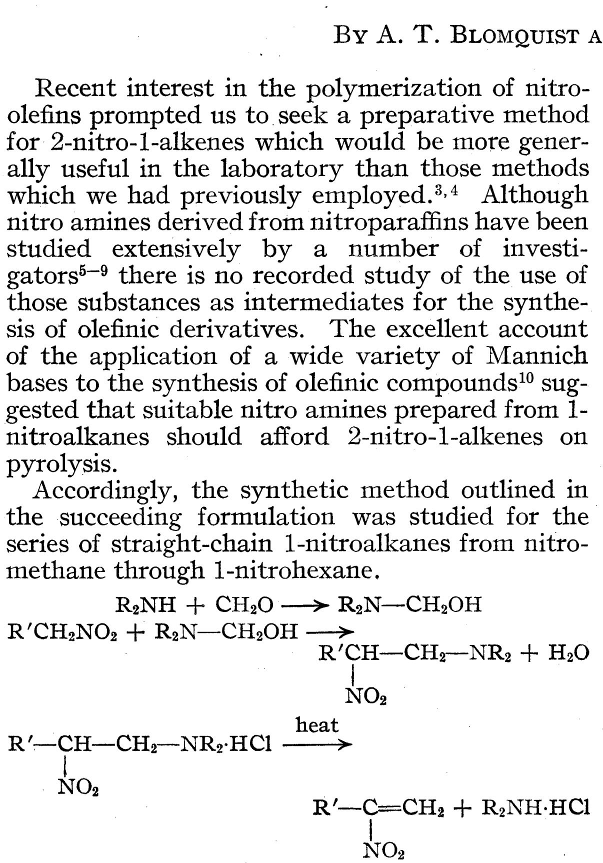
Preparation of 2-Nitro-1-alkenes from Nitro Amines[1]

BY A. T. BLOMQUIST AND T. H. SHELLEY, JR.[2]

Recent interest in the polymerization of nitroolefins prompted us to seek a preparative method for 2-nitro-1-alkenes which would be more generally useful in the laboratory than those methods which we had previously employed.[3,4] Although nitro amines derived from nitroparaffins have been studied extensively by a number of investigators[5–9] there is no recorded study of the use of those substances as intermediates for the synthesis of olefinic derivatives. The excellent account of the application of a wide variety of Mannich bases to the synthesis of olefinic compounds[10] suggested that suitable nitro amines prepared from 1-nitroalkanes should afford 2-nitro-1-alkenes on pyrolysis.

Accordingly, the synthetic method outlined in the succeeding formulation was studied for the series of straight-chain 1-nitroalkanes from nitromethane through 1-nitrohexane.



$$R_2NH + CH_2O \longrightarrow R_2N{-}CH_2OH$$

$$R'CH_2NO_2 + R_2N{-}CH_2OH \longrightarrow \underset{\displaystyle NO_2}{R'CH}{-}CH_2{-}NR_2 + H_2O$$

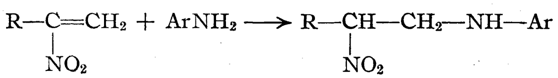
$$\underset{\displaystyle NO_2}{R'{-}CH}{-}CH_2{-}NR_2{\cdot}HCl \xrightarrow{\text{heat}} \underset{\displaystyle NO_2}{R'{-}C}{=}CH_2 + R_2NH{\cdot}HCl$$

Following the procedure of Cerf,[6] Senkus[8] and of Johnson,[9] nitro amines derived from diethylamine, formaldehyde and the 1-nitroalkanes 1-nitropropane through 1-nitrohexane were obtained readily in excellent yield (70–80%) as colorless to pale-yellow liquids which could be distilled without decomposition under reduced pressure. The base derived from nitroethane and diethylamine, however, decomposed violently when its distillation was attempted. By substituting piperidine for diethylamine nitroethane formed a nitroamine which could be purified by distillation without difficulty. Nitromethane, under all conditions studied, afforded only a di-substituted base when treated with N-hydroxymethylpiperidine.

Pyrolysis of the free nitro amines derived from the nitroparaffins was not regarded as a suitable method for obtaining the desired nitroölefins for several reasons. Nitroölefins are known to be reactive toward amines[11,12] and their polymerization is catalyzed by bases.[3] On the other hand, pyrolysis of the nitro amine hydrochlorides would obviate these difficulties. It was observed that thermal decomposition of the several nitro amine hydrochlorides proceeded smoothly and rapidly at moderate temperatures. Initial decomposition started at temperatures in the neighborhood of 100–115° and was complete by gradually raising the pyrolysis temperature to 165–175°. By carrying out the decompositions under reduced pressure (50–100 mm.) the nitroölefins were all removed rapidly from the zone of heating. The several nitroölefins were obtained as blue-green, lachrymatory liquids in excellent yield after purification by redistillation (70–80%).

Since it was not possible to convert nitromethane into a suitable nitro amine, nitroethylene could not be prepared by the procedure described above.

In searching for solid derivatives which might be used to characterize the 2-nitro-1-alkenes attention was given the reaction of aromatic amines with nitroölefins first reported by Wieland and Sakellarios[11] and extended by Worrall.[12] According to these investigators primary aromatic amines should add to the 2-nitro-1-alkenes as follows



$$\underset{\displaystyle NO_2}{R{-}C}{=}CH_2 + ArNH_2 \longrightarrow \underset{\displaystyle NO_2}{R{-}CH}{-}CH_2{-}NH{-}Ar$$

p-Toluidine added rapidly and smoothly to the nitroölefins affording solid crystalline derivatives which were easily purified. Unfortunately, the melting points of all of the *p*-toluidine derivatives prepared were found to lie in a rather narrow temperature range (*ca.* 68–82°).

Some evidence bearing on the structure of these derivatives was obtained through an independent synthesis of one of them, namely, N-(2-nitrobutyl)-*p*-toluidine. It was prepared di-

rectly from 1-nitropropane by condensation with one mole each of *p*-toluidine and formaldehyde according to the method of Johnson.[9] Treatment of 1-nitropropane with two moles of *p*-toluidine and of formaldehyde gave a di-substituted *p*-toluidine derivative, 2-nitro-2-ethyl-1,3-bis-(*p*-toluino)-propane.

Acknowledgment.—The authors wish to express their gratitude to Miss Lois Ann Capella who assisted in much of the preparative and analytical work.

Experimental[13]

Nitroparaffins.—Nitromethane, nitroethane and 1-nitropropane, obtained from the Commercial Solvents Corporation, were freshly distilled before use.

1-Nitrobutane, 1-nitropentane and 1-nitrohexane were prepared by the method of Victor Meyer.[14]

Nitro Amines.—These were prepared by the condensation of the appropriate nitroparaffin with a suitable N-hydroxymethylamine. The preparation of N-(2-nitrobutyl)-diethylamine illustrates the general procedure.

To a solution of 73 g. (1 mole) of redistilled diethylamine in an equal volume of water contained in a 1-liter flask fitted with stirrer, thermometer, dropping funnel and condenser there was added dropwise with rapid stirring 84 cc. (1.0 mole) of formalin (36% solution) over a period of half an hour. The temperature was maintained at 18° during the addition. The reaction mixture was then stirred at room temperature for an additional half hour after the addition of formalin was completed. To this aqueous solution of the N-hydroxymethylamine there was added all at once with rapid stirring 89 g. (1 mole) of 1-nitropropane. This addition was accompanied by an 8–10° rise in temperature. Rapid stirring of the mixture was continued for three to four hours. The two-layer mixture was then extracted with 100 cc. of ether, and the aqueous layer again extracted with 20 cc. of ether following the addition of 10 g. of sodium chloride. The ether solutions were combined, dried with anhydrous magnesium sulfate and distilled under reduced pressure. After removal of the ether the nitro amine was obtained by distillation at 2 mm. pressure under nitrogen. **N-(2-Nitrobutyl)-diethylamine**, 138 g. (79%), was obtained as a pale yellow liquid; b. p. 79° (2 mm.), n^{20}D 1.4405.

Anal. Calcd. for $C_8H_{18}N_2O_2$: mol. wt., 174. Found (by titration): mol. wt., 178, 180.

Some decomposition occurred when the product was distilled at 14 mm. as described by Cerf.[6]

Using the procedure outlined above, the following nitroamines were prepared in 70–75% yield.

N-(2-Nitroamyl)-diethylamine; b. p. 84° (1 mm.), n^{20}D 1.4421. *Anal.* Calcd. for $C_9H_{20}N_2O_2$: mol. wt., 188. Found (by titration): mol. wt., 191, 186.

N-(2-Nitrohexyl)-diethylamine; b. p. 91–93° (1 mm.), n^{20}D 1.4447. *Anal.* Calcd. for $C_{10}H_{22}N_2O_2$: mol. wt., 202. Found (by titration): mol. wt., 204, 202.

N-(2-Nitroheptyl)-diethylamine; b. p. 102–103° (1 mm.), n^{20}D 1.4465. *Anal.* Calcd. for $C_{11}H_{24}N_2O_2$: mol. wt., 216. Found (by titration): mol. wt., 222, 220.

N-(2-Nitropropyl)-diethylamine.—This base derived from nitroethane, when prepared by the general procedure, decomposed violently when attempts were made to distil it at low pressures (1 mm.). However, a product of reasonable purity was obtained by working up the usual reaction mixture from nitroethane and N-hydroxymethyldiethylamine in the following manner. The organic layer was washed three times with cold water, dried over Drierite in the refrigerator for fourteen hours, and finally stripped of low-boiling material by heating to 45° for forty-five minutes under nitrogen at 2 mm. This gave an 83% yield of a golden-yellow liquid; n^{25}D 1.4420, d^{20}_4 0.9751; *MR*D calcd., 44.1; found, 43.1.

N-(2-Nitropropyl)-piperidine.—This base derived from nitroethane and N-hydroxymethylpiperidine was obtained in 41% yield and could be distilled; b. p. 87° (1 mm.), n^{20}D 1.4469.

Anal. Calcd. for $C_8H_{15}N_2O_2$: mol. wt., 171. Found (by titration): mol. wt., 178, 176.

2-Nitro-2-methyl-1,3-bis-(N-piperidyl)-propane.—This substance was formed as an accessory product in the preparation of N-(2-nitropropyl)-piperidine and was isolated as a residue in the distillation of the nitropropylpiperidine. From a 0.5 mole run there was obtained 6 g. of solid material which after crystallization from ethyl alcohol melted at 101.5–102°.[15]

Anal. Calcd for $C_{14}H_{27}N_3O_2$: N, 15.60. Found: N, 15.75.

2-Nitro-1,3-bis-(N-piperidyl)-propane.—All attempts to effect the condensation of nitromethane with N-hydroxymethylamines in a 1:1 mole ratio were unsuccessful. Regardless of the proportion of reactants and the mode of addition nitromethane always condensed with 2 moles of the N-hydroxymethylamine. Thus with N-hydroxymethylpiperidine only 2-nitro-1,3-bis-(N-piperidyl)-propane was formed. Henry[16] claims to have prepared this compound but did not describe its preparation and properties, nor did he report its analysis.

Addition of 0.5 mole of nitromethane to an aqueous solution containing 0.5 mole of N-hydroxymethylpiperidine gave 54 g. (85% based on the amine) of crude product which was obtained as light tan crystals from ethyl alcohol, m. p. 93.5–94°.

Anal. Calcd. for $C_{13}H_{25}N_3O_2$: C, 61.14; H, 9.85; N, 16.46; mol. wt., 255. Found: C, 61.26; H, 9.90; N, 16.57; mol. wt. (cryoscopic in benzene), 253.

This substance was also prepared by adding 2 g. of piperidine to a solution of 1 g. of 2-nitro-1,3-propanediol in 10 cc. of methyl alcohol. After refluxing the mixture for two hours, 1 g. of crystalline material separated on cooling which, after recrystallization from ethyl alcohol, melted at 93.5–94°. A m. p. of a mixture of this preparation and the material obtained from nitromethane showed no depression.

2-Nitro-1-alkenes.—The nitroölefins were obtained by pyrolysis of the respective nitro amine hydrochlorides under reduced pressure. By operating under reduced pressure the nitroölefin was removed rapidly from the zone of heating and losses resulting from thermal polymerization were minimized. As the various nitroölefins were prepared by essentially the same procedure only one of these is described in detail.

2-Nitro-1-pentene.—The hydrochloride of N-(2-nitroamyl)-diethylamine was prepared by passing dry hydrogen chloride for four hours into a cooled stirred solution of 58.2 g. (0.31 mole) of the amine in four times its volume of dry toluene. The initially formed white precipitate later redissolved upon the continued passage of the hydrogen chloride to yield a blue-green solution.[17] This solution was transferred to a 500-cc. Claisen flask and after removal of the toluene and excess hydrogen chloride by heating with a water-bath (final bath temperature 70°) at 50 mm. pressure a white solid remained. Heating was then continued with an oil-bath and at a regulated pressure of 100 mm. The solid began to melt at 90° while at 115–120° it started to decompose smoothly to yield a blue-green liquid distilling at 110–115° (vapor temperature). The pyrolysis was complete within forty-five

---

[13] All melting points and boiling points are uncorrected.

[14] Meyer, *et al.*, *Ann.*, **171**, (1874); **175**, 88 (1875); **180**, 111 (1876).

[15] Henry reported a m. p. of 98–99°; *cf.* ref. 4.

[16] Henry, *Ber.*, **38**, 2027 (1905).

[17] This curious solubility behavior was also observed for the nitro amine hydrochlorides derived from 1-nitropentane and 1-nitrohexane. In preparing the hydrochloride of N-(2-nitrobutyl)-diethylamine in toluene two liquid layers were formed. The hydrochloride of N-(2-nitropropyl)-piperidine separated quantitatively from toluene as a crystalline solid.

minutes with the final temperature within the flask being 165°. The crude distillate, 35.2 g. (99%), was dissolved in ether, the ether solution washed with water and dried over anhydrous magnesium sulfate in the refrigerator. After removal of the ether the crude product was distilled under reduced pressure using a 14 × 0.75 in. column packed with 0.75 in. glass helices. There was obtained 25 g. (75%) of pure product; b. p. 68° (50 mm.), $n^{20}D$ 1.4403.

Anal. Calcd. for $C_5H_9NO_2$: N, 12.17. Found: N, 12.28.

The residue in the pyrolysis was shown to be diethylamine hydrochloride by its m. p. after crystallization from ethyl alcohol (220–224°, lit. 215–223°) and conversion to its benzenesulfonyl derivative, m. p. 59–60°.

2-Nitropropene was obtained similarly by pyrolysis at 105–160° of the hydrochloride of N-(2-nitropropyl)-piperidine under 70 mm. pressure in 50% yield. It was identical with the 2-nitropropene prepared by other methods.[3]

2-Nitro-1-butene was obtained in 73% yield by pyrolysis of the hydrochloride of N-(2-nitrobutyl)-diethylamine at 100–175° under 100 mm. pressure; b. p. 60.5° (50 mm.), $n^{20}D$ 1.4356. It was identical with an authentic sample of 2-nitro-1-butene synthesized by pyrolysis of the benzoate of 2-nitro-1-butanol.[18]

2-Nitro-1-hexene was obtained in 70% yield by pyrolysis of N-(2-nitrohexyl)-diethylamine at 105–165° under 50 mm. pressure; b. p. 81–82° (50 mm.), $n^{20}D$ 1.4462.

Anal. Calcd. for $C_6H_{11}NO_2$: N, 10.86. Found: N, 10.89.

2-Nitro-1-heptene was obtained in 70% yield by pyrolysis of N-(2-nitroheptyl)-diethylamine at 110–150° under 50 mm. pressure; b. p. 93–94° (30 mm.), $n^{20}D$ 1.4482.

Anal. Calcd. for $C_7H_{11}NO_2$: N, 9.76. Found: N, 9.85.

p-Toluidine Derivatives of the 2-Nitro-1-alkenes.—Solid derivatives of the nitroölefins were readily obtained through reaction with *p*-toluidine. The general procedure used in their preparation is described. To 5 g. of the pure 2-nitro-1-alkene, cooled to 0–5°, there was added an equivalent amount of *p*-toluidine. The solution became warm and deep red in color. After maintaining the reaction mixture at 60° for five minutes it was cooled to room temperature and the crude product crystallized. Pure derivatives, as bright yellow solids, were obtained in 80–95% yield after one recrystallization from ethyl alcohol. These compounds are listed in Table I.

TABLE I

N-(2-NITROALKYL)-*p*-TOLUIDINES

Compound, *p*-toluidine	M. p., °C.	N analyses, % Calcd.	N analyses, % Found
N-(2-Nitropropyl)-	81.5–82.5	14.42	14.38
N-(2-Nitrobutyl)-	67.5–68.5	13.45	13.37
N-(2-Nitroamyl)-	72 –72.5	12.60	12.86
N-(2-Nitrohexyl)-	68.5–69	11.86	12.18
N-(2-Nitroheptyl)-	72.5–73.5	11.19	11.51

The *p*-toluidine derivatives of samples of 2-nitropropene and 2-nitro-1-butene prepared by other methods[3] were identical with those described in Table I.

N-(2-Nitrobutyl)-*p*-toluidine (Table I) was also prepared by an independent method. Using the procedure of Johnson,[9] 1-nitropropane, formaldehyde and *p*-toluidine reacted to give a 26% yield of the crude *p*-toluidine derivative, m. p. 60–66°. After recrystallization from methanol its m. p., 67.5–68.5°, was not depressed when mixed with the toluidine derivative prepared from 2-nitro-1-butene.

2-Nitro-2-ethyl-1,3-bis-(*p*-toluino)-propane, a di-substituted *p*-toluidine derivative, was prepared as a check on the mono-substituted derivative described above. To a refluxing mixture of 107 g. (1 mole) of *p*-toluidine, 44.5 g. (0.5 mole) of 1-nitropropane, 1 g. of potassium hydroxide and 300 cc. of ethyl alcohol, 82 g. (1 mole) of 37% formalin solution was added over a period of six hours. After refluxing an additional two hours and standing at room temperature for two days the mixture was cooled in ice and filtered. There was obtained 35 g. (25%) of light tan crystals melting at 101–102° which were recrystallized from ethyl alcohol, m. p. 103–104°.

Anal. Calcd. for $C_{19}H_{25}N_3O_2$: N, 12.84. Found: N, 12.73.

Summary

A series of 2-nitro-1-alkenes has been readily obtained by thermal decomposition of appropriate nitro amine hydrochlorides derived from 1-nitroalkanes.

The 2-nitro-1-alkenes may be characterized by crystalline solid derivatives formed by their reaction with *p*-toluidine.

Reactions with Tetraphenylcyclopentadienone. II. Condensation with 1-Phenyl-1,3-butadiene[1]

BY OLIVER GRUMMITT AND ERNEST I. BECKER[2]

2,3,4,5-Tetraphenylcyclopentadienone (tetracyclone) is of interest in diene chemistry through its addition reactions with α,β-unsaturated carbonyl compounds[3] and with conjugated dienes.[4,5] In the case of butadiene the adduct contains two tetracyclone groups as the result of 1,2 and 3,4 addition at the 2,5 positions of the tetracyclone ring.[4] With cyclopentadiene only one tetracyclone reacts, the addition occurring at the 2,3 double bond and at the 2,5 positions of tetracyclone.[5]

These addition reactions are usually considered

to be Diels–Alder reactions.[6] Although tetracyclone has an α,β-unsaturated carbonyl group, and therefore might behave as a dienophile, it characteristically reacts as a conjugated diene. In the presence of tetracyclone a conjugated diene behaves as a dienophile. In terms of the structures associated with typical Diels–Alder reactions, tetracyclone and the diene show reversed functions.

A survey of the addition reactions of 1-phenyl-1,3-butadiene has shown that most reagents preferentially add 3,4 instead of 1,2 or 1,4.[7] Furthermore, unsymmetrical reagents which add 3,4 usually obey Markownikoff's rule. Since styrene also shows normal addition in most cases, this behavior of phenylbutadiene is in accord with the principle of vinylogy.[8] As a continuation of the study of the mode of addition of both tetracyclone and phenylbutadiene, an investigation of the reaction of these compounds is reported here.

Although 1-phenyl-1,3-butadiene has been made by several different reactions,[7] the synthesis of this hydrocarbon in good yields proved to be quite difficult. The reaction of cinnamaldehyde and methylmagnesium bromide to give methylstyrylcarbinol followed by dehydration of this carbinol was tried first.[9] Although the carbinol can be made in 80–90% yields, dehydration of it gave poor yields because of rapid polymerization of the hydrocarbon during dehydration. The relatively high boiling point of phenylbutadiene aggravates this problem, because it cannot be quickly removed from the reaction mixture, as is possible for lower boiling hydrocarbons.

von der Heide[10] modified this synthesis by hydrolyzing the intermediate Grignard addition compound in acid solution so that phenylbutadiene was formed without isolation of the methylstyrylcarbinol. This reaction also gave low yields until the conditions of hydrolysis were thoroughly explored. By hydrolysis in 30% sulfuric acid solution under carefully controlled conditions of time and temperature, it is now possible to prepare 1-phenyl-1,3-butadiene consistently in 70–80% yields.

In the absence of an inhibitor phenylbutadiene polymerizes more rapidly than 1,3-butadiene.[11] To facilitate work with this compound several inhibitors were tested at a concentration of 1% and at a temperature of 100°. The experiments summarized in Table I were run by noting the time required for samples to flow vertically in 7-mm. reaction tubes. The interval of time elapsed for the flow time to exceed one second was arbitrarily taken as the inhibition period.

TABLE I

POLYMERIZATION INHIBITORS FOR 1-PHENYL-1,3-BUTADIENE[12]

Inhibitor	Inhibition period, hr.
Blank	<9.5
Picric acid	21
m-Dinitrobenzene	21
Phenyl-β-naphthylamine	21
Diphenylamine	21
Triphenylamine	<9.5
p-Phenylenediamine	<9.5
Hydroquinone	<9.5
t-Butylcatechol	5
Benzoquinone	9.5
Chloranil	5

The aromatic nitro compounds and certain of the amines are considerably more effective than the phenols and quinones. Phenyl-β-naphthylamine was selected as the most suitable inhibitor. It is interesting to note that this compound is relatively less effective for styrene and 3,4-dichlorostyrene.[13]

Tetracyclone and 1-phenyl-1,3-butadiene were found to react almost quantitatively at 80° in a 1/1 mole ratio, thus resembling the addition to cyclopentadiene.[5] Two structurally isomeric products are possible (chart 1): (A) is the result of 1,2 addition and (B) of 3,4 addition. Since the reaction product was a single compound, it presumably had either the (A) or (B) structure. To establish this structure it was desirable to convert the six-membered ring to a benzenoid ring. As the first step in this process, an effort was made to eliminate the endocarbonyl group by thermal decomposition. However, this characteristic reaction of endocarbonyl compounds[6b] could not be carried out because of a competitive dissociation of the adduct to tetracyclone and phenylbutadiene.[14]

In order to stabilize the adduct it was hydrogenated with the consumption of one equivalent of hydrogen. If the structure of the adduct is assumed to be (B), hydrogenation probably occurred in the styryl side chain (C), since Dilthey[15] has shown the ring double bond to be stable under the conditions employed here. The hydrogenated adduct proved to be sufficiently resistant to decomposition that heating at 180° or above eliminated the endocarbonyl group to give the cyclohexadiene derivative (D). Aromatization of (D) was effected by chloranil at 140° or by palladium on charcoal at 240°. Decarbonylation and aromatization occurred consecutively when (C) was refluxed in *p*-cymene with the palladium catalyst.

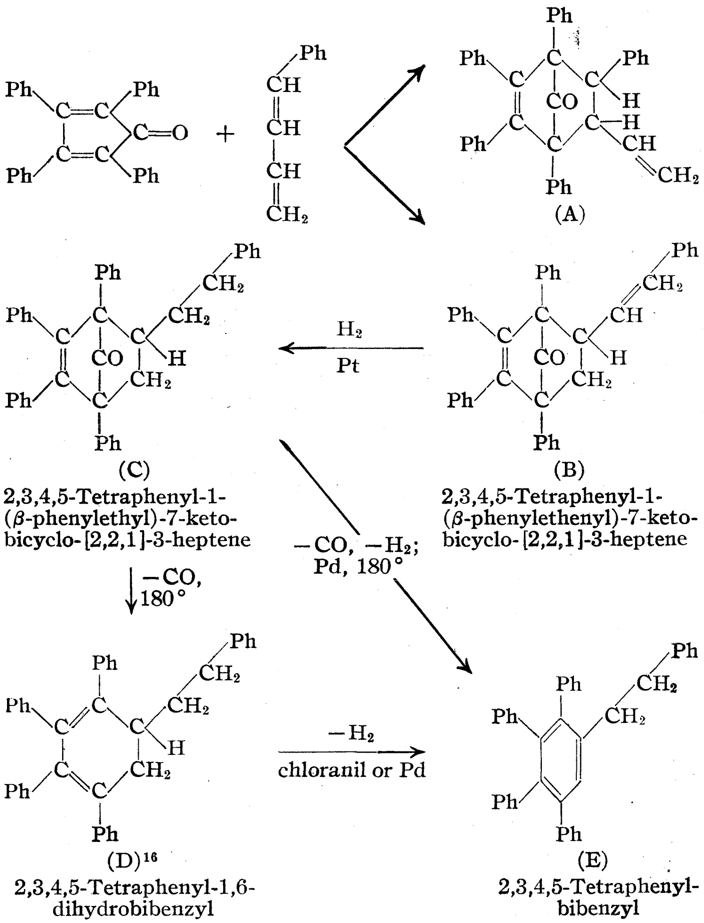
CHART 1



(A)

(B)
2,3,4,5-Tetraphenyl-1-(β-phenylethenyl)-7-keto-bicyclo-[2,2,1]-3-heptene

(C)
2,3,4,5-Tetraphenyl-1-(β-phenylethyl)-7-keto-bicyclo-[2,2,1]-3-heptene

(D)[16]
2,3,4,5-Tetraphenyl-1,6-dihydrobibenzyl

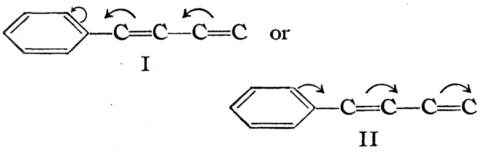
(E)
2,3,4,5-Tetraphenylbibenzyl

The final product (E) is 2,3,4,5-tetraphenylbibenzyl, or, if adduct (A) had formed, the corresponding product is pentaphenylethylbenzene.

Attempts to establish the structure of the benzene derivative by oxidation to tetraphenyl- or pentaphenylbenzoic acid were unsuccessful. However, the non-crystallizable oxidation products responded to qualitative tests for a benzoin, thus pointing to structure (E). Conclusive evidence for (E) was obtained by an independent synthesis from tetracyclone with 4-phenyl-1-butyne[17] or with 4-phenyl-2-bromo-1-butene.

The authentic 2,3,4,5-tetraphenylbibenzyl from these reactions proved to be identical with the product (E) from the tetracyclone–phenylbutadiene sequence of reactions. Therefore, tetracyclone added 3,4 to 1-phenyl-1,3-butadiene in preference to 1,2 addition. This result is in accord with most addition reactions of this diene.[7]

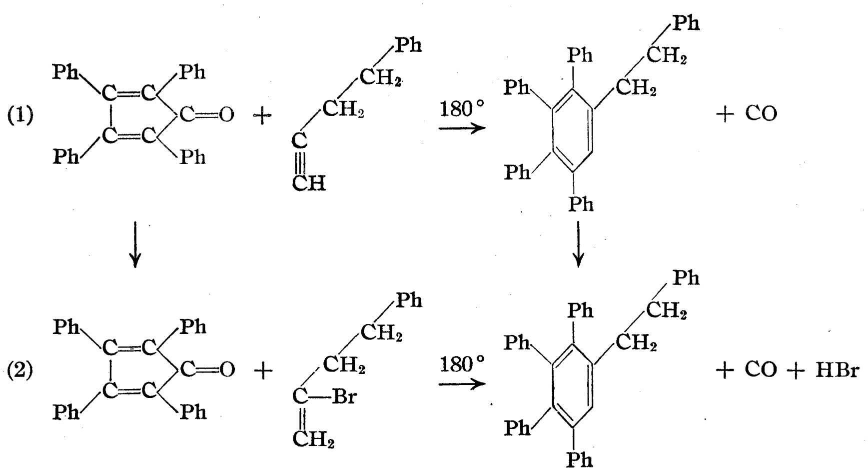
The explanation for the preferential 3,4 addition is two-fold: first, the steric hindrance from the phenyl group at the 1,2 double bond would favor 3,4 addition, especially in the case of large molecules such as tetracyclone.[18] Possibly of greater importance is the nature of the activated phenylbutadiene molecule. According to the usual electronic interpretations,[19] the butadienyl side chain could be activated in the course of addition of polar reactants by electron displacements toward or away from the ring



I

II

Because of the *conjugated* bonds in the side chain this polarization affects *both* double bonds, thus making addition to either double bond theoretically possible, but also creating the greatest relative charge on the terminal carbon atom. There-



---

[16] The position of the double bonds in this compound was not established.

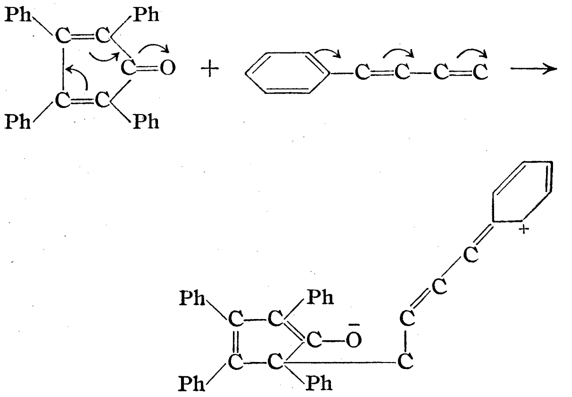
[17] Tetracyclone reacts with acetylene, phenylacetylene and other acetylenic compounds by addition to the triple bond. The resulting endocarbonyl derivatives very readily lose carbon monoxide. See Dilthey, *et al.*, *Ber.*, **66B**, 1627 (1933).

[18] In the addition of maleic anhydride (Robey, Morrell and Weise, THIS JOURNAL, **63**, 627 (1941)) and of sulfur dioxide (Craig, *ibid.*, **65**, 1006 (1943)) to piperylene, it has been shown that the steric hindrance from the methyl group in the *cis* piperylene will retard addition, but the *trans* isomer shows normal reactivity. The phenylbutadiene used in this experiment is very likely a mixture of geometric isomers (Wright, *J. Org. Chem.*, **1**, 457 (1936)). Presumably, the steric factor would be significant only in the case of the *cis* isomer.

[19] Wheland, "The Theory of Resonance," John Wiley and Sons, Inc., New York, N. Y., 1944, p. 245.

fore addition is usually initiated at this point with the result that 3,4 addition occurs more frequently. The direction of the polarization is postulated as in II, *i. e.*, the ring acts as an electron donor, in order to account for the normal addition of unsymmetrical reagents.[20]

The reactivity of tetracyclone in this reaction would result from a polarization in its conjugated system to make carbon atom 5 electrophilic. Thus the first step in the addition



This activated intermediate complex can have various structures. The form in which ring closure occurs to give the adduct (B) would have a nucleophilic number 2 carbon atom in tetracyclone and an electrophilic number 3 carbon atom in phenylbutadiene. This mechanism, which is comparable to that frequently proposed for orthodox Diels–Alder additions,[21] accounts for the behavior of tetracyclone as a conjugated diene rather than as an α,β-unsaturated carbonyl derivative.[22]

Experimental

Preparation of Reactants.—Tetraphenylcyclopentadienone was made by the condensation of benzil and dibenzyl ketone in alcoholic base.[15,23]

Since adequate directions for preparing 1-phenyl-1,3-butadiene are not in the literature, considerable time and effort were expended in finding the optimum conditions described here. In a 1-liter three-necked flask fitted with a mercury seal stirrer, reflux condenser protected with a calcium chloride tube, a 125-ml. dropping funnel, and a nitrogen inlet tube are placed 0.515 mole of methylmagnesium bromide in 250–350 ml. (1.5–2.0 *N*) of ether. The Grignard reagent is cooled to 0–10° with stirring and under a current of nitrogen, and a solution of 66.1 g. (0.5 mole) of cinnamaldehyde in 60 ml. of absolute ether is added so that the temperature does not exceed 10°. This addition requires about one hour. The cinnamaldehyde should be freshly purified by washing with sodium carbonate solution, then with water, dried over Drierite, and distilled under nitrogen; b. p. 101–102° (2–3 mm.), $n^{20}\text{D}$ 1.6195.

The contents of the reaction flask are transferred to a 500-ml. dropping funnel. The apparatus is reassembled, omitting the nitrogen inlet tube and drying tube, and 175 ml. of 30% (by weight) sulfuric acid placed in the flask. With vigorous stirring and without cooling, the Grignard addition compound is rapidly added to the acid solution. With an efficient reflux condenser this time of addition is five to seven minutes. The mixture is then heated at gentle reflux on the steam-bath until the *total* time of hydrolysis is twenty minutes. The conditions of this hydrolysis are very important in determining the yield of phenylbutadiene. Vigorous stirring was attained by a Hershberg[24] nichrome-wire stirrer run at 1500–1700 r. p. m. The time of addition and of reflux are critical in avoiding polymerization of the product and contamination by methylstyrylcarbinol.

The contents of the flask are *immediately* transferred to a 1-liter separatory funnel, the lower aqueous layer is discarded, and the ether solution is washed successively with (1) 50 ml. of water, (2) a mixture of 50 ml. of 5% sodium hydroxide solution and 50 ml. of saturated ammonium chloride solution, and (3) 50 ml. of water. Before each washing the air in the funnel is displaced by nitrogen. When the second wash solution is added, 0.3 g. of phenyl-β-naphthylamine is dissolved in the ether solution. The washed solution is dried with 20 g. of anhydrous sodium sulfate for one-half hour and then overnight with 15 g. of anhydrous potassium carbonate.

The ether solution is distilled to a volume of 80–100 ml. on the steam-bath, cooled, and dried further by shaking with 15 g. of potassium carbonate for five to ten minutes. The solution is filtered into a 125 ml. modified Claisen flask[25] and distilled under nitrogen at reduced pressure into a receiver containing 0.3 g. of phenyl-β-naphthylamine. The crude phenylbutadiene is collected at 81–85° (10–11 mm.); the yield is 52–54 g., 80–83% of the theoretical. To remove traces of water and methylstyrylcarbinol, this distillate is dried with 5 g. of potassium carbonate, filtered and redistilled. The distillate consists of 47–49 g. (72–75%), b. p. 78–81° (8 mm.), $n^{20}\text{D}$ 1.6070. The reactions with tetracyclone were run with this product.

A highly purified sample of 1-phenyl-1,3-butadiene was made by distilling the above product through a 12-plate, glass helix packed column of the total reflux variable take-off type and collecting a middle fraction representing about 50% of the sample taken. The following physical constants were noted: b. p. 86° (11 mm.), $n^{25}\text{D}$ 1.6088 ± 0.0002, d^{25}_4 0.9237 ± 0.0002. A qualitative test for nitrogen by sodium fusion and formation of Prussian blue was negative, showing that phenyl-β-naphthylamine had not distilled.

Anal. Calcd. for $C_{10}H_{10}$: C, 92.25; H, 7.75. Found: C, 92.25; H, 7.81.

Tetracyclone–Phenylbutadiene Adduct (B).—In a typical experiment 2.50 g. (0.019 mole) of 1-phenyl-1,3-butadiene, 7.00 g. (0.018 mole) of tetracyclone (m. p. 219–220°), and 0.01 g. of phenyl-β-naphthylamine in 50 ml. of reagent-grade benzene were refluxed on the steam-bath for four hours. No carbon monoxide, as indicated by tests with palladium chloride solution, was evolved. Benzene and unreacted phenylbutadiene were removed by steam distillation and the residual pink solid dried at 50° to give 9.40 g. (100%), m. p. 170–175° (dec.). Crystallization from 90 ml. of a 1:1 mixture of benzene and petroleum ether (b. p. 60–70°) gave 6.0 g. of almost colorless fine needles, m. p. 178–180° (dec.). A second crop weighed 2.05 g. and melted 177–180° (dec.). The behavior on melting is noteworthy: at 140–145° the colorless crystals began to turn pink. The color deepened with increasing temperature and at 178–181° the solid melts to a deep red liquid.

Anal. Calcd. for $C_{39}H_{30}O$: C, 91.02; H, 5.88; mol.

[21] Price, "Reactions at Carbon–Carbon Double Bonds," Interscience Publishers, Inc., New York, N. Y., 1946, p. 49.

[22] It is not suggested that all reactions of tetracyclone proceed by this mechanism. The addition of maleic anhydride and similar molecules probably differ in mechanism because of the electron deficient character of the carbon–carbon double bond in maleic anhydride.

[25] "Organic Syntheses," Coll. Vol. I, 130 (1941); Fig. 9(b).

wt., 515. Found: C, 91.11; H, 5.93; mol. wt., 517 (cryoscopic in benzene).[26]

This product is unsaturated with respect to bromine in bromobenzene and potassium permanganate in acetone. It does not give a positive ketone test with 2,4-dinitrophenylhydrazine reagent.[27] It is very soluble in benzene and acetone, moderately soluble in ethyl acetate, slightly soluble in ethyl alcohol and insoluble in petroleum ether. When a benzene or ethyl acetate solution is boiled, decomposition occurs, as shown by the formation of a pink color.

Attempted Decarbonylation of (B).—Experiments were run in refluxing toluene (b. p. 110°), chlorobenzene (b. p. 132°), bromobenzene (b. p. 155°), and *p*-cymene (b. p. 175°). For example, a solution of 1.0 g. of the addition compound (B) in 15 ml. of chlorobenzene was refluxed in a 25-ml. flask fitted with a nitrogen inlet tube. The top of the condenser was attached to a trap and to a gas bubbler containing 2–3 ml. of 0.025% palladium chloride. After two hours of refluxing no more carbon dioxide was evolved. The product, 0.8 g. of dark red solid melting 80–84°, was recovered by steam distillation, filtration, and drying at 50°. Repeated crystallization from benzene–petroleum ether (60–70°) gave only impure products of wide melting range. Examination of the solids under the microscope showed that fine, black crystals, closely resembling tetracyclone, were present. Varying the reaction temperatures by the use of other solvents gave no better results. Apparently the product of decarbonylation and the tetracyclone from dissociation could not be separated.

Hydrogenation of (B).—The hydrogenated addition compound (C) was made by low pressure hydrogenation of (B) in ethyl acetate solution with 5% palladium on charcoal as the catalyst. Ten and three-tenths grams (0.020 mole) of (B) in 200 ml. of absolute ethyl acetate plus 0.5 g. of catalyst was hydrogenated at about 30 lb. pressure in a Burgess–Parr apparatus. In three minutes the pressure drop indicated the consumption of 0.023 mole of hydrogen. After filtration of the catalyst, concentration of the filtrate to 120 ml., and cooling to 0°, 6.2 g. of colorless, thick flat crystals, m. p. 207–208.5° (dec.), was obtained. Two successive crops from the mother liquor made the total yield 7.64 g., 74% of the theoretical. Crystallization from 1:1 benzene–petroleum ether (60–70°) did not alter the melting point behavior.

Anal. Calcd. for $C_{39}H_{32}O$: C, 90.65; H, 6.25; mol. wt., 517. Found: C, 90.53; H, 6.34; mol. wt., 514 (cryoscopic in benzene).

This product is saturated with respect to bromine in bromobenzene but unsaturated to potassium permanganate in acetone. Unlike compound (B), a boiling benzene or ethyl acetate solution does not decompose it.

Decarbonylation of (C).—A solution of 8.0 g. (0.015 mole) of compound (C) in 200 ml. of purified *p*-cymene was refluxed under a current of nitrogen until a positive test for carbon monoxide with palladium chloride solution was no longer obtained. This required about twelve hours. After steam distillation of the product and crystallization from benzene–petroleum ether (60–70°), 6.1 g., 81%, of light orange crystals melting 142–144° were obtained. The decarbonylation can also be run in the absence of a solvent by heating (C) in an oil-bath at 220–225° for one hour under nitrogen, but the yield of product melting 142–144° was only 63%. Repeated crystallizations from benzene–petroleum ether (30–35°) and acetone–ethyl alcohol gave almost colorless crystals melting 145–146°.

Anal. Calcd. for $C_{38}H_{32}$: C, 93.39; H, 6.61; mol. wt., 489. Found: C, 93.65; H, 6.70; mol. wt., 488 (cryoscopic in benzene).

Compound (D) was unsaturated to both bromine and potassium permanganate solutions. The position of the double bonds was not established, but the structure shown in Chart 1 is very probable because the double bonds are conjugated with respect to each other and to the aromatic double bonds of the phenyl substituents.

Dehydrogenation of (D) with Chloranil.—A solution of 500 mg. (1.02 millimoles) of (D) and 264 mg. (1.07 millimoles) of chloranil (m. p. 298–300°) in 5 ml. of xylene was refluxed for twenty-four hours. After cooling and filtering to remove tetrachlorohydroquinone, the filtrate was washed twice with 10-ml. portions of 4% potassium hydroxide solution, once with water, and steam distilled to remove xylene. The residue was crystallized three times from benzene–petroleum ether (60–70°) to give 247 mg., 49% of the theoretical yield, of solid melting 129–131°.

Dehydrogenation of (D) with Palladium.—In the catalytic dehydrogenation apparatus described by Fieser[28] 0.98 g. (2.0 millimoles) of (D) and 0.2 g. of 5% palladium on charcoal were refluxed in 5 ml. of 1-methylnaphthalene (b. p. 238–240°)[29] for six hours. During this time 88% of the calculated amount of hydrogen was evolved. After steam distilling to remove the solvent and crystallization of the residue from benzene–petroleum ether (60–70°), there was obtained 0.81 g., 83% of the theoretical yield, melting 134–138°. A mixed melting point with the impure product from the chloranil dehydrogenation gave 133–137° and with compound (D), 125–142°. Compound (E) is saturated to both bromine and potassium permanganate. For analysis a sample melting 135–137° was made by recrystallization.

Anal. Calcd. for $C_{38}H_{30}$: C, 93.79; H, 6.21; mol. wt., 487. Found: C, 93.65; H, 6.27; mol. wt. (Rast camphor), 491.

Combined Dehydrogenation and Decarbonylation of (D).—A mixture of 4.0 g. (7.7 millimoles) of (C) and 0.5 g. of 5% palladium on charcoal in 100 ml. of *p*-cymene was refluxed for eight and one-half hours. Carbon monoxide was evolved until the last fifteen minutes of heating. After steam distilling and crystallizing from benzene–petroleum ether, the product consisted of 3.0 g. (80%) melting 136–140°. A mixed melting point with (D) of melting point 135–137° gave 136–140°. Further crystallizations of the 136–140° product did not purify it. It was concluded that the palladium catalyzed dehydrogenation of (D) was the best method of preparation.

Chromic Acid Oxidation of (E).—Several attempts were made to oxidize (E) to 2,3,4,5-tetraphenylbenzoic acid, but only oils or impure solids could be obtained. For example, a solution of 2.5 g. of chromium trioxide in 4 ml. of water and 4 ml. of acetic acid was added dropwise to a solution of 1.55 g. (3.2 millimoles) of (E) in 5 ml. of acetic acid. After the exothermic reaction subsided, the product was isolated by pouring the mixture onto ice, filtering, and washing the solid with water. The solid was dissolved in 50 ml. of 1:1 benzene–ether and this solution was extracted with 10 ml. of 5% sodium carbonate solution. Acidification of the alkaline extract gave only 10 mg. of brown solid melting 40–50°, which was not investigated further. The benzene–ether solution yielded an oil which could not be crystallized. When this oil was dissolved in alcoholic potassium hydroxide and heated, a deep red-purple color formed, reminiscent of the behavior of benzoin-benzil mixtures.[30] Attempts to oxidize the oil further with sodium peroxide were unsuccessful. The original aqueous filtrate was extracted with ether in a continuous extractor and the ether extract yielded about 0.1 g. of solid melting 116–120°, which was shown to be benzoic acid by a mixed melting point.

---

[26] The molecular depression constant used was 5.49 deg./mole. This value was found experimentally by carefully determining the freezing point depression of several solutions of pure naphthalene in benzene. The constant frequently given in the literature of 5.12 was determined under *equilibrium* conditions (Bury and Jenkins, *J. Chem. Soc.*, 688 (1934). Such conditions do not exist in the usual cryoscopic molecular weight determination.

4-Phenyl-2-bromo-1-butene.—Although the synthesis of this compound has been reported,[31] the difference in boiling points observed makes it desirable to give the details of this synthesis. Benzylmagnesium chloride, made from 25.3 g. (0.20 mole) of distilled benzyl chloride (b. p. 72–73° (24 mm.)) and 4.9 g. (0.20 atom) of magnesium in 100 ml. of absolute ether, was added to 40 g. (0.20 mole) of 2,3-dibromo-1-propene[32] (b. p. 73–76° (75 mm.)) in 100 ml. of absolute ether so as to maintain a slow reflux. The mixture was then refluxed for two hours, followed by hydrolysis in 80 ml. of saturated ammonium chloride solution and 120 g. of ice. The ether layer was washed, dried, etc., and vacuum distilled; the forerun consisted of 12 g. of 2,3-dibromo-1-propene and the 4-phenyl-2-bromo-1-butene distilled at 85–87° (4–5 mm.). A residue of 11.1 g. was crystallized from methyl alcohol and shown to be bibenzyl by a mixed melting point. After twice redistilling the product, a fraction boiling 90–91° (4–5 mm.) showed d^{25}_{4} 1.2860 and n^{25}_{D} 1.5467. Previously reported[31]: b. p. 77–78° (5 mm.), d^{20}_{4} 1.2901, n^{20}_{D} 1.5450.

Anal. Calcd. for $C_{10}H_{11}Br$: C, 56.89; H, 5.25; Br, 37.86. Found: C, 56.48; H, 5.16; Br, 38.02 (Carius).

4-Phenyl-1-butyne.—Sodamide was prepared from 3.1 g. (0.133 atom) of sodium by the method of Murray and Cloke,[33] and the reaction with 10 g. (0.0474 mole) of 4-phenyl-2-bromo-1-butene was carried out according to Johnson and McEwen.[31] The product distilled at 72–78° (11 mm.) and weighed 3.9 g. (64%); n^{25}_{D} 1.5192. The mercury derivative, bis-(4-phenyl-1-butynyl)-mercury, melted 83.5–84.5°; reported, 83.5–84.5°.[31]

2,3,4,5-Tetraphenylbibenzyl from Tetracyclone and 4-Phenyl-1-butyne.—A solution of 1.0 g. (7.68 millimoles) of the acetylenic compound and 2.88 g. (7.50 millimoles) of tetracyclone in 15 ml. of *p*-cymene was refluxed under a slow current of nitrogen until carbon monoxide was no longer evolved (about five and one-half hours). The product was isolated by steam distillation and crystallization from a solution of 10 ml. of benzene and 50 ml. of petroleum ether (60–70°) to give 2.44 g. (67%) of fine, colorless crystals melting 135–137°. A mixed melting point with compound (E) gave 135–137°.

Anal. Calcd. for $C_{38}H_{30}$: C, 93.79; H, 6.21; mol. wt., 487. Found: C, 93.57; H, 6.42; mol. wt. (Rast camphor), 476.

With dioxane substituted for *p*-cymene as the solvent, the condensation required 204 hours and the yield of product melting 135–137° was 57%.

2,3,4,5-Tetraphenylbibenzyl from Tetracyclone and 4-Phenyl-2-bromo-1-butene.—A solution of 0.78 g. (3.70 millimoles) of the butene derivative and 1.36 g. (3.54 millimoles) of tetracyclone in 15 ml. of cymene was refluxed under a slow current of nitrogen for twenty-nine and one-half hours. During this time carbon monoxide and hydrogen bromide were evolved. The product was isolated as before. The yield was 1.04 g. (60%) melting 135–137°. A mixed melting point with a 2,3,4,5-tetraphenylbibenzyl prepared above showed no depression.

To show that the hydrogen bromide was eliminated from the adduct and not from the 4-phenyl-2-bromo-1-butene, a model experiment was run in which a solution of 0.78 g. of the butene derivative in 15 ml. of *p*-cymene was refluxed for sixteen hours. No hydrogen bromide was evolved during this time. The easy elimination of hydrogen bromide from the addition compound is due to the reactivity of the tertiary bromine atom and is comparable to the behavior of Diels–Alder addition compounds of chloromaleic anhydride.[34]

Summary

1-Phenyl-1,3-butadiene can be synthesized from cinnamaldehyde and methylmagnesium bromide in 70–80% yields. Phenyl-β-naphthylamine is an effective polymerization inhibitor for this hydrocarbon. 1-Phenyl-1,3-butadiene and 2,3,4,5-tetraphenylcyclopentadienone react in a 1/1 mole ratio to give 2,3,4,5-tetraphenyl-1-(β-phenylethenyl)-7-keto-bicyclo[2,2,1]3-heptene. The structure of the adduct was proven by degradation to 2,3,4,5-tetraphenylbibenzyl. The latter compound was synthesized independently from tetracyclone and 4-phenyl-1-butyne or 4-phenyl-2-bromo-1-butene. This reaction demonstrates further that the preferred mode of addition to 1-phenyl-1,3-butadiene is 3,4. This process is the result of steric hindrance by the phenyl group and of polarization throughout the butadienyl side chain by electron displacements away from the ring.

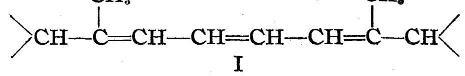
Acetylenic Glycols Related to Natural Polyenes[1]

BY LENA F. DEEMER, LEO LUTWAK AND F. M. STRONG

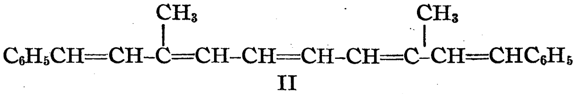
In connection with the general problem of the synthesis of carotenoid pigments and related compounds, it seemed of interest to attempt to prepare substances corresponding in structure to the central ten carbon atoms common to nearly all the natural carotenoids (formula I). Substances of this type



$$>CH-\overset{CH_3}{\overset{|}{C}}=CH-CH=CH-CH=\overset{CH_3}{\overset{|}{C}}-CH<$$

I

bearing terminal substituents which would facilitate further lengthening of the carotenoid chain were desired. As far as the authors are aware the only previously synthesized compound having the carbon skeleton in question is 3,8-dimethyl-1,10-diphenyldeca-1,3,5,7,9-pentaene (II), which was prepared by Kuhn and Wallenfels in 1938.[2]



$$C_6H_5CH=CH-\overset{CH_3}{\overset{|}{C}}=CH-CH=CH-CH=\overset{CH_3}{\overset{|}{C}}-CH=CHC_6H_5$$

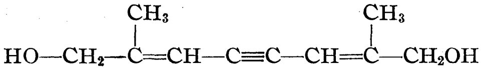
V

McCombie observed that the allylic shift occurred less readily with substances having terminal vinyl groups,[4] and similar behavior was encountered in the present instance. Nevertheless, the isomeric glycol, 2,7-dimethyl-octa-2,6-diene-4-yn-1,8-diol, VI, was obtained, albeit in poor yield.



$HO-CH_2-\overset{CH_3}{C}=CH-C\equiv C-CH=\overset{CH_3}{C}-CH_2OH$

VI

The structure of V was confirmed by an independent synthesis of the saturated glycol, VII,

and the corresponding diketone, which were identical with the reduction product of V and the corresponding diketone, respectively. A similar check on the structure of VI failed, since no solid reduction product or derivative thereof was obtained to compare with the saturated glycol, VIII, which was prepared by another method. How-

ever, the ultraviolet absorption spectrum of VI (Fig. 1) is convincing evidence that the three unsaturated linkages in V have actually been brought into conjugation. As expected, V showed no selective absorption in the ultraviolet.

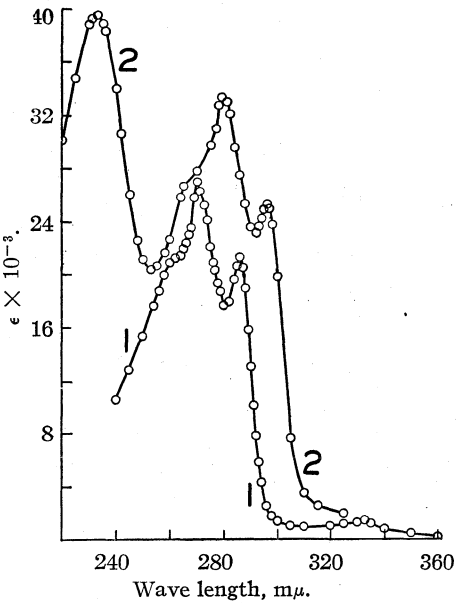

Fig. 1.—Curve 1, absorption spectrum of VI in alcohol solution; curve 2, dibenzoate of VI in alcohol solution.

Preliminary attempts selectively to hydrogenate VI to the corresponding triene and to oxidize it to the dialdehyde by Oppenheimer's method have been unsuccessful.

Experimental

α-Methylacrolein.—The commercial product[5] was distilled shortly before use, and yielded about 50% of a water-white product, b.p. 61–68° (741 mm.) plus higher boiling material. Operations involving this substance or its unsaturated condensation products were carried out under nitrogen and in peroxide-free solvents previously saturated with nitrogen. Usually a trace of hydroquinone was also added.

2,7-Dimethyl-octa-1,7-diene-4-yn-3,6-diol, V.—A solution of ethylmagnesium bromide in ether was prepared from 24 g. (1.0 gram atom) of magnesium turnings in a 1-liter, three-necked, round-bottom flask fitted with a stirrer, reflux condenser, dropping funnel and gas inlet tube. Tank acetylene purified by successive passage through water, concentrated sulfuric acid, calcium chloride and magnesium perchlorate was bubbled through the solution with continuous stirring for twenty-four hours at room temperature. Ether was added as necessary to maintain the volume at approximately 200 cc. At the end of this period analysis of the reaction mixture, by decomposing a small aliquot in water and measuring the proportion of the resulting gas absorbed by ammoniacal cuprous chloride solution, indicated that approximately 80% of the theoretical amount of acetylene di-magnesium bromide had been formed.

A solution of 70 g. (1.0 mole) of α-methylacrolein in 50 cc. of ether was then introduced over a period of one hour, and stirring was continued for two hours longer. Careful addition of 250 cc. of 10% sulfuric acid, followed by filtration, shaking out with ether, drying over "Drierite," and removing the solvent gave 69 g. of a red-brown, viscous liquid. This was distilled from a Claisen flask and yielded 7.2 g. of a pale yellow, mobile liquid, b.p. 30–110° (0.6 mm.) and 42.9 g. (52%) of a yellow, viscous oil, b. p. 135–140° (0.4 mm.). Earlier attempts to distil the crude product through a Vigreux column led to de-

composition with formation of water and much lower yields.

Redistillation of the lower-boiling material gave a colorless oil, b. p. 165–170° (741 mm.), which formed a semicarbazone, m. p. 169–170°. The same substance was obtained from the higher boiling fraction of the commercial α-methylacrolein. It does not appear to be identical with the hydrate or dimer studied by Gilbert and Donleavy.[6]

The higher boiling fraction crystallized almost completely on standing at 0°. The solid was washed free from oil with benzene, and on recrystallization from benzene formed colorless rectangular crystals, m. p. 70.5–71.5°.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C, 71.9; H, 8.49.

On quantitative microhydrogenation 10.45 and 8.30 mg. absorbed 5.90 and 4.60 cc. of hydrogen (S. T. P.), respectively. *Anal.* Calcd. for $C_{10}H_{14}O_2$: 4 moles of hydrogen per mole. Found: 4.19, 4.12.

The glycol showed no appreciable light absorption in the range 2200–4000 Å. Although attempts to prepare the diacetate, dibenzoate and diphenylurethan were made, no derivative was obtained, and no esterification appeared to occur.

In one preparation the product was found to melt at 88–91°. *Anal.* Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C. 71.8; H, 8.01. The lower melting isomer was also obtained in this case by redistillation of the mother liquors.

In other runs the product did not always crystallize. Redistillation of one such product gave a colorless, viscous oil, b. p. 126–130° (0.04 mm.). *Anal.* Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C, 72.26; H, 8.47.

2,7-Dimethyl-octa-4-yn-3,6-diol.—A solution of 36 g. of isobutyraldehyde in 20 cc. of ether was added dropwise with stirring during one hour to an ether solution of acetylene dimagnesium bromide prepared from 12 g. (0.5 gram-atom) of magnesium. After two hours of additional stirring the reaction mixture was worked up as described for compound V. Removal of the solvent left 30 g. of a reddish-yellow, viscous oil which largely solidified at 0°. The solid, recrystallized from benzene, formed colorless diamond-shaped crystals, m. p. 104–105°. A second product, flat plates, m. p. 61–63°, was obtained from the mother liquors. Two isomers, m. p. 69–70° and 105–106°, have been reported.[7] The total yield of the purified products was 27% of the theoretical. The higher melting product was analyzed. *Anal.* Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66. Found: C, 69.97; H, 10.61.

2,7-Dimethyloctane-3,6-diol, VII.—A solution of 2.12 g. of V, m. p. 70.5–71.5°, in 10 cc. of ethanol was shaken with 100 mg. of platinum oxide catalyst in an atmosphere of hydrogen until no further absorption of hydrogen occurred. Removal of the catalyst and solvent left 1.8 g. of a light amber viscous oil which possessed a distinct lemon odor. The oil partly solidified at 0° forming two types of crystals which were separated mechanically after triturating the pasty mass with a little cold benzene. Needles, m. p. 79–80°, and flat hexagons, m. p. 124–125°, were obtained.

2,7-Dimethylocta-4-yn-3,6-diol was similarly reduced, and formed an oil also possessing a lemon odor which on standing deposited needle crystals, m. p. 68–70°. Recrystallization from benzene raised the m. p. to 79–81.5°, and a mixture with the lower melting isomer above showed no depression. None of the higher melting isomer was obtained.

Anal. Calcd. for $C_{10}H_{22}O_2$: C, 68.9; H, 12.7. Found: C, 69.12; H, 12.74.

2,7-Dimethyloctane-3,6-dione.—To a solution of 2.0 g. of VII (mixed isomers) obtained from the reduction of V, in 20 cc. of benzene was added with continuous stirring over a period of one hour a mixture of 12.8 g. of sodium dichromate, 9 cc. of concentrated sulfuric acid, 30 cc. of water and 5 cc. of glacial acetic acid. The temperature was maintained at 5° during this time. The mixture was stirred for six hours longer at room temperature, the organic product collected in benzene, the extract washed with 5% sodium bicarbonate solution, then with water, dried over "Drierite" and the solvent removed. Since the oily product, 1.18 g., showed no tendency to crystallize, the dioxime was prepared. It separated from dioxane in irregular flat plates, m. p. 174–175°.

Anal. Calcd. for $C_{10}H_{20}O_2N_2$: C, 59.97; H, 10.07. Found: C, 60.5; H, 10.03.

The oily mixture of isomers resulting from the hydrogenation of 2,7-dimethylocta-4-yn-3,6-diol was similarly oxidized, and converted to the dioxime, which melted at 173.5–175° and gave no depression when mixed with the dioxime from V and VII. The literature reports the m. p. of this dioxime as 173–174°.[8]

2,7-Dimethylocta-2,6-diene-4-yn-1,8-diol, VI.—A mixture of 3 g. of V, m. p. 70.5–71.5°, 40 cc. of 95% ethanol and 160 cc. of 5% sulfuric acid was stirred under reflux for seven hours at 55° (±2°). The mixture was cooled, extracted with ether, washed with 5% sodium bicarbonate solution, then with water and dried over "Drierite." Removal of the solvent left 2.8 g. of a red-brown viscous oil. Molecular distillation at 1×10^{-4} mm. from a pot-type still gave 2.65 g. of a pale yellow, oily product which partially crystallized on standing. The solid after repeated crystallizations from benzene, weighed 0.29 g. and melted at 109–110°.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C, 72.8; H, 8.24.

The absorption spectrum in absolute ethanol was measured with a Beckman Universal spectrophotometer. Maxima were observed at 2700, 2860 and 3330 Å. with molecular extinction coefficients, at these wave lengths of 27,020, 21,140 and 1,430, respectively (Fig. 1, curve 1).

The dibenzoate was obtained readily and was crystallized from alcohol as needles, m. p. 108.5–109°.

Anal. Calcd. for $C_{24}H_{22}O_4$: C, 77.0; H, 5.92; saponification equivalent, 187.2. Found: C, 77.6; H, 5.72; saponification equivalent, 187.4.

The absorption curve of the dibenzoate is given in Fig. 1, curve 2.

It was found that the yield of VI, as measured by spectrophotometric analysis of the reaction mixtures, could be considerably improved by rearranging V with dry hydrogen chloride in absolute ethanol.[9] When held for one to two hours at 50–55° in a solution containing 1 g. of V and 100–200 milliequivalents of hydrogen chloride in 125 cc., the yield of VI was increased to approximately 45%. However, the product from such runs could not be induced to crystallize.

α,α-Dimethylsuberic Acid.—This substance was prepared by the method of Steele[10] from diethyl methylmalonate and 1,4-dichlorobutane. The crude dibasic acid, b. p. 150–160° (5 mm.) was crystallized from chloroform, m. p. 133.5–134°.

Anal. Calcd. for $C_{10}H_{18}O_4$: C, 59.4; H, 8.91; neutral equivalent, 101.1. Found: C, 59.2; H, 9.43; neutral equivalent, 100.8.

A second isomer was obtained from the mother liquors by crystallization from Skellysolve "B," m. p. 88.5–90°. *Anal.* Calcd. for $C_{10}H_{18}O_4$: C, 59.4; H, 8.91; neut. equiv., 101.1. Found: C, 58.9; H, 9.08; neut. equiv., 101.0.

Steele[10] likewise obtained two isomers melting at 132–133° and 91–92°, respectively.

The higher melting isomer formed a diamide, m. p. 214–215°. (*Anal.* Calcd. for $C_{10}H_{20}O_2N_2$: C, 59.96; H,

(10) Steele, THIS JOURNAL, **53**, 4939 (1933).

10.07. Found: C, 60.3; H, 9.99), and a bis-*p*-bromophenacyl ester, m. p. 125–126° (*Anal.* Calcd. for $C_{26}H_{28}O_6Br_2$: C, 52.38; H, 4.73. Found: C, 52.38; H, 4.71).

2,7-Dimethyloctane-1,8-diol, VIII.—Thirteen grams of α,α-dimethylsuberic acid, m. p. 133.5–134°, was esterified with methanol and concentrated sulfuric acid in the usual manner and yielded 12.5 g. of the dimethyl ester, b. p. 128° (3–5 mm.). *Anal.* Calcd. for $C_{12}H_{22}O_4$: sapon. equiv., 115.2. Found: sapon. equiv., 117.3. This ester was dissolved in alcohol and hydrogenated in a high pressure bomb over 2.5 g. of copper chromite catalyst at 200–250°.[11] Removal of the catalyst and solvent left 7.98 g. of a colorless, viscous oil, which could not be crystallized. It was characterized by preparation of the bis-3,5-dinitrobenzoate, which was recrystallized from benzene, m. p. 175–176°. *Anal.* Calcd. for $C_{24}H_{26}O_{12}N_4$: C, 51.24; H, 4.66. Found: C, 52.19; H, 4.62.

A sample of VI, 0.0528 g., m. p. 108.5–109.5°, was hydrogenated in alcohol solution with platinum oxide catalyst. The theoretical amount of hydrogen was absorbed. Removal of the catalyst and solvent left 0.0506 g. of a colorless, viscous oil. Several such preparations were converted to the bis-3,5-dinitrobenzoate. The products were oily and resisted all attempts at crystallization.

Summary

Acetylene and α-methylacrolein have been condensed to yield 2,7-dimethylocta-1,7-diene-4-yn-3,6-diol, which was rearranged to 2,7-dimethyl-octa-2,6-diene-4-yn-1,8-diol.

The Iodination of Certain Phenylsulfonamido- and Amino-heterocycles[1]

BY ROBERT G. SHEPHERD AND CATHERINE E. FELLOWS

Introduction

In a study of variously substituted sulfanilamido- and metanilamido-pyrimidines, the unique antimalarial effect of halogen substitution in the 5-position of the pyrimidine ring was discovered.[2] The preparation of iodinated pyrimidines was investigated in this connection and also because of their particular suitability for the preparation of cyano analogs.[2b] A satisfactory preparative method has now been found in the use of iodine and mercuric acetate. Using pyrimidines and other aromatic nuclei, this method was compared with the usual procedures involving iodine chloride and iodine in alkaline solution with the results set forth in the experimental section and Table II. Certain relationships of reactivity to structure were also investigated.

Experimental

The properties and analyses of the new compounds prepared in the subsequent procedures are listed in Table I by the Roman numerals accompanying them in the text.

Iodination of Aminoheterocycles. 2-Aminopyrimidine.—A solution of 23 g. (0.24 mole) of this amine in 200 cc. of water was treated with 32 g. (0.1 mole) of mercuric acetate and the mixture stirred for two minutes on the steam-bath. The initial yellow precipitate quickly turned to a thin white slurry which was treated at 70° with a solution of 50.8 g. (0.2 mole) of iodine in 200 cc. of hot dioxane. All of the iodine reacted during a half hour of stirring during which time considerable evaporation occurred. The thick slurry was poured into several volumes of 15% potassium iodide solution and washed on the filter with fresh iodide solution until white. Recrystallization from absolute alcohol (25 cc./g.) gave mercury-free **2-amino-5-iodopyrimidine** (I). Methanol and acetic acid are equally satisfactory purification solvents.

Iodination in hot acetic acid, as used for the sulfonamides, gave an orange-colored product in only 30% yield along with a large amount of mercury-containing tar.

The structure of the product was determined by conversion into 2-phenylsulfonamido-5-iodopyrimidine, the constitution of which had been previously demonstrated.[2b]

2-Aminopyridine.—The first method applied to this amine gave a 60% yield of product which was separated from the tarry by-product by ethylene dichloride extraction after the potassium iodide treatment. 5-Iodination was established by comparison (mixed m. p.) with **2-amino-5-iodopyridine** prepared according to the literature.[3]

Using two moles of iodine and one of mercuric acetate, **2-amino-3,5-diiodopyridine** (VIII) was obtained by hot ethylene dichloride extraction. After recrystallization from 95% alcohol (10 cc./g.) and ethylene dichloride (*ca.* 3 cc./g.), the melting point was 12° higher than that reported by Caldwell, *et al.*[4] Its identity was confirmed by nitrogen and iodine analyses and by conversion[4] to 2-hydroxy-3,5-diiodopyridine identical (mixed m. p.) with that prepared[4] by iodination of 2-hydroxypyridine. This amine differs from the mono-iodo derivative in being relatively insoluble in dilute acid and less soluble in ether.

Sulfonamides from Aminoheterocycles (Compounds VI, IX, X and XIII).—In this and other reactions of various benzenesulfonyl chlorides with amines in pyridine, the purification of the products has been aided materially by the addition of hot glacial acetic acid to the reaction mixture and isolation by cooling. The colored and alkali-insoluble materials which are thrown down by the usual addition of water remain in solution in this procedure which seems to have general application. The procedure for XIII given below illustrates the method.

A boiling solution of 3.5 g. (0.02 mole) of benzenesulfonyl chloride and 4.4 g. (0.02 mole) of 2-amino-5-iodopyrimidine in 3.2 cc. (0.04 mole) of dry pyridine was heated for fifteen minutes, allowing evaporation of the pyridine, to a final reaction temperature of about 150°. The temperature was then reduced to 105° for forty-five minutes and the crystalline mass was treated with 10 cc. of boiling glacial acetic acid and filtered at 30°: The 2-

[h] Caldwell, *et al.* (ref. 4), reported a m. p. of 135–137°. [i] Calcd.: I, 73.4. Found: I, 73.2. [k] This compound has been reported in French Patent 846,191 (1939) (through *C. A.*, **35**, 1185 (1941)) to melt at 234°. [m] Calcd.: Hg, 30.0. Found: Hg, 30.1. [n] Ref. 2b.

phenylsulfonamido-5-iodopyrimidine (XIII) was washed with acetic acid, 5 *N* hydrochloric acid (to remove the unreacted amine) and water. Yield was 78%; m. p. 255–256° unchanged by mixture with material prepared by iodination of 2-phenylsulfonamidopyrimidine.[5]

By this method, compounds IX and X were obtained in 80% yield from 2-amino-5-iodopyridine[3] which reacted rapidly at 70–80°. The products were identical with those prepared from the corresponding sulfonamides by the iodination method described below.

Iodination of Phenylsulfonamidoheterocycles (Compounds II, IV, V, IX, X, XIII and XIV).—With the sulfonamides, it was necessary for rapid reaction to use two equivalents (1 mole) of mercuric acetate. The reaction proceeded to completion rapidly at 120° but only slowly at 60°. It was generally preferable to add this salt to the refluxing iodine–acetic acid solution of sulfonamide. The effect of the mercuric acetate could not be duplicated by the use of sodium acetate or pyridine in the acetic acid medium or by the use of a pyridine or aqueous alkaline medium.

A. **Method.**—One mole of the phenylsulfonamidoheterocycle was almost completely dissolved in boiling glacial acetic acid (0.6–4 liters) and treated with 1.15 moles of iodine. The heating was stopped and one mole of powdered mercuric acetate was added with vigorous shaking. In some cases, an immediate precipitation of the mercury salt of the product occurred and in all cases, silky yellow leaves of mercuric iodide formed after a few minutes. The reaction mixture was kept almost at the boiling point by intermittent heating during twenty to thirty minutes. The excess iodine was removed only by long heating and neither this nor use of more iodine with brief heating produced any significant increase in yield. The product was precipitated by addition to 1–2 volumes of 15% potassium iodide solution. The solid was filtered and thoroughly washed on the filter with fresh potassium iodide solution and water. The material at this point contained too little mercury to be detected with ammonium sulfide solution. However, precipitation from alkaline solution and hydrogen sulfide treatment changed the white suspension to gray. This test was negative after recrystallization from glacial acetic acid (10–80 cc./g.) or purification through the sodium salt. The latter was carried out by solution in ammonia followed by addition of excess sodium hydroxide or by treatment of a slurry in several volumes of water with 1.5 moles of 5 *N* alkali.

B. **Proof of Structure.**—To show that the position of iodination was the same in nitro- and acetaminophenylsulfonamido heterocycles, compounds IV, V and X were also prepared by acetylation (as for the preparation of compound VII) of the corresponding amines obtained from the reductions described below. In each case, the product was identical by mixed melting point with the material obtained by iodination of the acetaminophenylsulfonamide. Also, the amine III obtained from this reduction was shown to be identical with the amine prepared by acid hydrolysis of 2-(N^4-acetaminophenylsulfonamido)-pyrimidine after iodination.

Compounds IV and V were shown to be 5-iodopyrimidines by hydrolysis to 2-amino-5-iodopyrimidine (I) in 80% yield by the action of 65% sulfuric acid for one-half hour at the boiling point.

The proof of structure of the mono-iodo phenylsulfonamidopyridines (IX and X) is described in the preceding section. Attempted reaction of these products with more iodine failed to produce any di-iodination even under more drastic conditions.

Qualitative Test for Iodine.—Earlier work[6] on certain iodoacetyl compounds had disclosed a useful qualitative test for iodine. The test employs concentrated sulfuric acid and is based primarily on the observation of the characteristic purple vapor of iodine which is evolved from the brown iodine solution. The brown color of the solution is often masked or duplicated by organic decomposition products but the color of the vapor and the subsequent formation of a characteristic crystalline sublimate make the test specific for iodine. The sensitivity is limited only by the minute amount of iodine required to produce a visible color. Since most substances dissolve in concentrated sulfuric acid at room temperature, it is possible to take advantage of the fact that iodine is formed from a sample test at a temperature characteristic of its chemical combination. Thus, iodine, inorganic iodides and various addition complexes[7] give the test at 20–30° while iodoacetyl compounds

(7) *E. g.*, the addition compound formed from 2-aminopyridine and iodine chloride: German Patent 503,920 (1930) and English Patents 264,508 and 283,576 (1927).

require moderate heating. Only at or near the boiling point is the iodine liberated from *unactivated* aromatic combination. These facts make it possible in many cases to distinguish between reagent, by-product (such as mercuric iodide) and desired product.

Reduction of Nitro Compounds II, IX and XIV.—When the nitrosulfonamide was boiled with one mole of commercial ammonium sulfide solution for two minutes, a heavy precipitate formed. A second precipitation occurred after addition of another mole of sulfide solution and six minutes of boiling. The red-brown mixture was added to excess 60% acetic acid and the solid purified by solution in dilute (1:3) ammonia (10 cc./g.) with charcoal treatment. The colorless filtrate was mixed with one volume of 5 *N* sodium hydroxide and after cooling, the sodium salt was separated and washed with alkali. After solution in warm 20% alcohol (10 cc./g.), the product was precipitated by addition to excess 60% acetic acid. Yields were 75–85% of amine III, 2-sulfanilamido-5-iodopyridine and 2-metanilamido-5-iodopyrimidine.

Comparatively brief heating with ammonium sulfide was used to avoid possible removal of the iodine.

N^1-Methyl-2-(N^3-acetylmetanilamido)-pyrimidine (VII).—The corresponding metanilamide[2b] (1 g.) was boiled with 2 cc. of glacial acetic acid and treated with 2 cc. (5 equivalents) of acetic anhydride. The product obtained on cooling was purified by recrystallization from 10 cc. of absolute alcohol.

2-Sulfanilamido-5-iodopyrimidine (III).—The insolubility of the alkali salts of IV and III and of the acid salts of III made the usual hydrolytic methods unsatisfactory for the preparation of this sulfanilamide. This difficulty was overcome by utilizing the high solvent power of 60% sulfuric acid (8.5 cc./g.) and a reaction time of three minutes at the boiling point. A 25% yield of 2-amino-5-iodopyrimidine was obtained in addition to 65% of the desired product.

In general, the iodine substitution produces a marked change in solubility of the salts of the phenyl, pyridine and pyrimidine sulfonamides. The parent compounds form very water-soluble sodium salts and less soluble ammonium salts while the corresponding iodo derivatives form very insoluble sodium salts which are precipitated from the solution of the highly soluble ammonium salts. These characteristics formed the basis for very sharp separation methods in several instances. Introduction of the iodine also causes the hydrochlorides of the metanilamido- and sulfanilamido-pyrimidines to lose their water solubility.

4-Iodoacetanilide.—Reaction of acetanilide with one mole of iodine and mercuric acetate occurred rapidly in glacial acetic acid at 90° and the iodo derivative was precipitated by addition of potassium iodide solution. This product, melting at 184°, was identical with that obtained by iodination with iodine chloride[8] or by acetylation of 4-iodoaniline.

In connection with the benzene *versus* heterocyclic specificity of the reagents, an equimolar mixture of acetanilide and 2-phenylsulfonamidopyrimidine was iodinated in two ways. Iodination with iodine and mercuric acetate in boiling acetic acid gave roughly equal yields of the iodo derivatives of each. However, iodine chloride reacted only with the acetanilide present in the mixture.

4′-Iodobenzenesulfonanilide (XI).—Benzenesulfonanilide slowly reacted with iodine chloride in acetic acid with the result shown in Table II. The reaction was rapid when iodination was carried out with six equivalents of iodine in 8 *N* potassium hydroxide solution. Neither of these products was further iodinated by treatment with an excess of either reagent. The iodinated sulfonamide was isolated only in low yield from the mercuric acetate iodination in acetic acid owing to the formation of mercury-containing tar and the consumption of several moles of iodine.

The products precipitated from the reaction mixtures above were purified by solution in 1.5 *N* sodium hydroxide (7 cc./g.) to obtain the crystalline sodium salts. The iodo derivatives obtained by acidification of the aqueous salts all gave no depression of the melting point of the sulfonamide prepared in 69% yield from 4-iodo-aniline and benzenesulfonyl chloride by the glacial acetic acid method.[9]

Comparative Iodinations of Various Aromatic Nuclei.—The iodination results with different nuclei are summarized in Table II for purposes of comparison. The alkaline iodine procedure of v. Schickh[3] was used except for aniline in which case sodium bicarbonate is more suitable. Iodine chloride experiments were carried out in boiling glacial acetic acid for three hours employing a 10–20% excess of reagent. The mercuric acetate iodinations were conducted in boiling glacial acetic acid for the sulfonamides and in aqueous dioxane at 70° for the amines. The reactivity of acetanilide toward all three reagents was destroyed by the para-sulfonamido substitution in N^4-acetylsulfanilamide.

TABLE II

IODINATION OF VARIOUS NUCLEI BY IODINATING AGENTS

Compound	Per cent. yield and product from I_2–KOH	ICl	I_2–$Hg(OAc)_2$
Aniline	80, 4-I[a]	[b]	Tar
Acetanilide	0, SM[c]	80, 4-I	92, 4-I
Benzenesulfonanilide	60, 4′-I	70, 4′-I	[d], 4′-I

2-(N^4-Acetylsulfanilamido)-pyrazine			0, dec.[o]

[a] "Organic Syntheses," Coll. Vol. II, 347 (1943). [b] Some control of substitution up to tri-iodoaniline can be obtained by using one, two or three moles; *cf.* ref. 8. [c] SM = starting material recovered after attempted reaction. [d] Very low due to side-reactions. [e] An addition complex is formed which iodinates only on heating with alkali; *cf.* ref. 7. [f] With one mole of iodine, a 60% yield of mono-substituted product was obtained. [g] Py = Pyridine. [h] About 0.3% of 2-amino-5-iodopyrimidine was isolated and identified. [k] Pm = Pyrimidine. [m] The lack of reaction here contrasts with the ready halogenation by chlorine and bromine; see ref. 2b. [n] Some non-ionic iodination product was formed but has not yet been characterized. [o] No evidence of iodination even when heating was carried to the decomposition point with partial recovery of starting material.

The results with 2-(4-nitrophenylsulfonamido)-pyridine were similar to those tabulated for the acetamino analog, the third reagent giving an 88% yield of mono-iodo derivative. The phenyl-substituted derivatives of 2-phenylsulfonamidopyrimidine were unreactive except to iodine–mercuric acetate which gave the following yields of 5-iodopyrimidines: 3-nitro, 67%; 4-nitro, 74%; 3-acetamino, 63%, and 4-acetamino, 80%. The ring N-methylated pyridine, 1-methyl-2-(N^4-acetylsulfanilimido)-1,2-dihydropyridine,[9a] reacted with iodine–mercuric acetate at 60–70° but the reaction appeared to take another course since very water-soluble products were formed. With 2-(N^4-acetylsulfanilamido)-thiazole, alkaline iodine gave a non-ionic iodination product and iodine–mercuric acetate caused a rapid reaction at 90° yielding water-soluble products.

Mercury bis-(Phenylsulfonamidopyrimidine) (XII).—A solution of 6.4 g. (0.02 mole) of mercuric acetate in 50 cc. of boiling glacial acetic acid was added to 4.7 g. (0.02 mole) of 2-phenylsulfonamidopyrimidine in 75 cc. of boil-

ing acetic acid and the clear mixture evaporated to about 50 cc. Slight cooling gave a heavy white precipitate which was washed with acetic acid and recrystallized from 90 cc. of acetic acid; yield was 85%.

Material, identical by mixed melting point, resulted from treatment of a cold solution of 2-phenylsulfonamidopyrimidine in 2.5% ammonia (8 cc./g.) with excess 16% mercuric acetate solution in water.

Both materials gave an immediate test for mercury on treatment with ammonium sulfide solution. The same result was obtained with the mercury derivative (m. p. 300°) of 2-phenylsulfonamido-5-chloropyrimidine[2b] which was prepared in hot acetic acid.

Discussion

The absence of iodination in those cases (SM) of Table II where the starting material was recovered was confirmed by the delicate qualitative test for iodine described above. This table illustrates the greater reactivity of iodine–mercuric acetate compared to the other reagents. The direct di-iodination of 2-aminopyridine is to be preferred from the standpoint of yield and time required to the four-step synthesis previously employed.[4] Preparation of iodo derivatives from the phenylsulfonamidopyrimidines themselves by the method described is more satisfactory than from sulfonylation of the iodoamine.[10] It is of interest to point out the retention of the high reactivity of the heterocyclic nucleus toward iodine–mercuric acetate after substitution with the deactivating sulfonamido group (Table II) and the heterocyclic specificity of this reagent in the presence of a benzene-activating acetamino group (IV, V and X). The undiminished reactivity of the nitrophenylsulfonamides (intermediate to II, IX and XIV) is in contrast to the results of chlorination of analogous sulfonamides where nitro substitution has been reported to reduce either the rate[11] or extent[12] of halogenation of the N-substituent. A further contrast with chlorination results is found in the case of benzenesulfonanilide (Table II) which has been observed to undergo *ortho* chlorination in an alkaline medium[13] and *para* chlorination under acidic conditions.[14] The most striking effect of simple structural variation on reactivity toward mercury-induced iodination is the lack of reaction caused by N^1-methylation of 2-(N^3-acetylmetanilamido)-pyrimidine (Table II).

Since the effect of mercuric acetate on pyrimidine iodinations could not be duplicated by other substances, the possibility of intermediate mercuration was investigated. This was shown to be unlikely and, instead, the intermediate appears to be the mercury salt of the sulfonamide. This salt might facilitate iodination by making possible the formation of N-iodine intermediates but the importance of the rearrangement of such compounds in halogenations is made questionable by the work of Orton, *et al.*[15] The high reactivity of the phenylsulfonamido- heterocycles to iodine–mercuric acetate in contrast to their lack of reactivity with other iodinating agents suggests the possibility that a covalent structure peculiar to the mercury salt is responsible for the high reactivity observed.

Acknowledgment.—We are indebted to Dr. Jackson P. English for his interest and counsel during the course of this investigation.

Summary

Iodine and mercuric acetate has been found particularly suitable for iodination of certain heterocyclic nuclei.

2-Aminopyrimidine, 2-aminopyridine and various phenylsulfonamido derivatives of both amines could be iodinated in the 5-position of the heterocyclic ring exclusively.

The hitherto unreported di-iodination of 2-aminopyridine has been accomplished by this method.

4′-Iodobenzenesulfonanilide was prepared by three iodination procedures as well as by coupling 4-iodoaniline in glacial acetic acid.

A mercury bis-sulfonamide salt was prepared and is discussed in relation to the iodination of the phenylsulfonamido-heterocycles.

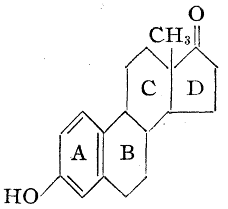
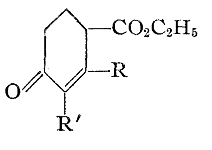
Synthetic Sterols. I. Model Experiments Employing Hagemann's Ester

BY JOHN A. HOGG

The procedure herein reported has been designed and carried out with the view of obtaining a new and somewhat general method of constructing the molecular framework of estrone (I). A special advantage of the method is that the four asymmetric centers present in octahydrophenanthrene compounds of the estrone type may be introduced in pairs in such a way that the isomer problem is simplified.



(I)



(II)

Hagemann's ester[1] (3-methyl-4-carboethoxycyclohexene-2-one-1 or II, $R = CH_3$ and $R' = H$) has been prepared by Bergmann and Weizmann,[2] and by Smith and Rouault,[3] by the condensation of formaldehyde with ethyl acetoacetate in the presence of piperidine with subsequent selective decarboethoxylation by heating with sodium ethoxide. Conclusive experiments[4] have shown that the alkylation of Hagemann's ester with alkyl halides and sodium ethoxide involves the 2-position.

When this fundamental reaction was applied in this work using *m*-methoxyphenethyl bromide[5] as the alkylating agent with sodium ethoxide in anhydrous ethanol, the yields were unsatisfactory due to extensive alcoholysis. 3-Methyl-2-(*m*-methoxyphenethyl)-4-carboethoxycyclohexene-2-one-1 (III) was, however, prepared in 58% yield by the use of sodamide as the basic catalyst in liquid ammonia. When hydrogenated at two atmospheres using a Pd–Norite catalyst, III absorbed an equivalent amount of hydrogen to give IV which was cyclized with concentrated sulfuric acid without further purification. A 65% over-all yield of crude V was obtained after hydrolysis, with alcoholic potassium hydroxide.

The structure of V was confirmed by selenium dehydrogenation to 1-methyl-7-methoxyphenanthrene (XIII). The picrate of the latter was prepared. The acid (V) was converted into its methyl ester (VI) with diazomethane.

Since Hudson and Hauser[6] were successful in the use of triphenylmethylsodium and alkyl halides for the alkylation of simple ethyl dialkylacetates, VI was subjected to a similar treatment. The characteristic wine-red color of triphenylmethyl sodium was found to disappear in an hour's time, whereupon treatment with methyl iodide produced a vigorous reaction. The hydrolysis of the resulting mixture of geometrical isomers in alcoholic potassium hydroxide required prolonged refluxing. The two forms of 1,2-dimethyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene-2-carboxylic acid (VII α, β) were easily separated since their sparingly soluble potassium salts differed in water solubility. One of them, which is regarded as the β (or *cis*) form, was present in small amounts and appeared after acidification of the aqueous alkaline filtrate. The α-form was obtained in 80% yield while only 2% of the β-form was obtained.

The α-form of VII was heated at 350° with selenium powder to yield 1,2-dimethyl-7-methoxyphenanthrene (VIII). This was confirmed by comparison with an authentic sample prepared from 1-keto-2-methyl-2-carbomethoxy-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene (IX).[5,7] The latter was hydrolyzed to X[7] and treated with an equivalent of methylmagnesium iodide. The resulting crude product (XI) was dehydrogenated with selenium to give VIII.

The cyclization of III was also effected directly with concentrated sulfuric acid to give, after hydrolysis, a yellow acid, 1-methyl-7-methoxy-3,4,-9,10-tetrahydrophenanthrene-2-carboxylic acid (XII, R = H), which readily decomposed at its melting point and was best purified through its methyl ester (XII, $R = CH_3$). This yellow acid is probably of the structure indicated because its color and instability are best accounted for by conjugation. Selenium dehydrogenation of XII ($R = CH_3$). Selenium dehydrogenation of XII (R = H) resulted in 1-methyl-7-methoxyphenanthrene. The picrate of this phenanthrene derivative showed no depression in melting point when mixed with the picrate of that obtained from V by an identical procedure.

The original investigation of the condensation of ethyl acetoacetate with aldehydes under the influence of basic catalysts was first carried out by Knoevenagel and Klages.[8] Horning, Denekas and Field[9] have extended the work of the latter investigators so that the preparation of 5-substituted

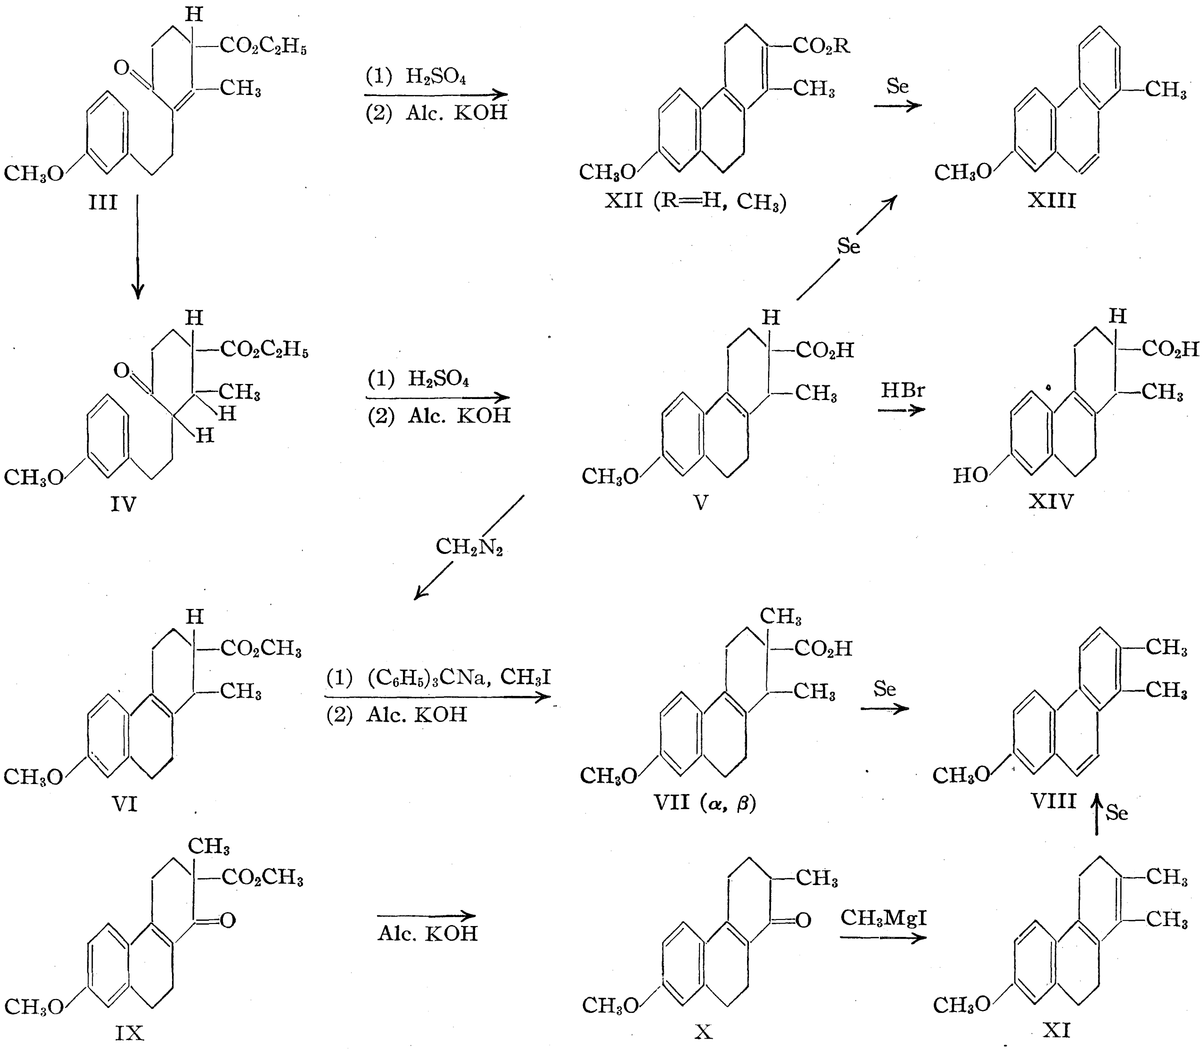
CHART I



"Hagemann esters" is easily carried out. Mannich and Fourneau[10] have prepared Hagemann's ester by the condensation of 1-diethylaminobutanone-3 with ethyl acetoacetate in the presence of sodium ethoxide. Other β-keto esters would be expected to yield compounds of type II (R′ = H and R variable) under similar circumstances. The variable nature of the products which may be synthesized by the method outlined in Chart I becomes apparent.

The two asymmetric centers present in the geometric isomers VII α and VII β correspond to those between the C and D rings of estrone (I). The resolution of VII α and VII β into their respective optical antipodes would result in a total of four stereoisomers (*d*-VII α, *l*-VII α, *d*-VII β and *l*-VII β). By the hydrogenation of the double bond, one would theoretically expect to obtain from each of these four isomers four additional diastereoisomeric compounds, or a total of sixteen forms which correspond to the sixteen theoretical isomers of the estrone molecule. In a procedure of this sort, the number of chemical species present for separation in any single operation is reduced to a minimum. The method may be regarded as applicable to a systematic approach to the difficult stereoisomeric problem associated with the synthesis of estrone (I). The synthesis of a compound of type XV for this purpose would follow the preparation of a material of type II, where R is of a nature chosen to facilitate the construction of the D ring of estrone. Work along these lines is now in progress.

Estrone		1.0

Experimental

3-Methyl-2-(*m*-methoxyphenethyl)-4-carboethoxycyclohexene-2-one-1 (III).—To 250 cc. of liquid ammonia containing 0.2 g. of hydrated ferric nitrate was added 13 g. (0.563 mole) of sodium in a piecewise manner with cooling only when necessary to facilitate the speed of addition. The mixture was stirred until the blue color was replaced by gray. The resulting suspension was cooled in an alcohol–Dry Ice-bath, and 102.5 g. (0.563 mole) of Hagemann's ester was added as rapidly as possible with the continued application of the cooling bath. The deep-red reaction mixture was stirred without cooling for twenty minutes and was then cooled again while 300 cc. of dry toluene and 50 cc. of sodium-dried ether were added. The cooling bath was removed and the mixture was stirred two hours at room temperature until nearly all of the ammonia had escaped. Then the reaction vessel was heated to boiling, whence the sodio derivative appeared as a yellow precipitate (some reddish gummy material collected on the sides).

One hundred and twenty grams (0.563 mole) of *m*-methoxyphenethyl bromide was added and the suspension was refluxed under a nitrogen atmosphere for eighteen hours. The resulting mixture was washed with dilute hydrochloric acid and then with water. The toluene layer was dried over magnesium sulfate, and the toluene was removed under reduced pressure. After a small forerun, distillation of the residue yielded 102 g. (58%) of III boiling at 180–184° (0.3 mm.).

Anal. Calcd. for $C_{19}H_{24}O_4$: C, 72.2; H, 7.58. Found: C, 71.6; H, 7.41.

1-Methyl-2-carboxy-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene (V) from Reduction and Cyclization of III.—Thirty-three grams (0.104 mole) of III in 100 cc. of 95% ethanol was hydrogenated at 35 lb. pressure using 4 g. of palladium–Norite catalyst.[11] The theoretical amount of hydrogen was absorbed in forty-five minutes. After filtration and removal of the solvent there remained a water-white oil of fruity odor. This oil was cooled to −20° in an alcohol–Dry Ice-bath, and to this was added 80 cc. of concentrated sulfuric acid which had been similarly cooled. The viscous content of the flask was stirred with a thermometer as the temperature was allowed to rise slowly. It was necessary to apply cooling from time to time. At no time was the temperature allowed to rise above 10°. After twenty minutes of shaking and stirring, the temperature was allowed to rise to 20°, and the mixture was then poured on a large excess of cracked ice (total reaction time was thirty minutes). A light-colored gum formed which was extracted with ether. The ether was removed, and the residue was hydrolyzed by refluxing for one hour in 200 cc. of a 6% solution of potassium hydroxide in 95% ethanol and 20 cc. of water. The alcohol was then removed under vacuum and diluted with water. The water solution was washed with ether and then acidified with concentrated hydrochloric acid. The acid came out as an oil and quickly solidified. There was obtained 18.5 g. (65%) of crude acid which melted at 174–178°. Two recrystallizations from 95% ethanol raised the melting point to 192–193°. The over-all yield of pure V was 14.2 g. or 50% of the theoretical.

Anal. Calcd. for $C_{17}H_{20}O_3$: C, 75.00; H, 7.35. Found: C, 74.95; H, 7.25.

One attempt to demethylate V with 48% hydrobromic acid yielded an oil, presumably (XIV).

Methyl 1-Methyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene-2-carboxylate.—A solution of 7.5 g. of V in ether was treated with an excess of ethereal diazomethane. The solvent was removed, and the residue was recrystallized from 95% ethanol to yield 7.3 g. (93%) of VI as plates melting at 107–108°.

Anal. Calcd. for $C_{18}H_{22}O_3$: C, 75.60; H, 7.68. Found: C, 75.61; H, 7.71.

1-Methyl-7-methoxyphenanthrene (XIII) from the Selenium Dehydrogenation of V.—One gram of V was heated for three hours with 6 g. of selenium powder at 350°. The reaction was carried out in a 50-cc. round-bottom flask turned at a 45° angle, with an outlet tube containing a restriction placed inside the flask and sealed with a movable glass bead. The outlet tube and flask were equipped with standard taper joints. The bead permitted the escape of hydrogen selenide and carbon dioxide without distillation of the product through the outlet. When the product collected on the upper sides of the reaction vessel the contact with selenium metal was renewed by rotating the flask.

The product was extracted with chloroform, filtered and the solvent was removed. The solid residue (0.7 g.) was distilled in vacuum over sodium to yield 0.5 g. of a white solid melting at 120–124°. Several recrystallizations of part of this from 95% ethanol raised the melting point to 132–133°. The reported melting point of 1-methyl-7-methoxyphenanthrene (XIII)[12] is 133–134°.

Purification was more easily effected through its picrate. The remainder of the crude product and mother liquors was treated with 25 cc. of a saturated alcoholic solution of picric acid. On cooling, orange needles developed which melted at 138–139° after one recrystallization from 95% ethanol.

Anal. Calcd. for $C_{22}H_{17}O_8N_3$: C, 58.70; H, 3.75; N, 9.32. Found: C, 58.70; H, 3.88; N, 9.39.

1-Methyl-2-carboxy-7-methoxy-3,4,9,10-tetrahydrophenanthrene (XII, R = H) from the Cyclization of III.—To 10 g. of III cooled in an Erlenmeyer flask to −20° was added 30 cc. of concentrated sulfuric acid also cooled to near its freezing point. The temperature was maintained at or below 10° until the main reaction had ceased, and the temperature was then allowed to rise to 20° as in the cyclization of IV. The contents of the flask were poured into a beaker of cracked ice, and the resulting gum was extracted with ether. After the removal of the ether the residue was hydrolyzed in 100 cc. of 10% alcoholic potassium hydroxide. The solvent was removed in vacuum, and the residue was diluted with water. After one extraction with ether the aqueous solution was acidified with dilute hydrochloric acid. There was formed 5.0 g. (58.5%) of a yellow product which melted at 175–188° with evolution of carbon dioxide. The material was further purified by recrystallization from acetic acid with considerable loss due to decomposition. The acid is soluble in 95% ethanol only with difficulty. The pure product melts at 192–195° (dec.).

Anal. Calcd. for $C_{17}H_{18}O_3$: C, 75.60; H, 6.67. Found: C, 75.62; H, 6.65.

The methyl ester (XII, R = CH_3) was obtained by treating the acid with ethereal diazomethane. The ester melts at 112–113°.

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.10; H, 7.05. Found: C, 75.32; H, 7.09.

1-Methyl-7-methoxyphenanthrene (XIII) from the Selenium Dehydrogenation of XII (R = H).—One-half gram of XII (R = H) was heated at 300° for six hours in an open tube with 2 g. of selenium powder. The product

---

[11] Hartung, THIS JOURNAL, **50**, 3370 (1928).

[12] Short and Stromberg, *J. Chem. Soc.*, 516–520 (1937).

was extracted with chloroform. The solvent was removed and the residue was distilled under vacuum from sodium. After solution in ethanol and the addition of a saturated ethanolic picric acid solution, an orange picrate was deposited which melted at 138–139°. A mixed melting point with the picrate obtained from the product obtained in the selenium dehydrogenation of V was not depressed.

The Angular Methylation of 1-Methyl-2-carbomethoxy-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene (VI).—A solution of triphenylmethyl sodium was prepared in ether and titrated according to the directions of Renfrow and Hauser.[13] An equivalent amount (0.0255 mole) of triphenylmethyl sodium was added to an ether solution of 7.3 g. (0.0255 mole) of VI in 300 cc. of sodium-dried ether in a 500-cc. glass-stoppered Erlenmeyer flask. All operations were carried out under an atmosphere of dry nitrogen.

The deep, wine-colored solution was allowed to stand at room temperature with occasional shaking for one hour, at which time the red color had faded to a light orange.

The addition of 25 cc. of methyl iodide caused the ether to reflux, and a copious precipitate of sodium iodide soon developed. After standing overnight the ether was removed, and the residue was refluxed eight hours with 10 g. of potassium hydroxide, 10 cc. of water and 200 cc. of 95% ethanol. The alcohol was removed under vacuum on the steam-bath, and the residue was diluted with water. The potassium salt was insoluble in water at ordinary temperature. Filtration gave a mixture of triphenylmethane and the salt. The filtrate was saved. Several washings with ether removed the triphenylmethane, leaving the white crystalline salt, which weighed 7 g., and represents a yield of 85% in the form of the salt. The latter was dissolved in 250 cc. of boiling water containing enough alcohol to effect solution. Acidification while hot with hydrochloric acid yielded nearly the theoretical amount of acid melting at 197–201° (softens at 190°). Recrystallization from 95% ethanol yielded 5.8 g. (80%) of needles in bundles melting at 206–207°. This compound is 1,2-dimethyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene-2-carboxylic acid.

Anal. Calcd. for $C_{18}H_{22}O_3$: C, 75.60; H, 7.68. Found: C, 75.88; H, 7.79.

The aqueous alkaline filtrate was acidified with hydrochloric acid to give 1.0 g. of a tacky solid which was dissolved in 25 cc. of 95% ethanol. After standing for two days, 150 mg. of beautiful prisms formed which melted at 171–173° with previous softening at 167°. One further crystallization from the same solvent raised the melting point to 172–173°. This product is regarded as the β (or *cis*) form of VII. *Anal.* Calcd. for $C_{18}H_{22}O_3$: C, 75.60; H, 7.68. Found: C, 75.61; H, 7.98.

1,2-Dimethyl-7-methoxyphenanthrene (VIII) from 1,2-Dimethyl-2-carboxy-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene (VII α).—One gram of VII α was treated with 7 g. of selenium metal in the same manner as V. After distillation from sodium under vacuum there was obtained 0.5 g. of a solid material melting at 120–125°. Several recrystallizations from methanol yielded prisms of 1,2-dimethyl-7-methoxyphenanthrene (VIII) melting at 154–155°. 1,2-Dimethyl-7-methoxyphenanthrene[14] is reported to melt at 154–155°.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.70; H, 6.73. Found: C, 86.61; H, 6.94.

The melting point of this material when mixed with an authentic sample of 1,2-dimethyl-7-methoxyphenanthrene, as prepared in the following experiment, was 154–155°.

Synthesis of 1,2-Dimethyl-7-methoxyphenanthrene (VIII).—1-Keto-2-methyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene[7] (X, m. p. 66–67°) was prepared by the alcoholic alkaline hydrolysis of 1-keto-2-methyl-2-carboethoxy-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene[6,7] (IX) in 63% yield.

To a solution of X (1 g.) in sodium-dried ether was added an excess of methylmagnesium iodide. The Grignard addition product was hydrolyzed with dilute sulfuric acid. The ether layer was separated, washed with water, and dried over magnesium sulfate. The solvent was removed, and the crude residue, which solidified readily, was heated four hours at 350° with 2 g. of selenium powder. After extraction with chloroform and distillation from sodium there was obtained 0.5 g. of a solid material which melted at 130–140°. After several recrystallizations from methanol there were obtained prisms of 1,2-dimethyl-7-methoxyphenanthrene melting at 154–155°.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.70; H, 6.73. Found: C, 86.80; H, 6.89.

This product was shown to be identical with that obtained in the previous experiment by the method of mixed melting points.

Acknowledgment.—The author wishes to extend his feeling of appreciation to Drs. James H. Hunter and Harold G. Kolloff for their helpful support and advice in behalf of this work. Miss Margery LePage has been of invaluable technical aid and Messrs. Harold Emerson and William Struck and Misses Celia Triemstra and Barbara Fausnaugh have carried out the analytical work involved.

Thanks are due to Dr. Marvin H. Kuizenga and Messrs. John Nelson and Stanley Lyster of the Department of Pharmacology and Endocrinology, The Upjohn Company, for the estrogenic assays involved.

Summary

Model experiments have been successfully completed which offer several advances in the problems associated with the synthesis of estrone and estrogenic substances:

1. A new method for the synthesis of the hydrophenanthrene portion of the estrone molecule has been developed. The method lends itself well to further development of the D-ring.
2. The procedure includes a method of introducing the angular methyl group ultimately required in sterol synthetic work.
3. An essentially important feature embodied in the method is a systematic approach to the stereoisomeric problem which complicates sterol synthesis.
4. Several potent estrogenic materials have been prepared. The α- and β-forms of 1,2-dimethyl-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene-2-carboxylic acid display estrogenic activity when tested by the Kahnt–Doisy method in the order of *0.240* γ and *5.1* γ, respectively.

The Chloro- and Bromoisobutyronitriles

BY CALVIN L. STEVENS[1]

As early as 1898, Henry[2] reported the isolation of a mixture of α-chloroisobutyronitrile (V) and methacrylonitrile from the reaction of acetone cyanohydrin with phosphorus pentachloride. Later the preparation of α-chloroisobutyronitrile[3,4] and α-bromoisobutyronitrile[5] from the reaction of acetone cyanohydrin with phosphorus pentachloride and phosphorus tribromide, respectively, was described.

Since sizeable amounts of α-chloroisobutyronitrile was needed in this Laboratory, the development of a method that would give this compound in good yields was undertaken. During this investigation, the halonitriles obtained by the procedures of the earlier workers from acetone cyanohydrin were found to have the halogen in the β- rather than in the α-position. The purpose of this paper is to describe the preparation of the α- and β-chloro- and bromoisobutyronitriles by reactions that produce known structures, and to report a new method for the preparation of α-chloro and α-bromoisobutyronitrile in high yields.

Authentic samples of α-chloro and α-bromoisobutyronitriles were prepared by dehydration of the corresponding α-haloisobutyramides. α-Chloroisobutyramide was prepared from isobutyric acid (I) by the sequence of reactions I to IV.

$$\underset{\text{I}}{(CH_3)_2CHCOOH} \xrightarrow{SO_2Cl_2}$$

$$(CH_3)_2CClCOOH + ClCH_2CH(CH_3)COOH \xrightarrow{SOCl_2}$$

$$(CH_3)_2CClCOCl + ClCH_2CH(CH_3)COCl$$

$$\big\downarrow \text{II} \qquad\qquad \text{III}$$

$$\underset{\text{IV}}{(CH_3)_2CClCONH_2} \xrightarrow{P_2O_5} \underset{\text{V}}{(CH_3)_2CClCN}$$

The chlorination of I by the method of Kharasch and Brown,[6] followed by the fractionation of the mixture of the chloroacid chlorides II and III, gave a 16% yield of α-chloroisobutyryl chloride (II) and a 36% yield of β-chloroisobutyryl chloride (III). Kharasch and Brown[6] showed the lower boiling chloroacid chloride to be α-chloroisobutyryl chloride by hydrolysis to the known α-chloroisobutyric acid[7]; the higher boiling, isomeric chloroacid chloride is, therefore, β-chloroisobutyryl chloride (III). The α-chloroisobutyryl chloride (II) was converted to α-chloroisobutyronitrile (V) in 59% yield. The dehydration of α-bromoisobutyramide[8] gave α-bromoisobutyronitrile in 86% yield. These α-halonitriles are different from the halonitriles prepared from acetone cyanohydrin.[3,4,5]

β-Chloro and β-bromoisobutyronitrile may be prepared by the addition of the appropriate hydrogen halide to methacrylonitrile. In this manner, β-chloroisobutyronitrile[9] was prepared in 79% yield and β-bromoisobutyronitrile in 72% yield. These β-haloisobutyronitriles correspond in physical properties to the halonitriles obtained from the reaction of acetone cyanohydrin with phosphorus pentachloride and phosphorus tribromide, to which the α-halo structures had been assigned.[3,4,5] Further evidence that the halogen is in the β-position is the fact that methyl β-chloroisobutyrate (VIII) prepared from III is identical with the ester obtained from VI by the following sequence of reactions

$$CH_2{=}C(CH_3)CN \xrightarrow{HCl} \underset{\text{VI}}{ClCH_2CH(CH_3)CN} \xrightarrow[HOCH_3]{HCl}$$

$$\underset{\text{VII}}{ClCH_2CH(CH_3)C(OCH_3){=}NH{\cdot}HCl} \left[\begin{array}{l} \xrightarrow{H_2O} \underset{\text{VIII}}{ClCH_2CH(CH_3)COOCH_3} \\ \xrightarrow{\Delta} \underset{\text{IX}}{ClCH_2CH(CH_3)CONH_2} \end{array} \right.$$

β-Chloroisobutyramide (IX) could not be prepared in the pure state by the action of ammonia on the acid chloride (III). However, methyl β-chloroiminoisobutyrate hydrochloride (VII), derived from the nitrile (VI), was quantitatively pyrolyzed to β-chloroisobutyramide. A sample of β-bromoisobutyramide was prepared by hydration of the β-bromonitrile with sulfuric acid.[10]

The formation of the β-chloronitrile (VI) from the reaction of acetone cyanohydrin with phosphorus pentachloride undoubtedly results from the initial formation of methacrylonitrile and the subsequent addition of hydrogen chloride, which is present in the reaction mixture, to this nitrile.

(10) McElvain, "The Characterization of Organic Compounds," Macmillan Co., New York, N. Y., 1946, p. 146.

The validity of this conclusion is shown by the fact that with milder conditions than those previously employed,[3,4] methacrylonitrile was isolated in 35% yield from the reaction of phosphorus pentachloride on acetone cyanohydrin.

During this investigation a new method of preparation of α-chloro- and α-bromoisobutyronitriles was developed. When equimolar amounts of isobutyronitrile and phosphorus pentachloride were heated under reflux, hydrogen chloride was evolved smoothly; distillation of the reaction mixture yielded α-chloroisobutyronitrile (78%) and phosphorus trichloride (80%). This reaction is represented as

$$(CH_3)_2CHCN + PCl_5 \longrightarrow (CH_3)_2CClCN + PCl_3 + HCl$$

The chloronitrile obtained from this reaction is identical with the one (V) prepared by the dehydration of α-chloroisobutyramide (IV). Also, the chloroamide corresponding to the chloronitrile prepared from isobutyronitrile is identical with IV.

α-Bromoisobutyronitrile was prepared in a similar manner from an equimolar mixture of bromine, isobutyronitrile and phosphorus tribromide. The α-bromoisobutyronitrile was isolated in 76% yield and is identical with the bromonitrile obtained by the dehydration of α-bromoisobutyramide.[8]

The assistance of Professor S. M. McElvain is gratefully acknowledged.

Experimental

α-Chloroisobutyramide.—To a solution of 150 ml. of concentrated ammonium hydroxide, which was cooled in an ice-bath and stirred vigorously, 17 g. of α-chloroisobutyryl chloride[6] was added at such a rate that the temperature did not rise above 10°. After the addition was finished, the reaction mixture was stirred for fifteen minutes and then the precipitated amide was filtered from the cold solution and dried. An additional 1 g. of amide was obtained when the filtrate was concentrated to 25 ml. and cooled. The dried solid was recrystallized from ethyl acetate; 10.1 g. (70%) of α-chloroisobutyramide, m. p. 115–118°, was obtained from the ethyl acetate solution and by concentration of the mother liquors. A sample, recrystallized from water, melted at 117–119°.

Anal. Calcd. for C_4H_8ClNO: Cl, 29.2; N, 11.5. Found: Cl, 29.2; N, 11.6.

α-Chloroisobutyronitrile. (a) From α-Chloroisobutyramide.—α-Chloroisobutyramide (21 g., 0.17 mole) and phosphorus pentoxide (30 g., 0.21 mole) were thoroughly mixed and placed in a flask equipped with a short still-head, which was attached to a Dry Ice trap. The mixture was heated to 150°; after about ten minutes at this temperature, α-chloroisobutyronitrile began to distil from the reaction flask. After 12.5 g. of nitrile had been collected and the rate of distillation began to diminish, the pressure within the system was reduced to 100 mm. In this way an additional 2.6 g. of nitrile was collected in the cold trap. The total yield of α-chloroisobutyronitrile was 15.1 g. (84%); b. p. 114–116°, $n^{25}D$ 1.4045; d^{25}_4 0.9808.

(b) From Isobutyronitrile.—A mixture of 25 g. (0.36 mole) of isobutyronitrile and 75 g. (0.36 mole) of phosphorus pentachloride was heated to the refluxing temperature. Hydrogen chloride was evolved smoothly and within an hour the solid phosphorus pentachloride had disappeared. After refluxing the clear solution until the hydrogen chloride ceased to be evolved (three hours), the reaction mixture was fractionated through a column of 8 theoretical plates. The first fraction consisted of 39.4 g. (80%) of phosphorus trichloride, b. p. 74–76°. After an intermediate fraction of 2.5 g., b. p. 76–114°, the α-chloroisobutyronitrile (29 g., 78%) was collected at 114–116°; $n^{25}D$ 1.4049.

Anal. Calcd. for C_4H_6ClN: Cl, 34.3; N, 13.5. Found: Cl, 33.8; N, 13.3.

One gram of this nitrile was heated with 2 g. of sulfuric acid and poured onto cracked ice. The precipitated amide, 0.9 g., was filtered, dried, and recrystallized from petroleum ether; m. p. 118–120°. The mixed melting point of this amide with the α-chloroisobutyramide made from the known α-chloroisobutyryl chloride showed no depression, m. p. 118–120°.

β-Chloroisobutyronitrile.—Dry hydrogen chloride was passed into 10 ml. of ether until 4.6 g. (0.12 mole) was absorbed, and then 8.4 g. (0.12 mole) of methacrylonitrile was added. After the ether solution had stood for twelve hours at room temperature, it was distilled; 10.2 g. (79%) of β-chloroisobutyronitrile,[9] b. p. 50–52° (6 mm.); $n^{25}D$ 1.4323; d^{25}_4 1.061, was obtained. This nitrile contained 13.2% nitrogen (calcd. 13.5%).

The chloronitrile obtained from the reaction of phosphorus pentachloride with acetone cyanohydrin by the procedure of Sobieranski and Chrzaszczewski[3] had the same physical properties as that prepared above from methacrylonitrile.

Methyl β-Chloroiminoisobutyrate Hydrochloride.—A solution of 15.8 g. (0.15 mole) of β-chloroisobutyronitrile in 5.1 g. (0.16 mole) of absolute methyl alcohol was cooled in an ice-bath and treated with hydrogen chloride until 5.9 g. (0.16 mole) was absorbed. The resulting homogeneous liquid was placed in a refrigerator for twenty-four hours, during which time it solidified. An equal volume of ether was added and the salt filtered off, dried in a desiccator, and triturated with ether. After drying again, the methyl β-chloroiminoisobutyrate hydrochloride weighed 25.7 g. (99%).

Anal. Calcd. for $C_5H_{11}Cl_2NO$: ionic Cl, 20.6. Found: ionic Cl, 20.6.

β-Chloroisobutyramide.—Five grams of the methyl β-chloroiminoisobutyrate hydrochloride was heated to 115° until methyl chloride ceased to be evolved. The resulting amide, which crystallized on cooling, melted at 100–103°; the yield was quantitative. One recrystallization from a mixture of petroleum ether and ethyl acetate gave 3.2 g. (92%) of β-chloroisobutyramide, m. p. 104–105°.

Anal. Calcd. for C_4H_8ClNO: N, 11.5. Found: N, 11.4.

One gram of the β-chloroisobutyronitrile, prepared from methacrylonitrile, was heated with 1.5 g. of sulfuric acid and then poured onto 5 g. of cracked ice. The precipitate was filtered off and recrystallized from a mixture of benzene and petroleum ether. The yield of β-chloroisobutyramide, m. p. 102–104°, was 0.25 g. This amide is identical with the one prepared from the β-chloronitrile obtained from acetone cyanohydrin.

Attempts to recover the remainder of the amide from the water solution by evaporation led only to an impure product, m. p. 70–85°. All attempts to prepare β-chloroisobutyramide from β-chloroisobutyryl chloride gave a product that melted over a wide range (m. p. 60–80°) even after numerous recrystallizations. This material undoubtedly contained a considerable amount of the dehydrochlorination product from the β-chloroisobutyric acid derivative.

Methyl β-Chloroisobutyrate.—Eight grams of methyl β-chloroiminoisobutyrate hydrochloride was shaken with 15 ml. of water until the salt completely dissolved. Within twenty minutes at room temperature the solution became turbid and the methyl β-chloroisobutyrate began to form a separate layer. After three hours the ester was separated and the aqueous layer extracted with ether. The ether extracts and product were combined, dried, and concentrated. Distillation under reduced pressure gave

5.4 g. (85%) of methyl β-chloroisobutyrate,[11] b. p. 93–95° (106 mm.); $n^{25}D$ 1.4242; d^{25}_4 1.1031. This ester contained 25.6% chlorine (calcd. 26.0%).

Methyl β-chloroisobutyrate also was prepared from the β-chloroisobutyryl chloride obtained from the chlorination of isobutyric acid with sulfuryl chloride.[6] The ester so obtained had physical properties identical with those of the methyl β-chloroisobutyrate prepared from β-chloroisobutyronitrile.

The Isolation of Methacrylonitrile from the Reaction of Acetone Cyanohydrin with Phosphorus Pentachloride.—This reaction was carried out in ether solution instead of benzene[3] to facilitate the isolation of methacrylonitrile. To a solution of 25 g. (0.3 mole) of acetone cyanohydrin in 25 ml. of absolute ether, 31 g. (0.15 mole) of phosphorus pentachloride was added slowly with cooling and stirring. As the ether was heated to the refluxing temperature, the phosphorus pentachloride dissolved and hydrogen chloride was evolved. After two hours of refluxing, 50 ml. of ether was added and the reaction mixture poured onto cracked ice. The layers were separated, the aqueous layer was extracted with ether, and then the combined ether solutions were dried and the ether evaporated. The only products that could be isolated from the residue were 3.5 g. (35% based on the phosphorus pentachloride) of methacrylonitrile, b. p. 86–90°, and 7 g. of unchanged acetone cyanohydrin; 5 g. of undistillable material remained in the flask. Hydrogen chloride was passed into the methacrylonitrile fraction at 50° until 1.5 g. was absorbed. Distillation of this reaction product gave 3 g. (57%) of β-chloroisobutyronitrile, b. p. 52–56° (9 mm.); $n^{25}D$ 1.4330.

α-**Bromoisobutyronitrile.** (a) **From** α-**Bromoisobutyramide.**—The α-bromoisobutyramide[8] used in this preparation was made by allowing α-bromoisobutyryl bromide, b. p. 162–163°, to react with concentrated ammonium hydroxide in the cold; after recrystallization from petroleum ether, it melted at 147–148°. The amide (18.6 g., 0.11 mole) and phosphorus pentoxide (21.3 g., 0.15 mole) were intimately mixed and heated under reflux at 140° for four hours. The α-bromonitrile was distilled from the reaction mixture at atmospheric pressure until the rate of distillation diminished, then the last of the nitrile was collected by evacuation of the system to 100 mm. and condensation of the volatile material in a cold trap. Redistillation gave 14 g. (86%) of α-bromoisobutyronitrile, b. p. 137–139°; $n^{25}D$ 1.4460; d^{25}_4 1.376.

(b) **From Isobutyronitrile.**—A mixture of 25 g. (0.36 mole) of isobutyronitrile and 98 g. (0.36 mole) of phosphorus tribromide was cooled in an ice-bath and 58 g. (0.36 mole) of bromine added with shaking. The reaction mixture was heated gently until hydrogen bromide ceased to be evolved (three hours), after which time the mixture was fractionated. The first fraction, after a small forerun, was α-bromoisobutyronitrile, b. p. 137–140°. The product was slightly colored due to an excess of bromine; however, the color was removed by washing an ether solution of the nitrile with a sodium bisulfite solution. Redistillation gave 40.4 g. (76%) of the water-white α-bromoisobutyronitrile, b. p. 138–140°; $n^{25}D$ 1.4447.

Anal. Calcd. for C_4H_6BrN: Br, 54.0; N, 9.45. Found: Br, 53.7; N, 9.2.

β-**Bromoisobutyronitrile.**—This nitrile was prepared in the same manner as the β-chloronitrile. From 9.5 g. (0.12 mole) of hydrogen bromide and 7.9 g. (0.12 mole) of methacrylonitrile, 12.6 g. (72%) of β-bromoisobutyronitrile, b. p. 60–62° (5 mm.), $n^{25}D$ 1.4680, d^{25}_4 1.465, was isolated.

Anal. Calcd. for C_4H_6BrN: Br, 54.0; N, 9.45. Found: Br, 53.7; N, 9.1.

β-**Bromoisobutyramide** was prepared by gently heating 0.5 g. of the β-bromonitrile and 0.75 g. of sulfuric acid on a hot plate until a reaction occurred and then pouring the mixture onto a small amount of cracked ice. The precipitated amide, 0.2 g., was filtered and recrystallized from petroleum ether, m. p. 103–105°.

Anal. Calcd. for C_4H_8BrNO: N, 8.4. Found: N, 8.1.

Summary

α-Chloroisobutyronitrile and α-bromoisobutyronitrile have been prepared by the dehydration of the corresponding amides; α-chloroisobutyramide is described for the first time.

β-Bromoisobutyronitrile was prepared by the addition of hydrogen bromide to methacrylonitrile. This nitrile has the same properties as the compound isolated from the reaction of phosphorus tribromide with acetone cyanohydrin, to which the α-bromoisobutyronitrile structure had been assigned by earlier workers. Similarly, the β-chloroisobutyronitrile corresponds to the nitrile isolated from the reaction of phosphorus pentachloride on acetone cyanohydrin.

A new and simpler method is described for the preparation of α-chloro and α-bromoisobutyronitriles in high yields by the halogenation of isobutyronitrile with the appropriate phosphorus pentahalide.

The Mercuration of 5-Nitroguaiacol[1,2]

BY NATHAN L. DRAKE, HILLMAN C. HARRIS[3] AND CHARLES B. JAEGER, JR.[4]

The present work was undertaken to determine the structure of the compounds obtained by direct mercuration of 5-nitroguaiacol. In addition to the present work, other chemical, pharmacological and clinical studies are in progress and will be reported elsewhere.

For our purpose, it was of fundamental importance that the 5-nitroguaiacol used be authentic and pure. Undoubtedly all of the possible mononitroguaiacols have been prepared,[5] but no fully satisfactory characterization of them has appeared in the literature. One of us has developed a complete characterization of the mononitroguaiacols,[6] as well as a synthesis of pure 5-nitroguaiacol. Details of the synthesis appear in the Experimental Section of this paper.

2-Amino-5-nitroanisole is a well-known dye intermediate. It is converted readily in high yield to 4-nitroguaiacol by treatment under reflux with aqueous alkali. 4-Nitroguaiacol whose melting point is 102–103°, melts at 96–97° when mixed with 5-nitroguaiacol, whose melting point is 104–104.5°. Both of these nitroguaiacols are converted by dimethyl sulfate and alkali to the same nitroveratrole. Furthermore, they yield different amines, and these amines are converted through their diazonium salts to different hydroxyguaiacols.

Inasmuch as the structure of 4-nitroguaiacol, prepared as above, seems hardly debatable, it is reasonable to conclude that the nitroguaiacol whose melting point is 104–104.5° is 5-nitroguaiacol.

The product from the mercuration of 5-nitroguaiacol with mercuric acetate in aqueous acetic acid in the presence of sodium acetate is an orange colored, amorphous solid having no clearly defined melting point. It is soluble in none of the usual organic solvents except glacial acetic acid. The position of the mercury in the isomers which comprise this product has been demonstrated by the method of Dimroth.[7]

Analyses for mercury show that the product contains 49–54% mercury (depending upon the exact mercuration conditions), which indicates a mixture of mono- and dimercurated derivatives, containing up to 60% dimercurated compound.

Replacement of mercury by bromine[7] yields a mixture of bromonitroguaiacols from which two compounds were isolated by a prolonged and tedious fractional crystallization. The first, I, was a monobromonitroguaiacol, whose melting point was 151–152°; the second, II, was a dibromonitroguaiacol which melted at 119–120°.

Only two monobromoguaiacols are mentioned in the literature.[8,9] Raiford and Silker have very kindly furnished us with a sample of their compound, which they characterized as 4-bromo-5-nitroguaiacol (m. p. 118–119°). Mixed melting point tests showed this to be different from our monobromonitroguaiacol. We have been unable to repeat the synthesis of the compound reported by Robertson following his directions for the bromination of 5-nitroguaiacol. He cites no evidence of the source of his 5-nitroguaiacol; we have not been able to brominate 5-nitroguaiacol by any of the usual methods.

The identity of compound I was established by eliminating the nitro group by reduction, diazotization of the resulting amine, and reaction of the diazonium salt with hypophosphorous acid.[10] This series of reactions yielded a product which melted at 62–63° and which was found to be 6-bromoguaiacol; an authentic sample was obtained from 6-nitroguaiacol[8] by replacement of the nitro group with bromine by way of the amine according to the Sandmeyer method. Compound I is, therefore, 6-bromo-5-nitroguaiacol.

A similar series of reactions starting with II gave a dibromoguaiacol which melted at 64–65°. An identical product was synthesized from 4-nitroguaiacol by bromination followed by replacement of the nitro group with bromine in the same way as before. Compound II is, therefore, 4,6-dibromo-5-nitroguaiacol. This was confirmed by the replacement of the nitro group of II by bromine; the substance thus obtained was the same tribromoguaiacol formed by direct bromination of guaiacol,[11] namely, 4,5,6-tribromoguaiacol.

Experimental

Guaicol Acetate.—Redistilled guaiacol (b. p. 204–205°) was acetylated by mixing it (124 g., 1 mole) with acetic anhydride (204 g., 2 moles) and 1 ml. of concentrated sul-

furic acid as catalyst and distilling the mixture until the acetic acid formed in the reaction was removed, as indicated by a still-head temperature equivalent to the boiling point of acetic anhydride. The reaction mixture was then cooled, washed with cold water, dried over calcium chloride, and fractionated under reduced pressure. The yield was 124 g. of guaiacol acetate which boiled at 123–124° (13 mm.).

5-Nitroguaiacol.—A solution of guaiacol acetate (135 g., 0.813 mole) in 120 ml. of glacial acetic acid was added all at once to a solution of 115 ml. of fuming nitric acid (sp. gr. 1.5) in 180 ml. of glacial acetic acid in a beaker of at least 3-liters capacity. The temperature rose slowly at first and then more rapidly, and an extremely vigorous nitration took place with much fuming and boiling and copious evolution of red-brown fumes. For safety this reaction was carried out under a closed hood. About ten minutes after the boiling had subsided, the mixture was poured over several liters of crushed ice and water. The oily precipitate first formed crystallized at once when it was stirred. The crystalline product was washed by decantation several times with cold water, separated by filtration, further washed with cold water until free from acid, and dried in a vacuum desiccator over concentrated sulfuric acid.

The crude 5-nitroguaiacol acetate so obtained was hydrolyzed by suspending it in 650 ml. of hot 10% sodium hydroxide and heating the mechanically stirred mixture to a temperature just below the boiling point until solution was complete. After addition of 65 g. of solid sodium chloride, the well-stirred mixture was cooled to 5°, and the thick precipitate of the sodium salt of 5-nitroguaiacol filtered off, pressed as dry as possible on the filter, and washed with a little cold, saturated sodium chloride solution. The product was dissolved in 1.5–2 liters of water and filtered. The solution was acidified with concentrated hydrochloric acid and the product separated by filtration, washed with water and dried in a vacuum desiccator over concentrated sulfuric acid. The material was purified by vacuum distillation (b. p. 110–112° (1 mm.)) and by recrystallization from benzene. The yield of material which melted at 104–104.5° was 57.7 g. (42%, based on guaiacol acetate). It is possible that the vacuum distillation may be unnecessary since the product from hydrolysis is fairly pure.

Nitration by the usual methods yields products containing appreciable amounts of 3-nitroguaiacol which is separated from 5-nitroguaiacol only with great difficulty. *Anal.* Calcd. for $C_7H_7NO_4$: C, 49.71; H, 4.15. Found: C, 49.91; H, 4.22.

Mercuration of 5-Nitroguaiacol.—5-Nitroguaiacol (100 g.) and 400 g. of mercuric acetate were dissolved in 3.5 liters of a 35% aqueous solution of acetic acid, containing 1% of sodium acetate. The solution was stirred mechanically and heated on a steam-bath for six hours, during which time an orange precipitate formed and gradually became thicker and deeper in color. After six hours, the mixture was cooled, the product separated by filtration, washed well with water, and dissolved in hot, dilute alkali; the solution was filtered through kieselguhr and the product precipitated with the desired acid. The yield was 290–325 g. (acetoxymercuri compound). *Anal.* Calcd. for $C_9H_9O_6NHg$: Hg, 46.90. Calcd. for $C_{11}H_{11}O_8NHg_2$: Hg, 58.45. Found: Hg, 48.90.[12]

Other runs were made in which the mercurated product contained up to 54% mercury. It appears that slight variations in procedure greatly affect the relative amounts of mono and di-mercurated products obtained.

Bromomercuri Derivative.—Fifty grams of acetoxymercuri compound was dissolved in hot 1 *N* potassium hydroxide and the solution filtered through kieselguhr. Hydrobromic acid (48%) was added dropwise, with stirring, to the cooled solution, until the yellow bromomercuri derivative had precipitated completely.

The product was separated by filtration, washed thoroughly with water, and pressed as dry as possible on the filter. It was dried in a vaccum desiccator over concentrated sulfuric acid. Yield was 51 g. *Anal.* Calcd. for $C_7H_6O_4NBrHg$: Hg. 44.71. Calcd. for $C_7H_5O_4NBrHg_2$: Hg, 56.18. Found: Hg, 46.50.

Dimroth Reaction (Mercurated 5-Nitroguaiacol and Bromine.—Fifty grams of bromomercuri derivative was dissolved in 500 ml. of glacial acetic acid on a steam-bath. Bromine was added slowly to the mechanically stirred solution while frequent tests for free bromine (starch–iodide paper) were made. When a positive test for free bromine persisted for thirty minutes, addition of bromine was halted and the solution was stirred for thirty minutes longer; about 18 g. of bromine was required. Excess bromine was destroyed by a little sodium bisulfite and the acetic acid was removed by distillation under reduced pressure. The residue was taken up in hot 1 *N* potassium hydroxide and the solution filtered through kieselguhr (or centrifuged) to remove inorganic mercury salts. Acidification by means of hydrochloric acid precipitated a yellow crystalline product which was contaminated with a small amount of gummy material. After it has been dried in an oven at 100°, the product was taken up in anhydrous ether, treated with 1–2 drops of bromine, and filtered. The ether solution was extracted with 1 *N* potassium hydroxide, and the bright red aqueous layer freed from ether by boiling and then acidified with hydrochloric acid. The crystalline product was separated by filtration, washed with water and dried *in vacuo* in an Abderhalden pistol over phosphorus pentoxide at the boiling point of ethyl alcohol. The yield was 23 g.; the product melted at 109–122°. *Anal.* Calcd. for $C_7H_6BrNO_4$: Br, 32.22. Calcd. for $C_7H_5Br_2NO_4$: Br, 48.89. Found: Br, 37.10.

Unsuccessful attempts were made to separate this mixture into pure components by fractional distillation and by fractional crystallization from a variety of solvent combinations. Separation was finally achieved by a prolonged and tedious fractional crystallization from aqueous acetic acid (50% by volume). The general procedure indicated by Morton[13] was used, and fractions of similar melting point were combined. For final purification, the end-products were washed thoroughly with cold water and recrystallized from methanol–water. From 20 g. of mixture were obtained 10.7 g. of a yellow crystalline compound, I, m. p. 151–152° and 2.2 g. of a second compound, II, m. p. 119–120° and 5.1 g. of intermediate fractions. *Anal.* I: Calcd. for $C_7H_6BrNO_4$: C, 33.87; H, 2.44; Br, 32.22. Found: C, 33.96; H, 2.53; Br, 32.33. II: Calcd. for $C_7H_5Br_2NO_4$: C, 25.71; H, 1.54; Br, 48.89. Found: C, 25.59; H, 170; Br, 48.51.

6-Bromo-5-nitroguaiacol Acetate.—One gram of product, I, above was acetylated with 0.5 ml. of acetic anhydride with a trace of concentrated sulfuric acid as catalyst. The solid product was recrystallized from a methanol–water mixture (*ca.* 4–1). The yield was 1 g. (85%); the substance melts at 126–127°. *Anal.* Calcd. for $C_9H_8BrNO_5$: C, 37.27; H, 2.78. Found: C, 37.40; H, 2.90.

4,6-Dibromo-5-nitroguaiacol Acetate.—Using the same procedure as in the previous experiment, 0.5 g. of product, II, was acetylated with 0.3 ml. of acetic anhydride. The yield was 0.52 g. (92%); the substance melts at 135–136°. *Anal.* Calcd. for $C_9H_7Br_2NO_5$: C, 29.30; H, 1.91. Found: C, 29.50; H, 2.13.

6-Bromoguaiacol from I.—Two grams of I was reduced with tin and hydrochloric acid. The solution was diluted with water, filtered, and freed from tin by treatment with hydrogen sulfide. After excess hydrogen sulfide had been removed by boiling, the residual solution was concentrated under reduced pressure to a volume of about 15 ml. Two ml. of concentrated hydrochloric acid was added and the solution was cooled to 5° and the amine diazotized by the slow addition of a cold solution of 0.6 g. of sodium nitrite in 5 ml. of water, using starch–iodide indicator. To the cold diazonium salt solution was added 16 g. of cold 50%

[12] Analyses for mercury by gravimetric and/or volumetric methods of Jamieson, *Ind. Eng. Chem.*, **4**, 206 (1919). Decompositions were effected by fuming nitric acid, *cf.* Hart and Herschfelder, THIS JOURNAL, **42**, 2680 (1920).

[13] Morton, "Laboratory Technique in Organic Chemistry," The McGraw-Hill Book Co., Inc., New York, N. Y., 1935.

hypophosphorous acid. The temperature was maintained at 0–5° for one hour and then the solution was stored in a refrigerator at 5–10° for twenty hours. Steam distillation of this solution yielded a crystalline product which was recrystallized from an ethanol–water mixture (*ca.* 5:1). The yield was 0.46 g. (28%); the product melted at 62–63° and showed no depression of melting point when mixed with varied quantities of 6-bromoguaiacol. *Anal.* Calcd. for $C_7H_7BrO_2$: Br, 39.38. Found: Br, 39.76.

4-Nitroguaiacol.—2-Amino-5-nitroanisole (50 g.) (Eastman Kodak Co. product No. P 2329 recrystallized from ethanol, m. p. 140–141°) was hydrolyzed with a solution of 50 g. of sodium hydroxide in 450 ml. of water by heating at the boiling point for thirty hours under reflux. When the reaction mixture was cooled, the sodium salt of 4-nitroguaiacol crystallized in bright red needles. The cold solution was filtered and the red crystals dissolved in 1.5 liters of hot water; the solution was filtered, cooled, and acidified with hydrochloric acid. The 4-nitroguaiacol was separated by filtration and dissolved in benzene; the solution was dried by removing the benzene–water azeotrope by distillation. The product was then crystallized from the dry benzene. The yield was 43.2 g. (86%); the 4-nitroguaiacol melted at 102–103°. *Anal.* Calcd. for $C_7H_2NO_4$: C, 49.71; H, 4.17. Found: C, 49.61, 49.86; H, 4.15, 4.21.

6-Bromo-4-nitroguaiacol from 2-Amino-3-bromo-5-nitroanisole.—The anisole derivative (20 g.) was heated in a bomb at 130° under pressure for four and one-half hours with 4 g. of sodium hydroxide in 100 ml. of water. Six grams of starting material was recovered unchanged. The filtered alkaline solution was boiled to expel ammonia and acidified. The yellow product was recrystallized from an ethanol–water mixture (5:1). The yield was 13 g. (93%); this specimen of 6-bromo-4-nitroguaiacol melted at 150° (dec.), and was found to be identical with the substance described directly below.

6-Bromo-4-nitroguaiacol from Bromination of 4-Nitroguaiacol.—A solution of 11.7 g. of 4-nitroguaiacol in 100 ml. of glacial acetic acid was brominated by the slow addition of 12.5 g. of bromine in 40 ml. of glacial acetic acid. After 1–2 ml. of the bromine solution had been added, the mixture was warmed with a flame until the evolution of hydrobromic acid was evident, whereupon addition of the solution of bromine was continued during one hour; stirring was continued one hour longer and the reaction mixture was then poured into 300 ml. of cold water. The yellow precipitate was separated by filtration and recrystallized from an ethanol–water mixture (5:1). The yield was 12.1 g. (70.3%); the product melted at 150° (dec.)

6-Bromo-nitroguaiacol Acetate.—6-Bromo-4-nitroguaiacol (1 g.) was acetylated in the presence of a trace of sulfuric acid by means of 0.5 ml. of acetic anhydride. The product was recrystallized from a methanol–water mixture (3.5:1). The yield was 1.1 g. (91%) of a substance which melted at 102–103°. *Anal.* Calcd. for $C_9H_8BrNO_5$: C, 37.27; H, 2.78. Found: C, 37.13; H, 2.90.

4,6-Dibromoguaiacol from 6-Bromo-4-nitroguaiacol.—6-Bromo-4-nitroguaiacol (4 g.) was reduced with tin and hydrochloric acid. The solution was diluted, filtered and freed from tin by treatment with hydrogen sulfide. After the solution had been boiled to rid it of excess hydrogen sulfide, it was concentrated under diminished pressure to a volume of *ca.* 30 ml. Three ml. of concentrated hydrochloric acid was added, the solution was cooled to 0° by immersion in an ice and salt mixture, and the dissolved amine salt was diazotized by the addition of a cold solution of 1.2 g. of sodium nitrite in 20 ml. of water. Starch–iodide paper was used as indicator. A solution of cuprous bromide was prepared as follows: 5 g. of crystallized copper sulfate was dissolved in 16 ml. of boiling water and 2.4 g. of potassium bromide was dissolved in the hot solution. To this hot solution was added slowly a solution of 1.1 g. of sodium pyrosulfite ($Na_2S_2O_5$), and 0.75 g. of sodium hydroxide in 8 ml. of water. The precipitated cuprous bromide was then washed twice with water by decantation and dissolved in 15 ml. of 40% hydrobromic acid. This solution was heated in an apparatus arranged for steam distillation and the cold diazonium solution above was added dropwise while the mixture steam-distilled simultaneously. The white solid which crystallized in the distillate was separated by filtration and recrystallized from aqueous ethanol. The yield was 1.2 g. (25.5%); the product melted at 64–65°. *Anal.* Calcd. for $C_7H_6Br_2O_2$: C, 28.02; H, 2.14; Br, 56.70. Found: C, 28.13; H, 2.23; Br, 56.59.

4,6-Dibromoguaiacol from II.—One and one-half grams of II was reduced with tin and hydrochloric acid. As before, the solution was diluted with water, filtered, freed of tin by treatment with hydrogen sulfide, and concentrated under reduced pressure to 15 ml. whereupon 3 ml. of concentrated hydrochloric acid was added. The solution was then cooled to 0° and the dissolved amine salt diazotized by addition of a cold solution of 0.36 g. of sodium nitrite dissolved in 15 ml. of water again using starch–iodide paper as an indicator. To the cold diazonium salt solution was added 10 g. of a cold 50% solution of hypophosphorous acid. The solution was maintained at 0–5° for one hour and then kept in a refrigerator at 5–10° for twenty-four hours. When the resultant solution was steam distilled, a white solid crystallized in the distillate and was separated by filtration and recrystallized from an ethanol–water mixture. The yield was 0.4 g. (31%); the product melted at 63–64°.

This product proved to be identical with that previously obtained from 6-bromo-4-nitroguaiacol. Mixed melting point tests resulted in no depression in melting point.

4,5,6-Tribromoguaiacol from II.—One and one-half grams of II was reduced with tin and hydrochloric acid, freed from tin, concentrated and diazotized as in the previous experiments. A solution of cuprous bromide in hydrobromic acid was prepared and the cold diazonium solution added dropwise to it while steam was blown through the mixture. A white crystalline product was filtered from the distillate and recrystallized from an ethanol-water mixture. The yield was 0.31 g. (18.7%), m. p. 114–116°. This product shows no depression in melting point when mixed with varied quantities of authentic 4,5,6-tribromoguaiacol.

4-Hydroxyguaiacol from 4-Aminoguaiacol.—A solution of 4.2 g. of the amine obtained by reduction of 4-nitroguaiacol was dissolved in 33 ml. of water and 33 ml. of concentrated sulfuric acid. This solution was diluted with 300 ml. of water and treated at −8°, with a solution of 2.1 g. of sodium nitrite dissolved in a small amount of water. After the diazotization was complete, the solution was warmed quickly and heated on a water-bath for thirty minutes. Extraction with ether followed by evaporation of the ether yielded 1.3 g. of product which melted at 80–82°. Two recrystallizations from benzene raised the melting point to 90–91°. *Anal.* Calcd. for $C_7H_8O_3$: C, 59.99; H, 5.76. Found: C, 60.09; H, 5.80.

5-Aminoguaiacol from 5-Nitroguaiacol.—5-Nitroguaiacol was reduced in ether at 70–100° in the presence of Raney nickel at a pressure of 1600 p. s. i. of hydrogen. The yield of a product which melted at 131–133° was 79%. Substantially the same yield was obtained using Adams catalyst and alcohol as solvent. Recrystallization from benzene yielded a product which melted at 130–131°. *Anal.* Calcd. for $C_7H_9O_2N$: C, 60.43; H, 6.45. Found: C, 60.44, 60.55; H, 6.44, 6.44.

5-Hydroxyguaiacol from 5-Aminoguaiacol.—The method used was like that described above for the preparation of 4-hydroxyguaiacol; 2.8 g. of amine yielded 1.5 g. of product. The 5-hydroxyguaiacol melted at 71–72° after two recrystallizations from benzene and ligroin. *Anal.* Calcd. for $C_7H_8O_3$: C, 59.99; H, 5.76. Found: C, 59.95; H, 5.74.

4-Nitroveratrole from 4- and 5-Nitroguaiacol.—Methylation of 4-nitroguaiacol by means of dimethyl sulfate and alkali yielded a product which, after recrystallization from ligroin and then from alcohol, melted at 97–98°. *Anal.* Calcd. for $C_8H_9NO_4$: C, 52.46; H, 4.95. Found: C, 52.47; H, 5.03.

Methylation of 5-nitroguaiacol yielded a product which, after recrystallization from ligroin, melted at 96–97°. A mixture of this substance and the one obtained from 4-nitroguaiacol melted at 96–97°.

Summary

It has been shown that the mercuration of 5-nitroguaiacol results principally in the formation of 6-acetoxymercuri-5-nitroguaiacol and 4,6-diacetoxymercuri-5-nitroguaiacol.

In the course of the work three new compounds, 6-bromo-5-nitroguaiacol, 4,6-dibromo-5-nitroguaiacol and 4,6-dibromoguaiacol, have been prepared and characterized.

Evidence has been offered that the substance mercurated was in fact 5-nitroguaiacol and not an isomer.

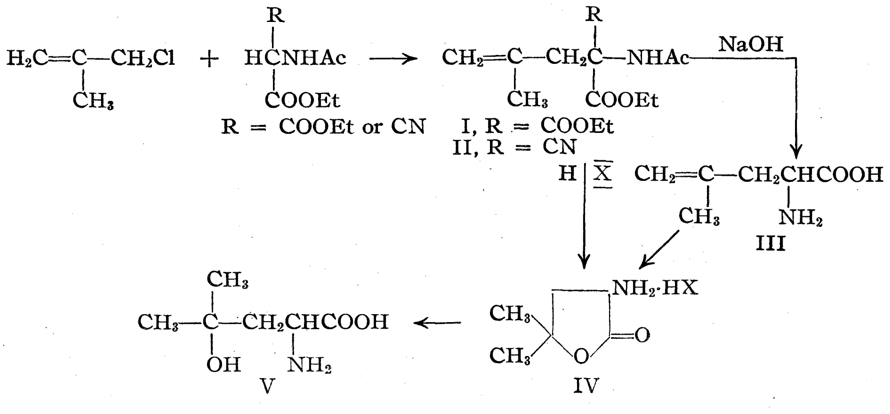
Amino Acid Intermediates: α-Amino-γ-lactones

BY JEANNE FILLMAN AND NOEL ALBERTSON

α-Amino-γ-lactones have been used not only for the synthesis of γ-hydroxyamino acids, but also for the preparation of such amino acids as methionine[1] and canaline.[2] In general, the lactones have been prepared by the reaction of the appropriate oxide with a malonic or acetoacetic ester. For example, γ-hydroxyproline has been synthesized from epichlorohydrin and malonic ester[3] and γ-hydroxyleucine (V) recently was synthesized from isobutylene oxide and actamidomalonic ester.[4] In the latter instance the condensation product was an oil so that hydrolysis gave glycine as an impurity difficult to remove.

Since lactones may also be prepared from β,γ- and γ,δ-unsaturated acids,[5] a possible route to γ-hydroxyamino acids would involve condensation of an allyl halide with an acylaminomalonic or acylaminocyanoacetic ester and conversion to the amino acid *via* the lactone.



Methylallyl chloride has been reported to condense with acetamidomalonic ester in 79% yield[6] and with acetamidocyanoacetic ester in 82% yield[7] of recrystallized product (I and II, respectively). Hydrolysis of I with hydrochloric acid for four hours gave an 85% yield of γ-hydroxyleucine lactone hydrochloride (IV). The same lactone was obtained on acid hydrolysis of the cyano intermediate (II) or methylallylglycine (III), the latter amino acid being obtained from I or II by basic hydrolysis.[7] Conversion of the lactone to γ-hydroxyleucine was accomplished by means of the flavianate according to the procedure of Dakin.[4]

This method of synthesizing γ-hydroxyleucine is simpler experimentally and gives better yields and a purer[8] product than the method using isobutylene oxide.

One would normally expect a γ-hydroxy acid to form a lactone, but Dakin points out that γ-hydroxyleucine does not readily give a lactone on boiling with hydrochloric acid. This is in marked contrast to the phenyl isocyanate derivative which has been obtained only in the form of the lactone. However, it has been found that under proper conditions (refluxing for five and one-half hours with concentrated hydrochloric acid) γ-hydroxyleucine is converted to the lactone hydrochloride as shown by mixed melting point and chlorine analysis. At the end of three and one-half hours the conversion was not yet complete, so that lactonization of this hydroxy acid requires relatively strenuous treatment. This is especially surprising in view of the structure of γ-hydroxyleucine. Since "substituent alkyl groups decidedly

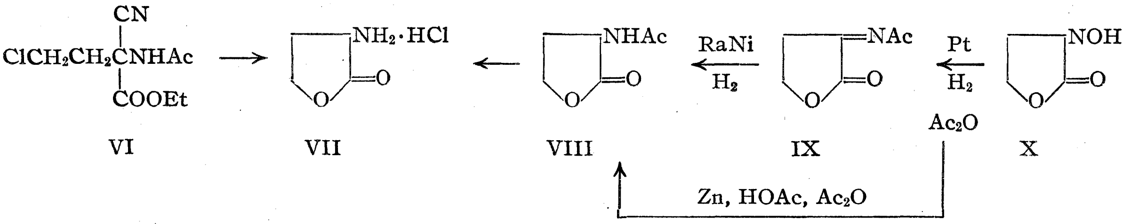
(8) Apparently the product prepared by Dakin (ref. 4) still contained a trace of glycine since it gave a phenyl isocyanate derivative melting at 188–189° with slight previous softening. We found that this derivative melted at 200–201°. The lactone (IV) gave a phosphotungstate, a copper salt, a Reinecke salt and a flavianate in agreement with the derivatives reported by Dakin.

favor the formation of lactones[9]" one might have anticipated an almost spontaneous lactonization. In contrast to the hydroxyamino acid (V) the unsaturated acid (III) is readily converted to the lactone by hydrochloric acid.

Inasmuch as Sorensen has prepared allylglycine in high yields by hydrolyzing allyl *o*-carboxybenzamidomalonic acid with concentrated hydrochloric acid,[10] it is apparent that allylglycine is not converted to the lactone under these conditions. It has been found, however, that either hydrobromic or hydriodic acid will convert allylacetamidocyanoacetic ester to the lactone, whereas the use of hydrochloric acid results in the formation of allylglycine. The lactone was converted to the benzoyl derivative and one *dl*-form was isolated.

In an attempt to extend this method of synthesis to γ-hydroxyproline the commercially available 1,3-dichloropropene was condensed with acetamidocyanoacetic ester and the product hydrolyzed with hydrochloric acid to give ω-chloro allylglycine. "Lactonization" of this amino acid should give the known α-amino-δ-chloro-γ-valerolactone from which γ-hydroxyproline has previously been prepared.[11] However, no lactone could be obtained by treatment of ω-chloroallylglycine with hydrobromic, hydriodic, sulfuric, perchloric or periodic acids or with hydrogen chloride in acetic acid, probably because of steric effects.

Inasmuch as γ-halogen substituted acids are also useful in the preparation of lactones an alternative synthesis of α-amino-γ-lactones would involve the preparation and hydrolysis of a γ-halogen substituted acetamidocyanoacetic ester. It was found that hydrochloric acid readily converted β-chloroethylacetamidocyanoacetic ester, VI, to the known α-amino-γ-butyrolactone hydrochloride, VII, an intermediate in the synthesis of methionine[1] and canaline.[2]



The β-chloroethylacetamidocyanoacetic ester was synthesized from ethylene chlorobromide and sodioacetamidocyanoacetic ester in toluene. Previous attempts to condense ethylene chloride or ethylene bromide with acylaminomalonic esters have been unsuccessful.[12] However, these attempted syntheses were carried out in alcohol in which case the sodium ethylate was undoubtedly basic enough to remove HX from the ethylene halide to form a vinyl halide which would escape from the condenser.

It is interesting to note that Painter[13] attempted to prepare β- and γ-halogen amino acids by hydrolysis of appropriately halogen substituted benzamidomalonic esters but was unable to isolate the desired amino acids after hydrolysis. It is very likely that, at least in the case of the γ-halogen acids, lactones were formed on hydrolysis.

An attempt to react VI with potassium benzohydroxamate with a view to synthesizing canaline was unsuccessful. Replacement of the chlorine by iodine still gave negative results.

An alternative synthesis of α-amino-γ-butyrolactone hydrochloride involved reductive acetylation of the readily available α-oximino-γ-butyrolactone followed by hydrolysis of the intermediate α-acetamido-γ-butyrolactone, VIII.[14] Although zinc dust reduced the oxime to the acetamido compound, catalytic reduction with a platinum catalyst in acetic anhydride solution resulted in the uptake of only one mole of hydrogen to give α-acetimido-γ-butyrolactone, IX. With a Raney nickel catalyst, IX was rapidly and quantitatively reduced to the acetamido compound VIII. Upon hydrolysis this gave α-amino-γ-butyrolactone hydrochloride identical with that previously prepared. Hydrolysis of the intermediate α-acetimido-γ-butyrolactone gave ammonium chloride as the only crystalline product.

Experimental

γ-Hydroxyleucine Lactone Hydrochloride (IV).—Seventy-one and six-tenths grams of diethyl methylallylacetamidomalonate[6] was refluxed for four hours with 250 ml. of concentrated hydrochloric acid. The resulting solution was concentrated *in vacuo* and the residue taken up in hot ethanol. Upon cooling and filtering there was obtained 28.8 g. of product. By concentrating the filtrate and cooling an additional 8.3 g. was obtained, m. p. 207–209°. The yield was 85%. An analytical sample, recrystallized from ethanol, melted at 208–209°.

Anal. Calcd. for $C_6H_{11}NO_2 \cdot HCl$: C, 43.51; H, 7.31; N, 8.46; Cl, 21.41. Found: C, 43.50; H, 7.20; N, 8.26; Cl, 21.49.

When methylallylacetamidocyanoacetic ester (II)[7] or methylallylglycine (III)[7] was used in the above experiment the same lactone was obtained.

The benzoyl derivative, recrystallized from aqueous methanol, melted at 176°.

Anal. Calcd. for $C_{13}H_{15}NO_3$: N, 6.01. Found: N, 6.01.

The carbobenzoxy derivative, recrystallized from aqueous ethanol, melted at 91–93°.

---

[14] This compound has been prepared by reductive acetylation of α-keto-γ-butyrolactone phenylhydrazone using Raney nickel catalyst: Snyder, Andreen, Cannon and Peters, *ibid.*, **64**, 2082 (1942).

Anal. Calcd. for $C_{14}H_{17}NO_4$: N, 5.32. Found: N, 5.32.

The phenyl isocyanate derivative, recrystallized from aqueous methanol, melted at 200–201°.

Anal. Calcd. for $C_{13}H_{16}N_2O_3$: C, 62.89; H, 6.50; N, 11.28. Found: C, 62.86; H, 6.41; N, 11.30.

The lactone gave a flavianate which decomposed at 273–276°.

γ-Hydroxyleucine (V).—Twenty-eight grams of γ-hydroxyleucine lactone hydrochloride (IV) was converted to γ-hydroxyleucine by use of flavianic acid according to the procedure of Dakin.[4] There was obtained 20.6 g. of amino acid melting at 220–222° when dried at 65°.

Anal. Calcd. for $C_6H_{13}NO_3\cdot H_2O$: N, 8.50. Found: N, 8.52.

When dried at 100° *in vacuo*, the amino acid lost water and melted at 230–232°.

Anal. Calcd. for $C_6H_{13}NO_3$: N, 9.52. Found: N, 9.38.

The amino acid gave a flavianate, reineckate and phosphotungstate agreeing in properties with those reported by Dakin.[4]

Lactone from α-Hydroxyleucine.—Five grams of γ-hydroxyleucine was refluxed for five and one-half hours with 1:1 hydrochloric acid. The solution was concentrated *in vacuo* and the residue recrystallized from ethanol, m. p. 208–209°. It did not depress the melting point of γ-hydroxyleucine lactone hydrochloride.

Anal. Calcd. for $C_6H_3NO_3\cdot HCl$: Cl, 193.1. Calcd. for $C_6H_{11}NO_2\cdot HCl$: Cl, 21.49. Found: Cl, 21.30.

When γ-hydroxyleucine was refluxed with hydrochloric acid for only three and one-half hours the reaction mixture was a mixture of hydroxy amino acid and lactone.

Allylglycine.—Allylacetamidocyanoacetic ester was refluxed with hydrochloric acid (6 ml. of 1:1 aqueous acid per gram of ester) for five hours. The solution was charcoaled, filtered and concentrated *in vacuo*. The residue was taken up in water and made basic with sodium hydroxide to expel ammonia. The mixture was then made just acid with hydrochloric acid, cooled and filtered to give platelets melting at 170–190°. Three recrystallizations from water gave crystals, m. p. 212–215°.

Anal. Calcd. for $C_5H_9NO_2$: N, 12.17. Found: N, 12.08.

Benzoyl-*dl*-allylglycine.—Three grams of the above lactone was benzoylated in the usual manner. The product, twice recrystallized from water, melted at 105–106°.

Anal. Calcd. for $C_{12}H_{13}NO_3$: N, 6.39. Found: N, 6.33. Bromine titration indicated 1.00 double bonds.

Benzamido-γ-hydroxynorvaline Lactone.—Hydrolysis of allylacetamidocyanoacetic ester was carried out as above with either hydrobromic or hydriodic acid. However, as soon as the ammonia had been expelled from the basic solution benzoyl chloride was added. The benzoyl derivative was isolated in the usual manner, freed of benzoic acid with Skellysolve B and recrystallized from small volumes of ethanol. The product was triturated with ether and finally recrystallized from water, m. p. 140–141°.

Anal. Calcd. for $C_{12}H_{13}NO_3$: N, 6.39. Found: N, 6.41. It absorbed no bromine.

ω-Chloroallylglycine.—1,3-Dichloropropene[15] was condensed with acetamido-cyanoacetic ester and the resulting product hydrolyzed with hydrochloric acid according to methods previously described.[7] The yield of ω-chloroallylglycine, recrystallized from aqueous ethanol, was 38% m. p. 236°.

Anal. Calcd. for $C_5H_8ClNO_2$: N, 9.30. Found: N, 9.38.

The benzoyl derivative, recrystallized from aqueous ethanol, melted at 150–151°.

Anal. Calcd. for $C_{12}H_{12}ClNO_3$: Cl, 13.97. Found: Cl, 13.68.

When chloroallylglycine was refluxed for four hours with hydrobromic, hydriodic, sulfuric, perchloric or periodic acid and the mixture then benzoylated only benzoyl-ω-chloroallylglycine was obtained. Hydrogen chloride in acetic acid gave only the amino acid hydrochloride.

β-Chloroethylacetamidocyanoacetic Ester (VI).—To a solution of 11.5 g. of sodium in 150 ml. of dry alcohol there was added 85 g. of ethyl acetamidomalonate. The alcohol was distilled off and toluene was dripped in simultaneously until no more alcohol remained. Then 338 g. of ethylene chlorobromide was added and the mixture refluxed twenty-nine hours. The precipitated sodium bromide (47 g.) was removed by filtration and the filtrate concentrated *in vacuo*. The residual oil (93.6 g.) was dissolved in alcohol and diluted with ice water. There was thus obtained 65 g. of crystalline product.

The product gave a precipitate when boiled with alcoholic silver nitrate and ammonia when boiled with sodium hydroxide. Probably a small amount of bromoethylacetamidocyanoacetic ester was also obtained in this reaction.

An analytical sample, recrystallized several times from ethyl acetate–Skellysolve B, melted at 109.5–111.5°.

Anal. Calcd. for $C_9H_{13}ClN_2O_3$: N, 12.04. Found: N, 11.46.

α-Amino-γ-butyrolactone Hydrochloride from VI.—When chloroethylacetamido-cyanoacetic ester was refluxed with concentrated hydrochloric acid for five hours, the solution concentrated to dryness, and the residue recrystallized several times from 95% alcohol the product was α-amino-γ-butyrolactone hydrochloride. The melting point was not depressed when mixed with a sample (m. p. 198–199.5°) obtained by the hydrolysis of 3,6-bis-(β-hydroxyethyl)-2,5-diketopiperazine.

α-Acetimido-γ-butyrolactone (IX).—Reduction of 11.5 g. of α-oximino-γ-butyrolactone[14] was effected in the presence of 0.3 g. of Adams platinum oxide catalyst, 28 ml. of acetic anhydride and 72 ml. of acetic acid at 50° and 50 lb. pressure. The residue, after removal of the solvent and catalyst, was washed well with water and recrystallized from methanol. The product, 7.0 g. of long needles, melted at 156°.

Anal. Calcd. for $C_6H_7NO_3$: N, 9.93. Found: N, 10.04.

Hydrolysis of this compound with hydrochloric acid gave ammonium chloride.

α-Acetamido-γ-butyrolactone (VIII) from IX.—A solution of 1.41 g. of α-acetimido-γ-butyrolactone was reduced in two minutes with a Raney nickel catalyst in ethanol. The product, after recrystallization from ethyl acetate, melted at 79–81°.[14] It did not depress the melting point of a sample prepared by reductive acetylation of (X) as described below. Hydrolysis of the product with hydrochloric acid gave α-amino-γ-butylactone hydrochloride.

α-Acetamido-γ-butyrolactone (VIII) from X.—A solution of 4.6 g. of oxime (X) in 100 ml. of acetic acid and 30 ml. of acetic anhydride was stirred during the addition of 12 g. of zinc dust portionwise. The mixture was filtered and the filtrate concentrated *in vacuo*. The residue was recrystallized from benzene–Skellysolve B and then ethyl acetate. Yield was 3.6 g. melting at 72–76°. Another recrystallization from ethyl acetate raised the melting point to 81–83°.

Summary

A synthetic approach to the synthesis of γ-hydroxyamino acids involving condensation of an allyl halide with an acylaminomalonic or acylaminocyanoacetic ester, hydrolysis to the lactone and conversion to the amino acid has been illustrated by the preparation of γ-hydroxyleucine.

The lactone of γ-hydroxynorvaline has also been synthesized by the same procedure, but the method failed to give the requisite α-amino-δ-chlo-

---

[15] A commercial sample obtained from Columbia Organic Chemicals Co., Inc., was used. Nearly all boiled at 104–106° at 761 mm., $n^{25}D$ 1.4651. It was therefore mainly the α form. *Cf.* Hatch and Moore, *ibid.*, **66**, 285 (1944).

ro-γ-valerolactone required for the synthesis of γ-hydroxyproline.

The preparation of α-amino-γ-butyrolactone by hydrolysis of β-chloroethylacetamidocyanoacetic ester is described.

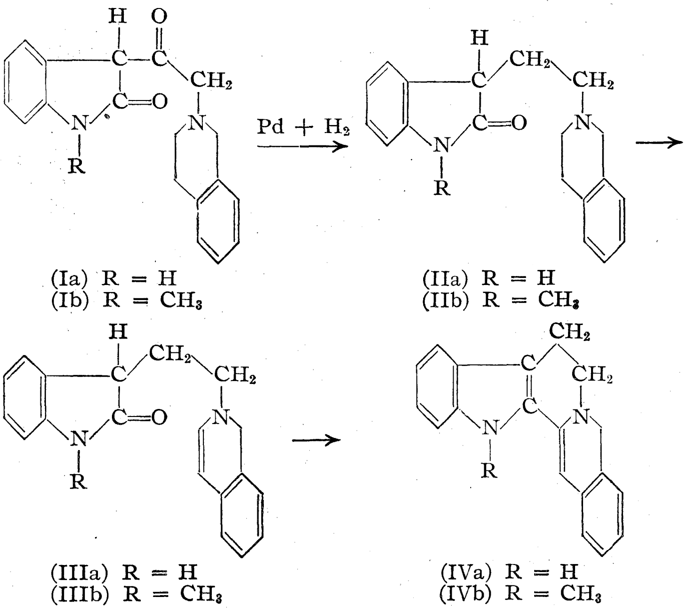
Studies in the Indole Series. VIII. Yohimbine (Part 1). The Mechanism of Dehydrogenation of Yohimbine and Related Compounds[1]

BY PERCY L. JULIAN, ARTHUR MAGNANI, JOSEF PIKL[2] AND WILLIAM J. KARPEL

The work reported in this communication had its origin in attempts to synthesize the basic ring structure of yohimbine by a procedure presented schematically with formulas I → IV.



(Ia) R = H
(Ib) R = CH_3

(IIa) R = H
(IIb) R = CH_3

(IIIa) R = H
(IIIb) R = CH_3

(IVa) R = H
(IVb) R = CH_3

At the time this investigation began, which was more than a decade ago, the successful preparation of the desired 3-(N-tetrahydroisoquinolylacetyl)-oxindole (Ia) from oxindole and ethyl N-tetrahydroisoquinolyl acetate,[3] as well as the reduction of Ia to 3-(2-N-tetrahydroisoquinolylethyl)-oxindole (IIa) could be predicted[4] and indeed was ultimately realized in practice. Sufficient information was also available then and later to indicate that, once compound IIIa were available, enolization of the hydrogen atom at position 3 of the oxindole nucleus could be used for ring closure. The crux of the whole synthesis, however, rested upon the ability to dehydrogenate IIa to IIIa, and this in turn directed closer attention to the end-products from the dehydrogenation of yohimbine and indeed to the mechanism of this dehydrogenation.

When the synthesis of the yohimbine ring structure outlined above was projected the accepted formula for yobyrine, one of the principal dehydrogenation products of yohimbine, was IVa.[5] This structure, like IIIa, is that of a 1,2-dihydroisoquinoline and repeated efforts to prepare 1,2-dihydroisoquinolines hitherto have resulted in failure.[6] Only one case of such a preparation is reported in the literature, namely, that of Cooke and Gulland[7] who claim dehydrogenation of 2-methyltetrahydroisoquinoline to 2-methyl-1,2-dihydroisoquinoline with palladous chloride. Their evidence, however, is poor and subject to question. Our early failures to dehydrogenate IIb to 1-methyl-3-(2-N-dihydroisoquinolylethyl)-oxindole (IIIb) threw grave doubt upon the validity of IVa as representing the structure of yobyrine, despite the fact that the continuous conjugation in IVa might presumably favor the formation of a 1,2-dihydroisoquinoline in the case of the dehydrogenation of yohimbine to yobyrine. Moreover, Pruckner and Witkop[8] in the meantime proposed a new structure for yobyrine, involving a mechanism for the dehydrogenation of yohimbine more consistent with our experiences and those of others. Their results we have substantiated by a complete synthesis of yobrine.[9]

Both 1-methyl-3-(N-tetrahydroisoquinolylacetyl)-oxindole (Ib) and its unmethylated analog, (Ia), on catalytic reduction gave material whose empirical analyses correspond to substances IIb and IIa, respectively. There seems to be no fundamental difference in this case between reduction of the unmethylated and methylated acyl oxindoles such as Horner has indicated.[10]

Because, up to quite recently 1-methyloxindole was more readily available to us than oxindole itself, and because the reduction of Ib led to two substances much more readily separable than the mixture obtained from reducing the unmethylated analog, we have employed Ib as a model in this study.

The reduction product of Ib is a fairly constant boiling oil in high vacuum and yields a hydrochloride that for a long time was thought to be a single entity. The recovered base from it, however, has been separated into two substances. The one of these is 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole (IIb), melting at 167°. The other is 1-methyl-2,3-dihydro-3-N-tetrahydroisoquinolylacetylindole (X), which we have been unable to induce to crystallize but which gave a pure crystalline hydrochloride. The formation of these two substances could be predicted by assuming, as a first reaction, 1,4-addition of hydrogen to each of the two possible enolic modifications of Ib.

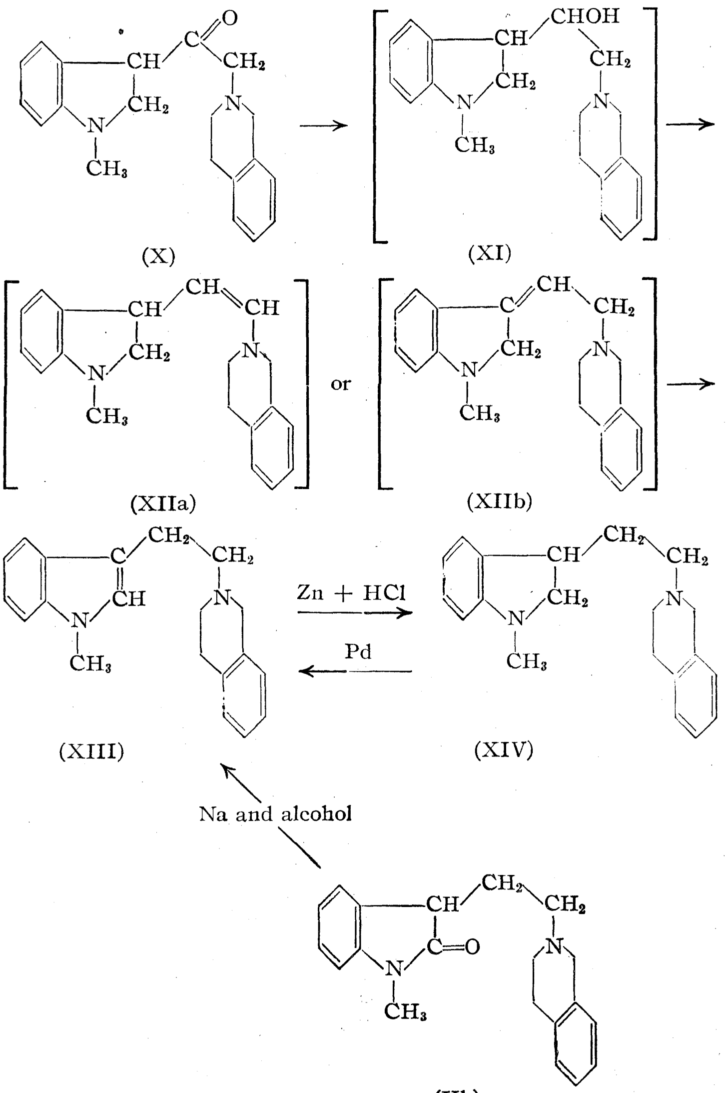
The constitution of our 167° melting compound (IIb) has been proved by two other unequivocal syntheses, schematically illustrated by formulas V → IIb and VII → VIII → IIb. Neither synthesis however proved to be an improvement over the reduction of Ib as far as yield is concerned. The reaction of the sodium salt of 1-methyl-3-acetyloxindole (V) with 1-bromo-2-N-tetrahydroisoquinolylethane (VI) resulted in poor yields of IIb, primarily because of the tendency of VI to condense with itself at elevated temperatures. The reaction of 1-methyl-3-(2-bromoethyl)-oxindole (VII) with tetrahydroisoquinoline in the cold led to 2,3-dihydro-8-methylfuro[2,3-b]indole (VIII) in quantitative yield. Heating the latter, however, with tetrahydroisoquinoline hydrobromide or heating the original mixture of VII and tetrahydroisoquinoline, resulted in a difficultly separable mixture of IIb and another substance whose constitution is not certain but the empirical analyses of which show the formula $C_{20}H_{20}ON_2$ (IX).

The constitution of the second product secured on the reduction of Ib, namely, X, has been demonstrated as diagrammatically outlined by reactions X → XIV, XIV → XIII, and IIb → XIII When the product (X) was reduced with sodium and alcohol it yielded a solid, m. p. 82°, containing no oxygen (XIII). This solid was identical with the compound secured on reducing IIb with sodium and alcohol. Considerable experience in this Laboratory (unpublished work) has convinced us that the transformation IIb → XIII is typical of oxindoles of this general character and compound XIII is therefore 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-indole and the mechanism of its formation from X is suggested in formulas XI and XIIb (or XIIa) of the diagram referred to above.

What is very significant for indole chemistry is the discovery here of a most interesting reduction of a 2,3-dihydro-3-acyl-indole (X) into a 3-alkyl indole (XIII) with sodium and alcohol. We hope to report later on the general application of this spontaneous rearrangement of XIIb or XIIa into XIII.

The dehydrogenation of IIb yielded considerable isoquinoline and about a 30% yield of a crystalline substance, m. p. 182°, of the formula $C_{20}H_{20}ON_2$ having the correct analysis for IIIb. All attempts to effect ring closure on this compound failed and we are loathe to assign to it the structure of a 1,2-dihydroisoquinoline (IIIb). Moreover, this dehydrogenation product is identical with the product (IX) which arises on treating IIb with tetrahydroisoquinoline hydrobromide. It is indeed difficult to explain how a 1,2-dihydroisoquinoline of structure IIIb would arise in such a reaction. The absorption spectrum of compound IX indicates that it is still an oxindole and does not give any additional peak which might be expected for the increased conjugation of a 1,2-dihydroisoquinoline. We have, therefore, concluded that dehydrogenation of yohimbine or compounds related to it like IIb does not lead to 1,2-dihydroisoquinolines and the projected synthesis of the yohimbine ring structure via IIIb is not possible.

Having failed to effect ring closure *via* IIIb →



(X) (XI) (XIIa) or (XIIb) (XIII) (XIV) (IIb)

IVb, we next attempted this through dehydrogenation of 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-indole (XIII). If the initial dehydrogenation attack were at the 3,4-position of the tetrahydroisoquinoline nucleus, such a ring closure should be possible. On carrying out the reaction, however, quantitative cleavage of XIII took place, giving isoquinoline and 1-methyl-2-ethylindole. Likewise a selenium dehydrogenation of IIb gave quantitatively isoquinoline. These findings are of great significance as they indicate that cleavage at the nitrogen atom is the preferred reaction on dehydrogenation of these compounds related to yohimbine. It has been demonstrated clearly by Scholz[11] that the so-called "tetrahydroyobyrine," one of the two principal degradation products of yohimbine with selenium, is the product of just such a cleavage. Pruckner and Witkop[8] have suggested that similarly, in the case of formation of the other dehydrogenation product of yohimbine, namely, yobyrine, the focal point of dehydrogenation is at the other vulnerable linkage to the nitrogen atom, instead of at the 3,4-position of the tetrahydroisoquinoline nucleus, as suggested by Barger and Scholz.[5] Thus, instead of structure IVa, they suggest that yobyrine is 3-*o*-xylyl-4-carboline. Our findings certainly support such a view for the mechanism of dehydrogenation.

Experimental

Tetrahydroisoquinoline.—The tetrahydroisoquinoline was prepared from distilled Eastman Kodak Co. "Practical" isoquinoline by catalytic hydrogenation[12] using copper chromite as described by Cromwell.[13] It distilled at 114–115° at 14 mm. pressure.

Ethyl N-Tetrahydroisoquinolylacetate.[3]—A mixture of 64.6 g. of tetrahydroisoquinoline, 50 g. of ethyl chloroacetate, 40 g. of finely powdered sodium carbonate and 200 cc. of benzene was refluxed vigorously for one hour on the steam-bath. Water was added, the benzene solution separated and distilled. The main fraction consisted of 72 g. boiling at 178–183°, 15 mm. Upon redistilling all fractions 74 g. of the ester was obtained, 180–182° (15 mm.).

1-Methyl-3-(N-tetrahydroisoquinolylacetyl)-oxindole (Ib).—To a solution of sodium ethylate from 5.5 g. of sodium in 60 cc. of absolute alcohol, a mixture of 37.5 g. of ethyl N-tetrahydroisoquinolylacetate and 24 g. of 1-methyloxindole[14] was added. After heating for one hour on the steam-bath, the mass was cooled and 55 g. of sodium salt was obtained after filtering and washing with absolute alcohol. The salt was suspended in 250 cc. of cold ethanol (ice-bath) dissolved by the addition of 5 *N* hydrochloric acid and then diluted with 600 cc. of ice water. Then the solution was made alkaline by the slow addition of sodium carbonate solution, and crystallization was induced by vigorous scratching. Yield was 42 g., m. p. 194–196°; on recrystallization from 95% ethanol, m. p. 199–200°.

Anal. Calcd. for $C_{20}H_{20}O_2N_2$: C, 74.98; H, 6.31. Found: C, 75.32; H, 6.77.

Like other oxindole ketones of this type which we have prepared, the compound was cleaved readily by strong acids and bases.

3-(N-Tetrahydroisoquinolylacetyl)-oxindole (Ia).—This acyloxindole was prepared in the same manner as described above for the N-methyl analog. From 22 g. of oxindole and 38 g. of ethyl N-tetrahydroisoquinolylacetate there was obtained 30 g. of the acyloxindole after crystallization from ethanol, m. p. 268–270°.

Anal. Calcd. for $C_{19}H_{18}O_2N_2$: C, 74.49; H, 5.92. Found: C, 74.63; H, 5.99.

Catalytic Reduction of 1-Methyl-3-(N-tetrahydroisoquinolylacetyl)-oxindole (Ib).—To 8.0 g. (0.025 mole) of the oxindole ketone dissolved in 80 cc. of glacial acetic acid was added 1.33 cc. of sulfuric acid followed by 0.8 g.

(12) We are indebted to Dr. Robert Baker and Mr. Ralph Olberg of Northwestern University for their coöperation in preparing a quantity of tetrahydroisoquinoline.

(13) Cromwell and Cram, THIS JOURNAL, **65**, 304 (1943).

(14) R. Stolle, *J. prakt. Chem.*, [2] **128**, 1–20 (1930).

of palladium oxide.[15] The solution was heated to 80° and hydrogenated at this temperature at 40–45 lb. pressure until two moles had been absorbed (four to six hours). While shaking, a precipitate usually separated which slowly went into solution as hydrogenation proceeded. The acetic acid was distilled under vacuum to a small volume, water was added, and if necessary hydrochloric acid added to give complete solution. The solution was extracted with ether to remove non-basic material, made basic with excess alkali, extracted with ether and the residue after evaporation of the ether subjected to distillation. Low boiling material proved to be tetrahydroisoquinoline (picrate, m. p. 199°) formed by cleavage. The main product distilled at 195–205° (bath temperature), 0.01 mm. pressure; yield 6.5 g., pale yellow oil. For analysis the oil was redistilled; b. p. 200–202° bath temperature (0.01 mm.).

Anal. Calcd. for $C_{20}H_{22}ON_2$: C, 78.43; H, 7.19. Found: C, 78.09; H, 7.35.

Treating the oil in alcohol solution with concentrated hydrochloric acid and then adding ether to make an ether–alcohol solution consisting of 30% alcohol gave 4.8 g. of crystalline hydrochloride, m. p. 183–186°. Recrystallization from ether–alcohol gave 4.0 g. of the hydrochloride melting at 186–188°.

Anal. Calcd. for $C_{20}H_{23}ON_2Cl$: C, 70.07; H, 6.72. Found: C, 70.08, 69.89; H, 7.31, 6.80.

The oil obtained from the hydrogenation was believed to be a single compound until it was found that a concentrated ethereal solution of the oil on long standing deposited sandy crystals, m. p. 163–165°, which proved to be 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole (IIb).

To separate the solid from the mixture, the hydrochloride of the mixture was repeatedly crystallized from ether–alcohol solution as described above. The hydrochloride of the solid, being more soluble, became concentrated in the mother liquors. The solid obtained from the mother liquors on rendering alkaline amounted to 5–7% of the weight of the original oil mixture, and crystallized readily from methanol, white prisms, m. p. 167°.

Anal. Calcd. for $C_{20}H_{22}ON_2$: C, 78.43; H, 7.19. Found: C, 78.24; H, 7.25.

It readily formed a hydrochloride crystallizing from ether–alcohol as white needles, m. p. 238–239°.

Anal. Calcd. for $C_{20}H_{23}ON_2Cl$: C, 70.07; H, 6.72. Found: C, 70.39; H, 6.51.

The picrate of the solid was prepared by adding an equimolecular quantity of picric acid in benzene to a hot solution of the solid in benzene. It was sparingly soluble in alcohol and in benzene, crystallizing as yellow needles, m. p. 208–209° dec.

Anal. Calcd. for $C_{26}H_{25}O_8N_5$: C, 58.32; H, 4.67. Found: C, 58.71; H, 4.54.

The other product of the hydrogenation, obtained as a colorless oil from its purified hydrochloride, is 1-methyl-2,3-dihydro-3-(N-tetrahydroisoquinolylacetyl)-indole (X). It distilled cleanly, b. p. 215–217°, (1 mm.).

Anal. Calcd. for $C_{20}H_{22}ON_2$: C, 78.43; H, 7.19. Found: C, 78.38; H, 7.48.

Its hydrochloride crystallized as fine white needles from ether–alcohol solution, m. p. 190–191°.

Anal. Calcd. for $C_{20}H_{23}ON_2Cl$: C, 70.07; H, 6.72. Found: C, 70.40; H, 6.99.

Catalytic Reduction of 3-(N-Tetrahydroisoquinolylacetyl)-oxindole (Ia).—The oxindole ketone (4.6 g.) was dissolved in 50 cc. of glacial acetic acid and there was added 1.5 g. of sulfuric acid and 0.5 g. of palladium oxide. The hydrogenation was carried out at 40–45 lb. pressure and at 75–80°. The time required for absorption of two moles of hydrogen was five hours. No precipitate formed in the solution. The reaction products were worked up as described above in the reduction of Ib. The acid soluble fraction distilled cleanly in high vacuum as a viscous pale yellow oil which slowly set to a glassy solid, b. p. 205–208° bath temperature (0.001 mm.).

Anal. Calcd. for $C_{19}H_{20}ON_2$: C, 78.05; H, 6.89. Found: C, 77.50; H, 6.72.

All attempts to crystallize the product from ether, alcohol, petroleum ether and combinations of these solvents failed. Likewise, although a hydrochloride and a picrate formed neither of these could be induced to crystallize. Further work on this compound was reserved for a later date and the work described in this paper was performed on the N-methyl analog which seemed to offer less complications in subsequent reactions.

Synthesis of 1-Methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole (IIb).—(a) From Sodium Salt of 1-Methyl-3-acetyloxindole (V) and 1-Bromo-2-N-tetrahydroisoquinolylethane (VI).—The sodium salt of the 1-methyl-3-acetyloxindole was prepared by adding a solution of sodium in absolute alcohol to a hot alcoholic solution of the acetyloxindole, care being taken to avoid an excess of sodium.

For the preparation of 1-bromo-2-N-tetrahydroisoquinolylethane, bromohydrin was treated with two moles of tetrahydroisoquinoline to yield 2-N-tetrahydroisoquinolylethanol,[16] b. p. 120–123° (2 mm.). This was converted into the bromo-compound by refluxing with 48% hydrobromic acid.[17] The bromo compound was isolated as the hydrobromide, insoluble white salt in acetone, and crystallized as white needles from acetone–alcohol mixture, m. p. 238–239°. It was analyzed by determining the amount of bromide ion in aqueous solution.

Anal. Calcd. for $C_{11}H_{15}NBr_2$: Br, 24.9. Found: Br, 25.4.

For use in the following condensation, the hydrobromide was suspended in ether and shaken with dilute alkali. The ethereal solution was washed with water, dried and the ether removed *in vacuo*.

A mixture of 6.0 g. of sodium salt of 1-methyl-3-acetyloxindole, 6.0 g. of 1-bromo-2-N-tetrahydroisoquinolylethane, 0.5 g. of sodium iodide, and 60 cc. of dry acetone was heated in a sealed tube at 100° for twenty-four hours. The resulting reddish solution was filtered to remove insoluble salts and the acetone removed. The residue was taken up in ether and washed with alkali to remove unchanged acetyloxindole. For deacylation, the remaining product was refluxed for twenty minutes in 20 cc. of absolute alcohol containing 1.0 g. of sodium, and poured into water. Washing the ether extract with water removed the greater portion of the reddish color. After removal of the ether and distilling there was obtained 2.1 g. of yellow oil distilling at 200–215° bath temperature (2 mm.). From the ethereal solution cooled overnight 0.25 g. of solid, m. p. 167°, was obtained. It was identical to the 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole (IIb) obtained by hydrogenation of the oxindole ketone (Ib). It also gave an identical picrate. On long standing the ethereal mother liquor deposited a further crop (0.2 g.) of the solid. A similar run heated at 140–150° gave the same results.

Upon heating the 1-bromo-2-N-tetrahydroisoquinolylethane alone on the water-bath, it quickly darkened and turned into a semisolid. A sample of the solid isolated from it melted over 300° and had no definite melting point. At lower temperatures the bromo compound did not react with the sodium salt of the 3-acetyloxindole. It was possible to run the reaction in dioxane heated at 80–90° for twenty-four hours. However, no increase in the yield of desired solid, m. p. 167°, was obtained.

(b) **From 1-Methyl-3-(2-bromoethyl)-oxindole (VII).**—1-Methyl-3-(2-phenoxyethyl)-oxindole was prepared by heating a mixture of 21.0 g. of sodium salt of 1-methyl-3-acetyloxindole, 100 g. of phenoxyethyl bromide, 15 cc.

---

(15) Obtained from American Platinum Works, Newark, New Jersey. Platinum oxide was not found suitable for these reductions.

of dry acetone and 5.0 g. of sodium iodide under reflux in a metal-bath for fifteen hours at 150–160°. The reddish solution was diluted with ether and washed with alkali to remove unchanged acetyloxindole. Upon distillation at diminished pressure 84 g. of phenoxyethyl bromide was removed. The residue was boiled for thirty minutes in 100 cc. of absolute alcohol containing 5.0 g. of sodium to remove the acyl group and poured into water. The product was taken up in ether, washed with water to remove colored materials, and distilled after removal of the solvent. There was obtained 15.0 g. of pale yellow oil which on standing slowly crystallized. A sample crystallized from petroleum ether as silky needles, m. p. 57°.

Anal. Calcd. for $C_{17}H_{17}O_2N$: C, 76.38; H, 6.41. Found: C, 76.23; H, 6.36.

1-Methyl-3-(2-bromoethyl)-oxindole (VII) was obtained from the 1-methyl-3-(2-phenoxyethyl)-oxindole by treating with hydrobromic acid.[18] There was obtained 11.5 g. of colorless oil, b. p. 165–168° (2 mm.), which crystallized on standing as white needles from petroleum ether, m. p. 63°.

Anal. Calcd. for $C_{11}H_{12}ONBr$: C, 51.98; H, 4.75. Found: C, 52.23; H, 4.78.

2,3-Dihydro-8-methylfuro[2,3-b]indole (VIII) was obtained quantitatively from the bromoethyloxindole (VII); (a) by heating in benzene solution with tetrahydroisoquinoline, (b) by reaction with tetrahydroisoquinoline alone in the cold, and (c) by treating in alcoholic solution with sodium ethoxide. The reaction in each case was rapid and required only ten to fifteen minutes for completion. With tetrahydroisoquinoline, the hydrobromide of the base separated from the mixture. The dihydrofuroindole was dissolved in ether and the basic materials removed by washing with dilute acid. The residue after removal of the ether was either crystallized directly or distilled, b. p. 152–155° (12 mm.). It crystallized from petroleum ether as white prisms, m. p. 84°.

Anal. Calcd. for $C_{11}H_{11}ON$: C, 76.30; H, 6.36. Found: C, 76.42; H, 6.38.

Upon refluxing with ten times its weight of 48% hydrobromic acid for six hours the bromoethyloxindole (VII) was formed, m. p. 52–53°.

To obtain 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole (IIb) 50.8 g. of the bromoethyloxindole (VII) (0.1 mole) and 26.6 g. of tetrahydroisoquinoline (0.2 mole) were mixed and heated gently on the steam-bath. The mixture solidified and was essentially a mixture of the dihydrofuroindole (VIII) and tetrahydroisoquinoline hydrobromide. This mixture was heated under nitrogen in a metal bath to 190° for three hours. The mixture was made alkaline and taken up in ether. A separation of basic from non-basic materials was made by washing with dilute acid. The basic fraction contained in the aqueous acidic washes was isolated in the usual manner and distilled. The low boiling fraction (5.0 g.) consisted of tetrahydroisoquinoline which was removed on the water pump. The main fraction was distilled in high vacuum. There was obtained 33.0 g. of yellow oil, b. p. 170–175° (0.005 mm.). It was dissolved in ether, concentrated, and allowed to crystallize. Two crops were obtained from ether; the ether was replaced with methanol and two further crops obtained. A total of 6.3 g. of solid was obtained, m. p. 146–150°, which proved to be a 50–50 mixture of the tetrahydroisoquinolylethyloxindole (IIb) and of a compound (IX), m. p. 182°.

The mixture was separated by fractional crystallization from ether and from methanol, and also mechanically. The compound (IX) is less soluble in methanol, but more soluble in ether than the tetrahydroisoquinolylethyloxindole (IIb) and crystallized in smaller prisms which when impure had a rose color. The tetrahydroisoquinolylethyloxindole (IIb) after crystallization from methanol melted at 166–167° and gave a picrate melting at 208° dec. The crude compound (IX) from the mixture melted at 172–178°. Treatment with norite in methanol removed all color and the compound crystallized as small colorless prisms, m. p. 182°.

Anal. Calcd. for $C_{20}H_{20}ON_2$: C, 78.92; H, 6.62; N, 9.19. Found: C, 78.71, 78.76; H, 6.76, 6.49; N, 9.19.

A picrate readily formed by admixing hot alcoholic solutions containing equimolecular quantities of the compound and picric acid; yellow prisms, m. p. 198° dec.

Anal. Calcd. for $C_{26}H_{23}O_8N_5$: C, 58.53; H, 4.34. Found: C, 58.42; H, 4.36.

Attempt to Dehydrogenate 1-Methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole (IIb).—One gram of the tetrahydroisoquinolylethyloxindole (IIb), m. p. 167°, was intimately mixed with 0.3 g. of palladium black[19] and the mixture heated at 60–80 mm. pressure for one hour at 190–200°. No further liberation of gas took place after forty minutes. The products of the reaction were then directly distilled. The low boiling fraction consisted of isoquinoline (picrate, m. p. 220°) indicating that some cleavage had occurred. The main fraction, 0.6 g. reddish oil distilled at 180–185° bath temperature (0.02 mm.). From a concentrated ethereal solution of the oil, there was obtained 0.25 g. of a solid compound, m. p. 172–175°. Recrystallized from methanol, it melted at 182° and gave no depression when mix-melted with compound (IX) obtained above.

Anal. Calcd. for $C_{20}H_{20}ON_2$: C, 78.92; H, 6.62; N, 9.19. Found: C, 78.78; H, 6.68; N, 9.07.

Its picrate, prepared as described above, melted at 198° dec.

All attempts to dehydrogenate at temperatures below 175° gave the tetrahydroisoquinolylethyloxindole back unchanged. Upon heating the tetrahydroisoquinolylethyloxindole alone at 200° for one hour 70% of it was recovered. The remainder was an uncrystallizable oil, but none of the 182° compound was isolated. However, when 0.3 g. was heated under identical conditions for the dehydrogenation with tetrahydroisoquinoline hydrobromide, a reddish oil was obtained from which 0.08 g. of the 182° compound was isolated with no recovery of the original.

Attempts to Ring Close Compound (IX).—Compound IX was at first thought to be 1-methyl-3-(2-N-dihydroisoquinolylethyl)-oxindole (IIIb) and several attempts at ring closure were made. Heating the compound in phosphorous oxychloride did not effect ring closure. Trials in which phosphorus pentoxide was added to a refluxing solution of the compound in xylene gave the compound back unchanged. In other attempts the compound was treated first with phosphorus pentachloride and then with aluminum chloride in nitrobenzene solution.[20] When the reactions were carried out at room temperature the solid was recovered unchanged. Similarly, at the temperature of the steam-bath, the solid was again recovered. Under more drastic conditions (175°) some of the solid was recovered and the remainder was converted into tar and halogenated products. Since all attempted ring closures failed, we felt that the compound was not a 1,2-dihydroisoquinoline.

Reduction of 1-Methyl-2,3-dihydro-3-N-tetrahydroisoquinolylacetylindole (X).—To a hot solution of 6.0 g. of the dihydro-tetrahydroisoquinolylacetyl-oxindole in 260 cc. of absolute ethanol was added 25.0 g. of sodium in portions over a period of two hours. The alcoholic solution, after removing the greater portion of the alcohol *in vacuo*, was diluted with water and the products were extracted with ether. The ethereal solution was washed with 10% hydrochloric acid to remove the basic materials. The basic fraction proved to be XIII which was crystallized directly from petroleum ether, yielding 3.1 g. of white prisms, m. p. 80–81°. A sample upon distillation gave a colorless oil, b. p. 190–192°, bath temperature (0.001 mm.), which solidified on cooling. Recrystallized from petroleum ether it melted at 82°.

Reduction of XIII with Zinc and Hydrochloric Acid.—A Clemmensen reduction was attempted on the ketone X without success. The Clemmensen procedure was employed on XIII on the assumption at that time that we were dealing with the hydroxy compound (XI). To a solution of 1.5 g. of XIII in 40 cc. of 50% acetic acid, 10 cc. of concentrated hydrochloric acid and 10 g. of freshly amalgamated 20-mesh zinc were added. The mixture was heated on the steam-bath for five hours with a further addition of 5 cc. of hydrochloric acid every hour. The acetic acid was removed *in vacuo* and the material taken up in ether after the addition of enough strong alkali to solubilize the zinc hydroxide. The ethereal solution was washed with water, then with 10% hydrochloric acid and the basic material obtained from the acidic washings. On distilling, 1.4 g. of 1-methyl-2,3-dihydro-3-(2-N-tetrahydroisoquinolylethyl)-indole (XIV) was obtained as a colorless oil, b. p. 190–195°, bath temperature (0.1 mm.).

Anal. Calcd. for $C_{20}H_{24}N_2$: C, 82.14; H, 8.27. Found: C, 82.17; H, 8.25.

Anal. Calcd. for $C_{26}H_{27}O_7N_5$: C, 59.88; H, 5.22. Found: C, 59.92; H, 5.20.

Upon treating the monopicrate in methanol with an additional mole of picric acid, a yellow dipicrate was obtained, m. p. 176°.

Anal. Calcd. for $C_{32}H_{30}O_{14}N_8$: C, 51.20; H, 4.03. Found: C, 51.30; H, 4.48.

This characteristic of such dihydroindoles to give red monopicrates and yellow dipicrates has been previously observed by Julian and Pikl.[21]

1-Methyl-3-(2-N-tetrahydroisoquinolylethyl)-indole (XIII). (a) Reduction of the Ethyloxindole (IIb).—The ethyloxindole (IIb) (2.0 g.) was dissolved in 50 cc. of absolute ethanol and over a period of two hours there was added 12.0 g. of sodium and 100 cc. of absolute ethanol in portions. The alcohol solution, after removal of part of the alcohol *in vacuo*, was diluted with water and the products extracted with ether. The ethereal solution was washed with dilute acid to remove the basic fraction which was isolated in the usual manner and was distilled. There was obtained 1.4 g. of pale yellow oil, b. p. 180–185° bath temperature which on exposure to air turned reddish, especially when warmed. A sample was redistilled for analysis, b. p. 180–182° (0.008 mm.).

Anal. Calcd. for $C_{20}H_{22}N_2$: C, 82.72; H, 7.63. Found: C, 82.54; H, 8.10.

The picrate formed by heating equimolecular portions of the oil and picric acid in methanol was a red oil which on standing solidified, m. p. 155–157° dec. Recrystallization from methanol gave yellow needles, m. p. 161° dec.

Anal. Calcd. for $C_{26}H_{22}O_7N_5$: C, 60.11; H, 4.85. Found: C, 60.30; H, 4.64.

Struck by the similarity between this picrate and that of the sodium reduction product of X, we examined the two picrates and found them identical. On seeding the distillate, from which the picrate was formed, it crystallized and melted at 82°.

(b) Dehydrogenation of the Dihydroindole (XIV).—A mixture of 0.69 g. of the dihydroindole and 0.22 g. of palladium black was heated to 195–200° for forty minutes. The evolution of gas was quite vigorous during the first fifteen minutes. The mixture after heating was deeply colored. On distillation there was obtained 0.54 g. of yellow oil which becomes colored on standing, b. p. 175–180° bath temperature (0.006 mm.). A sample was redistilled for analysis, b. p. 175–177° at the same pressure.

Anal. Calcd. for $C_{20}H_{22}N_2$: C, 82.72; H, 7.63. Found: C, 82.46; H, 7.28.

This oil likewise crystallized on seeding with the 82° melting solid (XIII) and the two proved to be identical.

The picrate formed by adding an equimolecular quantity of picric acid to a solution of the base in benzene was an oil which crystallized from benzene–methanol, m. p. 153–156° dec. When recrystallized from methanol it gave yellow needles, m. p. 161°. A mixed melting point with the picrate obtained above from the reduction of the ethyloxindole (IIb) gave no depression.

Anal. Calcd. for $C_{26}H_{25}O_7N_5$: C, 60.11; H, 4.85. Found: C, 59.91; H, 4.74.

Attempted Ring Closure of XIII by Dehydrogenation with Selenium.—1.0 g. of the solid, m. p. 82°, was intimately mixed with 0.7 g. of selenium and heated in a distillation tube. At 290–300° reaction ensued. Heating was continued for ten minutes. Working up and distillation in the usual manner gave 0.45 g. (the theoretical quantity) of isoquinoline, identified by its picrate, m. p. 222°.

Attempted Ring Closure of IIb by Dehydrogenation with Selenium.—In exactly the same manner as above 1.0 g. of IIb gave almost quantitatively isoquinoline.

Summary

1. For attempted synthesis of the basic ring structure of yohimbine, 1-methyl-3-(2-N-tetrahydroisoquinolylacetyl)-oxindole and its unmethylated analog have been prepared.

2. On catalytic reduction 1-methyl-3-(2-N-tetrahydroisoquinolylacetyl)-oxindole yields two products, 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole and 1-methyl-2,3-dihydro-3-(2-N-tetrahydroisoquinolylacetyl)-indole. The constitution of each product has been proved.

3. The conversion of a 1,2-dihydro-3-acyl-indole into the corresponding 3-alkyl indole by reduction with sodium and alcohol (followed by loss of water and rearrangement) is recorded.

4. Attempts to prepare the basic ring structure of yohimbine by ring closure on the dehydrogenation product of 1-methyl-3-(2-N-tetrahydroisoquinolylethyl)-oxindole failed. The dehydrogenation product is therefore probably not the desired 1,2-dihydroisoquinoline.

5. The dehydrogenation of yohimbine and related compounds seems to result primarily in cleavage at the nitrogen atom of the tetrahydroisoquinoline nucleus.

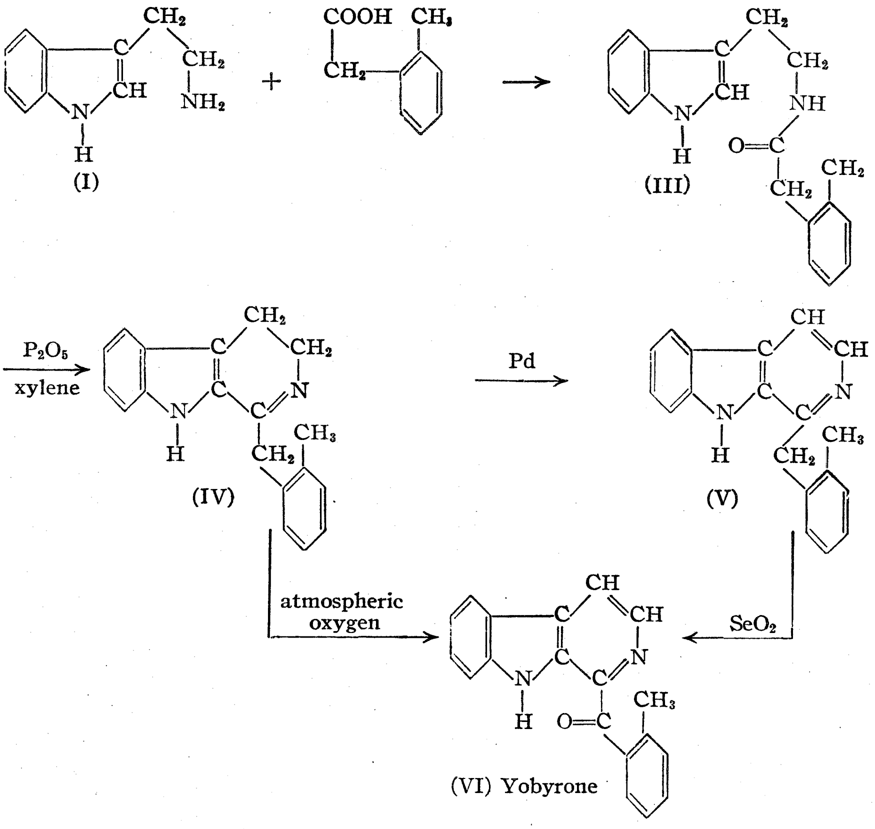
Studies in the Indole Series. X. Yohimbine (Part 2). The Synthesis of Yobyrine, Yobyrone and "Tetrahydroyobyrine"

BY PERCY L. JULIAN, WILLIAM J. KARPEL, ARTHUR MAGNANI AND EDWIN W. MEYER

In a previous communication[1] we have adduced new evidence and discussed investigations of others to show that on dehydrogenation of the alkaloid yohimbine with selenium, cleavage of the molecule takes place at the nitrogen atom of the tetrahydroisoquinoline nucleus. The reaction was first discovered by Mendlik and Wibaut[2] who gave the names yobyrine and tetrahydroyobyrine to the two principal products arising from this degradation, in the mistaken notion that both of them possessed the same fundamental ring skeleton. Recently Witkop[3] has given convincing evidence to indicate that yobyrine is 3-*o*-xylyl-4-carboline (V). Several years ago Scholz,[4] in a beautiful piece of work, proposed for "tetrahydroyobyrine" the structure XIII. Thus the name is a misnomer and "tetrahydroyobyrine" is actually 2-[3-(5,6,7,8-tetrahydroisoquinolyl)]-3-ethylindole.



In the present communication we are reporting the successful synthesis of both yobyrine and "tetrahydroyobyrine."[5] Our synthesis of yobyrine is, generally speaking, an application of the procedure worked out by Späth and Lederer[6] for the Harmala alkaloids. *o*-Tolylacetic acid (II) was prepared in 65% yield from *o*-xylene *via o*-xylyl bromide secured by the method of Atkinson and Thorpe.[7] This acid was condensed with tryptamine (I)[8] and the amide thus formed subjected to ring closure with phosphorus pentoxide in boiling xylene to produce dihydroyobyrine (IV). Dehydrogenation of IV with palladium black gave yobyrine (V).[9]

A novel synthesis of yobyrone (VI) was discovered in the atmospheric oxidation of dihydroyobyrine (IV). This compound had previously been prepared by the oxidation of yobyrine with chromic acid[4] and with selenium dioxide.[3,9] Comparison of our synthetic yobyrine and yobyrone with the products of natural origin showed their identity in all respects.

For final proof of structure and synthesis of "tetrahydroyobyrine" (XIII), the other principal degradation product of yohimbine with selenium, we needed 3-*n*-butyrylisoquinolines. 3-Acylisoquinolines have hitherto been unknown and a procedure had to be devised for their preparation.

[5] We have employed the name tetrahydroyobyrine in quotation marks throughout the manuscript rather than the proper chemical name. This is done purely for clarity because the name "tetrahydroyobyrine" is so strongly embedded in the literature that confusion might result if we discarded it, even though it is a misnomer.

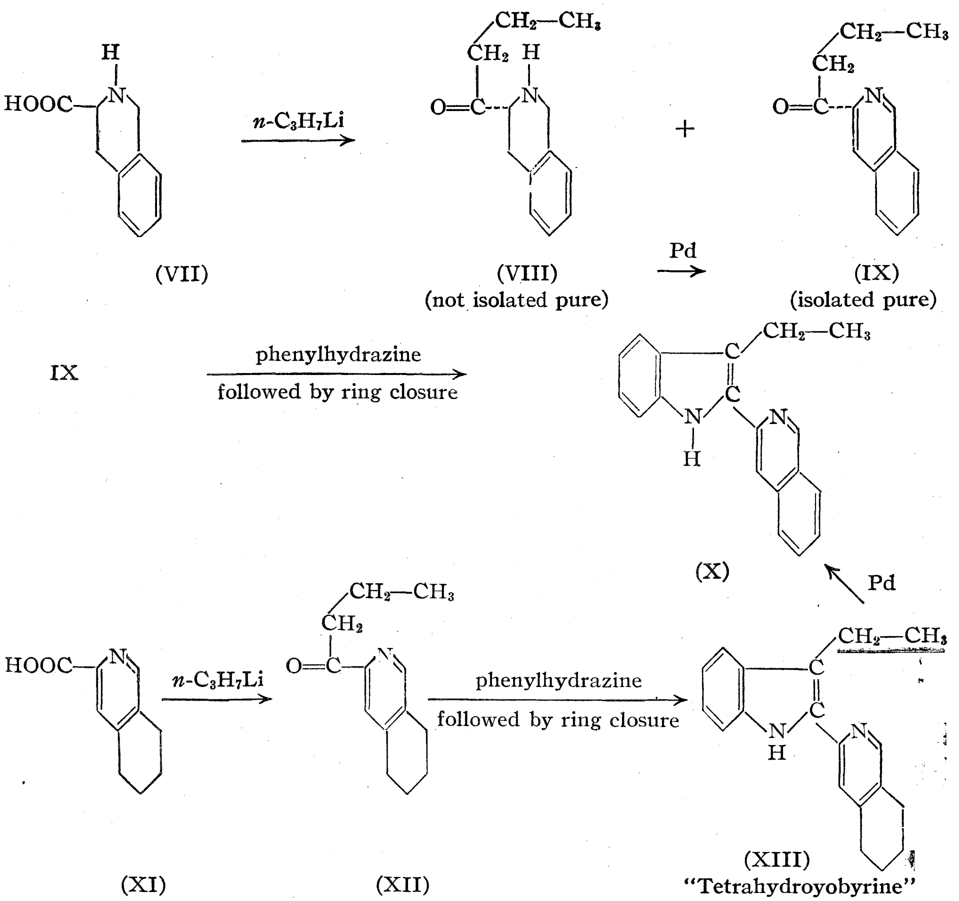
[9] After the submission of our original manuscript, the English Journal in which there appeared an almost identical synthesis of yobyrine by Clemo and Swan, *J. Chem. Soc.*, 617 (1946), was received by our library. This part of our original manuscript has, therefore, been abbreviated to include only a skeleton description of the synthesis of yobyrine and such new data in connection therewith as Clemo and Swan did not report.



A modification of the procedure of Pictet and Spengler[10] for the preparation of 3-carboxy-1,2,3,-4-tetrahydroisoquinoline (VII) from β-phenylalanine, gave the acid in 61% yield. On treating this acid with n-propyllithium,[11] a mixture of 3-butyryl-1,2,3,4-tetrahydroisoquinoline (VIII) and its dehydrogenation product, 3-butyrylisoquinoline (IX), was obtained. The ketone (VIII) resisted isolation in pure form but IX could be obtained in pure crystalline form and characterized. The mixture on dehydrogenation with palladium black gave pure IX. When the Fischer indole synthesis with phenylhydrazine was applied to either IX or the mixture of VIII and IX, 2-(3-isoquinolyl)-3-ethylindole (X) was obtained, identical with the product secured from "tetrahydroyobyrine" by dehydrogenation with palladium black.[3] Thus the constitution of "tetrahydroyobyrine" is firmly established by this complete synthesis of its dehydrogenation product.

To complete the synthesis of "tetrahydroyobyrine" itself, 3-carboxy-5,6,7,8-tetrahydroisoquinoline (XI) was prepared by the method of Scholz.[4] Treatment with propyllithium gave the desired ketone, namely, 3-butyryl-5,6,7,8-tetrahydroisoquinoline (XII), an oil which was readily purified and characterized by means of its crystalline picrate. This ketone underwent the Fischer indole reaction, giving "tetrahydroyobyrine" (XIII) identical in all respects with the product of natural origin. Taken together these syntheses of 2-(3-isoquinolyl)-3-ethylindole (X) and 2-[3-(5,6,7,8-tetrahydroisoquinolyl)]-3-ethylindole ("tetrahydroyobyrine") (XIII) represent virtually a complete synthesis of "tetrahydroyobyrine" and demonstrate conclusively the constitution of this product.

Experimental

Tryptamine (VI).—The method of Hoshino and Majima[8] was found to be the simplest route to this substance. For good yields of the amine, it was found desirable to employ ethyl iodide instead of the bromide for the Grignard complex.

***o*-Tolylacetic Acid (VII).**—*o*-Xylene was brominated by the method of Atkinson and Thorpe[7] to obtain *o*-xylyl bromide. The bromide was converted into the nitrile by treating it with potassium cyanide in the manner described in "Organic Synthesis" for the preparation of benzyl cyanide.[12] The nitrile was hydrolyzed to the acid by refluxing for five hours with 55% sulfuric acid. Upon cooling, the crystalline acid was filtered, washed with cold water and dried. It was recrystallized from aqueous methanol, m. p. 87–88°. The yield based on *o*-xylene was 65% and this procedure, therefore, constituted a very convenient route to the acid.

***o*-Tolylacetyltryptamine (VIII).**—At room temperature, mixing tryptamine with *o*-tolylacetic acid produces the

acetate salt of the amine, m. p. 170°. To prepare the amide 4.5 g. of tryptamine and 5.0 g. of the acid were heated at 195–200° for forty minutes. During the first twenty minutes there was vigorous liberation of water from the melt. After cooling, the brown residue was dissolved in ether and washed with 2% bicarbonate solution and 2% hydrochloric acid to remove unchanged acid and amine. The amide was obtained from the concentrated ethereal solution by the addition of petroleum ether (b. p. 35–60°). There was obtained 6.75 g., m. p. 96–97°. Recrystallized from ether–petroleum ether it melted at 97°.

Anal. Calcd. for $C_{19}H_{20}ON_2$: C, 78.05; H, 6.90. Found: C, 78.12; H, 7.04.

Ring Closure of *o*-Tolylacetyltryptamine (VIII) to Dihydroyobyrine (IX).—To a refluxing solution of dry xylene containing 0.58 g. of the amide there was added portionwise under an atmosphere of nitrogen 5.0 g. of phosphorus pentoxide over a forty-minute period. Heating was continued for an additional fifteen minutes. The mixture was cooled in an ice-bath and 30 ml. of 5% hydrochloric acid was added slowly with agitation. Enough methanol was added to dissolve the red gummy product upon vigorous agitation. The neutral products were removed from the acidic solution by ether extraction. The dihydroyobyrine (IX) was obtained from the acidic solution by basifying and extracting with ether. Crystallization from ether–petroleum ether (b. p. 35–60°) gave 0.35 g., m. p. 175–177°. Upon recrystallization from ether–petroleum ether it was obtained as clusters of fine white needles, m. p. 178–179°.

Anal. Calcd. for $C_{19}H_{18}N_2$: C, 83.18; H, 6.61. Found: C, 83.27; H, 6.65.

The mother liquor of crystallization on standing turned red and upon slow evaporation of the solvent, yellow crystals separated from the solution. They were digested with cold methanol and filtered, m. p. 172–175°. A mixed melting point with the dihydroyobyrine (IX) gave a depression. The compound distilled at 195–200° bath temperature (0.009 mm.) as a yellow oil which solidified on cooling. Crystallization from methanol gave yellow plates, m. p. 185°, which when admixed with known yobyrone gave no depression in melting point. It was found advisable, therefore, when recrystallizing the dihydroyobyrine to filter the product promptly to avoid contamination with yobyrone.

Yobyrine (IV) by Dehydrogenation of Dihydroyobyrine (IX).—An intimate mixture of 0.5 g. of dihydroyobyrine and 0.5 g. of palladium black was heated to 185–190° in a metal-bath at 20–25 mm. pressure for a half hour. Upon direct distillation, the product had a tendency to sublime. There was obtained 0.4 g. of colorless oil distilling at 200–205° bath temperature (0.001 mm.) which quickly crystallized on cooling, m. p. 209–211°. Crystallization from benzene gave 0.35 g. of needles, m. p. 211–212°. A sample crystallized from aqueous methanol also gave needles, m. p. 213°.

Anal. Calcd. for $C_{19}H_{16}N_2$: C, 83.79; H, 5.92. Found: C, 83.90; H, 5.90.

It was identical in every respect with the yobyrine obtained from the dehydrogenation of yohimbine with selenium by the method of Mendlik and Wibaut.[2] The yobyrine from natural sources melted at 213° and a mixed melting point with the synthetic yobyrine showed no depression.

Samples of the synthetic and natural yobyrine were each oxidized with selenium dioxide in boiling xylene[2] to yield yobyrone. In each instance, the yobyrone distilled at 190–195° bath temperature (0.008 mm.) and gave yellow plates on crystallizing from methanol, m. p. 185°. A mixed melting point of the two samples gave no depression.

The absorption spectrum of the synthetic material showed maxima at 237, 289, 327, 337 and 348mμ and minima at 269 and 299mμ, the same values as displayed by material of natural origin.[9]

3-Carboxy-5,6,7,8-tetrahydroisoquinoline.—This acid was prepared by the ozonization of tetrahydroyobyrine[2] essentially according to the method of Scholz.[4] However, it has been found that unless precautions are taken to ensure the decomposition of the ozonide, considerable difficulty is experienced in working up the reaction mixture. This is best accomplished by allowing the ozonized reaction mixture, after the addition of water, to stand for three–four hours at room temperature before proceeding. In this fashion 2.55 g. (72%) of the intermediate amide, m. p. 150–151°, was obtained from 3.2 g. of tetrahydroyobyrine. The amide was then hydrolyzed as described by Scholz[4] but for a period of eight hours. The product, 3-carboxy-5,6,7,8-tetrahydroisoquinoline, m. p. 203–206° dec., was obtained in a 95% yield.

3-*n*-Butyryl-5,6,7,8-tetrahydroisoquinoline.—A solution of *n*-propyllithium in 90 ml. of anhydrous ether was prepared under nitrogen from 1.0 g. of lithium metal and 10.5 g. of *n*-propyl bromide. Titration of an aliquot of the ethereal solution indicated the presence of 2.6 g. of *n*-propyllithium. After dilution to 125 ml. with anhydrous ether, 1.5 g. of 3-carboxy-5,6,7,8-tetrahydroisoquinoline was added to the ether solution. The mixture was stirred for eighteen hours, then decomposed with ice and extracted with ether. The ether extract was washed with water and the basic material separated with 3% hydrochloric acid. The acidic solution was made alkaline with 5% sodium hydroxide solution and extracted with ether. After washing the ethereal solution with water and drying, the solution was concentrated. There remained 1.5 g. of a light brown oil. Upon distillation at 6×10^{-3} mm., there was obtained 0.85 g. of a pale yellow oil which came over at 130–135° bath temperature. This material was not analytically pure but was employed for further experimentation. For purification for analysis the ketone was converted into the picrate which was recrystallized twice from methanol. The picrate was then decomposed and the base distilled.

Anal. Calcd. for $C_{13}H_{17}NO$: C, 76.81; H, 8.43; N, 6.89. Found: C, 76.73; H, 8.54; N, 6.71.

The picrate of this ketone, lemon yellow crystals, melted at 128° after recrystallization from methanol.

Anal. Calcd. for $C_{19}H_{20}N_4O_8$: C, 52.78; H, 4.66 Found: C, 52.90; H, 4.96.

"*Tetrahydroyobyrine.*"—A mixture of 691 mg. of crude 3-*n*-butyryl-5,6,7,8-tetrahydroisoquinoline and 414 mg. of phenylhydrazine was heated *in vacuo* on the steam-bath for one-half hour (water loss, 59 mg.). The mass was taken up in 25 ml. of anhydrous ethanol and while chilled in an ice-bath, saturated with dry hydrogen chloride. After standing at room temperature for one hour, the mixture was refluxed for one and one-half hours. The solution was then chilled in an ice-bath and the solid hydrochloride separated by filtration. This material, 0.2 g., is being further investigated. The filtrate was concentrated under partial vacuum with gentle warming to remove the ethanol. The residue was covered with ether and shaken with 5% sodium hydroxide solution. The ether extract was washed with water, dried and concentrated. There remained 0.9 g. of a brown gum which was crystallized from 3 ml. of methanol. This gave 180 mg. of pale yellow crystals which melted at 158–162°. A second crop of 100 mg., m. p. 154–157°, was isolated from the mother liquor. The total yield amounted to 30%. The "tetrahydroyobyrine" after purification by sublimation at 4×10^{-2} mm. and crystallization from methanol melted at 164.5°. It showed no depression in melting point when mixed with an authentic sample of "tetrahydroyobyrine."

3-Carboxy-1,2,3,4-tetrahydroisoquinoline.—This acid was previously prepared by Pictet and Spengler.[10] However, the following procedure is much simpler and has given consistently better results. A mixture of 75 g. of β-phenylalanine, 170 ml. of formalin (36%, neutral) and 575 ml. of concentrated hydrochloric acid was heated on a steam-bath for one-half hour with occasional swirling. After the addition of another 75 ml. of formalin and 150 ml. of concentrated hydrochloric acid, the mixture was heated for three hours. It was chilled and the solid separated by filtration. The filter cake was dissolved in 1000 ml. of hot water and 2000 ml. of hot ethanol was added. While still hot, the solution was neutralized to congo red with 10% ammonium hydroxide solution. After cooling, the crystalline mass was filtered, washed with ethanol and dried. The acid, 49.5 g. (61%), melted at 326°, dec. One recrystallization from aqueous ethanol gave glistening plates which melted at 335°, dec.[13]

Anal. Calcd. for $C_{10}H_{11}NO_2$: C, 67.78; H, 6.26. Found: C, 67.51; H, 6.15.

3-*n*-Butyrylisoquinoline.—A solution of *n*-propyllithium in 190 ml. of anhydrous ether was prepared from 3.3 g. of lithium and 30.0 g. of *n*-propyl bromide. An aliquot of the ethereal solution when titrated with standard acid indicated that the total solution contained 8.0 g. of *n*-propyllithium. Six grams of 3-carboxy-1,2,3,4-tetrahydroisoquinoline was added to the alkyllithium solution. This mixture was stirred for fifteen hours, decomposed with ice and extracted with ether. The water-washed, dried ethereal solution was concentrated to 5.5 g. of a red-brown, viscous oil. This oil was distilled at 7×10^{-3} mm. and the fraction, 2.9 g., distilling at 126° was collected. Higher boiling materials were present. The 2.9 g. of pale yellow sirup was redistilled at 5×10^{-3} mm. The fraction distilling at 115° amounted to 2.6 g. Efforts to obtain a pure compound from this material either through fractional distillation or fractional crystallization of the picrate were unsuccessful. From analytical data this material appeared to be, essentially, a mixture of 3-*n*-butyryl-1,2,3,4-tetrahydroisoquinoline and 3-*n*-butyrylisoquinoline. This was further substantiated by dehydrogenation. A 100-mg. sample of the mixture was heated with 100 mg. of palladium black at 160–170° (20 mm.) for fifteen minutes. The product was then distilled from the reaction mixture at 140° (0.5 mm.); yield practically quantitative of crystalline material, m. p. 62–65°. One recrystallization from petroleum ether (b. p. 35–60°) gave cream-colored needles of 3-*n*-butyrylisoquinoline melting at 72–73°.

Anal. Calcd. for $C_{13}H_{13}NO$: C, 78.36; H, 6.58; N, 7.02. Found: C, 78.21; H, 6.66; N, 6.81.

The picrate of this ketone, fine yellow prisms, melted at 161–163° (sintering at 151°) after several recrystallizations from methanol.

Anal. Calcd. for $C_{19}H_{16}N_4O_8$: C, 53.28; H, 3.77. Found: C, 53.43; H, 4.02.

2-(3-Isoquinolyl)-3-ethylindole.—A 2.7-g. sample of the mixture of 3-*n*-butyrylisoquinoline and 3-*n*-butyryl-1,2,3,4-tetrahydroisoquinoline was treated with 1.56 g. of phenylhydrazine at steam-bath temperature for thirty minutes. The liberated water was then removed *in vacuo* (water loss, 180 mg.). The residual material was taken up in 85 ml. of anhydrous ethanol and while chilled in an ice-bath saturated with dry hydrogen chloride. The mixture was allowed to stand at room temperature for thirty minutes and then refluxed for one and one-half hours. The crystalline material which formed on chilling was separated and the filtrate was concentrated *in vacuo* to the point of crystallization. After cautious dilution with ether, the hydrochloride was filtered and washed with ether–ethanol. This material weighed 0.7 g. and melted at 220–225°. Recrystallization of a small sample from ethanol raised the melting point to 233–235°. The bulk of the material was hydrolyzed with 5% sodium hydroxide solution and extracted with ether. The ether solution was washed with water, dried and concentrated. The residue was crystallized from ethanol. A total of 0.3 g. of tan crystals, m. p. 126–129°, was obtained in two crops. Purification by sublimation (8×10^{-3} mm.) and recrystallization from aqueous methanol gave fine needles melting at 132°. This gave no depression with an authentic sample of 2-(3-isoquinolyl)-3-ethylindole prepared from tetrahydroyobyrine by palladium dehydrogenation.[3] Furthermore, the absorption spectrum is practically identical with that described by Witkop and Pruckner[14] for the isoquinolyl-indole.

Anal. Calcd. for $C_{19}H_{16}N_2$: C, 83.79; H, 5.93. Found: C, 83.44; H, 5.41.

The picrate of 2-(3-isoquinolyl)-3-ethylindole melted at 208° dec., after crystallization from methanol.

Anal. Calcd. for $C_{25}H_{19}N_5O_7$: C, 59.88; H, 3.82. Found: C, 59.71; H, 3.82.

Some effort was made to isolate from the residual material the indole corresponding to the 3-(1,2,3,4-tetrahydroisoquinolyl) ketone. However, to date, resolution of this material has been unsuccessful. This phase is under further investigation.

Summary

1. Yobyrine, a degradation product of the alkaloid yohimbine, has been synthesized by condensation of tryptamine with *o*-tolylacetic acid, followed by ring closure and dehydrogenation. Its structure is therefore completely elucidated and yobyrine is shown to be 3-*o*-xylyl-4-carboline.

2. The preparation of yobyrone by air oxidation of dihydroyobyrine is reported.

3. The first synthesis of so-called "tetrahydroyobyrine" is herewith recorded and confirms its structure as 2-[3-(5,6,7,8-tetrahydroisoquinolyl)]-3-ethylindole.

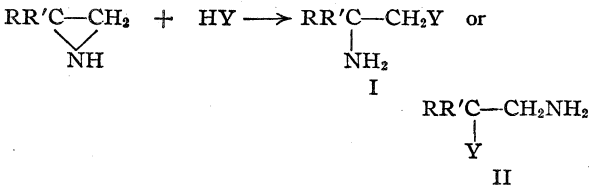
Reactions of Ethylenimines: With Ammonia and Amines

BY LEALLYN B. CLAPP

Ammonia and amines[1] in aqueous solution react with imines to give α,β-diamines and polymeric substances. The reaction between ethylenimine and various amines to give N-substituted ethylenediamines has also been carried out under anhydrous conditions in the presence of aluminum chloride[2] as a catalyst. Coleman and Callen used aqueous reactions in working up the reaction mixtures, however, which introduces some obvious disadvantages. The present paper deals with the reactions of homologs of ethylenimine with amines and liquid ammonia in the presence of ammonium chloride as a catalyst at elevated temperature and pressure. The α,β-diamines, ethylenediamine, isobutylenediamine and 1,2-butylenediamine, which are very difficult to isolate completely free from water when prepared by wet methods, can be obtained in anhydrous condition by the present method. The yields are 55–68%.

When the three-membered ring in an unsymmetrically substituted ethylenimine breaks in the presence of a substance, HY, containing an active hydrogen, products of type I and II are possible.



$$RR'C(-CH_2)NH + HY \longrightarrow RR'C(NH_2)-CH_2Y \text{ (I) or } RR'C(Y)-CH_2NH_2 \text{ (II)}$$

A few such reactions are recorded in the literature. Hydrolysis of unsymmetrical C-substituted imines in acid solution gives products indicating a break in the ring at the tertiary carbon[3] rather than at the primary (or secondary[4]) carbon. In reactions other than hydrolysis (catalytic hydrogenation[5] and addition of hydrogen bromide[6]), the cyclic imine ring breaks at the primary carbon. It was found that when HY is a primary or secondary amine, the rupture is predominantly at the primary carbon, yielding product I, although some of type II was obtained in three cases (Table II).

Competition in the addition of HY to the imine is furnished by molecules of the imine itself, the result of which is a polymer. Polymerization becomes important when the reaction between an imine and liquid ammonia is allowed to proceed at room temperature (Table I). It was reduced to a minimum by more rapid reactions at elevated temperature and pressure.

Polymerization may terminate at the dimeric stage to form a piperazine. The work of Jones[7] on the mechanism of polymerization suggests a symmetrical piperazine.

Proof that the principal product in the reactions of imines and amines is of type I where Y is –NHR or –NRR′ was obtained in the following way. When morpholine was treated with 2-ethylethylenimine, the only product isolated was shown to be N-β-aminobutylmorpholine by synthesizing it by a series of known reactions. Formaldehyde and morpholine were condensed to methylolmorpholine, which then condensed with 1-nitropropane by the method of Cerf de Mauny[8] to give N-β-nitrobutylmorpholine. This substance was reduced to the corresponding diamine. The N-β-aminobutylmorpholine prepared by the two methods gave the same phenylthiourea.

When 2,2-dimethylethylenimine was treated with 2-amino-2-methyl-1-propanol, the product was N-2-(β-aminoisobutylamino)-2-methyl-1-propanol. This was synthesized by the method of Senkus[9] and the phenylthiourea derivative in each case was the same compound.

In the reaction between aniline and 2,2-dimethylethylenimine, two products resulted, b. p. 110–111° (3 mm.) and 145–146° (3 mm.), respectively. The lower boiling compound is 2-amino-2-methyl-1-phenylaminopropane and the second compound is assumed to be 1-amino-2-methyl-2-phenylaminopropane. Johnson[10] has reported the first compound, b. p. 110° (3 mm.), 99° (1 mm.). Two products were also obtained in the reaction with 2-ethylethylenimine and aniline (also cyclohexylamine) and are assumed to bear a like relation to each other.

These last three cases indicate that the product of type (I) is only the predominant one and not the exclusive product in the reaction of an amine and an imine.

Only traces of products were found in the reactions between 2,2-dimethylethylenimine and diethylamine, di-*n*-butylamine and *n*-dodecylamine. Probably there is not enough room for the secondary amino nitrogen of diethylamine and di-*n*-butylamine to approach the primary carbon of the imine (where the bond is to be ruptured) and hence no reaction takes place at all. Added import is given to this view from the fact that the expected products are readily synthesized from a condensation of the secondary amine, formaldehyde, and

2-nitropropane to a nitroamine, followed by a catalytic reduction.[11] Johnson[10] suggests that the nitroamine is formed, first, by a condensation of the amine and formaldehyde to a methylolamine succeeded by a second condensation to form the nitroamine. These reactions are not subject to the steric effects pictured for the rupture of the imine ring.

When the imines were heated with amines without ammonium chloride present, essentially all the original imine was recovered. The imines alone in the presence of ammonium chloride at 100° for one week gave polymers having properties described by Jones.[7]

Experimental

1,2-Butylenediamine.—Thirty-five grams of 2-ethylethylenimine[12] with 5.3 g. of ammonium chloride and 500 cc. of liquid ammonia were heated in an iron bomb (capacity, 3 liters) by an air-bath to 100 ± 2° for fifty-one hours (maximum gage pressure, 800 lb., in about five hours). After the excess ammonia was allowed to boil away (carrying about 5 g. unreacted imine along), the reaction mixture was distilled rapidly from the dissolved ammonium chloride. The distillate was then fractionally distilled through an insulated bubble-cap column (4 bubble caps). One gram of unreacted imine, 19 g. of pure 1,2-butylenediamine, b. p. 140° (55% yield), 1 g. of an oil, b. p. 160–240°, and 2 g. of residue, were obtained.

It is concluded from results of other reactions carried out in similar manner (Table I) that the best yields of α,β-diamines obtain under the following conditions: temperature 100°, a forty-fold excess of liquid ammonia, about 0.2 mole of catalyst per mole of imine, and more than twelve hours heating time.

The head of the iron reactor was sealed with a lead washer and was also equipped with a thin iron blow-out patch obtained from the American Instrument Company. The system was similar in construction to the type which may be purchased from that company.

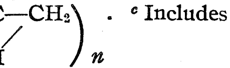
[a] Five hundred cc of liquid ammonia was used in all reactions except the last where 250 cc. was used. [b] Percentage based on formula



$\left(RR'C\text{—}CH_2 \atop NH\right)_n$. [c] Includes 19% diethylenetriamine. [d] Includes 20% piperazine.

The higher polymeric products obtained as designated in Table I from the reaction of ammonia with 2-ethylethylenimine were subjected to fractional distillation. Sixty-two grams of material, b. p. 150–255°, from the rapid distillation of the reaction mixture of ammonia and 2-ethylethylenimine was redistilled and various fractions collected. By a Kjeldahl nitrogen analysis, an estimate of the amount of nitrogen liberated with nitrous acid treatment, and/or the appearance of an insoluble nitroso compound, the probable content of these polymeric products was deduced: fraction b. p. 150–195°, mostly 1,2-butylenediamine; b. p. 195–235°, polymer and 2,5-diethylpiperazine; above 235°, polymer and a diethylenetriamine derivative.

A Diethylpiperazine.—From the fraction b. p. 195–235° just mentioned, 2 g. of a solid separated on standing at zero for several days. Three recrystallizations from acetone gave 0.5 g. of white crystalline plates, m. p. 87–89°, resembling piperazine in odor and crystalline character. It formed a white hydrochloride and an insoluble oily nitroso compound. This compound is probably 2,5-diethylpiperazine.

Anal. Calcd. for $C_8H_{18}N_2$: N, 19.70. Found: N, 19.56, 19.59.

Two-tenths gram of the piperazine was converted to the dibenzamide derivative, m. p. 167–168°.

Anal. Calcd. for $C_{18}H_{18}N_2O_2$: N, 7.99. Found: N, 8.13.

β-Nitrobutylmorpholine.—Using the method of Cerf de Mauny,[8] a condensation of methylolmorpholine and 1-nitropropane gave a 75% yield of β-nitrobutylmorpholine, b. p. 130–135° (10 mm.).

β-Aminobutylmorpholine. Method A.—The β-nitrobutylmorpholine was reduced to the corresponding diamine (following Cerf de Mauny[8] again) in alcohol using zinc amalgam[12a] and hydrogen chloride gas with a yield of 58%; b. p. 218–223°.

Method B.—Eight grams (0.11 mole) of 2-ethylethylenimine was sealed with 11 g. (0.15 mole) of morpholine and 0.1 g. of ammonium chloride in a glass tube and heated to 80° for twenty-four hours. The reaction mixture was distilled once rapidly from the solid ammonium chloride and then fractionally distilled through an insulated bubble-cap column (4 bubble-caps). The β-aminobutylmorpholine was collected, b. p. 220–222°; yield 8 g., 50%. With the same quantity of imine, a three-fold and a ten-fold excess of morpholine gave yields of 85 and 95%, respectively.

Phenylthiourea derivatives were made from portions of the products obtained by Methods A and B, which gave m. p.'s 138–139 and 140–141°, respectively. The mixed melting point gave no depression.

N-2-(β-Aminoisobutylamino)-2-methyl-1-propanol. Method A.—In the manner just described (Method B above) 9 g. of pure N-2-(β-aminoisobutylamino)-2-methyl-1-propanol was obtained, b. p. 233° (yield 20%)[13] from 25 g. (0.28 mole) of 2,2-dimethylethylenimine and 79 g. (0.9 mole) of 2-amino-2-methyl-1-propanol. After standing, the oil changed to a solid, m. p. 51–53°.

Method B.—N-2-(β-nitroisobutylamino)-2-methyl-1-propanol was prepared by the method described by Senkus.[9] Reduction of this compound at three atmospheres pressure of hydrogen with platinum oxide (Adams catalyst) gave 61% yield of N-2-(β-aminoisobutylamino)-2-methyl-1-propanol, b. p. 231–233°.

Phenylthiourea derivatives of the products from methods A and B gave m. p. 133–134° and 132–134°, respectively, and a mixed melting point gave no depression.

The results of other reactions between 25 g. of each of the two imines and a three-fold excess of various amines are shown in Table II, along with a number of derivatives and the analyses. The derivatives were all prepared by standard methods; the nitrogen analyses were run by the semi-

Summary

1. An improved method of preparing anhydrous α,β-diamines (both amine groups primary) has been found.

2. A number of α,β-diamines (one amine group primary and the other secondary or tertiary) and their derivatives have been prepared.

3. It has been shown that cyclic ethylenimine rings rupture preferentially but not exclusively at the primary carbon atom in the presence of amines and ammonium chloride, an acid catalyst.

Allyl Esters of Phosphonic Acids. I. Preparation and Polymerization of Allyl and Methallyl Esters of Some Arylphosphonic Acids

BY A. D. F. TOY

The use of organic esters of phosphoric acid as plasticizers for various resins is well known. These phosphorus containing esters have been of special importance because they not only are good plasticizers, but also impart a certain degree of flame resistance to the resins with which they are used. All these esters are incorporated with the resin as physical mixtures, but their usefulness is probably due to the fact that they serve as excellent hydrogen bonding agents.[1] It was thought to be of interest to study some phosphorus compounds which are not only plasticizers, but which (a) by themselves are capable of undergoing the process of polymerization into a resin or (b) upon mixing with other polymerizable monomers are capable of actually copolymerizing with and modifying the latter. Certain allyl esters of phosphoric acid, and substituted phosphoric acids, have been found to be modifiers for compounds such as styrene through copolymerization.[2] These compounds have been suggested for use in the preparation of polymeric materials.[3]

In our study of the chemistry of the esters of the organic phosphonic acids it has been noted that these substances are significantly different in many respects from the corresponding trisubstituted alkyl and aryl phosphates. For example, dioctyl benzenephosphonate possesses a somewhat higher thermostability than trioctyl phosphate. Likewise

we have found that the allyl phosphonates also have somewhat different properties from those characterizing the related esters of phosphoric acid.

The present paper is the first of a series dealing with the allyl esters of phosphonic acids. The preparation and polymerization of allyl and methallyl esters of benzene-, *p*-toluene- and *p*-chlorobenzenephosphonic acids are described. These substances are capable of being polymerized into hard, transparent, infusible and insoluble resins when heated in the presence of a peroxide catalyst.

In the synthesis of these substances, a new convenient process was developed for the preparation of dichloroarylphosphine oxide based upon the action of chlorine on a slurry of phosphoric anhydride in a dichloroarylphosphine (equation 1).

$$3ArPCl_2 + P_2O_5 + 3Cl_2 \longrightarrow 3ArPOCl_2 + 2POCl_3 \quad (1)$$

The allyl esters were then obtained by reaction between the dichloroarylphosphine oxide and allyl alcohol in the presence of pyridine (equation 2).

$$ArPOCl_2 + 2ROH + 2C_5H_5N \longrightarrow ArPO(OR)_2 + 2C_5H_5N.HCl \quad (2)$$

Experimental

Dichloroarylphosphine Oxides

Dichlorophenylphosphine Oxide.—Dichlorophenylphosphine (1611 g., 9 moles) was placed in a 3-liter 3-necked flask equipped with a reflux condenser, stirrer, thermometer and a chlorine inlet; 511 g., 3.6 moles of finely divided phosphoric anhydride was added and slurried with the dichlorophenylphosphine. Chlorine gas was then passed into the slurry. The heat of reaction caused the temperature to rise to around 150°. However, as more phosphorus oxychloride was formed, it refluxed and lowered the liquid temperature to around 130°. The rate of the introduction of chlorine was such as to maintain steady reflux of the phosphorus oxychloride. The reaction was complete in about four hours as indicated by the fact that the temperature began to drop. The addition of chlorine was then discontinued and the mixture fractionated. After the removal of most of the phosphorus oxychloride at atmospheric pressure, the dichlorophenylphosphine oxide was obtained by distillation under reduced pressure, b. p. 137–138° at 15 mm. or 104° at 4 mm. The yield was 1550 g. (88.4%), $n^{25}D$ 1.5581, sp. gr. 1.197 at 25°. The identity of the product was verified (a) by hydrolysis to benzenephosphonic acid, melts at 161–162° (uncor.), and (b) by the fact that no depression was observed in a mixed melting point determination with the compound obtained by the oxidation of benzenephosphinic acid.

Dichloro-*p*-tolylphosphine Oxide.—In an initial experiment a slurry of 200 g. (1.035 mole) of dichloro-*p*-tolylphosphine and 54 g. (0.38 mole) of phosphoric anhydride was chlorinated at 35–40° to avoid possible ring or side chain chlorination. Upon completion of the reaction, the mixture was fractionated. The dichloro-*p*-tolylphosphine oxide obtained boiled at 140–142° at 11 mm. The yield was found to be 190 g. (87.5%), $n^{25}D$ 1.5542, sp. gr. 1.154 at 25°.

That chlorination of the tolyl radical does not occur is indicated by the fact that even better yields are obtained at higher temperatures. In another experiment the chlorination reaction was carried out rapidly at 145° using 150 g. of dichloro-*p*-tolylphosphine and 40 g. of phosphoric anhydride. A yield of 140 g. (91.7%) was obtained under these conditions.

Anal. Calcd. for $CH_3C_6H_4POCl_2$: P, 14.8; Cl, 34.0. Found: P, 15.0; Cl, 34.1.

The compound is therefore identical with that previously described by Michaelis and Paneck.[4]

Dichloro-*p*-chlorophenylphosphine Oxide.—A slurry of 200 g. (0.936 mole) of dichloro-*p*-chlorophenylphosphine and 50 g. (0.352 mole) of phosphoric anhydride was chlorinated at 35–40°. Upon completion of the chlorination, the mixture was fractionated. The product so obtained boils at 121–123° at 3 mm. and is a water-white liquid. The yield was found to be 192 g. (88%), $n^{25}D$ 1.5743, sp. gr. 1.302 at 25°. This compound had previously been prepared by Michaelis[5] by the reaction of *p*-chlorophenylphosphorus tetrachloride with sulfur dioxide.

Anal. Calcd. for $ClC_6H_4POCl_2$: P, 13.5; Cl, 46.5. Found: P, 13.4; Cl, 47.0.

Allyl Esters of Arylphosphonic Acids

Diallyl Benzenephosphonate. (a) By the Action of Dichlorophenylphosphine Oxide on Allyl Alcohol in the Presence of Pyridine.—In a 3-liter 3-necked flask, equipped with a stirrer, a thermometer and a dropping funnel were placed 464 g. (8 moles) of allyl alcohol and 632 g. (8 moles) of pyridine. To this mixture was added with stirring 780 g. (4 moles) of dichlorophenylphosphine oxide. The temperature of the addition was maintained at 2 to 5° by means of an ice-salt-bath. Six hours were required for the addition. Upon completion of the addition the mixture was allowed to come to room temperature. Four hundred cc. of water was then added, the oily layer separated was distilled immediately under reduced pressure. Prolonged standing of the crude wet ester causes some hydrolysis. In effecting the distillation, it was necessary to raise the temperature slowly and during this process, to maintain the pressure at about 20 mm. up to 50°, at less than 10 mm. from 50 to 100°, and at less than 5 mm. up to 120°. In heating the crude ester to the distillation point, gaseous products were evolved which made it difficult to maintain the necessary low pressure unless a high free air capacity pump was used or the heating carried out slowly. Heating of the material too rapidly at too high a pressure caused some decomposition and resulted in low yields of the product. In any event, it was essential to avoid heating the residue to a temperature much above 170°, to prevent rapid decomposition. The distillation of the product was best carried out at 1 to 2 mm. in the presence of a little copper resinate inhibitor. The yield of the distilled product was 777 g. (81.6%), b. p. 128° at 1 mm., $n^{25}D$ 1.5128, sp. gr. 1.1097 at 25°.

Anal. Calcd. for $C_6H_5PO(OCH_2CH{=}CH_2)_2$: P, 13.0. Found: P, 12.96.

In another experiment, the original reaction was carried out at 25–30° instead of 2–5°. The yield of the distilled product was found to be 71%.

Substitution of dimethylaniline for pyridine was found to give lower yields and a product of lesser purity.

The reactions between dichlorophenylphosphine oxide and allyl alcohol in the presence of pyridine were also carried out using hexane and benzene as reaction media. While pyridine hydrochloride precipitates under these conditions, yields were consistently lower and more difficulty was experienced in working up the reaction mixture for isolation of the diallyl ester. Employment of a 20% excess of allyl alcohol using hexane as solvent did not appreciably increase the yield.

(b) By the Action of Dichlorophenylphosphine Oxide on Sodium Allylate in Toluene Solution.—To 46 g. (2 moles) of sodium dispersed in 2500 cc. of toluene there was added a 100% excess, 232 g. (4 moles) of allyl alcohol at 80–90°. The mixture was heated at 100° until all sodium had disappeared. To this slurry there was then added 195 g. (1 mole) of dichlorophenylphosphine oxide at 0 to 5°. The mixture was allowed to come to room temperature and then heated to 40°. Upon cooling, 900 cc. of water was added and the toluene layer separated and subjected to fractional distillation, yielding 100 g. (42%)

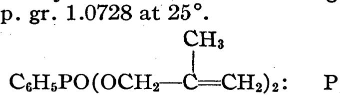
[5] Michaelis, *ibid.*, **293**, 193–325 (1896).

of a product, b. p. 148–158° at 6 mm. This yellowish compound was not very pure since it polymerized to give a yellowish gel under conditions where pure diallyl benzenephosphonate would have polymerized into a very hard and strong solid.

The pure diallyl benzenephosphonate is soluble in water to the extent of 2 g. per liter. It is soluble in most of the common organic solvents. It absorbs carbon dioxide readily. It is stable at room temperature with very little change over a period of more than a year. However, when it was stored in the presence of 4.5% benzoyl peroxide, it became a gel after forty days at room temperature.

Dimethallyl Benzenephosphonate.—Three hundred and ninety grams (2 moles) dichlorophenylphosphine oxide was allowed to react with 316 g. (4 moles) of pyridine and 288 g. (4 moles) of methallyl alcohol at 2–5°. The reaction mixture was processed as described for diallyl benzenephosphonate. The water-white product boils at 140–143° at 2–3 mm. The yield was found to be 285 g. (53.5%), $n^{25}D$ 1.5057, sp. gr. 1.0728 at 25°.

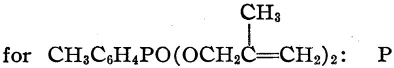


Anal. Calcd. for $C_6H_5PO(OCH_2\text{—}\overset{CH_3}{\overset{|}{C}}{=}CH_2)_2$: P, 11.66. Found: P, 11.84.

Diallyl *p*-Toluenephosphonate.—Seventy grams (0.335 mole) of dichloro-*p*-tolylphosphine oxide was allowed to react with 39 g. (0.67 mole) of allyl alcohol and 53 g. (0.67 mole) of pyridine at 2–5°. The crude diallyl *p*-toluenephosphonate was dried over anhydrous magnesium sulfate and then distilled. It boils at 134–136° at 1 mm. The yield was 47 g. (55.6%), $n^{25}D$ 1.5120, sp. gr. 1.089 at 25°.

Anal. Calcd. for $CH_3C_6H_4PO(OCH_2CH{=}CH_2)_2$: P, 12.3. Found: P, 12.4.

Dimethallyl *p*-Toluenephosphonate.—Seventy grams (0.335 mole) of dichloro-*p*-tolylphosphine oxide and 48.5 g. (0.67 mole) of methallyl alcohol and 53 g. (0.67 mole) of pyridine were allowed to react under conditions outlined above. The product boils at 146–149° at 1 mm. The yield was found to be 63 g. (67.2%), $n^{25}D$ 1.5070, sp. gr. 1.057 at 25°.

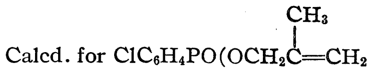


Anal. Calcd. for $CH_3C_6H_4PO(OCH_2\overset{CH_3}{\overset{|}{C}}{=}CH_2)_2$: P, 11.1. Found: P, 11.1.

Diallyl *p*-Chlorobenzenephosphonate.—Seventy-five grams (0.327 mole) of dichloro-*p*-chlorophenylphosphine oxide was allowed to react with 38 g. (0.655 mole) of allyl alcohol and 52 g. (0.658 mole) of pyridine. The diallyl *p*-chlorobenzenephosphonate was found to boil at 136–139° at 2 mm. The yield was 35 g. (40%), $n^{25}D$ 1.5208.

Anal. Calcd. for $ClC_6H_4PO(OCH_2CH{=}CH_2)_2$: P, 11.4; Cl, 13.0. Found: P, 11.6; Cl, 13.05.

Dimethallyl *p*-Chlorobenzenephosphonate.—Seventy grams (0.305 mole) of dichloro-*p*-chlorophenylphosphine oxide was allowed to react with 47.5 g. (0.66 mole) of methallyl alcohol and 52 g. (0.66 mole) of pyridine. The dimethallyl *p*-chlorobenzenephosphonate boiled at 137–140° at 1 mm. The yield was found to be 50 g. (53.8%). $n^{25}D$ 1.5162, sp. gr. 1.145 at 25°.



Anal. Calcd. for $ClC_6H_4PO(OCH_2\overset{CH_3}{\overset{|}{C}}{=}CH_2)_2$: P, 10.3; Cl, 11.8. Found: P, 10.5; Cl, 11.9.

Polymerization

In a preliminary study of the polymerization of the allyl esters of the arylphosphonic acids, it was found that all are capable of polymerizing into hard, clear, infusible and insoluble resins. The first experiments were carried out using 10-cc. samples of the monomer catalyzed with 2% benzoyl peroxide. The solution was put under nitrogen atmosphere and heated in an oil-bath at 85–90°, for eighteen to twenty hours. The monomer first became a viscous liquid, then a gel and finally a hard solid. The color of these resins varied from water-white to light yellow. The hardness of the resins when polymerized under identical conditions was found to depend on the chemical constitution of the monomer. The polymerization characteristics of these esters are very similar to those of the allyl esters of the organic dibasic acids.[6] The allyl arylphosphonate resins were found to possess the interesting property of flame resistance, being self-extinguishing when removed from the flame. The monomeric esters were also found to be capable of copolymerization with such unsaturated organic compounds as vinyl acetate, methyl methacrylate, diallyl esters of organic dibasic acids and unsaturated polyesters.

Acknowledgments.—The author expresses thanks to Dr. Howard Adler for his helpful advice and encouragement and to Mr. A. R. Wreath for the chemical analyses.

Summary

1. The preparation of dichlorophenyl-, dichloro-*p*-tolyl- and dichloro-*p*-chlorophenylphosphine oxides may be affected readily by chlorination of a slurry of phosphoric anhydride and the corresponding dichloroarylphosphine.

2. The dichloroarylphosphine oxides have been converted into the diallyl and dimethallyl esters of the arylphosphonic acids by action of the respective alcohols in the presence of pyridine.

3. The diallyl and dimethallyl esters of benzene-, *p*-toluene- and *p*-chlorobenzenephosphonic acids undergo peroxide catalyzed polymerization to form clear, infusible, insoluble resins and also are capable of copolymerization with various unsaturated organic compounds.

Absorption Spectra. V. The Ultraviolet and Visible Spectra of Certain Polyene Aldehydes and Polyene Azines[1]

BY ELKAN R. BLOUT AND MELVIN FIELDS

In this paper we should like to report the results of some studies on the ultraviolet and visible absorption spectra of certain compounds containing conjugated double bonds. The substances studied were aldehydes of the generic formula, I

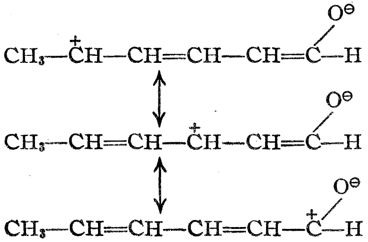
$$R-(CH{=}CH)_n-CHO \qquad \text{I}$$

where R is methyl or α-furyl and n ranges up to 7, and azines of the generic formula, II

$$R-(CH{=}CH)_n-CH{=}N-N{=}CH-(CH{=}CH)_n-R \qquad \text{II}$$

where R is methyl or α-furyl. Previous workers, notably Kuhn and his school, have prepared many compounds of the polyene type and have reported their absorption spectra. Their results on aldehydes of the Type I,[2,3] which did not extend beyond $n = 3$, are in essential agreement with our measurements.

The absorption spectra of the homologous series of aliphatic polyene aldehydes containing as many as seven conjugated carbon–carbon double bonds are shown in Figs. 1 and 2. The spectra of these compounds are characterized by a single intense absorption band which, in the higher members of the series, is accompanied by a weaker band at shorter wave lengths. As the length of the conjugated system is increased, both bands move toward longer wave lengths, but show no evidence of fine structure typical of the polyene hydrocarbons.[4] The intense band may probably be correlated with electronic transitions to relatively highly ionic states in which forms such as III (shown for 2,4-hexadienal) are prominent contributors. It is noteworthy that in the polyene aldehyde series the principal band lies at considerably longer wave lengths than the principal band of the aliphatic polyene hydrocarbon with the same number of carbon atoms. The carbonyl group produces a bathochromic effect by lengthening the conjugated system, increasing the number of resonance forms and thereby reducing the energy necessary to effect transitions from the ground state to the first excited state.[5]



$$\begin{gathered}CH_3-\overset{+}{C}H-CH{=}CH-CH{=}\overset{O^{\ominus}}{C}-H\\ \updownarrow\\ CH_3-CH{=}CH-\overset{+}{C}H-CH{=}\overset{O^{\ominus}}{C}-H\\ \updownarrow\\ CH_3-CH{=}CH-CH{=}CH-\overset{+\,O^{\ominus}}{C}-H\end{gathered}$$

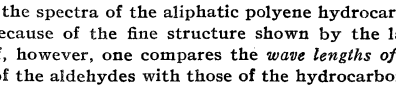
2,4,6,8,10-Dodecapentaenal	6	380[c]	Chloroform

[a] Booker, Evans and Gillam, *J. Chem. Soc.*, 1453 (1940). [b] See ref. 2. [c] Present work. [d] Kuhn and Grundmann, *Ber.*, **71**, 442 (1938), report maxima at 272, 284, 296 and 320 mμ. We find maxima at 272, 283, 295 and 310 mμ with the 295 maximum the most intense. [e] See also Kuhn, *Angew. Chem.*, **50**, 703 (1937).

The spectra of the α-furyl polyene aldehydes (shown in Figs. 3 and 4) exhibit the same general characteristics as those of the aliphatic polyene aldehydes. In the furyl series the second less intense absorption band first appears in the trienal. In line with an earlier observation on the lower members of the series[3] we find that the higher furyl polyene aldehydes absorb at approximately the same wave lengths as the aliphatic polyene aldehydes containing the same total number of double bonds (Table II). Although the linear extension of the conjugated system in the furyl aldehydes is decreased by the presence of two of the double bonds in a ring, the increased contribution of dipolar forms such as IV (shown for 5-α-furyl-



IV

(5) It is also possible that a group such as the carbonyl has an additional effect on the absorption due to its polar character. Since less energy is necessary to effect charge separation in a system containing a polar group, it is reasonable to assume that such a system will absorb light of longer wave lengths than a system containing an equal number of conjugated double bonds and no polar group. Comparison of the spectra of the aliphatic polyene aldehydes with the spectra of the aliphatic polyene hydrocarbons offers difficulty because of the fine structure shown by the latter compounds. If, however, one compares the *wave lengths of maximum absorption* of the aldehydes with those of the hydrocarbons this difficulty is obviated. These data are summarized in Table I. Except for the lowest members of the series, the data are in line with these considerations.

2,4-pentadienal) probably is sufficient to allow absorption at approximately the same wave length as the corresponding non-cyclic compound with the same number of double bonds. The increased contribution of forms such as IV may in turn be correlated with the ready acceptance of a positive charge by the ring oxygen atom.

In Fig. 7 we have plotted the wave lengths of the absorption maxima of the aliphatic and α-furyl polyene aldehydes as a function of the number of carbon–carbon double bonds. The plot for the main absorption bands, although definitely not a straight-line function with the lower members of the series, shows some evidence of linearity for several of the higher homologs. The position of the shorter wave length maximum appears to be a linear function of the number of double bonds for those members of the series examined. We have calculated the ratio of the wave length of maximum absorption of the longer wave length band to that of the shorter wave length band,[6] and find that in both series it decreases with increasing *n*. In this respect the absorption bands of the polyene aldehyde series differ from those of the

carotenoid and diphenyl polyene series where the ratio of the wave length of maximum absorption of the longest wave length band to that of a shorter wave length band increases with the length of the chain and approaches 2.

As suggested by Lewis and Calvin[6] for the diphenyl polyenes, we have also plotted the square of wave length of maximum absorption *versus* the number of double bonds for both of the polyene aldehyde series. Other investigators[7] have noted that in these cases the lowest members of the series show a linear relation between λ^2 and n. Calculated from our data, the points for the four higher homologs of each type also fall on straight lines, albeit different ones from those of the lower members.

The spectra of the aliphatic polyene azines, II, where n = 1, 2, 3 and 4 are shown in Fig. 5. Besides the expected bathochromic shift with increasing chain length, one observes some evidence of band splitting of the type seen in the aliphatic polyene hydrocarbons. Experimental difficulties, due to the insolubility of these compounds, have thus far limited our studies to the lower members of the series. The maximal absorptions of the aliphatic polyene azines lie at much shorter wave lengths than those of the aliphatic polyene hydrocarbons with the same number of double bonds (*cf.* Tables I and II). Since one might expect that systems containing the same number of conjugated double bonds and no highly polar groups would absorb at approximately the same positions, the absorption of the azines at much shorter wave lengths than their hydrocarbon analogs must mean that the effective absorbing system is shorter in

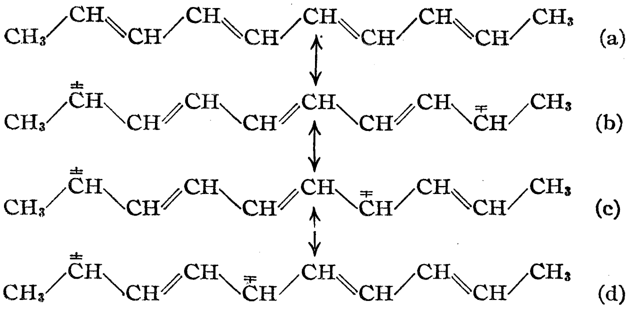
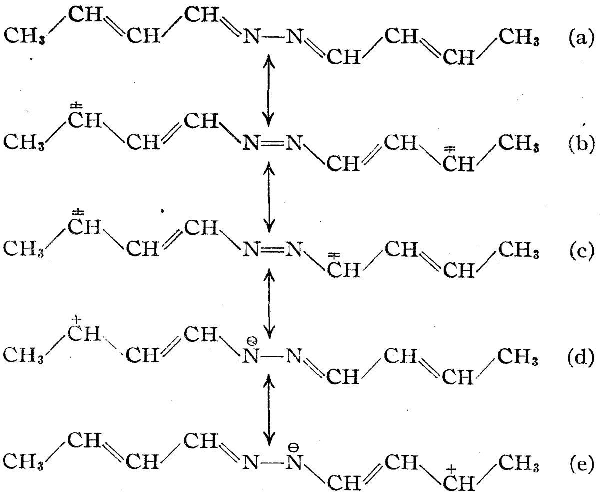
the nitrogen-containing compounds. Some of the possible resonance forms of a polyene hydrocarbon are shown in V



V

and of the azine with the same number of double bonds in VI.



VI

The presence of the relatively electronegative nitrogen atoms in the azines leads to an increased contribution of forms such as VId and e to the resonance hybrid VI as compared with the contribution of forms such as Vd to the resonance hybrid V, and this favors absorption at shorter wave lengths.

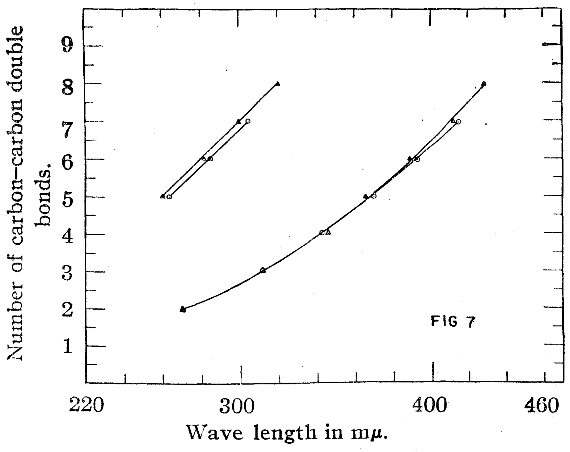


Fig. 7.—Wave lengths of maximum absorption *vs.* number of carbon–carbon double bonds in polyene aldehydes: ⊙—⊙, aliphatic polyene aldehydes; △—△, furyl polyene aldehydes.

The four lowest α-furyl polyene azines have similar absorption spectra (Fig. 6). Comparison of these spectra with those of the aliphatic polyene azines with the same number of double bonds (Fig. 5) shows that the maximal absorptions in the furyl series lie at shorter wave lengths than in the aliphatic series. This is consistent with the generalizations developed above inasmuch as in the furyl series forms containing negatively charged nitrogen atoms should be even larger contributors to the excited state because of the ready acceptance of the positive charge by the oxygen in the furan ring.

The absorption spectra of ω,ω′-diphenyl polyene azines containing as many as six double bonds in the linear portion of the molecule have already been measured by previous workers.[7] On comparing these data with the results of Kuhn's measurements[8] on some of the corresponding diphenylpolyene hydrocarbons, we note that in all cases the azines absorb at shorter wave lengths than the analogous hydrocarbons.

It has already been pointed out by Lewis and Calvin[5] that polyene azines should absorb at shorter wave lengths than the corresponding polyene hydrocarbons because of the greater "strain" of forms (such as VIb and c) which contain the —N=N— group. Our concept of this effect emphasizes the relatively greater contribution of forms containing charged nitrogen atoms as compared with forms in which the nitrogen atoms bear no formal charge. It appears to us that in this fact lies the reason for the differences in the ultraviolet absorption spectra of the polyene azines and the polyene hydrocarbons.

Acknowledgment.—We wish to acknowledge the assistance of Messrs. Marshall Kane and Claude Valle, who prepared many of the compounds, and Miss Adelaide Sutton, who measured the absorption spectra.

Experimental

Aliphatic Polyene Aldehydes.—These aldehydes were all prepared by modifications of the procedures of Kuhn and co-workers who condensed crotonaldehyde with itself or with acetaldehyde in the presence of piperidine acetate. Although the aliphatic polyene aldehydes undergo more or less rapid decomposition under ordinary conditions, they can be stored in vacuum at −50° for several months without change.

Condensation of Crotonaldehyde with Acetaldehyde.[9]—A solution of 380 cc. of acetaldehyde and 280 cc. of crotonaldehyde (Niacet, redistilled, b. p. 100–102°) in a 1-liter flask equipped with a Dry Ice condenser and a gas inlet tube was deaerated with nitrogen for thirty minutes; this precaution appears to be required in these reactions in

[8] Hausser, Kuhn and Smakula, *Z. phys. Chem.*, **29B**, 384 (1935).

[9] Kuhn, Badstübner and Grundmann, *Ber.*, **69**, 98 (1936).

order to approximate the yields of condensation products reported by Kuhn and co-workers. After addition of 4 cc. of piperidine and 2.8 cc. of acetic acid, the reaction mixture was allowed to stand under nitrogen for eighteen hours. The clear red solution obtained after extracting the mixture with 1 liter of ether was filtered, washed well with water, dried over anhydrous sodium sulfate and stored at 0° for forty-eight hours. The small quantity of the red 2,4,6,8,10,12-tetradecahexaenal which had separated was filtered, washed with ether, and crystallized from chloroform. The yield of the pure hexaenal, m. p. 194–195°,[10] was 0.29 g.

Distillation of the ether filtrate in vacuum afforded, in three fractions, crude 2,4-hexadienal, 2,4,6-octatrienal and 2,4,6,8-decatetraenal in approximately the quantities reported by Kuhn, Badstübner and Grundmann.[9]

Distillation of the crude dienal fraction through an efficient column afforded 18.1 g. of 2,4-hexadienal, b. p. 62–65° (14 mm.). The sample used for absorption spectra measurements was distilled, retaining the middle fraction, b. p. 63.0–63.5° (15 mm.) (n^{20}_{D} 1.5298), reported 64–66° (11 mm.),[1] n^{22}_{D} 1.5372.

Isolation of pure 2,4,6-octatrienal was most effectively accomplished by cooling the crude fraction in a Dry Ice-butyl cellosolve bath, filtering the crystalline product, and then distilling the residual oil. The distillation of this oil yielded a fraction boiling at 74–85° (1.5 mm.) which afforded a considerable quantity of crystalline trienal upon cooling in a Dry Ice-bath. The crystallization of the total amount of crude cystalline material from its own weight of hexane gave 7.2 g. of octatrienal, m. p. 57–59°. After two more crystallizations from hexane the aldehyde melted at 55.5–57°; reported, 55°.[11]

Distillation of the crude decatetraenal fraction in a manner similar to that described above yielded 0.7 g. of the pure aldehyde, which melted at 105.5–107°, in good agreement with the value reported by Kuhn and co-workers.[9]

Self-Condensation of Crotonaldehyde.—This reaction was performed with deaerated crotonaldehyde essentially as described by Kuhn and Grundmann.[12,13] Although the yields of crude 2,4,6-octatrienal, 2,4,6,8,10-dodecapentaenal, and 2,4,6,8,10,12,14-hexadecaheptaenal were approximately those obtained by the previous workers, the yields of the pure compounds were considerably lower.

Furylpolyene Aldehydes.—Syntheses of these aldehydes were also achieved by condensation reactions as described in the literature.[14,15] The properties of our samples of these compounds, summarized in Table II, correspond with those reported.

Polyene Azines.—Most of the azines studied were known compounds whose preparation was accomplished by refluxing for several hours an ethanol or dioxane solution of 2.1 moles of aldehyde with 1 mole of 85% hydrazine hydrate.

Because of difficulties encountered with the method of Hladík,[16] an improved procedure for the preparation of crotonaldehyde azine had to be developed. One hundred and twenty-six cubic centimeters of 85% hydrazine hydrate was added dropwise at 0° to 300 g. of vigorously stirred crotonaldehyde; extraction of the reaction mixture with hexane yielded a clear yellow extract. Stored overnight at −50°, the washed and dried hexane solution deposited 15 g. of crude crotonaldehyde azine, m. p. 63–94°. After several crystallizations from hexane 5.3 g. of material, m. p. 98–101°, was obtained. Although several more crystallizations failed to sharpen the melting point, the pure azine, m. p. 101.5–102°, was finally obtained with small loss by sublimation followed by one more crystallization from hexane. Crotonaldehyde azine is reported by Hladík to melt at 96°.

2,4,6,8-Decatetraenal Azine.—A satisfactory analytical sample of this azine could not be prepared. The extremely slight solubility of the substance rendered crystallization impracticable and high vacuum sublimation (10^{-4} mm.) was accompanied by considerable decomposition. The compound decomposed without melting at about 250°.

Anal. Calcd. for $C_{20}H_{24}N_2$: C, 82.14; H, 8.27. Found: C, 82.03; H, 8.87.

7-α-Furylheptatrienal Azine.—This substance crystallizes from dioxane in tiny bronze colored needles, m. p 241.5–242.5° dec.

Anal. Calcd. for $C_{22}H_{20}O_2N_2$: C, 76.75; H, 5.86. Found: C, 76.47; H, 6.30.

Spectral Measurements.—The absorption spectra measurements were made on a Beckman Quartz Spectrophotometer Model DU using a 1-cm. quartz cell and a hydrogen discharge tube as an ultraviolet source. Because of the wide variation in the solubilities of the substances investigated it was impossible to make all measurements in a single solvent. When, because of the lower solubility of the higher members of a homologous series it was necessary to change the solvent for spectral measurements, we obtained data for intermediate members in both solvents. Although the magnitude of the shift of the absorption maxima due to changes in solvent was not constant, it was always in the direction of shorter wave lengths when one changed from anisole or ethanol to dioxane (Table II).

Ethanol.—Commercial absolute ethanol was used without purification.

1,4-Dioxane.—The material used in the early phase of the work was purified by the standard method[17]; but when it was found that a commercial product[18] was satisfactory after refluxing for three days over sodium followed by distillation, the abbreviated treatment was adopted. Stored over sodium wire with minimum contact with air, the pure solvent, b. p. 100.5–101.0°, was suitable for spectrophotometric measurements at wave lengths as short as 238 mμ.

Anisole.—Distillation of Eastman Kodak Co. "White Label" grade gave a product, b. p. 152–153°, satisfactory for spectrophotometric measurements at wave lengths greater than 295 mμ.

Tetrachloroethylene.—The commercial product was distilled, retaining the middle fraction, b. p. 120–121°.

Summary

The ultraviolet and visible absorption spectra of certain polyene aldehydes of the type $R-(CH{=}CH)_n-CHO$, where R is methyl or α-furyl, have been determined. The spectra of azines prepared from the lower members of both polyene aldehydes series have been measured. Correlation of these data with those of other polyenic compounds has been attempted.

Absorption Spectra. VI. The Infrared Spectra of Certain Compounds Containing Conjugated Double Bonds

BY ELKAN R. BLOUT, MELVIN FIELDS AND ROBERT KARPLUS

This investigation is concerned with the infrared absorption spectra of compounds containing conjugated double bonds, and more particularly with the effects of increased conjugation on the spectra in the region of double bond absorption. It has been shown that in the ultraviolet and visible regions the absorption maxima in a series of polyenic compounds shift toward lower frequencies as the conjugation increases.[1,2,3] The question of whether the frequency of maximum absorption in the visible region approaches a limiting value for molecules with very long conjugated systems has not yet been settled.

Compounds containing isolated double bonds, such as butene[4] and squalene,[5] show in the infrared a characteristic absorption in the region 1640–1660 cm.$^{-1}$ attributed to these bonds. Substances such as butadiene and piperylene[4] which contain two conjugated double bonds have also been measured and show absorption at lower frequencies, generally around 1600 cm.$^{-1}$. 2,5-Dimethylhexatriene also shows an absorption maximum in this region.[4] In this paper we wish to report our results with compounds containing as many as ten non-cyclic conjugated double bonds.

1. Aliphatic Polyene Hydrocarbons

The simplest compounds containing conjugated carbon–carbon double bonds are the aliphatic polyene hydrocarbons. Investigation of the infrared spectra of the lower members of this series (Figs. 1–4) in the region 1440–1900 cm.$^{-1}$ shows in addition to the characteristic strong C–H frequency at 1445–1455 cm.$^{-1}$ several other bands of lower intensities. The symmetry of these molecules probably accounts for the lack of intense absorption in this region. Because of the multiplicity of the absorption maxima shown by these compounds in the general neighborhood of C=C absorption it is not possible at this time to interpret these spectra without mathematical analysis. Perhaps it is significant that in the region examined the diene has two, the triene three, and the tetraene four bands which are doublets or even higher multiplets. The strongest of the bands that may possibly be ascribed to double bond vibrations lies for each compound at or near 1650 cm.$^{-1}$; the simpler compounds containing double bonds, such as *cis*-2-butene,[6] also have a band in this region at 1660 cm.$^{-1}$.

2. Aliphatic Polyene Azines

The aliphatic polyene azine series, the lower members of which can be readily prepared from the corresponding aldehydes, offer an opportunity for the spectral examination of compounds containing a larger number of double bonds. In Figs. 5 through 9 are shown the spectra in the region 1440 to 1900 cm.$^{-1}$ for the aliphatic azines containing, respectively, 2, 4, 6, 8 and 10 double bonds. In addition to the characteristic C–H bending frequency around 1450 cm.$^{-1}$,[7] the strongest absorption band in these compounds occurs in the region 1580–1670 cm.$^{-1}$ and is attributable to motions of doubly bonded atoms. The frequency of maximal absorption decreases with increasing chain length. In Fig. 10 we have plotted this frequency as a function of the number of double bonds in the chain.

3. Furyl Polyene Azines

The general characteristics of the spectra in the region of double bond absorption obtained from the polyene azines having terminal α-furyl groups (Figs. 11–14) are similar to those of the corresponding aliphatic azines. The furyl compounds, however, show the C–H bending frequency around 1475 cm.$^{-1}$ rather than at 1450 cm.$^{-1}$. The frequency of the most prominent band decreases with increasing chain length as may be seen from the plot of the position of this maximum against the number of double bonds (Fig. 10). It is observed that the maxima for these bands may be brought into good superposition with the maxima in the aliphatic polyene azine series if each furan ring is weighted as one double bond. It is perhaps worthy of note that both decatetraenal azine (10 double bonds) and 7-furyl heptatrienal azine (10 "double bond equivalents") have very similar spectra in that each compound shows a secondary less intense band at a frequency slightly higher than that of the main band (*cf.* Figs. 9 and 14).

4. Aliphatic Polyene Aldehydes

All the aldehydes examined have one or more very strong bands in the 1500 to 1800 cm.$^{-1}$ region (Figs. 15–21). In addition, these compounds all show a band about 1450 cm.$^{-1}$.[7] The extinction coefficient at the center of this band is about one-

sixth as large as those at the centers of the strong bands between 1500 and 1700 cm.$^{-1}$.

If the frequencies of the strong lines are plotted against the total number of double bonds in the molecule (Fig. 22), two different curves are obtained for compounds containing up to five double bonds, whereas three curves are obtained for higher members of the series. The position and intensity of the high frequency band around 1672 cm.$^{-1}$ is essentially constant for aldehydes having more than two double bonds in the chain. The maximum absorption of the lowest frequency band, however, shifts with increasing chain length. It may be seen from Fig. 22 that this shift is always in the same direction (toward lower frequencies with increasing chain length) but the increment per double bond decreases for the longer molecules so that this curve of the lowest frequency band may also become asymptotic with sufficiently long chains of conjugated double bonds.

5. ω-Furyl Polyene Aldehydes

The infrared spectra of these compounds are very similar to those of their aliphatic analogs. They are characterized by the same band system (Figs. 23–28) consisting of a strong band around 1672 cm.$^{-1}$ whose position remains unchanged as the chain length is increased, a second strong band whose frequency decreases as the number of double bonds increases, and a weaker band whose position is constant around 1475 cm.$^{-1}$. In addition, as in the aliphatic series, a third band appears in the higher molecular weight compounds. The salient features of the spectra of this group of compounds can perhaps best be seen by referring to the plot of the frequency of maximal absorption *vs.* the number of double bonds (Fig. 29). It is of interest to observe that the contribution of the furyl group in the aldehyde series as in the azine series is again equivalent to approximately one aliphatic double bond.

Discussion

There are two causes from which one might derive these observations. First, with increasing conjugation, the apparent order[8] or double-bond character[9] of the double bonds decreases. This in turn results in a decrease in the force constants of the vibrations involving the double bonds, while an increase would be expected in the force constants appropriate to vibrations primarily involving single bonds. The decrease in force constants with unchanged or increased reduced masses is then responsible for the decrease in the normal vibration frequency. Second, the normal modes will be different. That is, the frequencies no longer correspond to the vibration of an individual bond as in ethylene; instead, for two identical double bonds, for instance, the normal modes would be in the in-phase and opposite-phase simultaneous vibration of the two bonds. Where there are more double bonds, the interactions become

more complicated. Where, finally, the bonds are no longer alike, as is the case with the polyene aldehydes and the polyene azines, the assignment of the vibrations to the oscillation of individual structures, or even to certain combinations of such oscillations, becomes impossible.

One can, however, in the case of the polyene aldehydes, say that the higher frequency band, the one that is almost unaffected by increasing chain length, is associated more with the carbonyl bond, while the other strong bands contain more carbon–carbon double bond vibration. It is sur-

TABLE I

The relative intensities for the different maxima are shown on a 1 to 10 scale by the figures in parentheses. They were calculated by determining the ratios of the absorptions of the less intense peaks to the most intense peak in any compound and multiplying these values by 10.

Compound	Physical state of spectral sample	Positions (cm.$^{-1}$) and relative intensities of main absorption maxima								
2,4-Hexadiene	Vapor, 85 mm.	1452			1656	1717		1795

prising, even in view of the resolving power of the spectrometer used in this investigation, that a greater number of distinct bands are not observed in the region examined. Since one would expect all the double bond vibrations to yield bands of comparable intensity (the molecules have no symmetry), the weak bands that appear above 1700 cm.$^{-1}$ in the more concentrated solutions must be assigned to overtones or combinations. Finally, one must consider the possibility that each of the observed strong bands in the region 1550—1700 cm.$^{-1}$ is actually a group of several unresolved bands. The ultimate solution to this problem awaits mathematical analysis.

Acknowledgment.—We wish to acknowledge the valuable assistance of Messrs. Claude Valle and Marshall Kane in the preparation of many of the compounds, and the aid of Mr. Dwight Merrill and other members of the spectrophotometric group in determining many of the spectra.

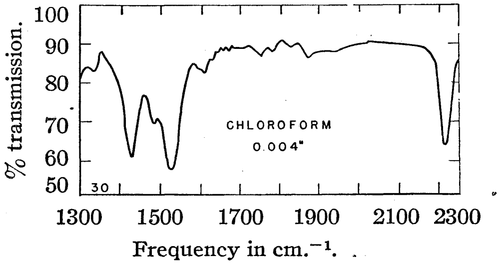
Experimental

The aliphatic polyene hydrocarbons were prepared according to the method of Kuhn and Grundmann.[10] The polyene azines and aldehydes were prepared according to the procedures described or referred to in a previous paper.[3]

The spectral measurements were made on a Perkin–Elmer infrared spectrometer Model 12-A using a 40 cycle chopper, a Strong[11] bolometer, an a.c. amplifier, and a Brown Instrument Company potentiometer. The data were obtained on a point-to-point basis, the points being taken from 5 to 10 cm.$^{-1}$ apart in the 1440 to 1900 cm.$^{-1}$ region. In the vicinity of the absorption maxima points were taken every 2 to 4 cm.$^{-1}$.

The vapor measurements were made in an 80-mm. cell having plane parallel rock salt windows. A second identical cell evacuated to 2 mm. was used to correct for reflection losses.

Chloroform, a useful solvent for spectral measurements in this region,[12] was purified by drying over phosphorus pentoxide followed by distillation; the material used gave the spectral curve shown in Fig. 30. As can be seen from Tables I–III and the figures, the lower members of each series were measured in chloroform solution. The cell used was constructed from two rock salt plates and had a thickness of 0.004″.[13] To correct for reflection and absorption losses the measurements were made against an identical cell containing only C. P. chloroform.



The decrease in solubility with the increasing number of double bonds in the higher molecular weight compounds made it necessary to use films of the less soluble materials which had been evaporated in high vacuum (<10^{-4} mm. of mercury) on rock salt discs. No measurements of film thickness were made. Evaporated films of the more unstable compounds, the aliphatic polyene aldehydes and 2,4,6,8,10,12-tetradecahexaene, were measured in a specially constructed evacuated cell.

Summary

The infrared spectra of twenty-six compounds containing two or more conjugated double bonds were determined in the region of double bond vibrational absorption. Polyene aldehydes and polyene azines show at least one strong absorption maximum which shifts toward lower frequencies as the length of the conjugated system is increased.

Steric Hindrance and Short Wave Length Bands in the Ultraviolet Spectra of Some Naphthalene and Diphenyl Derivatives[1]

By R. A. Friedel,[2] Milton Orchin[3] and Leslie Reggel[3]

Introduction

The aromatic cyclodehydrogenation studies being conducted in this Laboratory have provided a series of compounds that exhibit interesting relationships between ultraviolet absorption spectra and steric hindrance. Most of the work on the correlation of steric hindrance with ultraviolet spectra has been done on diphenyls,[4,5,6] but Jones[7,8,9] has studied more complex aromatic systems. He observed, for example, that in 9-phenylanthracene and 9,10-diphenylanthracene, the phenyl groups cannot be coplanar with the anthracene nucleus because of hindrance between neighboring hydrogen atoms. The resultant lack of coplanarity is manifested by the similarity of the spectra to that of anthracene. Jones[8] has noted the general effects of steric hindrance on the spectra of conjugated ring systems, such as increased fine structure, hypsochromic band shifts, and decreased intensity. The present paper discusses these effects as observed for several naphthalene and diphenyl derivatives, which were investigated down to 206 mμ.

Discussion and Results

Dinaphthyls.—The spectra of the three dinaphthyls[10] are shown in Fig. 1. 1,1′-Dinaphthyl (I) shows the greatest effect of steric hindrance as its spectrum is closest to that of naphthalene (Fig. 3); however, some resonance structures involving coplanarity probably exist, since fine structure is diminished. 2,2′-Dinaphthyl (II) should be free of steric hindrance; its spectrum shows a type of structure radically different from that of naphthalene with a very strong band at 254, a weaker broad band at 305, and a short wave length band at 212 mμ. 1,2′-Dinaphthyl (III) is, as expected, intermediate between the other two. Its spectrum is more similar to that of 1,1′-dinaphthyl (I); however, intensities are greater, fine structure is diminished, and bands are considerably broader than in (I).

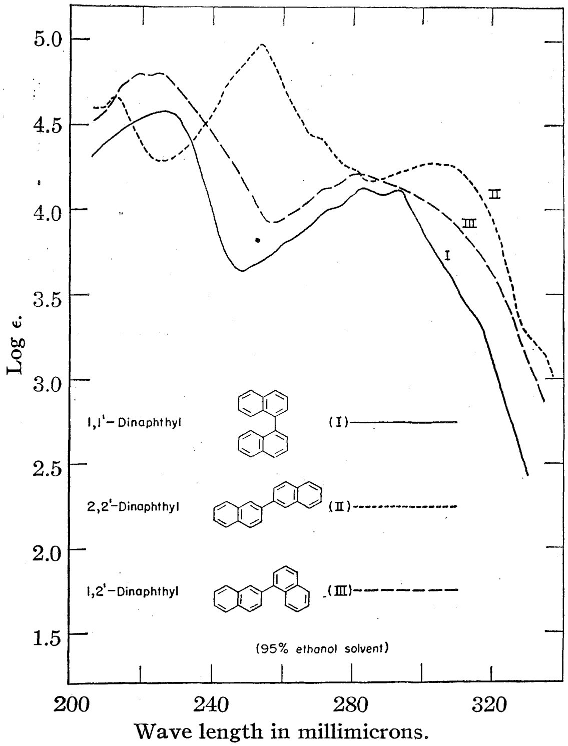

Fig. 1.

The spectrum of a dinaphthyl derivative,[11] 2,2′7,7′-tetramethyl-1,1′-dinaphthyl (IV) (Fig. 2), indicates very strong steric hindrance. Fine structure is developed, including the appearance of the typical naphthalene band at 319 mμ, and intensities are approximately double those of naphthalene. Also shown is the spectrum of a hydrogenated derivative, 3,4,3′,4′-tetrahydro-1,1′-dinaphthyl (V). Coplanarity is probably lacking in this compound also since the spectrum is very similar to that of 1,2-dihydronaphthalene.

Phenylnaphthalenes.—The spectra[12] of naphthalene (VI), 1-phenylnaphthalene (VII), and 2-phenylnaphthalene (VIII) are shown in Fig. 3. The 1-phenylnaphthalene (VII) spectrum resembles that of naphthalene, indicating strong steric hindrance; however, bathochromic shifts and greatly decreased fine structure indicate appreciable contribution from coplanar resonance

[10] Adams and Kirkpatrick, This Journal, **60**, 2180 (1938), determined the spectra of 1,1′- and 2,2′-dinaphthyl to 230 mμ. They found a band at 297 in 2,2′- which we do not find. Their low wave length band for 1,1′- is at 238, whereas ours lies at 226.

[11] Jones, This Journal, **67**, 2127 (1945), determined the spectrum of 2,2′-diamino-1,1′-dinaphthyl.

[12] Jacobs, Craig and Lavin, *J. Biol. Chem.*, **141**, 51 (1941), determined the spectra of 1- and 2-phenylnaphthalene down to 235 mμ.

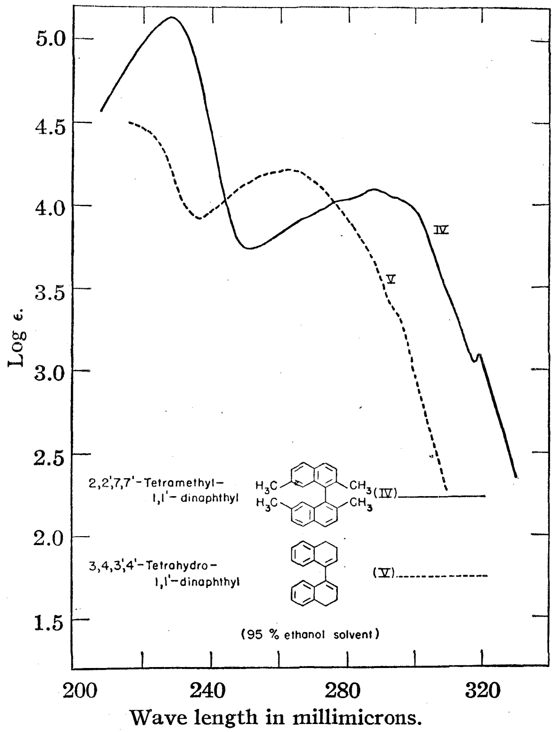

Fig. 2.

structures. The aromatic rings of 2-phenylnaphthalene (VIII), on the other hand, can assume a coplanar structure; accordingly the spectrum of this compound is quite different from that of naphthalene. The same bands observed by Jacobs, *et al.*, for (VIII) are found at 250 and 285; in addition a short wave length band appears at 212 mμ. Thus the general form of the spectrum of (VIII) is the same as that of unhindered 2,2'-dinaphthyl (II) (Fig. 1).

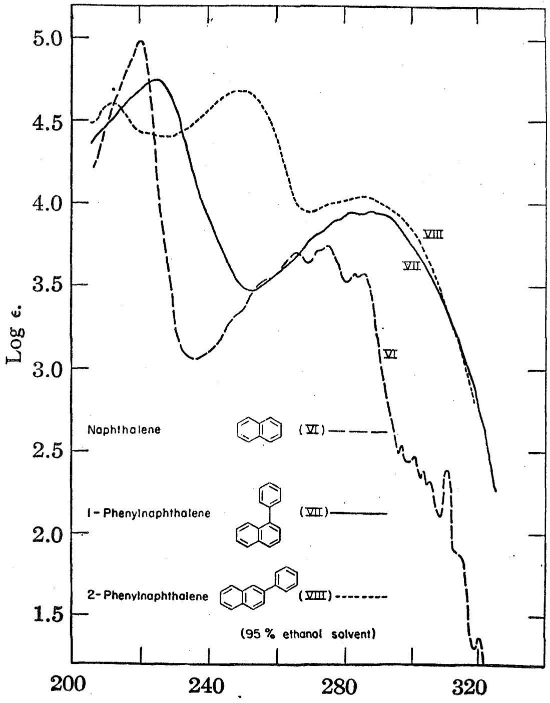

Fig. 3.

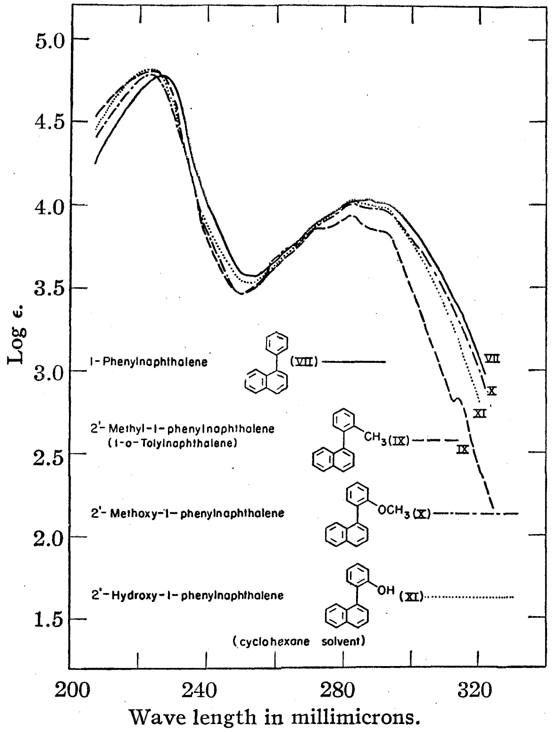

Fig. 4.

The spectra in Fig. 4 of 1-phenylnaphthalene (VII) and three of its derivatives, 2'-methyl-1-phenylnaphthalene (1-*o*-tolylnaphthalene) (IX), 2'-methoxy-1-phenylnaphthalene (X) and 2'-hydroxy-1-phenylnaphthalene (XI), show the effects of substituting the groups —CH_3, —OCH_3 and —OH, respectively, in the ortho position of the phenyl group of 1-phenylnaphthalene (VII). The methyl group in 1-*o*-tolylnaphthalene (IX) appreciably increases steric hindrance since its presence produces in the 280 mμ region a weaker, narrower band with typical naphthalene fine structure, including the band at 314 mμ. The methoxyl (X) and hydroxyl (XI) groups apparently cause only slight additional hindrance over that already present in 1-phenylnaphthalene (VII); the bands as a whole are somewhat narrower and definite peaks are produced at 282 and 283, respectively, giving band structures similar to that of the strongly hindered methyl derivative (IX). All of these spectra were determined in both 95% alcohol and cyclohexane. Differences are very slight if any, but the spectra shown were obtained in cyclohexane in order to remove any effect of a polar solvent.

The spectra of 2-phenylnaphthalene (VIII) and two of its derivatives, 2'-methyl-2-phenylnaptha-

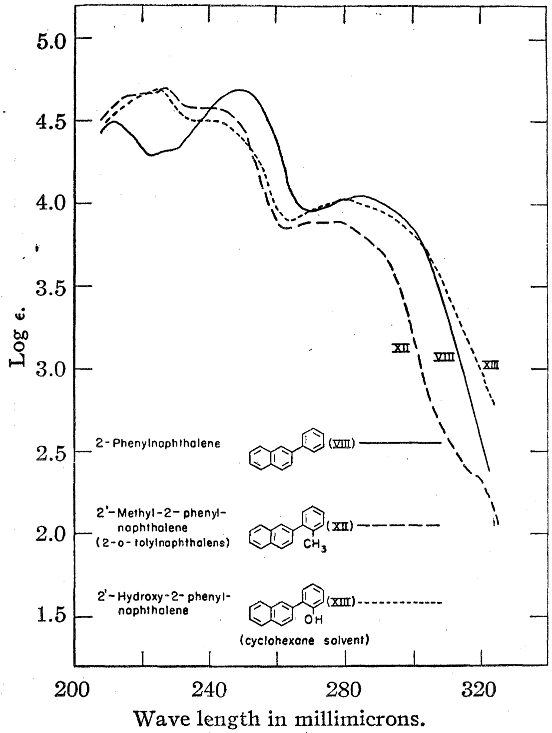

Fig. 5.

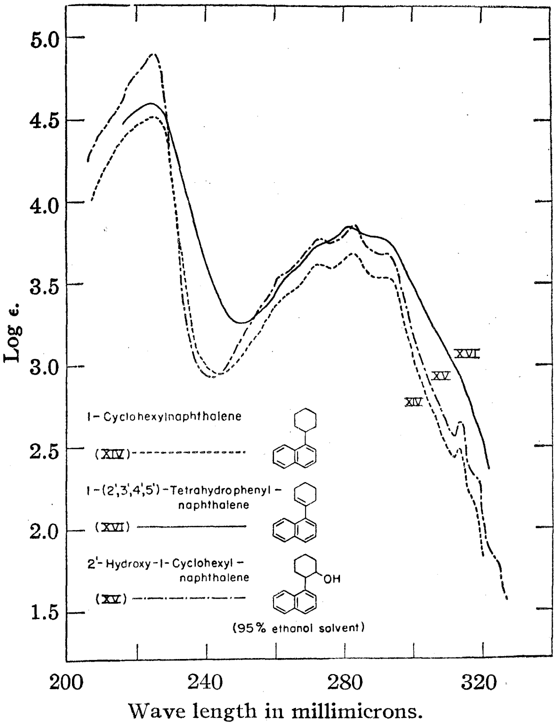

Fig. 6.

lene (2-*o*-tolylnaphthalene) (XII) and 2'-hydroxy-2-phenylnaphthalene (XIII) are given in Fig. 5 to permit comparison of the relative degrees of steric hindrance produced by the groups —CH_3 and —OH, in the ortho position of the phenyl group of unhindered 2-phenylnaphthalene. The methyl group, in 2-*o*-tolylnaphthalene (XII), again causes the greater steric hindrance; instead of the two 2-phenylnaphthalene bands at 250 and 212, one wide band with a doublet splitting occurs around 230 mμ. Further, the long wave length band undergoes a hypsochromic shift from 286 to 274 mμ. The spectrum of the hydroxyl derivative (XIII) exhibits the same spectral structure as (XII) indicating a surprising amount of hindrance due to the hydroxyl group. The wide long wave length band at 280 does not shift with respect to the same band in 2-phenylnaphthalene, probably because of a phenoxy contribution; in a polar solvent, 95% ethanol, this band is shifted 10 mμ to longer wave lengths and is considerably broader.

Other Naphthalene Derivatives.—The spectra of 1-cyclohexylnaphthalene (XIV), 2'-hydroxy-1-cyclohexylnaphthalene (XV) and 1-(2',3',4',5'-tetrahydrophenyl)-naphthalene (XVI) are shown in Fig. 6. The first two compounds produce spectra typical of naphthalene derivatives with one saturated substituent; their spectra are almost identical with that of strongly hindered 1-*o*-tolylnaphthalene (IX). The spectrum of the tetrahydro compound (XVI), in which the naphthalene nucleus is conjugated with one double bond, shows the usual band widening, decreased fine structure, and increased intensity which accompany conjugation.

Diphenyls.—The spectra of diphenyl (XVII) and three of its derivatives, 2-methyldiphenyl (XVIII), 2-methoxydiphenyl (XIX) and 2-hydroxydiphenyl (*o*-phenylphenol) (XX) (Fig. 7) exhibit the effect of —CH_3, —OCH_3 and —OH, in an ortho position of diphenyl. The methyl group in (XVIII) has the greatest effect with the 248 diphenyl band shifting to 235 mμ and the intensity decreasing appreciably. The same band in the spectrum of the methoxy derivative (XIX) shifts only 2 mμ to 246, which indicates very slight hindrance; but the decrease in intensity is significant. The hydroxyl group in *o*-phenylphenol (XX) appears to have an even greater effect; in cyclohexane solvent the 248 band shifts 3 mμ to 245 and the decrease in intensity is quite large. For (XIX) and (XX) in 95% ethanol, however, intensities of the band coincide and band positions are reversed; 2-methoxydiphenyl (XIX) is not affected by the polarity of the solvent, but for *o*-phenylphenol (XX) the band shifts from 245 to 246.5. The bands at 284 in the spectra of both oxygenated compounds are phenoxy bands.

Comparison of Diphenyls and Naphthalenes.—Diphenyl and its derivatives were investigated principally because of the similarity in the 250 mμ region between diphenyl (XVII) and the related unhindered naphthalenes, 2-phenylnaphthalene (VIII) and 2,2'-dinaphthyl (II). Since these compounds also produce bands at 212 mμ, diphenyl was investigated in the same region;

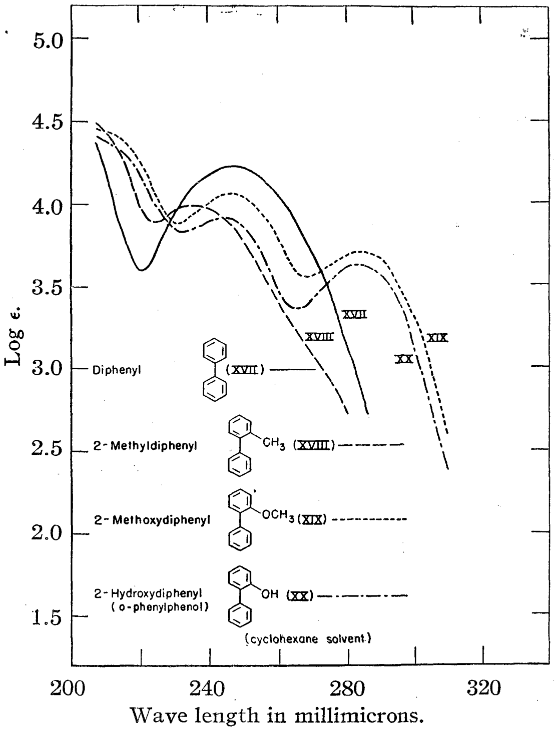

Fig. 7.

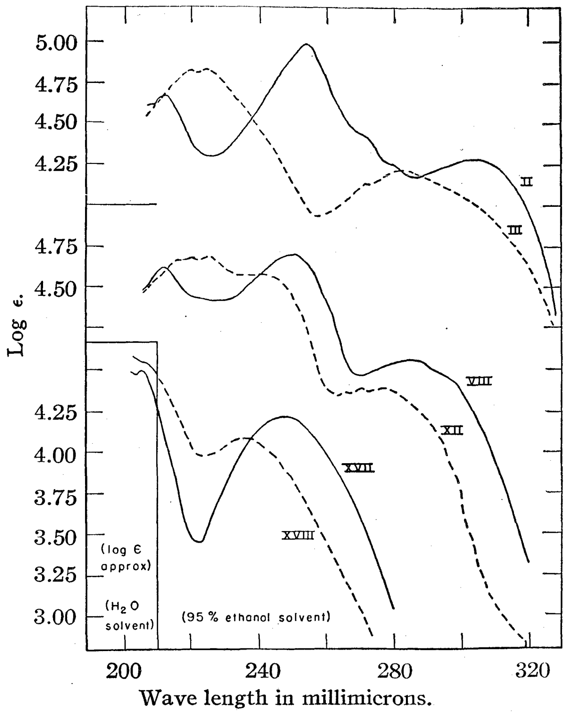

Fig. 8.—Comparison of diphenyls and naphthalenes. Convergence of bands with steric hindrance. Curves: (II) 2,2′-dinaphthyl, (III) 1,2′-dinaphthyl, (VIII) 2-phenylnaphthalene, (XII) 2-*o*-tolylnaphthalene, (XVII) diphenyl and (XVIII) 2-methyldiphenyl.

using water as a solvent at short wave lengths a new small band is found at 205 mμ.[13] The spectrum is given in Fig. 8 together with the spectra of (II) and (VIII).

Similarities in steric hindrance effects for the three compounds, (II), (VIII) and (XVII), are shown by plotting with each of them the spectra of the related sterically hindered derivatives, 2-methyldiphenyl (XVIII), 2-*o*-tolylnaphthalene (XII) and 1,2′-dinaphthyl[14] (III) (Fig. 8). In all three cases the 250 mμ bands of the respective parent compounds undergo hypsochromic shifts and decreased intensities with introduction of hindrance. On the other hand, the short wave length bands in the 210 mμ region appear to sustain bathochromic shifts and thus to converge toward the shifted 250 mμ bands. The effect is greater for the hindered naphthalene derivatives.

Spectrophotometry

The customary limit of the Beckman spectrophotometer used, with good absolute ethanol, is around 220 mμ. As is well known, this solvent always contains troublesome traces of benzene which are difficult to remove. Purification is simplified and the limit of the instrument reduced to 216 mμ by merely using 95% ethanol; this solvent has already come into general use. The limit is further reduced to 206 mμ by substituting for the original 2,000 megohm grid resistor in the phototube amplifier a 20,000 megohm, essentially noise-free, resistor.[15] A 10,000 megohm resistance results in a limit of 208 mμ. Increased resolution also results from these substitutions as seen in the spectra of naphthalene in Fig. 9; the decreased band widths made possible by such resistors are compared at one wave length. It is apparent from these curves, especially in the 305 mμ region that the 20,000 megohm resistor has effected some increased resolution over that obtained with 10,000 megohms. The former resistor was used throughout this investigation but because of the sluggishness of the galvanometer the latter is preferable for general use.

The lowest wave length attained for solutions is 202 mμ, with water as solvent. Water was resorted to in the short wave length measurements of diphenyl and methyldiphenyl since no bands are found down to 206 mμ, the limit of the instrument with 95% ethanol as solvent. Although the solubility of these compounds in water is very slight, it is found to be more than enough to make measurements in this region of intense absorption. For gases the lowest wave length attainable is slightly below 200 mμ, the end of the wave length scale.

In these regions of the spectrum scattered energy is a large percentage of the small total energy transmitted by the glass envelopes on hydrogen

---

[13] Carr and Stücklen, *J. Chem. Phys.*, **4**, 760 (1936), reported a small band for diphenyl vapor in the vacuum ultraviolet at 203 mμ.

[14] 1,2′-Dinaphthyl was used to show this steric effect in lieu of a hindered methyl derivative of 2,2′-dinaphthyl.

[15] Made by Victoreen Instrument Company, Cleveland, Ohio.

tube and phototube. Appropriate corrections for this scattered energy were applied to all spectra. Reliability of the low wave length bands reported is substantiated by the detection of the 207 and 203.5 mμ fine structure bands for benzene solution,[15a] found by Henri.[16] These bands were also observed on a borrowed Beckman which was modified for checking purposes by inserting a 20,000 megohm resistor in the amplifier.

Preparation of Compounds[17]

The preparation of 1,2′-dinaphthyl, 2,2′-dinaphthyl, 1-(2′,3′,4′,5′-tetrahydrophenyl)-naphthalene, 1-cyclohexylnaphthalene, 1-phenylnaphthalene,[18] 1,1′-dinaphthyl,[19] and 2-methyldiphenyl[20] have been described previously. The 2,2′,7,7′-tetramethyl-1,1′-dinaphthyl and 3,3′,4,4′-tetrahydro-1,1′-dinaphthyl were gifts of Professor M. S. Newman. *o*-Phenylphenol was a gift of the Dow Chemical Company and was purified by recrystallization, melting point 56.6–57.8°. The diphenyl was an Eastman Kodak Co. product which was chromatographed to remove fluorescent impurities and then recrystallized, melting point 68.5–69.4°. 2-Methoxydiphenyl[21] was prepared by Mr. E. O. Woolfolk by the methylation of *o*-phenylphenol with diazomethane. It was purified by chromatography, followed by recrystallization from petroleum ether and had melting point 28.8–29.4°. Semimicro methoxyl determination (E. O. W.) gave 16.6% methoxyl (calcd. 16.9). The preparation of 2′-hydroxy- and 2′-methoxy-1-phenylnaphthalene and 2′-hydroxy-2-phenylnaphthalene will be described in a future publication.

2-Phenylnaphthalene.[22]—1-Phenylnaphthalene (5.06 g.) was passed over silica gel at 405–460° during twenty minutes in the apparatus previously described.[23] The product (4.57 g.) was twice crystallized from alcohol and gave 1.0 g. of 2-phenylnaphthalene as colorless crystals, m. p. 102.4–103.8°. The sample used for ultraviolet absorption spectrum measurements was carefully purified by chromatographic adsorption on alumina.

The complex with *s*-trinitrobenzene was obtained from ethanol as yellow plates, m. p. 113.5–115.2° with sintering at 111°. *Anal.*[24] Calcd. for $C_{22}H_{15}N_3O_6$: N, 10.07; for $C_{28}H_{18}N_6O_{12}$: N, 13.33. Found: N, 12.8, 12.7. The analysis indicates that the complex of *s*-trinitrobenzene with 2-phenylnaphthalene is formed in the ratio of 2 moles of the nitro compound to one of the hydrocarbon. The complex is readily dissociated and difficult to purify. 2-Phenylnaphthalene did not form a complex with picric acid when solutions of both components were mixed in the usual fashion.

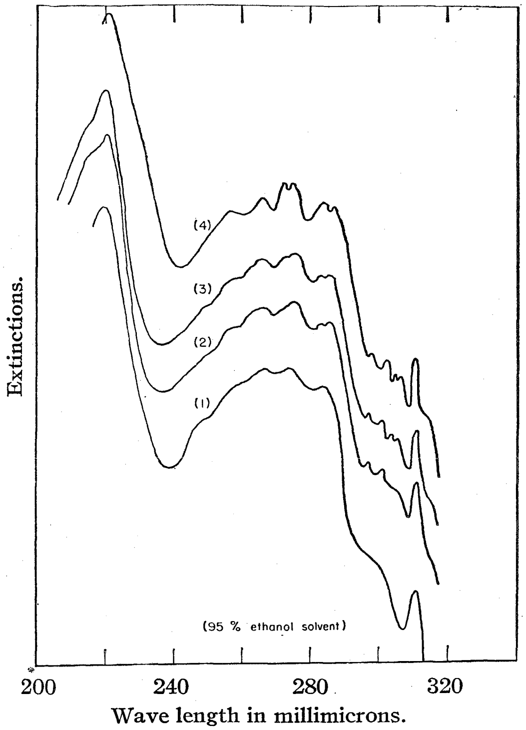

Fig. 9.—Spectra of naphthalene under varying resolving power. Amplifier grid resistance, R, and the usable band widths (B. W.) at 285 mμ are: (1), R = 2000 MΩ, B. W. = 13.6 Å.; (2), R = 10,000 MΩ, B. W. = 6.8 Å.; (3), R = 20,000 MΩ, B. W. = 5.1 Å.; (4), comparison curve from Mayneord and Roe, *J. Chem. Soc.*, 929 (1934).

1-*o*-Tolylnaphthalene.—To the Grignard reagent from 1.1 mole of *o*-bromotoluene and 1.21 moles of magnesium in 725 cc. of ether, there was added 1.0 mole of 1-tetralone[25] in 150 cc. of ether. The mixture was stirred and refluxed for sixteen hours, then decomposed with ammonium chloride solution. The ether layer was separated and dried. Evaporation of the ether left a mixture of crystals and oil which was filtered. The crystalline material was washed with cold petroleum ether and was obtained as colorless needles (34 g.). This material was investigated separately, and the results will be reported later. The filtrate containing the oil and petroleum ether was fractionally distilled. There was collected 64.12 g., b. p. 90–115° (1 mm.), of a first fraction which was nearly all recovered tetralone; 41.97 g., b. p. 115–142° (0.7 mm.); and a third fraction, b. p. 130–230° (0.3 mm.) which was a gum. The second fraction was redistilled from sodium and gave as a main fraction, 31.99 g., b. p. 130–138° (1 mm.). *Anal.*[26] Calcd. for $C_{17}H_{16}$: C, 92.68; H, 7.32. Found: C, 91.2; H, 7.5. This crude 1-(*o*-tolyl)-3,4-dihydronaphthalene (29.25 g.) was heated with 1.5 g. of 30% palladium-on-charcoal catalyst.[27] There was evolved 2720 cc. (N. T. P.) of hydrogen (91.3%). The product was distilled and 28.25 g. of material which solidified on cooling was collected. One crystallization from methanol gave 22.73 g. of colorless needles, m. p. 68.8–70.8°. The sample for ultraviolet absorption spectrum measurements was carefully purified by chromatographic adsorption on alumina.

2-*o*-Tolylnaphthalene.—To the lithium compound from 20.0 g. of 2-bromonaphthalene, 1.47 g. of lithium wire, 95 cc. of ether and 25 cc. of benzene there was added 11.9 g. of *o*-methylcyclohexanone in 45 cc. of ether. After four and one-half hours of refluxing with stirring the green mixture was decomposed with ice water. The organic layer was separated, dried and the solvents evaporated. The residual oil was heated at 160–170° for half an hour with 14 g. of potassium bisulfate. The

product was taken up in benzene, and the benzene evaporated. Distillation of the residue gave a first fraction which was discarded and a second fraction, b. p. 132–150° (0.4 mm.) weighing 11.13 g. This oil was heated with 1.00 g. of palladium-on-charcoal catalyst[27] at 320–360° for two hours during which time 1513 cc. (N. T. P.) of hydrogen (67.5%) was evolved. The material was distilled, and the distillate dissolved in petroleum ether and chromatographed on alumina. The least strongly adsorbed material was discarded (small amount of naphthalene), and the balance of the product with the exception of some very strongly absorbed material recovered. Crystallization from methanol gave 2.80 g. of colorless crystals, m. p. 44.7–46.6°. The pure sample used for ultraviolet absorption spectrum measurements had m. p. 45.7–48.0°.

2-*o*-Tolylnaphthalene did not form complexes with picric acid or 2,4,7-trinitrofluorenone[29] when solutions of the two components were mixed in the usual manner. A concentrated solution of the hydrocarbon and *s*-trinitrobenzene in alcohol gave a first crop of *s*-trinitrobenzene. The mother liquor precipitated bright yellow crystals, m. p. 101.2–102.5°, which were shown by analysis to contain one mole of the hydrocarbon to two moles of the nitro compound.

Anal.[29] Calcd. for $C_{29}H_{20}N_6O_{12}$: N, 13.04. Found: N, 13.1.

Acknowledgments.—The authors wish to acknowledge the helpful suggestions of Drs. J. J. McGovern and E. Solomon and the loan of the former's instrument for checking purposes. Thanks are due Lois Pierce and Ruth Borgman, who determined the spectra.

Summary

Steric hindrance effects are discussed in connection with the spectra of 1,1′-, 1,2′- and 2,2′-dinaphthyl, 1- and 2-phenylnaphthalene, diphenyl and various derivatives of some of these compounds. Short wave length peaks are detected in the region 205 to 212 mμ for compounds containing two aromatic ring systems conjugated without steric hindrance. These bands and the longer wave length bands appear to converge toward each other when the coplanarity of the systems is hindered by introduction of interfering groups.

All spectra were determined to 206 mμ on a Beckman spectrophotometer; two spectra were measured to 202 mμ. The simple methods for attaining this limit, as well as increased resolution, are described.

Kinetics of Neutralization of Nitroethane with Ammonia and Methylamines

BY RALPH G. PEARSON

The rates of neutralization of the simple nitroparaffins with hydroxyl ion and other charged bases have been measured by several investigators.[1] The reaction is a slow process conveniently

$$R_1R_2CHNO_2 + B^- \longrightarrow R_1R_2CNO_2^- + BH \quad (1)$$

measured at 0° in water solution. This paper reports the rates of neutralization of nitroethane with ammonia, methyl-, dimethyl- and trimethylamine in aqueous solution at 0 and 5.2°. The reactions were followed by the change in conductance as the ions were formed

$$CH_3CH_2NO_2 + B \underset{k_2}{\overset{k_1}{\rightleftarrows}} CH_3CHNO_2^- + BH^+ \quad (2)$$

where B stands for the neutral base and BH^+ for the conjugate acid.

The work was undertaken both to obtain fundamental data on the kinetics of ionization of neutral molecules in a solvent of high dielectric constant and to see how the rates for the various amines correlate with their base strengths. The increased basicity of methylamine and dimethylamine compared with ammonia and the sharp decrease in base strength for trimethylamine have been the subject of several papers.[2]

Experimental

Preparation of Materials.—Commerical Solvents nitroethane was dried with magnesium sulfate, refluxed with urea, dried with phosphorus pentoxide and fractionated through a 10-plate column. Small middle portions boiling within a 0.1° range were taken for use. The organic amines were obtained from Eastman Kodak Co. white label hydrochlorides or amines converted to hydrochlorides. The salts were recrystallized from water and the amines freed by adding measured amounts of sodium hydroxide and distilling in all glass carbon dioxide-free apparatus into conductivity water. For methylamine and dimethylamine, one-third of the amount of sodium hydroxide needed was added and the distillate discarded, another one-third of sodium hydroxide was added and the distillate collected. For trimethylamine the distillate from the first one-third equivalent of sodium hydroxide was collected. Ammonia was obtained by distilling C. P. ammonia into conductivity water. Solutions were made up 0.05 to 0.10 molar as determined by titration and stored in a carbon dioxide-free apparatus connected to a buret. Solutions of nitroethane were made up by direct weighing, adding conductivity water and storing in a cold room until used.

Apparatus.—Conductances were measured with a modified Jones–Josephs bridge[3] using an oscilloscope for a null point indicator. This combination of direct reading

bridge and rapid visual indicator greatly simplified the following of the resistance with time. A Washburn type cell for medium conductivities was used. Time was followed with a calibrated stop watch. Temperature control was obtained by using ice-water mixtures in a large Dewar flask at 0° and a solid-liquid benzene slush at 5°. With manual stirring temperature could be maintained constant to ± 0.02° during a run using the benzene freezing mixture. Low humidity, however, was essential for good results.

General Procedure.—The quantity of base needed to react with 10 cc. of nitroethane was run into a flask, stoppered and cooled to the reaction temperature. The separately cooled nitroethane solution was added with a pipet and the stop watch started during the course of the addition. After mixing, a sample was drawn into the conductance cell, placed in the bath and vigorously stirred for two or three minutes before readings were begun. The times required for sufficient readings ran from fifteen minutes to an hour. The cell contents and bath were placed in a cold room for a day or two and the equilibrium value of the resistance read after bringing back to the reaction temperature. Wrapping the entire system in aluminum foil greatly aided in preserving the benzene-bath.

Calculations.—The kinetics are complicated by the simultaneous reactions of nitroethane with the amine and hydroxyl ion and by the reversal of reaction (2).

$$\mathrm{CH_3CH_2NO_2 + OH^-} \xrightarrow{k_3} \mathrm{CH_3CHNO_2^- + H_2O} \quad (3)$$

However, the rate constant, k_3, for hydroxyl ion is known.[1c] Also we have sufficient data on the acid ionization constant of $C_2H_5NO_2$,[4] and the basic ionization constants of the amines[2a,5] to get the equilibrium constant for (2). We have

$$K_1 = \frac{k_1}{k_2} = \frac{K_aK_b}{K_w} \quad (4)$$

Since K_a for $C_2H_5NO_2$ is 2.67×10^{-9} at 0°, K_w for water is 1.14×10^{-15} at 0°,[6] and K_b for the amines runs from 10^{-5} to 5×10^{-4} we see that $k_1 > k_2$ by a factor of 30 to 1000 and that we can neglect the reverse reaction provided we do not carry the measurements too far.

The rate expression then becomes

$$d[\mathrm{C_2H_4NO_2^-}]/dt = k_1[\mathrm{C_2H_5NO_2}][\mathrm{B}] + k_3[\mathrm{C_2H_5NO_2}][\mathrm{OH^-}] \quad (5)$$

Now if we assume that the equilibrium

$$\mathrm{B + H_2O} \rightleftarrows \mathrm{BH^+ + OH^-} \quad (6)$$

is always maintained, we can write

$$[\mathrm{OH^-}] = K_b[\mathrm{B}]/[\mathrm{BH^+}] \quad (7)$$

where we now substitute for the activities the molar concentrations and use the thermodynamic equilibrium constant as we shall do throughout. The rate expression then becomes

$$\frac{dx}{dt} = k_1(a - x)^2 + k_3K_b\frac{(a - x)^2}{x} \quad (8)$$

where $x = [\mathrm{C_2H_4NO_2^-}] = [\mathrm{BH^+}]$, $a = [\mathrm{C_2H_5NO_2}]_0 = [\mathrm{B}]_0$, and $(a - x) = [\mathrm{C_2H_5NO_2}] = [\mathrm{B}]$. Equation (8) can be integrated by the use of partial fractions giving

$$t = c + \frac{k_3K_b}{(ak_1 + k_3K_b)^2}\ln\frac{(a - x)}{(k_1x + k_3K_b)} + \frac{1}{(ak_1 + k_3K_b)}\frac{a}{(a - x)} \quad (9)$$

The use of the integration constant, c, eliminates the necessity of matching the start of the reaction with the zero of time.

Assuming that equivalent conductances do not change over the range of ionic concentration encountered in an experiment, it is possible to write (9) in terms of the measured resistance R. It is necessary to allow for the conductance of the hydroxyl ion which is appreciable only during the early part of a run. Thus we have

$$\frac{z}{R} = \Lambda_{\mathrm{OH^-}}\, K_b\frac{(a - x)}{x} \times (\Lambda_{\mathrm{BH^+}} + \Lambda_{\mathrm{C_2H_4NO_2^-}})\, x \quad (10)$$

where z is a constant for the cell and the Λ's refer to the equivalent ionic conductances. This can be converted to

$$\frac{z}{R} = \frac{z(a - x)}{R_0x} + \frac{zx}{R_ca} \quad (11)$$

where R_0 is a quantity estimated from values of K_b, measured conductances of sodium hydroxide solutions in the cell used for the kinetic studies, and the transference numbers of Na^+ and OH^-. R_c is a value of the equilibrium resistance corrected for the incompleteness of reaction (2). If we let R_e be the measured value of the equilibrium resistance, then R_c differs from R_e by a factor of $K_1^{1/2}/(K_1^{1/2} + 1)$. Solving for x in (11)

$$x = \frac{aR_c}{R}\left(1/2 + R/2R_0 + 1/2\sqrt{1 + \frac{R^2}{R_0^2} + \frac{2R}{R_0} - \frac{4R^2}{R_0R_c}}\right) = \frac{aR_c'}{R} \quad (12)$$

Actually the values of R_c' calculated from (12) differ by only a few per cent. from the constant value R_c. Equation (9) now becomes

$$t = c + \frac{k_3K}{(ak_1 + k_3K_b)^2}\ln\frac{(R - R_c')}{\left(k_1R_c' + \frac{k_3K_b}{a}R\right)} + \frac{1}{(ak_1 + k_3K_b)}\frac{R}{(R - R_c')} \quad (13)$$

We have from (13) that t is a function of the resistance and several constants of which only k_1 is unknown. For the three organic amines the log term is only a small correction factor and a good estimate of k_1 can be made by plotting t against $R/(R - R_c')$ and setting the slope equal to $1/(ak_1 + k_3K_b)$. Placing this value of k_1 in the log term it is possible to solve (10) algebraically using pairs of t and R readings and get a better value of k_1. For methylamine and dimethylamine the k_1 values calculated for pairs selected at random usually agree to 1 or 2%. For trimethylamine and ammonia k_1 show a systematic decrease as the reaction proceeds. For ammonia the log term is

---

[4] Turnbull and Maron, THIS JOURNAL, **65**, 212 (1943).

[5] Everett and Wynne-Jones, *Proc. Roy. Soc.* (*London*), **A169**, 190 (1938).

[6] Harned and Owen, "Physical Chemistry of Electrolytic Solutions," Reinhold Publishing Corp., New York, N. Y., 1943.

quite important, and it is necessary to try several values of k_1 until the calculated values agree with the starting one.

Another method of analyzing the data is to write (10) as

$$t = c + \frac{1}{ak_1 + k_3K_b} F(R) \qquad (14)$$

where

$$F(R) = \frac{k_3K_b}{(ak_1 + k_3K_b)} \ln \frac{R - R'_e}{(k_1R'_e + (k_3K_bR/a))} + \frac{R}{(R - R'_e)} \qquad (15)$$

and use the estimated value of k_1 to solve for $F(R)$. Then plotting t against $F(R)$ should give a straight line with a slope from which k_1 can be found. Figures 1 and 2 show the results obtained in this way with the four bases in typical runs. The values of the rate constants from the best values of the slopes agree with the one used to get $F(R)$. The falling off of the rate constant for ammonia and trimethylamine is clearly evident. The extent of reaction in the measured portions for various runs was approximately from 10 to 25% for ammonia, from 20 to 40% for trimethylamine, and from 25 to 75% for methylamine and dimethylamine. Table I is a tabulation of the rate constants k_1 obtained at 0 and 5.2°. The units of

5.2	Hydroxyl ion		59.5

all rate constants are liters/mole-minute. The corresponding data for hydroxyl ion have been included for comparison using the results of Maron and LaMer.[1c]

From the relationship indicated in (4) we can calculate k_2 also, the rate constant for the recombination of the ions. Unfortunately the constants k_1 are seen to be not quite independent of concentration, decreasing somewhat in solutions more concentrated than 0.04 molar. Neglecting the results for these more concentrated solutions where the interionic effects will be greatest, we can calculate the values of k_2 for the range 0.02 to 0.04 molar which will be at least comparable for the several bases. From the variation of k_1 with temperature the activation energy, E_{act}, can be found. Also using the transition state theory of reaction velocity[7]

$$k = \frac{RT}{Nh} e^{\Delta S^{\neq}/R} \, e^{-\Delta H^{\neq}/RT} \qquad (16)$$

and

$$E_{\text{act}} = \Delta H^{\neq} + RT$$

we can calculate the heats and entropies of activation for the reaction (2). Then the corresponding quantities for the reverse reaction can be obtained from

$$\Delta H^0 = \Delta H_1^{\neq} - \Delta H_2^{\neq} \qquad (17)$$

and

$$\Delta S^0 = \Delta S_1^{\neq} - \Delta S_2^{\neq} \qquad (18)$$

where the subscripts 1 and 2 refer to the forward and reverse processes. The standard state is unit activity though actually we are neglecting the difference between activity and concentration for reactants, products and activated complex alike. Table II summarizes all of this information calculated at 0°. The source of the thermodynamic data is from references (2a), (4) and (5). Since the data on nitroethane do not go down to 0°, it was assumed that $\Delta C_p^0 = -40$ cal./degree for the ionization of nitroethane in computing ΔH^0 and ΔS^0 at 0° from the data at 10 and 25°. According to Pitzer[8] this is a reasonable value for the heat capacity change in the ionization of a weak acid if the change in entropy is negative. The correction involved is small and will not affect the relative values for the four bases.

Water	1.66×10^{-5}	24.3	+ 3.0

Discussion

It is evident that there is no linearity between the rates of neutralization and the base strengths of the amines, dimethylamine and particularly trimethylamine, reacting more rapidly than their basicities would warrant. This is in accord with previous observations that substitutions close to the center of reaction destroy any linear free energy relationships between rates and equilibria.[9] It is interesting also to compare the values of k_2 determined in these experiments with those calculated from an equation due to Junell,[1b] who measured the rates of combination of a number of neutral acids with the anion of nitroethane. Junell found that k_2 would be calculated from K_a, the acid ionization constant by the equation

$$\log k_2 = 1.54 + 0.37 \log K_a \qquad (18)$$

Taking K_a for the ammonium ions as K_w/K_b, we find for k_2 6.6×10^{-3}, 1.95×10^{-3}, 1.90×10^{-3} and 5.2×10^{-3} for NH_4^+, $CH_3NH_3^+$, $(CH_3)_2NH_2^+$ and $(CH_3)_3NH^+$, respectively. We see from Table II that NH_4^+ and $CH_3NH_3^+$ react more slowly and $(CH_3)_2NH_2^+$ and $(CH_3)_3NH^+$ react more rapidly. In fact, the reason for the low basicity of trimethylamine, judging from this one reaction, is the abnormally high rate of conversion of the ion to the neutral base.

The heats of activation for the forward reaction appear to be normal for bimolecular reactions in solution. The entropies of activation, while fairly large and negative, compare with that for the hydroxyl ion reaction. For the reverse process $\Delta H^{\neq}$ is high, in agreement again with the hydroxyl ion reaction. The trimethylammonium ion has a conspicuously low heat of activation. The entropies of activation for the reverse reaction are large and positive. The interpretation of this in terms of the transition state theory is as follows: if we identify the entropy decrease in ionization with the electrostriction of the solvent or the binding of solvent molecules around the ions, the activated complex is solvated more than the neutral reactants but less than the product ions. Hence there is a loosening of structure in going from the ions to the complex and $\Delta S_2^{\neq}$ is positive. The desolvation of the ions accounts for the high energy barrier in forming the complex. Trimethylammonium ion does not appear to be as strongly solvated then as the other ions. This would be expected in view of the hydrophobic nature of the

methyl groups compared with the hydrogen atoms that they displace.

Summary

1. The second order rate constants for the reaction of nitroethane with ammonia, methyl-, dimethyl- and trimethylamine in water at 0 and 5.2° are reported.

2. The values of the rate constants at 0° are calculated from equilibrium data for the reaction of ammonium ion, methyl-, dimethyl- and trimethylammonium ions with the anion of nitroethane.

3. The heats and entropies of activation for the above reactions are computed.

4. The interpretation of the data indicates that the activated complex is not as strongly solvated as the product ions but more solvated than the reactants.

5. The decreased base strength of trimethylamine appears to be due to the decreased solvation energy and hence increased reactivity of the trimethylammonium ion.

CONTRIBUTION FROM THE ARMOUR RESEARCH FOUNDATION OF THE ILLINOIS INSTITUTE OF TECHNOLOGY]

Crystallization of *p,p'*-DDT from Binary Melts

BY VICTOR GILPIN,[1] WALTER MCCRONE, ANNETTE SMEDAL AND HELEN GRANT

Introduction

Little work has been reported in recent years on the linear crystallization velocity (C.V.) of supercooled melts of organic compounds. Undoubtedly, part of this lack of interest has been due to the belief that C.V. measurements have no physical significance, because the problem of conducting the heat of crystallization away from the solid-liquid interface has made true temperature measurements difficult.[2,3] This difficulty has arisen in two ways. In the first place, the majority of investigators have been interested in the maximum C.V.; as Michel[4] has shown, this quantity is of value as a criterion of purity, but, due to the rapid movement of the crystal front, the temperature recorded is that of the thermostat, not that of the interface. In the second place, most previous workers employed capillary tubes of several millimeters bore; the crystal front accordingly had only a small portion of its surface exposed to the thermostat.

It is believed that the method recently developed for microscopic quantitative analysis of *p,p'*-DDT[5] avoids both these difficulties, and permits the measurement of true equilibrium temperatures over a limited range. The method employs thin films of the melt (less than 0.1 mm.) which have a correspondingly larger fraction of the interface in contact with the thermostat. Measurements are made on the lower temperature branch of the C.V. *vs.* temperature curve, in which region the rates are relatively slow, and where, moreover, rate measurements are uncomplicated by the transition in the reverse direction. It should be possible to attempt theoretical interpretation of data obtained in this way. The aim of the present and future work is to provide such data.

No claim of originality is made for the method of measuring such rates under the microscope. Dreyer[6] appears to have been the first to measure the C.V. on microscope slides.

Experimental Results

Effect of Temperature.—The technique described previously for *o,p*-DDT/*p,p'*-DDT mixtures[5] was used to establish C.V. *vs.* temperature curves for various mixtures of *p,p'*-DDT with 1,3,5-triphenylbenzene (TPB) and with 5-methyl-2-isopropylphenol (thymol). Figure 1 shows the general form of such curves. To avoid crowding, some experimental curves were omitted. In agreement with much earlier work on binary melts[7] the scatter of experimental points becomes considerable for *p,p'*-DDT mixtures containing more than about twenty-five weight per cent. of a second component. Thymol results are indicated in the smoothed curves of Fig. 2, in the rate *vs.* composition form used previously,[5] because a rate *vs.* temperature plot leads to undue crowding here. A similar increase in C.V. on addition of certain types of impurities was first noted by Dreyer.[8]

In Fig. 4 of the previous publication,[5] the Arrhenius lines were drawn through the raw experimental data. Because of the scatter of experimental points, it is now believed that a better representation of the true trend of the Arrhenius lines is achieved by using smoothed data from the C.V. *vs.* temperature curves. In Fig. 3, the best line was drawn through the smoothed data for pure *p,p'*-DDT, and the other lines were drawn parallel (except for thymol). The same procedure was used in constructing the graph for TPB mixtures (Fig. 4). Only one point of the one per cent. thymol line has been included, and several thymol

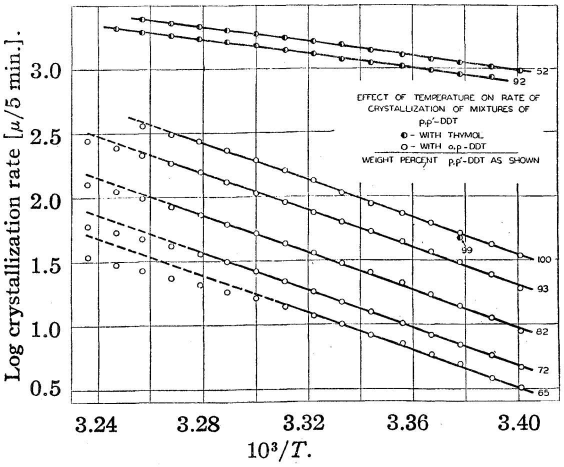

Fig. 3.—Arrhenius-type relations for mixtures of p,p'-DDT with o,p-DDT and thymol.

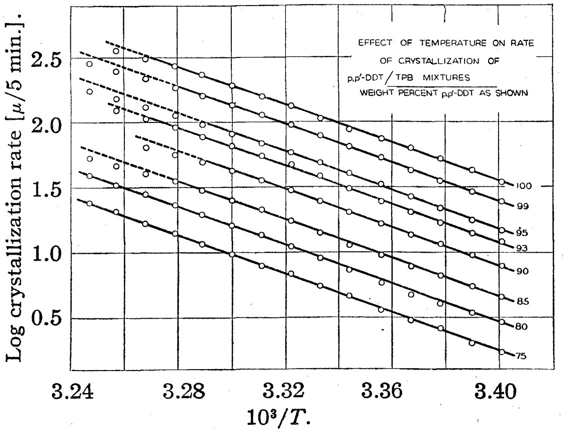

Fig. 4.—Arrhenius-type relations for p,p'-DDT/TPB mixtures.

lines have been omitted, to avoid crowding the graph. Because of very poor reproducibility of results for thymol mixtures, of compositions between 99 and 92% DDT, no data were recorded in this range.

Figures 3 and 4 show the Arrhenius-type relation.

$$\text{C.V.} = Be^{-E_c/RT}$$

holding remarkably well at lower temperatures. At these lower temperatures, the apparent activation energy of crystallization (E_c) for p,p'-DDT is 33.4 kcal., and this does not change when this compound is growing from mixtures containing TPB, o,p-DDT, or very small amounts of thymol. In other words, these compounds do not make it easier or harder for p,p'-DDT to crystallize. They do decrease the rate, however by lowering the value of B. The importance of B, which may include an entropy term, suggests that structural symmetry of the second component may play some part in the rate determining process in these mixtures. Larger concentrations of thymol, however, do lower the apparent activation energy to 12.1 kcal., and do appear to make it easier for p,p'-DDT to crystallize in thymol mixtures.

A survey of earlier work reveals only three compounds for which enough of the lower temperature branch of the C.V. *vs.* temperature curve has been reported to make possible a calculation of E_c. Dreyer's figures[6] for benzil-o-carboxyllic acid yield a value of 32.9 kcal. From the data of Michel[4] on cholesterol methyl carbonate, E_c is calculated to be 13.2 kcal. The glycerol data of Volmer and Marder[9] give a value of 10.2 kcal. for E_c. A theoretical interpretation of these activation energies must await further experimental work.

The B parameter bears a linear relation to the concentration of o,p-DDT and TPB, as shown in Fig. 5. If mole fraction is plotted, instead of weight fraction, the lines for o,p-DDT and TPB do not coincide. This disagrees with von Pickardt[10] but agrees with Dreyer.[8]

It is possible to derive equations relating the

variables for crystallization of mixtures containing *o,p*-DDT or TPB. These equations are more accurate in predicting rates, over a wider variety of conditions, than the equation developed previously.[5] For *p,p'*-DDT, or for mixtures in which E_c does not change

$$\text{C.V.} = Be^{-33,400/RT}$$
$$\text{or } \log \text{C.V.} = \log B - 7.30 \times 10^3/T$$

From Fig. 5

$$\log B = 26.36 - 3.06 \times 10^{-2}C \text{ (for } o,p\text{-DDT mixtures)}$$
$$\log B = 26.27 - 5.05 \times 10^{-2}C \text{ (for TPB mixtures)}$$

where C.V. is in microns per five minutes, and C is the weight per cent. impurity.

Table I compares rates predicted by these equations with the observed values. The deviation of calculated from observed values becomes considerable at the highest experimental temperatures, where the Arrhenius equation ceases to hold accurately.

TABLE I

COMPARISON OF OBSERVED AND CALCULATED VALUES OF C.V.

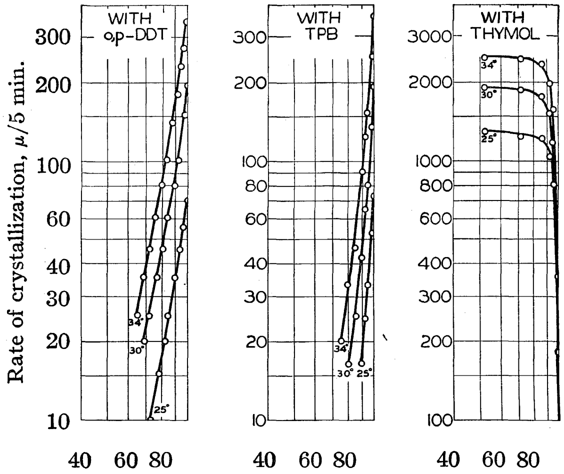
33	33	28	31	25	16.6	14.2

Effect of Concentration.—The nature of the crystallization of *p,p'*-DDT is such that the crystal front advances, apparently, into a melt of nearly constant composition. Consequently, the isothermal rates measured for a given concentration are constant, unless the second component exceeds about 25%, when irregularities begin to appear. The same phenomenon occurs for many organic compounds if the capillary method is used. Were this not so, it would be impossible to measure the C.V. at different concentrations, for the C.V. of the major component of the mixture would change as the impurity concentration increased ahead of the crystal front.



Concentration–weight per cent. of *p,p'*-DDT.

Fig. 6.—Effect of second component on C.V. of *p,p'*-DDT.

The apparent "order" of the crystallization process in mixtures may thus be calculated, using the van't Hoff method (Fig. 6). From the slopes of the isothermal curves it is found that the order falls with decreasing *p,p'*-DDT concentration. For *o,p*-DDT mixtures, the order falls from about seven to nearly five; for TPB mixtures the corresponding decrease is approximately from twelve to seven. Rawitzer[11] applied essentially the same method to the data of Tammann[12] for benzil/azobenzene and dinitrophenol/acetanilide mixtures. The lines plotted by Rawitzer, however, were straight, and values of the apparent order varied between six and nine, according to the isotherm and mixture chosen. It is hard to understand why the present work and Rawitzer should disagree on the constancy of the order for a given isotherm, unless it be that the nature of the process differs for different compounds and mixtures.

By curve fitting methods it is possible to straighten the curving isotherms. For example, the *o,p*-DDT mixture yields the relation

$$\text{C.V.} = K(C + 100)^{13.7} = K'\ (c + 1)^{13.7}\ (c = \text{weight fraction } p,p'\text{-DDT})$$

Adequate discussion of these kinetics must await further experimental studies.

Summary

The linear rate of crystallization of p,p-DDT from some supercooled binary melts has been determined, as a function of temperature and melt concentration. The second component of the melt may increase or decrease the rate. The apparent activation energy for the crystallization of pure p,p'-DDT is 33.4 kcal.

Fractionation and Physical–Chemical Studies of a Commercial Preparation of the Specific Polysaccharide of Type I Pneumococcus[1]

BY ROBERT A. ALBERTY AND MICHAEL HEIDELBERGER

The specific polysaccharide of Type I pneumococcus (SI)[2] is similar to the proteins in its electrochemical and solubility characteristics because it is also an amphoteric colloidal electrolyte. For this reason an attempt was made to apply the alcohol fractionation techniques which have been developed in the purification and separation of plasma proteins[3,4] to the purification of this polysaccharide. As with proteins, electrophoresis has proved a useful method for analyzing crude products[5] and those obtained by fractionation and in determining the isoelectric points of the components.

Experimental

The electrophoresis experiments were carried out in the usual Tiselius apparatus equipped with a cylindrical lens schlieren optical system. The mobilities were calculated by using the conductivity of the buffer in Donnan equilibrium with the electrophoresis sample determined at the temperature of the thermostat, 1°. Because of the high viscosity of the polysaccharide solutions the concentrations of the electrophoresis samples were made 0.5% or less.[6] Throughout the paper, mobilities on the descending side are given, as well as analyses obtained by averaging the results from the ascending and descending patterns.

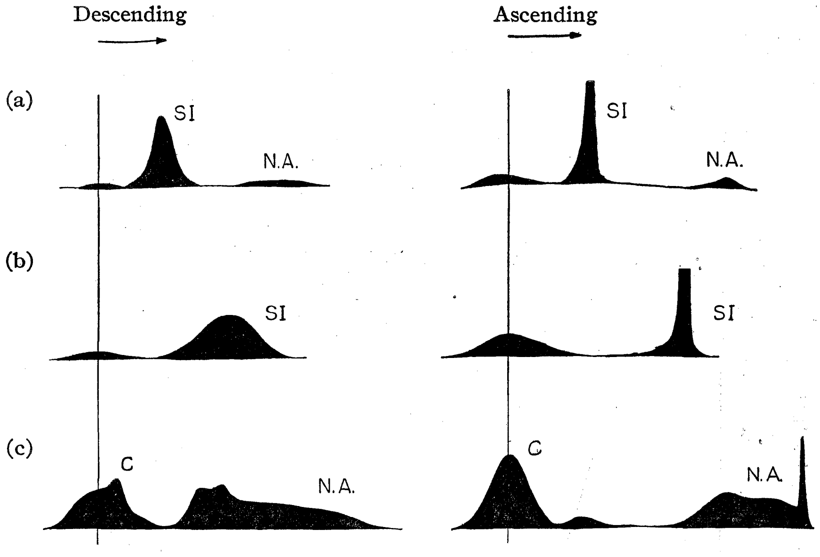

Fig. 1.—Electrophoresis diagrams: (a) commercial preparation, pH 3.90, $\Gamma/2 = 0.10$, after 144 minutes at 3.60 volts/cm.; (b) fraction A, pH 6.90, $\Gamma/2 = 0.10$, after 79 minutes at 3.28 volts/cm.; (c) fraction C, pH 6.90, $\Gamma/2 = 0.10$, after 80 minutes at 3.26 volts/cm.

The SI polysaccharide used as starting material was prepared by E. R. Squibb and Sons and supplied by the Commission on Pneumonia of the U. S. Army Epidemiological Board. The electrophoresis pattern for this preparation at pH 3.9, 0.10 ionic strength acetate buffer, is shown in Fig. 1a. The fast component which makes up 19% of the area of the moving peaks in the pattern contains nucleic acid, and the largest peak represents the SI polysaccharide. These components were identified after electrophoresis by withdrawal of small samples from various levels in the electrophoresis cell by means of a syringe with a long needle. The sample taken just below the fastest ascending peak showed the typical ultraviolet absorption of nucleic acid, with a

(6) The relative viscosity of a 0.1% solution of SI in 0.9% sodium chloride is 1.69; ref. 2c.

maximum at 255 mμ. Samples tested serologically showed that the slower moving component was SI and that the C polysaccharide (the somatic polysaccharide common to all types of pneumococci) did not move in the electrical field or moved so slowly it was not resolved from the salt boundary. The C substance had previously been observed[7] to move with a low mobility (-2.2×10^{-5} at *p*H 7.85 and -1.2×10^{-5} at *p*H 6.20) at 0.05 ionic strength. Since there was no resolution at 0.10 ionic strength it was difficult to estimate the amount of C substance present, but it could not exceed 10% because the area of the stationary boundary was 10–15% of the total area of the electrophoretic pattern in experiments at various *p*H and ionic strengths (see Fractionation). The areas in the electrophoresis pattern were not weighted for differences in refractive index increment for the polysaccharide and nucleic acid since the increments are presumably about the same.[8] Although a trace of nucleoprotein was believed present, it did not appear in the electrophoresis patterns because of the small amount or because its mobility was close to that of one of the other components.

In spite of the high viscosity of the polysaccharide solutions the velocity of the nucleic acid boundary on the ascending side where it moves up into buffer was only slightly higher (about 15%) than on the descending side where it moved into the viscous polysaccharide solution. This difference is caused by the presence of the conductivity gradient at the stationary boundary, the nature of which is understood[9] so that the mobility of the nucleic acid is relatively independent of the viscosity due to the polysaccharide.

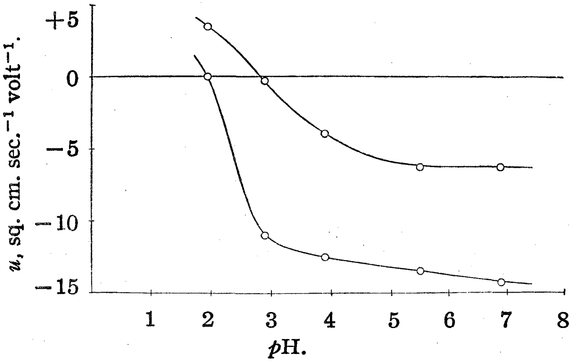

Fig. 2.—Determination of isoelectric points at $\Gamma/2 = 0.10$; upper curve, SI polysaccharide; lower curve, nucleic acid.

Results and Discussion

1. Determination of Isoelectric Point.—The isoelectric point of the SI and nucleic acid in the crude mixture were determined at 0.10 ionic strength from mobility determinations at several *p*H with sodium glycinate, acetate and cacodylate buffers. Figure 2 is a plot of mobility *vs.* *p*H for the two moving components in this material. The isoelectric point for the SI at this ionic strength is *p*H 2.8, and that for the nucleic acid is *p*H 2.0. Since the experiments were performed on mixtures, there is the possibility of some interaction between the components, although this was not evidenced by the electrophoretic patterns.[10] The isoelectric point for the nucleic acid is in agreement with earlier values.[11] The presence of basic groups in the SI polysaccharide is confirmed by the positive mobility at *p*H 2.0.

A sample of SI prepared by earlier methods[2] had a mobility of -5.5×10^{-5} at *p*H 6.9, $\Gamma/2 = 0.10$, in agreement with the mobility of the commercial preparation. Another sample prepared from cultures concentrated by heat and purified in part by precipitation from alkaline solution showed a mobility of -6.5×10^{-5} at *p*H 5.5 in agreement with that obtained for the undegraded SI in spite of the known removal, under these conditions, of an O-acetyl group.[12]

2. Fractionations.—Several fractionations with alcohol were performed on the commercial preparation in the cold in attempts to obtain SI free from nucleic acid and C substance. Addition of ethyl alcohol to dilute solutions (0.5%) at the low ionic strengths ($\Gamma/2 = 0.01$ to 0.1) most suitable for the fractionation of proteins at 0° produced voluminous gels which were not suitable for fractionation. With isopropyl and *n*-propyl alcohols and the much higher ionic strengths customarily used in the precipitation of carbohydrates (3% sodium acetate), there was less tendency to form gels. Figure 3 shows the flow sheet for a fractionation with the electrophoretic analysis (electro.) and serological assay (serol.) of the various fractions. The analytical electrophoresis experiments were carried out at *p*H 6.9 in a cacodylate buffer of 0.10 ionic strength (0.02 *N* sodium cacodylate, 0.08 *N* sodium chloride). The percentage given for the "fast" component includes material with a more negative mobility than -10×10^{-5}. Fraction C contained a large amount of such material (Fig. 1c), although only a portion was nucleic acid as determined with the Beckman spectrophotometer at a wave length of 255 mμ and the extinction values given by Kunitz.[13] Fraction A showed a single symmetrical gradient in electrophoresis and precipitated 90% as much antibody[14] as the same amount of the most active sample of SI available. The electrophoresis pattern is given in Fig. 1b.

Fraction C showed an abnormally large stationary boundary in electrophoresis because of the

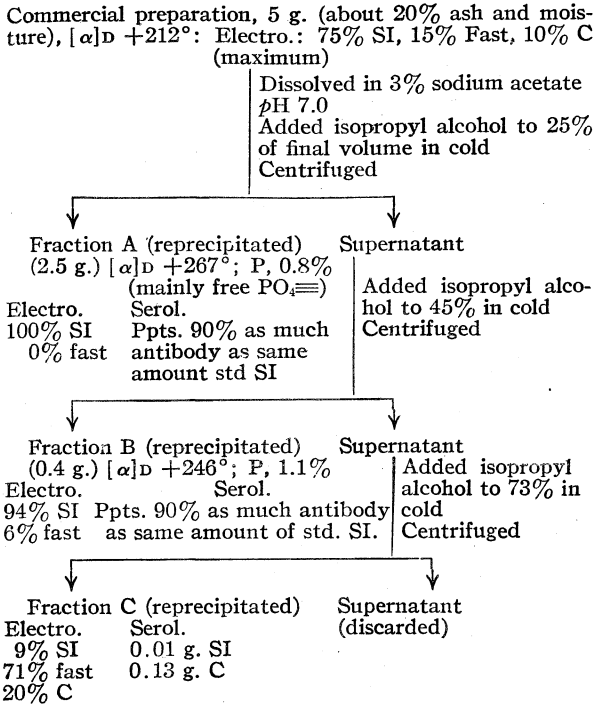

Fig. 3.—Fractionation flow sheet

presence of C substance (see Fig. 1c). The buffer dilution factor at the stationary boundary was calculated from the area of the rising and descending moving peaks. The portion of the area of the ϵ boundary due to salt was calculated by assuming the buffer dilution factor to be equal to the dilution factor for the fast peak. The values indicate that Fraction C contains approximately 20% C.[15] Electrophoresis indicated more SI in Fraction C than did serological assay, but the serological activity of SI may possibly be partially inhibited by excess C substance. Isopropyl alcohol has been found to be a useful reagent in the fractionation and purification of other specific bacterial polysaccharides.

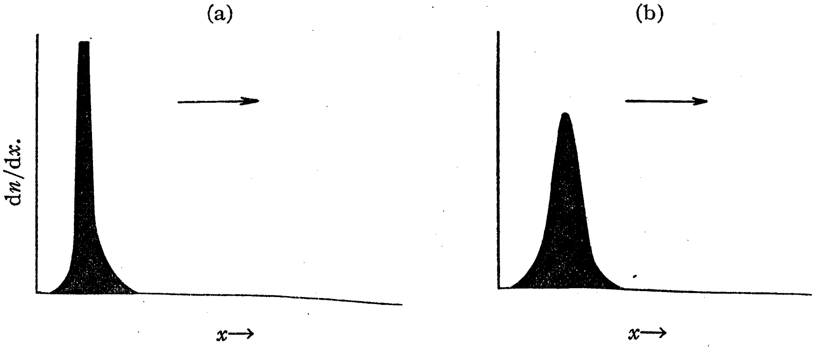

Fig. 4.—Sedimentation diagrams for purified SI (Fraction A) at 50,400 r. p.m. (pH 5.5, acetate buffer, Γ/2 = 0.10): (a) 0.5% solution after 119 minutes, s_{20_w} = 1.2S; (b) 0.15% solution after 119 minutes, s_{20_w} = 2.3S.

3. **Sedimentation Velocity.**—Several sedimentation experiments with the purified SI were carried out at 50,400 r. p. m. in the standard Svedberg oil turbine velocity ultracentrifuge with a cell having a 12-mm. optical path. Both the sedimentation constant and the rate of boundary spreading are quite dependent on concentration as shown in Fig. 4. However, as shown by Gralén,[16] the calculated value of s taken from the apex of the peak does not correspond to the same molecules in experiments at different concentrations. Information as to homogeneity and molecular weight of this material may be obtained only by extrapolation of sedimentation constants and rate of boundary spreading to infinite dilution.

Acknowledgment.—The authors wish to express their appreciation for the interest and helpful suggestions of Dr. J. W. Williams.

Summary

Fractionation procedures with isopropyl alcohol have been applied to the purification of the specific polysaccharide of Type I pneumococcus (SI). Electrophoretic and serological assays were used for the analysis of products. The isoelectric points of the SI and nucleic acid in the crude preparation have been determined by electrophoresis.

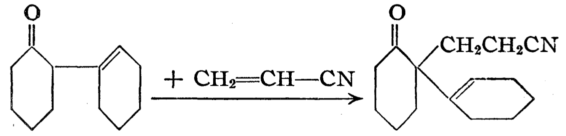
The Chemistry of Acrylonitrile. VII. Cyanoethylation of Ketones and Sulfones

BY HERMAN A. BRUSON AND THOMAS W. RIENER

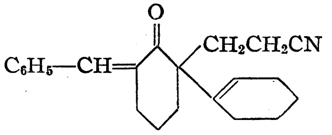
During the course of an investigation on the reactions of acrylonitrile in the presence of alkalies with various types of active methylene compounds,[1] the behavior of 2-cyclohexenylcyclohexanone (I) toward cyanoethylation was examined.

It was found that with one molecular equivalent of acrylonitrile, monocyanoethylation first occurs largely on the methenyl group to give 2-(β-cyanoethyl)-2-cyclohexenylcyclohexanone (II) in about 50% yield, together with unchanged 2-cyclohexenyl-cyclohexanone and higher cyanoethylation products.



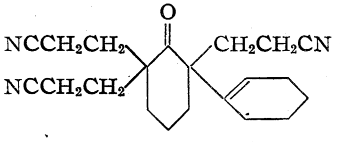
(I) (II)

That the methylene group adjacent to the carbonyl in (II) is intact, is shown by the fact that (II) readily yields a crystalline mono-benzylidene derivative (II) with benzaldehyde.



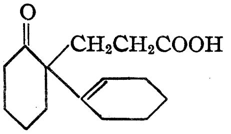
(III)

Further cyanoethylation of (II) with two additional molecular equivalents of acrylonitrile yields the *tri*-cyanoethylation product (IV).

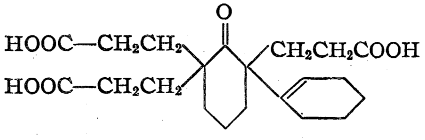


(IV)

Upon alkaline hydrolysis (II) and (IV) yield the respective carboxylic acids (V) and (VI).

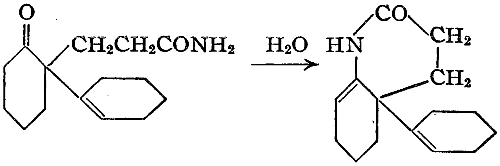


(V)



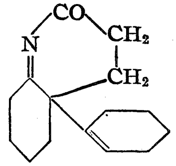
(VI)

When (II) is treated with aqueous sulfuric acid (1 mole sulfuric acid plus 1 mole water per mole of II) a product is obtained which is not the anticipated amide (VII), but a dehydration product thereof, presumably a cyclohexenyl hexahydroquinolone (VIII)



(VII) (VIII)

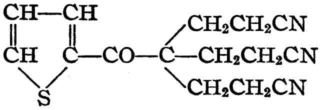
or



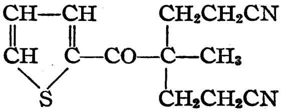
(VIII)

such as would be expected to form when a δ-ketonic amide (VII) or nitrile (II) reacts with aqueous mineral acids.[2]

The reaction of acrylonitrile with 2-acetylthiophene and 2-propionylthiophene gave good yields of the corresponding *tri*- and *di*-cyanoethylation products (IX) and (X), respectively.

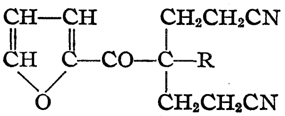


(IX)



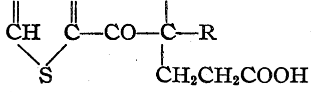
(X)

In a similar manner, acrylonitrile added to 2-acetylfuran, 2-propionylfuran and 2-butyrylfuran to give the crystalline cyanoethylation products (XI), (XII) and (XIII), respectively.



(XI) R = —CH_2CH_2CN
(XII) R = CH_3—
(XIII) R = CH_3CH_2—

Upon alkaline hydrolysis of the cyano groups, (IX) and (X) gave the corresponding carboxylic acids, (XIV) and (XV), respectively.



(XIV) R = —CH_2CH_2COOH
(XV) R = CH_3—

The cyanoethylation reaction was also applied to an active methylene sulfone, namely, benzyl phenyl sulfone $C_6H_5CH_2—SO_2—C_6H_5$. This reacted smoothly with two equivalents of acrylonitrile in the presence of "Triton B" to give (XVI)

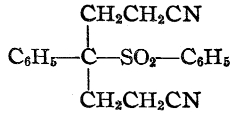
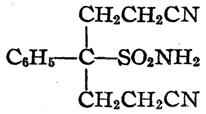
[2] Allan and Ball, *ibid.*, **59**, 686 (1937); Kohler, Graustein and Merrill, *ibid.*, **44**, 2536 (1922); Kohler and Souther, *ibid.*, **44**, 2903 (1922); Kohler and Allen, *ibid.*, **46**, 1522 (1924).



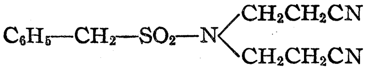
$$C_6H_5-\overset{CH_2CH_2CN}{\underset{CH_2CH_2CN}{C}}-SO_2-C_6H_5 \qquad (XVI)$$

In a previous article[5] it was reported that the cyanoethylation of α-toluene sulfonamide yielded γ-phenyl-γ-(sulfonamido)-pimelonitrile (XVII).



$$C_6H_5-\overset{CH_2CH_2CN}{\underset{CH_2CH_2CN}{C}}-SO_2NH_2 \qquad (XVII)$$

A reinvestigation of this reaction indicates however that the two cyanoethyl groups are attached to the nitrogen atom of the sulfonamido group instead of on the methylene carbon atom, and that the compound is therefore N,N-bis-(2-cyanoethyl)-α-toluenesulfonamide (XVIII).



$$C_6H_5-CH_2-SO_2-N\begin{smallmatrix}\diagup CH_2CH_2CN\\ \diagdown CH_2CH_2CN\end{smallmatrix} \qquad (XVIII)$$

This was established by the synthesis of (XVIII) from the reaction of benzylsulfonyl chloride with bis-(β-cyanoethyl)-amine, $HN(CH_2CH_2CN)_2$.

Upon alkaline hydrolysis of (XVIII) one of the cyanoethyl groups is eliminated with the formation of benzylsulfonamidopropionic acid $C_6H_5CH_2SO_2NHCH_2CH_2COOH$ (XIX).

Experimental

All melting points are uncorrected.

2-(β-Cyanoethyl)-2-cyclohexenylcyclohexanone (II).—To a stirred mixture of 100 g. of *t*-butyl alcohol, 5 g. of aqueous 40% benzyltrimethylammonium hydroxide ("Triton B") and 178 g. of 2-cyclohexenylcyclohexanone[3] (1 mole), there was added dropwise 53 g. of acrylonitrile (1 mole) during the course of thirty minutes. The exothermic reaction was maintained at 25–30° by cooling. The mixture was stirred for two hours at room temperature after the addition of the acrylonitrile, and was then acidified to congo with dilute hydrochloric acid. The mixture was washed twice with water, dried *in vacuo* to remove moisture and solvent, and the residual oil was distilled under high vacuum (0.2 mm.) to give the following cuts: (a) 25 g., b. p. 110–138°; (b) 44 g., 138–162°; (c) 103 g. 162–172°; (d) 7 g., 172–245°; (e) 16 g., 245–255°; (f) 32 g. residue. Fraction (c) was redistilled to give 91 g. of product which came over as a colorless oil at 152–156° (0.1 mm.), and which solidified to a crystalline solid on standing. Upon recrystallization from petroleum ether it formed white crystals, m. p. 61–62°. An additional 19 g. was obtained by redistilling fraction (b); total yield of product, 110 g. or 47.6%.

Anal. Calcd. for $C_{15}H_{21}NO$: C, 77.92; H, 9.09; N, 6.06. Found: C, 77.90; H, 9.18; N, 6.12.

6-Benzylidene-2-(β-cyanoethyl)-2-cyclohexenylcyclohexanone (III).—Freshly distilled benzaldehyde (10.6 g.) was added to a stirred solution of 23.1 g. of II, 50 g. of ethanol and 2 g. of 35% methanolic potassium hydroxide solution. The solution was allowed to stand for forty-eight hours during which time a crystalline deposit formed. The filtered crystals (26 g.) were recrystallized first from methanol and three times from ethanol to give white crystals m. p. 169–170°, which apparently contained a trace of amide.

Anal. Calcd. for $C_{22}H_{25}NO$: N, 4.39. Found: N, 4.04.

2-Cyclohexenyl-2,6,6-tri-(β-cyanoethyl)-cyclohexanone (IV).—A mixture of 57.8 g. of II, 100 g. of *t*-butyl alcohol and 3 g. of "Triton B" was stirred, and 29 g. of acrylonitrile was added dropwise thereto during the course of thirty minutes at 40–45°. The mixture was stirred thereafter for ten hours at room temperature, and then made faintly acid to congo with dilute hydrochloric acid. The product was washed with water, taken up in ethylene dichloride, washed with water several more times and the ethylene dichloride layer was evaporated to dryness *in vacuo* on the steam-bath.

The residual thick oil was mixed with about three times its volume of methanol and set aside in the refrigerator at 4° to crystallize. After a few hours the light tan crystalline deposit was filtered off; yield was 48.5 g. Upon recrystallization from methanol with a little Norite, the sample for analysis was obtained in white crystals, m. p. 111°.

Anal. Calcd. for $C_{21}H_{27}N_3O$: C, 74.78; H, 8.01; N, 12.46. Found: C, 74.73; H, 8.12; N, 12.34.

2-(β-Carboxyethyl)-2-cyclohexenylcyclohexanone (V).—A mixture of 11.5 g. of II, 11.5 g. of potassium hydroxide and 90 g. of water was boiled under reflux until an almost clear solution was formed. This required about twenty hours. The filtered solution was acidified with hydrochloric acid and the taffy-like mass which precipitated was taken up in benzene. The benzene solution was evaporated to dryness *in vacuo* and the residual oil was distilled under high vacuum to give 9 g. of colorless, very viscous oil boiling at 175–180° (0.2 mm.) which crystallized upon rubbing with petroleum ether in the cold. Upon recrystallization from petroleum ether it formed white crystals, m. p. 60–61°.

Anal. Calcd. for $C_{15}H_{22}O_3$: C, 72.00; H, 8.80. Found: C, 71.78; H, 8.81

2-Cyclohexenyl-2,6,6-tri-(β-carboxyethyl)-cyclohexanone (VI).—A mixture of 6 g. of IV, 72 g. of water and 8 g. of sodium hydroxide was boiled under reflux for ten hours, until practically all the oily material had dissolved. The solution was filtered and acidified with hydrochloric acid to precipitate the crude tricarboxylic acid as a dough-like mass which hardened on standing It was dried in the air and crystallized twice from nitroethane to form white crystals, m. p. 158–159°.

Anal. Calcd. for $C_{21}H_{30}O_7$: C, 63.96; H, 7.61. Found: C, 63.50: H, 7.76.

Cyclohexenylhexahydroquinolone (VIII).—To a stirred solution of 23.1 g. of II and 50 g. of ethylene dichloride there was added dropwise with cooling, a solution of 10 g. of 98% sulfuric acid and 1.8 g. of water during the course of ten minutes. The reaction temperature was between 30 and 40°. After all had been added the mixture was stirred for fifteen minutes at room temperature and then heated for five hours at 45–50° with constant stirring, and allowed to stand overnight. Water (200 cc.) was then added and the mixture stirred. The white solid which separated was filtered off, washed and dried. Yield was 5 g. Upon crystallization from nitromethane it formed white needles m. p. 213–214°. The analytical sample was dried at 100° in high vacuum.

Anal. Calcd. for $C_{15}H_{21}NO$: C, 77.92; H, 9.09; N, 6.06. Found: C, 77.70; H, 9.10; N, 6.13.

From the ethylene dichloride layer there was obtained upon evaporation an additional 10 g. of product, m. p. 212–214° after crystallization from nitromethane. Total yield was 15 g. or 64.9%.

1,1,1-Tri-(β-cyanoethyl)-methyl 2-Thienyl Ketone (IX).—Acrylonitrile (31.8 g.) was added dropwise to a stirred solution of 25.2 g. of 2-acetylthiophene, 25 g. of *t*-butyl alcohol and 2 g. of "Triton B" while maintaining the reaction mixture at 25–30° by cooling. The addition required about thirty minutes during which time crystals began to separate and clog the stirrer so that 50 cc. of additional *t*-butyl alcohol had to be added to form a thinner

suspension. After the addition, the mixture was stirred for two hours, then acidified with dilute hydrochloric acid and the crystalline product filtered off. Yield was 50 g. of a tan-colored, air-dried product or 87.7%. Upon recrystallization from ethanol the sample for analysis formed white, feathery crystals, m. p. 146–147°.

Anal. Calcd. for $C_{15}H_{15}N_3OS$: C, 63.15; H, 5.26; N, 14.73; S, 11.22. Found: C, 63.04; H, 5.20; N, 14.77; S, 11.28.

γ-Methyl-γ-thienoyl-pimelonitrile (X).—To a stirred solution of 55 g. of 2-propionylthiophene, 50 g. of *t*-butyl alcohol and 3 g. of "Triton B," there was added dropwise 42.4 g. of acrylonitrile while cooling the mixture to 25–30°. After the addition the mixture was stirred for twenty-four hours during which time the product separated in crystalline form. The mixture was neutralized with dilute hydrochloric acid and the crystals filtered off. Yield was 94 g. of air dried product or 98%. Upon crystallization from ethanol the sample for analysis formed white flaky crystals, m. p. 81–82°.

Anal. Calcd. for $C_{13}H_{14}N_2OS$: C, 63.41; H, 5.69; N, 11.38; S, 13.00. Found: C, 63.34; H, 5.65; N, 11.31; S, 13.27.

Tri-(β-cyanoethyl)-2-acetylfuran (XI).—To a stirred mixture of 6 g. of "Triton B," 200 g. of *t*-butyl alcohol and 99 g. of 2-acetylfuran[4] there was added dropwise 143 g. of acrylonitrile during the course of an hour while cooling the mixture to 22–28°. During the addition a heavy crystalline mush formed. To assist the stirring, 150 g. more of *t*-butyl alcohol was added, and the mixture was stirred for eighteen hours at room temperature. The catalyst was then neutralized with dilute hydrochloric acid and the crystalline product filtered off sharply by suction. Yield was 216 g. After recrystallization from ethanol it formed white crystals, m. p. 121–122°.

Anal. Calcd. for $C_{15}H_{15}N_3O_2$: C, 66.91; H, 5.57; N, 15.61. Found: C, 66.77; H, 5.68; N, 15.52.

γ-Furoyl-γ-methylpimelonitrile (XII).—The 2-propionylfuran used was prepared from furan, propionic anhydride and hydrogen iodide by the method of Hartough and Kosak.[4] It was thoroughly freed from traces of acidity (which poison the catalyst), by several washings with soda solutions and two distillations.

Acrylonitrile (32.4 g.) was added dropwise to a stirred solution of 38 g. of 2-propionylfuran, 50 g. of *t*-butyl alcohol and 3 g. of "Triton B" at 24–28°. The mixture was stirred for twenty-four hours thereafter at room temperature, then neutralized with dilute hydrochloric acid and washed with water. The oil layer was separated and dried *in vacuo* at 90°. The product formed a thick oil (69 g.) which crystallized slowly on scratching and standing eventually forming a solid, waxy mass. After several recrystallizations from ethanol, the sample for analysis formed white crystals, m. p. 49°.

Anal. Calcd. for $C_{13}H_{14}N_2O_2$: C, 67.83; H, 6.09; N, 12.17. Found: C, 67.89; H, 6.11; N, 12.06.

γ-Furoyl-γ-ethylpimelonitrile (XIII).—The 2-butyrylfuran used was prepared from furan, hydrogen iodide and butyric anhydride.[4] It boiled at 83–84° (10 mm.). It must be freed from traces of acidity which poison the catalyst.

A mixture of 30 g. of 2-butyrylfuran, 30 g. of *t*-butyl alcohol and 2 g. of "Triton B" was treated with 23 g. of acrylonitrile as described above. The dark resinous sirup obtained gradually crystallized to yield 36 g. of white crystalline product after washing with a little *t*-butyl alcohol. The sample for analysis was recrystallized twice from ethanol to give large prisms, m. p. 102°.

Anal. Calcd for $C_{14}H_{16}N_2O_2$: C, 68.85; H, 6.56; N, 11.47. Found: C, 68.70; H, 6.58; N, 11.39.

1,1,1-Tri-(β-carboxyethyl)-methyl 2-Thienyl Ketone (XIV).—A mixture of 14.3 g. of IX, 100 g. of water and 12 g. of sodium hydroxide was boiled under reflux for twelve hours. The filtered solution was acidified with hydrochloric acid. A heavy oil separated which solidified to a crystalline mass. Yield was 14 g. of air-dried product. Upon crystallization from nitromethane it formed white crystals, m. p. 183–184°. The sample for analysis was dried in high vacuum at 100°.

Anal. Calcd. for $C_{15}H_{18}O_7S$: C, 52.63; H, 5.26; S, 9.35. Found: C, 52.65; H, 5.34; S, 9.23.

γ-Methyl-γ-thienoylpimelic Acid (XV).—A mixture of 12.3 g. of (X), 100 g. of water and 12 g. of sodium hydroxide was boiled under reflux for eight hours. The filtered solution was acidified with hydrochloric acid. An oil precipitated which gradually solidified to a crystalline mass. Yield of air-dried product was 12 g. Upon crystallization from nitromethane, the product formed white crystals, m. p. 137–138°.

Anal. Calcd. for $C_{13}H_{16}O_5S$: C, 54.92; H, 5.63; S, 11.26. Found: C, 54.44; H, 5.83; S, 11.23.

γ-Phenyl-γ-phenylsulfonylpimelonitrile (XVI).—To a stirred solution of 5.8 g. of benzyl phenyl sulfone, 40 g. of acetonitrile and 0.5 g. of "Triton B" there was added dropwise 2.7 g. of acrylonitrile while the reaction mixture was maintained at 32–38° by occasional cooling. The mixture was then stirred for eighteen hours at room temperature, neutralized with dilute hydrochloric acid and the product washed with water and dried *in vacuo*. The residual oil (5 g.) crystallized when rubbed with ethanol. After recrystallization from ethanol the product formed white crystals, m. p. 180°.

Anal. Calcd. for $C_{19}H_{18}N_2O_2S$: C, 67.45; H, 5.32; N, 8.29; S, 9.47. Found: C, 67.80; H, 5.53; N, 8.26; S, 9.25.

N,N-bis-(2-Cyanoethyl)-α-toluenesulfonamide (XVIII).—To a solution of 6.2 g. of bis-β-cyanoethylamine in 50 g. of benzene, there was added 8.5 g. of benzylsulfonyl chloride (obtained from Eastman Kodak Co.). The clear solution gradually deposited a slimy precipitate. After standing two hours, the mixture was filtered free from this material and the filtrate allowed to stand overnight. The white crystalline deposit which separated therefrom was filtered off and recrystallized from ethanol. It melted at 103° and was identical with the product obtained from the cyanoethylation of α-toluenesulfonamide.[5]

A mixed melting point of the two products showed no depression.

β-(Benzylsulfonamido)-propionic Acid (XIX).—A mixture of 10 g. of (XVIII), 12 g. of sodium hydroxide and 80 cc. of water was boiled under reflux for six hours. The clear solution obtained was acidified with hydrochloric acid and the crystalline precipitate filtered off and dried. Yield was 9 g. After recrystallization from hot water the product formed white flaky crystals, m. p. 151–152°, having an acid no. 230 (calcd., 230).

Anal. Calcd. for $C_{10}H_{13}NO_4S$: C, 49.38; H, 5.35; N, 5.76; S, 13.16. Found: C, 49.13; H, 5.64; N, 5.68; S, 13.26.

Acknowledgment.—To Mr. Clyde W. Nash for all analyses and to Mr. Raymond Luckenbaugh for preparing several of the intermediates.

Summary

1. Acrylonitrile reacts with 2-cyclohexenylcyclohexanone to yield a *mono-* and a *tri-*cyanoethylation product from which the corresponding carboxylic acids were prepared.

2. Mono-cyanoethylcyclohexenylcyclohexanone yields a cyclohexenylhexahydroquinolone upon treatment with sulfuric acid.

3. Cyanoethylation products of 2-acylthiophenes and 2-acylfurans were prepared.

4. Cyanoethylation of benzyl phenyl sulfone

---

[4] Hartough and Kosak, This Journal, 68, 2641 (1946). The product should be free from traces of acidity.

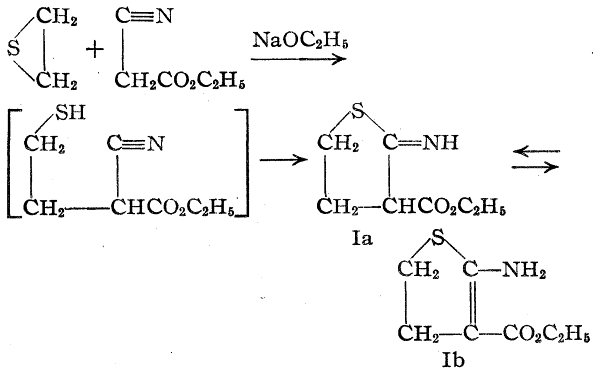
The Synthesis of 2-Iminothiophanes from Ethyl Cyanoacetate and Alkene Sulfides

BY H. R. SNYDER AND WYVONA ALEXANDER[1]

The structural similarity of alkene sulfides to alkene oxides suggests that these sulfur compounds may be useful in the alkylation of active methylene compounds. Such alkylations with the alkene oxides have become important synthetic methods[2] and they appear to be of quite general application.[3]

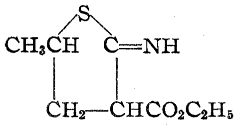
Preliminary tests of reactions between simple olefin sulfides and ethyl malonate, ethyl acetoacetate and ethyl cyanoacetate in the presence of sodium ethoxide indicated that alkylation occurred readily only with the last-named ester. The yield of the condensation product from ethylene sulfide and ethyl cyanoacetate was not large (23%), much of the cyclic sulfide being lost through polymerization. As might have been expected, the yields from propylene sulfide and isobutylene sulfide, which have less tendency toward polymerization, were higher (30 and 60%, respectively). The products of the reactions were solid basic esters which could be converted to hydrochlorides and acetyl derivatives. The presence of a basic group and an ester group in the molecule from ethylene sulfide and the cyanoacetate suffices to establish the structure of the substance as I. The structure is confirmed by the conversion of the product to γ-thiobutyrolactone[4] by alkaline hydrolysis and decarboxylation, and to γ,γ'-dithio-bisbutyric acid[4] by alkaline hydrolysis, decarboxylation and oxidation.



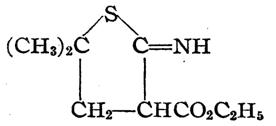
Ia

Ib

In the alkylation of ethyl cyanoacetate with propylene oxide and isobutylene oxide the less highly alkylated carbon atom of the oxide becomes attached to the active methylene carbon atom.[3] Accordingly, one would expect the products from propylene sulfide and isobutylene sulfide to have the structures II and III. The properties of the compounds are compatible only with these structures (or their tautomers). Hydrolysis, decarboxylation and oxidation of II gave the known γ,γ'-dithio-bis-valeric acid, and similar treatment of III gave a disulfide which proved identical with γ,γ'-dithio-bis-isocaproic acid synthesized by another method. An independent proof of the orientation of the methyl groups in III resulted from the desulfurization with Raney nickel alloy.[5,6] The desulfurization was carried out in aqueous alkali under conditions such that hydrolysis first occurred; the product unquestionably was isobutylmalonic acid.



II



III

When the condensations of propylene sulfide and isobutylene sulfide with ethyl cyanoacetate were carried out in methanol solution ester interchange occurred and the methyl esters corresponding to II and III were obtained.

Experimental

The Preparation of the Alkene Sulfides.—The ethylene, propylene and isobutylene sulfides used in this investigation were obtained from the oxides through treatment with aqueous potassium thiocyanate as described in an earlier paper.[7]

Condensation of Ethyl Cyanoacetate with Ethylene Sulfide.—No entirely satisfactory procedure was found for this condensation; the best results were obtained by the following method. To a solution prepared by dissolving 2.3 g. of sodium in 250 ml. of absolute ethanol was added 20 g. of ethyl cyanoacetate; this mixture was refluxed while 6 g. of ethylene sulfide was added dropwise over a period of one hour. Refluxing was continued for one hour, after which time the ethanol was distilled. The residue was extracted with ether, leaving large amounts of insoluble, probably polymeric, material. The sirup remaining

after evaporation of the ether crystallized very slowly. A solution of this material in about 5 ml. of ethanol was diluted to turbidity with water, chilled and seeded to yield about 4 g. (23%) of 2-imino-3-carbethoxythiophane, melting at 74–78°. Further recrystallization of a sample raised the melting point to 79.5–80°.

Anal. Calcd. for $C_7H_{11}O_2NS$: C, 48.55; H, 6.41. Found: C, 48.59; H, 6.62.

The **hydrochloride** precipitated as a colorless hygroscopic solid when dry hydrogen chloride was passed into an ether solution of the imino ester. The neutralization equivalent of the salt, determined by titration with sodium hydroxide in the presence of phenolphthalein, was 212 (calcd., 210).

The **acetyl derivative** was prepared by heating the imino ester with about 10% excess of acetic anhydride; after recrystallization from ethanol it melted at 73–74°.

Anal. Calcd. for $C_9H_{13}O_3NS$: C, 50.22; H, 6.09. Found: C, 50.58; H, 6.21.

Condensation of Ethyl Cyanoacetate with Propylene Sulfide.—The reaction mixture prepared as described for the ethylene sulfide reaction, except that the propylene sulfide (7.4 g.) was added in one lot, was refluxed one hour and then concentrated to 20 ml. The ethanol solution was decanted from the viscous sirup and poured into ice water. Recrystallization (from aqueous ethanol) of the resulting solid yielded 6 g. (30%) of 2-imino-3-carbethoxy-5-methylthiophane melting at 50–51°.

Anal. Calcd. for $C_8H_{13}O_2NS$: C, 51.31; H, 7.00. Found: C, 51.34; H, 7.06.

From a similar reaction carried out in methanol 2-imino-3-carbomethoxy-5-methylthiophane, m. p. 96–98°, was isolated; the acetyl derivative, m. p. 87–88°, was analyzed.

Anal. Calcd. for $C_9H_{13}O_3NS$: C, 50.22; H, 6.09. Found: C, 50.45; H, 6.28.

Condensation of Ethyl Cyanoacetate with Isobutylene Sulfide.—To a solution prepared from 2.3 g. of sodium and 300 ml. of ethanol was added 15 g. of ethyl cyanoacetate and this mixture was refluxed while 9 g. of isobutylene sulfide was added over a period of one hour. Refluxing was continued for one hour after completion of the addition, and the solution was concentrated to a volume of about 50 ml. The concentrated solution, filtered if not clear, was poured into ice-water to precipitate the product. After recrystallization from aqueous ethanol the 2-imino-3-carbethoxy-5,5-dimethylthiophane, weight 12 g. (60%), melted at 53–54°.

Anal. Calcd. for $C_9H_{15}O_2NS$: C, 53.65; H, 7.51. Found: C, 53.88; H, 7.67.

The **hydrochloride** melted at 122–124° and had a neutralization equivalent of 244 (calcd., 238).

The **acetyl derivative** melted at 69–70°.

Anal. Calcd. for $C_{11}H_{17}O_3NS$: C, 54.30; H, 7.05. Found: C, 54.12; H, 7.26.

2-Imino-3-carbomethoxy-5,5-dimethylthiophane, prepared by the use of methanol instead of ethanol in the above procedure, melted at 137.5–139°.

Anal. Calcd. for $C_8H_{13}O_2NS$: C, 51.31; H, 7.00. Found: C, 51.53; H, 7.19.

Hydrolysis of Condensation Products with Strong Alkali.—Hydrolysis by ten per cent. sodium or potassium hydroxide was brought about by refluxing for an hour. The γ-thiolactone of the corresponding dicarboxylic acid was formed. From 2-imino-3-carbethoxythiophane a liquid acid was obtained which was readily decomposed to γ-thiobutyrolactone (n^{20}D 1.5241) (lit.[4] n^{20}D 1.5242). Hydrolysis of 2-imino-3-carbethoxy-5,5-dimethylthiophane yielded a solid acid (2-keto-5,5-dimethylthiophane-3-carboxylic acid) which melted with decomposition at 90–91°.

Anal. Calcd. for $C_7H_{10}O_3S$: C, 48.26; H, 5.79; neutralization equivalent, 174. Found: C, 48.31 H, 6.09; neut. equiv., 174.

Hydrolysis and Oxidation of the Condensation Products.—The products of condensation were hydrolyzed by refluxing for about six hours with an excess of 10% sodium carbonate solution. The hydrolysis mixture was cooled, acidified and extracted with ether. Evaporation of the ether left a residue of a liquid mercapto acid which was readily oxidized to the solid disulfide by the addition of aqueous iodine-potassium iodide solution.

Compound I yielded γ,γ'-dithio-bisbutyric acid, melting at 108–109° (lit.[4] 109–110°). Compound II yielded γ,γ' dithio-bis-valeric acid melting at 117–118° (lit.[8] 118–121°). The neutral equivalent was determined as 132 (calcd. 133). The liquid mercapto acid obtained by the hydrolysis of compound III had the reactions of a tertiary mercaptan; it distilled at 110° (10 mm.).

Anal. Calcd. for $C_6H_{12}O_2S$: C, 48.62; H, 8.16. Found: C, 49.52 H, 8.30.

The solid acid obtained by oxidation melted at 84–85°.

Anal. Calcd. for $C_{12}H_{22}O_4S_2$: C, 48.95; H, 7.53; neut. equiv., 147. Found: C, 49.26; H, 7.79; neut. equiv., 144.

This acid showed no depression in melting point when mixed with a sample of γ,γ'-dithio-bis-isocaproic acid prepared by the method described below.

Preparation of γ,γ'-Dithio-bis-isocaproic Acid.—Fifteen grams of Δ^{β}-isohexenoic acid, prepared according to Goldberg and Linstead,[9] was mixed with about 15 ml. of liquid hydrogen sulfide and 2 g. of flowers of sulfur in a steel bomb and heated at 180° for ten hours. Addition of hydrogen sulfide to olefinic compounds under these conditions has been shown to follow Markownikoff's rule.[10] The residue, after evaporation of the hydrogen sulfide, was dissolved in 100 ml. of ether and washed several times with sodium bicarbonate solution. No γ-mercaptoisocaproic acid was found in the aqueous extract, presumably because of thiolactone formation. The residue from the removal of the ether was refluxed for sixteen hours with 8 g. of sodium carbonate in 100 ml. of water. The mixture was cooled, acidified and extracted with ether. From the ether extract, 7 g. (44%) of γ-mercaptoisocaproic acid, boiling at 107–109° (10 mm.), was obtained. Oxidation by aqueous iodine yielded γ,γ'-dithio-bis-isocaproic acid, melting at 84–85°.

Isocaproic Acid from Compound III.—A Raney nickel-aluminum alloy reduction of 2-imino-3-carbethoxy-5,5-dimethylthiophane by the procedure described by Papa, Schwenk and Whitman[6] gave isobutylmalonic acid which melted at 105–106.5° (lit.[11a] 108°). No depression of melting point was noted when this compound was mixed with an authentic sample. The neutralization equivalent was determined as 80 (calcd. 80). Bromination yielded α-bromoisobutylmalonic acid which decomposed at 134.5–136° (lit.[11b] 139–141°). Isobutylmalonic acid was readily decarboxylated. The resulting isocaproic acid boiled at 198° (lit.[11c] 199.7° at 732 mm.); the anilide melted at 110–111° (lit.[12] 112°), and the *p*-bromophenacyl ester melted at 76–77° (lit.[13] 77°).

Summary

In the presence of sodium ethoxide ethylene sulfide reacts with ethyl cyanoacetate to give 2-imino-3-carbethoxythiophane, the reaction evidently consisting in alkylation followed by cyclization through interaction of the thiol and cyano groups. Propylene sulfide and isobutylene sulfide react similarly to give 2-imino-3-carbethoxy-5-methylthiophane and 2-imino-3-carbethoxy-5,5-dimethylthiophane, respectively.

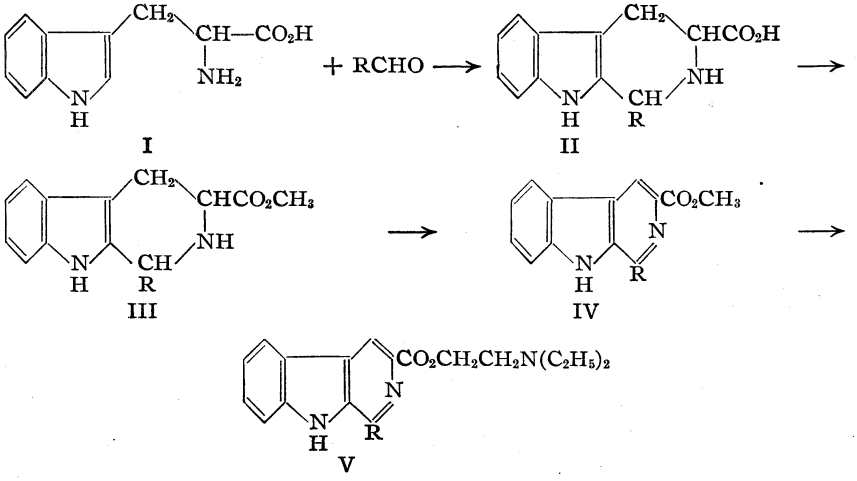
The Synthesis of Derivatives of β-Carboline. II. Syntheses from *dl*-Tryptophan and Aldehydes[1]

BY H. R. SNYDER, CORWIN H. HANSCH,[2] LEON KATZ,[3] STANLEY M. PARMERTER[4] AND EARL C. SPAETH[5]

Although compounds containing the β-carboline nucleus have been of great interest in connection with their occurrence in certain alkaloids, particularly in *Peganum harmala*[6] and *Alstonia constricta*,[7] relatively few synthetic members of this class have been prepared in quantity sufficient for physiological studies. Methods of synthesis have been devised,[6] but comparatively inaccessible raw materials such as *l*-tryptophan and tryptamine have been employed. Since *dl*-tryptophan is now readily available[8] it is of interest to consider its use in the preparation of derivatives of β-carboline.

The condensation of *l*-tryptophan with aldehydes, including formaldehyde, acetaldehyde and benzaldehyde,[9–11] has been extended to the racemic amino acid. The aldehydes which have been employed in the condensation are acetaldehyde, benzaldehyde, phenylacetaldehyde, homoanisaldehyde, *p*-nitrobenzaldehyde, *p*-dimethylaminobenzaldehyde and hydratropic aldehyde (see Table I). The products (formula II) were obtained as mixtures of two racemic modifications in yields of 63–90%. The products from *dl*-tryptophan would not be expected to be identical with those from the natural amino acid. It is of interest that one of the isomers obtained from benzaldehyde and the racemic acid had a melting point (225–226°) near that reported (223–226°) for the product from the optically active amino acid,[9] whereas the products from acetaldehyde differed widely in melting points (247–248 and 258° for the racemic compounds, as compared to 290[10] or 297°[9] for the optically active substance).



The formation of isomers and the tendency to hydration often made the isolation of analytically pure specimens of the tetrahydro acids (II) extremely difficult, but did not interfere with the utilization of the substances in further syntheses. The condensation was unsuccessful when applied to chloral hydrate, chloroacetal or formamide.

The methyl esters, obtained by esterification of the crude acids with methanol and dry hydrogen chloride, also formed hydrates, but in several instances analytically pure samples of the esters were obtained with much less difficulty than had been experienced with the acids. However, the separation of the diastereoisomeric forms proved no less difficult with the esters than with the acids.

The products from acetaldehyde, phenylacetaldehyde and benzaldehyde were dehydrogenated to the fully aromatic compounds (IV, R = CH_3, $C_6H_5CH_2$ and C_6H_5, respectively). Various dehydrogenation procedures were tested on these and other tetrahydro esters, but no satisfactory general procedure was evolved. Methyl 1-methyl-β-carboline-3-carboxylate (IV, R = CH_3) and methyl 1-benzyl-β-carboline-3-carboxylate (IV, R = $C_6H_5CH_2$) were prepared by dehydrogenation with sulfur in refluxing xylene, and methyl 1-phenyl-β-carboline-3-carboxylate was prepared by dehydrogenation with chloranil[12,13] in refluxing tetrachloroethane.

The aromatic acids corresponding to IV were prepared by saponification of the esters. Thionyl

[a] W, water; E, ethanol; M, methanol; I, isopropyl alcohol. [b] Calculated for the anhydrous product. [c] Samples were dried at 100° or above *in vacuo* for many hours. [d] Calculated for the monohydrate. [e] Samples were dried *in vacuo* usually at room temperature. [f] The analytical samples evidently contained varying amounts of water. However, either isomeric acid could be converted to the pure completely aromatized derivative (see text).

chloride proved satisfactory for the conversion of the acids to the chlorides, two of which were treated with β-diethylaminoethanol to give the esters (V, R = CH_3 and C_6H_5, respectively).

The analogy to the conversion of amides of tryptamine to 3,4-dihydro-β-carbolines[14–17] suggested that some of the intermediates of the tryptophan synthesis might be converted directly to β-carboline derivatives. Accordingly, numerous attempts to effect the cyclization of acetyltryptophan and of ethyl α-acetamino-α-carbethoxy-β-(3-indole)-propionate were made. Each substance was heated alone in phenyl ether, with phosphorus oxychloride in benzene, with zinc chloride in acetic anhydride, and with acetaldehyde in water, and the second substance was also heated with phosphorus pentoxide in phenyl ether. The methyl ester of acetyltryptophan also was heated with phosphorus oxychloride in benzene. All these experiments were unsuccessful.

Experimental

A. Preparation of the 1,2,3,4-Tetrahydro-β-carboline-3-Carboxylic Acids (see Table I).—1-Methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid was prepared according to the following modification of the method of Jacobs and Craig.[9] In a one-liter flask connected to a Dry Ice condenser with ground-glass joints were placed 26.39 g. of *dl*-tryptophan (0.13 mole), 132 ml. of 1 *N* sulfuric acid, 350 ml. of water and 70 ml. of freshly-distilled acetaldehyde. This suspension was heated in a water-bath at 50–60° for one hour. The resulting clear solution was then heated directly on the steam-bath for one and one-half hours. The Dry Ice condenser was now removed and heating was continued for four and one-half hours to remove the excess acetaldehyde (hood). The solution was made strongly basic with concentrated ammonium hydroxide, heated for one-half hour on the steam-bath with decolorizing carbon and filtered. The clear yellow filtrate was concentrated to a volume of about 150 ml., and the resulting mixture was cooled at 5° for nine hours. The white to cream-colored crystals were filtered by suction, washed with cold water and dried at 80°. The dry crystals were allowed to stand in the air for thirteen hours until the weight had become constant and the material existed principally as the monohydrate. Concentration of the mother liquor usually caused the separation of additional small quantities of the same material. However, occasionally the material obtained by concentration proved to be higher-melting, and the high-melting isomer (m. p. 258°) was obtained by recrystallization of such samples from water.

1-Phenyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid was prepared according to the general procedure outlined above. It was not necessary to use a Dry Ice condenser, but it was found helpful to stir the reaction mixture with a Hershberg-type stirrer. The reaction mixture consisting of 0.10 mole of tryptophan, 0.11 mole of benzaldehyde, 100 ml. of 1 *N* sulfuric acid, 300 ml. of water and 40 ml. of ethanol (95%) was stirred and heated for four hours. After the addition of 100 ml. of concentrated ammonium hydroxide the mixture was heated with decolorizing carbon for twenty minutes, diluted with 50 ml. of concentrated ammonium hydroxide and filtered. The pale yellow solution was cooled in an ice-bath and extracted with two 75-ml. portions of ether. The aqueous solution was then concentrated and the product isolated as described for the 1-methyl tetrahydro acid. The main product was a methanol-insoluble portion which could be purified by extraction with methanol and recrystallization from dilute ammonia and then from 50% ethanol. The methanol extracts contained small amounts of the low-melting isomer, which was purified by recrystallization from methanol.

1-Benzyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid was prepared from phenylacetaldehyde by the procedure described for the 2-phenyl tetrahydro acid. Fifty per cent. ethanol was used as the solvent for the reaction, and a reaction time of seventeen hours was necessary. Most of the alcohol was removed by distillation at the end of the reflux period prior to purification and isolation of the product.

The preparation of the 1-homoanisyl-, 1-*p*-nitrophenyl-, 1-*p*-dimethylaminophenyl- and 1-α-phenylethyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acids was carried out with essentially the same procedure described for the 1-phenyl tetrahydro acid. The bisulfite addition product of homoanisaldehyde was used satisfactorily in place of the free aldehyde.

B. Preparation of the Methyl 1,2,3,4-Tetrahydro-β-carboline-3-carboxylates (see Table I).—Ten grams of 1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid was suspended in 75 ml. of dry methanol, and the mixture was saturated with dry hydrogen chloride.

(16) Asahina and Osada, *Chem. Zentr.*, **98**, I, 1479 (1927).

(17) Tatsui, *ibid.*, **99**, II, 668 (1928).

After a one-hour reflux period, the solution was concentrated and cooled in an ice-bath. The solid ester hydrochloride was filtered, suspended in water, and treated with an excess of saturated sodium bicarbonate solution. The ester was taken up in ether, and the resulting solution, after drying over magnesium sulfate, was evaporated to yield the crude methyl 1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylate.

The other esters in this series are not very soluble in ether, so the procedure was modified slightly. After the reflux period (two to three hours) the reaction mixture was cooled and poured onto ice and carefully made basic by the slow addition of ammonium hydroxide. The crude ester was then separated and allowed to stand under cold water for one hour. The solid was then filtered by suction, washed well with water, and dried to constant weight at room temperature in a vacuum desiccator.

It has been found that sulfuric acid can be used in place of hydrogen chloride for these esterifications.

C. Dehydrogenation of the Methyl 1,2,3,4-Tetrahydro-β-carboline-3-carboxylates. Preparation of Methyl 1-Methyl-β-carboline-3-carboxylate.—In a 250-ml. flask equipped with a reflux condenser were placed 15.28 g. of methyl 1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylate, 4.16 g. of sulfur and 100 ml. of dry xylene. This mixture was refluxed for four and one-half hours. The evolution of hydrogen sulfide was noted throughout most of the reflux period. A red crystalline solid precipitated on the walls of the flask. The mixture was cooled overnight at 5° and the pink solid was filtered by suction, washed with 40 ml. of cold xylene and then liberally with low-boiling petroleum ether. The yield was 12.69 g. (85%), m. p. 246–248° (dec.). A sample recrystallized from methanol melted at 245°.

Anal. Calcd. for $C_{14}H_{12}N_2O_2$: C, 69.96; H, 5.04; N, 11.66. Found: C, 69.86; H, 5.12; N, 11.67.

Methyl 1-Benzyl-β-carboline-3-carboxylate was prepared by the same method, but in poor yield; m. p. (after three recrystallizations from *n*-butanol) 237–238°.

Anal. Calcd. for $C_{20}H_{16}N_2O_2$: C, 75.93; H, 5.10. Found: C, 76.19; H, 5.14.

Methyl 1-Phenyl-β-carboline-3-carboxylate.—In a 100-ml. flask equipped with a reflux condenser were placed 5.88 g. of methyl 1-phenyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylate,[18] 9.91 g. of chloranil, and 80 ml. of purified *s*-tetrachloroethane. This mixture was heated under reflux for one hour and twenty minutes. The clear dark-colored solution was stored at 5° overnight and the dark crystals which formed were filtered and washed with *s*-tetrachloroethane, the washings being added to the mother liquor. The solid was discarded. The mother liquor was diluted with a large amount of low-boiling petroleum ether (until no further cloudiness resulted) and the solid was collected and washed with low-boiling petroleum ether. The dried material was extracted with 225 ml. of boiling 1 *N* hydrochloric acid in five portions. A small amount of tar remained undissolved. The combined acid extracts were cooled and treated with an excess of solid sodium bicarbonate, and, after cooling for an hour in an ice-bath, the product was filtered, washed well with water, and dried overnight at 80°. The yield was 5.26 g. (91%), m. p. 233–238° (dec.). The melting point could be raised to 252–253° by one recrystallization from *n*-butyl alcohol. After four such recrystallizations the melting point was constant at 254–255°.

Anal. Calcd. for $C_{19}H_{14}O_2N_2$: C, 75.48; H, 4.67. Found: C, 75.21; H, 4.76.

D. Preparation of the β-Carboline-3-carboxylic Acids, their Chlorides and β-Diethylaminoethyl Esters.—The esters were saponified by heating for three to seven hours with 1 *N* aqueous sodium hydroxide (25 ml. per gram of ester). The solutions were decolorized, cooled and acidified with acetic acid, and allowed to stand in the cold until crystallization was complete. 1-Methyl-β-carboline-3-carboxylic acid, m. p. 305–306° after recrystallization from 50% ethanol, apparently retained some water of crystallization even after drying *in vacuo* at 100° for twelve hours.

Anal. Calcd. for $C_{13}H_{10}N_2O_2$: C, 69.01; H, 4.45. Found: C, 66.45, 67.17; H, 4.74, 4.91.

1-Phenyl-β-carboline-3-carboxylic acid melted at 283.5–284° after recrystallization from aqueous dioxane.

Anal. Calcd. for $C_{18}H_{12}O_2N_2$: C, 74.99; H, 4.20. Found: C, 74.86; H, 4.19.

For the preparation of the β-diethylaminoethyl ester of 1-methyl-β-carboline-3-carboxylate the crude acid chloride (made by refluxing for one and one-fourth hours a solution of 1 part of the acid with 10 volumes of purified thionyl chloride, distillation of most of the excess reagent at atmospheric pressure and removal of the last traces by distillation at 25 mm. followed by addition and distillation of benzene) was employed. The acid chloride was stirred on a steam-bath with a large excess (9 ml. per gram of acid used in the preparation of the chloride) of freshly distilled diethylaminoethanol for five hours. The mixture was poured on ice, treated with concentrated ammonia, and diluted with water to a volume of ten times that of the diethylaminoethanol. The mixture was allowed to stand in an ice-bath for three hours, after which the solid was collected. It was recrystallized from a mixture of benzene and low-boiling petroleum ether to give a product of m. p. 168.5–170° in 74% yield. Samples purified by recrystallization from benzene–petroleum ether or from alcohol–water appeared to retain water of crystallization. A sample (m. p. 169.5–170°) dried by distillation of most of the benzene from a dilute benzene solution of the substance, followed by precipitation with petroleum ether, was anhydrous.

Anal. Calcd. for $C_{19}H_{23}O_2N_3$: C, 70.13; H, 7.12. Found: C, 69.92; H, 7.05.

β-Diethylamino 1-phenyl-β-carboline-3-carboxylate, m. p. 185–186.5°, was obtained in 86% yield by the same procedure. Recrystallization from benzene and low-boiling petroleum ether raised the melting point to 186–187°. Traces of colored materials which resisted the action of Darco on the benzene solution could be removed by decolorization of a solution in 95% ethanol. The last traces of water were removed from the analytical sample by distillation with benzene as described above.

Anal. Calcd. for $C_{24}H_{25}O_2N_3$: C, 74.39; H, 6.50. Found: C, 74.17; H, 6.36.

Summary

The preparation of a number of 1,2,3,4-tetrahydro-β-carboline-3-carboxylic acids by the condensation of *dl*-tryptophan with aldehydes is described. Certain carboline-3-carboxylic acids are prepared by dehydrogenation of the aldehyde-tryptophan condensation products, and the β-diethylaminoethyl esters of 1-methyl and 1-phenyl-β-carboline-3-carboxylic acid are described.

URBANA, ILLINOIS RECEIVED JULY 17, 1947

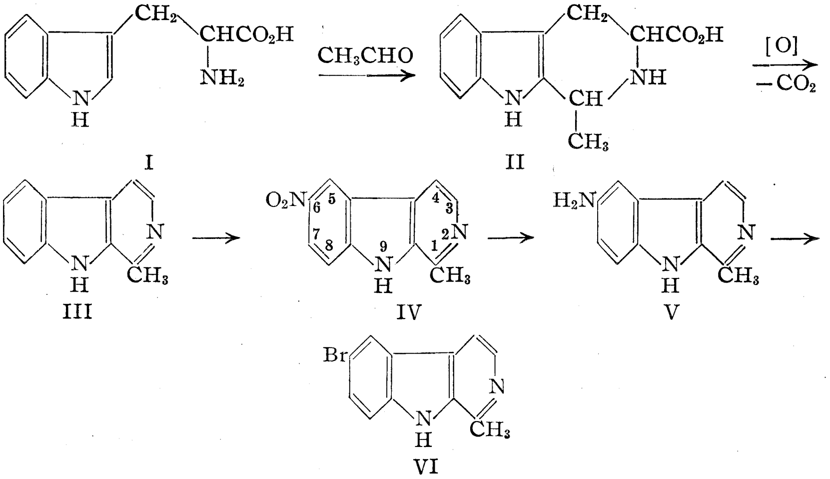
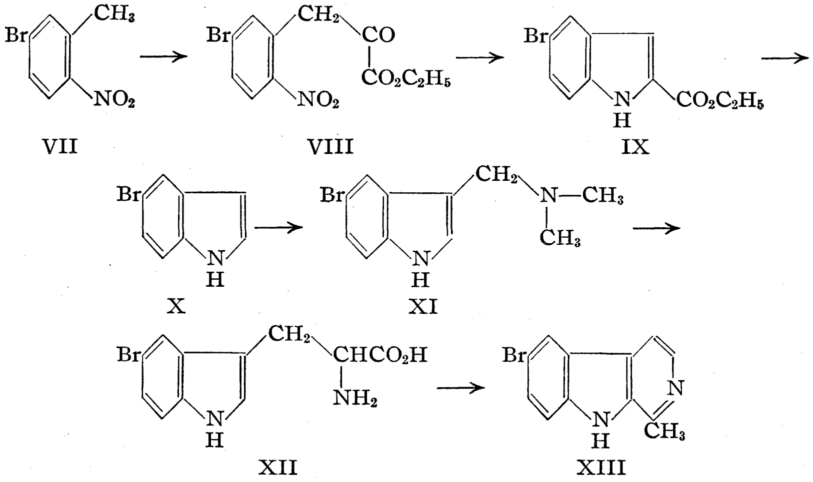
The Synthesis of Derivatives of β-Carboline. III. The Nitration of Harman[1]

BY H. R. SNYDER, STANLEY M. PARMERTER[2] AND LEON KATZ[3]

The preparation of harman (III) by the condensation of tryptophan (I) with acetaldehyde, followed by aromatization, oxidation and decarboxylation in a single step through the action of potassium dichromate,[4] becomes a practical synthetic method when the readily available *dl*-tryptophan is employed as the raw material.[1] It is therefore desirable to examine the substitution reactions of harman, some of which might be expected to lead to compounds of physiological interest. The present report is concerned with the preparation of two isomeric nitroharmans by direct nitration and with the proof of the structure of one of them (IV).





The preparation of harman (III) was carried out according to the method of Harvey and Robson,[4] except for the use of the racemic amino acid, without isolation of any of the intermediates and in 67% yield. The nitration was effected with the aid of concentrated nitric acid at temperatures of 40° or below. The higher-melting nitro derivative, now shown to be 6-nitroharman (IV), was formed in the larger amount (57%); the lower-melting isomer, presumably 8-nitroharman, was isolated in a yield of about 20%.

The higher-melting nitro compound (IV) was reduced to the amine (V) which proved not to be identical with the known 7-aminoharman.[5] Diazotization of the amine (V) was accomplished, and since both 6- and 8-methoxyharman are known, the conversion of the diazonium compound to the methyl ether should have sufficed to demonstrate the structure of IV. However, attempts to replace the diazonium group by methoxyl, either directly or by way of the hydroxy compound, have been unsuccessful.

It was possible to convert the diazonium compound to the bromo compound (VI), so an unequivocal synthesis of any of the compounds IV, V or VI would serve to confirm the identity of the high-melting nitro compound. The bromoharman (VI) was synthesized by the series of reactions shown in the accompanying chart. The 2-nitro-5-bromotoluene condensed readily with ethyl oxalate in the presence of potassium ethoxide to give the potassium salt of VIII, and this salt was reduced directly to the bromoindolecarboxylic ester (IX). The acid obtained by saponification of the ester IX proved unexpectedly resistant to decarboxylation. Of a number of decarboxylation procedures tested only vigorous heating with copper

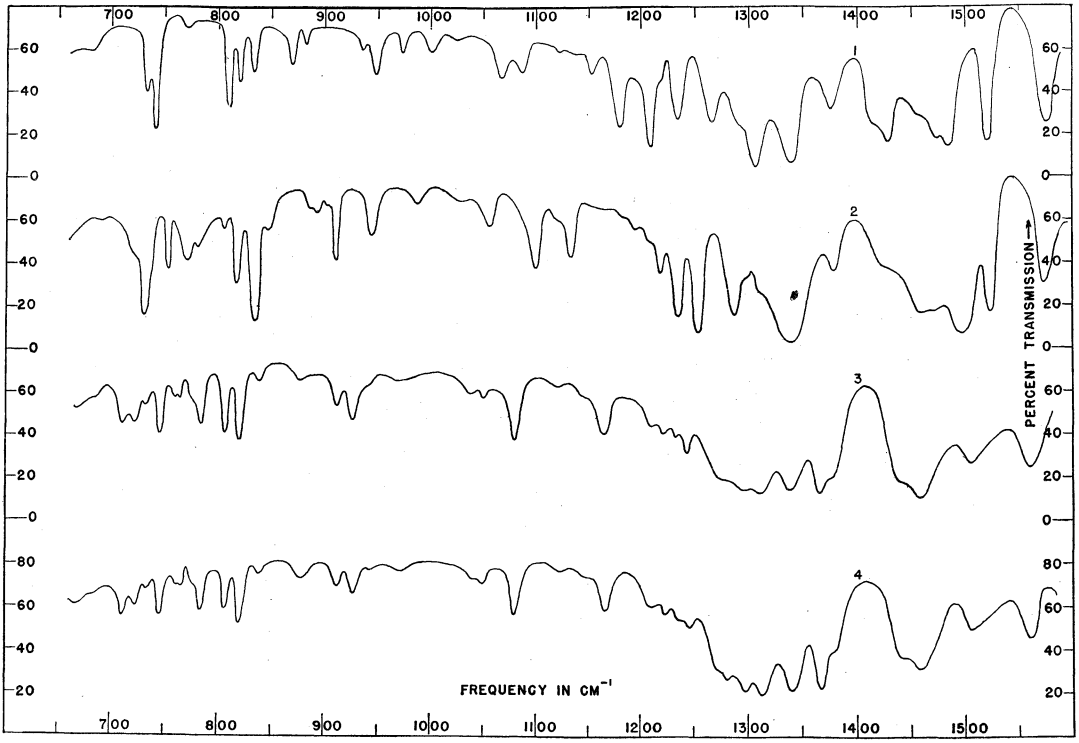

Fig. 1.—1, Nitroharman; m. p. 210°; 2, nitroharman; m. p. 301°; 3, picrate of 6-bromoharman; 4, picrate of bromoharman prepared from high-melting nitro isomer.

and copper chromite catalyst gave yields (*ca.* 20%) high enough to permit continuation of the projected series of reactions. This treatment apparently resulted in removal of bromine from some of the product, and the 5-bromoindole (X) so prepared could not be purified sufficiently for a satisfactory combustion analysis. 5-Bromoindole (X) of high purity could be obtained, but in very poor yield, by heating the ammonium salt of the acid in glycerol. It was found that the picrate of 5-bromogramine, prepared from the crude 5-bromoindole, could be obtained in the analytically pure state, so the synthesis was continued and the picrate of the 6-bromoharman (XIII) was prepared. This picrate was obtained in analytically pure state. The melting point of the picrate of the 6-bromoharman so obtained was identical with that of the picrate of the bromoharman prepared from the nitro compound (IV). A much more striking proof of the identity of the two picrates was obtained by comparison of the infrared absorption spectra of the two samples. The absorption curves[6] (Figs. 1 and 2) were identical in every detail.

Experimental

Harman (2-Methyl-β-carboline) (III).—The general procedure of Harvey and Robson[4] was followed. Twenty-five grams of *dl*-tryptophan and 50 ml. of freshly distilled acetaldehyde were added to 1 liter of water. The suspension was heated at 50–60° in a loosely-stoppered flask for three hours and then left at room temperature overnight. The resulting suspension was heated on a steam-bath to remove excess acetaldehyde, diluted to a volume of 6 l. and heated to boiling. To the hot solution was added 1200 ml. of 10% aqueous potassium dichromate and 240 ml. of glacial acetic acid. The brown suspension was heated for two to three minutes and then cooled under the tap. After treating the cold solution with sodium sulfite to remove the excess oxidizing agent, the mixture was made definitely alkaline with solid sodium carbonate. The solution was extracted exhaustively with ether (5–6 liters), the extracts dried over magnesium sulfate, and the solvent removed. The residue of crystalline harman, m. p. 228–230°, weighed 15.1 g. (67%).

6-Nitroharman (IV).—Crude harman was added slowly with stirring to concentrated nitric acid (10 ml. per g.). The temperature was held below 40° by occasional cooling. Most of the harman dissolved, and a light yellow solid separated. The mixture was stirred for one hour and filtered. The solid was suspended in dilute ammonium hydroxide to neutralize the nitric acid. The crude nitroharman was collected and dissolved in the minimum amount of hot pyridine. As the pyridine cooled, yellow needles separated. Concentration of the pyridine solution to half its original volume yielded an additional crop of needles. The total yield of nitroharman, m. p. 293–295°, was 57.1%. A sample recrystallized from 95% ethanol separated as clusters of yellow needles, m. p. 299–300°. The compound was soluble in acetic acid and pyridine, somewhat soluble in methanol and ethanol, and insoluble in water.

Anal. Calcd. for $C_{12}H_9N_3O_2$: C, 63.45; H, 3.99. Found: C, 63.66; H, 4.09.

Addition of water to the nitric acid used in the nitration gave additional quantities of yellow solid. This was collected and treated with ammonia to yield a lower-melting nitroharman. After recrystallization from 95% ethanol, it melted at 209–210°. It separated as octahedra or short needles. Dilution of the pyridine mother liquor

---

[6] The authors are indebted to Mrs. Agatha Roberts Johnson for the infrared study.

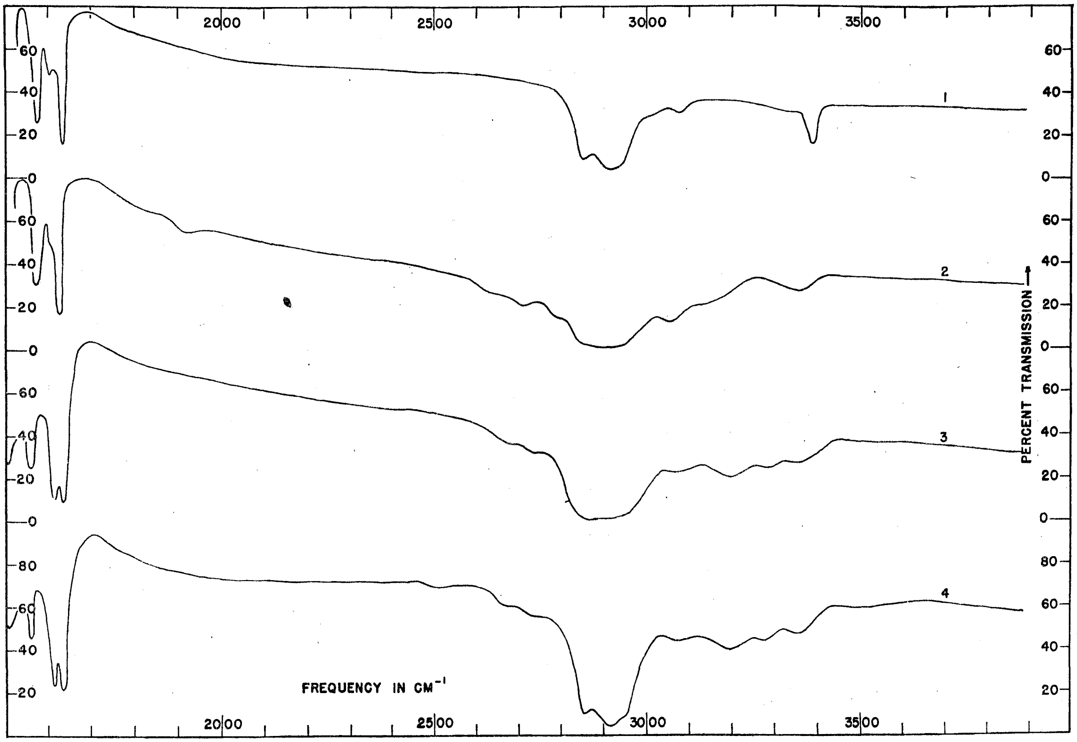

Fig. 2.—1, Nitroharman; m. p. 210°; 2, nitroharman; m. p. 301°; 3, picrate of 6-bromoharman; 4, picrate of bromoharman prepared from high-melting nitro isomer.

yielded additional amounts of this isomer, the total yield being 19.5%.

Anal. Calcd. for $C_{12}H_9N_3O_2$: C, 63.45; H, 3.99. Found: C, 63.59; H, 4.27.

6-Aminoharman (V).—To a solution of 2.2 g. of stannous chloride dihydrate in 2.5 ml. of concentrated hydrochloric acid and 10 ml. of water was added 0.5 g. of high-melting nitroharman. The solution was refluxed two hours and cooled in ice. The yellowish-green salt was collected and suspended in excess 10% aqueous sodium hydroxide to free the base. The solid was collected and washed with water. The yield of crude amine melting at 265–267° was 0.35 g. or 80% of the theoretical amount. After a second recrystallization, the light tan crystals melted at 269–271°. The base slowly darkens on exposure to air, and its solutions rapidly become deep red in color.

Anal. Calcd. for $C_{12}H_{11}N_3$: C, 73.09; H, 5.62. Found: C, 73.12; H, 5.57.

6-Bromoharman (VI).—A cold solution of 0.394 g. of aminoharman in 1.5 ml. of water and 1 cc. of 40% hydrobromic acid was diazotized by the addition of a solution of 0.15 g. sodium nitrite in 0.5 ml. of water. The diazonium salt partially crystallized. The suspension of diazonium salt was transferred to a hot solution of 0.158 g. of cuprous bromide in 0.3 ml. of 40% hydrobromic acid. Heating on a steam-bath for ten minutes caused evolution of gas and the separation of a green solid, which was collected and suspended in dilute ammonium hydroxide. The free amine was then recrystallized from 25 ml. of 50% ethanol. Pale yellow needles melting at 241–244° separated. When these were recrystallized from benzene, they separated as needles which slowly changed to pale yellow plates. Both crystalline forms melted at 246–247°.

Anal. Calcd. for $C_{12}H_9N_2Br$: C, 55.20; H, 3.47. Found: C, 55.40; H, 3.69.

The picrate, prepared for analysis by recrystallization from absolute ethanol, melted at 291–293° (dec.).

Anal. Calcd. for $C_{12}H_9N_2Br{\cdot}C_6H_3N_3O_7$: C, 44.08; H, 2.45. Found: C, 44.39; H, 2.73.

2-Nitro-5-aminotoluene.—The procedure of Fieser[7] for acetylation, nitration and deacetylation of aniline was followed, with *m*-toluidine obtained from Eastman Kodak Company. From 102 g. of *m*-toluidine, 79.5 g. of 2-nitro-5-aminotoluene, m. p. 130–132° (lit.,[8] 137–138°) was obtained.

2-Nitro-5-bromotoluene (VII).—A modification of the method of Geerling and Wibaut[9] was employed. To a finely divided suspension of 25 g. of 2-nitro-5-aminotoluene in a cold solution of 80 ml. of 48% hydrobromic acid and 150 ml. of water, was added a solution of 11.5 g. of sodium nitrite in 30 ml. of water. The solution of the diazonium salt was filtered and run rapidly into a hot (75°) cuprous bromide solution prepared by boiling 20 g. of copper oxide, 20 g. of copper powder, 100 ml. of 48% hydrobromic acid and 80 ml. of water. The solution was stirred manually and then heated on a steam-bath for one-half hour. The 2-nitro-5-bromotoluene was isolated by steam distillation. The yield was 26 g. (75%); m. p. 55–56° (lit.,[10] 56°).

Potassium Salt of Ethyl 2-Nitro-5-bromophenylpyruvate (VIII).—A strong solution of potassium ethoxide was prepared by cautiously adding 3.2 g. of crust-free potassium to a mixture of 5 ml. of dry ether and 10 ml. of absolute alcohol; when the first violent reaction had subsided, 17 ml. of absolute alcohol was added and the solution was heated gently, if necessary, to effect complete solution of the metal. The solution was then cooled and diluted with 125 ml. of dry ether, and to this solution was added 12.3 g. of ethyl oxalate, followed fifteen minutes later by 15 g. of 2-nitro-5-bromotoluene. The solution was shaken gently and allowed to stand overnight. The red salt was collected, washed with dry ether, and used immediately. The yield was almost quantitative (24.5 g.).

5-Bromoindole-2-carboxylic Acid.—The above salt, 28 g., was suspended in a solution of 170 ml. of concentrated aqueous ammonia (sp. gr., 0.880) and 200 ml. of water. To the bright red suspension was added, with stirring, a hot solution of 180 g. of ferrous sulfate heptahydrate in 200 ml. of water. The mixture was heated on a steam-bath for one-half hour and then boiled for one-half hour. The suspension was filtered while hot, and the sludge was extracted three times by boiling the filter cake with 500 ml. of water and filtering. The filtrates were cooled and acidified with concentrated hydrochloric acid. A voluminous white precipitate was formed, but the solution was allowed to stand in a refrigerator at 5° overnight before filtration. The yield of white solid, m. p. 270–273°, was 9 g., 42.5%. A sample was sublimed for analysis; m. p. 279–280°.

Anal. Calcd. for $C_9H_6NO_2Br$: C, 44.98; H, 2.53. Found: C, 44.71; H, 2.73.

The ethyl ester (IX) was obtained by extraction of the dried ferric oxide sludge with ether in a Soxhlet extractor for seventy-two hours. Removal of the solvent yielded 2.7 g. of material; m. p. 162–164°. A sample was prepared for analysis by recrystallization from 95% ethanol; m. p. 165°.

Anal. Calcd. for $C_{11}H_{10}NO_2Br$: C, 49.25; H, 3.76. Found: C, 49.42; H, 3.75.

5-Bromoindole (X).—Two grams of 5-bromoindole-2-carboxylic acid, 1 g. of copper bronze and 1 g. of copper chromite catalyst were intimately mixed and placed in a large test-tube. The test-tube was flushed three times with nitrogen, placed in a metal block, and heated at 247 ± 10° for one and one-half to two hours. A white sublimate of fine needles collected in the upper portion of the tube which was kept cool throughout the heating period. The yield of 5-bromoindole, m. p. 77–82°, was 0.35–0.4 g. (21–24%). Small amounts of sublimed acid were present as an impurity. The use of amounts larger than 3 g. resulted in lowered yields. A sample was resublimed for analysis; m. p. 85.5–86°.

Anal. Calcd. for C_8H_6NBr: C, 48.98; H, 3.06. Found: C, 50.75; H, 3.22.

When the ammonium salt was decarboxylated by heating in glycerol, a small amount of material sublimed into the condenser. This was collected and recrystallized from 50% ethanol; m. p. 88.5–89°.

Anal. Calcd. for C_8H_6NBr: C, 48.98; H, 3.06. Found: C, 49.34; H, 3.29.

5-Bromogramine (XI).—To 7.6 g. of dimethylamine (25%) at 5° was added 6 g. of glacial acetic acid. To this solution, cooled to 5°, was added 3.2 g. of formalin (40%). The solution was agitated mildly and added to 7.5 g. of crude 5-bromoindole. A slight exothermic reaction occurred. The resulting straw-colored solution was kept at room temperature for ten hours and poured into 40 ml. of 10% sodium hydroxide, cooled in an ice-bath. The white precipitate was filtered, yielding 7.8 g. (79%) of crude XI; m. p. 143–145°. A sample subjected to repeated recrystallization from acetone–water melted sharply at 149.5–150°, but still evidently contained bromine-free impurities.

Anal. Calcd. for $C_{11}H_{13}N_2Br$: C, 52.17; H, 5.18. Found: C, 54.12; H, 5.28.

The picrate prepared from the crude 5-bromogramine was purified by recrystallization from ethanol; it melted at 174°.

Anal. Calcd. for $C_{11}H_{13}N_2Br \cdot C_6H_3N_3O_7$: C, 42.32; H, 3.33. Found: C, 42.52; H, 3.42.

Condensation of the Crude 5-Bromogramine with Acetamidomalonic Ester.—The condensation was run in xylene according to the procedure of Howe, Zambito, Snyder and Tishler,[11] and the condensation product was converted to the amino acid by the method of Snyder and Smith.[12] The carbon and hydrogen contents of the intermediates and of the 5-bromotryptophan all were high (see the analysis of the bromogramine above).

6-Bromoharman.—Sixty-five milligrams of 5-bromotryptophan (m. p. 264–267°, dec.) was suspended in 7 ml. of hot water and treated with 20 drops of freshly distilled acetaldehyde and 3 drops of 6 *N* sulfuric acid. The solution was heated on a water-bath for one hour, cooled, treated with 5 drops of acetaldehyde and left at room temperature for twelve hours. The cloudy solution was concentrated on a steam-bath and cooled. Opaque crystals, m. p. 218–220°, were deposited. This acid was dissolved in 15 cc. of hot water and treated with 3.5 cc. of 10% potassium dichromate and 0.5 cc. of glacial acetic acid. The solution was boiled for two minutes, made alkaline with solid sodium carbonate, and extracted with ether. Removal of ether yielded 35 mg. of solid; m. p. 227–230°. Repeated crystallization from benzene raised the melting point to 234–235°.

The picrate was prepared and recrystallized repeatedly from absolute ethanol. The analytical sample thus prepared melted with decomposition at 291–293°, alone or mixed with the picrate of 6-bromoharman (VI) prepared from the nitroharman (IV).

Anal. Calcd. for $C_{12}H_9N_2Br \cdot C_6H_3N_3O_7$: C, 44.08; H, 2.45. Found: C, 44.29; H, 2.76.

Summary

Harman is conveniently prepared by the condensation of *dl*-tryptophan with acetaldehyde, followed by aromatization and decarboxylation of the condensation product. The nitration of harman by concentrated nitric acid at moderate temperatures leads to two isomeric mononitro derivatives; the nitro derivative produced in the larger amount is shown to be 6-nitroharman.

The Synthesis of Quinolines from Aryloxyketones by the Method of Pfitzinger

BY ARTHUR M. DOWELL, JR.,[1] HOWARD S. MCCULLOUGH AND PAUL K. CALAWAY

In a recent investigation[2] in this Laboratory we have utilized the tolylthiopropanones in the preparation of substituted quinoline acids by the method of Pfitzinger.[3] The availability of the cresols suggested the preparation of the toloxypropanones[4] and their ultimate condensation with isatin and 5-methylisatin, respectively, to produce six substituted cinchoninic acids. We have studied also the condensation of 5-methylisatin with both α- and β-naphthoxyacetone.[5]

In previous papers[6,7] it has been demonstrated that the product of condensation of isatin with aryloxy ketones has been the 3-aryloxy-4-quinaldinecarboxylic acid rather than the isomeric 2-aryloxymethylcinchoninic acid.

The aryloxy ketones used in this investigation were prepared from the corresponding phenols and chloroacetone by the method of Hurd and Perletz.[8] The yields ranged from 57% of the theoretical, in the case of the *m*-toloxyacetone, to 97% for the β-naphthoxyacetone.

The potassium salts of the quinaldinecarboxylic acids prepared showed a tendency to foam in water solution and were salted out by high concentrations of potassium hydroxide. All of the acids exhibited a tendency to hold water of crystallization.[2] This water was removed by drying for several days in a vacuum desiccator over phosphorus pentoxide. Decarboxylation of the compounds was observed to start around 175°; hence melting point values varied with the rate of heating.

Experimental

Preparation of Aryloxyacetones.—The procedure used for the condensation of chloroacetone with phenols was based on the method of Hurd and Perletz.[8]

To a vigorously stirred and refluxing suspension of 0.41 mole of the phenol and 57 g. (0.41 mole) of anhydrous potassium carbonate in 150 ml. of dry acetone was added over a period of one hour a solution of 50 g. (0.54 mole) of chloroacetone and 3 g. of powdered potassium iodide in 50 ml. of dry acetone. The chloroacetone solution had been allowed to stand for twenty-four hours prior to addition. After refluxing for six hours, stirring was continued at room temperature for an additional twenty hours. The mixture was subjected to filtration, the precipitate washed well with dry acetone and the filtrate and washings combined. The solvent was distilled off and the residue distilled under diminished pressure. Table I contains the data on these preparations.

TABLE I

ARYLOXYACETONES, $ArOCH_2COCH_3$

ArO	B. p. or m. p., °C.	Pressure, mm.	Yield, %
p-Toloxy	108–112	6	58
m-Toloxy	110–111	5	57
o-Toloxy	105–106	5	71
α-Naphthoxy	156–165	9	31
β-Naphthoxy	72–73		97

Preparation of 3-*m*-Toloxy-4-quinaldinecarboxylic Acid.—Seven and thirty-five hundredths grams (0.05 mole) of isatin was dissolved in 125 ml. of 33% aqueous potassium hydroxide solution, and 8.2 g. (0.05 mole) of *m*-toloxyacetone was added. The resulting mixture was heated under reflux on the steam-bath for six hours, and, upon cooling, a solid cake of potassium 3-*m*-toloxy-4-quinaldinecarboxylate separated. The latter was disintegrated and dissolved in 500 ml. of hot water. The resulting solution was boiled with Nuchar, filtered, cooled in ice and the crude acid precipitated by the addition of acetic acid (1:1). The quinoline acid was separated by filtration, suspended in 500 ml. of hot water, and converted into the soluble potassium salt by the addition of the calculated amount of 33% potassium hydroxide solution. The solution was again treated with Nuchar, filtered, and made barely acidic by the addition of acetic acid. The quinoline acid was separated by filtration, washed twice with 100-ml. portions of cold water, suspended in 400 ml. of boiling water for forty-five minutes, and filtered while hot. Nine and eight-tenths grams (67% yield) of the 3-*m*-tolyloxy-4-quinaldinecarboxylic acid was obtained. The product melted with decomposition at 224°. Dried over anhydrous calcium chloride the acid retained two molecules of water of hydration (as indicated by analytical data for nitrogen content). This water was removed by drying over phosphorus pentoxide in a vacuum desiccator.

The remaining 3-toloxy-4-quinaldinecarboxylic acids were formed in essential accordance with this general procedure. Table II contains the data on these preparations.

TABLE II

3-ARYLOXY-4-QUINALDINECARBOXYLIC ACIDS

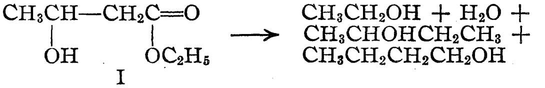
Hydrogenolysis of β-Oxygenated Esters to Glycols

BY RALPH MOZINGO AND KARL FOLKERS

Under the usual conditions for ester reduction,[1] esters containing negative substituents in the β-position to the carboalkoxy group do not give rise to the corresponding alcohols when submitted to hydrogenolysis[2] over copper–chromium oxide catalyst.[3] Under these conditions cleavage products result. However, it has now been found that with these compounds satisfactory ester hydrogenolysis, without additional cleavage at other points, may be accomplished when modified conditions are used.

When ethyl β-hydroxybutyrate is hydrogenated at 250° over copper–chromium oxide under hydrogen at 150–400 atmospheres, the final products obtained are ethyl alcohol, *n*-butyl alcohol and *s*-butyl alcohol,[4] according to the following scheme in which the bonds undergoing hydrogenolysis are indicated by lines.



$$\underset{\text{I}}{\underset{|\atop OH}{CH_3CH}-CH_2\underset{|\atop OC_2H_5}{C}{=}O} \longrightarrow \begin{array}{l} CH_3CH_2OH + H_2O + \\ CH_3CHOHCH_2CH_3 + \\ CH_3CH_2CH_2CH_2OH \end{array}$$

It would appear, however, that the reaction may take the course

$$\begin{array}{l} CH_3CHOHCH_2CO_2C_2H_5 \longrightarrow CH_3CHOHCH_2CH_2OH + C_2H_5OH \\ CH_3CHOHCH_2CH_2OH \longrightarrow CH_3CHOHCH_2CH_3 \text{ or } CH_3CH_2CH_2CH_2OH + H_2O \\ \qquad\qquad\qquad\qquad\quad \text{or} \\ \qquad\qquad\qquad\qquad\quad \longrightarrow 2C_2H_5OH \end{array}$$

If the reaction does proceed stepwise and the glycol is not isolated because the second reaction is the more rapid under the conditions which have been used and if sufficiently mild conditions can be found for the hydrogenation, it seems reasonable to expect that some of the glycol might be isolated. Such conditions were found and it was possible to isolate the glycol in reasonable yields.

Since, at any pressure above a certain minimum which is characteristic of the compound being hydrogenated, the effect of temperature is probably the greatest factor in controlling the hydrogenation products, lower temperatures of reaction seemed desirable. It had been demonstrated[5] that the hydrogenation of esters of certain sugar acids at 75° gives rise to the corresponding sugar alcohols. Ethyl α-hydroxyisobutyrate is hydrogenated at 200°.[6] Further, it had been shown that ethyl benzilate is hydrogenated rapidly to the corresponding 1,2-glycol at 125°.[7] In the last case this has been postulated to be due to tautomerization, and the same might be the controlling factor in all of these cases, since each ester contains an α-hydroxyl. The β-hydroxy esters cannot undergo such enolization, but must be hydrogenated in the ester form.

The hydrogenation of β-oxygenated esters was found to proceed smoothly at temperatures between 150 and 180° when relatively large amounts of copper–chromium oxide catalyst[3] were used. The hydrogenation of the β-oxygenated esters appears to be more satisfactory at higher hydrogen pressures (250–400 atmospheres) since the reactions are rather slow. The hydrogenolysis was carried out most successfully in methyl alcohol, which is quite contrary to the general practice when temperatures in excess of 220° are used for ester reduction.[8] For example, ethyl β-hydroxybutyrate (I) (or ethyl acetoacetate)[9] was hydrogenated to 1,3-butylene glycol (II) in 30% yield and ethyl β-ethoxypropionate (III) was converted into 3-ethoxy-1-propanol (IV) in 78% yield.

$$\underset{\text{I}}{CH_3CHOHCH_2CO_2C_2H_5} \longrightarrow \underset{\text{II}}{CH_3CHOHCH_2CH_2OH + C_2H_5OH}$$

$$\underset{\text{III}}{C_2H_5OCH_2CH_2CO_2C_2H_5} \longrightarrow \underset{\text{IV}}{C_2H_5OCH_2CH_2CH_2OH + C_2H_5OH}$$

Likewise, α-alkyl and α-alkylidine acetoacetic esters gave rise to the corresponding 1,3-glycols. Ethyl α-isobutylideneacetoacetate (V) and ethyl ethylacetoacetate (VI) were converted under these conditions into 2-isobutyl-1,3-butylene glycol (VII) and 2-ethyl-1,3-butylene glycol (VIII), respectively. Both of the racemic forms of these two glycols were formed in the reduction and were separated through their *p*-nitrobenzoyl derivatives.

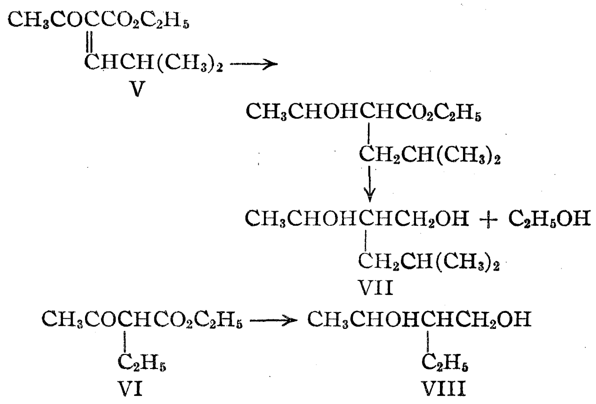
[8] Lazier, U. S. Patent 2,079,414 (May 4, 1937.)

[9] Since it has been demonstrated that the β-keto esters are converted rapidly to β-hydroxy esters below the temperature used here, the keto esters may be used (see Connor and Adkins, THIS JOURNAL, **53**, 1091 (1931)).



$$\underset{\text{V}}{CH_3COC(=CHCH(CH_3)_2)CO_2C_2H_5} \longrightarrow CH_3CHOHCH(CH_2CH(CH_3)_2)CO_2C_2H_5 \longrightarrow \underset{\text{VII}}{CH_3CHOHCH(CH_2CH(CH_3)_2)CH_2OH} + C_2H_5OH$$

$$\underset{\text{VI}}{CH_3COCH(C_2H_5)CO_2C_2H_5} \longrightarrow \underset{\text{VIII}}{CH_3CHOHCH(C_2H_5)CH_2OH}$$

The esters of the alkylmalonic acids (IX) were hydrogenated to 2-alkyl-1,3-propanediols (X).

$$\underset{\text{IX}}{C_2H_5O_2CCHRCO_2C_2H_5} \longrightarrow HOCH_2CHRCO_2C_2H_5 \longrightarrow \underset{\text{X}}{HOCH_2CHRCH_2OH}$$

Ethyl benzylmalonate, ethyl *s*-butylmalonate and ethyl ethylmalonate were converted into the corresponding 1,3-glycols in 26, 24 and 49% yields, respectively.

These results indicate that the β-oxygenated esters, such as acetoacetic esters, malonic esters and the like, may be converted into the corresponding 1,3-glycols (or their esters) as a general convenient preparative method. While many of the yields reported are low, the method offers a convenient way for the preparation of glycols. The yields reported are usually based upon a single run on each of the esters; no attempt has been made to obtain the maximum yield. The present experiments were merely intended to show that such products can be obtained.

Experimental

Copper–Chromium–Barium Oxide Catalyst.—The catalyst was prepared in the usual way.[3] The decomposition of the ammonium salts was done at the minimum temperature. The catalyst contained barium.

Purification of the Esters.—The esters were distilled over Raney nickel catalyst[10] before use.

Ethyl Isobutylideneacetoacetate.—This ester was prepared in 49% yield by a method for the preparation of ethyl butylideneacetoacetate.[11] The ester boiled at 79–80° at 2 mm.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.76. Found: C, 65.46; H, 9.21.

Hydrogenation of β-Oxygenated Esters.—The various esters were each hydrogenated in methyl alcohol over copper–chromium oxide under 250–400 atmospheres of hydrogen at about 160–180° in a manganese steel bomb. The exact temperature, amount of reactants, time, etc., are listed for each ester.

The product was isolated in each case by a standard method. The contents of the bomb was washed out with methyl alcohol and filtered. To the filtrate was added 1.5 equivalents of sodium or potassium hydroxide based on the amount of ester submitted to reduction and about 100 ml. of water. The mixture was then refluxed several hours to saponify any unconverted ester. The methyl alcohol was distilled. The aqueous solution was extracted with chloroform in a continuous extractor to remove the glycol. The chloroform solution was concentrated, and the residue was fractionated.

The liquid glycols and alcohols were converted into their *p*-nitrobenzoates for characterization.

Hydrogenation of Ethyl Acetoacetate.—Sixty-five grams of ethyl acetoacetate in 200 ml. of methyl alcohol was reduced to ethyl β-hydroxybutyrate at 125–140° with 30 g. of copper–chromium oxide for fifteen minutes under 100 atmospheres of hydrogen. The bomb was then cooled, and the pressure drop was the expected amount for one mole of hydrogen. The pressure was then increased to 250 atmospheres and the hydrogenation allowed to proceed at 166–170° for nine hours.

The 1,3-butylene glycol, b. p. 115–120° at 21 mm., obtained after saponification, weighed 13.6 g. (30%). The *p*-nitrobenzoate of the 1,3-butylene glycol melted at 101–102°.

Anal. Calcd. for $C_{18}H_{16}O_8N_2$: C, 55.67; H, 4.12; N, 7.21. Found: C, 55.75; H, 4.13; N, 7.18.

Hydrogenation of Ethyl Isobutylideneacetoacetate.—A solution of 43 g. of ethyl isobutylideneacetoacetate in 100 ml. of methyl alcohol was hydrogenated at 160° and 3400–4600 p. s. i. for thirty hours.

The 2-isobutyl-1,3-butylene glycol, b. p. 142–143° at 22 mm., weighed 6 g. (17%).

Anal. Calcd. for $C_8H_{18}O_2$: C, 65.71; H, 12.41. Found: C, 65.62; H, 12.32.

The di-*p*-nitrobenzoate of this glycol was prepared and found to be a mixture of the two racemic modifications. The product was repeatedly extracted with hot methyl alcohol. The methyl alcohol extracts were concentrated and then cooled. After several recrystallizations from methyl alcohol, this *p*-nitrobenzoate melted at 129–130°.

Anal. Calcd. for $C_{22}H_{24}O_8N_2$: C, 59.45; H, 5.45; N, 6.30. Found: C, 59.69; H, 5.54; N, 6.49.

The methyl alcohol insoluble residue was recrystallized from acetone to give the second form of the *p*-nitrobenzoate, m. p. 158–159°.

Anal. Calcd. for $C_{22}H_{24}O_8N_2$: C, 59.45; H, 5.45. Found: C, 59.31; H, 5.62.

From the water solution, there was isolated 23.8 g. of acidic material which was fractionated to give 16.1 g. (43%) of β-hydroxy-α-isobutylbutyric acid which after crystallization melted at 68–70°.

Anal. Calcd. for $C_8H_{16}O_3$: C, 59.97; H, 10.07. Found: C, 60.28; H, 10.30.

In another similar run, 8.4 g. (25%) of the glycol was obtained from 27.6 g. of the ester.

Hydrogenation of Ethyl Ethylacetoacetate.—A solution of 23.7 g. of ethyl ethylacetoacetate in 100 ml. of methyl alcohol was hydrogenated at 160–168° and 5000–5300 p. s. i. over 5 g. of copper–chromium oxide for eleven hours.

Fractionation of the chloroform extract gave 2.6 g. (15%) of 2-ethyl-1,3-butylene glycol, b. p. 110–120° at 21 mm., which was identified by conversion into its di-*p*-nitrobenzoate. The glycol was a mixture of both of the racemic modifications since it gave two *p*-nitrobenzoyl derivatives. These were separated by extraction with methyl alcohol as above. The methyl alcohol soluble fraction melted at 124–125° (from methyl alcohol).

Anal. Calcd. for $C_{20}H_{20}O_8N_2$: C, 57.69; H, 4.84; N, 6.73. Found: C, 57.60; H, 4.79; N, 6.98.

The second *p*-nitrobenzoate was recrystallized from acetone and melted at 139–140°.

Anal. Calcd. for $C_{20}H_{20}O_8N_2$: C, 57.69; H, 4.84; N, 6.73. Found: C, 58.05; H, 5.17; N, 7.05.

Hydrogenation of Ethyl β-Ethoxypropionate.—A solution of 146 g. of ethyl β-ethoxypropionate in 100 ml. of methyl alcohol was hydrogenated over 30 g. of copper–chromium oxide at 168–172° and 4200–6350 p. s. i. for twenty-three hours.

The 3-ethoxy-1-propanol, b. p. 160–161°, obtained as above, weighed 81.2 g. (78%). The usual esters of this

(11) Cope and Hofmann, THIS JOURNAL, **63**, 3456 (1941).

glycol appear to be liquids, but its boiling point agrees with the recorded value.[12]

Hydrogenation of Ethyl Benzylmalonate.—Nineteen grams of the ester in 100 ml. of methyl alcohol was hydrogenated over 8 g. of copper–chromium oxide at 160° and 4900–5600 p. s. i. for six hours. The 2-benzyl-1,3-propanediol was collected by distillation and boiled at 143–145° at 0.5 mm. After standing, the glycol crystallized and was recrystallized from benzene, after which it melted at 68–70°. The yield was 3.3 g. (26%).

Anal. Calcd. for $C_{10}H_{12}O_2$: C, 72.26; H, 8.49. Found: C, 72.52; H, 8.44.

The *p*-nitrobenzoate of this glycol melted at 130–131° (from chloroform–ether).

Anal. Calcd. for $C_{24}H_{20}O_8N_2$: C, 62.06; H, 4.35; N, 6.03. Found: C, 61.88; H, 4.27; N, 6.06.

Hydrogenation of Ethyl *s*-Butylmalonate.—A solution of 53.7 g. of ethyl *s*-butylmalonate in 85 ml. of methyl alcohol was hydrogenated over 12.5 g. of copper–chromium oxide catalyst at 157–162° and 4700–6400 p. s. i. for ten hours.

The 2-*s*-butyl-1,3-propanediol, isolated as above, boiled at 92–105° at 0.5 mm. and weighed 7.9 g. The *p*-nitrobenzoate of this glycol melted at 101–102°.

Anal. Calcd. for $C_{21}H_{22}O_8N_2$: C, 58.60; H, 5.15; N, 6.51. Found: C, 58.68; H, 5.03; N, 6.55.

Hydrogenation of Ethyl Ethylmalonate.—A solution of 28.2 g. of ethyl ethylmalonate in 100 ml. of methyl alcohol was reduced at 160–162° for nine hours and then at 180° for fifteen hours at 4100–5500 p. s. i. over 8 g. of copper–chromium oxide. The 2-ethyl-1,3-propanediol, b. p. 86–87° at 0.5 mm., weighed 7.7 g. (49%).

Anal. Calcd. for $C_5H_{12}O_2$: C, 57.66; H, 11.62. Found: C, 57.02; H, 10.99.

The *p*-nitrobenzoate prepared from this glycol was recrystallized from methyl alcohol and melted at 88–89°.

Anal. Calcd. for $C_{19}H_{18}O_8N_2$: C, 56.72; H, 4.51; N, 6.96. Found: C, 56.81; H, 4.44; N, 7.09.

Acknowledgment.—The authors wish to express their appreciation to Mr. William B. Wright for technical assistance and Messrs. R. N. Boos, D. F. Hayman, Wilhelm Reiss, W. K. Humphrey, E. Thornton and Leonard Rosalsky, and Mrs. E. H. Meiss for carrying out the analyses.

Summary

Hydrogenation of β-oxygenated esters has been found to give rise to 1,3-glycols or their ethers by a lower temperature ester reduction method. When the malonic esters, acetoacetic ester, the β-hydroxy esters and β-alkoxy esters are hydrogenated at 160–180° over copper–chromium oxide, the corresponding glycols and their derivatives are produced.

By this method, ethyl acetoacetate, ethyl ethylacetoacetate and ethyl isobutylideneacetoacetate were converted into 1,3-butylene glycol, 2-ethyl-1,3-butylene glycol and 2-isobutyl-1,3-butylene glycol. Ethyl β-ethoxypropionate gave 3-ethoxy-1-propanol. The ethyl alkylmalonates (ethyl, *s*-butyl and benzyl) give the corresponding 2-alkyl-1,3-propanediols. The yields were 15–78%.

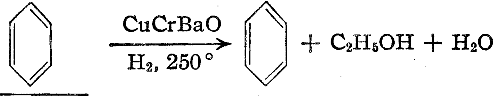
Hydrogenolysis of Aromatic Esters to Alcohols

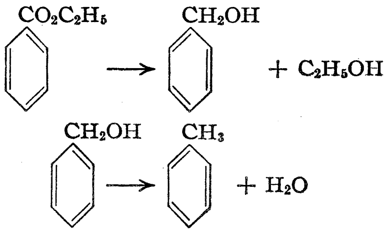
BY RALPH MOZINGO AND KARL FOLKERS

The hydrogenolysis of β-oxygenated esters and their ethers to 1,3-glycols and 1,3-glycol ethers[1] has lead to a reinvestigation of the hydrogenolysis of aromatic esters. While the hydrogenation of aromatic esters under the usual conditions[2] for ester hydrolysis leads to products in which the carboalkoxy group has been converted to a methyl group, it is possible by the low temperature technique previously described[1] to isolate the intermediate alcohol.

When an aromatic ester is hydrogenated at temperatures between 200 and 250° over a copper–chromium oxide catalyst[3] under 200 atmospheres of hydrogen it is converted rapidly into the corresponding methyl derivative. For example, ethyl benzoate gives toluene, ethanol and water.[2]



None of the corresponding alcohol has been obtained under these conditions and it has been suggested that the hydrogenolysis proceeds preferentially to the hydrocarbon.[4] However, it seems equally reasonable that the hydrogenation of an aromatic ester to the hydrocarbon may proceed stepwise.



This has now been found to be the case.

When hydrogenation is carried out between 125 and 175°, the exact temperature depending somewhat upon the ester, hydrogenolysis to the alcohol can be effected. For example, under these conditions ethyl benzoate (I, R = H) and its alkyl derivatives (I, R = CH_3, and II) and its

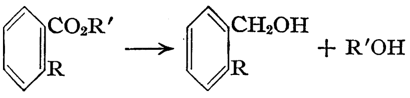
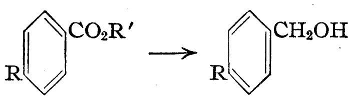
3,4-dimethyl derivative (III) are converted into benzyl alcohol (IV, R = H) and its alkyl derivatives (IV, V and VI).



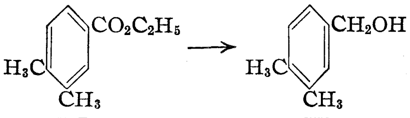
I IV

(R = H, CH_3; R′ = CH_3 or C_2H_5)

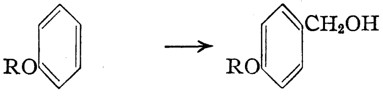


II V

(R = H, CH_3 or $(CH_3)_2CH$; R′ = CH_3 or C_2H_5)



III VI



VII VIII

(R = H or CH_3; R′ = CH_3 or C_2H_5)

Similarly, the oxygenated derivatives may be converted into corresponding alcohols. Methyl anisate (VII, R = CH_3) is converted into *p*-methoxybenzyl alcohol (VIII, R = CH_3) and ethyl *p*-hydroxybenzoate (VII, R = H) is converted into *p*-hydroxybenzyl alcohol (VIII, R = H).

The hydrogenolysis was carried out most successfully in methyl alcohol and, at the temperatures used here, decomposition of the methyl alcohol[4] apparently does not occur. With the aromatic esters the reduction is satisfactory, when pressures of 300 atm. or greater are used at temperatures in the range 125–175° with, in general, those near 160° giving the best yields of the alcohol. The yield of alcohol is greater when the reduction proceeds rapidly at a given temperature. Likewise, the amount of alcohol is usually greater when the reaction is interrupted at the point where its rate decreases markedly or the theoretical quantity of hydrogen has been consumed rather than when the reaction is allowed to proceed longer. Presumably, when the reaction is allowed to proceed beyond this point the benzyl alcohol is converted to the toluene derivative more rapidly than it is formed from the ester in the latter stages of the process.

Experimental

Copper-Chromium Oxide Catalyst.—The catalyst was prepared according to the usual method.[3] The thermal decomposition was carried out at the lowest possible temperature. The catalyst contained barium, except in one case noted.

Purification of Esters.—The esters were heated in a solvent with, or distilled over, Raney nickel catalyst[5] before use.

Hydrogenation of Aromatic Esters.—A solution of the ester in reagent methyl alcohol was hydrogenated over copper–chromium–barium oxide at 125–165° and under 300–400 atm. of hydrogen until the rate of hydrogen absorption became slow or the theoretical amount had been taken up. The amount of material, time, etc., are listed under each ester.

The products were isolated, after removing the catalyst, in the following way. To the solution of products in methyl alcohol were added 1.5 equivalents of potassium hydroxide (based on the original amount of ester) and 100 ml. of water. After refluxing the mixture for five hours or longer, most of the methyl alcohol was distilled. The residue was diluted with 150 ml. of water and extracted repeatedly with chloroform or benzene to remove the aromatic alcohol. The water solution from the chloroform extraction was made strongly acid with concentrated hydrochloric acid, cooled to 0°, and the acid removed by filtration.

The chloroform extract was combined with the methyl alcohol distillate, dried over anhydrous magnesium sulfate and fractionated. For complete identification of the liquid alcohols a solid ester, usually the *p*-nitrobenzoate, was prepared in each case by the pyridine method.[6]

Hydrogenation of Ethyl Benzoate.—A solution of 50 g. of the ester in 75 ml. of methyl alcohol was hydrogenated at 155–160° over 7 g. of copper–chromium–barium oxide for three and one-quarter hours. Eleven grams (25%) of benzoic acid, m. p. 121–122°, and 22.7 g. (63%) of benzyl alcohol, b. p. 103–104° at 23 mm., were isolated as above. The *p*-nitrobenzoate of the benzyl alcohol melted at 84–85° (from methyl alcohol), its recorded melting point.[7]

Another reduction, using 150 g. of ethyl benzoate in 100 ml. of methyl alcohol with 30 g. of catalyst, was carried out at 125–132° for ten and one-third hours. The yield in this case was 53.4 g. (49%) of benzyl alcohol.

In one experiment, barium-free copper–chromium oxide catalyst was used. In this case 75 g. of ethyl benzoate in 75 ml. of methyl alcohol was hydrogenated at 125–134° over 7.5 g. of copper–chromium oxide catalyst containing no barium for fourteen and one-half hours. The yield of benzyl alcohol, b. p. 106–108° at 25 mm., was 12.1 g. (22%) together with 17 g. of liquid boiling at 191–193° at 25 mm. presumably benzyl benzoate since in this case the esters were not saponified before distillation of the reaction mixture.

Hydrogenation of Methyl *o*-Toluate.—A solution of 23 g. of the ester in 120 ml. of methyl alcohol was hydrogenated over 5 g. of copper–chromium–barium oxide for two hours at 159–162°, then was worked up as above.

The products were 13 g. (70%) of *o*-methylbenzyl alcohol,[8] b. p. 120–122° at 23 mm., and 1.3 g. (6%) of *o*-toluic acid, m. p. 104–105°.

The *p*-nitrobenzoate of *o*-methylbenzyl alcohol, m. p. 100–101° (from methyl alcohol), was analyzed.

Anal. Calcd. for $C_{15}H_{13}O_4N$: C, 66.41; H, 4.83; N, 5.16. Found: C, 66.49; H, 4.85; N, 4.95.

Hydrogenation of Methyl *p*-Toluate.—A mixture of 50 g. of methyl *p*-toluate, 200 ml. of methyl alcohol and 10 g. of copper–chromium–barium oxide catalyst was agitated under hydrogen at 126–130° for eleven and one-quarter hours. The *p*-methylbenzyl alcohol,[9] m. p. 57–58° (from petroleum ether, b. p. 30–60°), weighed 28.4 g. (70%). The 3,5-dinitrobenzoate of the *p*-methylbenzyl alcohol melted at 117–118° (from ethyl alcohol).

Anal. Calcd. for $C_{15}H_{12}O_6N_2$: C, 56.96; H, 3.80; N, 8.86. Found: C, 57.00; H, 4.07; N, 8.91.

Hydrogenation of Methyl *p*-Isopropylbenzoate.[10]—When 26.9 g. of this ester, 120 ml. of methyl alcohol and 5 g. of copper–chromium–barium oxide catalyst were allowed to react with hydrogen at 156–160° for eight hours, the amount of *p*-isopropylbenzoic acid, m. p. 109–110°, isolated after hydrolysis was 4.0 g. (16%). The *p*-isopro-

pylbenzyl alcohol,[11] b. p. 135–136° at 26 mm., weighed 18.4 g. (81%) and gave a 3,5-dinitrobenzoate melting at 91–92°[12] (from petroleum ether, b. p. 60–70°).

Anal. Calcd. for $C_{17}H_{16}O_6N_2$: C, 59.30; H, 4.68; N, 8.14. Found: C, 59.20; H, 4.57; N, 8.37.

Hydrogenation of Ethyl 3,4-Dimethylbenzoate.—A solution of 89 g. of ethyl 3,4-dimethylbenzoate in 60 ml. of methyl alcohol was allowed to react with hydrogen over 10 g. of copper–chromium–barium oxide catalyst at 128–132° for twenty-four hours. The 3,4-dimethylbenzoic acid,[13] m. p. 165–166°, weighed 17.3 g. (23%). The 3,4-dimethylbenzyl alcohol,[14] m. p. 61–62° (from ethyl alcohol) amounted to 43.2 g. (64%).

Anal. Calcd. for $C_9H_{12}O$: C, 79.37; H, 8.88. Found: C, 79.24; H, 8.79.

The *p*-nitrobenzoate of this alcohol melted at 78–79° (from methyl alcohol).

Anal. Calcd. for $C_{16}H_{15}O_4N$: C, 67.36; H, 5.30; N, 4.91. Found: C, 67.38; H, 5.57; N, 4.81.

Hydrogenation of Methyl *o*-Methoxybenzoate.—A solution of 36 g. of the ester in 90 ml. of methyl alcohol was reduced over 5 g. of copper–chromium–barium oxide for six and one-third hours at 160–162°. The products were 4.5 g. (14%) of *o*-methoxybenzoic acid, m. p. 100–102°, and 16.7 g. (56%) of *o*-methoxybenzyl alcohol,[15] b. p. 134–135° at 20 mm. The *p*-nitrobenzoate of this alcohol melted at 81–82° (from methyl alcohol).

Anal. Calcd. for $C_{15}H_{13}O_4N$: C, 62.72; H, 4.56; N, 4.88. Found: C, 62.90; H, 4.77; N, 5.02.

When reduction of 33.2 g. of methyl *o*-methoxybenzoate, with the same amounts of other reactants as above, was carried out for three and one-third hours, 8 g. (26%) of the acid and 15.6 g. (57%) of the alcohol were isolated.

Hydrogenation of Methyl Anisate.—Eighty-three grams of methyl anisate in 60 ml. of methyl alcohol was hydrogenated over 10 g. of copper–chromium–barium oxide at 130–140° for twenty-three hours. A fore-run in the distillation, b. p. 84–85° at 27 mm., consisted of *p*-cresol methyl ether and weighed 4.0 g. (6.6%). The yield of anisyl alcohol, b. p. 150–151° at 27 mm., was 61.3 g. (89%). The *p*-nitrobenzoate of the anisyl alcohol melted at 93–94° (from 95% ethyl alcohol).

Anal. Calcd. for $C_{15}H_{13}O_5N$: C, 62.72; H, 4.53; N, 4.88. Found: C, 62.81; H, 4.65; N, 4.90.

Hydrogenation of Methyl Veratrate.[16]—A solution of 19.6 g. of methyl veratrate in 130 ml. of methyl alcohol was hydrogenated for three and two-thirds hours at 155–160° over 5 g. of copper–chromium–barium oxide. The recovered acid, m. p. 179–180°, amounted to 0.4 g. (2%). The 3,4-dimethoxybenzyl alcohol,[17] b. p. 135–140° at 1 mm., amounted to 14.4 g. (86%) and gave a *p*-nitrobenzoate melting at 108–109° (from methyl alcohol).

Anal. Calcd. for $C_{16}H_{15}O_6N$: C, 60.56; H, 4.77; N, 4.41. Found: C, 60.57; H, 4.76; N, 4.46.

Hydrogenation of Ethyl *p*-Hydroxybenzoate.—A mixture of 49.8 g. of ethyl *p*-hydroxybenzoate, 75 ml. of methyl alcohol and 10 g. of copper–chromium–barium oxide catalyst was submitted to hydrogenation at 155–160° for nineteen hours. In this case the phenol was separated from the acid by extracting the acid from a chloroform solution of the two with bicarbonate solution. The *p*-hydroxybenzoic acid, m. p. 205–207°, amounted to 7 g. (17%). The solid phenol after recrystallization from benzene weighed 22.5 g. (60%) and melted at 124–125°; the recorded melting point of *p*-hydroxybenzyl alcohol is 124–125°.[18]

Acknowledgment.—The authors wish to express their appreciation to Mr. William Wright for technical assistance and to Messrs. Richard Boos, D. F. Hayman, Wilhelm Reiss, H. S. Clark, W. K. Humphrey and E. Thornton for carrying out the microanalyses.

Summary

Several aromatic esters have been converted into the corresponding benzyl alcohols by catalytic hydrogenation over copper–chromium–barium oxide at 125 to 160° in 50–90% yield. Methyl alcohol has been found to be a suitable solvent for these reductions.

Using this method, it has been found that alkyl and alkoxy benzoic acid esters containing one or more substituents as well as the unsubstituted benzoic esters can be converted into the corresponding alcohols. Likewise, ethyl *p*-hydroxybenzoate gives *p*-hydroxybenzyl alcohol.

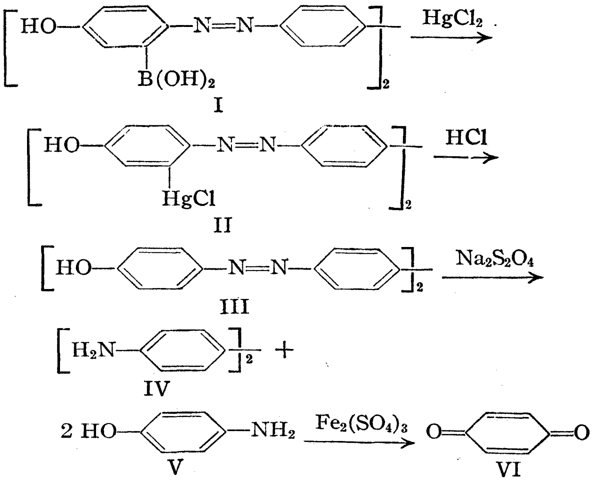
The Preparation of Some Azo Boronic Acids

By H. R. Snyder and Clay Weaver[1,2]

In an approach to the synthesis of boron-containing azo dyes desired for use in physiological studies the reactions of diazonium compounds with some aromatic boronic acids containing dialkylamino and hydroxyl groups have been examined. *m*-Hydroxybenzeneboronic acid and *m*-diethylaminobenzeneboronic acid were selected because of their ready availability. The diazonium compounds used in the coupling reactions were those obtained from benzidine, 4,4′-diaminodiphenic acid, *p*-aminobenzoic acid and *m*-aminobenzeneboronic acid.

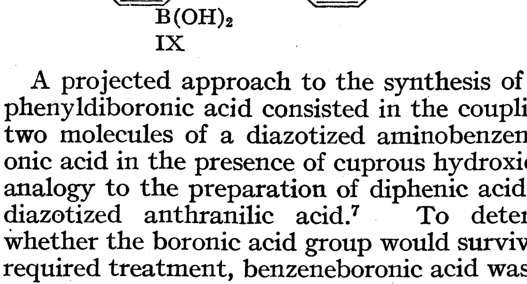
The most interesting question with regard to the proposed diazo coupling reactions concerned the stability of the aromatic boronic acids under the conditions required. *m*-Aminobenzeneboronic acid has been diazotized and the diazonium salt has been hydrolyzed to *m*-hydroxybenzeneboronic acid,[3] but the conditions employed differ greatly from those of coupling reactions. The boronic acid group is readily cleaved from the benzene ring by reagents such as copper[4] and silver[5] salts and aqueous solutions of the halogens,[4] and even by hot water,[4] so loss of the function during a diazo coupling would not be surprising.

The coupling of *m*-hydroxybenzeneboronic acid and *m*-diethylaminobenzeneboronic acid with the diazonium salts indicated was found to proceed without loss of the boronic acid function. Coupling would be expected to occur at the positions *para* to the hydroxyl and diethylamino groups. The dye from tetrazotized benzidine and *m*-hydroxybenzeneboronic acid was shown to have the expected structure (I). The structure proof was accomplished by removal of the boronic acid groups with mercuric chloride, hydrolysis of the mercury compound so formed, reduction of the resulting dye (III) to benzidine and *p*-aminophenol (V) which was identified by oxidation to *p*-benzoquinone.



m-Hydroxybenzeneboronic acid was coupled also with tetrazotized 4,4′-diaminodiphenic acid, with diazotized *p*-aminobenzoic acid and with diazotized *m*-aminobenzeneboronic acid. Evidently the boronic acid group can be present in either or both of the aromatic reagents subjected to the diazo coupling.

The *m*-diethylaminobenzeneboronic acid (VII) used was not isolated in the pure state. It was prepared from *m*-nitrobenzeneboronic acid by reduction in the presence of acetaldehyde.[6] No satisfactory solvent or solvent mixture for its recrystallization was found. Removal of the boronic acid group by treatment with ammoniacal silver nitrate converted it to diethylaniline (VIII), identified as the chloroplatinate, and the dye (IX) formed by coupling the crude *m*-diethylaminobenzeneboronic acid with diazotized *p*-aminobenzoic acid had the expected composition.



A projected approach to the synthesis of a biphenyldiboronic acid consisted in the coupling of two molecules of a diazotized aminobenzeneboronic acid in the presence of cuprous hydroxide, in analogy to the preparation of diphenic acid from diazotized anthranilic acid.[7] To determine whether the boronic acid group would survive the required treatment, benzeneboronic acid was subjected to the conditions of the diphenic acid preparation. The odor of benzene was evident immediately. The hydrocarbon was recovered by steam distillation and identified as the dinitro derivative. It appears unlikely that the so-called symmetrical coupling can be applied to diazotized aminoboronic acids.

(6) Emerson and Uraneck, *ibid.*, **63**, 749 (1941), describe the general method used.

(7) Atkinson and Lawler, "Org. Syn.," 2nd ed., Coll. Vol. I, 222 (1941).

One of the earliest methods of preparing aromatic boronic acids made use of the reaction between a diaryl mercury and boron chloride.[8] Apparently the use of more readily available mercurials, such as $ArHgOCOCH_3$ and $ArHgCl$, in similar reactions with esters of boric acid has not been attempted. Accordingly *o*-chloromercuriphenol and acetoxymercuribenzene were heated with *n*-butyl borate, but there was no evidence of the desired reactions when the reagents were heated in benzene or in the absence of solvents at temperatures as high as 150°.

Experimental

A. **Azo Dyes from *m*-Hydroxybenzeneboronic Acid.** (1) **2-(*p*-Carboxybenzeneazo)-5-hydroxybenzene-1-boronic Acid.**—A suspension of 0.9 g. of *p*-aminobenzoic acid in 10 ml. of 3 *N* hydrochloric acid was diazotized with 0.48 g. of sodium nitrite in 5 ml. of water. The cold diazonium salt solution was added dropwise to a cold solution of 0.9 g. of *m*-hydroxybenzeneboronic[3] acid in 10 ml. of 20% aqueous sodium hydroxide. The deep red mixture was allowed to stand for one hour, with occasional stirring, and then was added slowly to 10 ml. of cold 6 *N* hydrochloric acid. The gelatinous precipitate was coagulated by the addition of 50 ml. of ethanol and heating; after cooling the mixture was filtered through hardened filter paper. The orange solid was dissolved in 50 ml. of warm ethanol and caused to crystallize by dilution with an equal volume of warm water and cooling. After a second recrystallization it weighed 1.6 g. (88%) and melted at 254–256°. The boron content was determined by ignition of the residue from the combustion and weighing of the boric oxide so formed. Because of occlusion of carbonaceous material in the residue before final ignition, the carbon analyses of organoboron compounds often are low.

Anal. Calcd. for $C_{13}H_{11}BN_2O_5$: C, 54.6; H, 3.9; N, 9.8; B, 3.8. Found: C, 52.8; H, 4.3; N, 9.7; B, 4.2.

(2) a. **Preparation of 4,4′-bis-(2-Borono-4-hydroxybenzeneazo)-biphenyl.**[9]—The tetrazonium salt solution prepared from 6.7 g. of benzidine in 40 ml. of 7 *N* hydrochloric acid and 5 g. of sodium nitrite in 20 ml. of water was added to a cold (10°) solution of 10 g. of *m*-hydroxybenzeneboronic acid in a mixture of 20 g. of sodium carbonate in 80 ml. of water and 40 ml. of 10% aqueous sodium hydroxide. Stirring at 10° was continued for one hour. The deep purple mixture was poured into 50 ml. of cold concentrated hydrochloric acid and the solid was collected on a filter and washed free of chlorides with distilled water. The dry product weighed 12 g. It was recrystallized by dissolving it in the minimum quantity of hot ethanol, diluting with hot water and cooling. The deep red solid decomposed slowly at temperatures above 300°, but no definite melting or decomposition point could be discerned.

Anal. Calcd. for $C_{24}H_{20}B_2O_6N_4$: C, 59.8; H, 4.2; N, 11.6. Found: C, 61.6; H, 4.3; N, 11.4.

b. **Structure Proof.**—A solution of 12 g. of the dye in 200 ml. of hot ethanol was treated with an excess of mercuric chloride dissolved in 50% ethanol. The mixture was boiled under reflux for three hours, and the insoluble red mercury compound was collected and dried. A mixture of the red-brown powder (wt. 21 g.) and 100 ml. of 6 *N* hydrochloric acid was heated under reflux for two hours. The nearly black solid was collected by filtration and washed with water. After drying it weighed 11 g. It was mixed with 200 ml. of 10% sodium hydroxide at 60° and 25 g. of sodium hydrosulfite was added. After fifteen minutes, during which the temperature rose to 65°, a second 25-g. portion of sodium hydrosulfite was added. The mixture was heated on the steam-bath until no further fading of the color occurred. The solution was allowed to stand overnight and then neutralized to a *p*H of about 8 (Alk-Acid paper) with carbon dioxide. The tan precipitate was collected and digested twice with 50-ml. portions of warm 10% aqueous sodium hydroxide to separate the aminophenol from the benzidine. The combined extracts were acidified with 25% sulfuric acid and mixed with 100 g. of ferric sulfate and steam-distilled until 50 ml. of distillate had collected. On cooling, this distillate deposited 1.6 g. of *p*-benzoquinone, m. p. 113–115° (not depressed by admixture of authentic *p*-benzoquinone). The crude benzidine remaining from the alkaline extraction was heated with 100 ml. of water and the solution was decolorized. Cooling caused the separation of about 1 g. of pure benzidine, identified by melting point and mixed melting point.

(3) **4,4′-bis-(2-Borono-4-hydroxybenzeneazo)-diphenic Acid.**—A filtered solution of 2 g. of 4,4′-diaminodiphenic acid in 10 ml. of water and 5 ml. of concentrated hydrochloric acid was tetrazotized at 0° with 1 g. of sodium nitrite in 10 ml. of water. The resulting solution was added slowly to a cold solution of 2 g. of *m*-hydroxybenzeneboronic acid in 40 ml. of 5% aqueous sodium hydroxide containing 5 g. of sodium carbonate. The deep purple mixture was stirred for two hours, then heated to 75° and treated with a little charcoal. The filtered solution was added slowly with stirring to 20 cc. of cold concentrated hydrochloric acid. The resulting red colloidal suspension was heated to promote coagulation and filtered through a hardened filter paper. The solid was washed with water and dried (wt., 3.8 g.). It was redissolved in aqueous sodium hydroxide, treated with charcoal, filtered and acidified as before to yield a brick-red powder. This was dissolved in 50 ml. of ethanol, and the hot solution was filtered and diluted to incipient precipitation with hot water and cooled. The fine, red powder weighed 1.2 g.; an additional quantity of 1.9 g. was obtained by further dilution of the mother liquor. The solid had no definite melting point, but slowly decomposed at temperatures above 300°.

Anal. Calcd. for $C_{26}H_{20}B_2N_4O_{10}$: C, 54.8; H, 3.5; N, 9.8; B, 3.8. Found: C, 55.8; H, 3.9; N, 10.2; B, 3.2.

(4) **2-(3-Boronobenzeneazo)-5-hydroxybenzeneboronic Acid.**—*m*-Nitrobenzeneboronic acid was reduced catalytically in aqueous methanol and after displacement of the methanol by water the aminoboronic acid was diazotized without isolation. The diazonium solution prepared from 5.6 g. of the nitro compound was added slowly to a cold solution of 4.2 g. of *m*-hydroxybenzeneboronic acid in 100 ml. of 10% aqueous sodium hydroxide. The deep red solution was allowed to stand overnight and then poured into an excess of 25% sulfuric acid. The red colloidal suspension was decanted from a brown gum and the gum was extracted with hot water. The extract was combined with the suspension and the mixture was cooled and filtered. The brick-red solid (wt. 2 g.) was recrystallized from a mixture of 100 ml. of water and 10 ml. of ethanol. The product decomposed at temperatures above 350°. A solution of about 0.1 g. of the dye in 40 ml. of 50% ethanol containing 5 g. of mannitol was titrated against 0.05 *N* sodium hydroxide by means of a Hellige *p*H meter.

Anal. Calcd. for $C_{12}H_{12}B_2N_2O_5$: C, 50.4; H, 4.2; N, 9.8; B, 7.6; neut. equiv., 143. Found: C, 50.4; H, 4.4; N, 9.8; B, 7.7; neut. equiv., 142.

B. **2-(*p*-Carboxybenzeneazo)-5-diethylaminobenzeneboronic Acid.** (1) **Preparation of *m*-Diethylaminobenzeneboronic Acid.**—A solution of 3.4 g. of *m*-nitrobenzeneboronic acid and 3 ml. of glacial acetic acid in 30 ml. of ethanol was shaken with about 1 ml. of Raney nickel catalyst and filtered into a reduction bottle. After the addition of 3.4 ml. of freshly distilled acetaldehyde and about 0.05 g. of platinum oxide catalyst the mixture was shaken under hydrogen at 2–3 atmospheres pressure for thirty-six hours. The solution was filtered into a Claisen

[9] The prefix "borono" is used to designate the boronic acid [—$B(OH)_2$] group.

flask and concentrated under diminished pressure at room temperature. The residual oil was dissolved in 30 ml. of 10% sulfuric acid, treated with Darco and added slowly to 100 ml. of 15% aqueous sodium bicarbonate. The pink precipitate was dissolved in 5% aqueous sodium hydroxide and treated with Norite. The solution was acidified with 10% sulfuric acid and added to a bicarbonate solution. The nearly white product, after drying *in vacuo* over phosphorus pentoxide, melted at 142–144°. No satisfactory solvent for recrystallization was found. About 0.5 g. of the solid was treated with ammoniacal silver nitrate,[5] and the diethylaniline formed was recovered by steam distillation and identified as the picrate and the chloroplatinate by melting points and mixed melting points.

(2) **Coupling Reaction.**—The diazonium salt solution prepared from 1.8 g. of *p*-aminobenzoic acid in 20 ml. of 3 *N* hydrochloric acid and 0.9 g. of sodium nitrite in 5 ml. of water was added slowly at 0° to 2.5 g. of the diethylaminobenzeneboronic acid in 10 ml. of 3 *N* hydrochloric acid. The resulting mixture was poured with stirring into 15 ml. of 6 *N* sodium hydroxide solution. The precipitate which formed in the deep violet solution was collected and dissolved in 50 ml. of glacial acetic acid. The filtered solution was diluted with 100 ml. of water and the red-brown solid which precipitated was recrystallized from 50% ethanol, yielding 2.9 g. (65%) of the pure substance, m. p. 248–250°.

Anal. Calcd. for $C_{17}H_{20}BN_3O_4$: C, 59.8; H, 5.9; B, 3.2. Found: C, 59.7; H, 5.7; B, 3.3.

C. Conversion of Benzeneboronic Acid to Benzene by the Action of Cuprous Hydroxide.—The reducing solution prepared from ammoniacal cupric sulfate[7] and hydroxylamine was mixed with benzeneboronic acid under the conditions of the diphenic acid preparation.[7] The odor of benzene was evident immediately. The hydrocarbon produced from 1 g. of the boronic acid was recovered by steam distillation and treated with nitric and sulfuric acids. The *m*-dinitrobenzene so formed, m. p. 87–89°, was identified by melting point and mixed melting point.

D. Attempts to Use Mercuriphenyl Derivatives in the Boronic Acid Synthesis.—No evidence of reaction was observed when a mixture of 8.5 g. of acetoxymercuribenzene and 23 g. of *n*-butyl borate was heated on the steam-bath for one hour. The mixture was heated at 140–150° for three hours and poured into excess 3 *N* hydrochloric acid. Evaporation of ether extracts of the aqueous solution yielded no benzeneboronic acid. Similar results were obtained in experiments in which benzene was used as solvent for the reagents.

A mixture of 8.2 g. of *o*-chloromercuriphenol, 16 g. of *n*-butyl borate and 50 ml. of benzene was heated under reflux for fourteen hours and then poured into excess 6 *N* hydrochloric acid. The organic liquid was removed by distillation and the hot aqueous solution was filtered and cooled. The recovery of *o*-chloromercuribenzene, m. p. 150°, was almost quantitative.

Summary

Several azo dyes containing the boronic acid group have been prepared by the action of diazonium salts on *m*-hydroxybenzeneboronic and *m*-diethylaminobenzeneboronic acids. One such dye has been prepared by coupling diazotized *m*-aminobenzeneboronic acid with *m*-hydroxybenzeneboronic acid. There is no indication of the loss of the boronic acid function during these couplings.

The cuprous hydroxide solution prepared from ammoniacal cupric sulfate and hydroxylamine is an effective reagent for the removal of the boronic acid group from the benzene nucleus.

Attempts to effect reaction between *n*-butyl borate and *o*-chloromercuriphenol or acetoxymercuribenzene have been unsuccessful.

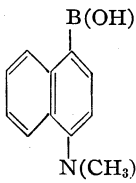
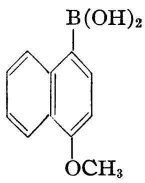
Synthesis and Reactions of Some Substituted Naphthaleneboronic Acids

BY H. R. SNYDER AND F. W. WYMAN[1]

It has been shown[2] that azoboronic acids can be obtained by coupling of diazonium compounds with *m*-hydroxybenzeneboronic acid and with *m*-diethylaminobenzeneboronic acid. There is no indication of displacement of the boronic acid function in such coupling reactions. In connection with a projected synthesis of boron-containing azo dyes of possible use in physiological studies, it became desirable to determine whether the boronic acid group attached to an aminonaphthyl or alkoxynaphthyl radical might be expected to withstand the conditions of the coupling reaction and other substitutions. It would appear that the most drastic tests of the stability of the boronic acid group in such substances could be made on compounds having the 1,4-orientation. Accordingly, 4-dimethylamino-1-naphthaleneboronic acid (I) and 4-methoxy-1-naphthaleneboronic acid (II) have been prepared for study.



I



II

The boronic acids (I and II) were prepared by the usual method from the Grignard reagents and butyl borate. Each substance melted with decomposition over a range which varied with the rate of heating and with the previous history of the sample. This behavior is characteristic of boronic acids and is to be ascribed to the dehydration of the substances (and their hydrates) to the boron oxides. Satisfactory combustion analyses of the compounds I and II were not attained, because of the varying degree of hydration of the analytical samples and the entrapment of particles of carbon in the glass-like residue of boric oxide

---

(2) Snyder and Weaver, THIS JOURNAL, **69**, 232 (1947).

formed in the combustion. However, both substances were alkali-soluble, showing the presence of the boronic acid group, and satisfactory neutralization equivalents were obtained on samples of both. The aminoboronic acid (I) was titrated with standard acid, with the aid of a *p*H meter, and the methoxyboronic acid was titrated with standard alkali in the presence of mannitol with phenolphthalein as the indicator.

The single recorded attempt to prepare *o*-dimethylaminobenzeneboronic acid apparently failed because of the extraordinary ease of hydrolysis of the substance, the only product isolated having been dimethylaniline.[3] This observation, together with that of detectable hydrolysis of 1-naphthaleneboronic acid during recrystallization from water,[4] leads to the prediction that 4-dimethylamino-1-naphthaleneboronic acid should be extremely labile. The properties of the substance are in accord with this prediction. Treatment of the aminoboronic acid, dissolved in cold glacial acetic acid, with dilute (1:1) nitric acid caused the displacement of the boronic acid group and the formation of 2,4-dinitro-1-dimethylaminonaphthalene. It is likely that the first step was the replacement of the boronic acid group, for under the identical conditions 1-dimethylaminonaphthalene was not nitrated. Enhancement of the reactivity of the boronic acid group by the amine group is indicated by the fact that α-naphthaleneboronic acid was only slightly attacked under the conditions mentioned, although it was converted to 1,3-dinitronaphthalene when the test was made with concentrated nitric acid and with a much longer time of reaction. A similar ejection of the boronic acid group from the benzene nucleus has been observed[3] in the nitration of benzeneboronic and *p*-methoxybenzeneboronic acids, but under unspecified conditions which may have been relatively more drastic than those employed here.

Both the boronic acid group and the dimethylamino group were replaced when the aminoboronic acid was treated with nitrous acid in strong acetic acid solution. Evidently 4-nitroso-1-dimethylaminonaphthalene first formed, but was hydrolyzed in the reaction mixture to the nitrosonaphthol. When the aminoboronic acid was heated with aqueous sodium bisulfite or with alcoholic picric acid the boronic acid group was replaced by hydrogen. The cleavage with picric acid, discovered in an attempt to prepare the picrate of the aminoboronic acid, occurred with surprising facility. In contrast, the boronic acid group was quite stable to hydrolysis by alkali in the absence of air; cleavage to 1-dimethylaminonaphthalene did occur, but part of the unchanged aminoboronic acid was recovered after four hours of boiling with 10% sodium hydroxide. More complicated reactions with aqueous alkali occurred in the presence of air; dimethylamine was evolved and a high-melting insoluble organic product containing neither boron nor nitrogen was formed.

When the aminoboronic acid was treated with diazotized *p*-aminobenzoic acid, the boronic acid group was replaced by the azobenzoic acid residue. The dye obtained was identical with that produced by the coupling with 1-dimethylaminonaphthalene and its conversion to 1,4-naphthoquinone established with certainty the 1,4-orientation of the amino and azo groups. 1-Naphthaleneboronic acid was stable to the diazonium salt under the conditions employed with I. Dyes obtained by coupling I with diazotized *m*-aminobenzoic acid, diazotized anthranilic acid and tetrazotized benzidine did not give qualitative tests for boron and were not further investigated.

4-Methoxy-1-naphthaleneboronic acid (II) was more stable to the various reagents. It was recovered from the treatment with dilute nitric acid in glacial acetic acid at temperatures near 0°, but was converted to 2,4-dinitro-1-naphthol when the reaction was carried out at room temperature. Similarly, it was unattacked by nitrous acid in strong acetic acid at about 0°, but at room temperature it was hydrolyzed to 1-methoxynaphthalene. Boiling 50% acetic acid converted it to the same product. When a solution of the boronic acid (II) in aqueous sodium hydroxide was boiled in an open beaker hydrolysis occurred slowly and 1-methoxynaphthalene was formed. The methoxyboronic acid (II) coupled with diazotized *p*-aminobenzoic acid, but the dye formed did not contain boron and it was not further investigated.

Experimental

4-(N,N-Dimethylamino)-1-bromonaphthalene.—N-Acetyl-1-naphthylamine was brominated according to the method of Meldola,[5] but with chloroform rather than acetic acid as the solvent. The bromoamide was hydrolyzed with ethanolic hydrochloric acid,[6] and the bromoamine was methylated by use of the procedure described by Gilman and Banner[7] for N,N-dimethyl-*o*-toluidine, except that a greatly increased quantity of water (2 liters for a run with 0.5 mole of amine) was employed in making up the reaction mixture. In most preparations the crude material was converted to the picrate by addition to a boiling 8% solution of picric acid (87.5% of the theoretical amount based on the amine methylated) in 95% ethanol. The crude picrate (m. p. 150–154°) which separated when the solution was cold was washed twice with cold ethanol, suspended in water, and treated with aqueous ammonia. The regenerated amine was collected in ether, dried over potassium carbonate and distilled; b. p. 137–139° (2 mm.); yield 55%. It was found possible to distil the crude amine, without the preliminary purification through the picrate, provided the pressure did not exceed 1 mm. nor the bath temperature 160°.

The amine was prepared also by direct bromination of dimethyl-1-naphthylamine, a procedure employed previously by Friedländer and Welmans,[8] who did not purify the product. In the present work an insufficient quantity

(95%) of bromine, as a 40% solution in carbon tetrachloride, was added during one and one-half hours to a cooled and stirred 1 *M* solution of the tertiary amine in the same solvent. The precipitated hydrobromide was collected, washed with the solvent and suspended in water. The free amine, regenerated by the addition of 10% sodium hydroxide solution, was collected in ether, dried and distilled at 1 mm.; b. p. 115–130° (1 mm.). Although this product contained some dimethyl-1-naphthylamine it could be used for the preparation of the Grignard reagent. It could be purified through the picrate, as described above, and the picrate was identical with that of the material made by methylation of the bromoamine; the melting point of either sample of picrate, after two recrystallizations from 95% ethanol, was 154–156°. The trinitrobenzene derivatives, m. p. 94–95°, also were identical; the trinitrobenzene derivative of a sample from the direct bromination was analyzed.

Anal. Calcd. for $C_{18}H_{15}O_6N_4Br$: C, 46.66; H, 3.24. Found: C, 46.80; H, 3.34.

To establish the 1,4-orientation of the product from the bromination a sample was converted to 4-dimethylamino-1-naphthoic acid by treatment of the Grignard reagent with carbon dioxide; the amino acid melted at 162–163° (lit.,[8] 163–165°).

4-Dimethylamino-1-naphthaleneboronic Acid.—The Grignard reagent was prepared by refluxing for two hours a mixture of 25 g. of the bromo compound, 2.4 g. of magnesium, a crystal of iodine and 250 ml. of dry ether. The resulting solution, cooled to room temperature, was added over a period of about one-half hour to a vigorously stirred solution of 50 g. of *n*-butyl borate in 500 ml. of dry ether, the temperature of which was maintained at −15°. The mixture was allowed to stand overnight in the cooling bath before it was hydrolyzed by the addition of 100 ml. of water. The ether layer was washed several times with 50-ml. portions of cold water and then extracted with six 25-ml. portions of 5% hydrochloric acid. The combined acid extracts were evaporated at room temperature to give 12.2 g. (48%) of crude hydrochloride of the aminoboronic acid (I). The material was stored in this form, and the free aminoboronic acid was generated as needed by the dropwise addition of 10% sodium hydroxide solution to an aqueous solution of the hydrochloride until no further precipitation occurred. After two similar reprecipitations from dilute acid and drying *in vacuo* at room temperature the 4-dimethylamino-1-naphthaleneboronic acid (I) melted at 82–85°. Its neutralization equivalent, as determined by titration with 0.05 *N* hydrochloric acid with the aid of a Hellige *p*H meter, was within the limits of 212–215 (calcd. 214.9).

Reactions of 4-Dimethylamino-1-naphthaleneboronic Acid. (a) **With Nitric Acid.**—To a stirred solution of 1 g. of the aminoboronic acid in 10 ml. of glacial acetic acid, cooled in an ice-bath, was added dropwise 1 ml. of a cold solution of equal volumes of water and concentrated nitric acid. After ten minutes the mixture was diluted with 75 ml. of cold water, and the yellow solid which formed was collected. This solid melted at 81–85°; after three recrystallizations from 95% ethanol it melted at 88–89°, alone or mixed with authentic[9] 2,4-dinitro-1-dimethylaminonaphthalene.

1-Naphthaleneboronic acid was recovered from similar experiments in which it was substituted for the aminoboronic acid. Even when the reaction mixture was allowed to stand overnight before dilution, the 1-naphthaleneboronic acid recovered was only slightly contaminated (m. p. 180–188°) and was readily purified [to a m. p. of 198–200° (lit.[3] not above 202°)] by a single reprecipitation from alkaline solution and one recrystallization from ethanol. When concentrated nitric acid was substituted for the diluted nitric acid and the reaction mixture was allowed to stand overnight, the only product isolated was 1,3-dinitronaphthalene, m. p. 143–144°, identified by a mixed melting point with an authentic specimen.

(b) **With Nitrous Acid.**—To a solution of 1 g. of the aminoboronic acid in 10 ml. of glacial acetic acid, vigorously stirred in an ice-bath, was added dropwise 1.5 ml. of 20% aqueous sodium nitrite solution. After fifteen minutes the mixture was diluted with 50 ml. of cold water and filtered. The solid was dissolved in dilute sodium hydroxide solution and reprecipitated with dilute hydrochloric acid. After recrystallization from aqueous ethanol it decomposed at 193–195° (lit.[10] for 4-nitroso-1-naphthol, 194°). It contained no boron.

Anal. Calcd. for $C_{10}H_7NO_2$: C, 69.36; H, 4.08. Found: C, 69.48; H, 4.09.

(c) **With Aqueous Sodium Bisulfite.**—A mixture of 2 g. of the aminoboronic acid and about 20 ml. of 20% aqueous sodium bisulfite solution was refluxed for four hours. Careful neutralization and reacidification of a portion of the cooled solution did not cause the separation of any solid; the addition of alkali caused the separation of an oily base. The oil was collected in ether, dried, recovered from the solvent and added to alcoholic picric acid. The picrate melted at 145–146° (lit.,[11] 145°) alone or mixed with the picrate of 1-dimethylaminonaphthalene.

(d) **With Picric Acid.**—To a boiling solution of 1 g. of picric acid in 25 ml. of 95% ethanol was added a solution of 1.2 g. of the aminoboronic acid in 10 ml. of ethanol. The mixture was refluxed for about fifteen minutes, after which it was cooled and the solid which separated was recrystallized from 95% ethanol. The picrate melted at 142–144°, and a mixture with the picrate of 1-dimethylaminonaphthalene melted at 143–144°.

Anal. Calcd. for $C_{18}H_{16}O_7N_4$: C, 54.00; H, 4.00. Found: C, 53.79; H, 4.05.

(e) **With Aqueous Sodium Hydroxide.**—A solution of 2 g. of the aminoboronic acid in 40 ml. of deoxygenated 10% aqueous sodium hydroxide was refluxed for four hours under an atmosphere of illuminating gas. Extraction of the cooled solution with ether and removal of the solvent gave a drop of an oil; this oil gave a picrate which melted at 145–146°, alone or mixed with the picrate of 1-dimethylaminonaphthalene. Acidification of the alkaline aqueous solution caused the separation of a solid which redissolved in excess acid. After two reprecipitations from dilute acid by the dropwise addition of dilute alkali the solid melted at 80–83°, and the melting point was not lowered by admixture of the aminoboronic acid (I).

In a similar experiment in which the alkaline solution was boiled in an open beaker for eight hours (with occasional addition of water to maintain an approximately constant volume) none of the aminoboronic acid was recovered. The only product isolated was a dark, neutral solid, containing neither nitrogen nor boron, for which no recrystallization solvent was found.

(f) **With Diazonium Salts.**—1. Diazotized *p*-aminobenzoic acid: To the cold diazonium chloride solution prepared from 1.3 g. of *p*-aminobenzoic acid were added a solution of 2 g. of the aminoboronic acid in 20 ml. of cold 10% hydrochloric acid and a solution of 14 g. of sodium acetate in 25 ml. of cold water. The mixture was stirred for six hours at 0–5° and then allowed to stand overnight at the same temperature. The red solid was separated, dried and recrystallized from absolute ethanol. The substance did not contain boron; it melted at 204–206° (dec.), and the melting point was unaffected by admixture of the dye [m. p. 204–206° (dec.)] obtained by coupling 1-dimethylaminonaphthalene with the same diazonium salt.

Anal. Calcd. for $C_{19}H_{17}O_2N_3$: C, 71.48; H, 5.36. Found: C, 71.86; H, 5.53.

---

(10) Shriner and Fuson, "Identification of Organic Compounds," 2nd ed., John Wiley and Sons, New York, N. Y., 1940, p. 229.

(11) "Organic Reagents for Organic Analysis," by the staff of Hopkin and Williams, Ltd., Chemical Publishing Co., Brooklyn, 1946, p. 138.

Reduction[12] of the dye and oxidation[13] of the diamine so formed gave 1,4-naphthoquinone, identified by melting point and mixed melting point.

2. Other diazonium salts: Coupling under the same conditions with diazonium salts from m-aminobenzoic acid, anthranilic acid and benzidine gave dyes which were found not to contain boron and were not investigated further.

4-Methoxy-1-naphthaleneboronic Acid.—To the Grignard solution (concentration about 0.8 M) from 4-methoxy-1-bromonaphthalene[14] was added dropwise an equimolar amount of n-butyl borate as an ether solution of concentration about 1.1 M while the temperature was maintained at $-60°$. The reaction mixture was allowed to remain in the cooling bath overnight. It was treated with water, and the product was recovered by several extractions of the ether solution with 2% aqueous sodium hydroxide. The crude boronic acid was obtained in 53% yield by acidification of the alkaline extracts. It was purified by reprecipitation from dilute alkali by acidification, followed by precipitation from ethanol by dilution with water. Samples dried *in vacuo* at room temperature underwent visible decomposition at about 150–155°, in an ordinary melting point determination, but the decomposition product (presumably the anhydride) did not melt completely at temperatures up to 250°. A reproducible melting point of 195° could be determined by the instant immersion method.[15] The boronic acid was titrated in 20% ethanol solution containing mannitol with 0.05 N sodium hydroxide solution to a phenolphthalein end-point; the neutralization equivalent was found to be within the limits of 199–203 (calcd. 201.8).

Reactions of 4-Methoxy-1-naphthaleneboronic Acid. (a) **With Nitric Acid.**—To a well-stirred suspension of one gram of the boronic acid in 10 ml. of glacial acetic acid at room temperature was added 1 ml. of a solution of equal volumes of concentrated nitric acid and water. Thirty minutes later the mixture was diluted with 50 ml. of cold water, and the solid which separated was recrystallized from 95% ethanol. The yellow solid melted at 138–139°, and the melting point was not changed by the addition of authentic 2,4-dinitro-1-naphthol.

When the experiment was repeated with the temperature of the reaction mixture maintained at about 2° the 4-methoxy-1-naphthaleneboronic acid was recovered.

(b) **With Nitrous Acid.**—To a vigorously stirred suspension of 1 g. of the acid in 10 ml. of glacial acetic acid at room temperature was added 1.5 ml. of 20% aqueous sodium nitrite solution. Thirty minutes later the mixture was filtered and the filtrate was diluted with 75 ml. of water. The diluted solution was extracted with ether and the oil which remained after evaporation of the ether was dissolved in ethanol, decolorized and treated with 1,3,5-trinitrobenzene. The crystals which formed melted at 138–139° (lit.[16] 138°) alone or mixed with the trinitrobenzene derivative of 1-methoxynaphthalene.

No reaction occurred when the experiment was carried out at 0°.

(c) **With Dilute Acetic Acid.**—A mixture of 1 g. of the boronic acid and 15 ml. of glacial acetic acid was refluxed for thirty minutes. Examination of the cooled solution revealed no evidence of reaction, so 10 ml. of water was added and the refluxing was continued for an additional half-hour. The cooled solution was diluted with 50 ml. of water and the oil which separated was extracted with ether. The ether extracts were washed with dilute alkali, dried and evaporated to give an oil which was identified as 1-methoxynaphthalene by conversion to the trinitrobenzene derivative as described in the preceding section.

(d) **With Aqueous Sodium Hydroxide.**—A solution of 1 g. of the boronic acid in 25 ml. of 10% aqueous sodium hydroxide was boiled gently for half an hour with occasional additions of water to keep the volume approximately constant. The cooled mixture was extracted with ether and the dried extracts were evaporated to give a small amount of an oil which was identified as 1-methoxynaphthalene by the melting point and mixed melting point of the trinitrobenzene derivative. Acidification of the alkaline solution caused the separation of 0.6 g. of the unchanged boronic acid (II).

Summary

4-Dimethylamino-1-naphthaleneboronic acid and 4-methoxy-1-naphthaleneboronic acid have been prepared and subjected to the action of various reagents. The boronic acid group of either substance is removed readily by mild hydrolysis or by replacement under the influence of reagents such as dilute acids, dilute bases, nitric acid, nitrous acid and certain diazonium salts. The boronic acid group is more highly labilized by the 4-dimethylamino group than by the 4-methoxyl group.

The Synthesis of β-Carbolines. IV. 3-Aminoharman and Some of its Derivatives[1]

BY H. R. SNYDER, STANLEY M. PARMERTER[2] AND HOWARD G. WALKER[3]

In the preceding paper the synthesis of 6-aminoharman by the reduction of the nitro compound was reported. It is to be expected that the isomeric 3-aminoharman may be prepared from harman-3-carboxylic acid by application of the Hofmann[4] or Curtius[5] reaction. This paper reports the synthesis of 3-aminoharman from the acid azide and its conversion to the sulfanilyl derivative (III) and the 3-diethylaminopropyl derivative (IV), isolated as the dipicrate.

Preliminary tests indicated that the ester (I) could be converted to the hydrazide much more

---

readily than to the amide, so that the Curtius reaction was chosen for the preparation of the amine (II). The azide, obtained by treatment of the hydrazide with cold aqueous nitrous acid, proved to be quite stable. It could be converted directly to the amine by refluxing with fifty per cent. acetic acid, but better yields of a more readily purified product resulted from the preparation and hydrolysis of the benzyl carbamate. The sulfanilyl derivative (III) was prepared by the reaction of the amine with acetylsulfanilyl chloride in the presence of pyridine[6] and hydrolysis of the acetyl group in the usual fashion. The 3-diethylaminopropyl derivative of the amine was prepared by refluxing an ethanol solution of the amine and 3-diethylaminopropyl chloride containing a trace of potassium iodide. The resulting triamine has been purified as the dipicrate; the free base and its salts with various mineral acids and carboxylic acids have resisted all attempts to induce crystallization.

Experimental

Harman-3-carbonyl Hydrazide.—A mixture of 10 g. of methyl 3-harmancarboxylate,[7] 50 ml. of 85% hydrazine hydrate, 100 ml. of *n*-amyl alcohol and 28 ml. of absolute ethanol was refluxed four hours. The solution was cooled overnight in the refrigerator (5°) before the tan needles were collected and washed with cold water and ether. The crude material melting at 295° (dec.) weighed 9.0 g. (yield, 90%). Concentration of the mother liquor gave 0.7 g. of less pure material. A sample recrystallized from ethanol (95%) melted at 288°.

Anal. Calcd. for $C_{13}H_{12}N_4O$: C, 64.99; H, 5.04. Found: C, 65.04; H, 5.31.

Harman-3-carbonyl azide was prepared by dissolving 4.16 g. of the hydrazide in 200 ml. of water containing 2.5 ml. of concentrated hydrochloric acid. The solution was cooled to below 5°, and a solution of 1.38 g. of sodium nitrite in 5 ml. of water was added. The resulting mixture was allowed to stand in the cold with occasional stirring for fifteen minutes, and was then neutralized by the addition of excess saturated sodium bicarbonate solution. The pasty suspension thus formed was rather difficult to filter, but this method was found most satisfactory for the isolation of the solid azide. The crude azide was washed with cold water and then with ether before being dried to constant weight *in vacuo*. An approximately quantitative yield of azide was obtained. The crude product was used without purification. The compound appeared to be completely stable at room temperature.

Benzyl 3-Harmylcarbamate.—The preparation of the benzyl carbamate was carried out in a 100-ml. flask with a reflux condenser provided with a drying tube. A mixture of 4.27 g. of the azide, 40 ml. of dry xylene and 4.0 ml. of redistilled benzyl alcohol was placed in the flask and the temperature raised to 110–120° by means of an oil-bath. The evolution of nitrogen proceeded smoothly at this temperature. The heating was maintained for one-half hour and the reaction mixture was allowed to stand in the refrigerator overnight. The product was filtered, washed with cold xylene followed by low-boiling petroleum ether and dried; yield 4.48 g. (81%); m. p. 188–190°. No appreciable amount of material could be obtained by the addition of low-boiling petroleum ether to the mother liquor. A sample was recrystallized twice from *n*-butyl alcohol, m. p. 186–186.5°.

Anal. Calcd. for $C_{20}H_{17}O_2N_3$: C, 72.48; H, 5.19; N, 12.68. Found: C, 72.07; H, 5.50; N, 12.96.

3-Aminoharman from the Benzyl Carbamate.—A mixture of 9.75 g. of the carbamate, 50 ml. of diethylene glycol, 8.35 ml. of water and 8.35 g. of potassium hydroxide was stirred for one-half hour in a 200-ml. round-bottom flask equipped with an air condenser and immersed in an oil-bath at 150–160°. The cooled contents of the flask were poured into 325 ml. of ice and water and allowed to stand in an ice-bath for one and one-half hours before the solid product was filtered. The crude product (m. p., 223–226°) was recrystallized from dilute aqueous ethanol, yielding 4.80 g. (83%) of dried product, m. p. 226–227°. A sample of the 3-aminoharman which had been recrystallized several times from dilute ethanol melted at 228–229°.

Anal. Calcd. for $C_{12}H_{11}N_3$: C, 73.09; H, 5.62. Found: C, 72.97; H, 5.58.

3-Sulfanilamidoharman.—In a 100-ml., two-necked flask equipped with a sealed stirrer and a reflux condenser protected by a drying tube was placed 3.72 g. of 3-aminoharman, 48 ml. of dry pyridine and 4.55 g. of acetylsulfanilyl chloride (commercial grade recrystallized once from chloroform). The mixture was heated on the steam-bath with stirring for three hours and then poured into 700 ml. of cold water. A crystalline product formed slowly and was allowed to stand in an ice-bath for one hour before it was filtered and washed well with cold water. A sample of this product was dried, m. p. 287–289° (dec.). The wet product (7.24 g.) was suspended in 207 ml. of 12% hydrochloric acid and heated on the steam-bath for thirty-five minutes with stirring. Since most of the solid had gone into solution at the end of this time, the solution was filtered. The residue remaining on the filter was heated for fifteen minutes with an additional 30-ml. portion of the dilute acid, and after filtration of this mixture the acid filtrates were combined, cooled and made alkaline with concentrated ammonium hydroxide. The mixture was allowed to stand in an ice-bath for one hour, and the slightly yellow crystals were filtered and recrystallized from a pyridine–water mixture. There was obtained 3.70 g. of recrystallized 3-sulfanilamidoharman (57%), m. p. 301–302° (dec.).

Anal. Calcd. for $C_{18}H_{16}O_2N_4S$: C, 61.35; H, 4.58. Found: C, 61.46; H, 4.41.

3-(3′-Diethylaminopropylamino)-harman.—A mixture of 0.85 g. of 3-aminoharman, 0.79 g. of γ-diethylaminopropyl chloride and 8.5 ml. of ethanol (95%) containing a crystal of potassium iodide was refluxed on the steam-bath for about thirty hours.[8] At the end of this time, the alcohol was removed by distillation, water was added

to the reaction product and the resulting solution made basic with excess ammonium hydroxide. The organic material was taken up in chloroform, washed with water and dried over sodium sulfate. The product was converted to a picrate by removing the chloroform at reduced pressure, dissolving the residue in a minimum of absolute ethanol and adding an excess of a chilled, saturated solution of picric acid in absolute ethanol. After standing overnight in the refrigerator the crude picrate was filtered and placed in a Soxhlet extraction cup. The material was extracted with methanol until no further crystallization from the hot solvent occurred. There was obtained 1.35 g. of orange solid, m. p. 210–212° (dec.), which evidently was the dipicrate of 3-(3′-diethylaminopropylamino)-harman. After two more recrystallizations from methanol it melted at 213.5–215° (dec.).

Anal. Calcd. for $C_{31}H_{32}N_{10}O_{14}$: C, 48.44; H, 4.20. Found: C, 48.33; H, 4.20.

Summary

3-Aminoharman is prepared from methyl harman-3-carboxylate by means of the Curtius reaction. 3-Sulfanilamidoharman and 3-(3′-diethylaminopropylamino)-harman (as the dipicrate) are prepared from 3-aminoharman.

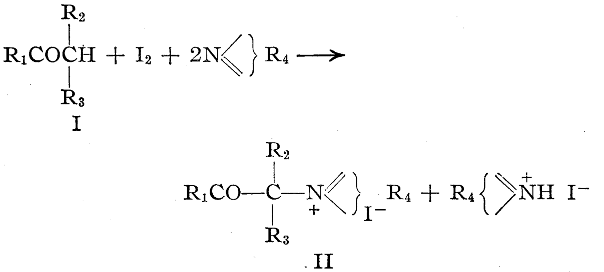
The Reaction of Ketones with Iodine and Pyridine

BY L. CARROLL KING, MARGARET MCWHIRTER AND R. L. ROWLAND

Previous papers from this Laboratory,[1] and from the National Cancer Institute,[2] have reported the preparation of quaternary salts of type (II) by means of the following reaction.



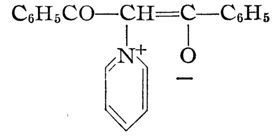
where $R_3 = R_2 = H$

Salts have been reported where R_1 was aryl[1a,1b,2] or a cyclopentanophenanthrene derivative[1a] and where N⟨⟩R₄ was any of a number of heterocyclic nitrogeneous bases.[1c,2] In the present paper this reaction has been extended to include variation in R_2 and R_3 and additional variation in R_1.

The quaternary salts obtained when R_1 was 2- or 3-phenanthryl, thienyl or any of a variety of substituted phenyl groups are listed in Table I. When R_2 was an alkyl or aryl side chain the reaction gave the expected quaternary salt in each case but with increasing length of the alkyl side chain the salts became more difficult to purify and crystallize. A pure quaternary salt was not obtained from isobutyrophenone ($R_2 = R_3 = CH_3$). Data for these materials are also reported in Table I.

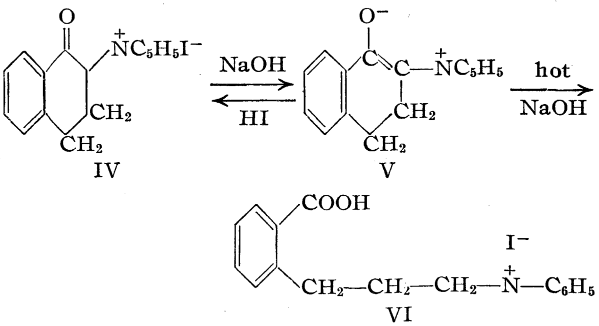
In addition to the substances reported in the tables, quaternary salts were prepared from dibenzoylmethane (R_2 = benzoyl), and from α-tetralone.

From the reaction of dibenzoylmethane with iodine and pyridine, 1-phenacylpyridinium iodide was isolated. The betaine (III) reported to be produced in 40% yield from the reaction of bromodibenzoylmethane with pyridine[3] was not observed.



III

From the reaction of α-tetralone with pyridine and iodine, 1-keto-2-tetrahydronaphthylpyridinium iodide (IV) was obtained. When (IV) was treated with cold alkali an orange betaine (V) separated. This substance could be reconverted to the salt (IV) and on prolonged alkaline hydrolysis in the presence of potassium iodide (IV) was converted to (VI). This behavior is analogous to that reported by Krollpfeiffer and Müller[4] for the corresponding pyridinium bromide.



Each of the quaternary salts reported was subjected to alkaline hydrolysis. The acids produced in these experiments are listed in Table II. No isodurylic acid was obtained from 1-(2,4,6-tri-

methylphenacyl)-pyridinium iodide by alkaline hydrolysis. This is consistent with the observation of Fuson[5] and co-workers for the corresponding pyridinium chloride.

This investigation was partially supported by a grant from the Abbott fund of Northwestern University and by a Grant-in-aid from the National Cancer Institute.

Experimental

Preparation of Ketones.—The ketones, with the exception of p-methylmercaptoacetophenone, are known. 2- and 3-acetophenanthrene were prepared by the procedure of Mosettig and van de Kamp,[6] and p-nitroacetophenone by the method of Walker and Hauser.[7] α-Tetralone, methyl thienyl ketone and dibenzoylmethane were prepared by methods described in "Organic Syntheses." The other ketones were prepared by Friedel–Craft reactions

using benzene or a substituted benzene and the appropriate acid chloride. In general the boiling point or melting point data for each of the ketones was in good agreement with that recorded in the literature.

***p*-Methylmercaptoacetophenone.**—To a mixture of 0.5 mole of phenyl methyl sulfide[8] and 1.0 mole of anhydrous aluminum chloride in carbon disulfide, 0.5 mole of acetyl chloride was added. After one hour the reaction mixture was decomposed by addition to a mixture of ice and hydrochloric acid and the water-insoluble product was crystallized from Skellysolve C; yield 70%, m. p. 79–80°.

Anal. Calcd. for $C_9H_{10}OS$: C, 65.03; H, 6.06. Found: C, 65.20; H, 6.26.

2,4-Dinitrophenylhydrazone m. p. 231–232°; crystallized from chloroform.

Anal. Calcd. for $C_{15}H_{14}O_4N_4S$: N, 16.18. Found: N, 16.14.

The para position for the methylmercapto group is indicated by conversion to the quaternary salt and subsequent alkaline cleavage to the known *p*-methylmercaptobenzoic acid.

Preparation of Quaternary Iodides.—The experimental procedure was identical with that previously reported.[1] The product from the reaction of 0.1 mole of ketone with 0.1 mole of iodine and excess pyridine was washed with ether and then with water. The residue was then crystallized from a suitable solvent. The solvents used for crystallization, the melting points, analyses, and percentage yields are listed in Table I.

Slight variations in the procedure were required for reactions of *n*-butyl phenyl ketone and *n*-amyl-phenyl ketone with iodine and pyridine. The following procedure facilitated the isolation of analytically pure products from these substances. The reaction mixtures were washed with ether and then extracted with acetone. Addition of water or ether to the acetone extracts resulted in the separation of an oil. This oil was crystallized twice from an acetone–ether mixture by cooling in a Dry Ice–acetone-bath. The crystals, which were collected by filtration, melted upon warming to room temperature. By drying this product *in vacuo*, an amber-colored glass with the proper carbon, hydrogen and iodine analyses was obtained from the reaction using *n*-butyl phenyl ketone. The liquid obtained by this method from the reaction of *n*-amyl phenyl ketone crystallized after two days.

Preparation of Quaternary Perchlorates.—The perchlorates were prepared in a manner similar to that reported in other papers.[1]

It is not possible by this method to prepare crystalline perchlorate salts from 1-(1-benzoylbutyl)-pyridinium iodide or from 1-(1-benzoylamyl)-pyridinium iodide. Attempts to prepare picrates from these two iodides also failed.

Alkaline Hydrolysis of Quaternary Iodides.—This was effected in a manner similar to that previously reported.[1] The data on yield and identity of the acids are reported in Table II.

Reaction of Dibenzoylmethane with Iodine and Pyridine.—This reaction was carried out in a manner similar to the general procedure described above with the exception that, during the reaction and in the process of purification, care was taken to exclude water. Nevertheless, no product possessing the characteristics of dibenzoylmethyl pyridinium betaine or the characteristics expected of 1-(dibenzoylmethyl)-pyridinium iodide was isolated. Instead, the only crystalline product was a solid, obtained in 20–25% yield, which was presumed to be 1-phenacylpyridinium iodide on the basis of the following properties; m. p. 213°.

Anal. Calcd. for $C_{13}H_{12}ONI$: N, 4.31; I, 39.0. Found: N, 4.05; I, 39.2.

1-Keto-2-tetrahydronaphthylpyridinium Iodide (IV).—One-tenth mole of α-tetralone was allowed to react with 0.1 mole of iodine and 0.2 mole of pyridine. The product was isolated as indicated in a previous paper,[1] and crystallized from water–alcohol; yield 55%, m. p. 218–220°.

Anal. Calcd. for $C_{15}H_{14}ONI$: C, 51.32; H, 4.02; I, 36.14. Found: C, 51.59; H, 4.25; I, 36.16.

The perchlorate m. p. 180–181°.

Anal. Calcd. for $C_{15}H_{14}O_5NCl$: C, 55.65; H, 4.36. Found: C, 55.46; H, 4.57.

The above iodide, by chromic acid oxidation, was converted to phthalic acid (identified as the anhydride).

1-Keto-2-tetrahydronaphthylpyridinium Betaine (V).—An excess of cold sodium hydroxide solution was added to a suspension of (IV) in water. A golden-red solid precipitated at once. The material which was collected by filtration was unstable on standing and was found to darken at about 65°. A sample of (V) when suspended in water and treated with perchloric acid was converted to the perchlorate of (IV); m. p. 179–180°. The filtrate from which (V) was isolated contained 93% of the iodine originally associated with the salt.

3-(2-Carboxyphenyl)-propylpyridinium Iodide (VI).—A suspension of 11.0 g. of (V) was warmed for one hour with dilute sodium hydroxide containing potassium iodide. The solution was then acidified with hydrogen iodide and the insoluble material separated by filtration. The filtrate was evaporated to a volume of 50–100 cc. and cooled. The light colored precipitate was taken up in absolute alcohol and precipitated with ether. The product weighed 4.0 g.; m. p. 180–182°.

(8) Knapp, *Monatsh.*, **56**, 66 (1930).

Anal. Calcd. for $C_{15}H_{16}O_2NI$: N, 3.80. Found: N, 3.68.

Summary

1. A series of quaternary salts, of interest in chemotherapy studies of cancer, has been prepared by treating iodine and pyridine with substituted methyl aryl ketones, with α-substituted acetophenones, and with α-tetralone.

2. The products obtained from the α-substituted acetophenones became increasingly difficult to purify as the length of the side chain increased, and no pure quaternary salt was obtained from isobutyrophenone.

3. Each of the quaternary salts, except that prepared from acetomesitylene, was converted into a characteristic carboxylic acid by the action of aqueous alkali.

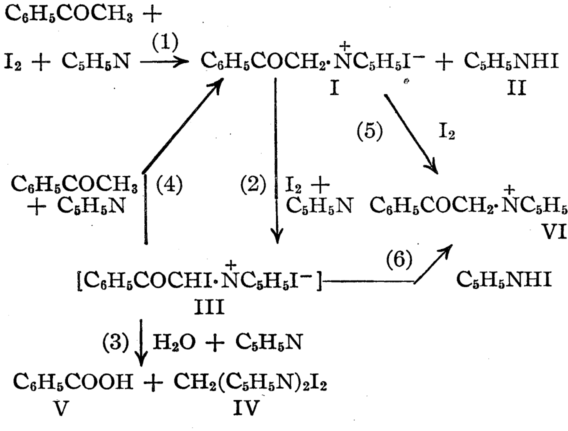
EVANSTON, ILLINOIS RECEIVED JULY 21, 1947

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF NORTHWESTERN UNIVERSITY]

The Reaction of Ketones with Iodine, Pyridine and Water[1]

BY L. CARROLL KING

Acetophenone, on reaction with iodine, pyridine and water, gives a mixture consisting of phenacylpyridinium iodide (I), pyridine hydriodide (II), methylenedipyridinium diiodide (IV), phenacylpyridinium triiodide (VI) and benzoic acid (V). These products result from a number of reactions proceeding at the same time and may be explained by assuming the formation of α-iodophenacylpyridinium iodide (III) as an intermediate, thus



The salt (I) is first formed (reaction 1) and this may then react with iodine and pyridine to form III (reaction 2). Compound III may then react irreversibly with water and pyridine to form IV and V (reaction 3), or it may react with unchanged ketone and pyridine to regenerate I (reaction 4). Reaction 3 is the favored one in very dilute or homogeneous solution even if the ketone is present in excess (see example 4 of the experimental). Reaction 4 is favored in heterogeneous reaction mixtures or when the ketone concentration is high (see example 2 of the experimental). Reactions which produce phenacylpyridinium triiodide (VI) (reactions 5 and 6) are favored in heterogeneous reaction mixtures by an excess of iodine, whereas, in dilute or homogeneous solution, Reaction 3 is favored by excess iodine (see example 1 of the experimental).

Phenacylpyridinium iodide (I), when it reacted with iodine, pyridine and water, gave IV and V in somewhat better yields than those obtained when starting with the corresponding ketone. With a limited amount of water compound VI also was observed.

In experiments where both yields were measured, the mole yield of benzoic acid (V) was always in excess of the mole yield of methylenedipyridinium diiodide (IV) (see example 1 of the experimental). This discrepancy may be due to isolation difficulties, or it may be due to a reaction where iodine in water solution causes oxidation of I to benzoic acid and carbon dioxide.[2]

An attempt to isolate α-iodophenacylpyridinium iodide (III) from the reaction mixture failed. An attempt to prepare III by a method found satisfactory for preparation of the corresponding α-bromophenacylpyridinium bromide[3] (VII) gave none of the expected III but gave phenacylpyridinium triiodide (VI) in almost quantitative yield.

$$C_6H_5COCHBr\cdot\overset{+}{N}C_5H_5\ Br^- \qquad \text{VII}$$

Some reactions of the analogous α-bromophenacylpyridinium bromide (VII) would indicate that the intermediate (III) can enter into the reactions suggested but that III should not be isolable from these reactions. Thus, VII reacted with acetophenone and then with pyridine to give phenacylpyridinium bromide (analogous to reaction 4), with pyridine hydroiodide to give VI (analogous to reaction 6), and with water and pyridine to give methylenedipyridinium dibromide[3] (analogous to reaction 3).

The methylenedipyridinium diiodide (IV) isolated in the reaction studies was in each case compared in detail with an authentic specimen prepared by action of pyridine on methylene iodide.

[1] Paper no. 6 on the Reaction of Ketones with Halogens and Nitrogeneous Bases. For other papers in this series see King and co-workers, THIS JOURNAL, **66**, 894, 1612 (1944); **67**, 2089 (1945); **68**, 717 (1946); **70**, 239 (1948).

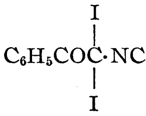
[2] Such a reaction was observed[3] when bromine water reacted with phenacylpyridinium bromide.

[3] Kröhnke, *Ber.*, **66**, 1386 (1933).

The compound described as phenacylpyridinium triiodide is new. The structure is based on two lines of evidence: (a) it is produced in nearly quantitative yield by reaction of iodine and phenacylpyridinium iodide (I) in glacial acetic acid, and (b) it was found to react with pyridine and acetophenone to give pyridine hydroiodide (II) and phenacylpyridinium iodide (I). This latter compound was present at the end of the reaction in mole quantity about twice that of the starting triiodide. The appearance of pyridine hydroiodide and this extra phenacylpyridinium iodide is evidence that iodine reacted with acetophenone and pyridine.[1] This may be represented as

$$C_6H_5COCH_2\overset{+}{N}C_5H_5I_3^- + C_5H_5COCH_3 \quad 2C_5H_5N \longrightarrow$$
$$2C_6H_5COCH_2\cdot\overset{+}{N}C_5H_5I^- + C_5H_5NHI$$

Had the compound VI been an iodinated substance such as VIII no pyridine hydroiodide



$$C_6H_5CO\overset{I}{\underset{I}{C}}\cdot NC_5H_5I$$

VIII

would have been produced in this reaction. Furthermore, since α-halogenated salts of this type (for example, VII) were shown to react readily with acetophenone and pyridine, three moles of I would have been produced for each mole of the starting substance had the starting substance been VIII.

Experimental

Reaction of Acetophenone with Iodine, Pyridine and Water.—These reactions were studied by determination of the amount of some of the isolable reaction products under a variety of conditions. A summary of the general procedure and typical results is illustrated by the following examples.

Example 1.—A mixture consisting of 0.025 mole of acetophenone, 0.05 mole of iodine, 20 cc. of pyridine and 2.5 moles of water[4] in an open flask was heated to dryness on the steam-bath. The residue was leached with ether (1.6 g., 55%[5] of benzoic acid was isolated from the ether extract). The solid remaining was leached with acetone (25 mg. of phenacylpyridinium triiodide[6] (VI) was isolated from the acetone extract). The solid remaining after the acetone extraction was then leached with hot absolute alcohol. (From the alcohol extract 1.2 g., 14%,[5] of phenacylpyridinium iodide (I) and a quantity of pyridine hydroiodide[7] was obtained.) The residue left after alcohol extraction was methylenedipyridinium diiodide[6] (IV); yield 2.5 g. or 24%.[5]

A duplicate experiment gave 1.7 g. of I and 1.7 g. of IV.

Example 2.—A mixture consisting of 0.1 mole of acetophenone, 0.1 mole of iodine, 20 cc. of pyridine and 45 g. (2.5 moles) of water[8] in an open flask was heated for fifteen hours on the steam-bath. From the residue 18.5 g., 57%,[5] of I, pyridine hydroiodide in quantity and a trace of IV were obtained.

Example 3.—A mixture consisting of 0.025 mole of acetophenone, 0.025 mole of iodine, 20 cc. of pyridine and 45 g. (2.5 moles) of water,[4] when heated as in Example 1, gave 0.7 g., 14%,[9] of IV, a quantity of pyridine hydroiodide, a trace of phenacylpyridinium iodide (I) and benzoic acid.

Example 4.—A solution consisting of 5.0 g. (0.041 mole) of acetophenone, 100 cc. of pyridine, 300 cc. of water and 1.0 g. (0.004 mole) of iodine[4] was evaporated to dryness on the steam-bath. The residue consisted of pyridine hydroiodide, benzoic acid and 0.30 g. of IV, 36%.[9] No phenacylpyridinium iodide could be detected.

Reaction of Phenacylpyridinium Iodide with Iodine, Pyridine and Water.—A solution of 0.025 mole of I in 50 cc. of water was treated with 10 cc. of pyridine and 0.025 mole of iodine. The solution was placed in an open flask and heated to dryness on the steam-bath. Benzoic acid was present as a sublimate. The residue was successively leached with ether, acetone and absolute alcohol, and finally crystallized from alcohol containing a small amount of water; yield 4.4 g. (42%) of methylenedipyridinium iodide.[6] When a similar experiment was carried out using a limited amount of water, a mixture similar to that described in example 1 was obtained.

α-Bromophenacylpyridinium Bromide (VII).—This substance was prepared according to the directions of Kröhnke.[3] It was crystallized twice from glacial acetic acid; m. p. 219°.[10]

Anal. Calcd. for $C_{13}H_{11}ONBr_2$: Br, 44.8. Found: Br, 45.5.

Reaction of VII with Pyridine and Acetophenone.—A mixture of 5.0 g. of VII, 7 cc. of acetophenone and 10 cc. of pyridine was heated for three hours on the steam-bath. The mixture was diluted with ether and filtered. The product was phenacylpyridinium bromide; yield 7.8 g.; m. p. 219°.

Anal. Calcd. for $C_{13}H_{12}ONBr\cdot H_2O$: Br, 27.0. Found: Br, 26.2. The perchlorate had m. p. 189.°

Reaction of VII with Pyridine Hydroiodide.—A mixture of 0.01 mole of VII and 10 g. of pyridine hydroiodide was dissolved in boiling glacial acetic acid. An intense iodine color developed. The solution was cooled, filtered, and the solid leached with acetone. Phenacylpyridinium triiodide (VI) was recovered from the acetone extract; yield 1 g.; m. p. 111–112°.

Methylenedipyridinium Diiodide (IV).—A mixture consisting of 3 cc. of methylene iodide and 10 cc. of pyridine was heated for one hour on the steam-bath. The crystalline product which separated was washed with ether and crystallized four times from alcohol containing a little water; m. p. 223–224°. This substance is insoluble in absolute alcohol, and very soluble in water.

Anal. Calcd. for $C_{11}H_{12}N_2I_2$: I, 59.7; N, 6.42. Found: I, 59.0; N, 6.72.

The diperchlorate showed m. p. 232–235°.

Anal. Calcd. for $C_{11}H_{12}N_2Cl_2O_8$: N, 7.57. Found: N, 7.63.

The picrate gave m. p. 245–249°.[11]

Phenacylpyridinium Triiodide (VI): Method I.—A solution of 5 g. of phenacylpyridinium iodide (I) in 40 cc. of hot water–alcohol was added to a solution of 10 g. of potassium iodide and 5 g. of iodine in 40 cc. of water. A red oil precipitated; it was separated by decantation, dissolved in hot absolute alcohol, and the solution cooled. The red-brown flaky crystals obtained were crystallized four times from absolute alcohol; yield 5 g.; m. p. 114–115°.

---

[4] This mixture was homogeneous after heating for a few minutes on the steam-bath.

[5] Based on the ketone.

[6] Characterized by detailed comparison with the authentic material as described elsewhere in this paper.

[7] The amount of this substance was not determined. It was present in considerable quantity in all reaction mixtures.

[8] This mixture was not homogeneous.

[9] Based on iodine assuming all iodine was used according to reactions 1, 2 and 3.

[10] Kröhnke[3] reported the melting point of this compound as 219° after crystallizing from water or alcohol. The substance prepared in this Laboratory shows marked decomposition in the range 120–150°, but most of it persists until 219–220°.

[11] The melting point of this substance was reported as 230° by Schmidt, *Arch. Pharm.*, **251**, 186 (1913). In several preparations we have never observed this value.

Anal. Calcd. for $C_{13}H_{12}NOI_3$: I, 65.8; N, 2.42. Found: I, 63.0; N, 2.48.

This substance is very slightly soluble in water, benzene and ether, moderately soluble in absolute alcohol, and very soluble in acetone. A suspension of it in water slowly turns starch to a blue color.

Method II.—A solution of 0.05 mole of phenacylpyridinium iodide in 75 cc. of boiling glacial acetic acid was treated with 0.05 mole of iodine. On cooling, the triiodide (VI) separated; yield, 95%; m. p. 111–113°.

Reaction of Phenacylpyridinium Triiodide (VI) with Acetophenone and Pyridine.—A solution consisting of 2.57 g. (0.0044 mole) of VI in 5 g. of acetophenone and 5 g. of pyridine was heated for two hours on the steam-bath. At the end of this time most of the color had disappeared and a light brown crystalline solid was present in the reaction flask. This solid was separated and thoroughly washed with ether; yield 3.6 g. of crude solids. The material was then digested with 10 cc. of warm water, the suspension cooled in an ice-bath and filtered. The solid, weight 2.54 g. (0.0078 mole), was phenacylpyridinium iodide (I). The water-soluble portion was concentrated and treated with perchloric acid. Pyridine perchlorate, 0.9 g. (0.0044 mole), m. p. 285°, separated. This was considered proof that pyridine hydroiodide was present in the reaction mixture as an ether insoluble salt and hence had been formed in the original reaction.

Summary

1. The reaction of acetophenone with iodine, pyridine and water was studied and five products separated and identified. A reaction scheme to explain these products is given and independent experiments were carried out to establish each of the postulated reactions.

2. Phenacylpyridinium triiodide was prepared and it was demonstrated that it contains the triiodide ion.

The Action of Formic Acid on Ethynylcarbinols[1]

BY J. D. CHANLEY

Ethynylcarbinols on treatment with formic acid yield isomeric unsaturated carbonyl compounds. Rupe,[2] in the years 1926–1929, studied this isomerization in a number of instances and originally concluded that the reaction products were unsaturated aldehydes. Fischer and Löwenberg,[3] however, showed that the interaction of 1-ethynyl-1-cyclohexanol (IA) and formic acid yielded the isomeric ketone, 1-acetyl-1-cyclohexene (IIA) and not cyclohexylideneacetaldehyde (IIIA), as postulated by Rupe; they suggested that ketones always were the main products of this type of reaction and that aldehydes, if formed, were present in small quantities. Rupe,[4] accepted their evidence and suggestion, but insisted that some aldehyde was present in each reaction product he had previously described.[5] Hurd and Christ[6a] also repeated Rupe's work on 1-ethynyl-1-cyclohexanol and phenylmethylethynylcarbinol and chose for further study the action of formic acid on ethynylbornyl alcohol. They reported that only the corresponding ketones 1-acetyl-1-cyclohexene, acetophenone and 2-acetyl-6-hydroxycamphane were formed and went beyond Rupe's modified concept by doubting the presence of any aldehydes in Rupe's reaction products. However, their products must have contained some aldehydes, since their ketones, like Rupe's, gave a positive test for aldehydes with Schiff reagent. However, they discounted the significance of this test.[6b]

In the present paper evidence will be offered to show that 1-ethynyl-1-cyclohexanol (IA) on treatment with formic acid and after careful fractionation gives, in addition to the main product, 1-acetyl-1-cyclohexene (IIA) (50% yield), a small but significant quantity of cyclohexylideneacetaldehyde (0.8% yield). As a second example we prepared the new 1-ethynyl-2,2-dimethyl-1-cyclohexanol (IB) which on similar treatment gave the new ketone 2,2-dimethyl-1-acetyl-1-cyclohexene (IIB) (56% yield) and the new aldehyde 2,2-dimethylcyclohexylideneacetaldehyde (IIIB) (6% yield). Neither of the above mentioned pure ketones gave a positive test for aldehydes with Schiff reagent.

(3) Fischer and Löwenberg, *Ann.*, **475**, 203 (1929).

(4) Rupe and Hirschmann, *Helv. Chim. Acta*, **14**, 688 footnote (1931).

(5) Subsequently Rupe claimed that 1-ethynyl-2-isopropyl-5-methyl-1-cyclohexanol, 1-ethynyl-3-isopropyl-6-methyl-1-cyclohexanol and ethynylfenchyl alcohol were rearranged exclusively to unsaturated aldehydes of type III (see Rupe and Kuenzy, *Helv. Chim. Acta*, **14**, 708 (1931); **17**, 283 (1934)).

(6a) Hurd and Christ, THIS JOURNAL, **59**, 118 (1937).

(6b) *Cf.* also Price and Meisel, *ibid.*, **69**, 1497 (1947).

It is further shown that the unsaturated ketones IIA and IIB may be oxidized to the corresponding unsaturated glyoxals which are rearranged under the influence of hydroxyl-ion to the glycolic acids.

The empirical formulas of both aldehydes (IIIA and IIIB) were established by analysis of the liquids or their semicarbazones. Their structures were ascertained by air oxidation to their respective acids, cyclohexylideneacetic acid (IVA) and 2,2-dimethylcyclohexylideneacetic acid (IVB), which showed no depression in melting point on admixture with the corresponding authentic samples.[7a,b] The semicarbazone of cyclohexylideneacetaldehyde melted at 188–192°. Although this is not in agreement with the values reported in the literature,[8a] its ultraviolet spectrum, $\lambda_{\max} = 269$ mμ, $\epsilon_{\max} = 33{,}800$, is in fair agreement and the spectrum of the liquid aldehyde, $\lambda_{\max} = 237$ mμ, $\epsilon_{\max} = 14{,}400$, confirms the findings of Aldersley and Burckhardt[8b]. This corroborative evidence shows that our sample of cyclohexylideneacetaldehyde was reasonably pure. The ultraviolet spectrum of the new aldehyde (IIIB) and that of its semicarbazone was very similar to that of aldehyde (IIIA) and its semicarbazone (Fig. 1); both aldehydes gave positive tests with Schiff reagent.

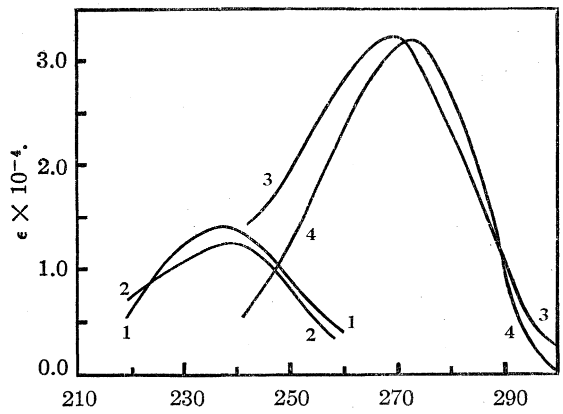

Fig. 1.—Molecular extinction curves of: (1) cyclohexylideneacetaldehyde; (2) 2,2-dimethylcyclohexylideneacetaldehyde; (3) semicarbazone of cyclohexylideneacetaldehyde; (4) semicarbazone of 2,2-dimethylcyclohexylideneacetaldehyde.

The assignment of structure IIB to the new ketone, prepared from the corresponding ethynylcarbinol (IB), is based on its synthesis, analysis and ultraviolet absorption spectrum. Its spectrum and that of its semicarbazone closely resemble those of compound IIA and its semicarbazone[9] (Fig. 2). The possibility that a methyl group may have migrated or that a five-membered ring might have been formed and thus lead to an isomeric unsaturated ketone may be discounted, since no plausible rearrangement could give an α,β-unsaturated ketone.

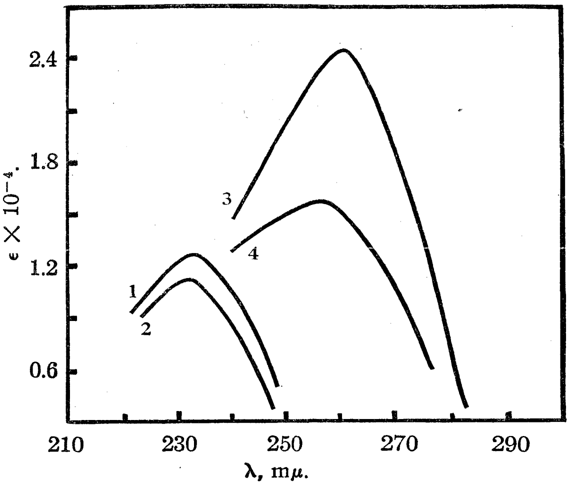

Fig. 2.—Molecular extinction curves of: (1) 1-acetyl-1-cyclohexene; (2) 2,2-dimethyl-1-acetyl-1-cyclohexene; (3) semicarbazone of 1-acetyl-1-cyclohexene; (4) semicarbazone of 2,2-dimethyl-1-acetyl-1-cyclohexene.

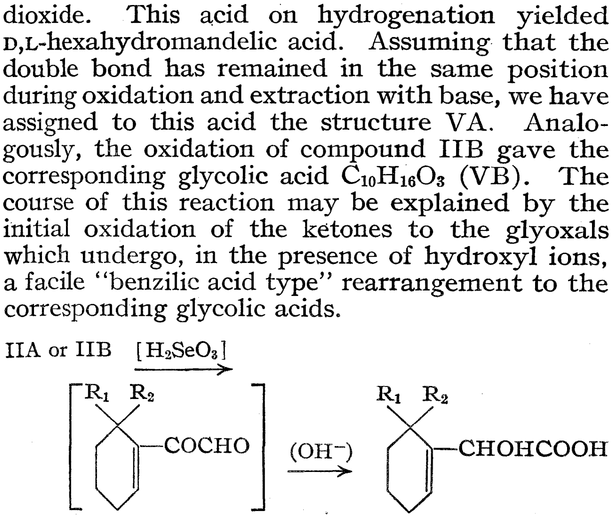
1-Acetyl-1-cyclohexene (IIA), on oxidation with selenous acid, yielded a red oil which was extracted with sodium carbonate solution and then with sodium hydroxide solution. Acidification of the sodium hydroxide extract gave a solid acid, $C_8H_{12}O_3$, which was now soluble in sodium bicarbonate solution with evolution of carbon dioxide. This acid on hydrogenation yielded D,L-hexahydromandelic acid. Assuming that the double bond has remained in the same position during oxidation and extraction with base, we have assigned to this acid the structure VA. Analogously, the oxidation of compound IIB gave the corresponding glycolic acid $C_{10}H_{16}O_3$ (VB). The course of this reaction may be explained by the initial oxidation of the ketones to the glyoxals which undergo, in the presence of hydroxyl ions, a facile "benzilic acid type" rearrangement to the corresponding glycolic acids.



VA, $R_1, R_2 = H$
VB, $R_1, R_2, = CH_3$

(7) (a) Wallach, *Ann.*, **365**, 261 (1909); (b) Elliot and Linstead, *J. Chem. Soc.*, **776** (1938).

(8) (a) Dimroth, Ber., **71**, 1333 (1938), gives a m. p. of 210°; Aldersley and Burckhardt, *J. Chem. Soc.*, 545 (1938), report m. p. of 205°.

(8) (b) Aldersley, Burckhardt, Gillam and Hindley, *J. Chem. Soc.*, 10 (1940), report $\lambda_{\max} = 240$ mμ, $\epsilon_{\max} = 15{,}900$ for the aldehyde and $\lambda_{\max} = 272$ mμ, $\epsilon_{\max} = 28{,}000$ for the semicarbazone, whereas Dimroth (ref. 8a) gives $\lambda_{\max} = 232$ mμ, $\epsilon_{\max} = 17{,}400$ and $\lambda_{\max} = 274$ mμ, $\epsilon_{\max} = 32{,}300$ for the two compounds, respectively.

(9) The low value, $\lambda_{\max} = 255$ mμ, for the semicarbazone of compound IIB is not unique. A more extreme case is β-ionone, $\lambda_{\max} = 293.5$ mμ, the semicarbazone of which has a maximum at $\lambda = 276.5$ mμ. See Burawoy, *J. Chem. Soc.*, 20 (1941).

Experimental[10,11]

2,2-Dimethyl-1-cyclohexanone.—Crude dimethylcyclohexanone was prepared in 2-mole batches from 2-methyl-1-cyclohexanone[12] essentially according to Haller and Cornubert.[13] Sodamide was freshly prepared,[14] and methyl iodide was used rather than methyl sulfate. The crude reaction product was fractionated through a packed column of 13–15 theoretical plates and the impure ketone fraction boiling at 168–173° was collected and purified by regeneration from its pure semicarbazone.[15] Pure ketone, boiling at 170–170.5° (cor.) (761 mm.), $n^{20}\text{D}$ 1.4482 was obtained in an over-all yield of 30%; reported[15] b. p. 169–170°, (cor.) (768 mm.), $n^{25}\text{D}$ 1.4460. The semicarbazone melted at 199–201°; reported m. p. 197–198°,[15] 201–202°[7b]; oxime m. p. 93–94°; reported 93–93.5°.[16]

Anal. Calcd. for $C_8H_{14}O$: C, 76.13; H, 11.18. Found: C, 75.56; H, 11.14. Calcd. for $C_9H_{17}N_3O$: C, 58.98; H, 9.35; N, 22.92. Found: C, 59.00; H, 9.12; N, 23.30.

1-Ethynyl-1-cyclohexanol (IA), b. p. 72.5–73° (11 mm.), $n^{25}\text{D}$ 1.4810, m. p. 28–30°, was prepared in 1-mole batches in 50% yield according to the directions of Campbell and co-workers.[17]

1-Ethynyl-2,2-dimethyl-1-cyclohexanol (IB), b. p. 113–113.5° (49 mm.), $n^{25}\text{D}$ 1.4790 was prepared analogously[17] in 0.5-mole batches in 68% yield from the pure ketone (IIB) and sodium acetylide. It gave a white precipitate with alcoholic silver nitrate solution.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.89; H, 10.59. Found: C, 78.82; H, 10.63.

1-Acetyl-1-cyclohexene (IIA) and Cyclohexylideneacetaldehyde (IIIA).—The conditions of the reaction described below are those of Rupe with minor modifications. A mixture of 65 g. (0.5 mole) of 1-ethynyl-1-cyclohexanol and 400 ml. of formic acid (90%) was gently heated under reflux until a vigorous reaction ensued. After heating under reflux for forty–fifty minutes the mixture was poured into 2 liters of ice water. The petroleum ether extract was washed with sodium hydroxide solution (10%) and the residue from the petroleum ether was steam-distilled. The organic layer in the steam distillate was separated, dried and gave a positive test with Schiff reagent. It was carefully fractionated under reduced pressure through a column of 8–10 theoretical plates which was fitted with a total condensation still head and an electrically heated outer jacket. This column had an internal diameter of 12.5 mm. and was packed for 30 cm. with 1.5 mm. diameter single helices made from 25 gauge stainless steel. Table I gives the properties of the five fractions collected.

The **semicarbazone** prepared from fraction B, 1-acetyl-1-cyclohexene melted at 220–221°, $\lambda_{\max.}$ = 260.5 mμ, $\epsilon_{\max.}$ = 24,200. Reported m. p. 220–221°[6a] and $\lambda_{\max.}$ = 260.5 mμ, $\epsilon_{\max.}$ = 20,150.[18]

The **semicarbazone** prepared from fraction E, cyclohexylideneacetaldehyde, melted at 188–192° and further recrystallizations from ethanol and methanol did not alter the melting point.

TABLE I

Fraction	Yield, g.	B. p., °C., 49 mm.	$n^{20}\text{D}$	$\lambda_{\max.}$, mμ	$\epsilon_{\max.}$	Schiff reaction[b]
A	3.5	76–111	1.4435– 1.4893	...	....	Neg.

(18) Evans and Gillam, *J. Chem. Soc.*, 815 (1941); 565 (1943), also report $\lambda_{\max.}$ = 233.5 mμ, $\epsilon_{\max.}$ = 9,660 for this ketone.

from 216 to 300 mμ and gave a white precipitate with alcoholic silver nitrate solution.

Anal. Calcd. for $C_{10}H_{14}$: C, 89.49; H, 10.51. Found: C, 89.47; H, 10.30.

Oxidation of Cyclohexylideneacetaldehyde (IIIA) to Cyclohexylideneacetic Acid (IVA).—One-tenth of a ml. of Fraction E (Table I) was allowed to stand exposed to the air for three days. The resulting semisolid crystalline mass was dissolved in ether and extracted several times with 10% sodium carbonate solution. The combined alkaline extracts, on acidification, yielded 40 mg. of the acid, m. p. 89–90°, which after recrystallization from petroleum ether (b. p. 40–60°), melted at 90–92° and showed no depression of melting point on admixture with authentic cyclohexylideneacetic acid, m. p. 90–92°, prepared by the dehydration of (1-hydroxycyclohexyl)-acetic acid[19] according to the direction of Wallach[7a] who reports m. p. 91°.

Oxidation of 2,2-Dimethylcyclohexylideneacetaldehyde (IIIB) to 2,2-Dimethylcyclohexylideneacetic acid (IVB).—In a similar manner 1 ml. of 2,2-dimethylcyclohexylideneacetaldehyde, after standing two weeks, exposed to the air, gave 300 mg. of 2,2-dimethylcyclohexylideneacetic acid, m. p. 89–90°. The acid after recrystallization from acetic acid, melted at 90–91° and showed no depression of melting point on admixture with an authentic sample[20]; m. p. 90–91°; reported[7b] m. p. 91–92°.

(1-Cyclohexenyl)-glycolic Acid (VA).—A solution of 6.2 g. (0.05 mole) of 1-acetyl-1-cyclohexene and 6.5 g. (0.05 mole) of selenous acid in 40 ml. of dioxane was heated under reflux for three and one-half hours, decanted from the precipitated selenium and evaporated to dryness *in vacuo* under nitrogen. The ethereal solution of the residue was thoroughly extracted with sodium carbonate solution (10%). (At this point, much red selenium precipitates and is allowed to sink into the carbonate solution.) The carbonate extract gave only intractable tars upon acidification. The ether layer was then extracted six times with dilute sodium hydroxide solution (10%). The combined sodium hydroxide extracts were filtered, warmed on the steam-bath, acidified with a slight excess of warm dilute hydrochloric acid and filtered from precipitated tarry material. The filtrate was saturated with salt and precipitation induced by scratching the sides of the container; 1.5 g. of a yellow colored solid, m. p. 122–124° was collected. After recrystallization from Skellysolve L (b. p. 97–129°), with Norite, a colorless solid acid, m. p. 126–126.5° was obtained. It was now soluble in sodium bicarbonate solution with evolution of carbon dioxide; yield 1.4 g.

Anal. Calcd. for $C_8H_{12}O_3$: C, 61.52; H, 7.75; neut. equiv., 156.2. Found: C, 61.61; H, 8.04; neut. equiv., 159.0.

Hydrogenation of Compound VA to D,L-Hexahydromandelic Acid.—Two hundred and forty-seven mg. (0.00157 mole) of compound VA, in glacial acetic acid, was hydrogenated at atmospheric pressure with platinum oxide; 98% of the theoretical amount of hydrogen was absorbed. The resulting acid recrystallized from chloroform melted at 134–135° and showed no depression of m. p. in admixture with D,L-hexahydromandelic acid of m. p. 135–136°, prepared from D,L-mandelic acid by hydrogenation. Reported m. p. 134–135°.[21]

(2,2-Dimethyl-1-cyclohexenyl)-glycolic Acid (VB).—Similarly, 4.2 g. ($^1/_{30}$ mole) of 2,2-dimethyl-1-acetyl-1-cyclohexene (IIB) was treated with 3.6 g. ($^1/_{30}$ mole) of selenous acid in 20 ml. of dioxane with the following modifications. The sodium hydroxide extract after acidification was not filtered, since the acid separates in a semi-solid state at this point. The precipitated orange-colored crude acid was purified by dissolving in a small amount of hot sodium carbonate solution (10%) treated with norite, filtered and reprecipitated by the addition of dilute hydrochloric acid solution. Yield was 0.9 g., m. p. 118–120°. Two recrystallizations from ethanol–water mixture gave the pure colorless acid, m. p. 121°.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.76; neut. equiv., 184.2. Found: C, 65.08; H, 8.71; neut. equiv., 186.5.

Acknowledgment.—The author wishes to thank Dr. Harry Sobotka for his interest and suggestions, and Mrs. Edith Rosen Kaplan and Miss Bernice Hamerman for their very able assistance.

Summary

1. 1-Ethynyl-1-cyclohexanol is isomerized under the influence of formic acid to 1-acetyl-1-cyclohexene (50% yield) and cyclohexylideneacetaldehyde (0.8% yield). Similarly 2,2-dimethyl-1-ethynyl-1-cyclohexanol gave 2,2-dimethyl-1-acetyl-1-cyclohexene (56% yield) and 2,2-dimethylcyclohexylideneacetaldehyde (6% yield).

2. The selenous acid oxidation product of 1-acetyl-1-cyclohexene on treatment with a dilute solution of sodium hydroxide yielded (1-cyclohexenyl)-glycolic acid. Similarly 2,2-dimethyl-1-acetyl-1-cyclohexene yielded (2,2-dimethyl-1-cyclohexenyl)-glycolic acid. An interpretation of the course of this reaction is given.

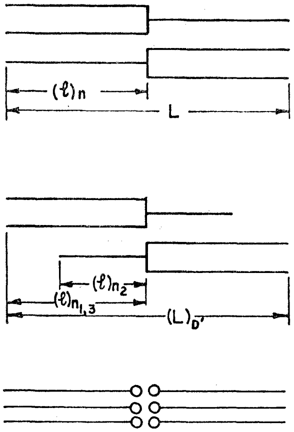
Triple Chain-Length Structures of Saturated Triglycerides[1]

BY E. S. LUTTON

The nature of the polymorphism of the glyceride series, tristearin, tripalmitin, etc., has been made clear by the work of Clarkson and Malkin[2] and others.[3,4,5] The "triple-melting" phenomena of these glycerides are due to three crystalline forms—α, β' and β. These forms are of double-chain-length (DCL) structure, with their molecules presumably in Malkin's "tuning fork" type of configuration. The arrangement is indicated schematically in Fig. 1 along with other DCL structures, one for a fatty acid and another for a mixed triglyceride.



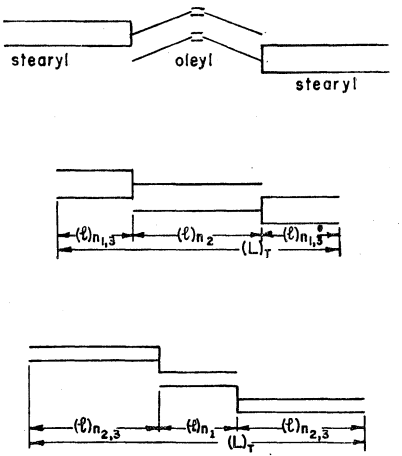
(a) Simple triglyceride

(b) Mixed triglyceride

(c) Fatty acid

Fig. 1.—Double-chain-length structures.

According to Malkin, *et al.*,[6] and others[7,8] many mixed saturated triglycerides are analogous to tristearin in their polymorphic forms. But these authors have shown that there may be serious departures from the tristearin plan, notably with regard to long spacings and DCL structure. No comprehensive scheme has been advanced which treats in any clear-cut way these departures from DCL structure. The presentation of such a scheme is attempted in this paper. It is shown that most, but not all, departures from normal long spacing values can be explained by crystallization of the mixed glycerides in triple-chain-length (TCL) structures similar to those proposed for the mixed saturated-unsaturated triglyceride 2-oleyl distearin.[5,9] In the saturated case, as in the unsaturated case, the TCL structures are presumed to arise from the sorting of chains, short chains from long chains instead of unsaturated from saturated chains. This process of sorting apparently gives rise to both tuning fork structures and a newly proposed "chair" type of molecular arrangement (see Fig. 2).



(a) 2-Oleyldistearin

(b) Symmetrical or "tuning fork" arrangement

(c) Unsymmetrical or "chair" arrangement

Fig. 2.—Triple-chain-length structures.

The quadruple-chain-length (QCL) structures which are discussed later are regarded as doubled DCL structures.

A simple geometric basis is proposed for classifying the various reported triglyceride forms as DCL, TCL or QCL structures. In developing this basis the following assumptions are made:

1. With regard to cross-sectional structures, as characterized by short spacings, there are three structure types which may be identified according to Table I.

TABLE I

CROSS-SECTIONAL STRUCTURE TYPES

Type	Identification
α	A single strong line corresponding to approx. 4.15 Å.
β'	Usually two (but occasionally more) strong lines corresponding to approx. 4.2 and 3.8 Å.
β	A strong (usually strongest) line corresponding to approx. 4.6 Å.

2. With regard to longitudinal structure, as revealed by long spacings, there are three structure types which are distinguished as indicated in Table II. Each of these conceivably may be, and one of them actually is, associated with all three cross-sectional types.

TABLE II

LONGITUDINAL STRUCTURE TYPES

Type	Identification
DCL	Long spacings of approx. normal length
TCL	Long spacings approx. 50% longer than normal
QCL	Long spacings approx. twice normal

There is, in theory, no exclusion of the possibility of other cross-sectional and longitudinal structure types.

Calculation of Long Spacings

If it be assumed that for any specified cross-sectional type the angle of tilt and consequently the contribution to long spacing per chain is approximately the same as in single fatty acid triglycerides, a simple calculation for long spacings can be postulated. Contributions per chain are indicated by (l) values shown in Table III.

TABLE III

CONTRIBUTIONS OF SINGLE CHAINS

Triglyceride	n	Long spacings of simple triglycerides $L\alpha^b$	$L\beta'^c$	$L\beta^b$	Long spacing per chain $(l\alpha)_n$	$(l\beta')_n$	$(l\beta)_n$
Tricaprin	10	(30.6)[a]	(28.2)[a]	26.8	15.3	14.1	13.4
Trilaurin	12	35.6	32.85	31.2	17.8	16.4	15.6
Trimyristin	14	41.2	37.65	35.8	20.6	18.8	17.9
Tripalmitin	16	45.6	42.3	40.6	22.8	21.15	20.3
Tristearin	18	50.6	46.8	45	25.3	23.4	22.5

[a] Extrapolated. [b] Malkin, *et al.*, ref. 2. [c] Lutton, ref. 4.

Obviously $(l_\alpha) = {}^1/_2L_\alpha$, etc.

Now it follows from the linear variation of (l) values with number of carbons that the following simple expressions can be given

$$(l_\beta)_n = 2.0 + 1.138\ n \qquad (1)$$

$$(l_{\beta'})_n = 2.5 + 1.163\ n \qquad (2)$$

$$(l_\alpha)_n = 2.8 + 1.250\ n \qquad (3)$$

Arithmetically the long spacing calculation for mixed glycerides is simply a matter of obtaining the average chain length contribution, C, and multiplying by the right "multiplicity factor," *i. e.*, 2 for DCL, as indicated in Table IV.

TABLE IV

CALCULATED LONG SPACING VALUES IN TERMS OF (l) VALUES

β Cross-sectional type

Long spacing type	Calculated value	
DCL	$(L\beta)_\mathrm{D} = 2 \times \dfrac{(l\beta)_{n_1} + (l\beta)_{n_2} + l\beta)_{n_3}}{3} = 2\ C\beta$	(4)
TCL	$(L\beta)_\mathrm{T} = 3 \times \dfrac{(l\beta)_{n_1} + (l\beta)_{n_2} + (l\beta)_{n_3}}{3} =$ $(l\beta)_{n_1} + (l\beta)_{n_2} + (l\beta)_{n_3} = 3\ C\beta$	(5)
QCL	$(L\beta)_\mathrm{Q} = 4 \times \dfrac{(l\beta)_{n_1} + (l\beta)_{n_2} + (l\beta)_{n_3}}{3} = 4C\beta$	(6)

Similar values are postulated for beta prime and alpha cross-sectional types.

Now, from relations (1), (2) and (3), (L) values may be simply derived from the total number of acyl carbons, *e.g.:* letting $(n_1 + n_2 + n_3) = N$

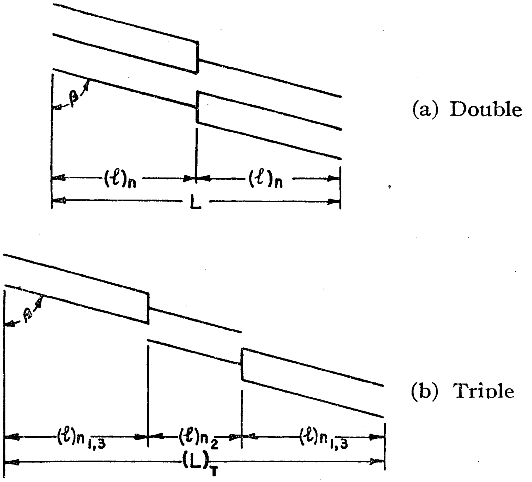
$$(L_\beta)_\mathrm{T} = 3\ C_\beta = 6.0 + 1.138\ N \qquad (7)$$

$$(L_{\beta'})_\mathrm{T} = 3\ C_{\beta'} = 7.5 + 1.163\ N \qquad (8)$$

$$(L_\alpha)_\mathrm{T} = 3\ C_\alpha = 8.4 + 1.250\ N \qquad (9)$$

with corresponding relations for DCL and QCL structures. By these equations, all calculated long spacing values were derived.

Geometrically, TCL structures may be represented as in Fig. 2 (in projection) or Fig. 3 (with the tilt indicated). It is not possible to represent DCL structures neatly for mixed glycerides. In Fig. 1 such a structure is represented with long spacing value designated as $(L)_{\mathrm{D}'}$ to distinguish it from the shorter $(L)_\mathrm{D}$ value defined as in equation (4). QCL structures are regarded as essentially doubled DCL structures, the manner and basis for doubling not being understood except that they are in some way associated with chain length difference in the glycerides.



(a) Double

(b) Triple

Fig. 3.—Assumed constancy of tilt angle for given "form."

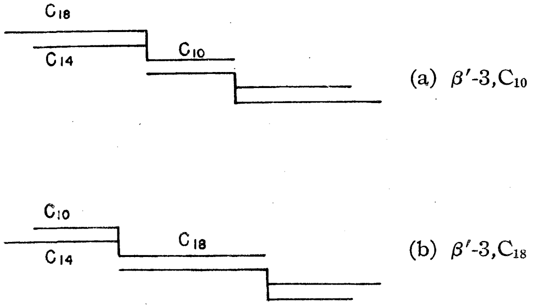
Additional quantities are defined to express the departure of experimental from calculated values

$$(\Delta_\beta)_\mathrm{D} = L_\beta - (L_\beta)_\mathrm{D} \qquad (10)$$

$$(\Delta_\beta)_\mathrm{T} = L_\beta - (L_\beta)_\mathrm{T} \qquad (11)$$

$$(\Delta_\beta)_\mathrm{Q} = L_\beta - (L_\beta)_\mathrm{Q} \qquad (12)$$

where L_β is the experimental value, (L_β) values are calculated as previously described and (Δ_β) values represent the differences.



(a) β'-3,C_{10}

(b) β'-3,C_{18}

Fig. 4.—Alternative triple structures for C_{18}, C_{14}, C_{10}.

Similar (Δ) values are defined for alpha and beta prime forms.

In Tables V and VI, the experimental L and derived (Δ) values are recorded for all mixed saturated glycerides for which data have been published.

Fortunately only one (Δ) value needs to be calculated for a given form. It is generally evident by inspection if, for instance, $(\Delta)_T$ is preferable to $(\Delta)_D$ or $(\Delta)_Q$.

The L values of Tables V and VI are plotted in Figs. 5 and 6 along with lines which express the calculated (L) values. It is these plots which most strikingly reveal that all the available long spacing data with one exception correspond with the concept of either DCL, TCL or QCL structure.

TABLE V

DIFFERENCES BETWEEN EXPERIMENTAL[6a,b,c,d,e] AND CALCULATED LONG SPACINGS

Recording of $(\Delta)_D$, $(\Delta)_T$ or $(\Delta)_Q$ value signifies, respectively, double, triple, or quadruple (doubled double) chain length structure.

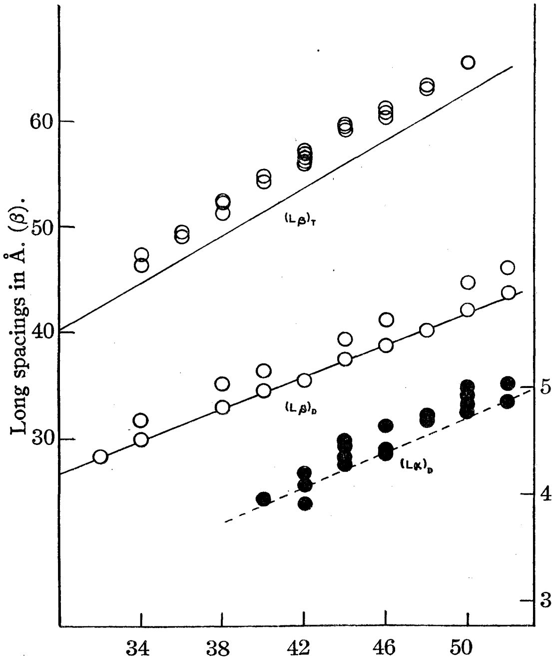
Agreement of Calculation and Experiment

Alpha Form (None reported for triacid triglycerides)

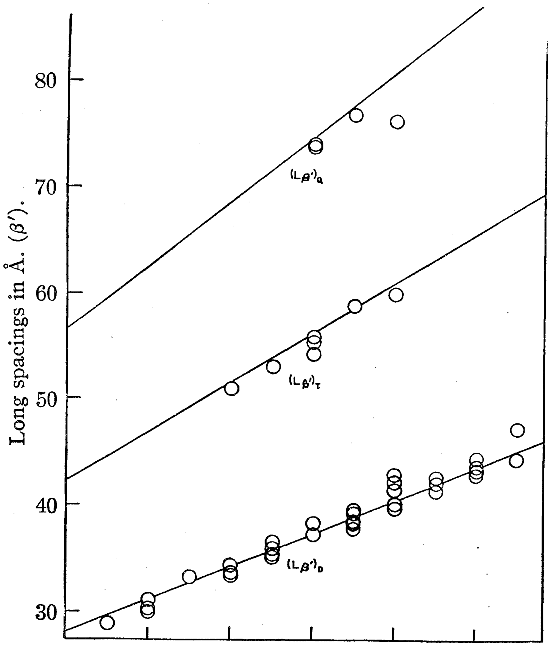
Among the cases for which data are reported for alpha forms, there are fourteen examples of agreement within 1.6 Å. between experiment and calculated DCL structure. Experimental error is usually of the order 0.5 Å. (but in individual cases it may be greater). In the untilted hydrocarbon chain each carbon corresponds to 1.27 Å. of length, wherefore it might be said that the correspondence between calculation and experiment is, in these cases, within about 1 carbon atom.

The six cases of rather poor agreement (1.6 < (Δ), absolute value <2.9) involve glycerides having a large difference (4, 6 or 8 carbons) between



N = total no. acyl carbons per triglyceride.

Fig. 5.—O—experimental long spacings (β), ●—experimental long spacings (α); solid lines—calculated long spacings for β-2 and β-3, dashed line—calculated long spacings for α-2.



N = total no. acyl carbons per triglyceride.

Fig. 6.—Circles, experimental long spacings (β'); solid lines, calculated long spacings for β'-2, -3, and -4.

longer and shorter chains. It might be expected that the fit in these cases would be irregular at the chain ends. In the case of $C_{10}C_{18}C_{18}$ agreement is so poor for any basis of calculation that (Δ) values are given only in a footnote.

Beta Prime Form

Diacid Triglycerides.—Agreement between experiment and calculation is better for the beta prime form. There are twenty-seven examples of DCL structure showing agreement within 1.1 Å. and two with (Δ) values of 1.7 and 2.1 Å. For three glycerides, the evidence points to TCL structure with agreement within 1.4 Å. (For $C_{18}C_{12}C_{12}$, the author's data indicate both double and triple structures, of which Malkin reported only the double structure.) Only for the beta prime form are QCL (or doubled DCL) structures obtained. There are three cases whose agreement is within 2 × 0.7 Å. and a single case of poor agreement, 2 × 2.5 Å.

It should be pointed out that the stable forms of the $C_{n-2}C_nC_{n-2}$ glycerides are tabulated as beta prime. Both the data of Malkin[5a] and data of this Laboratory[10] are best interpreted as indicating that these compounds are dimorphous exhibiting alpha and beta prime forms but not beta. Likewise Malkin's so-called beta forms of $C_{12}C_{16}C_{12}$, $C_{14}C_{18}C_{14}$, and $C_{10}C_{18}C_{18}$ seem to be best classified as beta prime.

Triacid Triglycerides.—The designation of forms for the $C_{18}C_{n2}C_{n3}$ glycerides by Filer, *et al.*,[7] was stated by them to be tentative. They simply labelled the lower melting of two forms beta prime and the higher melting beta. Several changes are here made to bring the designations more nearly in line with the recognized short spacing basis for labelling glyceride forms. These designations should perhaps be as tentative as those of Filer, *et al.*,[7] and they lead into as yet untested speculations.

There are five forms recorded as DCL beta prime. Experiment and calculation agree within 0.8 Å. except in the case of $C_{18}C_{16}C_{12}$ which shows a (Δ) value of -2.2 Å.

There are four forms designated as TCL beta prime, two for one compound, $C_{18}C_{14}C_{10}$. Agreement with experiment is within 1.1 Å. except in one case where $(\Delta) = 2.1$ Å. The form of $C_{18}C_{12}C_{10}$ is interpreted to be analogous with the beta prime form of $C_{18}C_{10}C_{10}$. That of $C_{18}C_{16}C_{10}$ is probably analogous with the beta prime form of $C_{10}C_{18}C_{18}$ (listed by Malkin as beta, but here as beta prime). All four of these structures are presumably of the chair type as opposed to the tuning fork type of structure.

The forms of $C_{18}C_{14}C_{10}$, because of alternative possibilities are of special if somewhat speculative interest. They can be interpreted to be of the chair type, but as differing according to whether C_{14} goes with C_{10} or C_{18}, *i.e.*, whether C_{10} or C_{18} is the lone chain (see Fig. 4). An alternative "tuning fork" type structure seems to be ruled out because it is unlikely that C_{10} and C_{18} would line up side by side.

It is assumed simply on the basis of $(\Delta)_T$ values that the lower melting form of $C_{18}C_{14}C_{10}$ is more nearly analogous to the TCL beta prime form of $C_{18}C_{12}C_{10}$, and is therefore β'-3,C_{18} (C_{18} being the lone chain) and the higher melting form corresponds to that of $C_{18}C_{16}C_{10}$, and is therefore β'-3,-C_{16}. Examination of the detailed short spacing data of Filer, *et al.*,[7] gives little support to this association of forms, but does not preclude it in any way.

Beta Form

Diacid Triglycerides.—There are 15 DCL beta structures indicated. Of these eight show (Δ) values of 0.7 or smaller. Seven show values near 2.5 Å. It will be noted that where (Δ) values are large, the glycerides are of the general types $C_{n-2}C_nC_n$ and $C_{n-4}C_nC_n$.

It is of special interest that more than half of the reported beta forms or 18 out of 33 correspond to TCL structure. In these cases $(\Delta_\beta)_T$ has an average value of $+2.9$ Å. Deviations from this value in no case exceed 1.1 Å. It might be that the greater number of glyceryl groups per chain (2 for 3 instead of 1 for 2) accounts for the increased length, or, of course, a real difference in angle of tilt between DCL and TCL structures may be involved.

TCL structures do not appear for beta forms of these diacid glycerides unless one chain is 4 carbons longer than the other and not then for $C_{n-4}C_nC_n$ glycerides.

Of further interest is the absence of any beta form for $C_{12}C_{16}C_{12}$ and $C_{14}C_{18}C_{14}$ which are near relatives of $C_{n-2}C_nC_{n-2}$ glycerides whose stable forms appear to be beta prime. The glyceride $C_{10}C_{14}C_{10}$ does show a beta form but of TCL structure.

Triacid Triglycerides.—Of the forms that are unequivocally beta, all are of TCl structure except those of $C_{18}C_{16}C_{14}$ and $C_{16}C_{14}C_{12}$ which are DCL in analogy to the beta forms of $C_{18}C_{16}C_{16}$ and $C_{16}C_{14}C_{14}$ or $C_{16}C_{16}C_{14}$ and $C_{14}C_{14}C_{12}$ but unlike those of $C_{18}C_{14}C_{14}$ and $C_{18}C_{12}C_{12}$. The glycerides $C_{18}C_{14}C_{16}$ and $C_{16}C_{12}C_{14}$ which are more nearly symmetrical show TCL structure.

The $(\Delta)_T$ values for the TCL structures show an average of $+3.4$ in good agreement with the $+2.9$ value for diacid triglycerides. Perhaps a better relation than (7) for calculating TCL values for beta forms would be

$$(L_\beta)_{T'} = 3C_\beta + 3.0 = 9.0 + 1.138\,N \quad (13)$$

Evidence from Intensities.—The postulated triple (or sextuple) structure for 2-oleyldistearin was supported by approximate agreement of observed relative intensities with those calculated from a very simple model.[9] No adequate intensity data on long spacings for the saturated

---

(10) Quimby and Lutton, unpublished.

glycerides here considered have been reported. To observe such intensities the compound 1-stearyldilaurin was prepared after the manner of Malkin, *et al.*[6d] It was obtained in four polymorphic forms characterized in Table VII.

TABLE VII

FORMS OF 1-STEARYLDILAURIN

	Preparation	Main short spacings	M. p., °C.[a]
α	Melted, chilled 0°	4.13 VS	21.0
β'-2	Melted, crystallized 30 min. 22.0°	4.23 VS, 4.06 S−, 3.77 S+	31.0
β'-3	β'-2, held 10 min. 32°	4.30 M, 4.17 M, 3.94 S	38.0
β	Solvent crystallized 16°, or β'-3 held 1 day 38°	4.60 VS, 3.84 S	44.6

[a] Malkin, ref. 6d, gave m. p's. as 20, 31, 41.5 and 45°.

Two of the 1-stearyldilaurin forms are called "beta prime" in an effort to follow as closely as possible the basis for nomenclature outlined at the beginning of this paper. Long spacing observations distinguish sharply between the so-called "beta prime" forms. A partial record appears in Table VIII.

TABLE VIII

LONG SPACING DATA FOR 1-STEARYLDILAURIN

Form	Magnitude of L. S.	Relative intensity 2nd and 3rd orders	Probable structure type	(Δ) Å.
α	41.7	$3 >> 2$	Double	$(\Delta\alpha)_D = 1.1$
β'-2	38.0 (38.7[a])	$3 \geqq 2$ $(2 << 1)$	Double	$(\Delta\beta')_D = 0.5$
β'-3	55.0	$2 >> 3$	Triple	$(\Delta\beta')_T = -1.25$
β	57.2 (57.0[a])	$2 > 3$	Triple	$(\Delta\beta)_T = 3.8$

[a] Malkin, ref. 6d.

Support for the TCL concept is given in Table VIII. The intensity results, so far as shown, correlate with postulated structure type. It is according to expectations that *a double structure for 1-stearyldilaurin should have a weak second order* and that *a triple structure should have a weak third order*. Attempts to find a more detailed agreement between observed and calculated intensities, according to previous procedure,[9] were unsuccessful. Failure was due, it is thought, to the degree of imperfection of the highly simplified model that was employed.

It is presumed that QCL structure would show intensity distributions similar to those of DCL structures, *i. e.*, weak fourth (instead of second as for DCL) and probably strong sixth (instead of third) order.

Conclusions

The following generalizations apply to the data now available. These can be best understood by reference to Tables VI, for triacid glycerides, and IX, a summary table for diacid triglycerides.

Alpha Forms.—DCL structures prevail among alpha forms. Long spacing values, all indicating DCL, have been reported for compounds having a difference of as much as 6 carbons in chain length, but no values have been reported for a difference of 8 carbons. It is possible that triple structures might occur for the larger difference.

TABLE IX

DESIGNATION OF STRUCTURE LENGTH FOR DIACID TRIGLYCERIDES. A SUMMARY FOR C_{10} TO C_{18}

Triglyceride type	No. compds.	α	β'	β
$C_{n-2}C_nC_n$	4	D[a]	D	D
$C_nC_{n-2}C_n$	4	D	D	D
$C_nC_{n-2}C_{n-2}$	4	D	D	D
$C_{n-2}C_nC_{n-2}$	4	D	D	[d]
$C_{n-4}C_nC_n$	3	D	D	D
$C_nC_{n-4}C_n$	3	D	D, (Q)[c]	T
$C_nC_{n-4}C_{n-4}$	3	(D)[c]	D	T
$C_{n-4}C_nC_{n-4}$	3	(D)[c]	D	[d] (T)[c]
$C_{n-6}C_nC_n$	2	(D)[c]	D), (Q)[c]	(T)[c]
$C_nC_{n-6}C_n$	2	D	(D), (Q)[c]	T
$C_nC_{n-6}C_{n-6}$	2	[D][c]	(D), [T][c]	T
$C_{n-6}C_nC_{n-6}$	2	[b]	(D)[c]	T
Mixed C_{10}-C_{18}	4	(?)[c,e]	T, (Q)[c]	T

[a] D = DCL; Q = QCL; T = TCL. [b] No data. [c] ( ) = one example; [ ] = one example, data of ESL. [d] Probably no form exists. [e] Uncertain from data, (Δ) > 7 Å.

Beta Prime Forms.—DCL structure is the usual one for beta prime forms. However, according to the data of Malkin, *et al.*, and Filer, *et al.*, if there is a chain length difference of as much as eight carbons, TCL structures predominate among beta prime forms of unsymmetrical triglycerides. (The author has found TCL structure with the six carbon difference in 1-stearyldilaurin.) In the case of beta prime only, QCL structures appear to be possible for chain length differences of four or more carbons.

Beta Forms.—Triple structure is much more likely for beta forms but seems not to occur unless there is a chain difference of at least four carbons. For difference of six carbons or greater there are no reported cases of other than TCL beta. The reported behavior of samples of *four carbon difference* can be described by the following four statements:

1. $C_{n_1}C_{n_2}C_{n_3}$, $n_1 > n_3 < n_2$ (or $n_3 > n_1 < n_2$)—Structures are double.
2. $C_{n_1}C_{n_2}C_{n_3}$, $n_1 > n_2 < n_3$—Structures are triple.
3. $C_nC_{n-4}C_{n-4}$—Structures are triple.
4. $C_{n-4}C_nC_{n-4}$—No beta form (beta prime may be stable as for $C_{n-2}C_nC_{n-2}$) except for $C_{10}C_{14}C_{10}$ which shows beta of triple structure.

It is a reasonable hope that, as further experimental evidence rounds out the record on triglyceride polymorphism, an increasing degree of order will become apparent.

Acknowledgment.—The author is indebted to Dr. R. H. Ferguson and others of this laboratory for many helpful discussions of this subject.

Summary

Polymorphic forms of many mixed saturated triglycerides show long spacing values which are abnormally large, that is, they are too large to per-

mit their associated crystal structures to be classified as typical double-chain-length structures. It is shown in this paper that most of these abnormal values can be interpreted as due to triple-chain-length structures analogous to that of the mixed unsaturated C_{18} triglyceride, 2-oleyldistearin. This triple structure presumably arises from a sorting of chains—sorting of short from long chains in the case of mixed saturated triglycerides, in manner similar to the sorting of unsaturated from saturated chains for 2-oleyldistearin.

These considerations lead to the proposal of a new type of molecular configuration in triglyceride crystals, a "chair" type of arrangement for certain unsymmetrical compounds in contrast to the generally accepted "tuning fork" arrangement.

Long spacings corresponding to quadruple-chain length structure have also been noted.

The Skraup Reaction with Acrolein and its Derivatives[1]

BY HARRY L. YALE AND JACK BERNSTEIN

A recent report[2] from these laboratories has described the synthesis of 6-methoxy-8-nitroquinoline in 42.3% yield, by a modified Skraup reaction. Some additional studies on the utilization of this reaction in the preparation of quinoline derivatives have now been completed. The results are summarized in Table I. Method A refers to the reaction conditions previously reported[2] while Method B is a new modification of the Skraup reaction employing acrolein and 85% phosphoric acid with arsenic acid as the oxidizing agent at 100°.

TABLE I

SKRAUP REACTION WITH ACROLEIN AND ITS DERIVATIVES

Amine	Quinoline derivative Yield, % Method A	Method B	M. p., °C. Found
Aniline[a]	Trace	3[b]	199–200
o-Nitroaniline	32	26	87–88
p-Nitroaniline	28	32	147–148
p-Anisidine	13	...	27
p-Bromoaniline	5[b]	5[b]	209
2-Amino-4-nitroanisole	5	59	148–149
2-Amino-5-nitroanisole[c]	30	67	147–148[g]
4-Amino-5-nitroveratrole	36	51	125–126
3-Nitro-4-aminoanisole[d,e,f]	42	60	157–158

[a] Ardashev, *J. Gen. Chem.* (*U. S. S. R.*), **16**, 47 (1946), recently has reported the synthesis of quinoline in poor yield from aniline and acrolein in the presence of sulfuric and hydrochloric acids. [b] Isolated as the picrate. [c] β-Ethoxypropionaldehyde by Method B gave 60% yield. [d] The acetylated amine with acrolein by Method A gave 43% yield. [e] The amine with various acrolein derivatives by Method A gave: with β-ethoxypropionaldehyde, 39%; with β-ethoxypropionaldehyde diethyl acetal, 34%; with acrolein diethyl acetal, 21%. [f] The amine with α-methylacrolein gave the corresponding methyl quinoline in 19% yield by Method A; in 59% yield by Method B, m. p. 173–174°. *Anal.* Calcd. for $C_{11}H_{10}O_3N_2$: C, 60.55; H, 4.59; N, 12.84. Found: C, 60.87; H, 4.64; N, 12.96, 12.76. [g] *Anal.* Calcd. for $C_{10}H_8O_3N_2$: N, 13.72. Found: N, 13.52.

In the preparation of 6-methoxy-8-nitroquinoline by Method B a 60% yield is obtained at 100°, however, at 25°, the yield is 25% and at 65°, 54%; The use of 100% phosphoric acid has only a very slight advantage over 85% acid (65% yield as compared to 60%) but a marked decrease in yields occur with 75% acid (35%) and 50% acid (24%).

Acrolein diethyl acetal, β-ethoxypropionaldehyde and β-ethoxypropionaldehyde diethyl acetal, each of which is capable of yielding acrolein under the modified Skraup conditions, were substituted for acrolein in the reaction with 3-nitro-4-aminoanisole and 2-amino-5-nitroanisole; each gave slightly lower yields of the substituted quinoline.

Acknowledgment.—The authors are indebted to Mr. W. A. Lott for his interest and encouragement. The microanalyses were carried out by Mr. J. F. Alicino.

Experimental

All temperatures are uncorrected.

Method B.—Skraup Reactions with Phosphoric Acid.—A mixture of 33.6 g. (0.2 mole) of 3-nitro-4-aminoanisole and 56.8 g. (0.4 mole) of arsenic acid in 200 ml. of 85% phosphoric acid was placed in a 1-liter, 3-necked flask fitted with a thermometer, dropping funnel, reflux condenser and mercury-sealed stirrer. The reaction mixture was warmed to 100° and 19 ml. (0.3 mole) of acrolein added dropwise with vigorous stirring. The rate of addition was regulated so as to maintain the temperature at 100 ± 2°. After all the acrolein had been added (twenty-five minutes), the reaction mixture was stirred for an additional thirty minutes during which time the temperature was maintained at 100° by warming with an oil-bath. The solution was poured into 800 ml. of water, treated with Hyflo and decolorizing carbon and filtered. The filtrate was made alkaline with aqueous ammonia and the precipitated product filtered. The dried solid was refluxed with 600 ml. of ethyl acetate and decolorizing carbon, filtered, and concentrated until crystallization started. The product weighed 25 g. (60% yield), m. p. 157–158°.

Summary

A modified Skraup reaction with acrolein and α-methylacrolein has been carried out with substituted anilines. The reaction has been extended to include compounds capable of yielding acrolein, *in situ*.

Local Anesthetics. III. Aroyl Derivatives of β-Methyl-β-monoalkylamino Propanols

BY J. STANTON PIERCE, ROBERT D. GANO AND J. M. LUKEMAN

In previous papers[2,3] from this Laboratory, the preparation of alkoxybenzoates of β-monoalkylaminoethanols, β-methyl-β-monoalkylaminopropanols and β-monoalkylaminobutanols was described. Some of the products were found to be effective as local anesthetics. It thus seemed advisable to prepare esters of the above β-secondary aminoalkanols with other aromatic acids. Therefore, we have prepared cinnamates,[4] alkoxycinnamates, hydrocinnamates and alkoxyhydrocinnamates of β-monoalkylaminoethanols, β-methyl-β-monoalkylaminopropanols and β-monoalkylaminobutanols. Usually, the derivatives of β-methyl-β-monoalkylaminopropanols proved to be more readily purified than the derivatives of the other amino alcohols, so the esters of this series were studied more thoroughly than the others and are reported in this paper. Also, phenylurethans of β-methyl-β-monoalkylaminopropanols are being prepared and will be reported in a subsequent publication.

[y] Purchased.

Experimental

p-**Butoxybenzaldehyde.**—The alkoxybenzaldehydes were made by converting phenolic aldehydes into alkoxybenzaldehydes by the method Cohen and Dudley[5] used for the preparation of alkoxybenzoic acid esters. In a typical synthesis, one half mole each of *p*-hydroxybenzaldehyde and *n*-butyl bromide were added to 200 ml. of absolute alcohol in which 11.5 g. of sodium had been dissolved. After refluxing for six hours, the alcohol was distilled off and the residue was added to 500 ml. of water. Twenty-five grams of salt then was added and the mixture was extracted thrice with ether and the solution was washed with sodium hydroxide solution. The ether then was distilled off and the residue was vacuum distilled.

p-**Methoxycinnamic Acid.**—The alkoxycinnamic acids, when not obtainable from Eastman Kodak Co., were made by condensing alkoxybenzaldehyes with malonic acid, with pyridine as catalyst, as described by Pandya and Vahida.[6] *p*-Methoxycinnamic acid was prepared by heating 0.50 mole each of *p*-methoxybenzaldehyde and malonic acid and 0.20 mole of pyridine in an open tube at 130° for twelve hours. The acid was isolated by dissolving the mixture in dilute sodium hydroxide, filtering, acidifying and filtering with suction. It was purified by recrystallization from aqueous alcohol.

p-**Propoxyhydrocinnamic Acid.**—The alkoxyhydrocinnamic acids were prepared by reduction of the corresponding alkoxycinnamic acids with hydrogen, with Raney nickel as catalyst. *p*-Propoxycinnamic acid (52 g.) was hydrogenated in 200 ml. of alcohol with 3 g. of Raney nickel under 25 lb. pressure in two hours. The alcoholic solution was concentrated to half its volume and hot water was added. On cooling the *p*-propoxyhydrocinnamic acid was precipitated almost quantitatively.

p-**Amyloxycinnamoyl Chloride.**—In a typical preparation of an alkoxycinnamoyl chloride, *p*-amyloxycinnamic acid was refluxed for one hour with four equivalents of thionyl chloride. The excess reagent was removed by evaporation in vacuum with the addition of benzene. The crude *p*-amyloxycinnamoyl chloride was used for condensation with amino alcohol hydrochlorides without further purification.

o-**Ethoxyhydrocinnamoyl Chloride.**—The alkoxyhydrocinnamoyl chlorides were prepared by the action of phosphorus pentachloride on the acids. *o*-Ethoxyhydrocinnamoyl chloride was prepared by refluxing equimolar

[a] In this table are listed only the amino alcohol esters which were satisfactorily purified by recrystallization of the hydrochloride or distillation of the free base. These products are being tested pharmacologically by Dr. H. B. Haag, of the Medical College of Virginia, and will be reported elsewhere. [b] Chloride was determined by the Volhard method as modified by J. R. Caldwell and H. V. Moyer, *Ind. Eng. Chem., Anal. Ed.*, **7**, 38, 39 (1935). [c] Nitrogen was determined by titration of the free base with standard hydrochloric acid, with modified methyl red as indicator.

quantities (0.15 mole) of *o*-ethoxyhydrocinnamic acid and phosphorus pentachloride on a boiling water-bath for one hour. The phosphorus oxychloride was removed by vacuum distillation and the acid chloride was purified by vacuum distillation.

Hydrochlorides of β-Methyl-β-monoalkylaminopropyl Cinnamates, Alkoxycinnamates, Hydrocinnamates and Alkoxyhydrocinnamates.—The β-monoalkylamino-β-methylpropanols were prepared and condensed with aroyl halides by methods described in previous publications[2,3] from this Laboratory. Equimolar quantities of amino alcohol hydrochlorides and aroyl halides were heated on a water-bath from one to six hours, depending on the rate of reaction. In a few cases an oil-bath, heated gradually to 150°, was used. As in previous reports, the reaction mixture was dissolved in water, filtered and extracted with isopropyl ether to remove impurities, and treated with sodium hydroxide to set free the amino alcohol esters. These esters were taken up in isopropyl ether and the hydrochlorides precipitated by addition of dry hydrogen chloride. Various solvents were used for recrystallization but a mixture of anhydrous acetone and anhydrous ether proved satisfactory in most cases. In a few cases in which recrystallization of the hydrochloride of the amino alcohol ester did not take place readily, the free base was purified by vacuum distillation.

Summary

The hydrochlorides of a series of β-methyl-β-monoalkylaminopropyl cinnamates, hydrocinnamates, alkoxycinnamates and alkoxyhydrocinnamates have been prepared and described.

The Occurrence of Rutin in a Wild Cherry, *Prunus melanocarpa* (A. Nels.) Rydb.

BY JAMES F. COUCH

In connection with the researches being conducted at this Laboratory[2] on the production of rutin for medicinal use a species of wild cherry was examined with the result that significant quantities of rutin were found in the leaves. This is the first species of the genus *Prunus* from which this glucoside has been isolated, although the presence of other flavonol glucosides in different species of the genus has been reported.

Rochleder[3] found a trace of a quercetin glucoside in *P. cerasus* L., and Finnemore[4] isolated quercimeritrin from a commercial bark probably of *P. emarginata* Walp. Power and Moore[5] obtained less than 0.1% of a quercetin glucoside which they named serotrin from the leaves of *P. serotina* Ehrh. This substance melted at the same temperature as quercimeritrin but on comparison with an authentic sample the authors concluded that it was a different substance.

Rutin has now been found in the leaves of "black chokecherry" (*P. melanocarpa* (A. Nels.) Rydb.) in substantial quantities. This species ranges from Alberta and British Columbia southward to California and New Mexico[6] in accessible

localities and may prove to be a commercial source of the drug. Several samples of leaves collected at different stages of growth and at two different altitudes were examined. The leaves were collected in 1936 and 1937 near the Salina Experiment Station, Salina, Utah, in connection with studies on poisoning of livestock by cyanogenetic plants. They were air dried and had been stored in the laboratory for ten years. Crude rutin was obtained from a composite lot of these samples in 1937 but was not investigated further at that time. Analyses of the samples are in Table I.

TABLE I

Lot no.	Date collected, 1936	Approximate altitude, ft.	Moisture,[7] %	Rutin,[7] % mfb
47-7	June 15	8000	6.00	1.57
47-6	Aug. 17	8000	7.20	1.44
47-9	Aug. 20	8500	6.15	3.13
47-10	Composite	8000	7.60	1.63
	1937			
47-8	June 17	8500	6.40	3.88

The figures indicate a considerably greater content of rutin in leaves collected at the higher altitude but do not show much difference between young (June collections) and older (August) leaves.

Experimental

A quantity of the air-dried leaves (6,646 g.) was coarsely powdered, moistened with alcohol and extracted in a glass percolator with alcohol. The solvent was distilled from the percolate and the greenish residue was thoroughly extracted with boiling distilled water. The water solution was filtered from the fatty materials and allowed to cool. After standing several days a considerable quantity of brown flocculent material separated. This was filtered and redissolved in boiling water. The filtered solution deposited the substance on cooling. The crude rutin (24.0 g.) was greenish in color and contained 88% of the pure glucoside. This was bottled and preserved for several years. The rutin (2 g.) was purified by dissolving in alcohol (50 ml.), filtering from some amorphous matter, and diluting to 500 ml. with water containing 2 ml. of concentrated hydrochloric acid. The rutin which slowly precipitated during the ensuing twenty-four hours was of bright yellow color and crystallized in the characteristic microscopic fan-shaped bundles of needles. It was filtered, washed with water and dried at 110°. The plastic range ("melting point") was 172–174° raised by recrystallization from alcohol and from water to 190–192°. A spectrophotometric examination by W. L. Porter identified the substance as rutin by the following constants: The ultraviolet absorption spectrum of the anhydrous sample was characterized by absorption maxima near 3627 and 2577 Å., specific extinction coefficient, 32.6 liter g.$^{-1}$ cm.$^{-1}$ at 3627 Å., extinction ratio of 0.875 for wave lengths 3752 and 3627 Å. The corresponding figures for authentic rutin are: 3627 and 2577 Å., 32.5 at 3627 Å. and 0.875.

Anal.[8] Calcd. for $C_{27}H_{30}O_{16}$: C, 53.11; H, 4.95. Found: C, 52.92; H, 4.99.

Summary

Rutin has been isolated in significant quantities from black chokecherry, a species native to the mountain region of the western United States.

Isolation of Rutin from a Citrus Hybrid

BY C. F. KREWSON AND J. F. COUCH

The discovery of Szent-Györgyi and co-workers[2] that citrus fruits contain a substance not identical with hesperidin or any other identified constituent of these fruits has led to much chemical and physiological research in an endeavor to isolate and characterize the active compound, which has been termed vitamin P.[3] Investigations begun in 1943 have established the fact that rutin, a flavonol glucoside present in some forty species of plants, has the physiological activity attributed to vitamin P.[4] The question whether the activity reported from citrus fruits which may be due to the presence of rutin has been investigated in this Laboratory. Valencia oranges, grapefruit and both green and ripe lemons, reported to be most active of the citrus fruits with respect to vitamin P activity, have been examined without revealing the presence of rutin. These have been subjected to three extraction procedures: the usual alcoholic technique,[5] a special process involving enzymatic hydrolysis of pectin, and an alkali extraction. In no case was rutin found by the alcoholic extraction. In the instance of a hybrid fruit, rutin was found by the other two processes, the alkali extraction described below being more effective.

Two years ago we obtained from the orchard of A. C. Krewson, Plymouth, Florida, specimens of a citrus fruit of the size and form of grapefruit but with a distinct odor and flavor of the lemon. The

(5) J. F. Couch and C. F. Krewson, U. S. Department of Agriculture Mimeograph Circular AIC-52, July, 1944.

juice of these fruits served to make excellent "lemonade." The hybrid has been tentatively identified by F. E. Gardner of the Bureau of Plant Industry, Soils, and Agricultural Engineering, United States Department of Agriculture, as a cross between grapefruit and Satsuma orange, produced during experiments on cross-breeding citrus fruits and named Satsumelo.

Examination of the peel of these fruits finally resulted in the isolation of significant quantities of rutin after the usual alcoholic extraction had been unsuccessful. Exhaustive maceration with alkalies extracted the constituent slowly. Rind of green fruits picked January 3, 1946, gave 3.2% of rutin (moisture-free basis), whereas the rind of ripe fruit picked the previous year, February 10, 1945, gave approximately 0.9%, and that of overripe fruit picked April 28, 1945, yielded about 0.1% of rutin.

These data are consistent with the facts obtained with other rutiniferous plants[6] that immature tissues, plants or fruits contain more rutin than more mature tissues. Rutin appears to be associated with the most actively metabolizing portions of the plant, a fact in harmony with Szent-Györgyi's view that the flavonols form part of the oxidation–reduction chain in the plant cell.[7]

No trace of rutin was found, in repeated attempts both by alcoholic and alkali extraction techniques, in the peeled fruit, the pressed juice of the peeled fruit, the pulp of the peeled fruit, the fermented whole fruit, or in the air-dried leaves of the tree from which the fruits were obtained.

Experimental

The minced peel of the hybrid (258.5 g.) was mixed with 757 ml. of distilled water and sufficient 3 *N* sodium hydroxide solution to bring the mixture to a *p*H of 11, and stirred for one hour. The residue after filtration was again macerated with sodium hydroxide solution for one hour and filtered. This treatment was repeated twice more. The filtrates were separately adjusted to *p*H 4.5 with hydrochloric acid and allowed to stand in a refrigerator. The first two extracts yielded 1.50 and 0.36 g. of rutin, respectively, a total of 1.86 g. or 3.23% of the moisture-free material. The substance recrystallized from boiling water gave a plastic range ("melting point") of 185.5 to 187.5° (cor.). Spectrophotometric examination of the material after recrystallization from absolute ethanol revealed absorption maxima at wave lengths 2575 and 3625 Å. with a specific extinction coefficient of 32.74 at 3625 Å. Purified rutin from buckwheat, after recrystallization from absolute ethanol, shows maxima at the same wave lengths, with a coefficient of 32.55 at 3625 Å.[8]

A portion of the rutin was further purified by solution in alcohol and recrystallization from water.

Anal.[9] Calcd. for $C_{27}H_{30}O_{16}$: C, 53.11; H, 4.95. Found: C, 53.07; H, 5.11.

Hydrolysis of Rutin.—The purified glucoside (0.200 g.) was heated one hour with 8 ml. of 5% sulfuric acid and cooled overnight. The precipitated quercetin was filtered, washed and recrystallized from ethanol. When it was dried at 110° it melted at 313–313.5°.

Anal.[9] Calcd. for $C_{15}H_{10}O_6$: C, 59.61; H, 3.34. Found: C, 59.57; H, 3.45.

The pentaacetate melted at 194–196° and showed no depression when mixed with authentic quercetin pentaacetate. The carbohydrates produced by hydrolysis of the rutin were identified as rhamnose and glucose by the usual methods.

Summary

Rutin has been isolated from the rind of Satsumelo, a hybrid citrus fruit resulting from a cross between grapefruit and Satsuma orange.

PHILADELPHIA 18, PA. RECEIVED AUGUST 9, 1947

[6] J. F. Couch, J. Naghski and C. F. Krewson, *Science*, **103**, 197–198 (1946).

[7] S. Szent-Györgyi, "Studies on Biological Oxidation and Some of Its Catalysts," Barth, Leipzig, 1937, pp. 67–98.

[8] The specific extinction coefficient of purified rutin from buckwheat previously reported (THIS JOURNAL, **69**, 572–573 (1947)), 31.9 liter g.$^{-1}$ cm.$^{-1}$, is raised to 33.22 by addition of a small quantity of acetic acid to the rutin solution prepared for spectrophotometric examination. The addition of this acid increases the coefficient but renders it insensitive to accidental traces of alkali present on the glassware or in the solvent. See W. L. Porter, B. A. Brice, M. J. Copley and J. F. Couch, U. S. Department of Agriculture Mimeograph Circular AIC-159, July, 1946, "Tentative Spectrophotometric Method for the Determination of Rutin in Various Preparations." Recrystallization of the purified buckwheat rutin from absolute ethanol, followed by application of the modified procedure, results in a specific extinction coefficient of 32.55 at 3625 Å., with an unchanged extinction ratio of 0.875 ± 0.004 for wave lengths 3750 and 3625 Å. We are indebted to W. L. Porter for the spectrophotometric work.

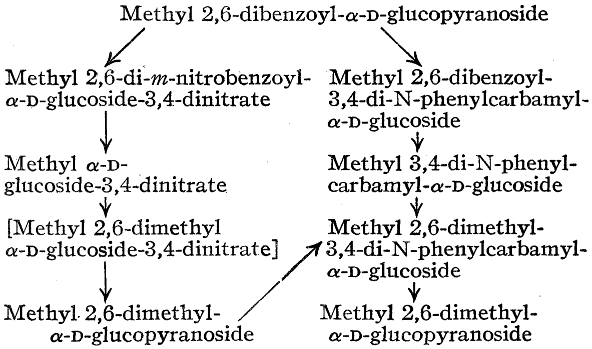
Methyl 2,6-Dimethyl-α-D-glucopyranoside

BY RICHARD E. REEVES

In connection with current work an alkali-stable glucopyranoside substituted in positions 2 and 6 was desired; accordingly, the preparation of methyl 2,6-dimethyl-α-D-glucoside was undertaken. The β-form of this glucoside has been prepared by Bell and Synge.[1a] The α-glucoside was obtained by two different routes, as shown in the diagram below. All substances except the starting material are previously unreported; the compound enclosed in brackets was not characterized.



The glucoside has not yet been obtained in the crystalline state, but the preparations from the two series exhibited almost identical rotatory values and gave satisfactory analyses. The nature of the reactions employed allows the belief that the α-pyranoside structure persisted throughout both series. This view is supported by the high positive rotation of the final glucoside, and by its quantitative reconversion to the crystalline methyl 2,6-dimethyl-3,4-di-N-phenylcarbamyl-α-D-glucoside.

The nitrate series of reactions is of significance with regard to the assignment of structure to the final product because, as Bell and Synge[2] have pointed out, nitrate groups do not migrate.

Nitration of methyl 2,6-dibenzoyl-α-D-glucopyranoside at positions 3 and 4 proceeded smoothly with simultaneous nitration of the benzoyl radicals. The di-m-nitrobenzoyl derivative, obtained in fair yield, was a satisfactory intermediate.

N-Phenylcarbamyl derivatives (phenylurethans, carbanilates) are extensively used to characterize alcohols, and they have been so employed in the sugar series.[3] They have also been used by Hearon, Hiatt and Fordyce[4] to block certain positions, taking advantage of their relatively great resistance against acid catalyzed alcoholysis to allow the selective removal of acyl radicals at other positions.

Methyl 2,6-dimethyl-α-D-glucopyranoside in cuprammonium hydroxide solution was found to be strongly dextrorotatory as expected from the study of other cuprammonium-glucoside complexes. The rotatory shift (sp. rot. cupra − sp. rot, water) was approximately +950°. The corresponding value previously found[5] for methyl 2-methyl-β-D-glucopyranoside (+1054°) was attributed to complex formation at the 3-4 position although in that instance there was some uncertainty due to the presence of a free hydroxyl group at position 6. The present glucoside, having the 6 position blocked by a methyl group, allows no doubt as to its site of complex formation being the 3-4 position. It is intended to discuss in a later communication the significance of the properties of various cuprammonium–glycoside complexes with regard to conformation of the pyranoside ring.

Experimental

All melting points were observed between crossed polaroids by means of a Fisher–Johns melting point apparatus, drilled to allow the passage of a 1 mm. beam of light.

Except where the mercury blue line is specifically mentioned, the optical rotations were measured with the sodium D line. The mercury blue line (436 mμ) was isolated for aqueous solutions by Corning filters 511 and 038; for cuprammonium solutions, by filter 038 only. All rotations were measured at 25°.

The cuprammonium contained 15 g. copper, 240 g. ammonia and 1 g. glycerol per liter.

Methyl 2,6-dibenzoyl-α-D-glucopyranoside, m. p. 141.5–142°, was prepared in small lots by the method of Lieser and Schweizer.[6]

The Nitrate Series

Methyl **2,6-*Di-m*-nitrobenzoyl-α-D-glucoside 3,4-Dinitrate.**—Methyl 2,6-dibenzoyl-α-D-glucopyranoside, 1.4 g., was dissolved in a mixture of 49 ml. of chloroform and 21 ml. of 100% nitric acid, previously cooled to 0°. The solution was kept for fifteen minutes in an ice-bath after which ice water was added and the chloroform layer extracted, washed with ice water, cold potassium bicarbonate solution, water and dried over calcium chloride. Removal of solvent *in vacuo* left a sirup which yielded 1.6 g. of crystals from alcohol. After two recrystallizations from alcohol the product melted at 148–149°, sp. rot. +167° ± 3° ($CHCl_3$, *c*, 1.1).

Anal. Calcd. for $C_{21}H_{18}O_{16}N_4$ (582.38): C, 43.31; H, 3.11; N, 9.62. Found: C, 43.18, 43.25; H, 3.11, 3.20; N, 9.52, 9.55 (micro Dumas).

Methyl α-D-Glucoside 3,4-Dinitrate.—Two grams of the substance described above was dissolved in 6 ml. of absolute methanol containing 2.5 mg. of sodium. The solution turned slightly yellow and deposited crystals within a very short time. When crystallization appeared

[5] R. E. Reeves, *J. Biol. Chem.*, **154**, 49–55 (1944).

[6] Th. Lieser and R. Schweizer, *Ann.*, **519**, 271–278 (1935).

to be complete the solution was filtered and the crystals rinsed with cold methanol. After drying in a vacuum desiccator the crystals weighed 935 mg. and melted at 77–78°, alone or mixed with an authentic sample of methyl *m*-nitrobenzoate (m. 77–78°). The yield amounts to 74% of the theoretical amount of methyl *m*-nitrobenzoate.

The combined filtrate and washings were acidified with a trace of glacial acetic acid. Removal of solvent in a current of air left 1.3 g. of crystals. Two recrystallizations from benzene gave 0.86 g. of product, m. p. 132–134°, sp. rot. +183° ± 4° (methanol, *c*, 0.85).

Anal. Calcd. for $C_7H_{12}O_{10}N_2$ (284.18): C, 29.58; H, 4.27; N, 9.86. Found: C, 30.08, 29.85; H, 4.42, 4.33; N, 9.46, 9.52 (micro Dumas).

Methyl 2,6-Dimethyl-α-D-glucopyranoside.—The dinitrate described above, 1.075 g., was dissolved in 25 ml. of methyl iodide and refluxed with 5 g. of silver oxide and 2 g. of anhydrous calcium sulfate for eight hours. The solution was then filtered, the salts washed with boiling chloroform, and the combined filtrate and washings evaporated to dryness *in vacuo*. The sirupy product, weighing 1.09 g., consisted largely of methyl 2,6-dimethyl-α-D-glucoside 3,4-dinitrate.

Anal. Calculated for $C_9H_{16}O_{10}N_2$ (312.24): OCH_3, 29.82. Found: OCH_3, 31.1.

Since the above sirup did not seem amenable to further purification the entire sample was dissolved in 10 ml. of glacial acetic acid and warmed with iron dust and a few magnesium turnings. A violent reaction occurred and nitrogen oxide gases were evolved. In a few moments the diphenylamine test for nitrate became negative and the solution was then filtered. The salts were extracted with acetone and acetic acid. The filtrate and extracts were concentrated to dryness *in vacuo* and the residue was once taken to dryness with water, and once with absolute alcohol. The residue was extracted with warm acetone, filtered, and the filtrate transferred to a micro-distillation outfit. The solvent was removed in a current of air and the residue was distilled at 130–140° and approximately 0.01 mm. pressure. The distillate amounted to 333 mg. It was a viscous, almost colorless, sirup. Its specific rotation was as follows: D line +156° ± 2° (water, *c*, 1.44); Hg blue line +285° ± 3° (water, *c*, 1.44); Hg blue line +1230° ± 12° (cupra., *c*, 0.45). The substance was very hygroscopic; it was dried at 55° in vacuum over phosphorus pentoxide for analysis. The analytical values are in agreement with those required for a methyl dimethylglucoside.

Anal. Calcd. for $C_9H_{18}O_6$ (222.23): C, 48.64; H, 8.16; OCH_3, 41.89. Found: C, 48.12, 48.19; H, 8.22, 8.21; OCH_3, 41.7.

The N-Phenylcarbamate Series

Methyl 2,6-Dibenzoyl-3,4-di-N-phenylcarbamyl-α-D-glucoside.—Methyl 2,6-dibenzoyl-α-D-glucopyranoside, 4.02 g. was dissolved in 20 ml. of anhydrous pyridine and 40 ml. of anhydrous benzene. Five ml. (100% excess) of freshly distilled phenyl isocyanate was added and the solution was refluxed one and one-half hours, being protected from atmospheric moisture with a calcium chloride tube. The solvent and excess reagent were removed *in vacuo*. The residue was dissolved in alcohol and yielded crystals on cooling. After two recrystallizations from alcohol, 3 g. of product, m. p. was 202–203°, sp. rot. +103° ± 1° ($CHCl_3$, *c*, 2.8), was obtained.

Anal. Calcd. for $C_{35}H_{32}O_{10}N_2$ (640.63); C, 65.62; H, 5.04; N, 4.37. Found: C, 65.71, 65.61; H, 5.15, 5.05; N, 4.14, 4.33 (micro Kjeldahl).

Methyl 3,4-Di-N-phenylcarbamyl-α-D-glucoside.—Preliminary experiments indicated that the benzoyl groups could not be selectively saponified from the preceding compound using alcoholic alkali solutions. However, the following procedure was successfully employed: Two and five-tenths grams of the above substance was placed in a glass-stoppered flask with 20 ml. of absolute methanol containing 1% anhydrous hydrogen chloride. The flask was kept in an incubator at 40° with occasional shaking. After five days the substance had passed into solution, and after two more days the hydrogen chloride was removed with a cold solution of ethereal diazomethane, and the solvents removed *in vacuo*. The residue recrystallized from alcohol, melted at 213–218°, sp. rot. +128° ± 4° (acetone, *c*, 0.52), weighed 0.9 g.

Anal. Calculated for $C_{21}H_{24}O_8N_2$ (432.42): C, 58.33; H, 5.59; N, 6.48. Found: C, 58.42, 58.13; H, 5.54, 5.59; N, 6.38, 6.48 (micro Dumas).

Methyl 2,6-Dimethyl-3,4-di-N-phenylcarbamyl-α-D-glucoside.—Five and three-tenths grams of the preceding substance was dissolved in 50 ml. of alcohol-free acetone and 50 ml. of methyl iodide. The solution was stirred under reflux at 40–45° with 5 g. of silver oxide and 2 g. of anhydrous calcium sulfate. Fifteen grams more silver oxide was added during the reaction, which was allowed to continue for twenty-two hours. The mixture was filtered and the salts washed with boiling chloroform. The solvents were removed and the residue, dissolved in alcohol, slowly deposited 1.2 g. of crystals, m. p. 225–227. After recrystallization to constant m. p. from dilute alcohol the substance melted at 235–236°, and showed a sp. rot. of +87° ± 2° ($CHCl_3$, *c*, 0.72).

Anal. Calcd. for $C_{23}H_{28}O_8N_2$ (460.47): C, 59.99; H, 6.13; N, 6.09; OCH_3, 20.22. Found: C, 59.80, 59.88; H, 6.10, 6.09; N, 6.35, 6.08 (micro Dumas); OCH_3, 20.15.

Methyl 2,6-Dimethyl-α-D-glucopyranoside.—Two hundred and thirty mg. of the preceding product dissolved in alcohol was warmed under reflux. On adding 10 ml. of 0.39 *N* barium hydroxide solution through the condenser a white precipitate gradually formed. Refluxing was continued for four hours; then carbon dioxide was passed through the solution to remove the excess barium. The precipitate was removed by filtration and the solution evaporated to dryness *in vacuo*. The residue, amounting to 106 mg., was transferred to a micro distillation outfit and distilled at 120–140° at approximately 0.01 mm. The product, a colorless, viscous, sirup, showed approximately the same properties as the sample prepared from the nitrate series: sp. rot. D line, +152° ± 2° (water, *c*, 1.57); Hg blue line, +1240° ± 12° (cupra., *c*, 0.52).

Anal. Calcd. for $C_9H_{18}O_6$ (222.23): OCH_3, 41.89. Found: OCH_3, 41.22.

Di-N-phenylcarbamate of Methyl 2,6-Dimethyl-α-D-glucoside from the Nitrate Series.—Sixty-three mg. of glucoside was dissolved in 1.5 ml. of dry pyridine and 1 ml. of dry benzene containing 220 mg. of phenyl isocyanate. The solution was sealed in a small glass tube and kept at 100° for twenty hours. The tube was then cooled, opened and the volatile material removed under vacuum. The crystalline residue was treated with chloroform, filtered and the filtrate made up to 4-ml. volume. This solution showed an optical rotation of +1.45° (0.5 dm.) corresponding to 133 mg. of product of sp. rot. +87°. (The theoretical yield would be 131 mg.) The chloroform was removed in a current of air; and after two recrystallizations from dilute alcohol, 37 mg. of crystals m. p. 233–235°, sp. rot. +95° ± 3° ($CHCl_3$, *c*, 0.80), was obtained. The melting point of this preparation was not depressed when mixed with the corresponding substance from the N-phenylcarbamate series.

Acknowledgments.—The micro carbon–hydrogen and Dumas nitrogen analyses were performed by Lawrence E. Brown, and the Zeisel methoxyl analyses by L. W. Mazzeno, Jr.

Summary

Methyl 2,6-dimethyl-α-D-glucopyranoside has been synthesized by two different methods. Its optical rotations in water and cuprammonium hydroxide solution are given.

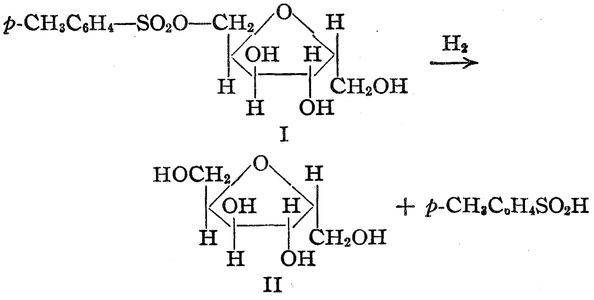
Alcohols of the Sugar Group. IV. 2,5-Anhydro-L-iditol

BY L. VARGHA, T. PUSKÁS AND E. NAGY

Experiments reported in Part III[1] of this series have resulted in the elucidation of the structure and configuration of a monotoluenesulfonyl anhydrohexitol[2] which has been shown to represent the 1-*p*-toluenesulfonyl 2,5-anhydro-L-iditol (I). However, we have been unable to prepare the 2,5-anhydro-L-iditol from this derivative by hydrolysis, or from the 1,6-diiodo derivative in the usual manner. In the meantime Professor Freudenberg has kindly called our attention to one of his earlier experiments in which he succeeded in producing diacetone-glucose from its 3-*p*-toluenesulfonyl derivative by reductive scission with sodium amalgam.[3] Since we have been interested in the elimination of the *p*-toluenesulfonyl group from its esters, we applied this method not only to (I) but also to the *p*-toluenesulfonyl esters of other polyhydric alcohols.

By treatment of (I) in dilute alcohol with sodium amalgam we obtained, beside the sodium salt of *p*-toluenesulfinic acid, a sirupy product, the acetate of which was separated into two fractions by distillation under diminished pressure. On saponification of the higher boiling fraction, a uniform, crystalline substance was obtained which proved to be the expected 2,5-anhydro-L-iditol (II). The lower boiling fraction, probably a dianhydrohexitol according to the analytical data, could not be brought to crystallization even after removal of its acetyl residues.



I

II

We also carried out, in a similar way, the reduction of the 6-*p*-toluenesulfonyl[4] and 5,6-di-*p*-toluenesulfonyl 1,2-monoacetone-glucofuranose,[5] respectively. From the former compound, beside a sirupy substance of unknown structure, crystalline 1,2-monoacetone-glucofuranose was obtained in about 40% yield, whereas the 5,6-di-*p*-toluenesulfonyl compound gave rise to 5-*p*-toluenesulfonyl 3,6-anhydro-1,2-monoacetone-glucofuranose[6] and a small quantity of an unidentified product.

From these results it can be concluded that although the reductive cleavage of the *p*-toluenesulfonyl esters into alcohols and *p*-toluenesulfinic acid often can be carried out without difficulty, yet, simultaneously, as undesirable by-products, anhydro compounds may also form by splitting out of *p*-toluenesulfonic acid from the esters. The occurrence of the latter process cannot be avoided by carrying out the reduction in approximately neutral medium as by passing carbon dioxide gas through the solution. Under such experimental conditions 6-*p*-toluenesulfonyl 1,2-monoacetone-glucofuranose gave 5,6-anhydro-1,2-monoacetone-glucofuranose[7] in surprisingly good yield (70%), while the 5,6-di-*p*-toluenesulfonyl 1,2-monoacetone-glucofuranose remained unchanged.

Experimental

Reduction of 1-*p*-Toluenesulfonyl 2,5-Anhydro-L-iditol by Sodium Amalgam. 2,5-Anhydro-L-iditol Tetraacetate and Dianhydro-hexitol Diacetate.—Ten grams of 1-*p*-toluenesulfonyl 2,5-anhydro-L-iditol (I) in 160 cc. of 80% alcohol was stirred three days at 15° with 200 g. of 2% sodium amalgam. The solution was then neutralized with carbon dioxide, filtered from the precipitated sodium bicarbonate and evaporated to a residue which was extracted with 30 cc. of pyridine. From the aqueous solution of the insoluble part crystalline *p*-toluenesulfinic acid (m. p. 88°) was isolated by treatment with strong sulfuric acid. Concentration of the pyridine solution *in vacuo* yielded a thick sirup (4.6 g.) which was acetylated by treatment overnight with 20 cc. of acetic anhydride and 30 cc. of pyridine at room temperature. After removal of the pyridine *in vacuo* the residue was dissolved in chloroform, the solution treated with water, dried, then the solvent evaporated. The sirupy substance was submitted to fractionate distillation under 0.003 mm. pressure. The first fraction distilled at 108–124° bath temperature, the second one at 124–140°; yields, 1.8 and 3.3 g., respectively.

According to analytical data, the first fraction represents a dianhydro-hexitol diacetate. It is a clear sirup, easily soluble in organic solvents, but almost insoluble in water or petroleum ether; $[\alpha]^{20}_D$ +5.15° in chloroform solution (*c*, 2.329).

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13. Found: C, 52.14; H, 6.25.

The second fraction shows similar solubility behavior and, according to the analytical data, consists of 2,5-anhydro-L-iditol tetraacetate; $[\alpha]^{20}_D$ −13.2° in chloroform solution (*c*, 1.9556).

Anal. Calcd. for $C_{14}H_{20}O_9$: C, 50.60; H, 6.06. Found: C, 50.97; H, 6.52.

2,5-Anhydro-L-iditol (II).—After addition of 11 g. of barium hydroxide dissolved in 130 cc. of water to the solution of 3.3 g. of 2,5-anhydro-L-iditol tetraacetate in 20 cc. of alcohol, the mixture was shaken on the machine for twenty-four hours. Then the excess alkali was neutralized with carbon dioxide, the barium carbonate filtered off, and the soluted barium precipitated by the equiv-

[7] Ohle and Vargha, *ibid.*, **62**, 2345 (1929).

alent amount of sulfuric acid. After filtration the solution was concentrated *in vacuo*, the remaining sirup dissolved in a little absolute alcohol and the solution mixed with absolute ether to incipient turbidity. The substance crystallized at 0° in colorless prisms which were easily soluble in water; yield, 1.1 g., m. p. 111–113°; $[\alpha]^{20}_D$ +12.6° in aqueous solution (*c*, 2.525).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 43.94; H, 7.55.

Dianhydro-hexitol.—The solution of 1.8 g. of dianhydrohexitol diacetate in 12 cc. of alcohol was shaken for twenty-four hours with 7 g. of barium hydroxide in 80 cc. of water. After removal of the barium as described above and concentration of the solution *in vacuo*, there was obtained a sirup which was easily soluble in water and in alcohol; $[\alpha]^{20}_D$ +12.3° in aqueous solution (*c*, 3.079).

Anal. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.80. Found: C, 49.63; H, 7.02.

Reduction of the 6-*p*-Toluenesulfonyl 1,2-Acetone-glucofuranose by Sodium Amalgam.—Two grams of the substance was stirred at 15° for twenty-four hours in 30 cc. of 80% alcohol with 25 g. of 2% sodium amalgam. After neutralization and removal of the barium as described above, the solution was concentrated *in vacuo* and the residue extracted with ethyl acetate. The insoluble portion proved to be the sodium salt of *p*-toluenesulfinic acid. From its aqueous solution the crystalline acid with m. p. 88° was isolated. From the concentrated ethyl acetate solution the 1,2-acetone-glucofuranose with m. p. 158° crystallized; yield, 0.5 g. After evaporation of the mother liquid an oily residue (0.6 g.) remained.

The reduction was also carried out by simultaneous introduction of carbon dioxide gas. In this case a colorless substance was isolated which showed, after recrystallization from benzene, all the properties of the 5,6-anhydro-1,2-acetone-glucofuranose; yield, 70%, m. p. 132°. The crystals had $[\alpha]^{20}_D$ −26.4° in aqueous solution (*c*, 3.025).

Reduction of the 5,6-Di-*p*-toluenesulfonyl 1,2-Acetone-glucofuranose by Sodium Amalgam.—The reduction was carried out as described above. From the concentrated ethyl acetate extract a colorless substance was isolated which proved to be identical with 5-*p*-toluenesulfonyl 3,6-anhydro-1,2-acetone-glucofuranose; m. p. alone and also in admixture with an authentic sample 133°. The ethyl acetate mother liquor contained a small quantity of an oily product. When the reduction was carried out in the presence of carbon dioxide gas the starting material was recovered almost quantitatively.

Summary

The reductive cleavage of several *p*-toluenesulfonyl polyhydric alcohols by sodium amalgam has been investigated under various experimental conditions.

It has been found that the reaction, in consequence of reduction, often yields the corresponding polyhydric alcohols and *p*-toluenesulfinic acid, but simultaneously, as products of a competitive reaction, anhydro compounds may also form by splitting out of *p*-toluenesulfonic acid.

By treatment of 1-*p*-toluenesulfonyl 2,5-anhydro-L-iditol with sodium amalgam 2,5-anhydro-L-iditol in crystalline state has been prepared.

Addition Compounds of Sulfur Dioxide with Three Isomeric Lutidines[1]

By Henry A. Hoffman and Calvin A. VanderWerf

The interesting results obtained in a recent study[2] of the sulfur dioxide–pyridine and the three sulfur dioxide–picoline systems suggested the present investigation, which comprises temperature–composition equilibria studies of the three systems consisting of sulfur dioxide with each of the bases, 2,6-lutidine, 2,3-lutidine and 2,4-lutidine.

Experimental[3]

Purification of Materials.—Dry sulfur dioxide was obtained by passing commercial grade[4] gas through a train consisting of one tower containing saturated barium chloride solution, a tower containing calcium chloride granules, and finally two towers containing phosphoric anhydride. The rate of flow was controlled carefully and a slow stream of sulfur dioxide was allowed to pass through the train for an hour before the required amount was collected in a special freezing point cell[5] which was cooled in a Dry Ice-bath and attached to a drying tube containing phosphoric anhydride. The freezing point of sulfur dioxide collected in this manner was −74.0°.[6]

Purification of 2,6-lutidine[7] was accomplished through the crystalline urea–2,6-lutidine complex reported by Reithof.[8] The crystals of the complex were washed first with cold water, then with alcohol, and finally steam distilled. The portion of distillate boiling constantly at 95.6° under a pressure of 739 mm. was made alkaline with sodium hydroxide pellets and the lutidine layer separated and dried over three separate portions of sodium hydroxide pellets. Distillation of the dried product through a Todd column into a receiver protected from the atmosphere by means of a drying tube containing potassium hydroxide yielded 2,6-lutidine which boiled at 143.7°[9] at 741 mm. and gave a freezing point (from cooling curve) of −5.9°.[10]

The 2,3-lutidine was purified through a previously unreported urea–2,3-lutidine complex which melted at 119.8–121.7°. The crystalline complex was washed with cold water, then with alcohol, and dried. Fusion of the

dry material brought about decomposition with the formation of two layers. The top layer, consisting of 2,3-lutidine, was separated, dried for two weeks over sodium hydroxide pellets, refluxed over solid sodium hydroxide, and finally fractionated through a Todd column to yield the pure amine, b. p. 161.0° at 736 mm.,[11] f. p. (from cooling curve), −9.8°.

The 2,4-lutidine was first distilled through a three-foot Vigreux column, a middle fraction boiling between 142 and 150° at 743 mm. being collected in a receiver protected from the atmosphere by means of a drying tube containing sodium hydroxide pellets. The distillate was stored over sodium hydroxide pellets for two weeks, then refluxed over solid sodium hydroxide for twenty-four hours, and finally fractionated through a Todd column. The pure material boiled at 158.5° at 742 mm.; repeated attempts to obtain a freezing point resulted only in the formation, at low temperatures, of an extremely viscous glass.

Apparatus and Procedure.—A freezing point cell similar to that described in a previous publication from this Laboratory[5] was employed in the determination of the temperature–composition diagrams. A Leeds and Northrup Micromax recorder, calibrated at the melting point of ice, the boiling point of ammonia, the freezing point of pyridine, and the sublimation point of carbon dioxide, was used for the direct recording of the cooling curves. Appreciable reduction of the abnormal supercooling often encountered when an excess of any of the lutidines was present could be realized if the sample was first cooled rapidly until crystallization occurred, then warmed until the last crystal just disappeared, and finally cooled again, this time very slowly. The level to which the temperature rose immediately after the first break in the cooling curve for the second cooling, was taken as the equilibrium temperature. All freezing points were determined at least twice. Data obtained in this way are believed to be correct, even for the steeper portions of the freezing point curves, to 1.5°.

Results

The experimental data are shown below in graphical form. Compositions, as indicated, are given in mole per cent.

A. As shown in Fig. 1, sulfur dioxide and 2,6-lutidine form a single stable compound, $SO_2\cdot(CH_3)_2C_5H_3N$, which melts congruently at 4.0°. The eutectics are: (1) 3.7 mole per cent. 2,6-lutidine, f. p. −75.5°, and (2) 78.1 mole per cent. 2,6-lutidine, f. p. −18.0°.

B. As indicated in Fig. 2, sulfur dioxide and 2,3-lutidine form a single stable compound, $SO_2\cdot(CH_3)_2C_5H_3N$, which melts congruently at 18.5°. The eutectics are: (1) 8.7 mole per cent. 2,3-lutidine, f. p. −78.8°, and (2) 76.5 mole per cent. 2,3-lutidine, f. p. −17.5°.

C. As indicated in Fig. 3, sulfur dioxide and 2,4-lutidine form two compounds, (1) probably either $2SO_2\cdot(CH_3)_2C_5H_3N$ or $3SO_2\cdot2(CH_3)_2C_5H_3N$, which undergoes decomposition into sulfur dioxide and solution at a temperature somewhat below its melting point and (2) $SO_2\cdot(CH_3)_2C_5H_3N$, which melts congruently at −8.3°. The eutectics are: (1) 4.9 mole per cent. 2,4-lutidine, f. p. −78.0°, and (2) 75.1 mole per cent. 2,4-lutidine, f. p. −23.1°. All attempts to establish points in the region beyond 80.0% 2,4-lutidine were unsuccessful because of the extremely high viscosities of the glassy mixtures formed in these concentration ranges.

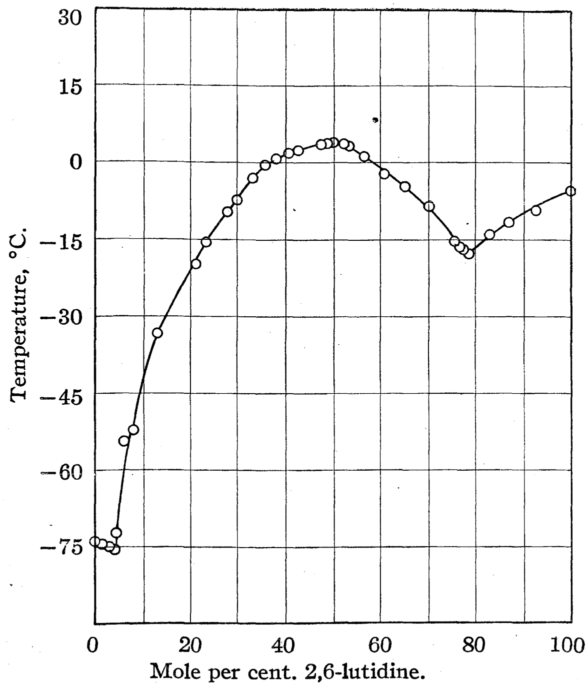

Fig. 1.—System sulfur dioxide–2,6-lutidine.

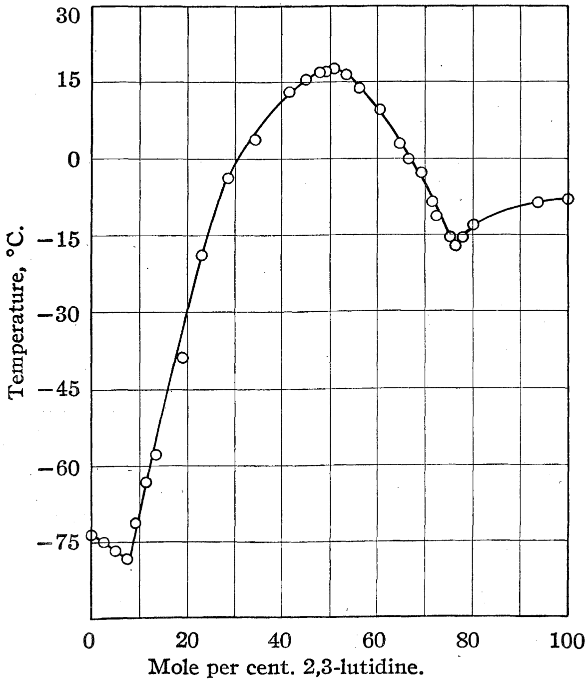

Fig. 2.—System sulfur dioxide–2,3-lutidine.

Discussion

A comparison of the behavior of the picolines and of the lutidines with respect to the formation of stable solid compounds with sulfur dioxide reveals that, in general, the presence of an additional methyl group, located at the α-position in the various picoline molecules, has little effect on the

---

[11] Finkelstein and Elderfield, *J. Org. Chem.*, **4**, 365 (1939), reported a boiling point of 162–164° at 760 mm.

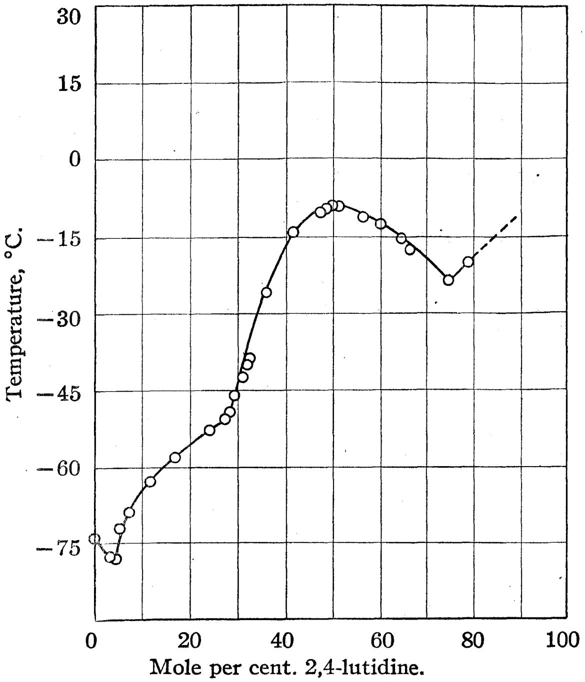

Fig. 3.—System sulfur dioxide–2,4-lutidine.

number or nature of solid compounds formed. Thus, the curve for the sulfur dioxide–2,3-lutidine system is strikingly similar to that for the sulfur dioxide–β-picoline system, a stable 1:1 solid compound being formed in each case. Likewise, the curve for the sulfur dioxide–2,4-lutidine system resembles closely that for the sulfur dioxide–γ-picoline system. Stable 1:1 solid compounds are formed in both cases; the unstable addition compound observed in the case of sulfur dioxide–2,4-lutidine appears to be either a 2:1 compound, corresponding exactly to that in the sulfur dioxide–γ-picoline system, or a 3:2 compound, which would correspond to the higher melting of the two compounds formed in the system sulfur dioxide–α-picoline.

In general, the slope of the sulfur dioxide–2,6-lutidine curve is markedly like that for sulfur dioxide–α-picoline. Stable 1:1 solid compounds are formed in both systems, but no stable solid analog of the 3:2 compound observed in the sulfur dioxide–α-picoline system was formed when 2,6-lutidine was used in place of α-picoline.

Summary

1. Temperature–composition data are presented for the three systems consisting of sulfur dioxide with 2,6-lutidine, 2,3-lutidine and 2,4-lutidine.

2. It has been shown that sulfur dioxide forms stable 1:1 solid addition compounds with each of the three lutidines studied. In addition, with 2,4-lutidine, either a 2:1 or a 3:2 compound, which undergoes transition near its melting point, is formed.

3. The behavior of sulfur dioxide in the formation of solid addition compounds with these three lutidines is compared with its behavior toward the picolines.

Phase Equilibrium Studies on Pyridine–Amide Systems[1]

BY STEPHEN STEPHANOU,[2] CALVIN A. VANDERWERF AND HARRY H. SISLER[3]

In studies of the systems acetamide–ammonia and formamide–ammonia, previously reported from this Laboratory,[4] evidence for the existence of the addition compounds $CH_3CONH_2{\cdot}NH_3$ and $HCONH_2{\cdot}NH_3$ was presented. By analogy with the ammonium salts of acetic and formic acids and with the sodium salts of acetamide and formamide, these addition compounds were considered to be ammonium aquo-ammono salts, in which a single N-hydrogen atom of the amide is, in each case, involved in the bonding between the amide and ammonia molecules. Similarly, it was suggested that the formation of a second addition compound of probable formula $HCONH_2{\cdot}2NH_3$, formed in the formamide–ammonia system, may perhaps take place through the interaction of the second hydrogen atom on the amide group with an ammonia molecule. It was pointed out, however, that the possibility that a second molecule of ammonia might be joined by the sharing of its electron pair with the electron deficient carbon atom of formamide is not precluded.

In the present investigation, a series of systems consisting of pyridine with each of several different amides has been studied in an attempt to explore the possibility of the formation of addition compounds of amines with amides which have no hydrogen atom available for bonding. Choice of pyridine as the base was dictated by the following advantages: it has a convenient melting point, it exhibits little tendency to undercool, and, as a tertiary amine, it cannot undergo exchange reactions with amides. The N,N-disubstituted amides

used were studied in the order of increasing positive charge on the carbonyl carbon atom, as predicted on theoretical grounds.

Experimental[5]

Materials.—The pyridine was dried over sodium hydroxide pellets for at least two weeks and then distilled through a 5-foot packed column; b. p. 114.6° at 740 mm., f. p. (from cooling curve) −41.5°.

The formamide was purified as described previously.[4]

N-Phenylformamide was obtained by four hours of refluxing of aniline with formic acid. Recrystallized three times from diethyl ether, the product was isolated as colorless prisms, f. p. (from cooling curve) 45.3°.

N,N-Diethylacetamide, prepared by refluxing diethylamine with excess acetic anhydride for four hours, was purified by distillation through a 5-foot packed column; b. p. 90.1–91.0° at 30 mm.

N,N-Diphenylacetamide was prepared by acetylation of diphenylamine with acetic anhydride and was obtained as colorless needles, m. p. 100.1°, by repeated recrystallization from alcohol–water.

N,N-Diphenylformamide was isolated as colorless prisms, m. p. 71.5°, by the recrystallization from alcohol–water of the crude product obtained by refluxing diphenylamine with formic acid.

N-Methyldiacetamide, prepared from N-methylacetamide[6] by treatment with acetic anhydride, was purified by distillation through a 5-foot packed column; b. p. 114.0–114.5° at 61 mm., f. p. (from cooling curve) −25.0°.[7]

Anal. Calcd. for $C_5H_9O_2N$: N, 12.2. Found: N, 12.5, 12.4.

N-Methylphthalimide, obtained by the reaction of phthalic anhydride with methylamine, was purified by distillation; b. p. 285.0–286.1° at 736 mm., m. p. 133.1–133.5°.

Method.—The systems were studied by means of the freezing point method; all cooling curves were recorded directly by means of a Brown Electronik Strip Chart Potentiometer. The cell used was similar to the one described in a previous paper from this Laboratory.[8] All points were determined at least twice. Data obtained by this method are believed to be correct, even for the steeper portions of the freezing point curves, to 1.0°. In order to increase the accuracy, all equilibrium temperatures above 65° in the system pyridine–N-methylphthalimide were determined in sealed tubes as previously described.[9] Each f. p. determined by this method is believed to be correct within 0.7°.

Results

The experimental data are shown below in graphical form. Compositions, as indicated, are given in mole per cent.

As represented graphically in Figs. 1, 2, 3, 4, 5

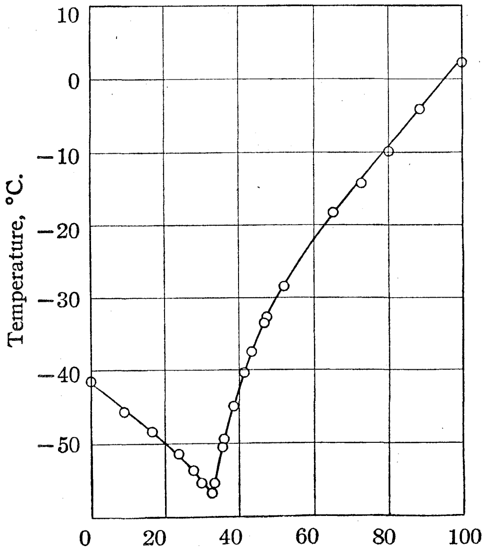

Fig. 1.—System pyridine–formamide.

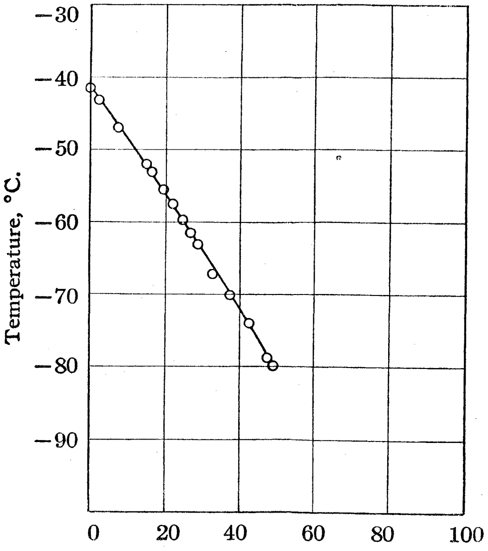

Fig. 3.—System pyridine–N,N-diethylacetamide.

---

[5] All melting and boiling points are corrected.

[6] Best obtained by method of Galat and Elion, THIS JOURNAL, **65**, 1566 (1943).

[7] D'Alelio and Reid, *ibid.*, **59**, 109 (1937), reported a melting point of −46°. Our product boiled at 194.5° at 741 mm., in agreement with their value 194.2°.

[8] Davidson, Sisler and Stoenner, *ibid.*, **66**, 779 (1944).

[9] Davidson and McAllister, *ibid.*, **52**, 507 (1930).

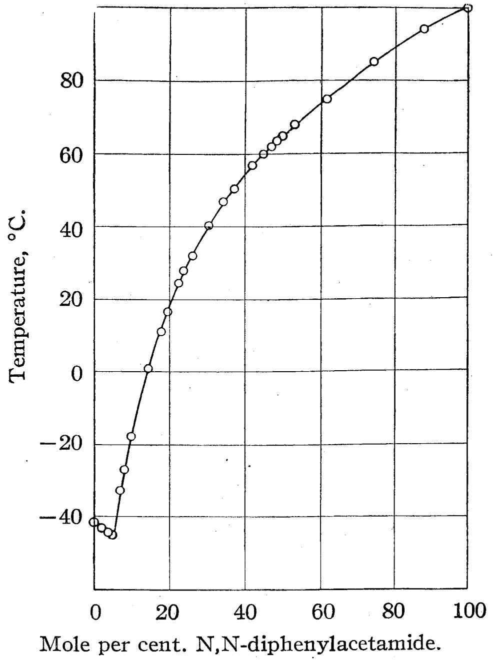

Fig. 4.—System pyridine–N,N-diphenylacetamide.

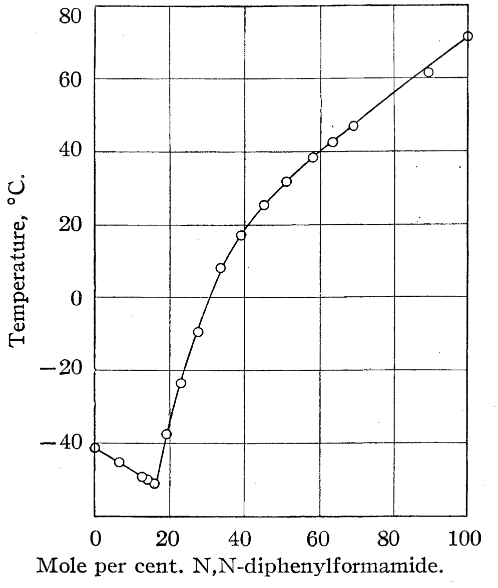

Fig. 5.—System pyridine–N,N-diphenylformamide.

and 6, respectively, the six systems consisting of pyridine with formamide, N-phenylformamide, N,N-diethylacetamide, N,N-diphenylacetamide, N,N-diphenylformamide and with N-methyldiacetamide showed no evidence of compound formation. The respective eutectics for the various systems are: 32.3 mole per cent. formamide, f. p. −56.7°; 33.0 mole per cent. N-phenylformamide, f. p. −71.0°; 4.9 mole per cent. N,N-diphenylacetamide, f. p. −44.9°; 16.2 mole per cent. N,N-diphenylformamide, f. p. −51.0°; 36.3 mole per cent. N-methyldiacetamide, f. p. −64.7°.

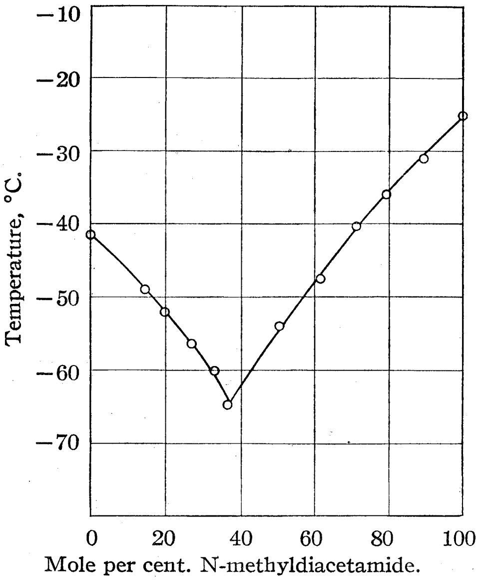

Fig. 6.—System pyridine–N-methyldiacetamide.

All attempts to establish points in the pyridine–N,N-diethylacetamide curve in the region from 49–100% amide were unsuccessful because of the extremely high viscosities of the glassy mixtures formed in this concentration range. The usual expedients, such as the sudden cooling, with liquid air, of a short platinum wire fused into the bottom

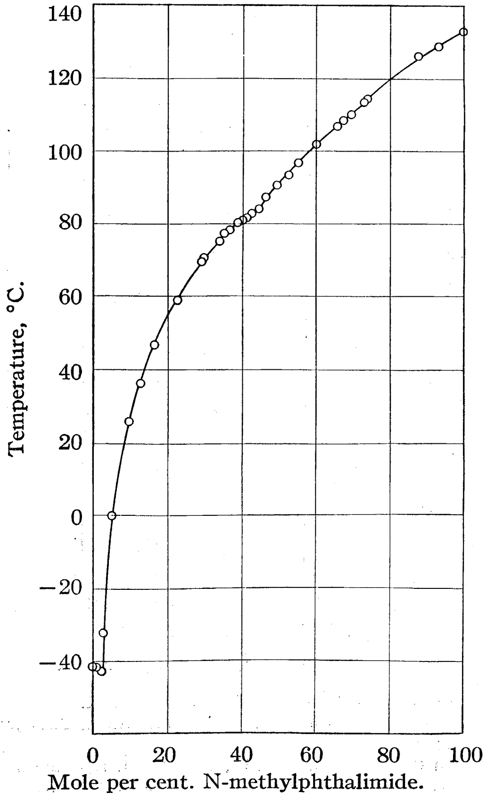

Fig. 7.—System pyridine–N-methylphthalimide.

of the freezing point cell, or prolonged storing of the mixture in a liquid air-bath, failed to induce crystallization.

As shown graphically in Fig. 7, pyridine and N-methylphthalimide form a single compound, $C_6H_4(CO)_2NCH_3 \cdot C_5H_5N$, which undergoes dissociation to N-methylphthalimide and solution at a temperature just below its melting point, which, as indicated by a short extrapolation, is approximately 82°. The eutectic is 2.2 mole per cent. N-methylphthalimide, f. p. $-42.7°$.

Discussion of Results

The fact that pyridine forms no solid addition compound with formamide in the temperature range indicated is not surprising, inasmuch as pyridine has a much lower tendency to donate its unshared electron pair than ammonia. Even with N-phenylformamide, which would be expected to be a stronger acid than formamide itself, no solid compound is observed. Of the remaining five amides, N,N-diethylacetamide, N,N diphenylacetamide, N,N-diphenylformamide, N-methyldiacetamide and N-methylphthalimide, the last-named would be expected, on the basis of the electron theory, to possess the most positive carbonyl carbon atom, *i. e.*, the carbonyl carbon atom of lowest electron density. It may possibly be significant, therefore, that, although no solid compound is formed between N,N-diethylacetamide, N,N-diphenylacetamide, N,N-diphenylformamide, or N-methyldiacetamide and pyridine, even down to eutectic temperatures as low as -51.0 and $-64.7°$, nevertheless N-methylphthalimide and pyridine form a solid 1:1 compound stable at temperatures up to 80°. At present, however, the structure of the compound $C_6H_4(CO)_2NCH_3 \cdot C_5H_5N$ is entirely problematical. Evidence for the type of bonding in such a solid binary compound can be obtained only by studies of the chemical reactions and crystal and molecular structures of the compound, and of the deviations from ideality in dilute solutions included in the system. Investigations of this type are in progress in this Laboratory.

Summary

1. Temperature–composition data are presented for the seven systems consisting of pyridine with each of the following amides: formamide, N-phenylformamide, N,N-diethylacetamide, N,N-diphenylacetamide N,N-diphenylformamide, N-methyldiacetamide and N-methylphthalimide.

2. It has been shown that N-methylphthalimide and pyridine form a 1:1 addition compound, the existence of which cannot be accounted for logically in terms of hydrogen-bonding.

The Absorption of Oxygen by Sodium in Liquid Ammonia: Evidence for the Existence of Sodium Superoxide

BY WILLIAM H. SCHECHTER, HARRY H. SISLER[1] AND JACOB KLEINBERG

It is well known that potassium, rubidium and cesium combine directly with oxygen[2] to form superoxides[3] of the formula MO_2, in which the oxygen exists as an ion of the structure $-:\ddot{\mathrm{O}}\overset{\cdot\cdot\cdot}{-}\ddot{\mathrm{O}}:$.[4] Similar compounds of alkaline earth metals have not yet been isolated in the pure form, although calcium superoxide (as an admixture to the extent of 8.7% in calcium peroxide) and barium superoxide (about 8% in barium peroxide) have been obtained by the action of 30% hydrogen peroxide on the corresponding hydroxides.[5] Magnetic studies on the impure calcium superoxide prepared in this manner demonstrate the presence of the O_2^- ion in this substance.[6]

Up to the present the existence of sodium superoxide has not been reported. Joannis[2a] described the preparation in liquid ammonia at $-50°$ of an oxide of the formula Na_2O_3, whereas Kraus and Whyte[2d] found no evidence for any oxide higher than the peroxide in the same solvent at $-33°$. Preliminary experiments in this Laboratory at approximately $-77°$ in liquid ammonia indicated the formation, by the direct combination of the elements, of a higher oxide than sodium peroxide. The results, however, were not consistent, indicating that the oxide formed was unstable; hence the oxygen uptake of sodium in liquid ammonia at $-77°$ was studied quantitatively. In the present report an apparatus is described for the study of low temperature reactions in liquid ammonia involving gas absorption, and evidence for the existence of sodium superoxide is presented.

Experimental

The apparatus employed (Fig. 1) is suitable for use only at temperatures at which the vapor pressure of the solvent has a known, moderately low value. The volume of gas absorbed by a solution can be calculated from the observed change in volume in the gas buret C; if the reaction is not too rapid, it is possible to determine its rate.

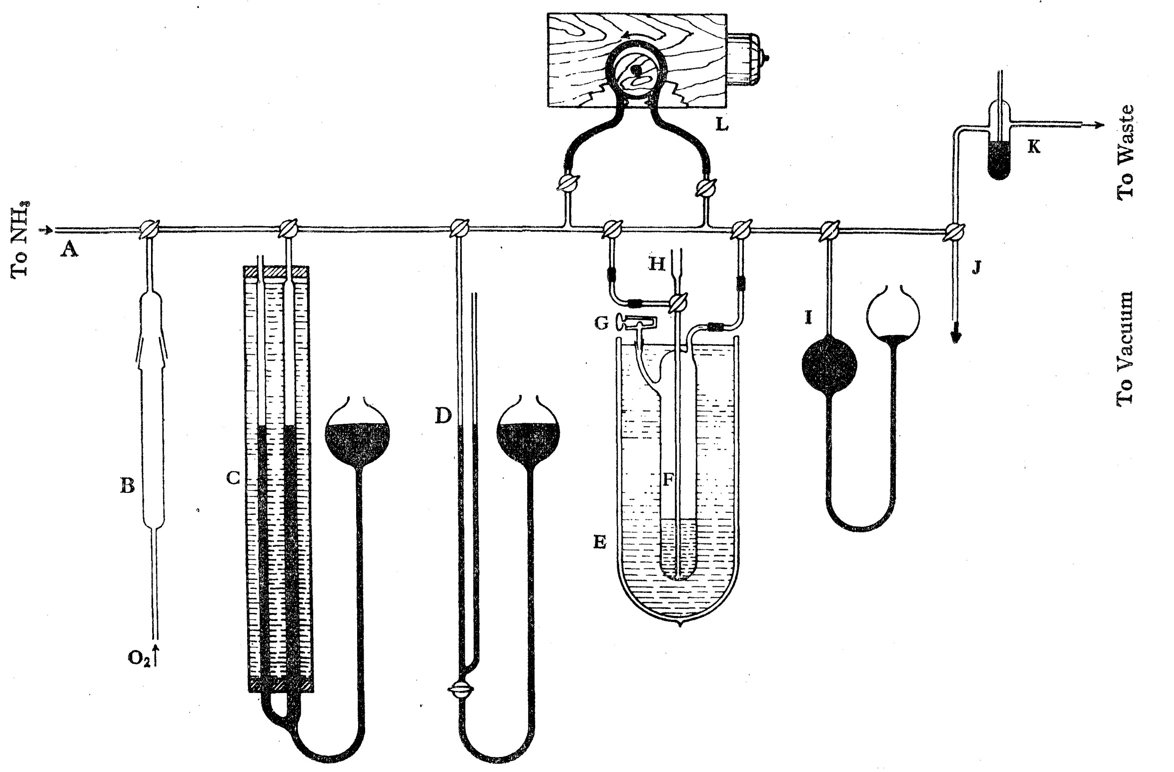

Fig. 1.

A sample of sodium of the desired size is cut in a dry-box containing phosphorus pentoxide. The metal is placed in the tared sampling stopcock G and the plug is rotated. After the ground glass cap has been replaced over the male joint, the stopcock is removed from the dry-box and weighed. The sampling stopcock is then placed at the point shown (Fig. 1) in the system, which has been previously dried by flushing for a considerable time with anhydrous (dried over sodium) ammonia.

The system is again flushed with ammonia, the stopcock J is closed, and the required volume of ammonia is condensed in the reaction cell F by means of the cold bath E, which consists of a mixture of equal volumes of carbon tetrachloride and chloroform to which Dry Ice has been added. The temperature of this mixture, by which the reaction cell is surrounded also during the process of oxidation, is between −77 and −79°.

When the ammonia has been condensed, oxygen is permitted to enter through the drying tube B, containing anhydrous magnesium perchlorate, until the buret C is almost filled. The system is then isolated by closing the stopcock above the drying tube. At this point, with the eccentric pump L turned on, oxygen from the buret is forced through the reaction cell and is collected in the reservoir I. With the manipulation of the appropriate stopcocks the gas is returned to the buret, and the cycling process is then repeated until the oxygen and the liquid ammonia are mutually saturated. During the cycling process and throughout subsequent operations, the level of the cooling liquid on the reaction cell is kept as nearly constant as possible, in order to avoid changes in oxygen volume. This is necessary because the sampling stopcock cannot be covered by the cooling bath.

Once the initial static volume in buret C has become constant, the pump L is turned on and, with the proper adjustment of stopcocks, oxygen at a rate of 850–900 cc. per minute is cycled through the reaction cell. (By regulated clamping of the rubber tubing leading to the pump, the rate of oxygen flow may be adjusted to any desired lower value.) By turning stopcock G the sodium sample is dropped into the liquid ammonia. The system is kept at approximately atmospheric pressure during the oxidation by raising the mercury leveling bulb of buret C to continually higher levels as the oxygen is consumed. When the oxygen has proceeded to the point where there is no longer any noticeable change in the mercury level in the buret, the pump is turned off, the system permitted to come to apparent equilibrium and the final static volume obtained. The change in volume is then corrected for temperature, pressure and the vapor pressure of liquid ammonia to give the standard volume of oxygen absorbed by the known weight of sodium.

After the absorption data have been obtained, the cold bath is removed and the ammonia allowed to boil off through the trap K to the waste jars. A slow flow of oxygen through the reaction cell is maintained during the removal of ammonia; this sweeps the last traces of ammonia from the system, thus preparing it for the analysis.

For the analysis the cell, now cooled by an ice–water-bath is connected with the measuring buret only, and both the cell and the buret contain oxygen at atmospheric pressure. A 10-ml. portion of catalyst solution (to be described presently) is added from H and the cell, which is connected to the rest of the system by means of Tygon tubing, is shaken to hasten the decomposition of oxide (or oxides); the quantity of oxygen liberated is calculated from the volume change in the buret. The decomposition of the cold, dilute, acidic solutions of hydrogen peroxide, formed upon the addition of acid to peroxides and superoxides of the alkali metals, is catalyzed by a solution which is 0.6 molar with respect to hydrochloric acid and 2 molar with respect to ferric chloride. To correct for the volume change due to the addition of the catalyst, a blank run is made with no oxide present.

Discussion of Results

The results of oxygen absorption studies are given in Table I. It is evident from these data that in liquid ammonia at −77°, sodium absorbs,

from oxygen which is being cycled rapidly through the solution, a volume approaching that required for sodium superoxide. It is apparent that in liquid ammonia a temperature below −33° is essential for the formation of an oxide higher than sodium peroxide, since Kraus and Whyte[2d] have demonstrated that the peroxide is the highest oxide formed by the rapid oxidation of sodium at the boiling point of ammonia.

As mentioned previously, the amount of oxygen absorbed by the sodium is calculated from the volume change in the buret during the oxidation. This calculation is made on the assumptions that oxygen behaves as an ideal gas under the conditions of the experiment, and that the absolute pressure of the ammonia in the buret is the same before and after the oxidation, *i. e.*, that it is equal to the vapor pressure of the liquid ammonia solution. The first assumption is valid within the experimental error, but the second is true only if sufficient time is allowed for the system to reach equilibrium. The calculated oxygen uptake data, as given in Table I, are based on the assumption that such equilibrium had been attained.

In no case was the theoretical absorption for sodium superoxide quite realized. It is possible that this may be accounted for in part by insufficient time having been allowed for the system to come to equilibrium after oxidation, and in part by contamination of the sodium during the sampling process. Nevertheless, there is no plausible explanation other than the formation of sodium superoxide that will account for the absorption of such large quantities of oxygen.

The unstable nature of the superoxide is indicated by the results of the analyses, which were made after the ammonia had been permitted to evaporate and the product allowed to reach room temperature. Roughly half the volume of oxygen required for sodium superoxide is liberated upon analysis. At present we have no explanation for the approximately constant values obtained on analysis. The quantity of oxygen liberated is too large to be accounted for solely on the basis of decomposition of sodium peroxide. In each case the volume liberated is approximately 50% greater than that calculated for the peroxide. The reaction product before analysis is visibly heterogeneous, appearing to be a mixture of a yellow[7] and a white substance.

Acknowledgment.—The authors are indebted to the Office of Naval Research for a grant which made this and continuing investigations possible.

Summary

1. An apparatus for studying low temperature reactions in liquid ammonia involving gas absorption is described.

2. Evidence for the existence of sodium superoxide, based upon oxygen absorption in liquid ammonia at −77°, is presented.

LAWRENCE, KANSAS RECEIVED JULY 1, 1947

A Thermal Investigation of the Ternary System Mg–Na–Pb. II. The Compound MgNaPb and Several Cross Sections

BY GEORGE CALINGAERT, HYMIN SHAPIRO AND IVAR T. KROHN

In a recent note,[1] it was disclosed that the compound $Mg_4Na_4Pb_3$ had been discovered in the course of a thermal investigation of the ternary system Mg–Na–Pb. The investigation has now resulted in the discovery of a second compound and the partial elucidation of several important cross sections. The new compound, MgNaPb, was shown to be of the peritectic type rather than of the open maximum type, as the first compound, $Mg_4Na_4Pb_3$.

Method of Investigation

In this thermal study, two principal methods of attack were used: the investigation of cross sections of the ternary diagram, and the investigation of alloys having atomic ratios of small whole numbers. The first method was used mostly for determining the locations of ternary eutectic points and binary eutectic curves, and in the regions close to the binary compounds—in other words, for clarifying the general structure of the equilibrium diagram. The choice of cross sections was limited to those between binary compounds, between a compound and an element, and at a fixed concentration of one of the elements. The second method was used in spot attempts to discover ternary compounds, since compounds are usually characterized by atomic ratios of small whole numbers. Of course, the usefulness of this method is limited to compounds having open maxima. For peritectic compounds it is necessary to correlate several types of data, as will be discussed later.

The thermal analysis data for each alloy were plotted with millivolts and time as the coördinates. The cooling curves were interpreted after the manner of Tammann.[2] The differences in millivolts between successive readings were sometimes plotted against time in order to evaluate the precision of the results.

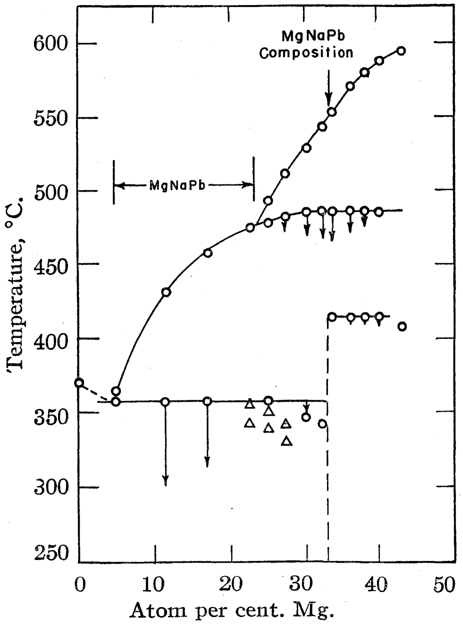

Fig. 1.—NaPb–Mg cross section (passing through 50% Na–50% Pb): time scale for temperature breaks, 50° = twenty minutes.

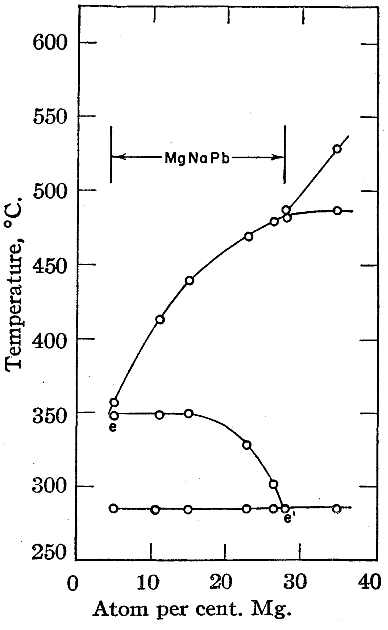

Fig. 2.—Cross section parallel to NaPb–Mg cross section and passing through 47.5% Na–52.5% Pb.

Experimental

Chemicals, Apparatus and Procedure.—All alloy melts were prepared from mixtures of magnesium, lead and NaPb or Na_4Pb alloy. The magnesium was Dow extruded bar of purity over 99.9%, and the lead was Asarco brand, over 99.95% pure. The NaPb was alloy from the stock used for the manufacture of tetraethyllead. The Na_4Pb was prepared from sodium and the Asarco lead, and analyzed 30.96% sodium as compared with the theoretical of 30.74%. The analytical figures were used in computing the quantities of alloy ingredients required.

The alloy melts were made in 200- to 300-g. batches under an atmosphere of nitrogen or helium purified over hot copper filings; the gases seemed to be equally effective up to about 550°, but above this temperature helium was

[a] Supercooled break. Initial and maximum temperatures are given.

used exclusively. Both open iron crucibles and closed iron bombs were employed. Iron was used because the binary equilibrium diagrams show that iron does not interact with any of the three metals in the system within the temperature range of this study; examination of the vessels after many experiments substantiated this fact. Above 600° the closed bombs were used exclusively on account of the substantial vapor pressure of the alloy at the higher temperatures. These bombs, 2 in. i.d. and 2.125 in. inside height, were threaded on the upper outside edge for 0.75 in., and fitted with 0.5-in. thermocouple wells extending in through the bottom. For easy removal, the screw covers were hexagonal in shape.

The open crucibles, of $^1/_{32}$-in. wall thickness, were covered with a slotted iron disc which centered a stirrer and thermocouple in the melt. The thermocouple was encased in 4-mm. Pyrex tubing, which was not attacked at the temperatures employed. The stirrer consisted of a $^1/_{16}$-in. iron rod welded perpendicularly to a 1-in. iron disc. The crucible was centered in an iron pot by means of a triangular tripod. The pot, cylindrical in shape and of 0.125-in. thickness, was fitted with a special cover

[a] Break of doubtful validity.

which was fastened to the pot by screws and contained two holes corresponding to those in the crucible cover. The cover was also fitted with a steel gas inlet tube. The entire pot assembly could be lifted by means of two bolts screwed into the cover. The pot fitted closely into a Hoskins electric furnace, whereas the bomb assembly was centered in the furnace by means of a magnesia block.

The alloy was cooled either against room temperature, with the heat turned off, or at a constant cooling rate of 1°/minute. For the latter, a calibrated electrical system was used consisting of a Variac and a variable resistor connected in parallel to the furnace. During heating, the resistor was by-passed.

The crucible or bomb was charged with the proper mixture of magnesium, lead, and NaPb or Na_4Pb, in a box flushed for a minimum of one hour with inert gas. The assembly of the apparatus was completed under inert gas, after which it was placed in the furnace chamber and fitted with an iron–constantan thermocouple. When the crucible was used, nitrogen or helium was passed through the iron pot at the rate of 1 or 2 liters/min. With the bomb, an inert atmosphere was not required in the furnace chamber.

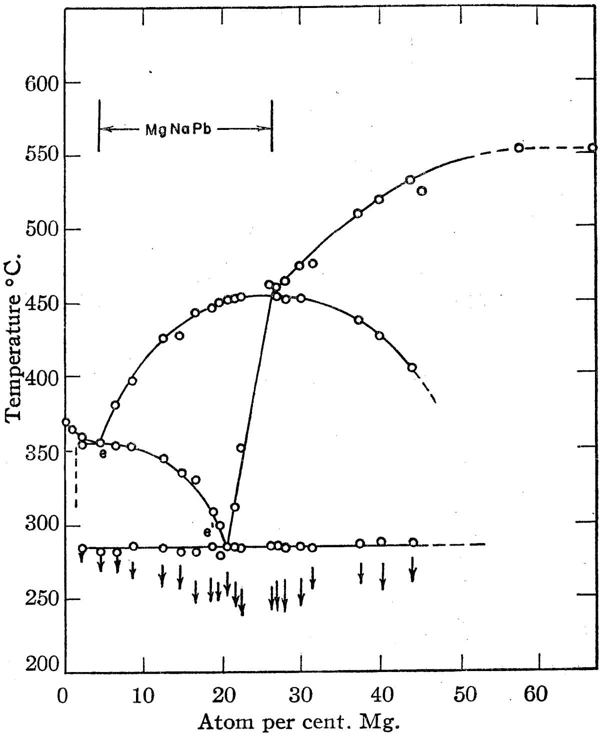

Fig. 4.—NaPb–Mg_2Pb cross section: time scale for temperature breaks, 50° = twenty minutes.

The constituents of the alloy were heated to a temperature 75 to 100° above the predicted temperature of the primary break in the cooling curve of the alloy, if above 450°. For alloys with lower primary breaks, it

[a] Supercooling.

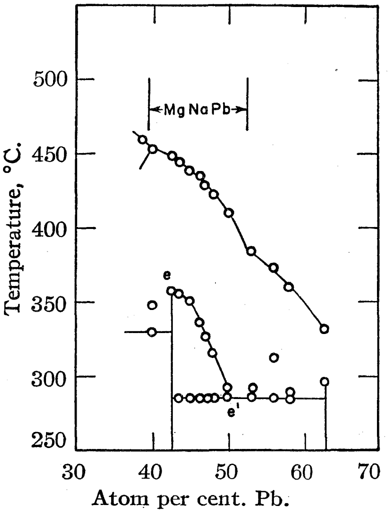

Fig. 5.—Cross section at 15 atom per cent. magnesium.

was necessary to raise the temperature to approximately 500° to dissolve the magnesium. Alloys made in crucibles were stirred for a minimum of forty-five minutes to ensure complete solution of the ingredients at the maximum heating temperature. Similarly, alloys made in bombs were vigorously shaken by means of tongs for at least five minutes over a forty-five minute heating period. No trouble was encountered in dissolving the alloy metals in the bombs since the temperatures were usually above 650°, the melting point of magnesium, the highest melting ingredient.

After the alloy was thoroughly mixed, shredded magnesia insulation was placed over the furnace to a depth of about 3 in. If the crucible was being used, the stirrer was lifted out of the molten alloy and fixed in this position by a small clamp. The temperature of the furnace was held constant for about thirty minutes to bring the insulation to temperature equilibrium.

Most of the alloys were cooled at the constant rate of 1°/minute to give a more easily interpreted cooling curve and to favor the establishment of equilibrium conditions in the alloy. Cooling against room temperature was used as a check on roughly half of the alloys cooled at the constant cooling rate, and sometimes when the necessary time for constant rate cooling (about five hours) was lacking.

The cooling rates for cooling against room temperature varied from approximately 4°/minute at 500° to approximately 1°/minute at 250°. For a few alloys, heating curves were taken, in order to detect temperature breaks below 200° and to confirm temperature breaks obtained on cooling. The heating rates varied from 1°/minute to 4°/minute, the former rate being used on alloys of special interest.

After the cooling curve was obtained, the alloy apparatus was cooled to room temperature and opened in an inert atmosphere. The alloy was coarsely crushed and was inspected for undissolved constituents, if any, crystallinity, color, and brittleness. It was then stored in paraffin-sealed bottles for microscopic examination. Thirty alloy specimens were polished and photomicrographed.

Results and Discussion

The results of thermal analysis are given in Tables I–VI. Two abbreviations are used: R. T., denoting cooling against room temperature; and S. C., cooling at a constant rate of 1° per min. The alloys are classified as belonging either to a specific cross section, such as Na_4Pb–Mg_2Pb, NaPb–Mg_2Pb, NaPb–Mg, Na_2Pb_5–Mg_2Pb, 15% atom magnesium, or 50% atom lead, or to a region, such as the lead corner. An alloy located at the intersection of two cross sections is found in the tables for both cross sections.

For alloys in the various cross sections of Tables I–IV, the temperature breaks are plotted in Fig. 1–6. The length of the solid vertical line immediately below an isothermal break is proportional to the time of the break. In several cross sections, notably the Na_4Pb–Mg_2Pb cross section, the final temperature breaks were characterized by a sharp rise and fall in temperature, which indicates a high degree of supercooling. This type of break is designated in the plots by triangles, which show both the beginning and the end of the temperature rise.

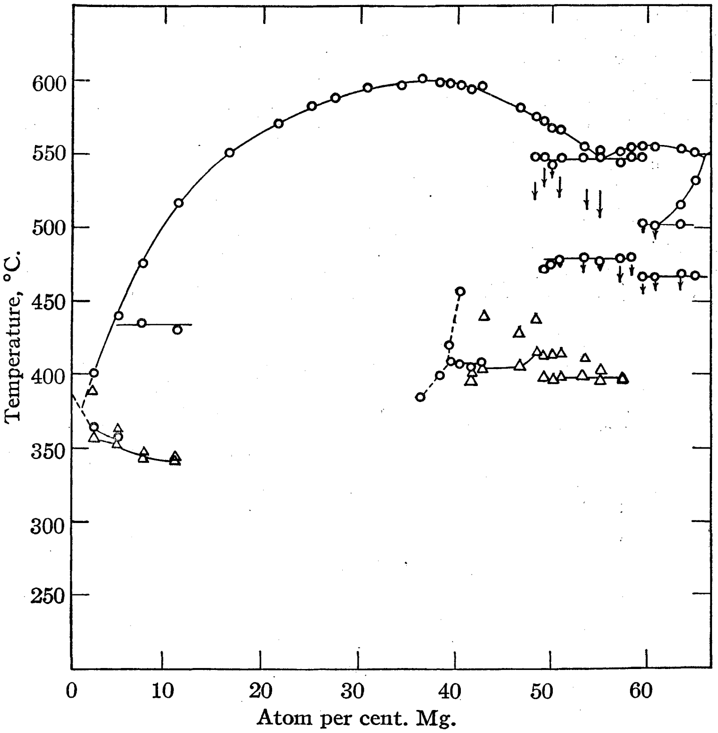

Fig. 6.—Na_4Pb–Mg_2Pb cross section. Time scale for temperature breaks, 50° = twenty minutes.

MgNaPb Surface of Primary Crystallization.—The surface of primary crystallization of the compound MgNaPb is bounded in part by the two incomplete binary eutectic curves and the one peritectic curve (GG') shown in Fig. 7. The temperatures along the curves are given at various points. The loci of the curves were determined from Fig. 1–5 and also from several other cross-sectional plots not shown in this paper.[3] The lim-

---

(3) The complete experimental data are given in Ethyl Corporation reports LTD 46-22 and LTD 47-32, which are available on request.

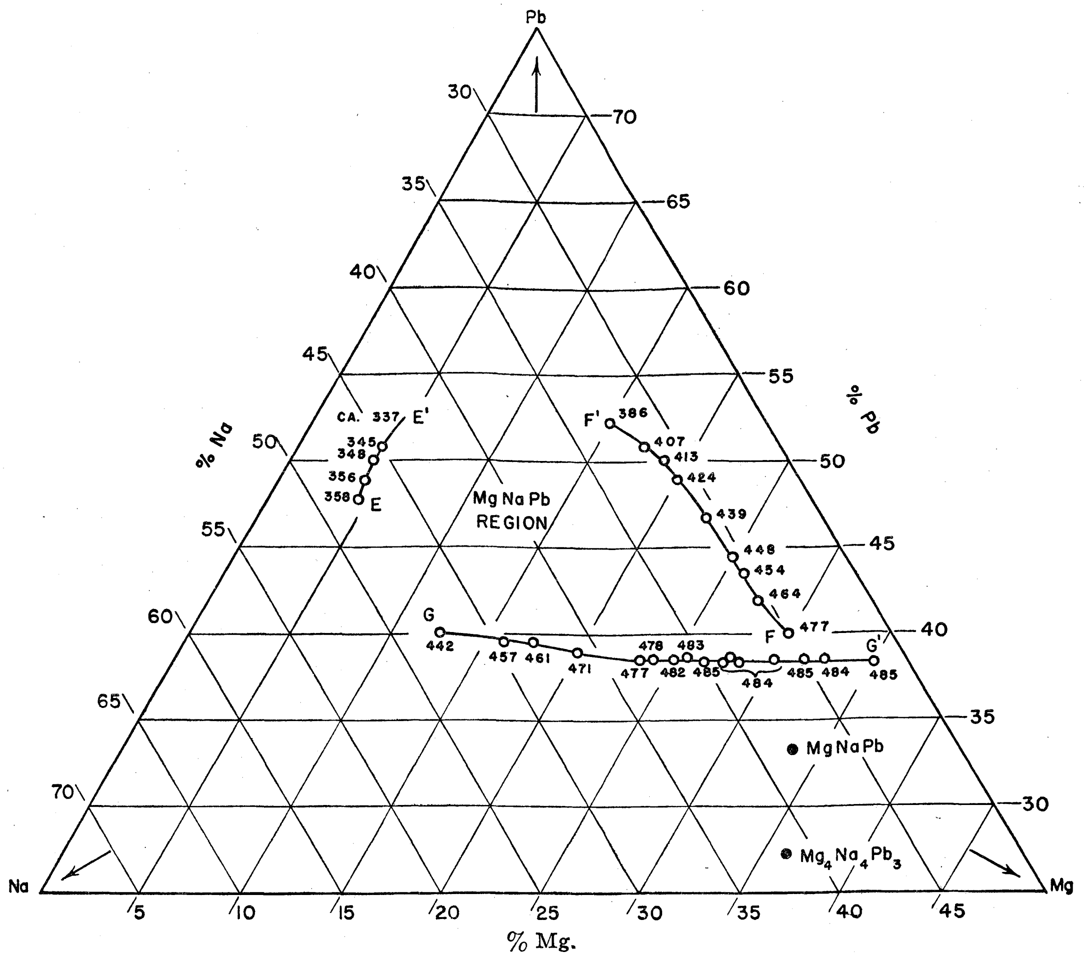

Fig. 7.—Binary eutectic curves of the region of primary crystallization of MgNaPb.

its of the surface of primary crystallization of MgNaPb are also indicated in Fig. 1–5.

From the cross-sectional shapes of the surface of primary crystallization of the compound (Fig. 1–5) and the isothermal plots of the primary temperature breaks (Fig. 8), it is evident that the surface of primary crystallization possesses no open-maximum point. It should be noted that the alloys in this region exhibited two or three temperature breaks; in general, the primary break was represented by a sharp change in the slope of the cooling curve and not by an isothermal flat.

MgNaPb Composition.—The method used to locate the compound MgNaPb is based on the fact that within the region of primary crystallization of a compound all alloys along a straight line passing through the compound composition will give the same secondary break, representing the intersection of the line with a binary eutectic curve bounding the region. Several such lines, each representing a simple secondary temperature break on the same binary eutectic curve, must themselves intersect at the location of the ternary compound.

Of the available data on the two eutectic curves (EE′, FF′) shown in Fig. 7, only that portion of the curve EE′ descending in temperature from the NaPb–Mg cross section in the direction of the Pb corner was used to locate the MgNaPb compound. The curve GG′ cannot be used for this purpose, since it cannot be reached *via* the primary precipitation of this compound.

In Fig. 2, 4 and 5, the curves for the secondary temperature breaks corresponding to the curve EE′ are indicated by ee′. By and large, the curves ee′ are well established. They show a gradual but sufficient change in temperature to define the lines of interest (the alloy compositions having the same secondary temperature break). Figure 9 shows four such lines, for the secondary breaks of 358, 340, 320 and 285°. (The 285° line gives, in reality, those compositions which show a second and final temperature break corresponding to a 285° eutectic.) On extrapolation, these lines intersect at the alloy composition $33^1/_3$ atom per cent. Mg, $33^1/_3$ atom per cent. Na and $33^1/_3$ atom per cent. Pb, or MgNaPb.

From the aforementioned analysis curves EE′ and FF′ in Fig. 7 are binary eutectic curves char-

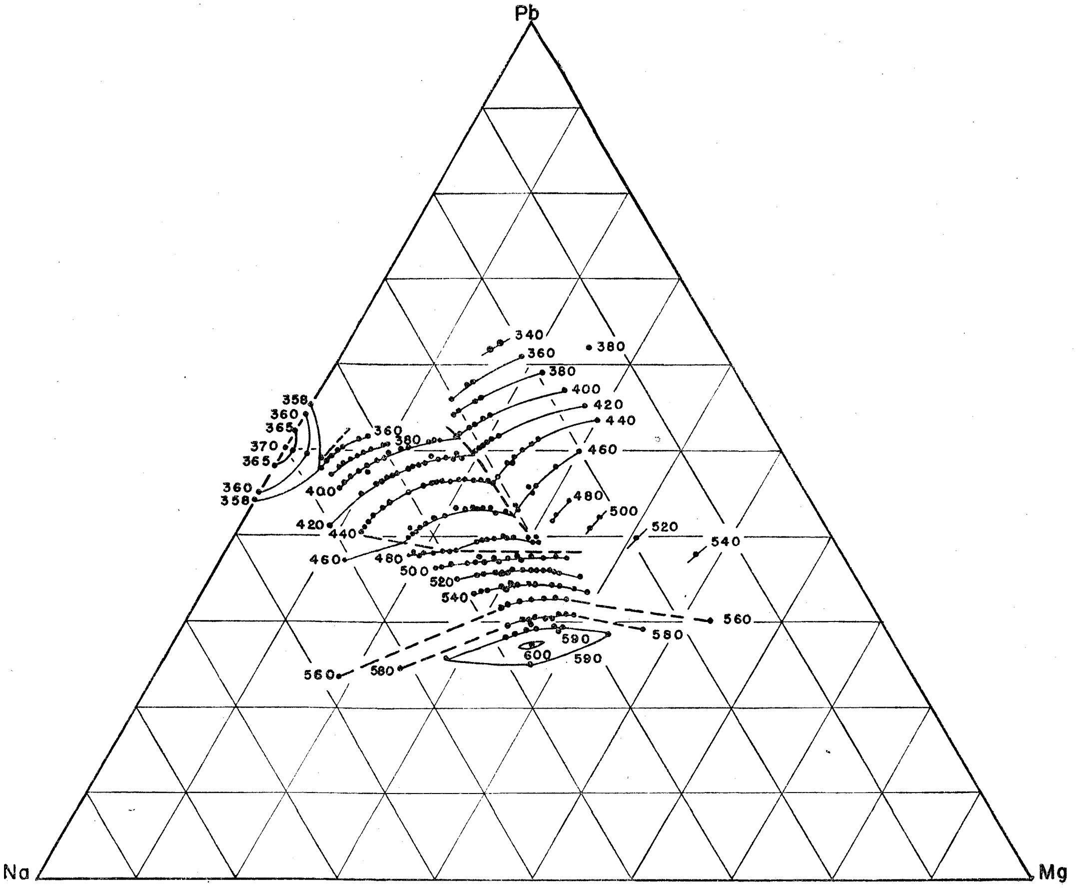

Fig. 8.—Isothermal curves of primary crystallization of the MgNaPb region and surrounding area.

acterized by the simultaneous crystallization of two different species. On the other hand, curve GG′ is apparently a binary peritectic curve at which solid and liquid react to give a second solid phase. The reaction must be

$$Mg_4Na_4Pb_3 + \text{liq.} \longrightarrow MgNaPb$$

Microscopic examination of the polished surface of the alloy MgNaPb revealed two regions. The main phase was dark-colored and constituted more than 90% of the surface area. The minor region was silver in color. Other alloys examined in the neighborhood of the alloy MgNaPb disclosed two or three regions, with the main phase being present in amounts below 90%.

Na_4Pb–Mg_2Pb Cross Section.—The Na_4Pb–Mg_2Pb cross section is shown in Fig. 6. The range of primary crystallization of the ternary compound $Mg_4Na_4Pb_3$ (at 36.36 atom per cent. magnesium in the Na_4Pb–Mg_2Pb cross section) appears to be quite large. The absence of lower breaks within part of the range is suggestive of solid solution in the compound. On the other hand, the ranges of primary crystallization of the binary compounds within the ternary system are very limited. Na_4Pb extends into the ternary diagram for less than 2.5 atom per cent. magnesium and Mg_2Pb for less than 2.0 atom per cent. sodium (approximately equivalent to 65 atom per cent. magnesium). The approximate equality of the initial temperature breaks between 55 and 65 atom per cent. magnesium might suggest a very flat surface of primary crystallization for Mg_2Pb. However, the existence in this region of non-isothermal breaks and of several lower temperature breaks precludes this possibility, which ordinarily would require a single secondary temperature break. The long duration of the initial temperature breaks for these alloys (Table IV) suggests that a ternary compound of high magnesium-to-sodium ratio may exist close to the cross section.

Temperature breaks characterized by a sharp rise were observed principally in the Na_4Pb–Mg_2Pb cross section.

Solid Solubility in the NaPb–Mg_2Pb Cross Section.—The NaPb–Mg_2Pb cross section, shown in Fig. 4, is well defined up to 45 atom per cent. magnesium. The limit of solid solubility in NaPb lies somewhere between 0.91 and 2.24 atom per cent. magnesium as measured along the cross section. With the former alloy, only a single temperature break was obtained and the presence of a single phase was confirmed by micro-

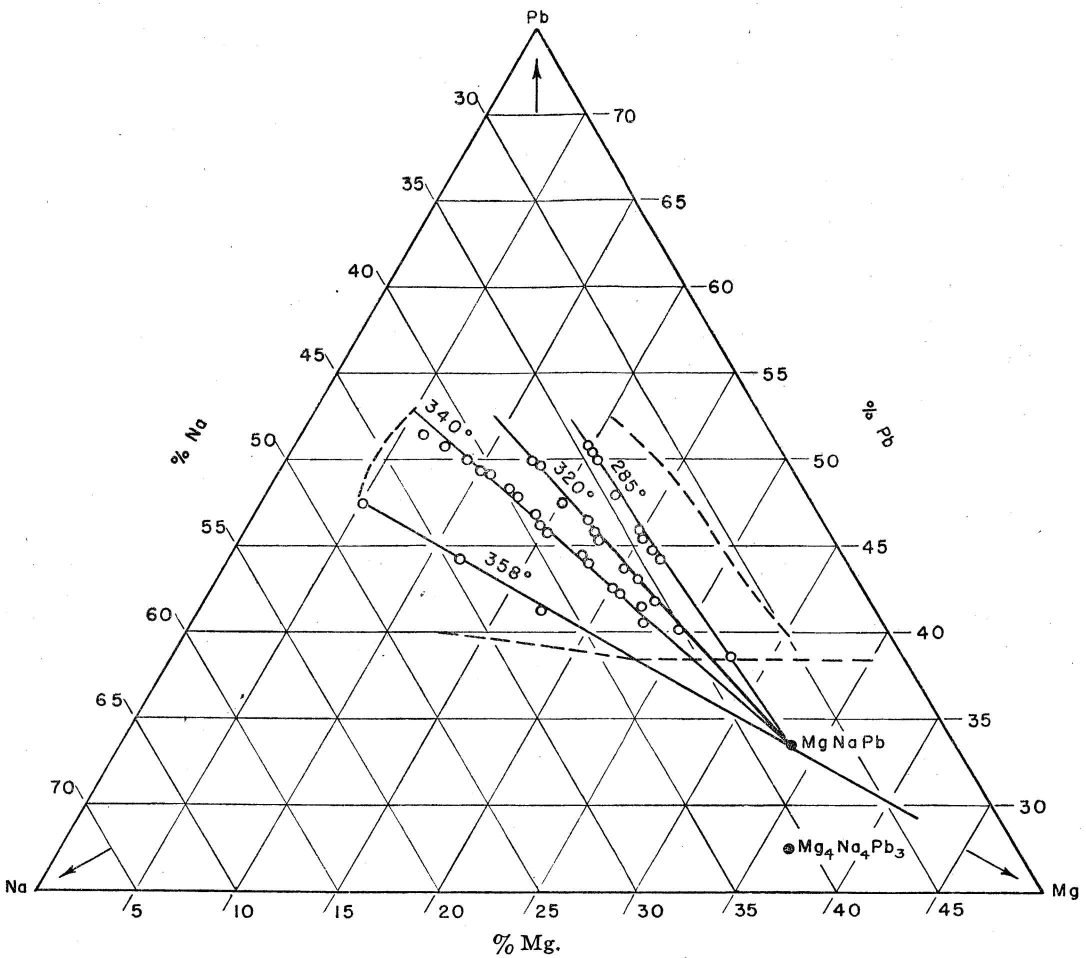

Fig. 9.—Method of locating the compound MgNaPb.

scopic investigation. With the latter alloy, three temperature breaks were obtained. No further attempt was made to establish more exactly the limits of solubility.

Summary

Approximately 120 individual alloy compositions within the ternary system Mg–Na–Pb were investigated by thermal analysis. The system was shown to be complex. A second compound, MgNaPb, was discovered, but unlike the first compound, $Mg_4Na_4Pb_3$ (which is of the open maximum type), it is of the peritectic type.

Several important cross sections of the system were partly elucidated. The lead corner was indicated to be the simplest region, while solid solutions were discovered in two regions and supercooling in others. Thirty alloys were photomicrographed, including the compound MgNaPb.

Magnetic Measurements on 2,2'-Benzothiazyl Disulfide and bis-(9-Ethoxy-10-phenanthryl) Peroxide

BY HOWARD G. CUTFORTH[1] AND P. W. SELWOOD

The purpose of this investigation was to test the possible formation of free radicals in appreciable concentrations from diaryl disulfides and diaryl peroxides.

The existence of reversible dissociation to free radicals has been amply demonstrated for the C–C, N–N and Cl–Cl bonds.[2] It has also been shown that the following apparently do not dissociate: Si–Si, Ge–Ge, Sn–Sn, Pb–Pb and As–As.

There appears to be no direct evidence that diaryldisulfides dissociate. But some of these compounds show deviations from Beer's law, an ability to react with triarylmethyl radicals, and certain chemical properties which suggest free radical reaction mechanism.[3]

Most of the evidence for free radical formation from peroxides lies in the kinetic evidence from polymerization reactions.[4–6] Other evidences include deviations from Beer's law and subnormal molecular weights at the freezing point of benzene.[7,8] The photochemical dissociation of peroxides into free radicals has often been proposed.[9–11] But the existence of univalent oxygen can scarcely be considered as established.

The possible formation of free radicals by disulfides and peroxides is of interest because it would add to the very small list of elements (C, N, Cl) which definitely show reversible dissociation. There are also practical reasons for wanting to know whether free radical concentration can be appreciable in polymerization and vulcanization, and in cystine and related compounds and derivatives of biochemical interest.

Our choice of the two compounds: 2,2'-benzothiazyl disulfide and bis-(9-ethoxy-1-phenanthryl) peroxide was based on the following considerations: The disulfide is of importance in the processing of rubber, although the mechanism by which it operates is little understood. There is a possibility that this mechanism involves free radicals. Furthermore, the compound is reversibly thermochromatic; the color begins to appear in toluene solution at about 80°.

The peroxide was chosen for study because the phenanthryl groups appear to offer a good opportunity for resonance stabilization of an aroxy radical, and because molecular weight studies by Goldschmidt[8] indicate that dissociation occurs.

Experimental

Preparation of Materials.—The 2,2'-dibenzothiazyl disulfide was obtained from the United States Rubber Company through the courtesy of Dr. R. H. Ewart.

The bis-(9-ethoxy-10-phenanthryl) peroxide was prepared from crude phenanthrene in three steps. First, phenanthrenequinone was prepared as described by Adkins.[12] From the quinone, 9-ethoxy-10-phenanthrol was prepared by the method of Fourneau and Matti.[13] The phenanthrol with ethyl alcohol of crystallization had a melting range of 77–79° which agrees with 77° as reported by Japp.[14] bis-(9-Ethoxy-10-phenanthryl) peroxide was obtained by mild alkaline oxidation of the phenanthrol.[2] The peroxide was crystallized from a very small amount of benzene. The resulting sample decomposed at 138–139°, which agrees with 138° reported by Goldschmidt. *Anal.* C, found 83.88, calcd. 83.78; H, found 6.14, calcd. 6.07; O, found 9.98, calcd. 10.15. This is for the peroxide crystallized with two moles of benzene.

Benzene and toluene used as solvents in these studies were prepared by repeated extraction with concentrated sulfuric acid until the acid layer had no color. After the solvent was washed with distilled water, sodium bicarbonate solution, and again with distilled water, it was dried overnight over sodium. Finally it was distilled from sodium, and the middle third collected for use.

Density and Magnetic Susceptibility Measurements.—Density measurements and magnetic measurements on the Gouy balance have been described,[15,16] as has the treatment of data.[17]

The effect of light on the magnetic susceptibility of the diaryl peroxide was investigated on a very sensitive type of magnetic balance, using a horizontal suspension and a permanent magnet. This balance will be described in a forthcoming publication.

Preparations of Solutions.—The disulfide and peroxide solutions investigated on the Gouy balance were prepared in an apparatus shown in Fig. 1, as follows:

The apparatus was evacuated through E, with metallic sodium in A. This was allowed to stand overnight. The solute was introduced to chamber D, and the solvent was poured into bulb A. After the apparatus had been evacuated and sealed at E, the solvent was distilled from A to F by cooling F. Subsequently, the solvent was filtered through a sintered glass disc, the solute in D was dissolved, the solution was filtered through a second sintered glass disc, and the remainder of the apparatus was sealed off at I.

The peroxide dissolved quite readily, but the toluene had to be heated to get appreciable disulfide into solution. By tilting the apparatus the magnetic sample tube J and the expansion pycnometer K were filled to the correct height and were sealed off at their respective constrictions.

Photochemical Dissociation.—No further description is needed for the Gouy type of magnetic measurements, which were performed over a range of temperature. But the method

used for determining the effect of light on the magnetic susceptibility of peroxide solutions requires some further description.

A sample of peroxide was dissolved in benzene by mixing the two at room temperature. The magnetic sample tube and a 10-ml. weighing bottle were filled from a pipet. No special precautions were taken to exclude air because oxygen is reported to have little effect on peroxides of this type.[8] The solution so obtained was roughly analyzed for weight per cent. of peroxide.

The temperature of the suspended system during these observation was 25°. Changes of susceptibility were observed as linear displacements of the sample tube. These displacements were observed with a microscope and micrometer eyepiece. First, the sample was irradiated until a constant displacement was obtained. Then the system was left in the dark until a rest point was obtained.

Irradiation of the sample was furnished by two 200-watt tungsten lamps and by one mercury vapor lamp. However, as the sample tube was Pyrex glass, very little ultraviolet light reached the sample.

The time required for equilibrium in displacement was approximately thirty-five minutes. Observations were continued for thirty minutes after equilibrium had been reached.

Control experiments were made on pure benzene.

The quantity measured in the horizontal balance is the displacement, D. This displacement is perpendicular to the lines of flux in the magnetic field, and is caused by a change in magnetic susceptibility of the solution. Displacements could easily be read to 1×10^{-4} centimeter. This displacement was equivalent to a change of 4.68×10^{-10} unit of susceptibility.

Both in the light and in the dark we have the familiar relationship that $\chi_m = \chi_1 p_1 + \chi_2 p_2$, where χ_m is the susceptibility of the solution, χ_1 and χ_2, susceptibilities of the solute and solvent, and p_1 and p_2, weight fractions of solute and solvent. The temperature, fraction of solvent and susceptibility of solvent remain constant in light and dark; hence, the change in susceptibility on illumination of the sample

$$\Delta\chi = p_1(\chi_1^{\text{light}} - \chi_1^{\text{dark}})$$

but χ_1^{light} is equal to the algebraic sum of χ_1^{dark} and the susceptibility of any free radical which may be formed. Therefore,

$$\Delta\chi = p_1\chi_r$$

where χ_r is the susceptibility of the free radical. The molar paramagnetism for one unpaired electron spin at 25° is 1280×10^{-6}, so that the paramagnetic susceptibility for complete dissociation would be

$$2 \times 1280 \times 10^{-6}/M$$

where M is the molecular weight of the peroxide.

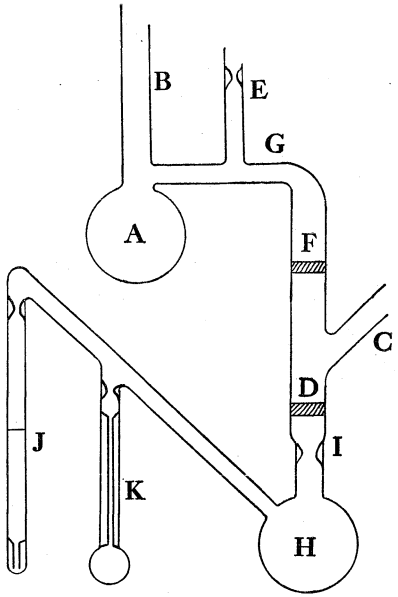

Fig. 1.—Apparatus for preparing peroxide and sulfide solutions and for filling pycnometer and magnetic sample tube.

The fraction of peroxide converted to free radicals is then

$$\alpha = \chi_r M/2 \times 1280 \times 10^{-6}$$

or, in terms of displacement in the horizontal magnetic balance

$$\begin{aligned}\alpha &= \Delta\chi M/2 \times 1280 \times 10^{-6} p \\ &= 1.8 \times 10^{-3}\, DM/p_1\end{aligned}$$

At a concentration of 3% peroxide, as little as 0.15% dissociation could be detected.

Results

Calibration of the Gouy magnetic balance was done with pure benzene and toluene, for which the susceptibilities at 25° were taken as -0.7065×10^{-6} and -0.7060×10^{-6}, respectively. The densities and susceptibilities at other temperatures as determined for this investigation are given in Table I. Table II shows the densities and susceptibilities of the diaryl peroxide dis-

solved in benzene and in toluene. The susceptibilities of the solutions are shown, in addition to the susceptibilities of the solute.

It will be noted that the solute is diamagnetic in all cases, and that it shows no temperature coefficient of susceptibility. The susceptibilities in toluene are numerically smaller than expected, but the low concentration of the solution renders the results in this solvent less accurate. We conclude that, under the conditions of these experiments, the diaryl peroxide is not dissociated to free radicals to an extent greater than 2%. This compares with a dissociation of 62% at room temperature reported by Goldschmidt.

However, the effect of light on the peroxide gave a positive change of susceptibility. The results are shown in Table III. The deflection was in the direction of increasing algebraic susceptibility. If this change is due to dissociation, then the degree of dissociation under these conditions is 6%. The measurements on the Gouy balance are done with the sample in the dark. Presumably Goldschmidt's molecular weight determination was done with the sample not specially protected from the light. He reports that the dissociation proceeds slowly. There is, therefore, not necessarily any contradiction between the earlier results and those reported here.

Some comment is called for on the correction to be applied for the diamagnetism of the free radical. There are three ways of obtaining this correction. The first is to assume that no dissociation occurs at room temperature, hence the diamagnetism per gram of free radical is -0.6012×10^{-6}. Possibly this should be modified slightly because of the rupture of an S–S bond. The second method is by the use of Pascal's constants. These give a diamagnetism for the free radicals of -0.5400×10^{-6}. The third method is to measure the susceptibility of mercaptobenzothiazole and to correct for the additional hydrogen. The susceptibility of mercaptobenzothiazole at 25° was measured in toluene solution and found to be -0.5554×10^{-6}. Correction for the hydrogen atom gives a diamagnetism of the free radical of -0.5411×10^{-6}. This value was used in calculating the results shown in Table IV. Use of the larger diamagnetism derived from the disulfide at 25° would raise the degrees of dissociation somewhat.

However, the important conclusion is that the disulfide definitely forms free radicals. It is assumed that this occurs through dissociation across the sulfur–sulfur bond, but pending completion of ebullioscopic and other measurements now in progress it can scarcely be accepted as proved that dissociation produces the free radicals. Excitation to a triplet state would yield comparable magnetic results.

If dissociation actually occurs with the formation of thiol radicals then it is clear that the sulfur–sulfur bond breaks with considerably more difficulty than the carbon–carbon bond in hexaarylethanes. This result is, of course, not unexpected. The results reported here are scarcely accurate enough to make worthwhile a calculation of a heat of dissociation for the disulfide. But the heat is obviously greater than the 11 or 12 kilocalories per mole found for the hexaarylethanes.

The most interesting phase of these observations is the fact that free radicals must be formed in large amounts at temperatures used in the vulcanization of rubber with the disulfide. There is also raised the possibility that free radical concentration may be calculated for disulfides of biochemical interest at the temperature of the animal body.

It is a pleasure to acknowledge the support of the United States Rubber Company in connection with this work.

Summary

Magnetic measurements show that bis-(9-ethoxy-10-phenanthryl) peroxide does not dissociate appreciably in the dark in benzene or toluene solutions up to 50°. But exposure of the solu-

tion to light results in a magnetic change which could be interpreted as being due to appreciable dissociation.

A considerable degree of free radical formation is observed with 2,2′-dibenzothiazyl disulfide. The concentration of the thiol radicals in toluene has been measured up to 150°.

Reaction Kinetics of Aliphatic Tertiary β-Chloroethylamines in Dilute Aqueous Solution. I. The Cyclization Process[1]

BY BARNETT COHEN, ERVIN R. VAN ARTSDALEN[2a] AND JOSEPH HARRIS[2b]

In contrast to ordinary alkyl halides, alkylamines possessing a halogen atom in the beta to omega position undergo a distinctive intramolecular transformation as the initial detectable reaction in polar solvents. The transformation yields halide ion and a more or less stable heterocyclic compound. In the case of the primary and secondary amines, the heterocycle may be either an imine or an imonium ion, depending on the *p*H of the solution. The tertiary amines can yield only the corresponding imonium ions.

The kinetics of the initial cyclization of a number of *primary* halogenated alkylamines has been reported.[3] The forward process of ring-formation was established as a unimolecular reaction, the rate of which was shown to be influenced by the length of the side-chain, by the substituents thereon, by the nature of the halogen and, especially, by the nature of the solvent.[4] The process is known to be reversible, but the kinetics of the reverse reaction seems not to have been studied, except for unsuccessful attempts[5] to determine an equilibrium constant in the β-bromoethylamine system. The failure was due to interference by side-reactions. It is known that in certain cases, at least, cyclic dimerization and linear polymerizations of the haloalkylamines can take place and become quantitatively important,[6] especially in concentrated solutions and at elevated temperatures.[7]

This report on a series of nine tertiary β-chloroethylamines supplements the older observations on the analogous primary amines. The compounds were of the general type $RR'NCH_2CH_2Cl$, where R and R′ represent an alkyl group or a β-substituted ethyl group. Analytic evidence adduced here and elsewhere[6,8] shows that these compounds undergo the following initial reversible reaction

$$RR'NCH_2CH_2Cl \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} RR'\overline{\overset{+}{N}CH_2C}H_2 + Cl^- \quad (1)$$

The first-order kinetics of the forward reaction can be established with relative ease because the reverse reaction is very much slower. The cyclic imonium ion is a reactive compound, but it possesses in many cases a fair degree of stability in water and can accumulate as reaction (1) proceeds.[6] The properties in solution and the reaction kinetics of the ethylenimonium ion will be considered in a subsequent report. In connection with the present discussion, it may be stated that the reaction kinetics indicates unequivocally that this ion is a singly charged cation.

Cyclization cannot occur when a proton is coordinated with the nitrogen atom of the amine. Consequently, in the case of these compounds, which are more or less weak bases, the rate of cyclization becomes a function of *p*H in solutions of moderate and low *p*H. In such cases, the observed rate constant, k'_1, is defined by the relation

$$k'_1 = \alpha k_1 = \frac{K'_a k_1}{K'_a + [H^+]}$$

where k_1 is the rate constant at *p*H conditions under which the ammonium ion is fully dissociated ($\alpha = 1$), and K'_a is the apparent dissociation constant of the ammonium ion as an acid.

It is obvious that the subsequent cyclization of a second and a third β-chloroethyl group, if present in these tertiary amines, is possible only after the antecedent heterocycle has been broken down,[9] *e. g.*, by hydrolysis. The rates of such subsequent cyclizations can best be determined by kinetic study of the corresponding chlorohydrins, as has been done in the case of N-methyl-bis-(β-chloroethyl)-amine and its chlorohydrin (see

Table I, last two compounds). Unless otherwise specified, this report deals with the first cyclization process.

Experimental

Temperatures (except at 0°) were maintained to ±0.05° in an electrically controlled, light-oil bath. Crushed melting ice surrounded the vessel of well-stirred solution in the measurements at 0°.

Materials.—The stable crystalline hydrochlorides of nine tertiary β-chloroethylamines[10] were employed. The free amines were sufficiently soluble in water for the purposes of these studies; however, the low solubilities of N-benzyl- and N-cyclohexyl-bis-(β-chloroethyl)-amines did not permit comparable evaluation of their properties. The purity and identity of the hydrochlorides is indicated by our analytical data shown in Table I. Total chlorine was determined after digestion of the samples in strong NaOH. Ionic chlorine (not recorded in Table I) was also determined and found to check the analyses reported. The melting points were accompanied by more or less sintering and decomposition.

Determination of pK'_a.—The apparent acid dissociation constant of each amine was determined by electrometric titration. The measuring system consisted of a glass electrode and a Type 7660 Leeds and Northrup potentiometer–electrometer. The electrode was standardized with 0.05 M potassium acid phthalate (primary standard, reagent grade) on the basis of the following values: pH 4.005[11] at 0° and pH 4.00[11,12] at 10° and 25°. Linearity in response of the electrode to pH-change was checked in standardized (Clark and Lubs) phosphate buffers at pH 6 and 8. In more alkaline regions, the electrode was standardized in borate buffers of known pH.

The titrations were made with standardized 2 N sodium hydroxide delivered from a calibrated microburet graduated in 0.001 ml. into 100 ml. of an aqueous 0.0025 M solution of each amine hydrochloride. The volume change was negligible, and the added Na^+ ion was too low in concentration to influence the glass electrode significantly in the alkaline region. Instability of some of the compounds made it necessary to complete their titrations within 5 to 8 min. The degree of contamination from carbon dioxide of the air during a titration was found to be 1 × 10^{-4} milliequiv./minute per 100 ml. of water at pH 9.0, and 15°. Titrations of the amines were so conducted as to hold the maximum carbon dioxide-contamination to less than 0.001 milliequiv. for the total of 0.250 milliequiv. of compound titrated. The apparent dissociation constant, in terms of pK'_a, was calculated from the titration data in the usual manner,[13] using for pK_w the values: 14.940 at 0°, and 14.340 at 15° (ionic strength 0.0025).[14] The pK'_a values thus determined are shown in Table I. The temperature coefficient, $-\Delta pK'_a/\Delta 10°$, was found to be 0.2 (range, 0.17 to 0.23 ± 0.02). Increase in ionic strength from 0.0025 to 0.15, with sodium chloride, produced the same increase (0.05) in pK'_a as that reported for the NH_4^+ ion.[14]

Rate Measurements.—In order to hold side reactions, such as polymerizations, within negligible limits, the compounds were studied at sufficiently low concentrations. The criterion for this was established by the uniformity of the first order rate constants found for the cyclization in 0.0005 to 0.1 M solutions of the type compound, N-methyl-bis-(β-chloroethyl)-amine. In general, the concentration used was 0.0025 M. The kinetics of the cyclization was determined most conveniently and accurately by the rate of production of Cl^-, and confirmed on occasion by measurement of the rate of decrease of the parent amine or of production of the cyclic imonium ion.

The stock solution of each amine hydrochloride, 0.1 to 0.5 M, was prepared by dissolving the appropriate, accurately weighed amount of carefully dried hydrochloride in iced 0.001 to 0.05 N HCl. In sufficiently acid stock solutions, cyclization with Cl^- evolution did not occur at a measurable rate. The solutions of compounds with $pK'_a > 6$ could be preserved for one to three days at 0 to 5° without detectable decomposition. The usual procedure in making a rate measurement was as follows. The aqueous medium, 99 ml., containing the calculated amount of sodium hydroxide for the predetermined pH, plus 0.0002 to 0.0004% sulfonphthalein indicator and other reagents as required, was brought to constant temperature; and then, under vigorous stirring, there was added rapidly from a chilled, calibrated, all-glass syringe, 1.00 ± 0.005 ml. of the stock solution. Zero time was taken at the half-time of delivery of the solution. The momentary, initial change in temperature was negligible. The reaction was quenched in successive samples by withdrawing usually 10 ml. and adding it with stirring to 0.01 to 0.02 N nitric or sulfuric acid. Time of quenching was taken

at the half-time of delivery of the sample. Cl^- evolved in the cyclization process was determined in the quenched samples by differential potentiometric titration with standardized silver nitrate.[15] Ethylenimonium ion was measured by its uptake of thiosulfate[6] and the residual $S_2O_3^=$ was determined iodimetrically. Residual amine was only roughly determined, after acidification of the mixture to quench the reaction, by rapid potentiometric acid–base titration at 0 to 5°.

The pH was held constant without buffers by adding micro-quantities of alkali or acid to the reaction mixture as required and using a glass electrode or the appropriate sulfonphthalein as pH indicator. The acid production was evaluated according to the experimental conditions and was assignable (a) to more or less slight hydrolysis of the initial cyclic product of the amine, (b) to H^+ from the ammonium ion of the amine when the cyclization was conducted at a pH at which $\alpha < 1$, or (c) to zero-order contamination by atmospheric carbon dioxide during prolonged runs. Under proper conditions, there was little or no pH-change during the major part of the cyclization process when the product was one of the more stable ethylenimonium ions.

A stopwatch, reading to 0.01 minute and standardized against an electric clock, was used to time the reactions.

Errors.—In the case of the more strongly basic amines, the reaction was necessarily conducted at a pH at which α was less than 1. This involved an error of ±0.02 to 0.05 in the pK'_a determination and the pH maintenance. In the case of those compounds having a pK'_a between 6.5 and 7.0, the corresponding maximum probable error in the rate constant was 2 to 3%. For the two compounds with a pK'_a higher than 7 (see Table I), the corresponding maximum probable errors were three to five times as great. The fact that duplicate determinations agreed to ±5% was probably due to a compensation of errors. Errors due to temperature variations and the preparation and analysis of the solutions were small. In most cases the over-all error was within 10%; it was somewhat greater, within 15%, for the last compound of Table I.

Results and Discussion

Rapid, successive acid–base titrations of one of these tertiary amines as the reaction progressed gave symmetrical titration curves, centered at $pH = pK'_a$, which finally merged with the titration curve of water of the same ionic strength. The disappearance of the amine during the reaction, and the absence of other titratable base in the pH range 3 to 11 are consistent with the interpretation that the transformation product is a quaternary ammonium ion.

		Av. 1.61 ± 0.16

$k_1 = 0.0161/0.715 = 0.023$ min.$^{-1}$

The initial cyclization of each of the compounds followed a uniform unimolecular course throughout the major portion of the process. By way of illustration, Tables IIa and IIb show the results of two typical determinations based on measurements of the production of chlorine ion.

Within the experimental error, the rate of Cl — evolution from the type compound, N-methyl-bis-(β-chloroethyl)-amine, was independent of the ionic strength of the solution (Table III).

TABLE III

EFFECT OF IONIC STRENGTH ON RATE OF CYCLIZATION

0.005 M $CH_3N(CH_2CH_2Cl)_2$, pH 8.0, 30.0°

$[Na_2SO_4]$ mole/liter	Total ionic strength	k_1 min.$^{-1}$

0.005	.020	.190
.050	.155	.187
.50	1.51	.199
.93	2.80	.202

Subsequent hydrolysis of the cyclic imonium ion was generally much slower, so that the second cyclization, if any, did not make a detectable appearance until the initial cyclization was well advanced. This is in accord with repeated observations that the early phase of the cyclization, when conducted under appropriate pH conditions, occurred without detectable acid production at 0° and 15°. A closer examination was made of the acid production during the initial cyclization of N-methyl-bis-(β-chloroethyl)-amine at 25°, with the aid of the glass electrode. The titration, compared with the per cent. cyclization (computed), during the first eight minutes gave the results shown in Table IV. The very small amount of acid produced and its progressive increase agree, within experimental error, with the values computed from the separately determined constants for a system of two consecutive first-order proc-

---

In the presence of $S_2O_3^{=}$, the rates of initial cyclization of the bis-(β-chloroethyl)-amines determine the rates of thiosulfate uptake by the corresponding cyclic transformation products. In such cases, the cyclization rates measured by the thiosulfate uptakes agreed well with those measured by the production of Cl^-. An example is shown in Table V which includes also the result obtained by direct titrimetric estimation of the decomposing amine.

The results of the kinetic measurements at 0 and 15° are summarized in Table I in which the compounds are listed in the order of decreasing k_1 at 15°. Inspection of this table shows that the rate constants for members of the homologous series of compounds, N-methyl- through N-*n*-butyl-bis-(β-chloroethyl)-amine, including the isopropyl homolog, fall in the order of the electron-donating abilities of these amines as measured by the respective pK_a' values.

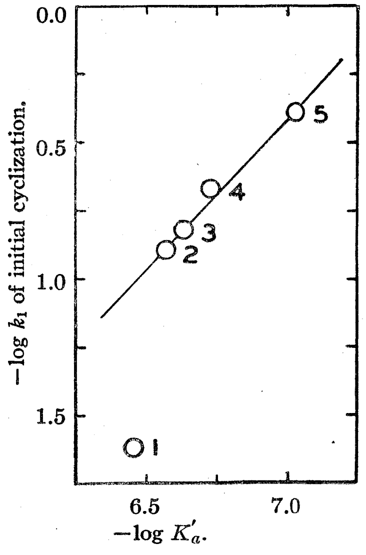

Fig. 1.—Relation of rate and dissociation constants at 15° of homologous tertiary bis-(β-chloroethyl)-amines, $RN(CH_2CH_2Cl)_2$: 1, R = methyl; 2, ethyl; 3, *n*-butyl; 4, *n*-propyl; 5, isopropyl.

TABLE V

INITIAL CYCLIZATION RATE OF $(CH_3)_2CHN(CH_2CH_2Cl)_2$

Temp. 0.0°. Initially, [amine·HCl] = 0.0025, and $[Na_2S_2O_3]$ = 0.025 mole/liter; 0.0002% phenol red; NaOH to pH 7.4; $\alpha = 0.557$.

Reaction time, min.	$S_2O_3^{=}$ uptake, %[a]	$\alpha k_1 \times 10^2$ min.$^{-1}$

By amine decomp. = .057 ± 0.007 min.$^{-1}$

[a] 100% = 1 mole $S_2O_3^{=}$ per mole of amine.

Figure 1 shows that the relation between log k_1 and log K_a' is linear for these homologous bis-(β-chloroethyl)-amines, with appreciable deviation only in the case of the N-methyl homolog. Deviation is often observed in the case of the first member of a series of alkyl homologs in numerous properties. The similar, but not strictly homologous compound N-β-methoxyethyl-bis-(β-chloroethyl)-amine does not fit into this linear relation, its cyclization rate being about ten times greater than would be predicted from its pK_a' value. The significance of this behavior has not been established. The effect might be due to the basicity of the methoxyl group or to direct interaction of this group with the β-chlorine atom. The unlikely possibility of competitive cyclization involving displacement of the methoxyl group is excluded because such competition would be expected to *retard* the apparent rate of normal cyclization as measured by production of Cl^-.

Illustrative of the importance of the properties determining the pK_a' in controlling the rate of cyclization is the following comparison in which the amines *a* to *c* are arranged in decreasing order of pK_a' and k_1. On ordinary statistical grounds,

		pK_a'	k_1
(*a*)	$(C_2H_5)_2NCH_2CH_2Cl$	8.82	0.145
(*b*)	$C_2H_5N(CH_2CH_2Cl)_2$	6.57	.128
(*c*)	$N(CH_2CH_2Cl)_3$	4.39	.073

compound *a* might be regarded as having one, *b* two, and *c* three chances for the initial cyclization to occur; yet compound *a*, despite this least favorable chance, undergoes the most rapid cyclization. In the above series of three compounds, the progressive decrease in pK_a' is due to the cumulative decrease in basicity of the central nitrogen atom induced by successive β-substitutions of chlorine.

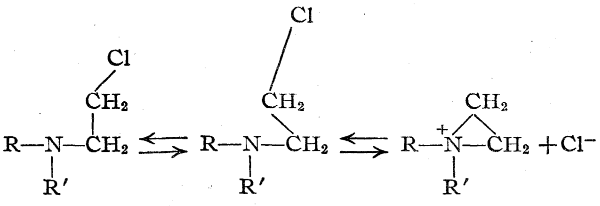
In terms of the transition state theory of chemical reaction, the linear relationship between log k_1 and log K'_a suggests that the free energy changes ($-RT$ ln k_1) associated with the equilibrium between the initial and transition states in the cyclization of the homologous bis-(β-chloroethyl)-amines is directly proportional to the free energy changes ($-RT$ ln K'_a) involved in the acid–base dissociations of the corresponding amines. Such a relation in a group of closely related reactions has been observed[16] frequently, for example in general acid–base catalysis,[17] and in the second order reactions of certain types of substituted benzene derivatives.[16] The present limited series of homologous aliphatic tertiary amines involving a unimolecular process provides a further instructive example of this correlation.

The parameters E and A of the empirical Arrhenius equation

$$k_1 = Ae^{-E/RT}$$

have been computed. The values for the activation energy, E, are given in Table I. The frequency factor, A, in the kinetics of this series of compounds is found to have values between $10^{14.9}$ to $10^{16.4}$ sec.$^{-1}$, and compares with the value of 10^{15} sec.$^{-1}$ recomputed from the data[4] for the cyclization of primary β-bromoethylamine. This level of A, associated with the displacement of the halogen for closure of the three-membered ring, is about 10^1 to 10^3 times greater than the values, 10^{13} to $10^{13.7}$ sec.$^{-1}$, reported for the closure of analogous primary amines to 4-, 5- and 6-membered rings,[4] or the values 10^{13} to 10^{14} sec.$^{-1}$ predictable from the theory of absolute reaction rates for unimolecular reactions with low entropy of activation and high transmission coefficient.[18] The higher frequency factor, which can be regarded as a measure of the greater occurrence of cyclization, is consistent with the concept of a coiled configuration of the side chain incident to formation of the incipient ring in the activated complex of the β-chloroethylamines in water.

The process of cyclization evidently consists of an intramolecular displacement of the alkyl halogen by the basic nitrogen atom of the tertiary β-chloroethylamine. In this process, the strongly polar molecule tends to coil up toward the ring position under the influence of the polar solvent, so that the general configuration of the activated complex (II) would be expected to resemble both the normal molecule (I) and the cyclic end-product (III).



(I) (II) (III)

The thermally activated complex, upon rupture of its stretched C–Cl bond, would yield a carbonium ion. The latter, however, should have but a momentary existence, because its need for sharing an electron pair is most easily satisfied by the unshared pair on the nitrogen, the positive charge moving from C to N in the newly formed ring compound. The ring closure must be much more rapid than either the possible reaction of the carbonium ion with water or the activation of the parent amine with ejection of Cl^-, because electron donor–acceptor reactions are much faster than those associated with thermally activated covalent bond dissociations, which in the present case involve the not inconsiderable strengths of the oxygen–hydrogen and carbon–chlorine bonds. Thus the carbonium ion concentration during the cyclization of these amines should be practically nil, and the experimental observations previously discussed, and illustrated in Table IV, are in harmony with this interpretation.

Summary

1. The apparent acid dissociation exponents (pK'_a) of nine tertiary β-chloroethylamines have been measured in dilute aqueous solution at 0 and 15°.

2. Studies of the initial, detectable reaction of these compounds, in dilute aqueous solution under controlled conditions of pH at temperatures between 0 and 30°, show that a chloride ion and a relatively stable cyclic imonium ion are formed by a strictly first order process. A mechanism for this reaction has been proposed. A linear correlation has been shown to exist between pK'_a and $-\log k_1$ for this process in the case of a series of homologous alkyl bis-(β-chloroethyl)-amines.

Metalation Studies in the Thiophene Series. I. Preparation of 2-Thienylsodium and the 5-Halo-2-thienylsodiums

JOHN W. SCHICK AND HOWARD D. HARTOUGH

It has been found that 2-thienylsodium can be prepared in 84% yields from 2-chlorothiophene and metallic sodium in an inert solvent above 50°. Likewise, yields up to 89% have been obtained from thiophene, sodium amalgam, and an alkyl or aryl halide. The yields were determined from the isolated 2-thiophenecarboxylic acid after carbonation and acidulation.

Schorigin[1] metalated thiophene with diethylmercury and sodium. Gilman and Breuer[2] metalated thiophene in substantially the same fashion with 2,2′-difurylmercury and sodium to obtain a 16% yield of 2-thiophenecarboxylic acid after carbonation.

Investigations in these laboratories indicated that thiophene could not be metalated directly. Further, it was found that thiophene, an alkyl or aryl halide, and sodium gave no 2-thienylsodium. This would indicate that mercury is essential to the metalation.

When 2-chlorothiophene and sodium reacted in an inert solvent above 50°, the normal metathetical reaction occurred to yield 84% of 2-thienylsodium. Table I indicates the solvents and temperatures that were employed and the products that were isolated.

TABLE I

EFFECT OF SOLVENT AND TEMPERATURE ON THE METALATION OF 2-CHLOROTHIOPHENE

Solvent	Temp., °C.	% Yield of 2-thiophene-carboxylic acid
Anisole	40	..
Anisole	50–55	3
Diphenyl ether	40	..
Butyl ether	40–50	..
Butyl ether	50–55	3
Isopropyl ether	67–70	<1
Diethyl ether	−30	..
Diethyl ether	0	16[a]
Diethyl ether	35–39	92[a]
Benzene	80–84	84
Toluene	112	31

[a] The product isolated was 5-chloro-2-thiophenecarboxylic acid.

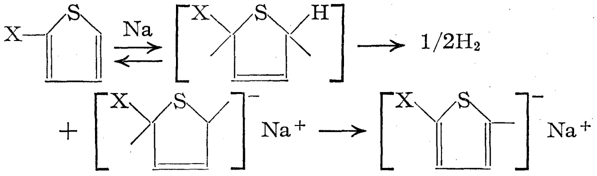
Solvent volume had a marked effect upon the yield of 2-thiophenecarboxylic acid from 2-chlorothiophene and sodium. The yields decreased from 84 to 20% when the benzene solvent volume was decreased from one liter to 100 ml. per mole of 2-chlorothiophene. A marked increase in reaction rate was noted with lower amount of solvent and cooling was necessary in order to control the reaction.

Further studies revealed that 5-halo-2-thienylsodium compounds, heretofore unknown, could be prepared by the direct metalation of the 2-halothiophenes with sodium below 50° if ethyl ether was employed as a solvent.

Direct metalation of a heterocyclic ring involving replacement of an acidic hydrogen by an alkali metal has been carried out in small yields by other investigators. Gilman and Breuer[2] metalated furan and 2-methylfuran with a liquid sodium–potassium alloy. Somewhat better yields of the organo-alkali compounds were obtained by indirect metalation, or "transmetalation," through the action of sodium on dialkyl- or diaryl-mercury in the presence of heterocyclic compounds. Wooster and Mitchell[3] and Conant and Wheland[4] arranged the very weak acids (hydrocarbons) in a series of acid strengths, based on their metathetical reaction with organo-alkali compounds.

Gilman and Wright[5] prepared 3-furylsodium by reacting 3-iodofuran with a sodium-potassium alloy. Subsequent carbonation yielded 3-furoic acid.

The 2-halo(chloro-, bromo- and iodo-)-thiophenes are unique in their reaction with sodium in that the same reaction does not occur as with 3-iodofuran. Instead, they metalate in the 5-position with the liberation of hydrogen and the formation of 2-halo-5-thienylsodium (preferable nomenclature is 5-halo-2-thienylsodium). A possible mechanism can be indicated as



Carbonation and acidulation of the 5-halo-2-thienylsodium yielded the corresponding 5-halo-2-thiophenecarboxylic acid.

Factors influencing the yield of 5-chloro-2-thienylsodium are the quantity of ether solvent, the particle size of the sodium, the presence of mercury, and the temperature.

Diethyl ether was the only solvent in which the reaction took place. No reaction was observed in butyl ether, diisopropyl ether, diphenyl ether, anisole, hexane, benzene, and toluene. Judging

(5) Gilman and Wright, *ibid.*, **55**, 2893 (1933).

from the work of Scott, Walker and Hansley[6] methyl ether, methyl ethyl ether and the dialkyl ethers of ethylene glycol would also be suitable solvents.

The yields are dependent on the amount of ether solvent used. Yields decreased from 92 to 50% on reducing the amount of solvent from one liter to 100 ml. per mole of 2-chlorothiophene. The reaction rate is increased greatly and cooling is necessary with less solvent.

Reduction of the particle size of the sodium from approximately 16 mesh to a fine dust increased the yields from 20 to 70%. In order to produce more finely divided or more active sodium, a 70% sodium amalgam was employed. In this manner the yields of 5-chloro-2-thiophenecarboxylic acid were increased from 70 to 92%. The mercury was recovered without appreciable loss.

The optimum temperature is the reflux temperature of ethyl ether, 35–39°. Below that temperature the yields decrease for comparable reaction times, and the reaction proceeds slowly below 0°.

The 5-chloro- and 5-bromo-2-thienylsodium are brown amorphous materials while 5-iodo-2-thienylsodium has a blue cast. They are only slightly soluble in ether. They are stable in an inert atmosphere, but when free of solvent and exposed to air they are oxidized rapidly with evolution of light and heat, similarly to Raney nickel.

Lithium did not appear to react in ethyl ether solvent and potassium yielded scission products.

Most of the work was carried out with 2-chlorothiophene. Since only single runs were made with 2-bromothiophene and 2-iodothiophene to study the versatility of the reaction, the yields of 35 and 33%, respectively, need not be considered the highest obtainable.

Experimental

Preparation of Sodium Shot.—The sodium shot was prepared from molten sodium in toluene by vigorous stirring while cooling until there was no chance of coagulation. The excess toluene was decanted through a glass-wool plug in the side arm of the flask and the sodium shot was blanketed with the solvent to be used in the next step. Sodium amalgam was prepared in a similar manner.

Transmetalation of Thiophene with Ethyl Chloride and Sodium Amalgam Sand.—A cold mixture of 16 g. (0.25 mole) of ethyl chloride in 200 ml. of anhydrous diethyl ether was added dropwise over a one hour period to a cooled (5–10°), vigorously stirred mixture of 49 g. (0.58 mole) of thiophene, 100 ml. of anhydrous diethyl ether and freshly prepared sodium amalgam sand containing 15 g. (0.65 gram atom) of sodium and 25 g. (0.125 gram atom) of mercury. The reaction was carried out in the usual Grignard type apparatus under a nitrogen atmosphere. After the addition was completed, the ice-bath was removed and the reaction mixture was refluxed for two and one-half hours. After cooling to 25°, it was carbonated with freshly crushed Dry Ice. The temperature rose momentarily, but it was kept below 30°. The unreacted sodium was destroyed with 50 ml. of ethanol after which 150 ml. of distilled water was added cautiously. Acidulation of the aqueous layer with 75 ml. of concentrated hydrochloric acid yielded 19 g. (60%) of crude 2-thiophenecarboxylic acid. White needles were obtained from hot water, m. p. 128–129°. The neutral equivalent was 124 (calculated, 128). A mixed melting point with an authentic sample of 2-thiophenecarboxylic acid[7] gave no depression.

Transmetalation of Thiophene with Bromobenzene and Sodium Amalgam Sand.—A cold mixture of 78 g. (0.5 mole) of bromobenzene in 300 ml. of anhydrous diethyl ether was added dropwise over a one-hour period to a cooled mixture (5–10°) of 200 ml. of anhydrous diethyl ether, 63 g. (0.75 mole) of thiophene and sodium amalgam sand containing 25 g. (1.09 gram atoms) of sodium and 10 g. (0.05 gram atom) of mercury. After the addition was completed, the mixture was stirred an additional half an hour before removing the ice-bath. When the mixture was warmed slightly, the temperature rose rapidly and an ice-bath was required to control the reaction. After subsiding, it was warmed to reflux for two hours after which it was cooled to 5° and carbonated with freshly crushed dry ice. The unreacted sodium was destroyed with 50 ml. of ethanol and 150 ml. of distilled water was added cautiously. The acidulation of the aqueous layer with 70 ml. of concentrated hydrochloric acid yielded 57 g. (89%) of crude 2-thiophenecarboxylic acid.

Metalation of 2-Chlorothiophene with Sodium.—A mixture of 118 g. (1 mole) of 2-chlorothiophene was added directly to 1000 ml. of benzene and sodium amalgam sand containing 50 g. (2.17 gram atoms) of sodium and 29 g. (0.145 gram atom) of mercury. The mixture was warmed at 80–82° for four hours. The reaction was cooled to 5–10° and carbonated with freshly crushed Dry Ice. The excess sodium was destroyed with 20 ml. of ethanol after which 400 ml. of distilled water was added cautiously. The aqueous solution was filtered and acidulated with 225 ml. of concentrated hydrochloric acid, yielding 108 g. (84%) of crude 2-thiophenecarboxylic acid.

The same procedure was followed when solvents other than benzene were used.

Preparation of 5-Chloro-2-thienylsodium and 5-Chloro-2-thiophenecarboxylic Acid. a. 2-Chlorothiophene and Sodium.—A solution of 118 g. (1.0 mole) of 2-chlorothiophene in 700 ml. of anhydrous diethyl ether was added dropwise with stirring (in an atmosphere of nitrogen) over a period of four hours to a suspension of 35 g. (1.5 gram atoms) of freshly prepared sodium shot in 300 ml. of refluxing anhydrous diethyl ether in the usual Grignard reaction apparatus. The surfaces of the sodium shot darkened immediately and in a short time the ether solution acquired a gray cast. After the addition was complete, the reaction mixture was refluxed for an additional two hours. It was then cooled in an ice-bath to 25° and carbonated by adding freshly crushed Dry Ice. The temperature rose momentarily, but was never permitted to rise above 30°. The temperature fell rapidly when the carbonation was complete. One hundred milliliters of ethanol was added dropwise to destroy the unreacted sodium after which 350 ml. of distilled water was added cautiously. The aqueous solution was separated and acidulated with 230 ml. of concentrated hydrochloric acid. The precipitated 5-chloro-2-thiophenecarboxylic acid weighed 115 g. (70%). White needles were obtained from hot water—m. p. 153–153.5°.[8,9] The observed neutral equivalent was 163 (calcd. 162.5). A mixed melting point with an authentic sample of 5-chloro-2-thiophenecarboxylic acid[7] gave no depression.

b. 2-Chlorothiophene and Sodium Amalgam Sand.—A solution of 118 g. (1.0 mole) of 2-chlorothiophene in 700

---

[6] Scott, Walker and Hansley, THIS JOURNAL, **58**, 2442 (1936).

[7] Prepared by the method of Hartough and Conley, THIS JOURNAL, **69**, 3096 (1947).

[8] Gattermann and Romer, *Ber.*, **19**, 690 (1886), lists the melting points of 5-chloro-, 5-bromo- and 5-iodo-2-thiophenecarboxylic acid as 140, 139.5 and 131°, respectively.

[9] Steinkopf, Jacob and Penz, *Ann.*, **512**, 161 (1934), gave m. p. of 146–147° for 5-chloro-2-thiophenecarboxylic acid and 141–142° for 5-bromo-2-thiophenecarboxylic acid.

ml. of anhydrous diethyl ether was added dropwise with stirring (in an atmosphere of nitrogen) over a period of two hours to a suspension of sodium amalgam sand containing 35 g. (1.5 gram atoms) of sodium and 25 g. (0.125 gram atom) of mercury dispersed in 300 ml. of refluxing anhydrous diethyl ether. The same procedure was followed as described in "a." Acidulation of the aqueous layer with 174 ml. of concentrated hydrochloric acid yielded 150 g. (92%) of 5-chloro-2-thiophenecarboxylic acid.

Preparation of 5-Bromo-2-thienylsodium and 5-Bromo-2-thiophenecarboxylic Acid from Sodium and 2-Bromothiophene.—Following the procedure described in "a" above, 41 g. (0.25 mole) of 2-bromothiophene was reacted with 13.5 g. (0.59 gram atom) of sodium and the mixture worked up as before: eighteen grams (35%, of a red oil separated which crystallized on cooling. White needles of 5-bromo-2-thiophenecarboxylic acid were obtained by sublimation, m. p. 140.5–141.5°.[8,9] The observed neutral equivalent was 202 (calcd. 207). A mixed melting point with an authentic sample (m. p. 141–141.5°) of 5-bromo-2-thiophenecarboxylic acid[7] gave no depression.

Preparation of 5-Iodo-2-thienylsodium and the Corresponding 5-Iodo-2-thiophenecarboxylic Acid from Sodium and 2-Iodothiophene.—Following the procedure described in "a" above, 55 g. (0.25 mole) of 2-iodothiophene was treated with 9 g. (0.38 gram atom) of sodium and worked up as before. Twenty-one grams (33%) of a red oil separated from solution which crystallized on cooling. White needles of 5-iodo-2-thiophenecarboxylic acid were obtained by sublimation, m. p. 132.5–133.5°.[8,10] The observed neutral equivalent was 250 (calcd. 253).

Acknowledgment.—The authors wish to thank Dr. D. E. Badertscher for his advice and interest and Mrs. Josephine S. Piel for her assistance in the experimental work.

Summary

2-Thienylsodium has been prepared in yields of 60–89% from an alkyl or aryl halide, sodium amalgam, and thiophene, and in yields of 84% from 2-chlorothiophene and sodium amalgam.

2-Chloro-, 2-bromo- and 2-iodothiophenes have been metalated with sodium without replacement of the halo- atom, and the 5-halo-2-thienyl sodium compounds so formed were carbonated to give 2-chloro-, 5-bromo- and 5-iodo-2-thiophenecarboxylic acids in yields of 70, 35 and 33%, respectively. With 70% sodium amalgam, instead of sodium, the yield of 5-chloro-2-thiophenecarboxylic acid was 92%. Diethyl ether was the only solvent which gave satisfactory results. A decrease in solvent volume resulted in lower yields, but increases in the rate of reaction were noted. The reaction proceeded satisfactorily at 30–40°, but above 50° normal replacement of the halogen atom by sodium occurred.

RECEIVED JUNE 12, 1947

---

[10] Rinkes, *Rec. trav. chim.*, **53** [4], 640 (1934), lists m. p. of 133–134° for 5-iodo-2-thiophenecarboxylic acid.

Aromatization Studies. VI. Aminobiphenyls and Naphthylamines

BY E. C. HORNING, M. G. HORNING AND E. JANE PLATT[1]

The preparation of alkyl anilines from alkylcyclohexenones, by aromatization of the corresponding azines, was described in a previous paper.[2] This method provides a way of obtaining amines with alkyl substituents whose character or position are such that the compound would be difficult or impossible to obtain by ordinary aromatic substitution routes. Further investigation of this method has now shown that it can be applied also to the preparation of aminobiphenyls and naphthylamines; it appears therefore to be generally applicable in the aromatic series.

The aminobiphenyls obtained were 3-amino-5-methyl-4′-methoxy-biphenyl, 3-amino-5-methyl-2′,3′-dimethoxybiphenyl and 3-amino-5-methyl-3′,4′-dimethoxybiphenyl. The azines were prepared from the corresponding arylcyclohexenones,[3] and the aromatization was carried out in triethylbenzene with a 5% palladium–carbon catalyst. The amines were isolated in the form of their acetyl derivatives. The yields were uniformly in the vicinity of 50%, as in the case of alkylanilines,[2] but we have as yet no information on the fate of the rest of the material or on the mechanism of the reaction.

The tetralones which were converted to the corresponding aminonaphthalenes were tetralone-1, 7-methyltetralone-1 and 7-ethyltetralone-1. 7-Substituted tetralones may be obtained readily by the usual succinoylation method from benzene derivatives, and this route offers a means of obtaining many 7-substituted 1-naphthylamines. The yields here were lower (about 20%), although this appeared to be due more to difficulties in isolation of pure acetyl derivatives than to the aromatization itself.

The aromatization of these azines in a boiling solvent at a moderate temperature (214°) with a reflux period of only thirty minutes indicates the high degree of effectiveness of Hartung's palladium–carbon catalyst[4] in aromatization reactions.

Acknowledgment.—We are indebted to the Research Corporation for a grant in support of this work.

[a] Recrystallized from cyclohexane–ethyl acetate. [b] Recrystallized from benzene–ethyl acetate.

Preparation of Azines. 3-Methyl-5-(*p*-methoxyphenyl)-2-cyclohexen-1-one Azine.—A mixture of 10.8 g. of 3-methyl-5-(*p*-methoxyphenyl)-2-cyclohexen-1-one, 1.9 g. of 85% hydrazine hydrate and 1 drop of concentrated hydrochloric acid, in 30 ml. of ethanol, was maintained under reflux for one hour. The product crystallized from solution during the reflux period; the yield was 6.3 g. (58%) of yellow azine, m. p. 186–189°. Recrystallization from methanol gave a sample melting at 190.5–191.5°, with shrinking.

The yields, properties, and analyses of the azines prepared are described in Table I. The general method of preparation was modified in each case as described in the footnotes.

Aromatization of Azines.—The aromatization reaction was carried out in the same fashion for all azines, but the method of isolation of the resulting aromatic amines varied. In cases where the hydrochlorides of the amines were water-insoluble, it was not possible to use the previously described method.[2] A typical aromatization is described.

A mixture of 5.0 g. of 3-methyl-5-(*p*-methoxyphenyl)-2-cyclohexen-1-one azine, 1.5 g. of 5% palladium–carbon catalyst,[4] and 15 ml. of triethylbenzene was heated under reflux for thirty minutes. After cooling, the catalyst was removed by filtration, and washed with 15 ml. of warm benzene.

In this case, the solution was added to 200 ml. of water containing 15 ml. of concentrated hydrochloric acid and steam-distilled. The aqueous solution was chilled and filtered to remove 3.5 g. of crystalline hydrochloride, m. p. 230–232° (dec.). The hydrochloride was treated with 50 ml. of 5% sodium hydroxide solution and 50 ml. of ether. The alkaline solution was extracted with ether, and the combined ether solutions washed and dried. After evaporation, the residue was acetylated by adding 15 ml. of pyridine and 10 ml. of acetic anhydride. This mixture, after standing overnight, was poured into 100 ml. of ice water and the crystalline material removed by filtration. The yield and properties of the product are in Table II.

In the case of the other two aminobiphenyls, the isolation procedure followed that described previously.[2]

The alkylnaphthylamines could not be extracted satisfactorily from ether with aqueous acid. In consequence, the benzene–triethylbenzene solution was treated immediately with 25 ml. of pyridine and 15 ml. of acetic anhydride. After standing overnight, the solution was poured into water and steam-distilled. On cooling, the product separated in part as a colorless, crystalline precipitate, and in part as a gummy, dark mass. The gum was removed mechanically, and the crystalline material collected separately. It was found in each case that the crystalline material was of a high state of purity, and that a smaller amount of additional considerably less pure material could be obtained by treatment of the gum with appropriate solvents. The yields given in Table II represent only the yield of pure material obtained directly.

Summary

The aromatization of several 3-methyl-5-aryl-2-cyclohexen-1-one and tetralone-1 azines to the corresponding 3-amino-5-methylbiphenyls and 1-aminonaphthalenes, using a palladium–carbon catalyst in boiling triethylbenzene, is described. This method has been applied previously to the synthesis of alkyl anilines; it is apparently general for the aromatic series.

Chromatography of Cuban Blackstrap Molasses on Clay; Some Constituents of an Odor and Pigment Fraction[1]

BY W. W. BINKLEY[2] AND M. L. WOLFROM

In continuation of our work[3-5] on the chromatographic isolation of constituents of cane juice and cane blackstrap molasses, we have isolated from the latter a fraction which is only weakly held by the adsorbents employed. Concentrated in this fraction are the odoriferous constituents to which the molasses, and the rums derived therefrom, owe in the main their characteristic taste and odor. The concentration of such a fraction had been noted previously.[5] Further amounts have now been prepared and subjected to some detailed study. The fraction least adsorbed on a fuller's earth type of clay was isolated from 1 kg. of a typical Cuban cane blackstrap molasses by ethanol–acetone elution in the presence of some water. The aqueous solution obtained after organic solvent removal was extracted with petroleum ether and the extract on solvent removal yielded a viscous, green liquid with a strong odor of cane molasses. The yield was 0.4% of the original molasses. The odor of this material was highly volatile and disappeared completely on standing in the laboratory for several weeks. It could be trapped by condensation at low temperatures. The condensate (Fraction A) reacted with 2,4-dinitrophenylhydrazine. It is under further investigation.

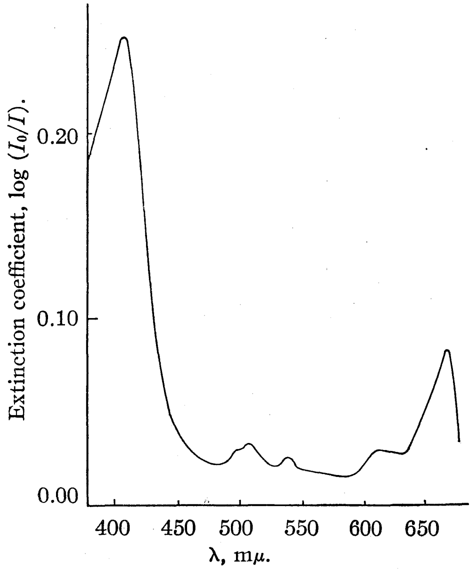

Fig. 1.—Absorption spectrum of green coloring matter (in ether) from Cuban Blackstrap molasses: Beckman spectrophotometer (Model DU); 1.00-cm. cell; measured by Mr. Bernard Wildi of this Laboratory.

The fraction (Fraction B) residual after Fraction A removal was further chromatographed on Silene-EF[6] and was divided into six fractions (Table I). The green color of this hydrocarbon-soluble mixture was identified as chlorophyll *a* by its absorption spectrum (Fig. 1). This spectrum shows that the substance is nearly pure chlorophyll *a* containing no more than a few per cent. of what is probably chlorophyll *b* as indicated by the slight absorption in the region 560–570 mμ. The presence of such unaltered chlorophyll *a* in blackstrap molasses seems remarkable.

TABLE I

EFFLUENT FRACTIONS FROM THE CHROMATOGRAM FROM 2.0 g. OF FRACTION B FROM CANE BLACKSTRAP MOLASSES[a]

Fraction	Eluate volume, ml.	Color	Yield, mg.	Substances present
1	250	Golden	511	Fats, "melissyl" alcohol, sterols
2	100	Colorless	39	"Melissyl" alcohol, trace of sterols
3	250	Green	146	Sterols, chlorophyll[a]
4	250	Green	149	Sterols, chlorophyll[a]
5	150	Light green	8	Chlorophyll[a]
6[b]			882	
		Total	1735 (86.7%)	

[a] See experimental portion for details. [b] By acetone extraction of column.

From the various Silene fractions there was isolated "melissyl" (synonym "myricyl") alcohol, a sterol fraction and a fat fraction. "Melissyl" alcohol was found free in the molasses, which had however been subjected to some alkaline treatment in its manufacture. Melissyl alcohol has been reported as a major component of the cane wax[7-9] isolable from the clarification muds formed in the manufacture of raw sugar. The melting point of natural "melissyl" alcohol will vary with the source. Its formula is generally considered to be $CH_3(CH_2)_{28}CH_2OH$ but actually it is very probably a mixture of close homologs, as has been

demonstrated by Koonce and Brown[10] for the "melissyl" alcohol fraction of carnauba wax.

The sterol fraction ((m. p. 142–143°, cor.), $[\alpha]^{26}\mathrm{D}$ $-38°$ in chloroform) isolated was a typical phytosterol such as has been reported in studies on crude cane wax.[9] It is undoubtedly a mixture of the sitosterol type but was obtained in this work in too small amount to allow of further fractionation.

Saponification of the main fat fraction yielded further quantities of "melissyl" alcohol, glycerol (identification by a color test) and an unsaturated acid that on catalytic hydrogenation yielded stearic acid and on hydroxylation yielded a tetrahydroxystearic acid which was shown by its melting point (156°, cor.) and analysis to be essentially α-sativic acid.[11] The parent unsaturated acid is thus in all probability linoleic acid. It is of interest to note that this acid is the major acid present in cane wax.[9]

Finally, we wish to call attention to the demonstration that the chromatographic techniques established for separation of carbohydrate mixtures are also applicable to the separation of non-carbohydrate systems.

Experimental

Chromatographic Isolation of an Odor and Pigment Fraction.—The Cuban cane blackstrap molasses employed in this work was the same sample described previously.[3,5] One kilogram of this molasses was diluted with 250 ml. of water and made into a smooth paste by the addition of 400 g. of clay.[12] This paste was added with good agitation to a mixture of 3.6 liters of absolute ethanol and 2.4 liters of acetone; the agitation was continued for one hour after the addition of the paste. The supernatant liquor was removed with the aid of a siphon. The precipitate was transferred to a percolator and washed with 3 liters of acetone. The supernatant liquor and the percolator effluent were combined and concentrated to a volume of approximately 1 liter under reduced pressure at a bath temperature of 50°. This concentrate was poured into a 2-liter liquid-liquid extractor,[13] diluted with 1 liter of water and extracted for twenty-four hours with petroleum ether (b. p. 30–60°). A turbid, green extract was obtained. Removal of solvent under reduced pressure yielded a viscous, green liquid with a strong odor of cane blackstrap molasses; yield 4.1 g. (0.41% of the original molasses).

Separation of the Molasses Odor Fraction (Fraction A).—The concentrate (4.1 g.) was heated for two hours at 100–110° under a pressure of 0.03 mm. and the distillate (Fraction A) that formed was collected in traps surrounded with a mixture of solid carbon dioxide and acetone. The traps were washed with ethanol (95%). The collected washings had a strong odor of molasses and gave a precipitate with 2,4-dinitrophenylhydrazine reagent. The undistilled concentrate (Fraction B, 4.0 g.) had a fatty odor. The nature of Fraction A is under further investigation. It is highly volatile.

Chromatography of the Residual Fraction (Fraction B).—An amount of 2.0 g. of the residual concentrate dissolved in 40 ml. of benzene, was added at the top of a 150 × 80 mm. (diam.) column[14] of a mixture (150 g.) of 5 parts (by wt.) of "Silene-EF"[15] and 1 part of "Celite."[16] The chromatogram was developed with 1250 ml. of 500/1 benzene[17]/ethanol[18] (volume ratio). The effluent was collected in five fractions and pertinent data relative to these fractions are listed in Table I. The column was extruded and extracted for twenty-four hours with acetone in a Soxhlet extractor. The substances eluted from the adsorbent (Fraction B-6) were waxy solids with a strong fatty acid odor. They were completely soluble in 0.1 *N* sodium hydroxide.

Anal. Saponification equiv., 694 (1.44 ml. of 0.1 *N* sodium hydroxide per 100 mg.).

Isolation of "Melissyl" Alcohol, a Sterol Fraction and a C_{18} Unsaturated Fatty Acid Fraction from Fraction B-1.—Fraction B-1 (Table I) was a viscous, light amber liquid with a fatty odor.

Anal. Unsaponifiable matter, 65%; saponification equiv., 741 (1.35 ml. of 0.1 *N* sodium hydroxide per 100 mg.); free fatty acid, absent; iodine no., 96 (7.57 ml. of 0.1 *N* I_2 per 100 mg.).

An amount of 426 mg. of Fraction B-1, 5 ml. of ethanol (95%) and 0.5 ml. of aqueous 50% potassium hydroxide were heated under reflux for two hours on a steam-bath. The reaction mixture was cooled to room temperature and extracted with ether. The ether-soluble fraction (Fraction B-1-a) was washed with water until free of alkali; yield 267 mg.

An amount of 242 mg. of Fraction B-1-a, dissolved in 5 ml. of benzene was added at the top of a 175 × 35 mm. (diam.) column of a mixture (45 g.) of 5 parts (by wt.) of "Silene-EF" and 1 part of "Celite." The chromatogram was developed with 90 ml. of 500/1 benzene/ethanol. The column was extruded and two well-defined zones, a narrow upper zone 70 to 75 mm. from the top of the column and a wide zone at the bottom of the column, were detected with the aid of ultraviolet light. The zones were isolated and eluted with acetone. Zone yields for the upper and lower zones were 124 and 110 mg., respectively after solvent removal. The material from the upper zone crystallized from ethanol (95%) as needles; yield 40 mg., m. p. 139–141° (cor.); Liebermann–Burchard sterol test[19] positive. Plates were obtained from a benzene solution of the lower zone; yield 30 mg., m. p. 83–84° (cor.). These crystalline substances were identical with those of a similar nature (phytosterol fraction and "melissyl" alcohol, respectively) described and further characterized below.

The potassium hydroxide solution (Fraction B-1-b), containing fatty acids and glycerol, from the saponification of Fraction B-1 was acidified with hydrochloric acid and extracted with three 25-ml. portions of chloroform. The water layer was set aside for glycerol recovery (see below). The residue, 137 mg., from the chloroform extracts was a soft paste with a fatty odor. This paste reacted with alkaline permanganate and bromine in carbon tetrachloride; its ethanolic solution was acid to litmus; its lead salt was soluble in ether.

Anal. Neutral equiv., 302 or 3.31 ml. of 0.1 *N* sodium hydroxide per 100 mg., iodine no., 118 or 9.28 ml. of 0.1 *N* I_2 per 100 mg.

Following the general procedure of Brown and coworkers[20] for the separation of unsaturated from saturated fatty acids by low temperature crystallization, an amount of 150 mg. of the above fatty acid fraction was dissolved

in 1 ml. of acetone and cooled to −50 to −60° by a bath of solid carbon dioxide and trichloroethylene. The frozen mass was allowed to thaw slowly until an amorphous solid separated. This solid was collected rapidly on a filter and washed with 0.5 ml. of cold acetone; yield 30 mg. An ethanolic solution of this solid yielded a noncrystalline, highly solvated, amorphous solid. A viscous liquid (Fraction F) was obtained from the filtrate of the above precipitation after removal of the acetone; yield 120 mg. This liquid (120 mg.) was dissolved in 10 ml. of absolute ethanol and hydrogenated in the presence of 50 mg. of platinic oxide. After six alternate evacuations and additions of hydrogen (to 1 atm. pressure), the reaction mixture was warmed to 50° and shaken for several hours. The catalyst was removed by filtration. The filtrate was allowed to reflux for two hours with 150 mg. of potassium hydroxide to saponify any ethyl esters formed during the hydrogenation. This solution was diluted with 50 ml. of water and acidified with hydrochloric acid. The precipitated fatty acid was collected on a filter; yield 116 mg. An ethanolic (95%) solution of the precipitate gave crystals; m. p. 68–68.5°. Recrystallization from absolute ethanol gave plates, m. p. 69–69.5° (cor.) undepressed on admixture with an authentic specimen of stearic acid (m. p. 70–71°, cor.).

In another experiment, an amount of 100 mg. of the above unsaturated fatty acid fraction (Fraction F) was dissolved in 30 ml. of 0.03 *N* potassium hydroxide and to the cooled (5°) solution was added dropwise under good agitation a solution of 20 mg. of potassium permanganate in 5 ml. of water. Five minutes after the completion of the addition, the reaction mixture was decolorized with sulfur dioxide. A white, flocculent precipitate formed which was crystallized from ethanol; yield 30 mg. (0.008% original molasses), m. p. 156° (cor.).

Anal. Calcd. for $C_{17}H_{31}(OH)_4CO_2H$: C, 62.04; H, 10.42. Found: C, 61.96; H, 10.28.

The aqueous layer from the fatty acid isolation was adjusted to *p*H 7–8, evaporated to dryness on a steam-bath and extracted with ethyl acetate. A few droplets of a viscous liquid was obtained after solvent removal and this residue gave a positive pyrogallol–sulfuric acid test for glycerol.[21]

Isolation of "Melissyl" Alcohol from Fraction B-2.—This fraction was crystalline. Plates were obtained on recrystallization from benzene; yield 20 mg. (total yield of "melissyl" alcohol, 0.01% original molasses), m. p. 83–84° (cor.) undepressed on admixture with a specimen of "melissyl" alcohol (m. p. 87–87.5°, cor.) separated from carnauba wax by fractional crystallization. The mother liquor showed a positive Liebermann–Burchard[19] sterol test.

Anal. Calcd. for $C_{30}H_{62}O$: C, 82.11; H, 14.24. Found: C, 81.74; H, 14.18.

Conversion to the acetate with sodium acetate and acetic anhydride gave crystals; m. p. 66–67° (cor.).

Characterization and Further Isolation of the Phytosterol Fraction and Identification of Chlorophyll *a*.—Fractions B-3 and B-4 were crystalline. When an ethanolic solution of these fractions was allowed to evaporate at room temperature, nearly colorless, elongated plates formed near and on the bottom of the container. The green color and some crystals collected higher up on the walls of the container. Careful washing with cold ether removed nearly all of the green color. The washings were used for the determination of absorption spectra (see below). A total of 250 mg. of crystals was obtained from Fractions B-3 and B-4. These were combined and yielded colorless crystals from ethanol (95%); m. p. 142–143° (cor.), $[\alpha]^{26}\mathrm{D}$ −38° (*c* 4.9, 2-dm. tube, chloroform), Liebermann–Burchard sterol test[19] positive. A benzene solution of these crystals fluoresced in ultraviolet light.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.88; H, 11.99. Found: C, 83.64; H, 11.90.

The material of Fraction B-5 was amorphous. The green colored substance from Fractions B-3, B-4 and B-5 was combined and its absorption spectrum in ether solution is shown in Fig. 1. The spectrum is that of chlorophyll *a* with a probable slight admixture of chlorophyll *b* or pheophytin *a*; yield 0.00004% original molasses (calcd. from absorption spectrum).

Acknowledgment.—The laboratory assistance of Mr. John Kolbas is acknowledged. We are pleased to acknowledge also the assistance of Professor Paul Rothemund of this department and the Kettering Foundation, Yellow Springs, Ohio, in interpreting the absorption spectrum data.

Summary

By chromatographic methods the following trace constituents were isolated from a sample of Cuban cane blackstrap molasses: "melissyl" alcohol, chlorophyll *a* (identification by absorption spectrum), a phytosterol fraction (m. p. 142–143°, $[\alpha]^{26}\mathrm{D}$ −38° in chloroform) and a fat fraction in which the presence of glycerol and linoleic acid was indicated. The highly volatile odor fraction was concentrated and shown probably to consist in part of carbonyl compounds.

Esters of Lima Bean Pod and Corn Cob Hemicelluloses

BY J. F. CARSON AND W. DAYTON MACLAY

This paper describes the preparation of the acetate, propionate and butyrate of lima bean pod hemicellulose and the acetate, propionate, butyrate, caprate, laurate, myristate, palmitate and benzoate of corn cob hemicellulose. It also reports studies on the fractionation of some of these esters by extraction with organic solvents.

Husemann[2] obtained molecular weights of xylans from wheat straw and beechwood by osmotic and viscometric measurements of the corresponding methyl ethers, mixed methyl ether acetates, and benzyl ether acetates. His results indicated that undegraded xylans from wheat straw and beechwood were homogeneous, with chain lengths of approximately 150 repeating anhydroxylose units. Both Husemann[2] and Heuser and Schlosser[3] reported that xylan diacetates were poorly soluble in organic solvents, hence the application of the more soluble mixed ether acetates. Recently Millatt and Stamm[4] have prepared acetates of aspen hemicellulose from which molecular weights were determined.

Numerous investigators[5] have studied the xylan–glucuronide type of hemicellulose by fractional precipitation from alkaline solutions and by copper precipitation. In most cases, convincing evidence of the homogeneity of the various fractions was lacking. Many of the fractions contained varying amounts of hexosan either chemically combined in the xylan chain or simply as mixtures. O'Dwyer[6] and Anderson and co-workers[7] have presented evidence that some hemicellulose fractions, particularly from the sapwood of English oak, lemon wood, and black locust sapwood contain anhydroglucose units chemically united to anhydroxylose units. These fractions were observed to give violet to blue colors with iodine. Digestion with taka-diastase or saliva produced polysaccharides free of hexose no longer giving the color with iodine, but the enzymatic hydrolysis required a considerably longer time than expected for a physical mixture of xylan and starch.

The hemicelluloses used for esterification were obtained by alkaline extraction of corn cob and lima bean pod holocellulose. The holocellulose was extracted successively with boiling water, 2% sodium carbonate, and 5 and 24% potassium hydroxide solutions. The yields and composition of the two fractions of corn cob and lima bean pod hemicelluloses obtained by extraction with potassium hydroxide are recorded in Table I.

TABLE I

HEMICELLULOSE FRACTIONS

Holocellulose	Concn. of potassium hydroxide	Yield[a]	$[\alpha]^{25}D$ (2% KOH)	Xylan,[b] %	Uronic anhydride[c]	Methoxyl[d]
Corncob	5	22	−98.2	89.3	6.2	0.7
Corncob	24	8	−91.1	83.4	4.5	.7
Lima bean pod	5	17	−44.7	74.8	7.9	1.4
	24	8	−58.9	71.8	4.7	0.7

[a] Yields are based on dry weight of the hollocellulose. [b] Xylan was determined by furfural distillation and precipitation as the phloroglucide and was corrected for the furfural equivalent of the uronic anhydride. [c] Uronic anhydride analyses were performed by the procedures of Lefevre and Tollens, as modified by McCready, Swenson and Maclay (*Ind. Eng. Chem., Anal. Ed.*, **18**, 290 (1946)). [d] Methoxyl was determined by Clark's modification of the Vieböch–Schwappach method (*J. Assoc. Off. Agr. Chem.*, **22**, 100, 622 (1939)). The samples contained no adsorbed alcohol, as was demonstrated by humidification in a desiccator over water.

The esters, except the benzoate, were prepared by reaction with pyridine and acid anhydride or acid chloride under relatively mild conditions. Benzoylation was performed by reaction with benzoyl

TABLE II

HEMICELLULOSE ESTERS

Source of xylan	Ester	Acyl, % Calcd.[a]	Acyl, % Found[b]
Lima bean pod	Acetate	38.8	39.3
Lime bean pod	Propionate	45.1	45.8
Lima bean pod	Butyrate	50.9	51.0
Corncob	Acetate	39.0	39.5
Corncob	Propionate	45.2	45.5
Corncob	Butyrate	51.3	50.8
Corncob	Caprate	70.0	69.9
Corncob	Laurate	73.0	70.0
Corncob	Myristate	75.7	72.2
Corncob	Palmitate	77.9	76.4
Corncob	Benzoate	60.9	57.5

[a] The theoretical per cent. acyl was calculated from the composition of the original hemicellulose. The original hemicelluloses were analyzed for xylan, methoxyl and uronic anhydride, and the residual unaccounted-for material was assumed to be hexosan. The calculated values include the contribution of each of these, assuming no loss on esterification. [b] % acyl was measured by alkaline saponification of the esters by the procedure of Genung and Mallatt (*Ind. Eng. Chem., Anal. Ed.*, **13**, 369 (1941)). The caprate, laurate, myristate, palmitate and benzoate were also analyzed by saponification, followed by acidification, extraction of the free organic acid and titration.

TABLE III

FRACTIONATION OF LIMA BEAN POD HEMICELLULOSE ESTERS

Ester	Fractionation Solvent	Insoluble %	Composition of hemicellulose regenerated from insoluble fraction, % Xylan	Uronic anhydride	Methoxyl	$[\alpha]^{25}D$ (2% KOH)
Acetate	Chloroform-acetone (1:1) 100 parts	92	76	8.1	1.3	....
Propionate	Chloroform-acetone (1:1) 100 parts	90	77	8.0	1.2	....
Butyrate	Chloroform-acetone (1:1) 100 parts	85	75	9.1		....
Butyrate[a]	Dioxane, 100 parts	88	77	6.4		−45.1
Acetate	Pyridine, 50 parts	86	77	8.0	1.2	−44.9
Propionate	Pyridine, 50 parts	82	75	5.4	1.4	−44.4
			Composition[b] of original hemicellulose (5% KOH extraction)			
			75	7.9	1.4	−44.7

[a] A second fractionation of the dioxane-insoluble butyrate under the same conditions yielded an insoluble portion amounting to 90%. Analysis of the regenerated polysaccharide indicated no change in composition. [b] Determination of L-arabinose by the diphenylhydrazine method of Wise and Peterson (*Ind. Eng. Chem.*, **22**, 362 (1930)) showed arabinose to be absent. Tests for mannose (phenylhydrazine) and for galactose (mucic acid) were negative.

chloride and aqueous sodium hydroxide. The esters and their analyses are recorded in Table II.

All of the esters had very low solubilities in organic solvents such as chloroform, dioxane, acetone, nitrobenzene and *m*-cresol. For example, only 25% of the dipropionate and 30% of the dibutyrate of corn cob hemicellulose were soluble in two hundred parts of dioxane, and only 8, 10 and 15% of lima bean pod hemicellulose diacetate, dipropionate and dibutyrate, respectively, were soluble in one hundred parts of chloroform–acetone (1:1). Since hexosan triesters, if not of too high molecular weight, are usually more soluble in organic solvents than are the xylan esters, it was thought that extraction of the esters with organic solvents and regeneration of the polysaccharide from the insoluble ester fraction would enrich the xylan content, if the non-pentosan components were merely present in a mixture. Lima bean pod diacetate, dipropionate, and dibutyrate were fractionated with a 1:1 chloroform–acetone mixture; the dibutyrate was also fractionated with dioxane, and the diacetate and dipropionate were fractionated with pyridine. In each case, the insoluble fraction was saponified and the regenerated polysaccharide analyzed for xylan and uronic anhydride. These results are compiled in Table III for comparison with the original hemicellulose.

The analyses in Table III show that, although in two cases the uronic anhydride content was decreased by treatment with organic solvents, the xylan content was increased only slightly and remained practically constant. The material unaccounted-for as xylan, uronic anhydride, and methoxyl in the original hemicellulose fraction was approximately 16.5% and for the saponified insoluble fractions the smallest figure obtained for this value was approximately 14.5%. Apparently very little extraction of hexosan was accomplished. Moreover, the specific rotation of the regenerated fractions were close to that of the original. Further, when the saponified pyridine-insoluble fractions of the lima bean pod hemicellulose diacetate and dipropionate were re-dissolved in alkali and precipitated by the copper method,[8] the polysaccharides were recovered in practically quantitative yields with the same specific rotations and xylan and uronic anhydride contents as the original. The lima bean pod hemicelluloses isolated by 5 and by 24% potassium hydroxide extraction, and all of the fractions isolated as described gave a violet to blue color with iodine. That the blue color was not due to starch carried through the fractionations was shown by the fact that digestion with saliva for five days did not change this property, and extraction with boiling calcium chloride solution[9] (density 1.3) left a residue still colored blue or violet when treated with iodine. The corn cob hemicelluloses did not give the colors. The failure to remove hexosan constituents by extraction with organic solvents furnishes an independent confirmation of the findings of O'Dwyer[6] and Anderson and co-workers[7] that anhydrohexose units are probably chemically combined with xylan in certain types of hemicelluloses.

Experimental

Preparation of Corn Cob and Lima Bean Pod Holocelluloses.—Corncobs and dried lima bean pods of normal canning maturity were reduced to twenty mesh and extracted successively with benzene–ethanol (2:1) for twelve hours in a large Soxhlet extractor, twice with thirty parts of boiling 0.5% ammonium oxalate solution for two-hour periods, and twice with thirty parts of boiling water. Delignification was accomplished by the sodium chlorite procedure of Wise, Murphy and D'Addieco[10] as follows: Two hundred grams of air-dried extracted material was heated to 70° with four liters of water in a six-liter flask in a fume hood. Glacial acetic acid (15 ml.) and technical sodium chlorite (30 g.) were added and the suspension held at 68–70° for an hour. Addition of acetic acid and sodium chlorite was repeated and heating was continued for another hour. This treatment produced a white fibrous holocellulose from the lima bean pods. A third addition

---

(8) The hemicelluloses were precipitated according to the directions of Angell and Norris (*Biochem. J.*, **30**, 2155 (1936)).

(9) The hemicellulose was treated according to the directions of Steiner and Guthrie (*Ind. Eng. Chem., Anal. Ed.*, **16**, 736 (1944)), who showed that quantitative extraction of starch from various plant materials can be accomplished with boiling calcium chloride solution.

(10) Wise, Murphy and D'Addieco, *Paper Trade J.*, **122** [2], 35 (1946).

of reagents and an additional hour of heating was required to produce a white product from the corn cobs. The suspension was cooled to room temperature, filtered on a cloth mat in a Buchner funnel, and the white holocellulose was washed repeatedly with large quantities of distilled water, 95% ethanol and acetone. Corncob and lima bean pod holocelluloses were obtained in yields of 81 and 90%, respectively. The yields were based on the dry extractive-free material.

Extraction of Hemicellulose Fractions from the Holocelluloses.—Four hundred grams of air-dried holocellulose was heated for two hours with six liters of boiling water, filtered, and then steeped for forty-eight hours in eight liters of 2% sodium carbonate (in the absence of oxygen), refiltered and washed with a liter of distilled water. The filter cake from the carbonate extraction was steeped for two hours in eight liters of 5% potassium hydroxide at 20–22°. Nitrogen was bubbled through the mixture to assist in mixing and removal of oxygen. The pale amber-colored suspension was filtered on hardened paper, and the filter cake was washed with two liters of distilled water without drawing air through the funnel. The hemicellulose fraction was isolated as a white curdy precipitate when the filtrate was poured into two volumes of 95% ethanol. The suspension was acidified (*p*H 4.5–5.0) with acetic acid and filtered. The hemicellulose was washed successively with 70% ethanol—5% acetic acid, 70, 85, and 95% ethanol and acetone, and air dried.

A second fraction was isolated by extracting the filter cake from the 5% potassium hydroxide extraction in the same general way but with four liters of 24% potassium hydroxide solution.

Hemicellulose Diacetate, Dipropionate and Dibutyrate.—Twelve grams of hemicellulose from corn cob or lima bean pod (dried *in vacuo* at 70°) was gelatinized by stirring for one hour at 63–65° with 250 g. of formamide. Pyridine (250 ml.) was added and the mixture was cooled to 25°. The appropriate acid anhydride (0.7–0.9 mole) was added in four equal portions over a four-hour period. The reaction mixture was stirred for six hours at 25–30° and allowed to stand overnight at room temperature. The esters were isolated by pouring the reaction mixture into 3 liters of water containing a kilogram of chopped ice. The esters, which precipitated either as flocs or as grainy precipitates, were filtered and washed successively with cold 2% aqueous hydrochloric acid, distilled water, 95% ethanol and ether. They usually had acyl contents one or two per cent. below the theoretical and were esterified a second time by treatment with pyridine and acid anhydride for several days at room temperature to yield the diesters in quantitative yields with maximum esterifications.

Hemicellulose Benzoate.—Eight grams of corncob hemicellulose (anhydrous) was stirred for one hour in 100 ml. of water at 80–85° and a smooth suspension was obtained. To the cooled mixture 100 ml. of 25% sodium hydroxide solution was added and the resulting clear amber solution was cooled to 5° with an ice-bath. Forty grams of benzoyl chloride was added in small quantities with vigorous stirring over a three-hour period and stirring was continued for two more hours at 7–10°. Xylan benzoate which precipitated as a white granular material was filtered and washed successively with 2% aqueous hydrochloric acid, hot (70°) distilled water, 95% ethanol and ether. Hemicellulose benzoate, 17.5 g., was obtained which had a benzoyl content of 55.8%, equivalent to 1.7 benzoyl groups per anhydroxylose repeating unit. A second esterification with pyridine and benzoyl chloride for two days at 22–25° yielded a benzoate containing approximately 1.8 benzoyl groups per repeating unit.

Hemicellulose Caprate, Laurate, Myristate and Palmitate.—These esters could not be prepared satisfactorily in formamide dispersion because of extensive side reactions between the acid chlorides and formamide. In a typical preparation, ten grams of hemicellulose was dispersed to a smooth paste by heating for fifteen minutes at 90° with 70 ml. of water in a 3-neck liter, round-bottom flask. To the paste 150 ml. of anhydrous pyridine was added, and the mixture was stirred mechanically and heated while pyridine and water were distilled off azeotropically. Fresh pyridine was added at intervals and the distillation continued until the distillation temperature reached 114° at which point the polysaccharide was practically free of water. The reaction mixture was cooled to 40°, additional pyridine was added to give a total volume of approximately 400 ml. and 0.3 mole of acid chloride was added in three equal quantities over a three-hour period. The reaction mixture was stirred for a total of six hours at 43–45°, allowed to stand overnight, and the esters recovered as waxy or resinous aggregates by pouring into two liters of ice water. In order to remove completely excess fatty acid, it was usually necessary to swell and partially dissolve the ester in dioxane and to re-precipitate into ethanol.

Acknowledgment.—The authors are grateful to Miss Nylan Jeung for analysis of methoxyl and uronic anhydride.

Summary

The acetate, propionate, butyrate, caprate, laurate, myristate, palmitate and benzoate of a corncob hemicellulose and the acetate, propionate, and butyrate of a lima bean pod hemicellulose have been prepared and their solubility characteristics studied.

Fractionation of the acetate, propionate and butyrate of the lima bean pod hemicellulose with organic solvents into soluble and insoluble fractions failed to accomplish an appreciable change in xylan content of the regenerated hemicellulose, which indicated that the non-pentosan part is probably chemically combined with the xylan in agreement with earlier observations of hemicelluloses extracted from sapwood tissue.

Aryl Carbamates of Cellulose Acetate

By W. M. Hearon and Jules L. Lobsitz

Phenyl and α-naphthyl isocyanates have been found to react readily with partially hydrolyzed cellulose acetates to produce colorless fibrous mixed esters with good solubilities in a variety of solvents.[1] The carbamate groups thus introduced are very resistant to acid hydrolysis and are only partially removed in alkaline media.[2] Recently, the reaction of chlorophenyl isocyanates with methyl cellulose has also been studied.[3]

We have now extended the study of the condensation of aryl isocyanates with partially hydrolyzed cellulose acetate to determine their relative rates of reaction, the solubilities of the products, and the ease of alkaline hydrolysis of the different carbamate groups. The relative rates of reaction of the isocyanates used at 2.5 times the theoretical with cellulose acetate containing 38.8% acetyl[3a] at 60° in order of increasing speed were as follows: *o*-tolyl, *p*-tolyl, phenyl, α-naphthyl, *o*-chlorophenyl and *p*-bromophenyl (see Fig. 1). The completely carbamated products were all soluble in acetone, pyridine, ethyl acetate, acetic acid, 1,4-dioxane, and chloroform, insoluble in methanol, and swollen in 75% ethyl aclohol. The phenyl, *p*-bromophenyl, and *o*-tolyl carbamates of cellulose acetate were soluble in cellosolve, while the *o*-chlorophenyl, *p*-tolyl, and α-naphthyl carbamates were merely swollen in the cold and soluble in that solvent hot.

Determination of acetyl by the Eberstadt method[4] in cellulose acetate carbamates has been modified[2] to compensate for the carbamyl lost during the alkaline conditions. After the usual saponification, the excess alkali is back-titrated to an end-point, excess acid then added and the carbon dioxide removed by boiling. A second alkaline titration is then carried out to a second end-point. The carbamate hydrolyzed corresponds to the carbon dioxide lost while the acetyl accounts for the rest of the alkali consumed. Using this method on the acetate aryl carbamates formed, the acetyl values were determined and on the assumption, previously found true,[1] that no acetyl is lost during carbamation, the amount of carbamyl which entered has been calculated. The acetyl determinations have also indicated the amount of carbamyl hydrolyzed during the acetyl determination and these values are given in Table I. The values reported are, however, probably more a function of physical form of the ester than nature of the carbamate.

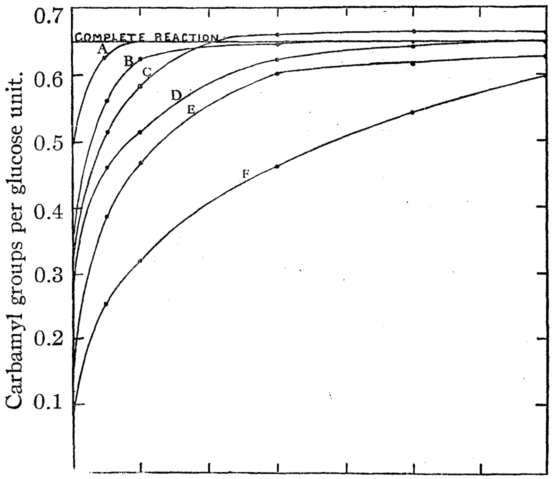

Fig. 1.—Rates of carbanilation of cellulose acetate (38.8% acetyl) with A, *p*-bromophenyl isocyanate; B, *o*-chlorophenyl isocyanate; C, α-naphthyl isocyanate; D, phenyl isocyanate; E, *p*-tolyl isocyanate; and F, *o*-tolyl isocyanate.

Table I

Hydrolysis of Carbamyl from Cellulose Acetate Carbamates after Forty-eight Hours of Saponification with 0.5 *N* Sodium Hydroxide

Cellulose acetate carbamates	% Carbamyl hydrolyzed	% Carbamyl originally	% of total carbamyl hydrolyzed
Phenyl	1.66	23.0	7.25
o-Chlorophenyl	9.45	27.8	34.0
p-Bromophenyl	1.98	33.2	5.97
o-Tolyl	2.37	25.1	9.46
p-Tolyl	1.24	25.1	4.96
α-Naphthyl	4.56	29.8	15.30

Experimental

Preparation of Carbamates.—The same procedure was followed for all rate studies. A 12.5-g. sample of cellulose acetate containing 38.8% acetyl, dried at 100° for forty-eight hours, was dissolved in 100 g. of dry pyridine and allowed to remain at 60° overnight in a tightly stoppered and previously dried flask. To the clear dope was added 2.5 times the theoretical of the isocyanate and the mixture was thoroughly shaken and left at 60 ± 0.5°. Samples were then withdrawn after 0.5, 1, 3, 5 and 7-hour intervals. Each sample was treated at once with 10 ml. of methanol to stop the reaction and precipitated into 600 ml. of rapidly stirred methanol. Purification of the white, fibrous product was completed by two additional precipitations into methanol from acetone dopes. The products were finally washed with water for two hours and dried at 60° for four hours. The yields in all cases were essentially quantitative. Acetyl analyses were carried out by the Eberstadt method[4] modified for carbamate[2] and gave the values listed in Table II.

Summary

1. Phenyl, *o*-chlorophenyl, *p*-bromophenyl, *o*-tolyl, *p*-tolyl, and α-naphthyl isocyanates reacted readily with 38.8% cellulose acetate at 60°.

2. The order of relative reaction rates of these isocyanates was as follows: *p*-bromophenyl (fastest), *o*-chlorophenyl, α-naphthyl, phenyl, *p*-tolyl, and *o*-tolyl (slowest).

3. The completely carbamated esters showed good solubilities in a variety of organic solvents.

4. All cellulose acetate carbamates formed hydrolyzed partially during deacetylation with aqueous alkali at room temperature.

Methyl Glucoside Carbanilates. II. α-Methyl-*d*-glucoside-2,3,6-tricarbanilate

BY W. M. HEARON

Carbanilates are excellent derivatives of methyl glucoside since they are readily formed, high melting, insoluble in water, readily crystallized and resistant to hydrolysis.

To the partially substituted methyl glucoside carbanilates previously reported[1] is now added the 2,3,6-tricarbanilate, which is of special interest because of its relation to carbanilated cellulose[2] and starch. The series of reactions for its preparation is given below

α-methyl-*d*-glucoside-2,3-dicarbanilate (I)
↓
6-trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate (II)
↓
6-trityl-α-methyl-*d*-glucoside-2,3-dicarbaniliate-4-acetate (III)
↓
α-methyl-*d*-glucoside-2,3-dicarbanilate-4-acetate (IV)
↓
α-methyl-*d*-glucoside-2,3,6-tricarbanilate-4-acetate (V)
↓
α-methyl-*d*-glucoside-2,3,6-tricarbanilate (VI)

As with methyl-*d*-glucoside,[3] tritylation and acetylation of α-methyl-*d*-glucoside-2,3-dicarbanilate could be carried out without isolation of the intermediate. That no migration of acetyl to the primary hydroxyl[4] occurred during detritylation was proved by retritylation of IV to III. No migration of acetyl occurred during carbanilation since (V) melted sharply about 70° below α-methyl-*d*-glucoside-2,3,4-tricarbanilate-6-acetate which was prepared by acetylation of the 2,3,4-tricarbanilate.[1] Finally, no inversions or loss of methoxyl occurred during this series of reactions since carbanilation of VI gave the previously reported α-methyl-*d*-glucoside tetracarbanilate.[5]

Experimental

6-Trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate (II).—A solution of 3.0 g. of α-methyl-*d*-glucoside-2,3-dicarbanilate[1] and 1.93 g. of trityl chloride in 6 ml. of dry pyridine was heated in a stoppered flask on a steam-bath for one hour. After cooling the solution was diluted with 20 ml. of ordinary pyridine and poured into cold water. The white precipitate, amounting to 4.8 g. or 98%, was recrystallized from hot methanol giving 3.1 g. or 63% yield melting at 121–122°; $[\alpha]^{25}\text{D}$ +57.3° (acetone, *C* 0.1).

Anal. Calcd. for $C_{40}H_{38}O_8N_2$: C, 71.2; H, 5.63; N, 4.16; trityl, 36.1. Found: C, 71.1; H, 5.75; N, 4.15; trityl, 36.2.

6-Trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate-4-acetate (III). A. By Acetylation of 6-Trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate.—A solution of 2.0 g. of 6-trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate and 4.5 ml. of acetic anhydride in 10 ml. of dry pyridine was heated in a stoppered flask on a steam-bath for thirty minutes. After cooling to room temperature water was added to a permanent cloudiness and the mixture was poured into cold water. The precipitate, amounting to 2.1 g. or 99%, crystallized from hot alcohol giving 1.9 g. or a 90% yield, m. p. 134–135°, $[\alpha]^{25}\text{D}$ +77.8° (acetone, *C* 0.1).

Anal. Calcd. for $C_{42}H_{40}O_9N_2$: C, 70.4; H, 5.58; N, 3.91; trityl, 33.9. Found: C, 70.0; H, 5.80; N, 3.75; trityl, 33.8.

B. By Tritylation and Acetylation of 6-Trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate.—A mixture of 15 g. of α-methyl-*d*-glucoside-2,3-dicarbanilate and 9.7 g. of trityl chloride in 30 ml. of dry pyridine was heated in a stoppered flask on a steam-bath for one hour. After cooling 15 ml. of acetic anhydride was added and the solution allowed to stand at room temperature for fifteen hours. After dilution with 45 ml. of ordinary pyridine the mixture was poured into cold water. The white precipitate was crystallized from hot alcohol giving 23.7 g. or 95.7% yield, m. p. 134–135°; mixed melting point with the material from A, above, 134–135°.

α-Methyl-*d*-glucoside-2,3-dicarbanilate-4-acetate (IV).—A cold solution of 6.2 g. of 6-trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate in 18 ml. of glacial acetic acid was treated with 18 ml. of hydrobromic acid in acetic acid (made by adding 11 ml. of 42% hydrobromic acid to 46 ml. of cooled acetic anhydride). The heavy precipitate of trityl bromide (2.3 g.) was sucked off and the filtrate run immediately into ice water. The white precipitate was sucked off, washed with water and dried; weight, 3.9 g., or 95%. Crystallization from alcohol and water gave 3.8 g. or 93%. Recrystallization by dissolving in chloroform and precipitating with *n*-butyl ether gave 3.5 g. or 85% yield melting at 119–120°, $[\alpha]^{25}\text{D}$ +85.3° (acetone, *C* 0.1).

Anal. Calcd. for $C_{23}H_{26}O_9N_2$: C, 58.2; H, 5.48; N, 5.90. Found: C, 58.3; H, 5.50; N, 5.89.

A small amount of the product, when treated in pyridine with the theoretical quantity of trityl chloride, gave a precipitate in water which melted at 133–134° (from alcohol) and did not depress the melting point of 6-trityl-α-methyl-*d*-glucoside-2,3-dicarbanilate-4-acetate.

α-Methyl-*d*-glucoside-2,3,6-tricarbanilate-4-acetate (V).—A solution of 1.5 g. of α-methyl-*d*-glucoside-2,3-dicarbanilate-4-acetate in 3 ml. of dry pyridine was treated with 0.5 g. of phenyl isocyanate (1.4 times theory) and heated in a stoppered flask on a steam-bath for one hour. After cooling, the solution was diluted with 1 ml. of methanol and allowed to stand ten minutes. Five ml. of ordinary pyridine was then added and the mixture poured into cold water. The precipitate was sucked off, washed and dried. After washing with hot ligroin to remove methyl carbanilate the precipitate weighed 1.7 g. or 91%. Crystallization from *n*-butanol gave 1.2 g. or 64% melting at 166–167°, $[\alpha]^{25}\text{D}$ +75.0° (acetone, *C* 0.1).

Anal. Calcd. for $C_{30}H_{31}O_{10}N_3$: C, 60.7; H, 5.22; N, 7.08. Found: C, 60.6; H, 5.36; N, 6.98.

α-Methyl-*d*-glucoside-2,3,6-tricarbanilate (IV).—A solution of 1.0 g. α-methyl-*d*-glucoside-2,3,6-tricarbanilate-4-acetate in 20 ml. of methanol containing 0.5% hydrochloric acid was refluxed for two hours. After cooling the hydrochloric acid was removed with barium carbonate, and the solution evaporated to dryness by an air stream. The white solid was purified by solution in acetone, addition of benzene and heating to remove most of the acetone. On cooling the product crystallized out and was sucked off. This purification, when repeated, gave 0.8 g. or 86% melting at 190–191°; $[\alpha]^{25}\text{D}$ +56.0° (acetone, *C* 0.1).

Anal. Calcd. for $C_{28}H_{29}O_9N_3$: C, 61.0; H, 5.27; N, 7.62. Found: C, 60.8; H, 5.32; N, 7.56.

α-Methyl-*d*-glucoside-2,3,4-tricarbanilate-6-acetate.—Acetylation of 1.5 g. of α-methyl-*d*-glucoside-2,3,4-tricarbanilate[1] in 10 ml. of dry pyridine with 5 ml. of acetic anhydride at room temperature for fifteen hours gave 1.5 g. crude (94%) and 1.0 g. pure (63%) of white crystals from hot alcohol melting at 235–237°; $[\alpha]^{25}\text{D}$ +71.0° (acetone, *C* 0.1).

Anal. Calcd. for $C_{30}H_{31}O_{10}N_3$: C, 60.7; H, 5.22; N, 7.08. Found: C, 60.7; H, 5.35; N, 7.16.

α-Methyl-*d*-glucoside-2,3,4,6-tetracarbanilate.—A small quantity of α-methyl-*d*-glucoside-2,3,6-tricarbanilate in pyridine with an excess of phenyl isocyanate was heated on a steam-bath for one hour. After cooling a little methanol was added to remove excess isocyanate and the mixture poured into cold water. The resulting white precipitate, after recrystallization twice from hot acetic acid, melted at 227° and did not depress the melting point of an authentic sample of α-methyl-*d*-glucoside-2,3,4,6-tetracarbanilate.[5]

Summary

1. Crystalline α-methyl-*d*-glucoside-2,3,6-tricarbanilate has been prepared by a five-step series of reactions from α-methyl-*d*-glucoside-2,3-dicarbanilate.

2. The intermediates in this synthesis, all crystalline, have been described and identified.

Branched-Chain Fatty Acids. V. The Synthesis of Optically Active 10-Methyloctadecanoic Acids[1]

BY FRANKLIN S. PROUT,[2,3] JAMES CASON[4] AND A. W. INGERSOLL

The synthesis of 10-methyloctadecanoic acid was undertaken as a continuation of the program to synthesize and compare the properties of the complete series of methyloctadecanoic acids.[5] The 10-methyl member of this series is particularly interesting, moreover, since tuberculostearic acid, a C_{19} branched-chain fatty acid isolated from the lipids of tubercle bacillus by Anderson and Chargaff,[6] has been assigned this structure.[7] The assignment of structure by Spielman was based on oxidative degradation of the natural acid and the synthesis of *dl*-10-methyloctadecanoic acid. The synthetic acid melted some ten degrees higher (20–21°) than the melting point (10–11°) reported for tuberculostearic acid. There was, however, close agreement in other properties, and it appeared probable that tuberculostearic acid, although reported to be optically inactive,

might be an active form with a very small rotation.

In view of this situation it was decided to prepare *dl*-10-methyloctadecanoic acid by a different method and also to prepare both active forms of this acid. It was expected that comparison of the isomeric acids with each other and with tuberculostearic acid might provide decisive evidence on the points at issue.

The results of this phase of the work have already been briefly reported.[8] It has been found that carefully purified *dl*-10-methyloctadecanoic acid melts at 25.4–26.1°, while the pure active forms melt at 13.0–13.5° and have specific rotations in the range 0.05–0.09°. A sample of tuberculostearic acid, derived from a sample of the methyl ester kindly supplied by Dr. R. J. Anderson[9] and purified by one crystallization from acetone, melted at 10.3–11.7° and showed a small but definite levo rotation. A mixture of this acid with approximately an equal amount of the synthetic levorotatory acid melted at 11.0–12.4°, while a similar mixture with the synthetic dextrorotatory acid melted at 19.4–20.1°. A mixture of the two synthetic acids melted at 21.0–25.8°. Further comparisons of the amides and tribromoanilides of the natural and synthetic acids (Table I) es-

(9) The methyl tuberculostearate was material purified by fractional distillation by Dr. Sidney F. Velick. Samples of the amide and tribromoanilide prepared by Dr. M. A. Spielman (ref. 7) were also supplied.

tablished beyond reasonable doubt the identity of tuberculostearic acid with levorotatory 10-methyloctadecanoic acid.[10]

Scheme of Synthesis

The scheme of synthesis and data on yields and specific rotations of active forms are shown in the accompanying chart. The first rotation value in each instance refers to the series of products derived from (+)-2-decanol. The purposes of the work required the selection of a combination of optical resolution and synthetic procedures which would assure not only structural and chemical purity of the desired 10-methyloctadecanoic acids, but also complete antipodal purity of both active forms. The plan adopted involved the preliminary preparation of both active forms of a suitable intermediate, namely, 3-methylhendecanoic acid (V), which would permit subsequent chain extension without racemization. This intermediate was selected rather than 2-methyldecanoic acid or 2-methyl-1-decanol. Both of these have the requisite 2-decyl terminal structure but appeared unlikely to permit satisfactory resolution into both forms[11] or chain extension without serious racemization.[11,12] It appeared improbable also that resolution of 3-methylhendecanoic acid itself would be satisfactory.[13]

The resolution step was carried out upon *dl*-2-decanol, the (+)-form being obtained by the method of Pickard and Kenyon[14] and the (−)-form by an original method. The conditions for the steps through the 3-methylhendecanoic acids were chosen to minimize racemization,[13,15] but this amounted to some 10–15% at the 2-decylmalonic acid stage. The key to complete antipodal purity of the 3-methylhendecanoic acids was the fact that fractional crystallization of the partially racemized 2-decylmalonic acids afforded a sharp separation of the more sparingly soluble active forms (m. p. 100.5°) from the *dl*-form (m. p. 75.5°). Decarboxylation of the pure malonic acids and all succeeding steps proceeded without racemization.

Configurative Relationships

The synthesis of the 3-methylhendecanoic acids from the 2-decanols appears to involve inversion of configuration accompanied by slight racemization in the bromination stage and again in the alkylation of malonic ester.[16,17] The remaining steps involve no further inversions. Hence (−)-10-methyloctadecanoic acid (tuberculostearic acid) has the same configuration as (−)-2-decanol and (+)-3-methylhendecanoic acid. The latter acid should have the same configuration as (−)-2-methylbutanoic acid[11b,13] which has been related to (−)-2-butanol[18] and to D-(+)-glyceraldehyde.[19,20] Accordingly, (−)-10-methyloctadecanoic acid may be assigned to the D-series but this classification is regarded as provisional since the correlation of (−)-2-methylbutanoic acid with (+)-glyceraldehyde is still somewhat uncertain.

Acknowledgment.—We are indebted to Professor R. J. Anderson of Yale University and his associates who kindly supplied us with the methyl tuberculostearate and other derivatives used for the comparisons with our synthetic materials.

Experimental[21]

Resolution of *dl*-2-Decanol

***dl*-2-Decanol (I).**[14,22]—The Grignard reagent from 970 g. of 1-bromoöctane,[23] b. p. 106–106.5° (35 mm.), in 1500 cc. of ether was treated with 220 g. of acetaldehyde in 750 cc. of ether at −5° to 5° to form 2-decanol in a yield of 634 g. (80.0%); b. p. 124–126° (31 mm.) (95% at 124.5–125.5° at 31 mm., column V45)[24]; f. p. −2.4°; $n^{25}\text{D}$ 1.4327. A forerun of 38.7 g., b. p. 43–40° (43–32 mm.), was presumably *n*-octane. A small fraction (9.2 g.) of b. p. 126–127° (31 mm.), was rejected. A 0.5-mole run using 0.9 equivalent of acetaldehyde gave the same yield (80.9%).

The **3,5-dinitrobenzoate** was obtained in 65% yield by reaction of 2-decanol with 3,5-dinitrobenzoyl chloride in the presence of powdered sodium carbonate; m. p. 49.8–51.5°. Two crystallizations from ligroin or 95% ethanol furnished the pure ester; m. p. 52.0–52.9°. Heilbron, Jones and Raphael[22b] give m. p. 44°.

***dl*-2-Decyl hydrogen phthalate** was prepared in a 2-mole run in 92.7% yield by essentially the procedure of Kenyon[25] for the preparation of *dl*-2-octyl hydrogen phthalate, except that the product was extracted with hexane.[26] The crude half ester melted at 26–38.6°. After three crystallizations from pentane[26] the m. p.

---

[10] After our previous communication (ref. 8) had been submitted it was learned (private communication) that Stina Stallberg-Stenhagen (Uppsala, Sweden) has recently prepared levorotatory 10-methyloctadecanoic acid by a completely different synthesis. From the information supplied the properties of her acid and ours are in close agreement.

[26] The solvents herein called hexane and pentane are redistilled fractions of Skellysolve B and Skellysolve F boiling at 63–69° and 36–38°, respectively.

remained constant at 38.0–39.4°. A sample prepared later by recrystallizing a mixture of equal amounts of the pure *l*- and *d*-forms had m. p. 37.4–39.5°. Pickard and Kenyon[14] give 48–49° as the melting point of the unrecrystallized half ester.

Resolution with Brucine.—The resolution of the crude *dl*-2-decyl hydrogen phthalate with brucine followed the procedures of Pickard and Kenyon[14] and Kenyon.[25] The salt of brucine (733 g.) and *dl*-2-decyl hydrogen phthalate (569 g.) was crystallized from 1200 cc. of acetone to give 477 g. of the crude brucine salt of the dextrorotatory half ester; m. p. 129–134.5°. Systematic recrystallization of this crop and the second crop (219 g.) furnished finally 456 g. (70% yield) of the pure salt; m. p. 135.2–137.1° (gas); $[\alpha]^{25}\mathrm{D}$ −5.48° (95% ethanol, *c*, 9.07); literature,[14] m. p. 136–138°; $[\alpha]\mathrm{D}$ −6.01° (alcohol, *c*, 5). The mother liquor was reserved for recovery of the levorotatory form of the half ester.

(+)-2-Decyl Hydrogen phthalate was obtained by dissolving 200 g. of the brucine salt of the dextrorotatory half ester ($[\alpha]^{24}\mathrm{D}$ −5.64°) in 250 cc. of ethanol and adding 100 cc. of concentrated hydrochloric acid in 1200 cc. of water. The ester was extracted by two portions of hexane (200 and 150 cc.). After these extracts had been washed twice with water and once with saturated sodium chloride solution and filtered through sodium sulfate, removal of solvent gave 87.2 g. (99%) of substantially pure half ester. Three recrystallizations of a sample of this ester from hexane (cooling at 5°) furnished product of high purity; m. p. 33.4–36.2°; $[\alpha]^{25}\mathrm{D}$ +47.1° (95% ethanol, *c*, 4.42); $[\alpha]^{25}\mathrm{D}$ +40.5° (acetone, *c*, 4.77); $[\alpha]^{25}\mathrm{D}$ +39.1° (hexane, *c*, 4.26). Pickard and Kenyon[14] give m. p. 38–39°; $[\alpha]\mathrm{D}$ +45.19° (alcohol).

(+)-2-Decanol.[14]—Crude (+)-2-decyl hydrogen phthalate (197 g.), as obtained directly by decomposition of pure brucine salt, was heated under reflux for thirty minutes with 144 g. of potassium hydroxide in 350 cc. of water and 700 cc. of 95% ethanol. The decanol was extracted from the diluted alkaline solution with hexane and distilled from a Claisen flask: yield, 99.0 g. (97.5%); b. p. 127–129° (35 mm.); f. p. 1.7°; $\alpha^{25}\mathrm{D}$ +6.98°[27]; $[\alpha]^{25}\mathrm{D}$ +8.50° (d^{25} 0.821[14]). The literature[14] value is $[\alpha]^{26.4}\mathrm{D}$ +8.55°.

(+)-2-Decyl 3,5-dinitrobenzoate was prepared in 33% yield by direct reaction between the active alcohol and the acid chloride; m. p. 41–44°. Crystallization from 95% ethanol furnished the purified ester. It softens at 49.5° and melts at 55.8–56.8° when heated at 1.8°/minute, hence is probably polymorphic. The rotation is $[\alpha]^{25}\mathrm{D}$ +34.4° (chloroform, *c*, 2.04).

Recovery of Partially Resolved (−)-2-Decyl Hydrogen Phthalate.—The brucine salts remaining in the mother liquors of the initial resolution were obtained in four successive fractions. The first (98 g.) crystallized from mother liquors of the recrystallization of the brucine (+)-phthalate. The combined mother liquors were concentrated *in vacuo* to about 1 liter and diluted with 2 liters of dry ether; 439 g. of salts separated after two days at room temperature and a further 200 g. after chilling at 5° for several days. The final fraction (not weighed) was residue from evaporation of solvents. The partially resolved half ester was obtained from each fraction as already described, the amounts being 43, 186, 88 and 19 g., respectively. The corresponding rotations ($[\alpha]^{25}\mathrm{D}$, hexane, *c*, 9–10) were −19.0, −27.6, −13.1 and −9.4°.

(−)-2-Decyl Hydrogen Phthalate.—In efforts to obtain the pure levorotatory half ester, resolutions of the partially resolved levorotatory ester were unsuccessfully attempted with cinchonidine, cinchonine and quinine. The cinchonidine salt crystallized, but was too soluble for satisfactory fractionation.[14] A process based upon fractional crystallization of the mixed hydrogen phthalates from hexane (*cf.* Kenyon[25]) gave a small yield of the pure (−)-phthalate but the method was too tedious for satisfactory use. The purification of the (−)-phthalate was readily effected by crystallization of the (+)-α-phenylethylamine salts.

Resolution with (+)-α-Phenylethylamine.—In a typical run 131 g. of 2-decyl hydrogen phthalate ($[\alpha]^{25}\mathrm{D}$ −15.1°, hexane; calculated (−)-form, 70%) was combined with 50.8 g. of (+)-α-phenylethylamine in 350 cc. of acetone. The initial crop (103 g., m. p. 98–113°) crystallized at room temperature as a loose mass of small nodules. Concentration of the mother liquor and cooling at 5° furnished two more crops: 29.7 g., m. p. 103–112.4° and 2.9 g., m. p. 65–96°, and a dark sirupy mother liquor. The solid fractions were recrystallized systematically; usually four or five crystallizations were required to furnish the pure salt of the levorotatory half ester as a mass of soft hair-like needles; m. p. 118.4–120.7°; $[\alpha]^{25}\mathrm{D}$ −19.2° (95% ethanol, *c*, 8.02). For analysis a sample was dried at 56° *in vacuo* and showed no loss in weight in two hours.

Anal. Calcd. for $C_{26}H_{37}O_4N$: N, 3.28. Found: N, 3.26 (Kjeldahl).

The yield of pure salt in this run was 92.1 g., corresponding to recovery of 74.3% of the total (−)-form originally present. Similar results were obtained in other runs. The fractionation is most satisfactorily followed by observation of the melting point and crystal habit of the salt. The separation of initial crops should be carried through promptly because in the presence of the amine acetone condenses fairly rapidly, forming eventually a black viscous mother liquor.

To obtain a sample of pure (−)-2-decyl hydrogen phthalate, 19.2 g. of the above (+)-α-phenylethylamine salt was decomposed with hydrochloric acid and the half ester extracted with hexane.[28] The extracts were concentrated to a volume of 60 cc. and the solution was cooled at 5° to furnish 8.49 g. of half ester; m. p. 33.4–36.5°. An additional 3.8 g. was obtained from the mother liquors: total yield, 89.3%. After one recrystallization the ester had m. p. 33.3–35.8°; $[\alpha]^{25}\mathrm{D}$ −46.6° (95% ethanol, *c*, 4.04); $[\alpha]^{25}\mathrm{D}$ −39.5° (acetone, *c*, 4.37); $[\alpha]^{25}\mathrm{D}$ −39.1° (hexane, *c*, 4.19). These properties agree closely with those of the dextrorotatory half ester.

(−)-2-Decanol was obtained by saponification of either the pure crystalline half ester or the half ester obtained, without crystallization, from the pure salt of (+)-α-phenylethylamine. Both methods gave *pure* optically active alcohol. A sample of pure crystalline (−)-2-decyl hydrogen phthalate (31.1 g., m. p. 33.6–35.9°, $[\alpha]^{25}\mathrm{D}$ −39.7° (hexane, *c*, 4.79)) was saponified and the product purified by the procedure used to obtain (+)-2-decanol. The yield was 15.1 g. (93.7%); b. p. 122° (28 mm.); f. p. 2.8°; $\alpha^{25}\mathrm{D}$ −7.03°; $[\alpha]^{25}\mathrm{D}$ −8.56°.

A sample of crude levorotatory ester (91.3 g. from 126 g. of amine salt) was saponified to furnish 46.4 g. (99.3%) of (−)-2-decanol; b. p. 119–121° (22–25 mm.); f. p. 2.2°; $\alpha^{25}\mathrm{D}$ −7.03°; $[\alpha]^{25}\mathrm{D}$ −8.56°.

(−)-2-Decyl 3,5-dinitrobenzoate was prepared from (−)-2-decanol and the acid chloride by boiling in a benzene solution containing dimethylaniline and crystallized three times from pentane and once from ethanol. The high yield (91.3%) by this procedure is noteworthy. The ester had m. p. 55.8–56.7° after sintering at 49.5° and is probably polymorphic; $[\alpha]^{25}\mathrm{D}$ −32.6° (chloroform, *c*, 4.09). A sample of dinitrobenzoate prepared similarly from partially resolved (−)-2-decanol showed no signs of separation on repeated crystallization.

The 3-Methylhendecanoic Acids

***dl*-2-Bromodecane (II).**[22c]—This bromide was made by the phosphorus tribromide procedure of Hsueh and Marvel[15] for the preparation of the active 2-bromo-octanes; except that the final hour of heating was omitted and potassium carbonate was used for drying instead of calcium chloride. From 31.7 g. of *dl*-2-decanol and 59.6 g. of

---

[27] In this paper observed rotations, $\alpha\mathrm{D}$, for liquids (without solvent) refer to 1 dm. The accompanying density value was used for calculation of specific rotation. Densities are given in absolute units (g./cc.).

[28] The (+)-α-phenylethylamine was recovered in 90% yield from the aqueous layers of the above extraction.

phosphorus tribromide there was obtained 35.0 g. (82.9%) of *dl*-2-bromodecane. A similar run with an hour of heating at 100° gave 84.3% yield. A run using less phosphorus tribromide (20% over equivalence) gave a much lower yield (59.9%). The product had b. p. 111° (11 mm.); d^{20} 1.0512, d^{25} 1.0470, d^{30} 1.0426, d^{35} 1.0375; $n^{25}\mathrm{D}$ 1.4526.

Anal. Calcd. for $C_{10}H_{21}Br$: Br, 36.13. Found: Br, 35.95.

(−)-2-Bromodecane.—The procedure used to make *dl*-2-bromodecane was employed with 36.9 g. of (+)-2-decanol ($[\alpha]^{28}\mathrm{D}$ +8.54°) and 69.7 g. of phosphorus tribromide. The yield was 33.6 g. (65.2%); b. p. 117–119° (20 mm.); $\alpha^{27}\mathrm{D}$ −32.8°; $[\alpha]^{27}\mathrm{D}$ −31.4° (d^{27} 1.045). The reaction proceeds with inversion of configuration.[16] In another preparation the yield was increased to 86.2% but the specific rotation was lowered to $[\alpha]^{25}\mathrm{D}$ −29.0°. Although no simple explanation of these variations is apparent, the results are in general accord with the reaction mechanism proposed by Gerrard[17] in which a small part of the product is formed with retention of configuration. There was no indication that racemization resulted from migration of halogen.[29]

(+)-2-Bromodecane was made using 47.7 g. of (−)-2-decanol ($[\alpha]^{25}\mathrm{D}$ −8.56°) and 89.9 g. of phosphorus tribromide. The yield was 50.2 g. (75.5%); b. p. 122–125° (24 mm.); $\alpha^{25}\mathrm{D}$ +32.4°; $[\alpha]^{25}\mathrm{D}$ +31.0°. Another run using (−)-2-decanol with a specific rotation of −8.63° furnished the bromide in 66.2% yield; $\alpha^{25}\mathrm{D}$ +33.7°; $[\alpha]^{25}\mathrm{D}$ +32.1°. This rotation value is probably close to maximum.

***dl*-2-Iododecane.**—Fifty grams of *dl*-2-decanol, 30 g. of red phosphorus and 120 g. of powdered iodine were stirred together at 0 to 5° for eight hours and then for nine hours longer while the temperature rose to 29°. The reaction mixture was poured into 300 g. of cracked ice, stirred with 200 cc. of ether and filtered by suction to remove the excess phosphorus. After extracting, drying over potassium carbonate and removing the ether, distillation furnished 78 g. (92%) of almost colorless iodide; b. p. 150–152° (44 mm.); d^{20} 1.2466, d^{25} 1.2412, d^{30} 1.2362, d^{35} 1.2308; $n^{25}\mathrm{D}$ 1.4831.

Anal. Calcd. for $C_{10}H_{21}I$: I, 47.32. Found: I, 47.13.

(−)-2-Iododecane.—Fifty grams of (+)-2-decanol ($[\alpha]^{25}\mathrm{D}$ +8.50°) furnished 81 g. (95%) of the levorotatory iodide; b. p. 146–147° (33 mm.); $\alpha^{25}\mathrm{D}$ −37.8°; $[\alpha]^{25}\mathrm{D}$ −30.4°. In view of the low rotation as compared to the reported values ($[\alpha]\mathrm{D}$ ±40°) for the *d*- and *l*-2-iodoöctanes,[14] it is clear that our iodide was considerably racemized. Because of this and further racemization in the malonic ester step (see below), the use of the iodide was abandoned. The dextrorotatory iodide was not prepared.

Dibutyl *dl*-2-Decylmalonate (III).—Sodium butoxide[30] was prepared from 85 cc. of dry butanol and 3.9 g. of sodium in a three-necked flask fitted with a condenser and stirrer and arranged for a nitrogen atmosphere. Diethyl malonate (27.0 g.) and *dl*-2-bromodecane (25.0 g.) were added and the mixture was heated at 100° for five hours. The cooled reaction mixture was washed twice with water and once with saturated sodium chloride solution. The aqueous washes were twice extracted with ether. After filtering the extracts through sodium sulfate and removing the solvent the product was distilled (V90). After removal of 8.9 g. of forerun (boiling mainly at 153–160° (24 mm.)), 30.8 g. (76.4%) of essentially pure dibutyl *dl*-2-decylmalonate was obtained; b. p. 170–188° (95% at 184–187°) (3 mm.). The analytical sample (center cut from the redistillation of a similar run) boiled at 178° (1 mm.); d^{20} 0.9186, d^{25} 0.9147, d^{30} 0.9113, d^{35} 0.9072; $n^{25}\mathrm{D}$ 1.4403.

Anal. Calcd. for $C_{21}H_{40}O_4$: sapn. equiv., 178.3. Found: sapn. equiv., 181.7.[31]

Redistillation of the forerun gave 3.2 g. of dibutyl malonate; b. p. 151–152° (26–24 mm.); $n^{26}\mathrm{D}$ 1.4234. In later preparations additional malonic ester (2.5 equiv.) gave no improvement in yield and shortening the heating to one hour reduced the yield somewhat. Toluene was an unsatisfactory solvent. With *dl*-2-iodododecane the yield of 2-decylmalonic ester was 81.2%.

Dibutyl (+)-2-decylmalonate was prepared from 100 cc. of butanol, 5.1 g. of sodium, 35.5 g. of diethyl malonate and 32.5 g. of (−)-2-bromodecane ($[\alpha]^{25}\mathrm{D}$ −31.3°). The yield was 43.9 g. (83.8%); b. p. 147–177° (90% at 165–176°) (0.5 mm.); $\alpha^{27}\mathrm{D}$ +0.28°; $[\alpha]^{27}\mathrm{D}$ +0.31° (d^{27} 0.914).

In another run with the bromide the yield was only 65.3%. When the reaction was run with (−)-2-iododecane ($[\alpha]^{25}\mathrm{D}$ −30.4°) the yield of ester was 87.5%; $[\alpha]^{25}\mathrm{D}$ +0.34°. The (−)-2-decylmalonic acid derived from this ester was considerably racemized (see below).

Dibutyl (−)-2-decylmalonate was prepared in 81.7% yield from 220 cc. of butanol, 8.6 g. of sodium, 60 g. of diethyl malonate and 55.2 g. of (+)-2-bromodecane ($[\alpha]^{25}\mathrm{D}$ +32.1°). The product (72.9 g.) was distilled at 2 mm. pressure; b. p. 160–182° (85% at 178–182°); $\alpha^{25}\mathrm{D}$ −0.33°; $[\alpha]^{25}\mathrm{D}$ −0.36°. A yield of 78.6% was obtained in another run.

2-Decylmalonic Acids (IV). Preliminary Chemical Purification.—In order to prepare the active 3-methylhendecanoic acids in maximum antipodal purity from intermediates containing small amounts of the *dl*-form it was necessary to employ fractional crystallization of the intermediate 2-decylmalonic acids, depending upon the markedly greater crystallizing power and lower solubility of the active acids as compared with the *dl*-form. This crystallization was best preceded by a double extraction designed to remove neutral materials and incidental impurities which tended to impede crystallization.

Dibutyl 2-decylmalonate (72 g.) was saponified by heating under reflux for an hour in a solution of 45 g. of potassium hydroxide, 300 cc. of 95% ethanol and 25 cc. of water. This mixture was diluted with 1200 cc. of water, acidified and the crude acid extracted with three portions of hexane (150, 100, 100 cc.). The extracts were washed with two 100-cc. portions of half-saturated sodium chloride solution and the crude malonic acid was extracted with 700 cc. of 10% sodium bicarbonate solution. The extract was filtered to remove traces of solid material, and acidified. The 2-decylmalonic acid, which sometimes partially solidified, was extracted with three portions of ether. The residue of crude acid (contaminated with some butanol), which remained after removal of solvent, solidified slowly and was usually slightly more than the theoretical amount. This material was fractionally crystallized from hexane.

***dl*-2-Decylmalonic Acid.**—The crude acid obtained by saponification of 34 g. of dibutyl *dl*-2-decylmalonate crystallized sluggishly at 5° from 100 cc. of hexane. The first crop of 12.4 g. (53.4%), m. p. 68.1–71.3°, was used for characterization of this acid. Four recrystallizations from hexane (cooling at room temperature) furnished the *dl*-acid as a microcrystalline powder; m. p. 73.6–75.5°. (A mixture of equal amounts of the purified active forms after one crystallization melted at 70.5–72.8°.)

Anal. Calcd. for $C_{13}H_{24}O_4$: C, 63.90; H, 9.90; equiv. wt., 122.2. Found: C, 64.14; H, 9.89; equiv. wt., 122.8.

(−)-2-Decylmalonic Acid. Antipodal Purification.—Saponification of 62.5 g. of dibutyl (+)-2-decylmalonate furnished 39.6 g. (92.8%) of crude acid. The initial series of crystallization of this acid from hexane afforded 34.45 g. (80.8%) of crystalline acid in four crops. The first crop (26.14 g., m. p. 94.3–97.3°) already had a high degree of antipodal purity ($[\alpha]^{25}\mathrm{D}$ −6.22° (acetone, *c*,

(30) Reid and Ruhoff, "Organic Syntheses," Coll. Vol. II, p. 474.

(31) Analytical saponification with 1 *N* alcoholic potassium hydroxide required three hours; preparative saponifications with stronger solutions were complete in one hour.

8.30), 88% of maximum value). The remaining crops had progressively much smaller rotations and lower melting points. From the rotation values (assuming −7.1° as maximum) the original mixture was estimated to contain about 89% of the (−)-form.

Systematic recrystallization was carried out with hexane containing about 4% acetone for the purer fractions. Foot fractions rich in the *dl*-form could be enriched in the active form by crystallization from hexane alone. The fractionation was followed by the melting point rise and by the change in crystal habit from a microcrystalline powder to distinct translucent blades characteristic of the active forms. The yield of pure levorotatory acid from this fractionation was 26.26 g.; m. p. 99.3–100.6°; $[\alpha]^{25}\mathrm{D}$ −7.17° (acetone, *c*, 8.18). This amounts to 61.7% of the acid present in the starting ester or to nearly 98% of the levorotatory acid calculated to be present in excess of the *dl*-form in the original crystalline fractions.

Anal. Calcd. for $C_{13}H_{24}O_4$: equiv. wt., 122.2. Found: equiv. wt., 122.2, 122.3.

One specimen of (−)-2-decylmalonic acid was prepared from partially racemized (−)-2-iododecane. Acid from this source had an initial calculated content of 72.5% (−)-form. The fractionation of this crude acid nevertheless gave pure (−)-acid amounting to 34% of the theoretical total.

(+)-2-Decylmalonic Acid. Antipodal Purification.—The saponification of 72.8 g. of dibutyl (−)-2-decylmalonate gave 54.2 g. (106%) of the crude acid. Recrystallization from 125 cc. of hexane gave a first crop of 40.40 g.; m. p. 96.2–98.3°; $[\alpha]^{25}\mathrm{D}$ +6.86° (acetone, *c*, 8.50). Two more crops (8.75 g.) having lower melting points and rotations were obtained: total yield, 49.15 g. (98.5%). The combined crops were calculated to contain 94% of the (+)-form. Systematic recrystallization of this acid by procedures described for the levorotatory antipode furnished 43.53 g. (87.1%) of pure acid; m. p. 99.6–100.5°; $[\alpha]^{25}\mathrm{D}$ +7.07° (acetone, *c*, 8.21).

Anal. Calcd. for $C_{13}H_{24}O_4$: equiv. wt., 122.2. Found: equiv. wt., 122.7.

In one run it was shown that partially resolved levorotatory 2-decanol could be used for the preparation of pure (+)-2-decylmalonic acid. (−)-2-Decanol ($[\alpha]^{25}\mathrm{D}$ −4.93°, 79% (−)-form) was converted to the dextrorotatory bromide, $[\alpha]^{25}\mathrm{D}$ +17.6° (*ca.* 78% (+)-form). This bromide was used to prepare (+)-2-decylmalonic acid (73.5% (+)-form). Systematic crystallization of this acid gave pure (+)-2-decylmalonic acid corresponding to 72% of the excess of this form initially present.

***dl*-3-Methylhendecanoic Acid (V).**—The crude malonic acid from 89.5 g. of the butyl ester was heated at 175–185° for an hour. Distillation then gave 51.3 g. (102%) of crude 3-methylhendecanoic acid; b. p. 147–153° (5 mm.). This acid, which contained some of its butyl ester, was used without further purification for conversion to the ethyl ester (below). A sample of pure acid was recovered from the unreduced portion remaining after reduction of the ester (below). The acid (3.3 g.) was distilled (P45); b. p. 147.5–148.5° (2 mm.); d^{20} 0.8906, d^{25} 0.8868, d^{30} 0.8832, d^{35} 0.8795; $n^{25}\mathrm{D}$ 1.4389. Rupe and Willi[32] give b. p. 165.5° (10 mm.).

Anal. Calcd. for $C_{12}H_{24}O_2$: equiv. wt., 200.3. Found: equiv. wt., 199.2.

The **amide** was obtained by a previously described method[5b] in 89% yield; m. p. 67–77°. After four crystallizations from acetone it appeared as long needles; m. p. 88.3–89.3°.

Anal. Calcd. for $C_{12}H_{25}ON$: C, 72.30; H, 12.64. Found: C, 72.54; H, 12.75.

The **tribromoanilide** was obtained in 79% yield[5a]; m. p. 106.4–109.9°. Four recrystallizations from methanol furnished feather-like crystals; m. p. 108.0–111.9°.

Anal. Calcd. for $C_{18}H_{27}Br_3ON$: C, 42.13; H, 5.30. Found: C, 42.03; H, 5.55.

(−)-3-Methylhendecanoic Acid.—Thirty-seven grams of carefully purified (−)-2-decylmalonic acid ($[\alpha]^{25}\mathrm{D}$ −7.17°) was heated at 165–180° for twenty minutes and the product distilled to yield 29.7 g. (97.7%) of acid; b. p. 142.5–138° (2–1 mm.); $\alpha^{25}\mathrm{D}$ −4.47°; $[\alpha]^{25}\mathrm{D}$ −5.04°; $[\alpha]^{25}\mathrm{D}$ −6.87° (acetone, *c*, 8.50).

The **amide** was prepared[5b] in 85% yield; m. p. 75–85°. Three crystallizations from acetone gave soft, long needles; m. p. 87.3–88.4°; $[\alpha]^{25}\mathrm{D}$ −2.54° (acetone, *c*, 2.51). A mixture of the *l*- and *dl*-amides had m. p. 88.9–91.5°.

The **tribromoanilide** was prepared[5a] in 84% yield; m. p. 121.3–128.2°. Three crystallizations from methanol gave soft needles; m. p. 128.8–129.6°; $[\alpha]^{25}\mathrm{D}$ −2.20° (chloroform, *c*, 4.19).

(+)-3-Methylhendecanoic Acid.—(+)-2-Decylmalonic acid (64.8 g., $[\alpha]^{25}\mathrm{D}$ +7.07–7.12°) was decarboxylated by heating at 165–180° for fifteen minutes and the product was distilled to give 52.4 g. (98.3%) of acid; b. p. 140–149° (0.5 mm.); $\alpha^{25}\mathrm{D}$ +4.45°; $[\alpha]^{25}\mathrm{D}$ +5.02°; $[\alpha]^{25}\mathrm{D}$ +7.13° (acetone, *c*, 7.95).

The **amide** was prepared in 93% yield; m. p. 87.6–88.6°; $[\alpha]^{25}\mathrm{D}$ +2.76° (acetone, *c*, 4.02). A mixture of the *d*- and *dl*-amides melted at 89.3–91.5°.

The **tribromoanilide** was made in 90% yield; m. p. 128.7–129.5°; $[\alpha]^{25}\mathrm{D}$ +1.99° (chloroform, *c*, 4.53).

The 10-Methyloctadecanoic Acids

Ethyl *dl*-3-Methylhendecanoate (VI).—The crude acid (51.3 g. obtained as previously described from 89.5 g. of dibutyl *dl*-2-decylmalonate) was heated under reflux for two hours with 400 cc. of absolute ethanol and 20 cc. of concentrated sulfuric acid. The ester was distilled (P45); yield 48.5 g. (84.6%); b. p. 118.5–120.5° (2 mm.). A sample of b. p. 122° (2.5 mm.) was used for analysis and constants: d^{20} 0.8605, d^{25} 0.8571, d^{30} 0.8532, d^{35} 0.8492; $n^{25}\mathrm{D}$ 1.4287.

Anal. Calcd. for $C_{14}H_{28}O_2$: sapn. equiv., 228.4. Found: sapn. equiv., 224.3.

Ethyl (−)-3-Methylhendecanoate.—Pure (−)-3-methylhendecanoic acid (44.16 g., $[\alpha]^{25}\mathrm{D}$ −5.04° to −5.05°) was esterified as described for the *dl*-ester. Distillation (P45) gave 46.96 g. (93.6%); b. p. 108.5–110.2° (1.5 mm.); $\alpha^{25}\mathrm{D}$ −2.01°; $[\alpha]^{25}\mathrm{D}$ −2.34°.

Ethyl (+)-3-Methylhendecanoate.—Pure (+)-3-methylhendecanoic acid (52.27 g., $[\alpha]^{25}\mathrm{D}$ +5.02°) was esterified as described for the *dl*-ester. Distillation (P45) gave 57.31 g. (96.0%); b. p. 104.5–107° (0.5–1 mm.); $\alpha^{25}\mathrm{D}$ +2.00°; $[\alpha]^{25}\mathrm{D}$ +2.33°.

***dl*-3-Methyl-1-hendecanol (VII).**—Fifty grams of ethyl *dl*-3-methylhendecanoate was reduced with 26.9 g. of sodium in 435 cc. of dry butanol.[33] After addition of water, the alcohol was extracted from the alkaline solution with hexane and distilled (P45). Besides a small forerun (0.24 g., b. p. 100–118° (3.5–2.5 mm.)) there was obtained 34.3 g. (84.5%) of the alcohol; b. p. 118–117° (2.5–2 mm.). A center cut boiling at 117° (2 mm.) was used for analysis and constants: d^{20} 0.8341, d^{25} 0.8309, d^{30} 0.8275, d^{35} 0.8241; $n^{25}\mathrm{D}$ 1.4409.

Anal. Calcd. for $C_{12}H_{26}O$: C, 77.35; H, 14.07. Found: C, 77.29; H, 13.90.

A non-volatile, water-soluble residue remained after distillation. A similar product, presumably the sodium salt of the acid corresponding to the ester reduced, was reported by Reid and his co-workers[33] from the reduction of butyl oleate. A sample of pure *dl*-3-methylhendecanoic acid (3.3 g.) was recovered from the aqueous phases as previously described.

The **3,5-dinitrobenzoate** was prepared in 76% yield by the method described for the dinitrobenzoate of (−)-2-decanol. Two crystallizations from pentane gave pure ester as clumps of short needles; m. p. 46.0–47.1°.

Anal. Calcd. for $C_{19}H_{26}O_6N_2$: C, 60.40; H, 6.93. Found: C, 60.36; H, 7.01.

[33] Reid, Cockerille, Meyer, Cox and Ruhoff, "Organic Syntheses," Coll. Vol. II, p. 468.

(−)-3-Methyl-1-hendecanol was obtained from 46.76 g. of ethyl (−)-3-methylhendecanoate ($[\alpha]^{25}_{D}$ −2.34°), 24.6 g. of sodium and 410 cc. of butanol. Distillation gave 32.76 g. (85.8%); b. p. 119° (3–2 mm.); α^{25}_{D} −3.37°; $[\alpha]^{25}_{D}$ −4.06.

The **3,5-dinitrobenzoate** was prepared in 78% yield. Two recrystallizations from pentane furnished the pure product; m. p. 39.9–40.6°; $[\alpha]^{25}_{D}$ −2.71° (acetone, *c*, 8.12).

(+)-3-Methyl-1-hendecanol was prepared from 57.3 g. of ethyl (+)-3-methylhendecanoate ($[\alpha]^{25}_{D}$ +2.33°), 30 g. of sodium and 500 cc. of butanol. Distillation gave 39.7 g. (86.7%); b. p. 118.5–116° (3–1.5 mm.); α^{25}_{D} +3.39°; $[\alpha]^{25}_{D}$ +4.08°.

The **3,5-dinitrobenzoate** was prepared in 84% yield; m. p. 39.5–40.5°; $[\alpha]^{25}_{D}$ +3.09° (acetone, *c*, 8.10).

***dl*-1-Bromo-3-methylhendecane (VIII).**—*dl*-3-Methyl-1-hendecanol (27.1 g.) was treated with gaseous hydrobromic acid by the procedure of Reid, Ruhoff and Burnett.[34] The product was distilled (P45) to give 30.4 g. (86.2%); b. p. 112–112.5° (1.5 mm.). A small forerun of 0.26 g., b. p. 112.5° (2 mm.), was discarded. A center cut, b. p. 112–112.2° (1.5 mm.), was used for analysis and constants: d^{20} 1.0421, d^{25} 1.0379, d^{30} 1.0334, d^{35} 1.0290; n^{25}_{D} 1.4569.

Anal. Calcd. for $C_{12}H_{25}Br$: Br, 32.07. Found: Br, 32.04.

(+)-1-Bromo-3-methylhendecane was prepared in 89.4% yield from 30.4 g. of (−)-3-methyl-1-hendecanol ($[\alpha]^{25}_{D}$ −4.06°) and gaseous hydrogen bromide. The product was distilled (P45) to give 36.4 g.; b. p. 102–105° (1 mm.); α^{25}_{D} +5.36°; $[\alpha]^{25}_{D}$ +5.17°.

(−)-1-Bromo-3-methylhendecane was prepared similarly in 69.7% yield from 37.5 g. of (+)-3-methyl-1-hendecanol ($[\alpha]^{25}_{D}$ +4.08°); yield 34.9 g.; b. p. 104–108° (1 mm.); α^{25}_{D} −5.36°; $[\alpha]^{25}_{D}$ −5.16°.

ω-Carbethoxycaproyl Chloride.[35a,d]—Ethyl hydrogen pimelate[35] was prepared by adaptation of the partial esterification method of Swann, Oehler and Buswell.[36] Distillation of the product (V90) gave the half ester in 44% yield (or 60% yield deducting the recovered diester); b. p. 159.5–160° (4 mm.). The half ester was treated with phosphorus pentachloride[5a] to give the ester acid chloride in 94% yield; b. p. 125–121° (6–3 mm.).

Ethyl *dl*-7-Keto-10-methyloctadecanoate (IX).—The preparation followed the general procedure for the synthesis of keto esters by the reaction of a dialkylcadmium compound with an ester acid chloride.[1,5a,5b,37] The preparation employed 2.43 g. of magnesium, 24.92 g. of *dl*-1-bromo-3-methylhendecane, 11 g. of cadmium chloride and 16.54 g. (0.8 equiv.) of ω-carbethoxycaproyl chloride. Distillation (P45) at 0.5 mm. gave: (a) 3.12 g., b. p. 49.58°; (b) 1.32 g., b. p. 90–95°; (c) 19.13 g., b. p. 175–193° (95% at 185–193°). There was 3.7 g. of residue. The yield (fraction (c)) was 56.2%, based on the bromide, or 70.3%, based on the acid chloride. A center cut was used for analysis and constants: d^{20} 0.896, d^{25} 0.893, d^{30} 0.889, d^{35} 0.886; n^{25}_{D} 1.4477.

Anal. Calcd. for $C_{21}H_{40}O_3$: sapn. equiv., 340.6. Found: sapn. equiv., 348.7, 350.6 (center cut); 368.7 (sample taken at end of fraction (c)).

The presence in fraction (c) of 9,14-dimethyldocosane (see below) from coupling of the Grignard reagent caused the divergence from theoretical saponification equivalents. Since it was expected that the hydrocarbon could be separated more readily at a later stage no effort was made to effect complete purification of the keto ester.

Fraction (a), principally **3-methylhendecane**, was washed with concentrated sulfuric acid and distilled; 1.8 g., b. p. 109–110° (32 mm.), n^{25}_{D} 1.4213.

Anal. Calcd. for $C_{12}H_{26}$: C, 84.61; H, 15.39. Found: C, 85.41; H, 15.26.

Fraction (b) was mainly diethyl pimelate. The acid (0.5 g.) obtained after saponification had m. p. 101.3–104.6°, alone or mixed with authentic pimelic acid.

***dl*-7-Keto-10-methyloctadecanoic acid** was obtained from the ester in 96% yield; m. p. 28–37°. Five crystallizations from pentane gave iridescent short blades, m. p. 38.6–39.9°. A sample of *dl*-acid later prepared by crystallizing equal amounts of both active antipodes melted at 38.3–39.3°.

Anal. Calcd. for $C_{19}H_{36}O_3$: equiv. wt., 312.6. Found: equiv. wt., 311.0.

The **semicarbazone** of the *dl*-keto acid was prepared in 89% yield.[38] Three crystallizations from acetone gave small cubic crystals; m. p. 97.8–98.6°.

Anal. Calcd. for $C_{20}H_{39}O_3N_3$: C, 65.01; H, 10.64. Found: C, 65.14; H, 10.68.

Ethyl (+)-7-Keto-10-methyloctadecanoate was prepared[1,5a] from 36.1 g. of (+)-1-bromo-3-methylhendecane ($[\alpha]^{25}_{D}$ +5.17°), 3.52 g. of magnesium, 16 g. of cadmium chloride and 24.0 g. of ω-carbethoxycaproyl chloride. Distillation of the product (V45) at *ca.* 0.5 mm. gave three fractions: (a) 6.39 g., b. p. 53–56°; (b) 1.74 g., b. p. 96–99°; (c) 25.60 g., b. p. 165–198° (80% at 190–198°), α^{25}_{D} +0.20°; $[\alpha]^{25}_{D}$ +0.22°. There was 7.0 g. of residue.

Fraction (c) contained the keto ester; yield 51.7% (based on bromide) or 64.8% (based on acid chloride). This fraction, however, contained 10–11% of (+)-9,14-dimethyldocosane (see below) which probably caused the observed rotation values to be somewhat greater than those of the pure keto ester.

Fraction (a), chiefly **(−)-3-methylhendecane**, was washed with sulfuric acid and distilled: 3.73 g.; b. p. 101.5–102.5° (20 mm.); α^{26}_{D} −5.95° (micro tube,[39] d^{25} 0.748 (1-cc. pycnometer)); $[\alpha]^{26}_{D}$ −7.96°.

(+)-7-Keto-10-methyloctadecanoic acid was obtained from the ester in 85% yield; m. p. 27–31°. Three crystallizations from pentane gave soft feather-like crystals; m. p. 30.7–32.2°; $[\alpha]^{26}_{D}$ +0.13° (acetone, *c*, 37.6, micro tube).[39]

The **semicarbazone** was prepared in 77% yield; m. p. 73–88°. Three crystallizations from acetone gave small plates; m. p. 94.8–95.4°.

Ethyl (−)-7-keto-10-methyloctadecanoate was prepared from 34.7 g. of (−)-1-bromo-3-methylhendecane ($[\alpha]^{25}_{D}$ −5.16°), 3.39 g. of magnesium, 15 g. of cadmium chloride and 23.0 g. of ω-carbethoxycaproyl chloride. Distillation gave three fractions: (a) 5.44 g., b. p. 61–55° (2–1 mm.); (b) 2.44 g., b. p. 100–102° (*ca.* 0.5 mm.); (c) 25.54 g. (53.9%, based on the bromide, and 67.5%, based on the acid chloride), b. p. 175–195° (*ca.* 0.5 mm.), α^{25}_{D} −0.15°; $[\alpha]^{25}_{D}$ −0.16°. There was 6.6 g. of residue.

Fraction (a), chiefly **(+)-3-methylhendecane**, was washed with sulfuric acid and redistilled: 3.54 g.; b. p. 97–98° (17 mm.); α^{26}_{D} +5.60° (micro tube[39]); $[\alpha]^{26}_{D}$ +7.49°.

(−)-7-Keto-10-methyloctadecanoic acid was prepared from the ester in 92% yield; m. p. 29–31°. Two crystallizations from pentane gave pure acid; m. p. 31.1–32.1°; $[\alpha]^{26}_{D}$ −0.07° (acetone, *c*, 27.9, micro tube[39]).

The **semicarbazone** was prepared in 46% yield; m. p. 71–89°. Three crystallizations from acetone gave small plates; m. p. 94.8–95.4°. The mixture with an approximately equal amount of the dextrorotatory antipode melted at 93.5–96°.

Ethyl *dl*-10-Methyloctadecanoate (X).—Ethyl *dl*-7-keto-10-methyloctadecanoate (11.36 g.) was reduced with

alcoholic hydrogen chloride and amalgamated zinc by the general procedure of Schneider and Spielman.[40] The ester was extracted from the diluted alcoholic mixture and distilled at *ca.* 0.5 mm. (P45). After a forerun of 1.25 g., b. p. 81–160°, was removed the main fraction (9.33 g., 85.7%) distilled at 160–172°.

The main product was contaminated with about 10% of unsaponifiable material as shown by analytical saponification of an intermediate fraction, b. p. 168.5–169° (*ca.* 0.5 mm.) (calcd.: sapn. equiv., 326.6. Found: sapn. equiv., 359.2). Purified ethyl ester was prepared later by esterification of the acid remaining in the combined mother liquors after crystallization of the *dl*-10-methyloctadecanoic acid (below). This ester (2.15 g.), formed and worked up by essentially the procedure used to make the esters of 3-methylhendecanoic acids, was distilled from a Claisen flask; b. p. 178–182° (2 mm.); d^{20} 0.862, d^{25} 0.858, d^{30} 0.854, d^{35} 0.852 (all densities in 1-cc. pycnometer); n^{25}_{D} 1.4447.

Anal. Calcd. for $C_{21}H_{42}O_2$: sapn. equiv., 326.6. Found: sapn. equiv., 323.7.

Ethyl (+)-10-methyloctadecanoate was prepared by reduction[40] of 21.72 g. of ethyl (+)-7-keto-10-methyloctadecanoate ($[\alpha]^{25}_{\mathrm{D}}$ +0.22°). The ester was distilled (V45) at *ca.* 0.5 mm. pressure. A forerun of 2.56 g., b. p. 91–160°, was removed and the main product (18.01 g., 86.5%) distilled at 160–182° (90% at 169–182°); α^{25}_{D} +0.12°; $[\alpha]^{25}_{\mathrm{D}}$ +0.14°. The saponification equivalent was 382 (theory, 326.6) indicating the presence of 14% unsaponifiable impurity.

Ethyl (−)-10-methyloctadecanoate was obtained similarly by the reduction of 20.11 g. of ethyl (−)-7-keto-10-methyloctadecanoate ($[\alpha]^{25}_{\mathrm{D}}$ −0.16°); yield, 16.87 g. (94.2%); b. p. 169–183° (*ca.* 0.5 mm.), (90% at 173–181°); α^{25}_{D} −0.13°; $[\alpha]^{25}_{\mathrm{D}}$ −0.15°; sapn. equiv., 370 (theory, 326.6, hence 12% impurity). A forerun of 2.05 g., b. p. 91–169°, was also obtained.

***dl*-10-Methyloctadecanoic Acid (XI)**.[7]—Ethyl *dl*-10-methyloctadecanoate (7.66 g.) was saponified with 100 cc. of 3% alcoholic potassium hydroxide and the solution was then diluted with an equal volume of water. The solution was extracted with three 35-cc. portions of hexane to extract unsaponifiable material. The extracts were washed successively with four 50-cc. portions of water, with addition of a little ethanol to break up emulsions. The hexane extracts were combined and reserved for the isolation of *dl*-9,14-dimethyldocosane (below).

The acid obtained from the combined aqueous phases was solid at 22° but liquid at 25°; yield, 5.38 g. (77.2%). This acid was crystallized once from pentane and three times from acetone (cooling in a mixture of hydrochloric acid and ice) to furnish 2.42 g. of purified acid as fine hard crystals; m. p. 25.4–26.1°; n^{25}_{D} 1.4512 (supercooled melt). (A mixture of approximately equal amounts of the *d*- and *l*-forms prepared later and crystallized from acetone had m. p. 21–25.8°.) For an unrecrystallized sample of *dl*-10-methyloctadecanoic acid prepared by another method Spielman[7] reported m. p. 20–21°, n^{25}_{D} 1.4512.

Anal. Calcd. for $C_{19}H_{38}O_2$: equiv. wt., 298.5. Found: equiv. wt., 298.8.

The **amide** was made by a previously described method[5b] and crystallized three times from hexane. It then had m. p. 77.5–79.2°. A sample of the amide prepared by Spielman[7] and kindly furnished by Dr. R. J. Anderson had m. p. 75.2–78.1° (Spielman[7] reported m. p. 76–77°).

The **tribromoanilide** was made by the method employed by Cason[5a] and after two crystallizations from methanol and five from acetone had m. p. 93.4–93.9°. Spielman[7] recorded m. p. 93–94°.

(+)-10-Methyloctadecanoic Acid.—Ethyl (+)-10-methyloctadecanoate (17.87 g., $[\alpha]^{25}_{\mathrm{D}}$ +0.14°) was saponified and the neutral material extracted in the manner described for the *dl*-form. From the combined aqueous layers there was obtained 11.8 g. (72.4%) of crude acid. Recrystallization of this acid once from acetone and once from pentane, preferably working in a cold room at 0–5°, furnished 8.16 g. of pure acid; m. p. 13–13.5° (uncor., mass method); f. p. 13° (uncor.), n^{25}_{D} 1.4512; α^{26}_{D} +0.08° (micro tube[39]); $[\alpha]^{26}_{\mathrm{D}}$ +0.09° (d^{25} 0.88[7]).

Anal. Calcd. for $C_{19}H_{38}O_2$: equiv. wt., 298.5. Found: equiv. wt., 300.8.

The amide, prepared as before,[5b] was crystallized five times from acetone: m. p. 75.5–76.4°; $[\alpha]^{25}_{\mathrm{D}}$ +0.10° (chloroform, *c*, 5.65, micro tube[39]).

The tribromoanilide, after three crystallizations from methanol and four from acetone, melted at 93.2–95.2°; $[\alpha]^{25}_{\mathrm{D}}$ +0.15° (chloroform, *c*, 15.3, micro tube[39]).

(−)-10-Methyloctadecanoic Acid.—Ethyl (−)-10-methyloctadecanoate (15.80 g., $[\alpha]^{25}_{\mathrm{D}}$ −0.15°) was saponified and the neutral material extracted as described for the *dl*-ester; yield, 13.1 g. (85.7%) of crude acid; f. p. 10.5°. The acid was recrystallized once from pentane and three times from acetone to give 7.15 g. of purified acid; m. p. 12.8–13.4°; n^{25}_{D} 1.4514, α^{26}_{D} −0.045° (micro tube[39]); $[\alpha]^{26}_{\mathrm{D}}$ −0.05°.

Anal. Calcd. for $C_{19}H_{38}O_2$: equiv. wt., 298.5. Found: equiv. wt., 299.2.

The **amide** was crystallized five times from acetone; m. p. 75.1–76.3°; $[\alpha]^{24}_{\mathrm{D}}$ −0.09° (chloroform, *c*, 25.4, micro tube[39]).

The **tribromoanilide** was obtained pure only after four recrystallizations from methanol and eight from acetone; m. p. 94.0–95.3°; $[\alpha]^{26}_{\mathrm{D}}$ −0.11° (chloroform, *c*, 28.2, micro tube[39]).

***dl*-9,14-Dimethyldocosane**.—The neutral extract from the saponification of ethyl *dl*-10-methyloctadecanoate was concentrated and the residue distilled as a yellow oil; b. p. 195–200° (4 mm.). After treatment with concentrated sulfuric acid the hydrocarbon was redistilled to furnish 1.14 g.; b. p. 186–188° (2 mm.); n^{25}_{D} 1.4475.

Anal. Calcd. for $C_{24}H_{50}$: C, 85.12; H, 14.88. Found: C, 85.35; H, 14.29.

(+)-9,14-Dimethyldocosane, similarly obtained as the neutral material from the saponification of ethyl (+)-10-methyloctadecanoate, weighed 1.85 g., b. p. 195–198° (3 mm.); α^{26}_{D} +0.50° (micro tube[39]); $[\alpha]^{26}_{\mathrm{D}}$ +0.63° (d^{25}, see (−)-form).

(−)-9,14-Dimethyldocosane, obtained as the neutral material from the saponification of ethyl (−)-10-methyloctadecanoate, weighed 1.26 g., b. p. 190–195° (2 mm.); α^{25}_{D} −0.48° (micro tube[39]); d^{25} 0.800 (1-cc. pycnometer); $[\alpha]^{25}_{\mathrm{D}}$ −0.60°.

Summary

1. A method for the total resolution of 2-decanol has been worked out. The use of this alcohol for the preparation of the active 3-methylhendecanoic acids by way of the malonic ester synthesis has afforded a means to prepare these acids in maximum antipodal purity.

2. The synthesis of the three stereoisomeric forms of 10-methyloctadecanoic acid has been accomplished by extension of the chain of the three stereoisomers of 3-methylhendecanoic acid.

3. Tuberculostearic acid has been shown to be (−)-10-methyloctadecanoic acid by comparison of the acid, amide and tribromoanilide with the (+)- and (−)-forms of 10-methyloctadecanoic acid and their corresponding derivatives.

The Structure of an Enzymatically Synthesized Reducing Disaccharide D-Glucosido-L-arabinose

BY W. Z. HASSID, M. DOUDOROFF, A. L. POTTER AND H. A. BARKER

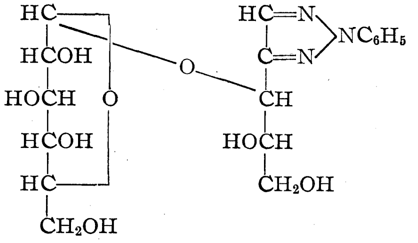
It has been shown that sucrose phosphorylase preparations from *Pseudomonas saccharophila* catalyze the reversible reaction between glucose-1-phosphate and certain ketose sugars forming disaccharides with the liberation of inorganic phosphate. Thus, sucrose and several other non-reducing disaccharides, namely, D-glucosido-L-sorboside, D-glucosido-D-xyloketoside, and D-glucosido-L-araboketoside[1,2,3,4] were prepared.

It appeared at first as though this enzyme were only capable of catalyzing the reaction between ketose monosaccharides and glucose-1-phosphate. Since these disaccharides are non-reducing and their ketose constituents exist in the furanose form, they can be considered as analogs of sucrose. However, it was later discovered that the same enzyme will catalyze a reaction between glucose-1-phosphate and L-arabinose to form a reducing disaccharide having no obvious structural relation to sucrose or to any of the previously prepared sucrose analogs.[4]

The present investigation is concerned with the structural configuration of the crystalline reducing disaccharide formed from α-D-glucose-1-phosphate and L-arabinose under the influence of the enzyme from *Pseudomonas saccharophila.*

This disaccharide reduces Fehling and alkaline ferricyanide solutions. It contains two molecules of water of crystallization and has a specific rotation $[\alpha]_D$ in water of +156°. On hydrolysis with acid it produces one mole of D-glucose and one mole of L-arabinose. The phenylosotriazole derivative of the disaccharide prepared according to Hudson, *et al.*,[5] is readily hydrolyzed with acid to D-glucose and L-arabinose phenylosotriazole, showing that the L-arabinose constitutes the free reducing unit in the disaccharide. Like the previously isolated disaccharides, it is formed by the agency of phosphorylase from *Pseudomonas saccharophila* as a result of "de-phosphorolytic" condensation involving α-D-glucose-1-phosphate, indicating that glucose exists in the disaccharide as the α-form.

On oxidation of the phenylosotriazole derivative of the disaccharide with sodium periodate, three moles of periodate are consumed with the formation of one mole each of formic acid and formaldehyde per mole of phenylosotriazole derivative. The structure of this compound is, therefore, 3-[α-D-glucopyranosido]-L-arabinose phenylosotriazole in which D-glucose is attached through carbon atom 1 to carbon atom 3 of L-arabinose as shown by Formula (I).



1. 3-[α-D-Glucopyranosido]-L-arabinose phenylosotriazole

If the D-glucose in the D-glucopyranosido-L-arabinose phenylosotriazole were attached to carbon atom 4 of the L-arabinose derivative, oxidation of this compound with sodium periodate would require two moles of periodate and would liberate one mole of formic acid with no formaldehyde production. Junction of D-glucose to carbon atom 5 of the L-arabinose phenylosotriazole would require three moles of periodate whereby one mole of formic acid would be produced, and no formaldehyde formed.

On methylation of the disaccharide with dimethyl sulfate and sodium hydroxide a hexamethylmethyl derivative of the carbohydrate was obtained. When this fully methylated derivative (II) was hydrolyzed with acid, 2,3,4,6-tetramethyl-D-glucose (III) and dimethyl-L-arabinose (IV) were produced. Since position 3 in the L-arabinose component (I) was shown to be occupied in glycosidic linkage with D-glucose, the dimethyl-L-arabinose could be either the 2,5- or 2,4-dimethyl derivative (IV), depending on whether the L-arabinose unit originally exists in the disaccharide in the furanose or pyranose form. The ring type of the L-arabinose was ascertained by subjecting the dimethyl-L-arabinose to oxidation with sodium periodate, after it had been oxidized with hypoiodite to the corresponding lactone (V) and subsequently hydrolyzed to the straight chain, dimethyl-L-arabonic acid (VI).

If the dimethyl derivative were the 2,5-dimethyl-L-arabonic acid, it would possess a pair of adjacent hydroxyls, on positions 3 and 4, which on oxidation with sodium periodate would consume one mole of periodate in the reaction. On the other hand, the 2,4-dimethyl-L-arabonic acid (VI), lacking a pair of adjacent hydroxyls, cannot

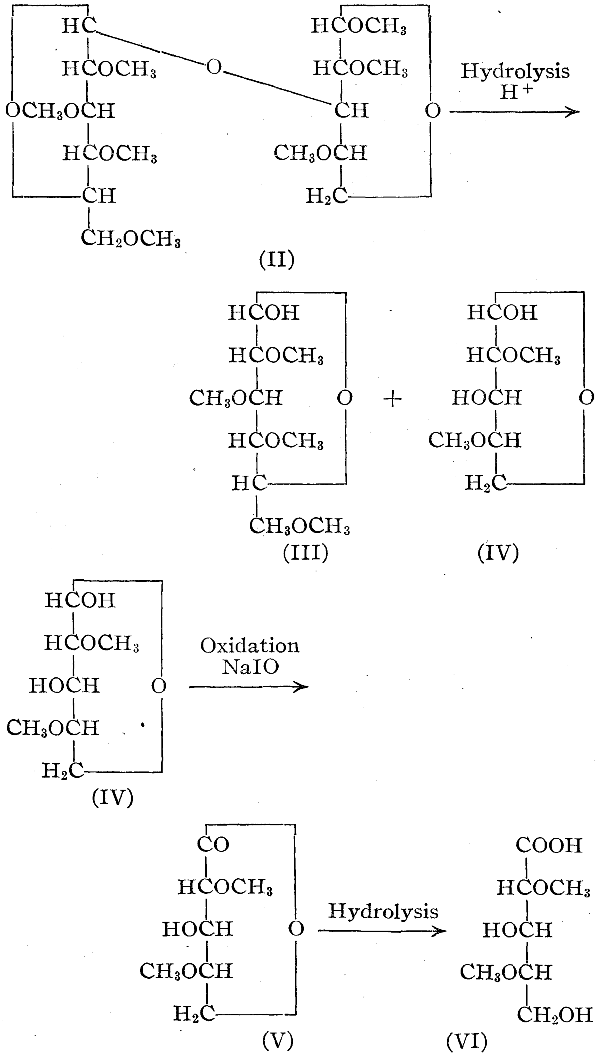
be oxidized. Actually, no periodate was consumed when the dimethyl-L-arabonic acid was treated with this reagent. This shows that the dimethyl derivative is 2,4-dimethyl-L-arabonic acid. The free hydroxyl in position 3 is obviously restored in the dimethyl-L-arabinose when the methylated disaccharide is hydrolyzed; the hydroxyl in position 5 is formed when its internal ring is broken in the process of hydrolysis of the lactone to dimethyl-L-arabonic acid, which is a straight chain compound.



A more direct confirmation that the dimethyl-L-arabinose possesses a pyranose configuration was obtained from the study of the rate with which its lactone derivative is hydrolyzed to the open chain acid. Haworth, *et al.*,[6] found that the six-membered ring sugar lactones hydrolyze in water to their corresponding straight chain acids at a distinctly greater rate than the five-membered ring sugar lactones. The gamma lactones require approximately two weeks for complete opening of the ring, while the delta lactones are converted completely into the open chain acids within a few hours. It is thus possible to determine whether a given lactone has a furanose or pyranose configuration.

When the dimethyl-L-arabono lactone was dissolved in water, it was found to be almost completely hydrolyzed within four hours. This was indicated by a change of its rotation from $[\alpha]_D$ + 60 to 24° (Fig. 1). A constant value of $[\alpha]_D$ +17° was reached within less than twenty-four hours. Since the rate of change in rotation of this methylated lactone due to hydrolysis is high, it strongly indicates that the lactone possesses a pyranose configuration. This observation confirms the periodate oxidation data, showing that the dimethyl derivative is 2,4-dimethyl-L-arabonic acid.

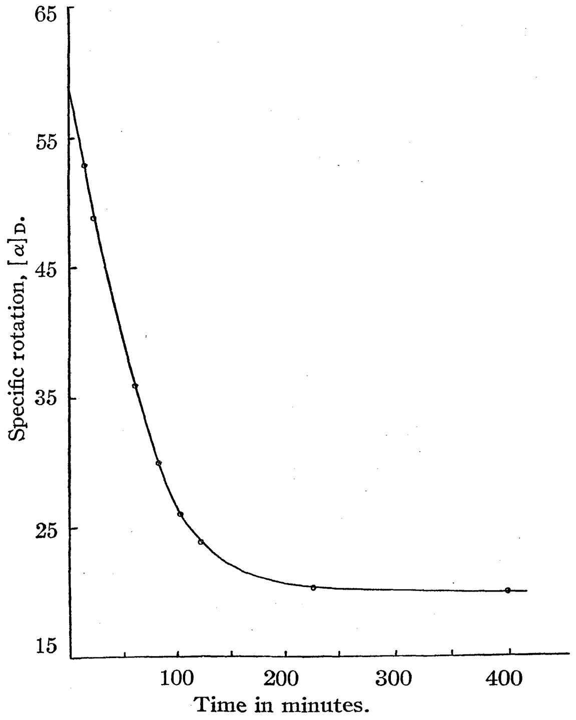


Fig. 1.—Hydrolysis of dimethyl-L-arabonolactone.

On the basis of these results the structural formula for this reducing disaccharide may be written as in Fig. 2.

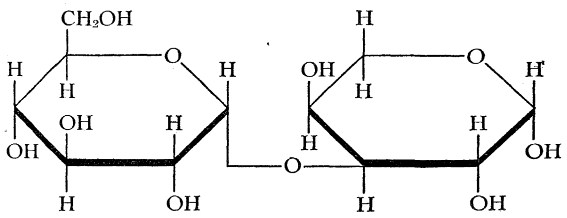

Fig. 2.

Experimental

Enzymatic Synthesis of D-Glucosido-L-arabinose.—A mixture of 30 g. of glucose-1-phosphate, 16 g. of L-arabinose and 400 ml. of 0.1 *M* barium acetate was incubated for eighteen hours at *p*H 7.0 and 35° in the presence of enzyme extracted from the bacteria *Pseudomonas saccharophila* by the method previously described.[1,2] The unused glucose-1-phosphate was removed by precipitation with alcohol and the unused L-arabinose by fermentation with a selected strain of *Escherichia coli*.[7] After passage through ion exchange columns and concentration of the solution *in vacuo*, the sugar was crystallized from absolute alcohol in the usual manner.[2,3] The yield was 5.4 g.

Properties of the Disaccharide.—The disaccharide is hygroscopic, very soluble in water and has a sweet taste. It reduces Fehling or alkaline ferricyanide solution and after hydrolysis with acid and subsequent neutralization gives the orcinol–hydrochloric acid reaction (Bial), characteristic for pentose sugars. This reducing disaccharide does not give the diazouracil reaction[8] specific for sucrose and the other synthetic disaccharides[2,3] which apparently contain the type of glycosidic glucose–fructose linkage existing in sucrose.

The carbohydrate is practically unaffected by yeast invertase and has a much greater resistance to acid hydrolysis than the previously synthesized non-reducing disaccharides, containing ketose units. Its rate of hydrolysis with acid is about one-third as great as that of maltose.

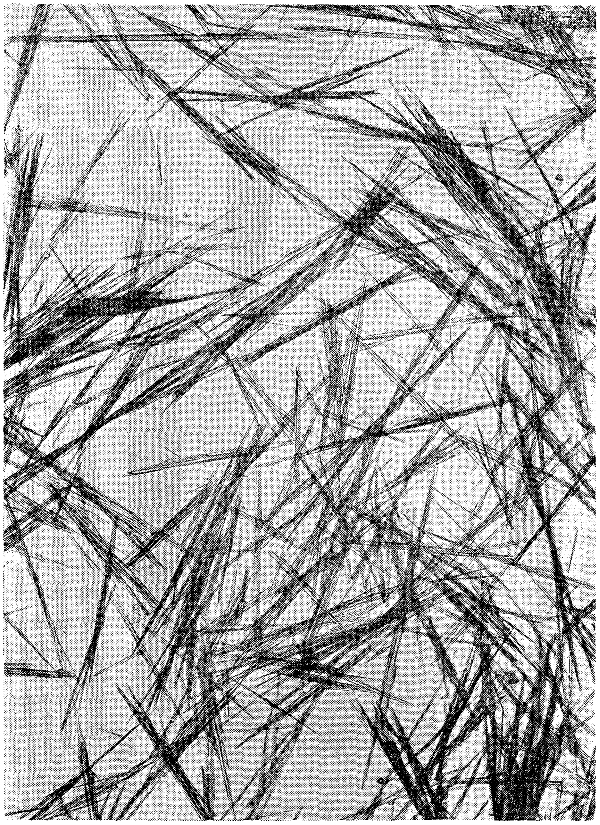

Fig. 3.—Phenylosazone of D-glucosido-L-arabinose (× 93).

Anal. Calcd. for $C_{11}H_{20}O_{10}\cdot 2H_2O$: C, 37.93; H, 6.90. Found: C, 38.26; H, 6.89; specific rotation $[\alpha]_D$ +156°, (in water, *c*, 2).

Hydrolysis of the Disaccharide and Identification of Products.—A 0.02-g. sample of the disaccharide was hydrolyzed with 0.5 *N* hydrochloric acid at 100° for six hours. Analysis of the hydrolyzed solution for reducing sugars by oxidation with ferricyanide,[9] showed a reducing value of 96% calculated on the basis of an equimolar mixture of glucose and L-arabinose and taking into consideration that the disaccharide contains two molecules of water of crystallization. After removal of the glucose from the hydrolyzate by fermentation with *Tortula monosa*, an osazone was prepared which was identified as arabosazone. Determination of pentose on an original sample of the disaccharide gave the theoretical value of L-arabinose.[10] A 2% solution of the disaccharide in 0.5 *N* hydrochloric acid hydrolyzed at 100° gave a final specific rotation $[\alpha]_D$ +71.0°. The calculated rotation of a hydrolyzed disaccharide consisting of D-glucose and L-arabinose and containing two molecules of water of crystallization is $[\alpha]_D$ +72.3°.

Rate of Hydrolysis of the Disaccharide.—The hydrolysis of a 2% solution of the D-glucosido-L-arabinose in 6 *N* hydrochloric acid was followed by observing the change of rotation at 50°. The rate of hydrolysis was compared with that of a similar solution of maltose under identical conditions. The course of hydrolysis of this disaccharide was represented by a logarithmic curve, indicating a first order reaction. The velocity constant *K* of the reaction is 4.37×10^{-3}. The velocity constant *K* of a 2% maltose solution, determined under the same conditions, is 1.28×10^{-2}, showing that the rate of hydrolysis of the D-glucosido-L-arabinose with acid is approximately one-third as great as that of maltose.

Phenylosazone.—One gram of the D-glucosido-L-arabinose was mixed in a test-tube with 2 g. of phenylhydrazine hydrochloride and 3 g. of sodium acetate. The mixture was dissolved in 14 ml. of water and heated on a steam-bath for thirty minutes. Upon cooling to room temperature crystals of the phenylosazone separated out, which appeared under the microscope as yellowish-green needles (Fig. 3). After placing the test-tube with the contents in the refrigerator for several hours at 4° the osazone was filtered, recrystallized from 50% alcohol and dried *in vacuo* at 30°. The yield was 0.735 g.

D-Glucosido-L-arabinose Phenylosotriazole.—A suspension of 0.50 g. of phenylosazone derivative of the new disaccharide was dissolved in 50 ml. of water, heated to the boiling point and a solution of 0.265 g. of copper sulfate pentahydrate (1.1 molecular equivalents) in 5 ml. of water was added. The mixture was heated under a reflux condenser for thirty minutes from the time of addition of the copper sulfate solution, then cooled and filtered. The filtrate, after neutralization with 0.20 g. of calcium carbonate, was extracted with ether to remove aniline. The solution was then run through ion exchange columns (Duolite C-3 and A-3, obtained from the Chemical Process Co., San Francisco) to remove inorganic impurities and evaporated to dryness *in vacuo* at 50°. The residue was extracted with hot alcohol, filtered, and the extract evaporated *in vacuo* to a small volume. Upon the addition of petroleum ether and upon stirring, crystals of the phenylosotriazole derivative were obtained. After cooling to 0°, the crystals were filtered on a sintered glass filter, washed with petroleum ether three times and dried *in vacuo* at 40°. The product was then recrystallized from 3 ml. of hot alcohol. A yield of 0.276 g. was obtained.

Anal. Calcd. for $C_{17}H_{23}N_3O_8$: C, 51.37; H, 5.83; N, 10.58. Found: C, 50.89; H, 5.82; N, 10.38; specific rotation, $[\alpha]_D$ +80° (in water, *c*, 2); melting point, 126.5°.

Oxidation of the D-Glucosido-L-arabinose Phenylosotriazole with Sodium Periodate.—A 0.0397-g. sample

---

[7] The removal by extraction of its osazone derivative was precluded by the reducing nature of the synthesized carbohydrate.

[8] H. W. Raybin, This Journal, **55**, 2603 (1933); **59**, 1402 (1937).

[9] W. Z. Hassid, *Ind. Eng. Chem., Anal. Ed.*, **9**, 228 (1937).

[10] W. Mejbaum, *Z. physiol. Chem.*, **258**, 117 (1939).

(0.1 millimole) of the derivative was oxidized at room temperature with 0.5 *M* sodium periodate. The amount of periodate consumed in the reaction and the amount of formic acid liberated was estimated by the usual procedure.[11] The formaldehyde produced in the reaction was determined photocolorimetrically with 1,8-dihydroxynaphthalene-3,6-disulfonic acid by the method of MacFayden.[12]

The results showed that three moles of periodate were consumed, giving rise to one mole of formic acid and one mole of formaldehyde in the oxidation of one mole of the phenylosotriazole derivative.

Acetylation.—A 0.1-g. sample of the disaccharide was acetylated with 0.46 ml. of acetic anhydride in the presence of pyridine at 0° as previously described.[1] The acetylated derivative was insoluble in water but soluble in chloroform and acetone. The yield was 0.11 g.

Anal. Calcd. for $C_{11}H_{13}O_{10}(CH_3CO)_7$: CH_3CO, 49.67. Found: CH_3CO, 48.88; specific rotation, $[\alpha]_D$ +111° (in chloroform, *c*, 2).

Methylation of D-Glucosido-L-arabinose.—The disaccharide was methylated by the method of Haworth and Leitch[13] as follows: One gram of the sugar was dissolved in a minimum of hot water (approximately 1 ml.) and the solution cooled to 30°. A total of 3.8 ml. of methyl sulfate and 8 ml. of 30% sodium hydroxide were added in eight equal portions with vigorous stirring. The first portion (0.5 ml.) of the methyl sulfate and that of the sodium hydroxide (1 ml.) were added at 30°. It is important that the sodium hydroxide be added very slowly so as not to allow the solution to become alkaline at any time during the methylation procedure. The temperature was then raised to 40° and the treatment was repeated with similar portions of methyl sulfate and sodium hydroxide solution. The mixture was then kept overnight at room temperature and on the following day tested for its reducing value. It was found to have no reducing property. Thereafter the temperature was raised to 60° and a third portion corresponding to one-eighth of the original volume of methyl sulfate was introduced and a similar proportion of sodium hydroxide was added drop by drop, with vigorous stirring. The remainder of the reagents was added at 70° in the same order and in similar fractions, stirring being continued throughout the addition. Finally the temperature was raised to 100° for a period of half an hour and the solution allowed to cool to room temperature. The solution was dried with anhydrous sodium sulfate, filtered and the chloroform distilled off. The yield was 1.03 g.

The incompletely methylated product was further methylated by the method of Pacsu and Trister[14] by dissolving in ether and treating with sodium and then methyl iodide. The yield obtained of the hexamethylmethyl D-glucosido-L-arabinose was 0.58 g.

Anal. Calcd. for $C_{18}H_{34}O_{10}$: OCH_3, 52.91. Found: 51.70; specific rotation, $[\alpha]_D$ +122° (in water, *c*, 2.34).

Hydrolysis of the Methylated Disaccharide and Separation of the 2,3,4,6-Tetramethyl-D-glucose and Dimethyl-L-arabinose.—The methylated D-glucosido-L-arabinose (0.56 g.) was dissolved in 20 ml. of 2 *N* hydrochloric acid and the solution was heated on a steam-bath for three hours. The hydrolyzate was cooled and extracted six times with equal volumes of chloroform. The solution was evaporated to a small volume on the steam-bath and dried by contact with a mixture of anhydrous sodium sulfate and anhydrous magnesium sulfate for forty minutes. A small amount of charcoal was then added and after fifteen more minutes the mixture was filtered. After evaporating this solution to dryness *in vacuo*, a yield of 0.31 g. (Fraction I) of crude 2,3,4,6-tetramethyl-D-glucose was obtained. The specific rotation of this product (in water, *c*, 1.67) was $[\alpha]_D$ +87°.

The tetramethylglucose was purified as follows: The crude product (Fraction I) was dissolved in 20 ml. of water, extracted six times with equal volumes of chloroform and the chloroform dried with a mixture of anhydrous sodium sulfate and anhydrous magnesium sulfate. A small amount of charcoal was then added and after a few minutes the solution was filtered. Upon evaporation of the chloroform solution to dryness, a yield of 0.27 g. of 2,3,4,6-tetramethyl-D-glucose was obtained.

Anal. Calcd. for $C_6H_8O_2(OCH_3)_4$: OCH_3, 52.6. Found: OCH_3, 51.6; specific rotation, $[\alpha]_D$ +81° (in water, *c*, 2).

The aqueous solution left after Fraction I was separated was again extracted six times with equal volumes of chloroform and the chloroform was evaporated, dried and clarified as before. Upon evaporation to dryness, 0.02 g. (Fraction II) of sirup was obtained. This small amount of sirup, probably dimethylarabinose, was discarded.

The aqueous solution contained practically all the dimethyl-L-arabinose, inasmuch as the dimethyl arabinose derivative is greatly in favor of the aqueous phase. The aqueous solution was passed through a 140-ml. capacity Duolite A-3 column to adsorb the hydrochloric acid. The column was washed with six volumes of water and the combined solutions evaporated to dryness *in vacuo*. The residue was then extracted with chloroform, clarified with charcoal, filtered and evaporated to dryness again. The yield of dimethyl-L-arabinose sirup was 0.180 g. (Fraction III).

Anal. Calcd. for $C_5H_8O_3(OCH_3)_2$: OCH_3, 34.8. Found: OCH_3, 34.2; specific rotation, $[\alpha]_D$ +61° (in alcohol, *c*, 1.56).

Oxidation of Dimethyl-L-arabinose to its Lactone.—The oxidation of the dimethyl-L-arabinose was carried out by a modified method of Goebel.[15] The sirup (0.165 g.) was dissolved in 33 ml. of 0.3 *N* barium iodide–iodine solution (7.5 g. of barium iodide and 3.81 g. of iodine dissolved in 100 ml. of water) to which 50 ml. of 0.4 *N* barium hydroxide was added in three minutes at constant rate of flow while stirring. The mixture was allowed to stand for fifteen minutes and was then acidified with 0.925 ml. of concentrated sulfuric acid which was diluted with 7.5 ml. of water. An excess of lead carbonate (7.5 g.) was immediately added and the mixture was rapidly stirred until it became neutral to congo red. The precipitate was permitted to settle and the supernatant liquid decanted. The precipitate was washed several times by decantation. The supernatant liquid and the washings, containing the methylated arabonate, was evaporated *in vacuo*, thus removing the iodine, and the concentrated solution filtered and the residue washed with water. The filtrate was then treated with 0.1 g. of silver sulfate to precipitate the iodide. The precipitate was filtered and the filtrate was treated with hydrogen sulfide to remove the excess silver and lead and filtered again. The solution was neutralized with barium hydroxide, allowed to stand for a few hours and filtered. It was then passed through a 25-ml. capacity Duolite C-3 column and washed with several volumes of water. The solution was concentrated *in vacuo* to dryness, adding water several times during the course of distillation, in order to remove any volatile acids that might be present. The dry residue was extracted with hot alcohol and the alcohol evaporated to dryness *in vacuo*. The yield of dimethyl-L-arabonic lactone was 0.14 g. When a sample of 0.0295 g. of the lactone was neutralized with 0.1 *N* sodium hydroxide, 1.50 ml. of this reagent was consumed. The theoretical requirement is 1.68 ml. of 0.1 *N* sodium hydroxide.

Anal. Calcd. for $C_5H_6O_3(OCH_3)_2$: OCH_3, 35.2. Found: OCH_3, 35.2.

Hydrolysis of Dimethyl-L-arabonolactone.—A sample of 0.0492 g. of the lactone was dissolved in 5 ml. of water and its rate of hydrolysis was followed by observing the

[15] W. F. Goebel, *J. Biol. Chem.*, **72**, 809 (1927).

change of rotation in a polariscope. It was found that the lactone was almost completely hydrolyzed to the acid within four hours. A change from the initial rotation of [α]D +60° to +24° occurred within that time. After twenty-four hours the rotation had reached [α]D +17°, which remained constant thereafter (Fig. 1). Since the rate of change in the rotation of this lactone due to hydrolysis is high, it is concluded that this methylated lactone, and therefore also the original pentose unit, possesses the pyranose configuration.

Oxidation of the Dimethyl-D-arabonic Acid.—A 0.017-g. sample of the lactone was oxidized by allowing it to remain at room temperature with 0.5 *M* sodium periodate[11] for thirty hours. In aqueous solution the lactone is converted to the straight chain acid in a few hours. Analysis of the solution showed that no periodate was used up, indicating that the substance was not oxidized, apparently, due to the fact that it did not contain any adjacent free hydroxyl groups. When a similar sample of 2,3,6-trimethylgluconic acid was oxidized with periodate under the same conditions, one mole of periodate was consumed in the reaction.

Acknowledgment.—The work reported in this paper was supported in part by a grant from the Corn Industries Research Foundation.

Summary

A reducing crystalline disaccharide consisting of D-glucose and L-arabinose has been synthesized from glucose-1-phosphate and L-arabinose by the agency of a phosphorylase from the organism *Pseudomonas saccharophila.*

On oxidation of the phenylosotriazole derivative of this disaccharide with sodium periodate, three moles of periodate are consumed with the formation of one mole each of formic acid and formaldehyde per mole of phenylosotriazole derivative. These data indicate that in the disaccharide D-glucose is linked through carbon atom 1 to carbon atom 3 of L-arabinose.

Methylation of the disaccharide produced a hexamethylmethyl derivative, which on hydrolysis with acid gave rise to 2,3,4,6-tetramethyl-D-glucose and 2,4-dimethyl-L-arabinose.

Evidence that the dimethyl-L-arabinose possesses the pyranose configuration was obtained from the rate of hydrolysis of the dimethyl-L-arabonolactone derivative to its acid and also from periodate oxidation of this lactone.

On the basis of these data, the new reducing disaccharide may be designated as 3-[α-D-glucopyranosido]-L-arabopyranose.

1,5-Anhydro-4-(β-D-glucopyranosyl)-D-glucitol,[1] 1,5-Anhydro-6-(β-D-glucopyranosyl)-D-glucitol and 1,5-Anhydro-D-galactitol[2]

BY HEWITT G. FLETCHER, JR., AND C. S. HUDSON

The palladium–catalyzed addition of hydrogen to the double bond of an acetylated 2-hydroxyglycal may, because of the new asymmetry introduced at carbon two, give rise to either or both of the predicted diastereomeric sugar alcohol anhydrides. Thus Zervas[3] reduced 2,3,4,6-tetraacetyl-2-hydroxy-D-glucal in a 61% yield to an anhydrohexitol which later was demonstrated[4] to be 1,5-anhydro-D-mannitol (styracitol), while Richtmyer, Carr and Hudson[4c] have more recently succeeded in obtaining a 4% yield of 1,5-anhydro-D-glucitol (polygalitol) by the same process.

The catalytic reduction of 2,3,4-triacetyl-2-hydroxy-D-xylal, which might lead to either 1,5-anhydro-xylitol or 1,5-anhydro-D-arabitol or to both, has recently been investigated[5]; only 1,5-anhydro-xylitol, isolated as its triacetate in a yield of 83%, was obtained.

In addition to the two cases above, the reduction of three other acetylated 2-hydroxy-glycals has been reported in the literature. Maurer and Plötner[6] reduced both heptaacetyl-2-hydroxy-cellobial (I) and heptaacetyl-2-hydroxy-gentiobial (V) in the presence of palladium to corresponding heptaacetyl-1,5-anhydro-(β-D-glucopyranosyl)-hexitols in yields, respectively, of 62 and 53%. The free anhydrides were termed "1.4-glucosido-styracitol" and "1.6-glucosido-styracitol," that is, as derivatives of an anhydride (styracitol) which is now known to have the mannitol configuration. Apparently these names were chosen solely on the assumption that the course of the reduction of the acetates of the two substituted 2-hydroxy-glycals had been similar to that of 2,3,4,6-tetraacetyl-2-hydroxy-D-glucal, which, as mentioned above, appears to give predominantly 1,5-anhydro-D-mannitol. Definitive proof, such as might have been obtained by the hydrolysis of the 1,5-anhydro-(β-D-glucopyranosyl)-hexitols, was apparently not adduced.

A third acetylated 2-hydroxy-glycal, 2,3,4,6-tetraacetyl-2-hydroxy-D-galactal (IX), was reduced in the presence of palladium by Freuden-

berg and Rogers[7] to give, in 70% yield, the tetraacetate of an anhydro-hexitol whose structure as either 1,5-anhydro-D-galactitol (XI) or 1,5-anhydro-D-talitol (X) remained uncertain.

The reductive desulfurization of acetylated 1-thio-aldose derivatives with Raney nickel which has recently been applied to the synthesis of 1,5-anhydro-D-glucitol,[4c,8a] 1,5-anhydro-xylitol[5] and 1,5-anhydro-D-arabitol,[8b] furnishes an easy method for preparing sugar-alcohol 1,5-anhydrides of unequivocal configuration. The present research was designed to afford such authentic anhydrides for comparison with the three reduction products of uncertain configuration mentioned above.

Phenyl 1-thio-β-cellobioside heptaacetate (III), prepared originally by Purves[9] through the condensation of heptaacetyl-α-cellobiosyl bromide with potassium thiophenolate, was subjected in warm ethanolic solution to the action of freshly prepared Raney nickel. The resulting crystalline heptaacetyl-1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol (II), as well as its parent polyalcohol (IV), obtained by catalytic deacetylation, was produced in satisfactory yield and they possessed melting points and rotations (Table I) which were at little variance from the corresponding values reported by Maurer and Plötner for the reduction product of heptaacetyl-2-hydroxy-cellobial. It appears, therefore, that the "1,4-glucosido-styracitol" of these authors is not a mannitol derivative as this name now implies but is 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol, a substituted polygalitol (4-(β-D-glucopyranosyl)-polygalitol).

[a] In chloroform solution. [b] In aqueous solution.

In accord with its structure, 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol (IV) was found on a molar basis to consume three moles of periodate with the simultaneous formation of one mole of formic acid.

Phenyl 1-thio-β-gentiobioside heptaacetate was obtained from β-gentiobiose octaacetate in a manner similar to its cellobiose analog; the substance is classed as a β-pyranose derivative by comparison of its rotation with that of methyl β-gentiobioside heptaacetate and on the strength of the analogy with the similar pair of substances in the cellobiose series (Table II).

TABLE II

COMPARISON OF SOME MOLECULAR ROTATIONS IN THE CELLOBIOSE AND GENTIOBIOSE SERIES

	Mol. wt.	[α]D (CHCl$_3$)	[M]D	Difference
Methyl β-cellobioside heptaacetate	651	−25.1°	−16300	4600
Phenyl 1-thio-β-cellobioside tetraacetate	729	−28.7°	−20900	
Methyl β-gentiobioside heptaacetate	651	−18.9°	−12300	4200
Phenyl 1-thio-β-gentiobioside heptaacetate	729	−22.7°	−16500	

Phenyl 1-thio-β-gentiobioside heptaacetate was also treated with Raney nickel to yield heptaacetyl-1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol (VI). The physical constants of this crystalline compound, together with those of its unacetylated parent (Table I), approached quite closely the constants for the corresponding compounds which Maurer and Plötner obtained through the reduction of heptaacetyl-2-hydroxy-gentiobial (V). It therefore appears that the "1,6-glucosido-styracitol" which these authors recorded is actually 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol, a substituted polygalitol (6-(β-D-glucopyranosyl)-polygalitol).

In conformity with its structure, 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol (VIII) reduces on a molar basis four moles of periodate with the simultaneous liberation of two moles of formic acid.

Reductive desulfurization with Raney nickel of 2′-naphthyl 1-thio-β-D-galactopyranoside tetraacetate (XII), prepared as recently reported by Haskins and Hudson,[10] gave tetraacetyl-1,5-anhydro-D-galactitol (XI). The physical constants of this latter compound as well as of the free crystalline 1,5-anhydro-D-galactitol (Table I) were found to differ markedly from those reported by Freudenberg and Rogers[7] for the comparable substances which they obtained by the reduction of 2,3,4,6-tetraacetyl-2-hydroxy-D-galactal (IX). The optical rotations of the two substances, for instance, were opposite in sign as well as numerically different from those reported by Freudenberg and Rogers. It would therefore appear that the anhydride of these authors is probably 1,5-anhydro-D-talitol (corresponding to X). A study directed to the synthesis of authentic 1,5-anhydro-D-talitol is at present being pursued in this Laboratory.

One of us (H. G. F.) held the Chemical Foundation Research Associateship while carrying out this research. We are indebted to Mr. Charles A.

Experimental[11]

1,5-Anhydro-4-(β-D-glucopyranosyl)-D-glucitol Heptaacetate (II).—Ten grams of phenyl 1-thio-β-cellobioside heptaacetate prepared according to the method of Purves,[9] melting at 225–226°[12] and rotating −28.7° in chloroform (*c*, 1.36), was suspended in 100 ml. of absolute alcohol, treated with approximately 100 g. of freshly prepared Raney nickel in absolute alcohol and then boiled gently for one hour. After cooling, the supernatant solution was decanted and the nickel washed by decantation with three successive 100-ml. portions of boiling absolute alcohol. The combined decantates, after filtration through a fine sintered glass plate, were concentrated at 80° (bath) under a slight vacuum to a volume of 125 ml.; crystallization of the product as a mass of very fine needles was spontaneous. Concentration of the mother liquor afforded a very small quantity of additional material: yield 5.9 g. or 69%. Two recrystallizations from warm 95% ethanol furnished with little loss material melting at 194–195° and rotating +4.0° in chloroform (*c*, 1.39).

1,5-Anhydro-4-(β-D-glucopyranosyl)-D-glucitol heptaacetate is readily soluble in acetone, chloroform and hot alcohol, and relatively insoluble in cold alcohol, water and pentane.

Anal. Calcd. for $C_{26}H_{36}O_{17}$: C, 50.32; H, 5.85. Found: C, 50.51; H, 5.73.

1,5-Anhydro-4-(β-D-glucopyranosyl)-D-glucitol (IV).—Three grams of 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol heptaacetate was deacetylated catalytically with barium methylate to give 1.4 g. (89%) of 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol as minute prismatic needles. Recrystallized from aqueous alcohol, the pure substance melted at 172° and appeared to decompose very slowly at this temperature. In water the compound showed a rotation of +29.3° (*c*, 4.64). It is readily soluble in water, somewhat soluble in alcohol and insoluble in ethyl acetate and pentane.

Anal. Calcd. for $C_{12}H_{22}O_{10}$: C, 44.17; H, 6.79. Found: C, 44.44; H, 6.72.

Sodium Metaperiodate Oxidation of 1,5-Anhydro-4-(β-D-glucopyranosyl)-D-glucitol.—The technique of Jackson and Hudson[13] was employed. The 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol (0.1013 g.) was dissolved in a little water, treated with 5.0 ml. of 0.480 *M* sodium metaperiodate solution and the solution diluted to 25.0 ml. with water. After twenty-four hours at room temperature a 5.0-ml. sample was titrated for formic acid and residual oxidant. On a molar basis the compound consumed 2.99 moles of oxidant while 1.22 moles of formic acid was liberated.

Phenyl 1-Thio-β-gentiobioside Heptaacetate (VII).—The procedure which Purves[9] devised for the preparation of phenyl 1-thio-β-cellobioside heptaacetate gave phenyl 1-thio-β-gentiobioside heptaacetate in a yield of 33% from β-gentiobiose octaacetate. The very fine needle-like crystals obtained by repeated recrystallization from 8 parts of alcohol melted at 172° and rotated in chloroform −22.7° (*c*, 1.64). Comparison of this rotation with that of methyl β-gentiobioside heptaacetate (Table II) indicates that the glycoside is of the β-configuration.

Phenyl 1-thio-β-gentiobioside heptaacetate is readily soluble in acetone, chloroform and boiling alcohol, very sparingly soluble in cold alcohol, and relatively insoluble in water and pentane.

Anal. Calcd. for $C_{32}H_{40}O_{17}S$: C, 52.74; H, 5.53; S, 4.40. Found: C, 52.54; H, 5.35; S, 4.15.

1,5-Anhydro-6-(β-D-glucopyranosyl)-D-glucitol Heptaacetate (VI).—Six grams of phenyl 1-thio-β-gentiobioside heptaacetate was desulfurized with Raney nickel in a manner similar to that described above for its cellobiose analog. Three recrystallizations of the crude product (3.7 g.; 72%), first from 7 parts of warm alcohol, then from a mixture of 1 part acetone and 3 parts of ether, and finally from seven parts of warm alcohol, gave with little loss pure 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol heptaacetate melting at 153° and rotating in chloroform +13.0° (*c*, 1.27).

The compound is soluble in methyl cellosolve, dioxane and ethyl acetate. At elevated temperature it dissolves in *n*-butanol, benzene and alcohol.

Anal. Calcd. for $C_{26}H_{36}O_{17}$: C, 50.32; H, 5.85. Found: C, 50.49; H, 5.80.

1,5-Anhydro-6-(β-D-glucopyranosyl)-D-glucitol (VIII).—Two grams of 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol heptaacetate was deacetylated in the customary manner with sodium methylate to give 0.6 g. (57%) of material as minute clusters of thin prisms. Recrystallized from a mixture of 1.7 parts of water and 2.5 parts of alcohol the 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol melted at 239–240° and rotated in water +3.6° (*c*, 4.43).

The compound is insoluble in benzene, acetone, ethyl acetate and alcohol. It may be recrystallized by solution in a limited quantity of warm water.

Anal. Calcd. for $C_{12}H_{22}O_{10}$: C, 44.17; H, 6.79. Found: C, 43.86; H, 6.93.

Sodium Metaperiodate Oxidation of 1,5-Anhydro-6-(β-D-glucopyranosyl)-D-glucitol.—The oxidation was carried out in the same manner as that of its isomer described above. On a molar basis 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol was found to consume 4.04 moles of oxidant with the concomitant liberation of 1.96 moles of formic acid.

1,5-Anhydro-D-galactitol Tetraacetate (XI).—Ten grams of 2′-naphthyl 1-thio-β-D-galactopyranoside tetraacetate (m. p. 113–114°; $[\alpha]^{20}D$ +6.55° ($CHCl_3$, *c*, 1.37)), prepared as recently reported by Haskins and Hudson,[10] was desulfurized with Raney nickel in absolute alcoholic solution and yielded 4.91 g. (73%) of nearly pure product. Recrystallized first from a mixture of 1.2 parts of ether and 0.6 parts of pentane and then from a mixture of 1.3 parts of absolute alcohol and 0.94 parts of pentane, the material melted at 75–76° and rotated in chloroform +49.1° (*c*, 0.82). 1,5-Anhydro-D-galactitol tetraacetate is soluble in acetone, ether and hot alcohol, and relatively insoluble in cold alcohol, pentane and water.

Anal. Calcd. for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07. Found: C, 50.67; H, 6.17.

1,5-Anhydro-D-galactitol (XIII).—Five grams of 1,5-anhydro-D-galactitol tetraacetate was deacetylated catalytically with barium methylate, the product (2.37 g., 96%) being precipitated from its concentrated solution in methanol by the addition of ethyl acetate. Recrystallized once from 7 parts of boiling absolute alcohol and once from aqueous alcohol, the small, clear prisms melted at 114–115° and rotated in water +76.6° (*c*, 1.08).

1,5-Anhydro-D-galactitol is readily soluble in water, sparingly soluble in alcohol, and relatively insoluble in ethyl acetate, benzene and pentane.

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 44.18; H, 7.38.

Sodium Metaperiodate Oxidation of 1,5-Anhydro-D-galactitol.—The quantitative oxidation of 1,5-anhydro-D-galactitol with sodium metaperiodate was carried out in the same manner as described for the two anhydrides above. On a molar basis the substance consumed 2.00 moles of oxidant while 0.97 mole of formic acid was liberated.

---

[11] Melting points below 200° were taken with a calibrated Anschütz-type thermometer completely immersed in the bath liquid; those above 200° were measured in a Berl and Kullmann copper block, the thermometer readings being corrected for stem exposure. Rotations are specific rotations for sodium light at 20°; concentration is expressed in g. of substance per 100 ml. of solution.

[12] Purves (ref. 9) reported that this compound "decomposed in the neighborhood of 295°." A sample of his material was found to melt at 225–226° either alone or in admixture with that prepared in the course of the present research.

[13] E. L. Jackson and C. S. Hudson, This Journal, **59**, 994 (1937).

Summary

Reductive desulfurization of phenyl 1-thio-β-cellobioside heptaacetate with Raney nickel has furnished 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol heptaacetate. The physical constants of this substance, as well as of the 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol obtained from it by deacetylation, conform quite closely with the constants which are recorded in the literature for the corresponding products obtained through the palladium catalyzed reduction of heptaacetyl-2-hydroxy-cellobial.

1,5-Anhydro-6-(β-D-glucopyranosyl)-D-glucitol and its heptaacetate have similarly been obtained through the reductive desulfurization of phenyl 1-thio-β-gentiobioside heptaacetate and found to possess physical constants in substantial agreement with those reported in the literature for the comparable substances arising through the palladium-catalyzed reduction of heptaacetyl-2-hydroxy-gentiobial.

1,5-Anhydro-D-galactitol and its tetraacetate have been prepared through the reductive desulfurization of 2′-naphthyl 1-thio-β-D-galactopyranoside tetraacetate. The physical constants of these two compounds depart markedly from those reported for the corresponding substances, derived through the palladium-catalyzed reduction of 2,3,4,6-tetraacetyl-2-hydroxy-D-galactal.

The behavior of 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol, 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol and 1,5-anhydro-D-galactitol toward sodium metaperiodate has been examined and found in each case to conform to the assigned structure.

The Deacetylation of Acetylated Carbohydrate Derivatives with Potassium Alkoxides

BY WILLIAM A. BONNER AND WAYNE L. KOEHLER

Fischer and Bergmann[1] were apparently the first to extend the catalytic deacylation of esters with sodium ethylate to the sugar acetates. In succeeding years Zemplén and his co-workers[2] gave a mechanistic interpretation to this reaction and extended it widely in the field of carbohydrates. Today the Zemplén–Pacsu deacylation, using a catalytic amount of sodium in methanol, is one of the standard tools employed by workers in this field.

One disadvantage inherent in deacylations with sodium methylate is the retention in solution of sodium ions. This is not serious where the deacylated product crystallizes directly from the methanol solvent and the sodium ion remains in the mother liquor. However it constitutes a source of non-removable impurity in cases where the deacylated product does not crystallize and must be isolated by distillation of the solvent and volatile constituents of the reaction mixture.

A procedure capable of obviating this difficulty is found in the use of barium methylate, a modification introduced by Weltzien and Singer[3] and subsequently extended by others.[4] In this technique the barium ion is quantitatively precipitated by addition of an equivalent amount of sulfuric acid. While excellent in principle, this method suffers from the colloidal nature of the precipitated barium sulfate and consequent added difficulties in its removal, as well as from the extra trouble involved in the preparation and standardizations of the solutions employed.

It became desirable to develop a simple and rapid procedure which would permit the isolation of sirupy deacetylation products in a substantially ash-free state. The procedure developed employs a potassium methylate or ethylate in place of the sodium or barium methylates used previously, followed by a quantitative precipitation of potassium ion as perchlorate on potentiometric titration with concentrated perchloric acid.

This procedure was tested by application to several known acetylated sugar derivatives. After deacetylation was complete and potassium was removed as perchlorate, the free sugar derivative was isolated from the filtrate by evaporation *in vacuo* of the volatile constituents. Physical constants and ash analyses were determined on the crude residues to determine their purity. The data obtained, tabulated in the Experimental Part, indicate that the method can be applied to instances where sirupy deacetylation products result with assurance that reasonably pure sirups will be obtained in substantially quantitative yield.

Although methanol has been the solvent commonly employed by previous workers, we have studied the efficacy of higher alcohols as solvents in deacetylations employing both sodium and potassium alkoxides as catalysts. Primary alcohols, whether straight-chained or branched, gave yields of deacetylated products very close to theoretical, but secondary and tertiary alcohols gave yields up to 55% high. This is apparently due to a decrease in the rate of deacetylation in these cases and, on grounds of steric hindrance, is in

[a] All rotations were taken in water at 23° at concentrations around 3%. [b] Rotations here were reported in water at 20°, with the exception of ref. 5 which was at 18°. [c] Deacetylation in ethanol gave rise to direct crystallization of about 75% of the methyl α-D-glucoside, The crystalline material, dried in the usual fashion, had m. p. 165.5–167° and $[\alpha]^{23}D$ 158.2° (c, 3.790; H_2O). The constants given in the table apply to the 25% of product remaining in the mother liquors. The yield is based on the total weight of both fractions. [d] It is interesting to calculate that, had the potassium not been removed in this case by precipitation, the quantities of inorganic impurity present would be about 6 to 7%, weighed as potassium alkoxide.

accord with the mechanism of deacetylation proposed by Zemplén.

It was believed possible to simplify the barium methylate deacetylation used previously[4] by a potentiometric titration of the barium ion with sulfuric acid. The method failed, however, since the pH required for complete precipitation of the barium was too low, and hydrolysis of the sugar derivatives occurred during subsequent processing. When pH values high enough to prevent hydrolysis were employed as an end-point in the titration, precipitation of barium was incomplete and the crude products contained excessive quantities of ash.

In applying the potassium methylate procedure to a typical deacetylation giving a sirupy product, we have deacetylated tetraacetyl-β-D-glucosylbenzene. β-D-Glucosylbenzene proved to be a clear, thick, non-reducing glass, isolable as an alcoholate. This substance, its tetrapropionate, and its tetrabenzoate are herein reported for the first time.

Experimental Part

Deacetylations with Potassium.—A sample of the acetylated sugar derivative (*ca.* 2 g.) was placed in a 50-ml. Erlenmeyer flask and methanol or ethanol added (10 ml. per gram of solute). A small chip of freshly cut potassium (20–35 mg.) was added, and the flask placed on the steam-bath for five minutes, removed, stoppered and permitted to stand at room temperature for about twenty-four hours. After this period the potassium was precipitated by titration with commercial 60% perchloric acid to a potentiometrically determined end-point using a Beckman pH meter. The pH value used for the end-point in methanol was 8.15 and in ethanol 7.55. These pH values were found in separate experiments when potassium perchlorate was permitted to stand with intermittent shaking for several hours in contact with these alcohols. Care must be taken in approaching the end-point, since it is easily passed when titrating with concentrated perchloric acid. Occasionally it was found expedient to titrate to one pH unit above the end-point with concentrated acid, and to approach the final end-point using perchloric acid diluted with solvent. It was found that the use of dilute perchloric acid during the entire titration led to a colloidal precipitate of potassium perchlorate which proved difficult to filter.

The precipitated potassium perchlorate was filtered and rinsed with a small amount of solvent, and the filtrate and washings placed in a small beaker. The beaker was placed under a micro bell jar and the latter evacuated with an aspirator. A fine stream of air, controlled by a pinch clamp, was directed onto the surface of the liquid through a capillary entering the top of the bell jar through a rubber stopper. The bell jar plate was warmed to 55° by controlled heating on a hot-plate. In this fashion the solvent and volatile products (methyl or ethyl acetates) were removed by vacuum evaporation under low heating.

The residual deacetylated sugar derivative was dried in a vacuum desiccator over phosphorus pentoxide for seventy-two hours, then in an oven at 60° for an additional twenty-eight hours. Melting points, rotations and ash analyses were taken on the resulting crude, dried, unrecrystallized products. Ash analyses were conducted by cautiously igniting 0.1 to 0.2 g. of the deacylated derivative in a platinum crucible.

Data on the known derivatives deacetylated in this manner are tabulated in Table I. The particular acetates employed were selected because preliminary experiments showed that their products would not precipitate directly from the solvent on deacetylation. This was desirable here, since the procedure was to be applied to acetates giving sirupy deacetylation products.

Deacetylations in Various Solvent Media.—Two sets of experiments were conducted, the first studying the completeness of deacetylations using sodium and potassium in three alcohols, and the second studying the completeness of deacetylation using potassium in ten alcohols.

In the first set approximately 2 g. of phenyl tetraacetyl-β-D-glucoside (weighed to mg.) was dissolved in 20 ml. of the solvent and a known weight (20–30 mg.) of freshly-cut sodium or potassium added. The solution was heated to 80–90° on the water-bath for five minutes, then allowed to stand for one day. The solvent was removed by vacuum evaporation, and the residue dried *in vacuo* over phosphorus pentoxide for seventy-two hours. The dried residue was weighed and the yield determined. The results are given in Table II; the yields are based on weights corrected for the amounts of metal alkoxides present in the residue.

TABLE II

DEACETYLATIONS WITH SODIUM AND POTASSIUM IN METHANOL, ETHANOL AND 2-PROPANOL

Solvent	Phenyl β-D-glucoside, % yield Sodium	Potassium
Methanol	98.8	99.4
Ethanol	102.1	100.7
2-Propanol	103.1	111.6

(6) Fischer and Armstrong, *Ber.*, **34**, 2885 (1901).

(7) Riiber, *ibid.*, **57**, 1797 (1924).

(8) Purves, THIS JOURNAL, **51**, 3626 (1929).

In the second set of experiments a known weight of phenyl tetraacetyl-β-D-glucoside (weighed to mg.) was dissolved in the alcohol (10 ml. per gram of acetate). The solution was treated with a known weight of potassium, then permitted to react and processed exactly as above. The dried residue was weighed (mg.) and the yield determined, correcting for the quantity of potassium alkoxide remaining in the residue. The data for these experiments appear in Table III. It is seen that the yield of phenyl β-D-glucoside is close to the theoretical in the case of primary alcohols but far above the theoretical in the cases of secondary and tertiary alcohols, indicating incomplete deacetylation in these latter cases.

TABLE III

DEACYLATIONS WITH POTASSIUM IN VARIOUS ALCOHOLS

Alcohol	Type	Phenyl β-D-glucoside, % yield
Methyl	Primary	99.4
Ethyl		100.7
n-Propyl		98.0
n-Butyl		101.5
Isobutyl		100.2[a]
n-Amyl		105.4[a]
Isoamyl		98.2[a]
Isopropyl	Secondary	111.6
s-Butyl		153.3[a]
t-Amyl	Tertiary	154.9[a]

[a] In these experiments the product crystallized directly from the reaction mixture, confirming the expected decrease in solubility of the free glucoside in higher alcohols.

Attempted Deacetylations with Barium.—This describes the attempted extension of the potentiometric titration method to barium deacetylations. Samples of phenyl tetraacetyl-β-D-glucoside, methyl tetraacetyl-α-D-glucoside and phenyl tetraacetyl-β-D-thioglucoside were dissolved in methanol and ethanol. A small chip of barium metal (*ca.* 20 mg.) was added to each of the six solutions. These were then heated for five minutes and allowed to stand for twenty-four hours. They were next titrated with alcoholic sulfuric acid (*ca.* 1 *N*) with the aid of a *p*H meter. The *p*H found for pure barium sulfate in methanol was 2.00 and for ethanol 2.63. (The same barium sulfate gave a *p*H of 6.3 when shaken with water.) These values were used as end-points in the present titrations. On filtration of the barium sulfate and vacuum evaporation of the filtrate, each of the samples underwent marked decomposition.

When the end-point of one such titration was taken as *p*H 7.4 methyl α-D-glucoside was recovered in a yield of 106.3% from methanol. This crude product, however, proved to contain 7.8% ash.

β-D-Glucosylbenzene.—Crystalline tetraacetyl-β-D-glucosylbenzene[9] (5.925 g.) was dissolved in methanol (30 ml.) and a small chip of freshly-cut potassium added. The mixture was warmed on the steam-bath for five minutes and the resulting amber solution permitted to stand at 25° for twenty-four hours. It was then decolorized by filtration through a small bed of Norit over Super-cel. The filtrate was potentiometrically titrated to the usual *p*H with 60% perchloric acid, and the solid filtered and rinsed with methanol. The product was isolated as before by vacuum evaporation, and was dried for several weeks *in vacuo* over phosphorus pentoxide. The product was a clear, non-reducing glass weighing 3.548 g. (89.9%). It proved to be an alcoholate, retaining one mole of methanol. Rotation: $[\alpha]^{23}\text{D}$ 18.25° (*c*, 2.740, H_2O). *Anal.* Calcd. for $C_{13}H_{20}O_6$: C, 57.35; H, 7.41. Found: C, 57.40, 57.15; H, 7.06, 7.64. When 0.228 g. of the product was ignited in a platinum crucible, there remained 0.2 mg. of residue; ash, 0.09%.

Tetrapropionyl-β-D-glucosylbenzene.—β-D-Glucosylbenzene methanolate (1.00 g.) was dissolved in pyridine (15 ml.) and propionic anhydride (15 ml.) added. The mixture stood for three days at room temperature with no color change. It was then poured into water (100 ml.) and allowed to stand for nine hours with intermittent shaking. A sirupy lower layer resulted. This was extracted into ether, and the extract washed with water, 4 *N* hydrochloric acid, water (twice), saturated sodium bicarbonate solution and finally water. The clear extract was dried over anhydrous sodium sulfate, filtered and the solvent distilled, last traces *in vacuo*. There resulted 1.76 g. (102%) of a clear, amber sirup which crystallized slowly on standing. This was recrystallized three times by dissolving in 2-propanol, adding water until faintly turbid and placing at 0°. The product, fine white needles, had m. p. 69.5° and $[\alpha]\text{D}^{25}$ −14.12° (*c*, 3.183; $CHCl_3$). *Anal.* Calcd. for $C_{24}H_{32}O_9$: C, 62.08; H, 6.94. Found: C, 62.68; H, 7.11.

Tetrabenzyl-β-D-glucosylbenzene.—β-D-Glucosylbenzene methanolate (0.80 g.) was dissolved in pyridine (20 ml.) and benzoyl chloride (10 ml.) added. Considerable warming and darkening occurred, and a thin paste resulted. This stood for three days and was thrown into water. On standing for nine hours with occasional shaking an oily second phase resulted. The aqueous layer was decanted and the oil treated with ether. The oily product crystallized to give 1.91 g. (98.5%) of white solid, m. p. 181–182.5°. The residual ether was used to extract the aqueous layer, and the extract processed as above. Removal of the solvent after decolorization of the extract gave 3.54 g. of a thin, amber liquid. This had a negligible rotation and was not investigated. The white solid proved very insoluble in 2-propanol, and was purified by extracting with 2-propanol in a Soxhlet extractor for several hours. The undissolved residue had m. p. 184.5–185.5°. A small amount of material crystallized from the pot solvent, m. p. 183.5–185.5°. The purer sample had $[\alpha]^{25}\text{D}$ −22.93° (*c*, 0.960; $CHCl_3$). *Anal.* Calcd. for $C_{40}H_{32}O_9$: C, 73.20; H, 4.91. Found: C, 73.10, 73.30; H, 4.97, 5.10.

Summary

1. Potassium methylate and ethylate have been found useful for the catalytic deacetylation of acetylated sugar derivatives. After reaction the potassium is removed as perchlorate, permitting isolation of substantially ash-free products, even if the latter are sirups.

2. Such deacetylations have been studied using a wide variety of alcohols as solvent. Primary alcohols generally gave good results, but incomplete deacetylation was noted when secondary or tertiary alcohols were used under comparable conditions.

3. β-D-Glucosylbenzene methanolate, tetrapropionyl-β-D-glucosylbenzene, and tetrabenzoyl-β-D-glucosylbenzene are described.

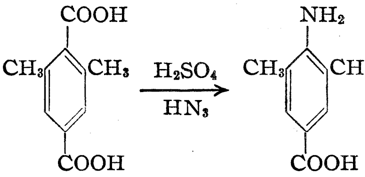
The Mechanism of the Schmidt Reactions and Observations on the Curtius Rearrangement[1]

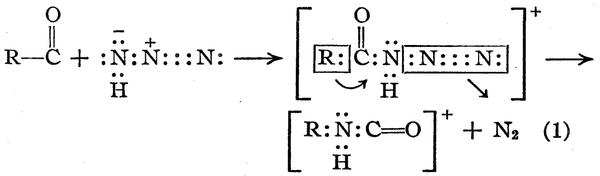
BY MELVIN S. NEWMAN AND HYMAN L. GILDENHORN[2]

During studies on the synthesis of 4-amino-2,6-dimethylbenzoic acid we made an observation which gave us a clue as to the mechanism of the Schmidt reactions[3] and led us to predict that the Curtius rearrangement should be acid catalyzed. In this paper we present mechanisms for the reactions of hydrazoic acid with acids and other compounds and also demonstrate that the Curtius rearrangement is catalyzed by protonic and nonprotonic acids.

The original observation which gave the impetus to this work was the fact that 2,6-dimethylterephthalic acid, I, yielded 4-amino-3,5-dimethylbenzoic acid, II, in the Schmidt reaction. Since the hindered carboxyl group reacted exclusively we were struck by the similarity between this Schmidt reaction and the sulfuric acid esterification of 2,4,6-trimethylbenzoic acid.[4] Since the mechanism for this esterification involves an oxocarbonium ion,[4,5] it seemed logical to propose a similar intermediate for the Schmidt reaction. Accordingly we submit that the Schmidt reaction with acids may proceed by an electrophilic attack of an oxocarbonium ion on nitrogen accompanied by a rearrangement.[6] The function of the sulfuric acid is to convert the acid, RCOOH, into an oxocarbonium ion, R—C⁺=O, or a dihydroxycarbonium ion, $R—C^+(OH)_2$.[7] The carbonium ion then attacks the nitrogen atom in hydrazoic acid which is attached to hydrogen. The unstable initial adduct loses nitrogen as a molecule of N_2 leaving the remaining nitrogen electronically deficient. This in turn sets up forces which cause the R group originally attached to the carbonium–carbon to rearrange to the nitrogen. In this migration the R group carries with it the pair of electrons which originally bound it to the carbonium–carbon. The final resulting electron-deficient complex may either remain as such in the reaction medium or, on dilution with water, react with water to yield the final products.

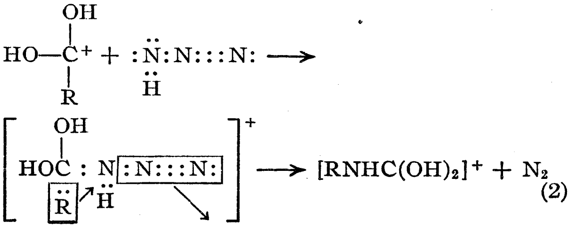


I II



$$R{-}\overset{\displaystyle O}{\overset{\|}{C}} + :\underset{H}{\overset{-}{\ddot{N}}}:\overset{+}{N}:::N: \longrightarrow \left[\boxed{R:}\overset{\displaystyle O}{\overset{\|}{C}}:\underset{H}{\ddot{N}}\boxed{:N:::N:}\right]^+ \longrightarrow \left[R:\underset{H}{\ddot{N}}:C{=}O\right]^+ + N_2 \quad (1)$$

$$[RNHCO]^+ + H_2O \longrightarrow RNH_3^+ + CO_2 \quad (1a)$$



$$HO{-}\underset{R}{\overset{OH}{C^+}} + :\underset{H}{\ddot{N}}:N:::N: \longrightarrow \left[HO\overset{OH}{\underset{\boxed{\ddot{R}}}{C}}:\underset{H}{N}\boxed{:N:::N:}\right]^+ \longrightarrow [RNHC(OH)_2]^+ + N_2 \quad (2)$$

$$RNH\overset{+}{C}(OH)_2 \longrightarrow RNH_3^+ + CO_2 \quad (2a)$$

Evidence supporting the first alternative was obtained by showing that with sulfuric and hydrazoic acids: (A) methyl 2,4,6-trimethylbenzoate, which has been shown to yield $(CH_3)_3C_6H_2C^+{=}O$ ions in the cold in sulfuric acid solution,[8] is converted into mesidine (2,4,6-trimethylaniline) at 0°; (B) 2,4,6-trimethylbenzoic acid which likewise yields $(CH_3)_3C_6H_2C^+{=}O$ ions in the cold in sulfuric acid solution[8] is converted into mesidine, even at 0°; (C) benzoic acid, which yields mainly $C_6H_5C^+(OH)_2$ ions in the cold in sulfuric acid, does not yield aniline in the cold. This evidence indicates that oxocarbonium ions[5] react readily with hydrazoic acid but does not exclude the pos-

[1] Part of the material herein presented is contained in the M.S. thesis presented by H. L. G. to the Ohio State University in June, 1947. This also formed the basis for part of the address given by M. S. N. to the Organic Symposium in Boston, Massachusetts, June 12, 1947. Additional work on the Schmidt reaction carried out in the Department of Chemistry of the Massachusetts Institute of Technology by Dr. Conrad Schuerch with Professor E. H. Huntress, executed independently of but concurrently with the present paper, will shortly be presented to THIS JOURNAL.

[3] Wolff in Adams "Organic Reactions," Vol. 3, John Wiley and Sons, Inc., New York, N. Y., 1946, p. 309–310. Under the heading of Schmidt reactions are included the reactions of organic compounds with sulfuric and hydrazoic acids.

[4] Newman, THIS JOURNAL, **63**, 2431 (1941).

[5] As a suitable system for the nomenclature of simple carbonium ions we propose that the central electron deficient carbon atom be used as a root and that the attached groups be named as usual. Thus $(CH_3)_3C^+$ would be called trimethylcarbonium ion, $CH_3C^+(OH)_2$ would be called methyl dihydroxy carbonium ion, and $CH_3—C^+{=}O$, methyl oxo carbonium ion. For more complicated carbonium ions a more systematic nomenclature would be necessary.

[6] It is to be understood throughout our discussion that the intermediate stages pictured in formulas have no significance other than to indicate formation and loosening of the bonds involved and to indicate driving forces for the reactions.

[7] The activated form for hydrazoic acid proposed by Hurd in Gilman's "Organic Chemistry," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1938, p. 699, is merely one of the contributing resonance structures and does not require sulfuric acid for its existence. See Hendricks and Pauling, THIS JOURNAL, **47**, 2904 (1925); Langseth and Nielsen, *Phys. Rev.*, **44**, 326 (1933); and Brockway and Pauling, *Proc. Natl. Acad. Sci.*, **19**, 860 (1933).

[8] Newman, Kuivila and Garrett, THIS JOURNAL, **67**, 704 (1945).

sibility that dihydroxycarbonium ions[5] may also react as shown in equation 2. However, the reaction with dihydroxycarbonium ions is undoubtedly much slower. This difference in reactivity of these two types of carbonium ions is strikingly illustrated by the course of the reaction in the case of I. Findings B and C (above) are also to be noted.

The fragments, $(RNHCO)^+$ and $[RNHC(OH)_2]^+$, react with water to yield the amine and carbon dioxide. In some cases, at least, carbon dioxide is evolved directly from the sulfuric acid solution. We noticed that the fragment $(RNHCO)^+$ should also be the species first formed when an isocyanate is dissolved in sulfuric acid. When we added phenyl isocyanate to sulfuric acid there was an immediate evolution of carbon dioxide and aniline was isolated from the reaction mixture.

The reaction pictured in equation (1) takes place at a temperature determined by the ease with which the acid in question yields appreciable quantities of oxocarbonium ion, $R—C^+{=}O$. In the case of 2,6-dimethylterephthalic acid, I, and 2,4,6-trimethylbenzoic acid, a temperature of 10° or lower is sufficient because of the tendency of these acids to undergo complex ionization[8,9] in sulfuric acid according to equation (3).[10]

$$RCOOH + 2H_2SO_4 \rightleftarrows R—C^+{=}O + H_3O^+ + 2HSO_4^- \quad (3)$$

But in the case of benzoic acid and many other acids, a temperature of 35 to 50° is required for the Schmidt reaction (equation 2). Acids of this type ionize according to equation 4 in sulfuric acid.[10]

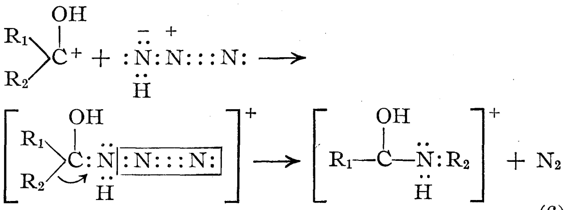
$$RCOOH + H_2SO_4 \rightleftarrows RC^+(OH_2) + HSO_4^- \quad (4)$$

The dihydroxycarbonium ions,[5] $RC^+(OH_2)$, thus formed evidently do not react with hydrazoic acid as easily as do the oxocarbonium ions,[5] $R—C^+{=}O$. The higher reaction temperature required for many Schmidt reactions may be needed to shift the equilibrium shown in equation 5 to the right or to provide a higher temperature for the reaction of the less reactive dihydroxycarbonium ions as shown in equation (2).

$$RC^+(OH)_2 \rightleftarrows R—C^+{=}O + H_2O \quad (5)$$

Should it prove possible to produce appreciable concentrations of oxocarbonium ions from acids of the benzoic type at lower temperatures by altering the reaction medium, we would expect reaction with hydrazoic acid. Thus it may be that reaction at low temperatures of a system with hydrazoic acid to yield nitrogen will prove to be a means of determining the presence of oxocarbonium ions, barring complications involving hydrazoic acid.

In the case of Schmidt reactions with aldehydes and ketones a similar mechanism has been used to account for the products formed.[11] The reaction of the hydroxycarbonium ion[5] formed from aldehydes and ketones in sulfuric acid[10] with hydrazoic acid is shown in equation 6.

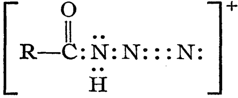


(6)

It should be pointed out that many of these reactions proceed at low temperatures. The complex ion formed loses a proton to yield an amide. In this connection it should prove interesting to compare the migration aptitudes of various groups in the Schmidt reaction with those obtained by Bachmann in the case of the rearrangement of symmetrical pinacols.[12] The qualitative results reported for a few ketones show that the migration aptitudes are roughly what one would expect using data from pinacol rearrangements.[11,12]

Further application of the principles outlined above allow reasonable mechanisms to be postulated for the reaction of a variety of other compounds with hydrazoic acid under acid conditions.[13]

If we return to the first reaction stage of equation 1, it is readily seen that this intermediate,



$$\left[R—\overset{\overset{\displaystyle O}{\|}}{C}:\underset{\underset{\displaystyle H}{..}}{\overset{..}{N}}:N:::N:\right]^+$$

, could likewise be obtained by the addition of a proton to an acid azide. Therefore, since the Schmidt reaction takes place readily at 35 to 50° and most azides decompose in solvents only at higher temperatures, we were led to predict that the Curtius reaction should be acid catalyzed.[14] This prediction was verified by showing that the rate of decomposition of benza-

---

(9) Raymond A. Craig has shown in unpublished work that acid I has an i factor of 2.4. Although the exact i factor for this acid could not be predicted its magnitude is in the region expected if one considers that the i factor of 2,4,6-trimethylbenzoic acid is 4 and that for 2,6-dimethylbenzoic acid is about 3.5. Thus substitution of the 4-methyl group by hydrogen causes a decrease in i factor (see Treffers and Hammett, THIS JOURNAL, **59**, 1708 (1937)). Further substitution of a carboxyl group in the 4-position, as in I, would be expected to produce a further decrease in the i factor.

(11) See Sanford, Blair, Arroya and Sherk, THIS JOURNAL, **67** 1941 (1945), for a comparison of mechanisms involving hydrazoic acid and hydroxylamine-O-sulfuric acid.

(12) See Wallis in Gilman's "Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1943, p. 969–970. Dr. P. A. S. Smith, University of Michigan, has informed us that he is studying this problem now.

(13) See the entire chapter of ref. 3 above.

(14) No mention of acid catalysis in the Curtius reaction is made either in the chapter on this reaction by Smith in "Organic Reactions," Vol. III, John Wiley and Sons, Inc., New York, N. Y., 1946, p. 337, *et seq.*, or in the chapter by Wallis and Lane, *ibid.*, p. 267, *et seq.* Since this article was written, Dr. Smith (see ref. 12) pointed out that Th. Curtius, *J. prakt. Chem.*, [2] **50**, 291 (1894), mentions briefly the decomposition of azides in ether containing hydrogen chloride.

zide in acetic acid was increased progressively by separate additions of chloroacetic, dichloroacetic, trichloroacetic and sulfuric acids. The rate of decomposition of benzazide in dioxane was also markedly increased by hydrogen chloride and by boron trifluoride.[15] We are now studying some quantitative aspects of this catalytic reaction.

Experimental[16]

3,5-Dimethyl-4-aminobenzoic Acid, II.—To a stirred mixture of 4.7 g. of pure 2,6-dimethylterephthalic acid[17] in 20 cc. of 100% sulfuric acid and 15 cc. of chloroform at 25° was added 1.05 g. of sodium azide over a period of two and one-half hours. After stirring for another fifteen minutes, the mixture was poured on ice and neutralized with sodium hydroxide. The chloroform layer was separated and the aqueous layer acidified with dilute hydrochloric acid. The white solid which separated was collected and dried. It weighed 2.3 g. (87% based on azide used) and melted with darkening and decomposition from 240 to 250°. After two recrystallizations from alcohol white crystals of pure II were obtained. The melting point of 251 to 252° with decomposition[18] was determined in a copper block by heating from 30 to 200° in ten minutes and then heating at a rate of 4° per minute.

Anal. Calcd. for $C_9H_{11}O_2N$: C, 65.4; H, 6.7; N, 8.5. Found: C, 64.9, 65.0; H, 6.6, 6.8; N, 8.5, 8.7.

This amino acid was diazotized and coupled with β-naphthol to yield a brilliant orange-red product, m. p. 285.5 to 288° with decomposition, when recrystallized from absolute alcohol (m. p. procedure same as for II).

Anal. Calcd. for $C_{19}H_{16}O_3N_2$: C, 71.2; H, 5.0; N, 8.8. Found: C, 71.0, 71.0; H, 5.2, 5.4; N, 8.8, 8.9.

In another experiment, the diazonium solution was heated with added copper sulfate[19] to yield a small amount of colorless crystals, m. p. 222–224°, of 3,5-dimethyl-4-hydroxybenzoic acid[20] on crystallization from benzene.

Further evidence for the structure of II was obtained in decarboxylation experiments. Our amino acid decarboxylated with difficulty whereas Noyes[17] reported that the isomeric 2,6-dimethyl-4-aminobenzoic acid decarboxylates readily. On heating our acid with a little copper carbonate[21] a small amount of an amine was obtained which formed an acetate, m. p. 170–174° after crystallization from alcohol and from benzene. The melting point of the acetate of *sym-m*-xylidine is 140.5°[22] whereas that of *vic-m*-xylidine melts at 177°.[23]

Schmidt Reactions at Low Temperature.—In two parallel experiments 5 g. of benzoic and 2,4,6-trimethylbenzoic acids were dissolved in 100% sulfuric acid and the solutions were cooled at 0°. Equivalent amounts of sodium azide were added to each solution during one hour. From the former no gas was evolved but from the latter a brisk evolution of nitrogen took place. Carbon dioxide was also formed but no carbon monoxide. After stirring an additional half hour the solutions were poured on ice. From the former a negligible amount of aniline was isolated but from the latter 51% of mesidine was obtained. The mesidine was identified as its formyl derivative, m. p. 175.5–176.5°.[24] We also prepared the 1,3,5-trinitrobenzene addition product of mesidine and found it to form deep reddish-brown needles, m. p. 133.5–134.0°.[25]

Anal. Calcd. for $C_{15}H_{16}O_6N_4$: C, 51.7; H, 4.6; N, 16.1. Found: C, 51.7, 51.9; H, 4.8, 5.0; N, 16.1, 16.2.

Mesidine from Methyl 2,4,6-Trimethylbenzoate.—To a solution of 5.2 g. of methyl 2,4,6-trimethylbenzoate in 40 cc. of concentrated sulfuric acid at 40° was added slowly 1.56 g. of sodium azide. The gases evolved amounted to 1020 cc., almost twice the theory for nitrogen. No tests on this gas were made other than to show it contained carbon dioxide and did not contain carbon monoxide. The reaction mixture was poured on ice and the mesidine formed was extracted from the alkaline solution and distilled. It boiled at 80° at 2 mm. and was isolated in 79% yield (based on azide). From the acid portion of the reaction mixture was recovered 13% of 2,4,6-trimethylbenzoic acid.

Acid Catalyzed Curtius Rearrangements.[26]—Qualitative experiments on the effect of acids on the decomposition of benzazide at 75° were carried out in a 500-cc., three-necked flask fitted with a sealed stirrer and dropping funnel and connected to an azotometer. Various acids were added to the acetic acid to make 50 mole per cent. solutions. The apparatus was equilibrated at 75° and was then pinched off and the flask cooled. A solution of benzazide in 10 cc. of acetic acid was then sucked in through the separatory funnel, followed by a rinse with 5 cc. of acetic acid. The pinchcock was then removed and the flask heated to 75°. The times required for collection of one-half of the total volume of gas evolved were as follows: acetic acid, 20 minutes; chloroacetic acid, 13 minutes; dichloroacetic acid, 10 minutes; trichloroacetic acid, 7 minutes; 2.5 cc. of 100% sulfuric acid in 50 cc. of acetic acid, 10 minutes; 50 mole per cent. sulfuric in acetic, 6 minutes. When benzazide was added to 100% sulfuric acid, an explosion occurred.[15] In three experiments in dioxane, the time for dioxane was 60 minutes, for a solution of 9 g. of boron trifluoride in 50 cc. of dioxane, 7 minutes, and for 2.3 g. of hydrogen chloride in 65 cc. of dioxane, 6 minutes.

Summary

A mechanism for the Schmidt reactions of acids and certain esters with hydrazoic acid in sulfuric acid solution is proposed.

Catalysis of the Curtius rearrangement of benzazide by protonic and non-protonic acids has been demonstrated.

The Schmidt Reaction: Experimental Conditions and Mechanism

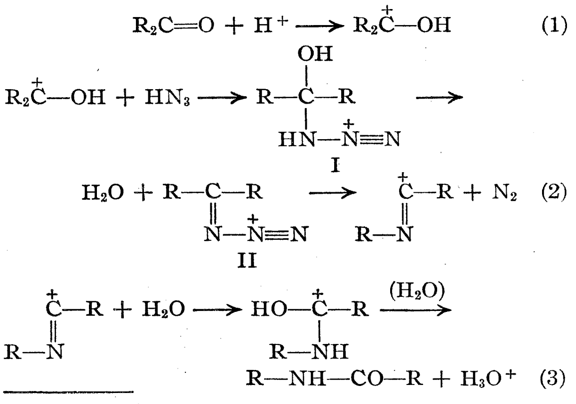
BY PETER A. S. SMITH

In 1944[1] we proposed a mechanism for the amination of the benzene ring by hydrazoic acid involving the radical NH or NH_2^+. On the other hand, we felt that the amination of carbonyl compounds by the same reagents, known as the Schmidt reaction,[2] proceeded by a carbonium ion mechanism,[3] but publication has been withheld pending more complete experimental confirmation. Recently, Newman proposed essentially the same mechanism,[4] and it seemed desirable, therefore, to present our work as it now stands. A review of other mechanisms which have been proposed for the Schmidt reaction through 1945 is available elsewhere.[2] Since then an oxatriazole intermediate has been suggested.[5]

The stoichiometry of the Schmidt reaction is represented by

$$R{-}CO{-}R + HN_3 = R{-}NH{-}CO{-}R + N_2$$

The reaction is carried out with the aid of at least equimolar quantities[2] of catalysts which are strong Lewis acids.[6] The mechanism now proposed consists of the formation of a carbonium ion from the carbonyl group and the acid catalyst; this is the initial step recently proposed by Sanford, Blair, Arroya and Sherk[7] for an otherwise somewhat different mechanism. The carbonium ion and hydrogen azide form a transitory intermediate (I), which loses water and undergoes *trans* rearrangement with loss of nitrogen, as detailed below.



$$R_2C{=}O + H^+ \longrightarrow R_2\overset{+}{C}{-}OH \qquad (1)$$

$$R_2\overset{+}{C}{-}OH + HN_3 \longrightarrow R{-}\underset{HN-\overset{+}{N}\equiv N}{\overset{OH}{\overset{|}{\underset{|}{C}}}}{-}R \longrightarrow$$

I

$$H_2O + R{-}\underset{N-\overset{+}{N}\equiv N}{\underset{\|}{C}}{-}R \longrightarrow \underset{R-N}{\underset{\|}{\overset{+}{C}}}{-}R + N_2 \qquad (2)$$

II

$$\underset{R-N}{\underset{\|}{\overset{+}{C}}}{-}R + H_2O \longrightarrow HO{-}\underset{R-NH}{\underset{|}{\overset{+}{C}}}{-}R \xrightarrow{(H_2O)} R{-}NH{-}CO{-}R + H_3O^+ \qquad (3)$$

It can be seen that this mechanism implies: (1) that the occurrence of the Schmidt reaction is dependent upon both the extent to which the carbonyl compound undergoes step (1) and the polarizing power of the particular carbonium ion in step (2); and (2), that insofar as the intermediate (II) has a finite existence, there should be a geometrical effect influencing the apparent "migration aptitudes" of the two groups in unsymmetrical ketones. In this paper a series of Schmidt reactions are described in which the carbonyl compound, the acid catalyst, and the solvent were varied in order to test the first conclusion. The investigation of the second conclusion by determining the ratios of the isomeric amides formed from unsymmetrical ketones is now in progress, and will be the subject of a future communication.

The occurrence and rate of the Schmidt reaction should depend on the equilibrium concentration of carbonium ion produced by step (1) if step (2) is rate-determining. As a first approximation, one may say that the more basic the carbonyl compound and the more acidic the reaction medium, the faster the reaction will go. Our experiments with nineteen carbonyl compounds of different types in solvents of varying basicity and with catalysts of different acid strength bear this out. Only a qualitative agreement would be expected, however, since each carbonium ion will of course have its own specific reaction rate in step (2).

The available data on the basic strengths of carbonyl compounds[8] permit as a rough generalization the assumption of the following order: cycloalkyl ketones > dialkyl ketones > aryl alkyl ketones > diaryl ketones > carboxylic acids. Cycloalkyl and dialkyl ketones were found to undergo the Schmidt reaction even in such basic solvents as water, alcohols, and ethers, but with the less basic types of carbonyl compounds the use of these solvents inhibited the reaction largely or completely.[9] Catalysts which are strong enough acids to bring about the Schmidt reaction with the more basic carbonyl compounds may not be strong enough to be effective with the less basic ones. Thus trichloroacetic acid was found to be an efficient catalyst for alkyl and aryl alkyl ketones, but it was only partially effective on diaryl ketones, and failed completely with all acids but formic. The carboxyl group of trichloroacetic acid itself does not show a measurable tendency to

form carbonium ions.[11] It is thus understandable that no catalyst was found strong enough to bring about the Schmidt reaction with it; and trichloroacetic acid is accordingly a satisfactory solvent in which to carry out the Schmidt reaction on other carbonyl compounds, using sulfuric acid as the catalyst if necessary. Trifluoroacetic acid has been reported[12] to be similarly resistant.

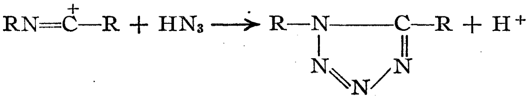
Our experiences lead us to some recommendations about the choice of experimental conditions. In general, the least strongly acid medium which will bring about reaction in a reasonable time gives the purest products. Concentrated aqueous hydrochloric acid has been found to be a useful solvent and catalyst for the reaction with aliphatic ketones; its use minimizes the formation of both tars and tetrazoles. Benzylacetone, for example, gave an 87% yield of mixed amides (consisting of 5% of N-methylphenylpropionamide and 95% of N-(β-phenylethyl)-acetamide when treated with sodium azide in hydrochloric acid, whereas with sulfuric acid[10] a yield of only 62% has been reported. Solutions of hydrogen chloride in alcohol[13] or dioxane are useful with relatively insoluble ketones, but most aliphatic ketones dissolve sufficiently in aqueous acid. While aqueous hydrochloric acid is not strong enough to bring about the Schmidt reaction on the less basic aryl alkyl ketones, the more acid medium provided by molten trichloroacetic acid gives excellent results. Acetophenone, β-acetonaphthone and α-tetralone gave yields of N-aryl amides of 89, 95 and 85%, respectively, whereas yields of 77,[14] 70 and 70%[14] were given by the unnecessarily strong catalyst sulfuric acid; in addition, purification of the products may be more difficult when sulfuric acid is used. Sulfuric acid appears to be the best catalyst for the even less basic diaryl ketones and carboxylic acids, but the use of only two molar equivalents of sulfuric acid with one of the carbonyl compound in trichloroacetic acid as a solvent provides a homogeneous and fluid reaction medium and lessens the danger of sulfonation. Work at present under way indicates that strong aprotic acids, such as aluminum chloride, in inert solvents favor tetrazole formation.

Among numerous applications of the mechanism here presented, which cannot be reviewed here, it is interesting to consider Götzky's[15] observation that benzhydrylidene diazide gives benzanilide in 98% yield when treated with 70% sulfuric acid. This reaction may be formulated in an analogous manner

$$\mathrm{Ar_2C(N_3)_2} \xrightarrow{(\mathrm{H^+})} \mathrm{HN_3} + \mathrm{Ar_2C{=}N{-}\overset{+}{N}{\equiv}N} \longrightarrow$$

$$\mathrm{N_2} + \mathrm{Ar{-}N{=}\overset{+}{C}{-}Ar} \xrightarrow{(\mathrm{H_2O})} \mathrm{Ar{-}NH{-}CO{-}Ar} + \mathrm{H_3O^+}$$

The imino-carbonium ion[16] resulting from step (2) may give rise to products other than amides in step (3) if it encounters a species other than water capable of forming a permanent attachment. If it should encounter a second molecule of hydrogen azide, a tetrazole would be produced



If a large quantity of alcohol is present, an imido-ester results instead of an amide. The same type of imino-carbonium ion probably arises[17] in the Beckmann rearrangement of oximes, and it is significant that tetrazoles and imido-esters result from the Beckmann rearrangement also when it is carried out in the presence of azide or alcohols, respectively. Most of the catalysts used in the Schmidt reaction cannot generate an imino-carbonium ion from amides and, accordingly, amides, once formed, do not react further with hydrogen azide. It is expected that we will be able to present a more detailed treatment of tetrazole formation at the completion of present work.

In view of the additional evidence presented by Newman and Gildenhorn, the carbonium ion mechanism seems to be fairly well established. A quantitative study of the rate of the Schmidt reaction as influenced by substrate, solvent, and catalyst is nevertheless felt to be a suitable addition to this work, and has recently been begun.

It was felt of interest to confirm the report[10] that methyl azide does not take part in a Schmidt reaction as does hydrogen azide. No N-methyl products could be detected in experiments with acetophenone, and the principal effect of mixtures of ketones and acids on alkyl azides appeared to be catalysis of their decomposition according to other paths.

Experimental

In the accompanying table the results of a number of Schmidt reactions are summarized. In the method usually employed, powdered sodium azide was added to the mixture of solvent, catalyst, and carbonyl compound. In certain experiments, indicated by a footnote, benzene solutions of hydrogen azide were used. In many experiments where the yield of product would be of little significance or preparative value, yields were not determined. These experiments are listed just before the table, or, for carbonyl compounds which do appear in the table, are mentioned in footnotes. Nitrogen evolution was used as the criterion of reaction in these cases, and the results were confirmed by a qualitative test for the products. All reactions were run at room temperature unless noted otherwise by a footnote. The organic chemicals used were Eastman Kodak Co. products, except monochloro- and trichloroacetic acids, which were Mallinckrodt products, and α-tetralone, phenylacetone, benzylacetone, and cyclohexanone-α-carboxylic ester, which were synthesized

TABLE I

YIELDS AND PRODUCTS OF SOME SCHMIDT REACTIONS

Carbonyl compd.	Solvent	Cat.	Product	Yield, %
Cyclohexanone	H_2O[b]	HCl	ε-Caprolactam	63
Cyclohexanone	CH_3COOH[c]	HBr	ε-Caprolactam	56
Cyclohexanone-α-carboxylic ester	H_2O	HCl	α-Aminopimelic acid	20
Benzylacetone	H_2O	HCl	Mixed amides[d]	87
Acetoacetic ester	H_2O	HCl	Glycine·HCl	56
α-Tetralone	Cl_3CCOOH[a]		Homodihydrocarbostyryl[e]	85
Acetophenone	CH_3COOH[f]	HBr	Acetanilide	21
Acetophenone	Cl_3CCOOH[a]		Acetanilide	89
Acetophenone	$C_6H_5NO_2$[g]	$AlCl_3$	1-Phenyl-5-methyltetrazole	42[h]
α-Acetonaphthone	Cl_3CCOOH[a]		α-Acetnaphthalide	90
β-Acetonaphthone	Cl_3CCOOH[a,i]		β-Acetnaphthalide	95
β-Acetonaphthone	H_2SO_4		β-Acetnaphthalide	55
β-Acetonaphthone	$C_6H_5NO_2$[j,g]	$AlCl_3$	1-β-Naphthyl-5-methyltetrazole	73[h]
β-Acetonaphthone	$CHCl_3$	$POCl_3$	β-Acetnaphthalide	42
Benzophenone	Cl_3CCOOH[a,i]		Benzanilide	59
Benzophenone	Cl_3CCOOH[a]	H_2SO_4	Benzanilide	99
Fluorenone	Cl_3CCOOH[a,k]		Phenanthridone	55
Fluorenone	H_2SO_4		Phenanthridone	99[l,m]
m-Toluic acid	Cl_3CCOOH	H_2SO_4	*m*-Toluidine	43

[a] Temperature between 55 and 65°. [b] Also reacts vigorously in dioxane or ether solution with hydrogen chloride as catalyst. [c] No reaction in acetic acid alone; moderate reaction in acetic acid with trichloroacetic acid as catalyst and in monochloroacetic acid alone; moderate to vigorous reaction in dichloroacetic acid alone and in trichloroacetic acid alone. [d] Consisted of N-β-phenylethylacetamide, 95%, and N-methylphenylpropionamide, 5%, as determined from hydrolysis products. [e] As its trichloroacetic acid salt. [f] No reaction in water or dioxane with hydrogen chloride catalyst. [g] Benzene solution of hydrogen azide used. [h] Based on hydrogen azide; these two preparations will be described in a forthcoming communication. [i] No reaction in dioxane with hydrogen chloride catalyst. [j] Almost no reaction in nitrobenzene with stannic chloride catalyst. [k] No reaction in dioxane, ethanol, or acetic acid with hydrogen chloride or bromide catalyst. [l] This experiment performed by Mr. Jerome Horwitz. [m] A yield of 70% has been obtained by L. P. Walls, *J. Chem. Soc.*, 1405 (1935), by adding an aqueous solution of sodium azide to fluorenone dissolved in sulfuric acid.

by standard procedures. Yields are reported for products purified only to the point where their identity could be definitely established by comparison, usually by mixed melting point, with known samples; in other cases, the products were in turn converted into identifiable derivatives. Following the tabulation, a more detailed description of selected typical experiments is given.

The following carbonyl compounds were treated with sodium azide in the solvents and with the catalysts named, without determining the yields: Methyl ethyl ketone in water or dioxane with hydrogen chloride catalyst reacted at a moderate rate; phenylacetone in aqueous hydrochloric acid reacted vigorously; formic acid alone did not react, nor did it in aqueous hydrochloric acid, but with trichloroacetic acid catalyst it reacted at a moderate rate; acetic acid did not react alone nor with trichloroacetic acid catalyst, but reacted vigorously with hydrogen bromide catalyst; benzoic acid did not react with aqueous hydrochloric acid, but reacted very slowly in molten trichloroacetic acid alone, and moderately rapidly in trichloroacetic acid with sulfuric acid catalyst; molten chloroacetic acid alone reacted very slowly, dichloracetic acid alone reacted slowly, and trichloroacetic alone or with sulfuric acid catalyst reacted not at all.

β-Acetnaphthalide from β-Acetonaphthone: A. With Trichloroacetic Acid.—To a solution of 1.70 g. (0.01 mole) of β-acetonaphthone in 15 g. of trichloroacetic acid at 60° was added 1.0 g. (0.015 mole) of powdered sodium azide all at once. After four hours at 60° with occasional stirring, the mixture was diluted with 75 cc. of water and alkalized with 10 cc. of concd. ammonium hydroxide. The nearly white product was filtered from the cooled solution and washed with water and warm petroleum ether; wt. 1.75 g. (95%), m.p. 125–130°. Recrystallization of a portion from aqueous alcohol gave snow-white crystals, m.p. 132–134° (lit.[18], 132°).

B. With Sulfuric Acid.—To a solution of 1.70 g. of β-acetonaphthone in 20 cc. of concd. sulfuric acid overlaid with 10 cc. of chloroform was added with stirring 0.9 g. of sodium azide in small portions over a five-hour period. When further addition caused no fresh gas evolution, the pasty mixture was poured on ice, alkalized with concd. ammonium hydroxide, and the organic material was taken up in ether. Evaporation of the extracts left a waxy solid, which was successively extracted with petroleum ether and recrystallized from benzene–petroleum ether. There was obtained 1.02 g. (55%) of impure β-acetamidonaphthalene; the filtrates yielded 0.17 g. (10%) of recovered β-acetonaphthone.

ε-Caprolactam from Cyclohexanone.—To a solution of 2.0 g. of cyclohexanone (0.02 mole) in 10 cc. of concd. hydrochloric acid at room temperature was added 2.0 g. (0.031 mole) of sodium azide in portions as fast as the vigor of the reaction permitted. After standing for several hours, the mixture was distilled to dryness *in vacuo*, and the residue taken up in a little water and alkalized with excess 50% sodium hydroxide solution. The yellow oil which separated was extracted with three portions of chloroform, and the extracts washed with a very little water and evaporated to a mass of crystals; wt. 1.3 g. (63%). Recrystallization from benzene–petroleum ether produced a colorless product, m.p. 63–64° (lit.,[19] 68–70°), with very little loss.

Acetophenone in Acetic Acid with Hydrogen Bromide.—To a solution of 2.4 g. of acetophenone in 15 cc. of 30% hydrogen bromide in acetic acid was added with stirring 1.0 g. of sodium azide in portions over thirty minutes. When the gas evolution subsided, the mixture was poured on ice, neutralized with ammonium hydroxide, and the excess acetophenone was removed by steam distillation. From the cooled residue was obtained 0.18 g. of acetanilide, and, on treatment with bromine water, 0.40 g. of *p*-bro-

---

(18) C. Liebermann and F. Scheiding, *Ann.*, **183**, 267 (1876).

(19) O. Wallach, *ibid.*, **312**, 187 (1900).

moacetanilide, m.p. 164–165° (lit.,[20] 167–168°); total yield 21%, based on sodium azide.

Phenanthridone from Fluorenone: A. With Trichloroacetic Acid.—On treatment with the same quantities of reagents under the same conditions as described above for β-acetonaphthone, 1.80 g. of fluorenone yielded 1.08 g. (56%) of crude phenanthridone; m.p. *ca.* 220° with sublimation, and 0.86 g. (48%) of crude recovered fluorenone.

B. With Sulfuric Acid.[21]—To a solution of 1.80 g. of fluorenone in 20 cc. of concd. sulfuric acid at room temperature was added with stirring 1.0 g. of sodium azide in portions over half an hour. The mixture was then poured on ice, and the precipitated phenanthridone was filtered off and washed with water and petroleum ether; wt. 1.93 g. (99%), m.p. 290–293° with sublimation (lit.,[22] 293°).

Methyl Azide and Acetophenone.—Solutions of methyl azide in petroleum ether or chloroform were prepared from methyl sulfate and 3.25 g. of sodium azide, according to the method of Dimroth and Wislicenus[23]; the methyl azide was passed in the gas phase through a long tube of soda-lime and potassium hydroxide pellets to remove completely any trace of hydrogen azide. The purity of the product so obtained was confirmed by testing liberal portions with alcoholic silver nitrate and with ferric chloride solution; no opalescence of silver azide was obtained with the first reagent, and no color developed with the second. Mixtures of the methyl azide solutions with 5 cc. of acetophenone and 10 cc. of concd. sulfuric acid foamed vigorously at room temperature. When the reaction subsided, the mixture was poured on ice, and the organic material extracted with ether and steam-distilled. Treatment of the residue in the still-pot with bromine water gave 0.1 to 0.28 g. of *p*-bromoacetanilide in different runs (0.9–2.6%), m.p. 166–168° (lit.,[23] 168°). In an experiment in which aluminum chloride in nitrobenzene was used in place of sulfuric acid, nitrogen evolution was vigorous, but only resinous products were isolated.

Homodihydrocarbostyryl from α-Tetralone.—A mixture of 1.46 g. (0.01 mole) of α-tetralone, 15 g. of trichloroacetic acid, and 1.0 g. (0.015 mole) of sodium azide was heated at 60° for six hours. Pouring the mixture into *ca.* 75 cc. of cold water deposited a brownish, crystalline solid; wt. 2.75 g. (85%), m.p. 109–113°, after washing with water and petroleum ether. Recrystallization from benzene gave an analytical sample; rectangular prisms, m.p. 126°, insol. water and petroleum ether, sol. other organic solvents.

Anal.[24] Calcd. for $C_{10}H_{11}ON{\cdot}Cl_3CCOOH$: C, 44.45; H, 3.70; Cl, 32.85. Found: C, 44.61; H, 3.88; Cl, 32.67.

This substance could be titrated sharply to a methyl orange end-point, and then left as residue pure homodihydrocarbostyryl, m.p. 139–141° (lit.,[14] 141°), with only mechanical losses. The same addition product was produced at room temperature when equimolar amounts of the components were mixed in concentrated benzene solution.

An attempt to prepare this addition product from α-tetralone oxime by causing it to rearrange in trichloroacetic acid at 60° produced only **α-tetralone oxime trichloroacetate**, silky needles m.p. 113–115°, insol. water and petroleum ether, sol. other organic solvents. Titration with sodium hydroxide to a methyl orange end-point gave an equivalent weight of 323 (calcd. 324.5) and regenerated α-tetralone oxime, m.p. 101–102° (lit.,[25] 102.5–103.5°), with only mechanical losses.

Summary

1. A qualitative study of the effect of solvents and catalysts on the Schmidt reaction has been made.

2. The occurrence of the Schmidt reaction appears to be governed by the acidity of the medium as determined by the acid strength of the catalyst and the basic strength of the solvent, and by the basic strength of the carbonyl compound undergoing the reaction.

3. Some improvements in carrying out the Schmidt reaction are suggested.

4. The factors influencing the Schmidt reaction are correlated with a carbonium ion mechanism.

Ketoxime-O-sulfonic Acids[1]

BY PETER A. S. SMITH

Recently,[2] Sanford, Blair, Arroya and Sherk reported on the reaction of hydroxylamine-O-sulfonic acid with ketones, finding that aryl alkyl ketones yield the same amide as obtained from the Beckmann rearrangement of the corresponding oxime, and that aliphatic ketones yield only the oximes. An explanation of these facts was suggested involving the addition of hydroxylamine-O-sulfonic acid to the carbonyl group, subsequent loss of sulfuric acid, and final rearrangement of the organic fragment either to an oxime or to an amide. A different course for this reaction was suggested to the writer by an observation by Sommer, Schulz and Nassau[3] that salts of ketoxime-O-sulfonic acids can be made by the interaction of ketones with neutralized aqueous solutions of hydroxylamine-O-sulfonic acid.

If the initial reaction between a ketone and hydroxylamine-O-sulfonic acid is the elimination of water to form a ketoxime-O-sulfonic acid, then an oxime might arise by hydrolysis of the sulfonyl group, or an amide might arise by direct rearrangement of the sulfonic acid, as indicated below. Some amide might also arise by the Beckmann rearrangement of the oxime under the influence of the sulfuric acid produced by the hydrolysis.

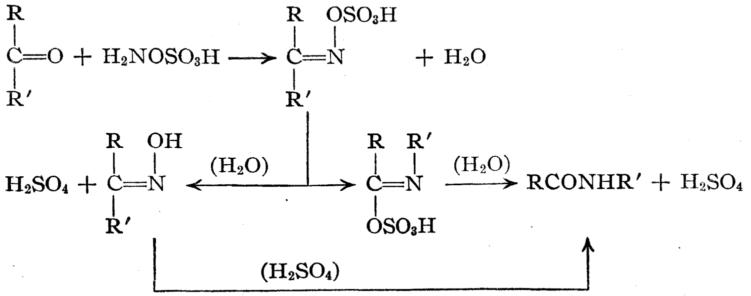
[3] F. Sommer, O. F. Schulz and M. Nassau, *Z. anorg. allgem. Chem.*, **147**, 142 (1925).



Continuing our studies[4] on derivatives of hydroxylamine-O-sulfonic acid to investigate this possibility, we have prepared the potassium ketoxime-O-sulfonates of cyclopentanone, cyclohexanone, heptanone-2, acetoacetic ester, phenylacetone, acetophenone, β-acetonaphthone, and α-tetralone. Because of the structural similarity to the O-arylsulfonyl ketoximes, $R_2C{=}NOSO_2Ar$, it was also felt to be of interest to compare the properties of these two classes of compounds.

The potassium ketoxime-O-sulfonates were found to be well-crystallized substances, indefinitely stable when pure and dry. Their solubility in water varies from large to very small, and all are somewhat soluble in boiling alcohol. All were found to oxidize hydriodic acid semiquantitatively, but with varying ease. The salts were caused to decompose by heating, either alone, in the presence of alcoholic alkali, or in the presence of moist or anhydrous hydrogen chloride. The aliphatic ketoxime-O-sulfonates yielded only the oximes when warmed with acid if water was present. In the complete absence of water, the derivatives of heptanone-2, cyclohexanone, and phenylacetone gave rise to basic products, which for the latter two ketones were found to be octahydrophenazine and 2,5-diphenyl-3,6-dimethylpyrazine, respectively; the derivatives of cyclopentanone and acetoacetic ester gave only tars. The aryl alkyl ketoxime-O-sulfonates gave amides in good yield when dry or nearly so, but increasing amounts of water favored hydrolysis to oxime and ketone.

The initial formation of ketoxime-O-sulfonic acids in the reaction of hydroxylamine-O-sulfonic acid with ketones is thus supported by two observations. The structure of the amides obtained from the few unsymmetrical ketones which have been subjected[2] to the reaction corresponds to the configuration of the oxime obtained by treatment of the ketone with hydroxylamine, strongly suggesting that here, too, *cis–trans* isomerism comes into play. That the ketoxime-O-sulfonic acids have the properties required of an intermediate in this reaction is shown by the observations reported in this paper that they can undergo hydrolysis to oximes and rearrangement to amides, and that the relative tendency to follow these respective courses is for different types of ketones the same as that observed in the direct reaction of hydroxylamine-O-sulfonic acid with ketones.

Neber and co-workers[5] have studied the behavior of O-arylsulfonyl ketoximes. These compounds give rise to amides, α-aminoketones, or pyrazines, according to the conditions to which they are exposed. We have found that ketoxime-O-sulfonates decompose to give qualitatively the same products under similar conditions; the reactions are usually not as clean, however. The yields of pyrazines obtained by treating ketoxime-O-sulfonates with alcoholic alkali were considerably lower than those obtained from the arylsulfonyl ketoximes. The ketoxime-O-sulfonates might nevertheless be useful for preparing pyrazines in cases where the corresponding arylsulfonyl ketoximes are too unstable to be handled easily; the isolation of some of the latter compounds is rendered inconvenient by the ease with which they deflagrate.

The mechanism by which pyrazines arise in the decomposition of ketoxime-O-sulfonates is not entirely clear, but is presumably similar to that which has been elucidated for the analogous reaction of arylsulfonylketoximes.[5] No evidence for the formation of a pyrazine from cyclopentanoxime-O-sulfonic acid could be obtained, which is reminiscent of the reported failure of α-chlorocyclopentanone to yield a pyrazine when treated with alcoholic ammonia,[6] although α-chlorocyclohexanone gave octahydrophenazine in 25% yield under this treatment.

Experimental

The potassium ketoxime-O-sulfonates were prepared by adding one-tenth equivalent of potassium carbonate or acetate in concentrated aqueous solution to an aqueous or methanolic solution of one-tenth equivalent each of hydroxylamine-O-sulfonic acid and ketone in an ice-bath. It is necessary first to allow sufficient time, usually about one minute, for the latter two reagents to react, as evidenced by the formation of a homogeneous solution. If this is not done, potassium hydroxylamine-O-sulfonate is obtained, which deflagrates with violence during subsequent operations. The desired salts crystallized on scratching, and were filtered and washed with water and/or methanol, followed by ether or benzene. Those salts which are appreciably soluble in water could not be freed of potassium sulfate by washing. Where purification could not be accomplished by recrystallization from water or alcohol, advantage was taken of the fact that potassium ketoxime-O-sulfonates as first formed are in highly supersaturated solution, but the contaminating potassium sulfate is present as a suspension in the alcoholic solution. Rapid filtration at this stage through a bed of Filter-Cel accomplished the desired purification. For the recrystallizations, it was found best to filter the hot solutions through

[a] Prepared from potassium acetate. [b] Prepared from potassium carbonate. [c] In the presence of moisture, cyclopentanoxime, 55%. [d] In the presence of moisture, cyclohexanoxime, 89%. When treated with alc. NaOH, only unident. oils produced. [e] When treated with alc. NaOH at T. > 40°, and worked up after Neber's[5] directions for *p*-tolylphenylacetoxime, there was produced 56% of 2,5-di-Ph-3,6-di-Me-pyrazine, m. p. 125–128°, or 22% of the acetate of 1-phenyl-1-aminoacetone diethyl acetal, m. p. 145–147°. [f] In the presence of moisture, 36% of acetophenoxime plus a smaller amount of acetanilide plus a little acetophenone. The dry salt heated alone gave 47% of acetanilide, m. p. 112–114°. [g] In the presence of several equivs. of water, β-acetonaphthoxime, 85%, plus a little β-acetonaphthone. [h] When heated in dry pyridine, a little dihydrohomocarbostyryl, m. p. 143–144°, was formed. When heated with alc. NaOH, only dark, nonbasic oils were formed.

a preheated, sintered-glass filter with the aid of compressed air, because of the sharp temperature gradient of the solubilities in the neighborhood of the boiling point. Yields on recrystallization were generally about 50–60%.

The hydroxylamine-O-sulfonic acid was prepared from hydroxylamine sulfate and chlorosulfonic acid.[3] α-Chlorocyclohexanone was obtained from Farchan Laboratories; heptanone-2, phenylacetone, α-tetralone, and cyclohexanoxime were prepared by standard procedures; and the remainder of the organic chemicals used were Eastman Kodak Co. products.

The potassium ketoxime-O-sulfonates were analyzed for potassium by fuming to dryness with sulfuric acid, and in addition were titrated iodometrically. The equivalent weights given by the latter determination are subject to an error of as much as 10%, because of the long time, usually about forty-eight hours, required for complete reaction with the iodide.

In the accompanying table are listed the principal properties of the potassium ketoxime-O-sulfonates prepared.

Rearrangement of Ketoxime-O-sulfonates.—Approximately 4 *N* solutions of hydrogen chloride in dioxane were prepared from tank hydrogen chloride dried successively over sulfuric acid and phosphorus pentoxide, and dioxane freshly distilled from sodium. Mixtures of the ketoxime-O-sulfonates and several equivalents of the acid solutions were heated near the boiling point for periods of from ten minutes to an hour, after which they were treated with water and worked up for the neutral, acidic and basic components. The products obtained are listed in the accompanying table; products obtained from other ways of decomposing the compounds are described in footnotes to the table.

Octahydrophenazine.—The product, m. p. 108–109°, which was extracted with some difficulty from the tars obtained as above from potassium cyclohexanoxime-O-sulfonate was identified with the octahydrophenazine, m.p. 107–108°, obtained in 25% yield by Godchot and Mousseron[6] by the action of ammonia on α-chlorocyclohexanone. Because these authors neglected to publish analytical data either for octahydrophenazine or its picrate, we repeated their preparation. The product was obtained in 37% yield using a six-day reaction time and a rapid addition of ammonia; separation of the product from tar was facilitated by precipitation from the acidified reaction mixture with ammonia instead of alkali, and recrystallizing alternately from acetone and petroleum ether, in which the tar is respectively very soluble and almost insoluble. *Anal.*[7] Calcd. for $C_{12}H_{16}N_2$: C, 76.60; H, 8.58; N, 14.92, mol. wt., 188. Found: C, 76.60; H, 8.55; N, 14.65; mol. wt. (ebullioscopic in benzene[8]), 192, 193.

A picrate was obtained as yellow prisms from ethanol; m. p. 162–163°. *Anal.*[7] Calcd. for $C_{12}H_{16}N_2{\cdot}2C_6H_3O_7N_3$: C, 44.60; H, 3.42; N, 17.35. Found: C, 44.58; H, 3.55; N, 16.83, 16.77. Godchot and Mousseron reported m.p. 163–164° for a "monopicrate" for which they gave no analysis.

A chloroaurate was obtained as tiny yellow needles from water; m.p. 145–146° after recrystallization from absolute ethanol. *Anal.*[7] Calcd. for $C_{12}H_{16}N_2{\cdot}HAuCl_4{\cdot}C_2H_5OH$: C, 29.28; H, 4.04; Au, 34.4. Found: C, 28.55; H, 4.14; Au, 36.05. No formulation for this compound which gives a more satisfactory agreement with the analytical data is immediately apparent.

Because of the singular reactions by which octahydrophenazine is formed, it was felt desirable to confirm its structure. An attempt to dehydrogenate it to phenazine by means of iodine in acetic acid[9] gave only an insoluble, black resin. But oxidation of 0.19 g. with potassium permanganate in alkaline solution gave 0.035 g., 14%, of a water-soluble, amphoteric solid, identified by its m.p. of 206–208° and the red-violet color given with ferrous sulfate solution as the expected pyrazine-2,3,5,6-tetracarboxylic acid.[10]

***p*-Toluenesulfonylcyclohexanoxime.**—A solution of 9.5 g. of *p*-toluenesulfonyl chloride in 15 cc. of pyridine was added dropwise with stirring to one of 5.6 g. of cyclohexanoxime in 10 cc. of pyridine in an ice–methanol-bath. The mixture was kept at 0° for four hours and then poured

on a slurry of ice and dilute sulfuric acid. The oil which separated in large amount crystallized in a few seconds, but upon warming to room temperature during filtration and washing, it deflagrated vigorously. In subsequent preparations, it was therefore taken up in cold benzene and dried and handled in that solvent. Treatment of such a benzene solution with hydrogen chloride in dioxane gave no crystallizable product. Treatment with alcoholic sodium hydroxide yielded less than 5% of octahydrophenazine. *p*-Toluenesulfonylphenylacetoxime likewise gave no crystalline products when treated with hydrogen chloride in dioxane.

Summary

1. The potassium oxime-O-sulfonates of eight ketones have been prepared.

2. Aqueous acid hydrolyzes these compounds to the corresponding oximes; anhydrous hydrogen chloride converts aryl alkyl ketoxime-O-sulfonates to amides by a Beckmann-type rearrangement, and converts some dialkyl ketoxime-O-sulfonates to pyrazines in low yield.

3. These reactions are related to the direct reaction of hydroxylamine-O-sulfonic acid with ketones, and to the reactions of O-arylsulfonyl ketoximes.

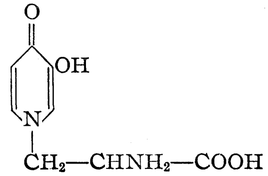
On the Structure of Leucaenine (Leucaenol) from *Leucaena Glauca* Bentham. III

BY A. F. BICKEL[1]

According to the experimental evidence now available, the most probable structure of leucaenine, an amino acid occurring in the tropical plant, *Leucaena glauca* Bentham, is β-[N-(3-hydroxypyridone-4)]-α-aminopropionic acid (I). The formation of 3,4-dihydroxypyridine on pyrolysis[2,3,4] and of N-methyl-3-methoxy-pyridone-4 on degradative methylation[5,6,7] proved the presence of a 3,4-dihydroxypyridine ring in leucaenine. These two reactions made it very probable that the part of the molecule containing the amino-acid residue is *not* bound to one of the carbon atoms of the pyridine ring. Since leucaenine is not split by treatment with 48% hydrobromic acid,[2] the alanine side-chain can*not* be bound to one of the hydroxyl groups of the ring. Hence, structure I was assumed to be the most probable.



I

The object of the present investigation was to attempt to provide definite proof of the existence of an alanine side-chain and to demonstrate its position in the molecule. It is known that a compound of a structure comparable to that of leucaenine, N-methyl-3-hydroxypyridone-4, yields methylamine[5] on oxidation with potassium permanganate. Should the oxidation of leucaenine proceed in the same way, formation of α,β-diaminopropionic acid may be expected. This diamino acid is, however, oxidized by potassium permanganate. Thus it was imperative to find an oxidizing agent capable of breaking the ring, while leaving the diamino acid unattacked. An aqueous solution of bromine proved to be a suitable reagent; hence the reaction of leucaenine with this oxidizing agent has been investigated more closely.

Upon oxidation of an aqueous suspension of leucaenine with bromine, a small amount of a compound $C_3H_9O_2N_2Br$ is formed. The specific rotation is $[\alpha]^{27}\mathrm{D}$ +13° (33 mg. dissolved in 5 cc. of 0.37% hydrochloric acid). Aqueous solutions of this substance as well as of *dl*-α,β-diaminopropionic acid hydrobromide, prepared by synthesis, show an acid reaction (*p*H of the saturated solution in both cases, 4), react with an acidified aqueous solution of silver nitrate to yield silver bromide, and show a strong ninhydrin reaction. On heating in a melting point capillary, both compounds (as well as their mixture) gradually turn brown above 200° and melt above 236° with decomposition.

Geiger counter spectrometer diffraction patterns of the two substances were prepared with CuKα radiation. These patterns both show a large number of sharp diffraction lines, identical in positions and intensities in both cases.

Ultraviolet absorption spectra of aqueous solutions were found to be essentially the same for both compounds; they showed gradually increasing absorption with decreasing wave length, but no characteristic maxima.[8] The shape of the curves obtained closely resembles that found by Ley and Vanheiden[9] for *dl*-α,β-diaminopropionic acid hydrochloride.

The above facts clearly prove that the substance isolated is α,β-diaminopropionic acid hydrobro-

(9) Ley and Vanheiden, *Z. anorg. allgem. Chem.*, **188**, 251 (1930).

mide; hence an alanine side-chain is bound to the nitrogen atom of the pyridine ring in leucaenine. This evidence establishes formula I as the correct structure for leucaenine.

The α,β-diaminopropionic acid *hydrochloride* showing a positive rotation is structurally related to the natural $l(-)$-serine.[10] Since the *hydrobromide* isolated also shows a positive rotation, it is very probable that leucaenine has the same stereochemical configuration as the other naturally-occurring amino acids. Natural leucaenine should therefore tentatively be designated as $l(-)$-leucaenine. (This result should be confirmed by comparison of the hydrochloride of the oxidation product with $l(+)$-α,β-diaminopropionic acid hydrochloride.)

Crystal structures of a racemic compound and of the corresponding *l*- and *d*-compounds are in general not the same; hence, one may expect a difference in melting points and X-ray diffraction patterns. The identity of these properties in the case of *dl*-α,β-diaminopropionic acid hydrobromide and the optically-active compound obtained on oxidation suggests, therefore, the absence of a racemic compound.

Another product obtained on oxidation of leucaenine by means of aqueous bromine solution is oxalic acid. It was isolated as the diammonium salt.

The optical rotation of leucaenine has been carefully re-determined and found to be $[\alpha]^{24}\text{D}\ -22°$, in good accord with the value for mimosine given by Renz.[11]

With sulfuric acid, leucaenine forms a sulfate of the composition $C_8H_{10}O_4N_2{\cdot}H_2SO_4{\cdot}1.5\ H_2O$.

Experimental

All melting points given are corrected.

α,β-Diaminopropionic Acid Hydrobromide. (A) From Leucaenine.—Leucaenine (2 g.) was suspended in 60 cc. of water, and bromine was added at room temperature until the color persisted (2.5 cc., or 5 moles of bromine per mole of leucaenine). After an hour the brown solution was evaporated *in vacuo* until the excess bromine had been removed, and then boiled with a great excess of lead carbonate until the evolution of carbon dioxide ceased. During this process the precipitate of lead bromide turned brown and a strong, aldehydic odor developed. After addition of Nuchar W, the reaction mixture was kept in the refrigerator overnight, and the lead bromide then filtered off and washed with ice-water. The yellow filtrate (*p*H 3) was treated with hydrogen sulfide, and the lead sulfide filtered off and washed with water. The final filtrate was evaporated *in vacuo* to dryness and the residue was dissolved in a small amount of water. After filtration, the brown solution was brought to *p*H 6 with 28% ammonia (0.5 cc.), again filtered, evaporated on the steam-bath until brown crystals separated, and filtered after cooling. One recrystallization from water (Nuchar W) gave colorless crystals which were dried in a vacuum desiccator over phosphorus pentoxide. Yield was 11 mg. (0.6%); m. p., above 236° with decomposition. In a second experiment the yield was 34 mg. (from 3 g. of leucaenine) or 1.2%.

Anal.[12] Calcd. for $C_3H_9O_2N_2Br$: C, 19.47; H, 4.90; N, 15.14; Br, 43.19. Found: C, 19.82; H, 4.64; N, 14.97; Br, 43.42.

(B) **From α,β-Dibromopropionic Acid.**—The preparation was carried out according to the directions of Winterstein.[13] Yield was 48%; m. p., above 236° with decomposition.

Anal. Calcd. for $C_3H_9O_2N_2Br$: C, 19.47; H, 4.90; N, 15.14; Br, 43.19. Found: C, 19.67; H, 4.71; N, 15.21; Br, 43.41.

A mixture of the hydrobromides from (A) and (B) melted above 236° with decomposition.

Ammonium Oxalate.—Leucaenine (1 g.) was dissolved in 5 cc. of 10% hydrobromic acid and bromine was added at room temperature until the color persisted. The excess bromine was removed *in vacuo* and the solution was evaporated in the vacuum desiccator over potassium hydroxide. The residue was dissolved in a small amount of water and the solution rendered neutral with 28% ammonia. On cooling, the needles which separated were filtered off, recrystallized once from water (Nuchar W), and dried at 110°. Yield was 50 mg.; m. p. 216–216.5° with decomposition.

Anal. Calcd. for $C_2H_8O_4N_2$: C, 19.36; H, 6.50; N, 22.58. Found: C, 19.71; H, 6.42; N, 22.78.

Ammonium oxalate prepared from oxalic acid and ammonia melted at 218–218.5° with decomposition; mixed melting point, 217.5–218° with decomposition.

Leucaenine Sulfate.—Leucaenine (0.99 g.) was dissolved in a warm solution of 0.52 g. of 95% sulfuric acid in 2 cc. of water. On cooling, the colorless crystals which separated were filtered off, and washed successively with water, ethanol, and ether. Yield was 1.53 g. (95%); m. p. 143–143.5°, with decomposition.

Anal. Calcd. for $C_8H_{10}O_4N_2{\cdot}H_2SO_4{\cdot}1.5H_2O$: C, 29.70; H, 4.68; N, 8.67. Found: C, 29.49; H, 4.79; N, 8.68.

Acknowledgment.—The author expresses his gratitude to Dr. E. R. Weidlein, Director of Mellon Institute, for enabling him to carry out this investigation, and to Dr. Leonard H. Cretcher, Head of the Department of Research in Pure Chemistry, for his interest and encouragement.

Summary

A compound, $C_3H_9O_2N_2Br$, obtained on bromine oxidation of *leucaenine* has been proved to be α,β-diaminopropionic acid hydrobromide. This result establishes the structure of leucaenine as β-[N-(3-hydroxypyridone-4)]-α-aminopropionic acid.

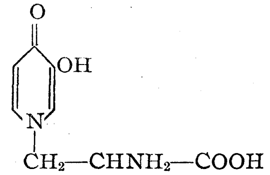
On the Structure of Leucaenine (Leucaenol) from *Leucaena Glauca* Bentham. IV

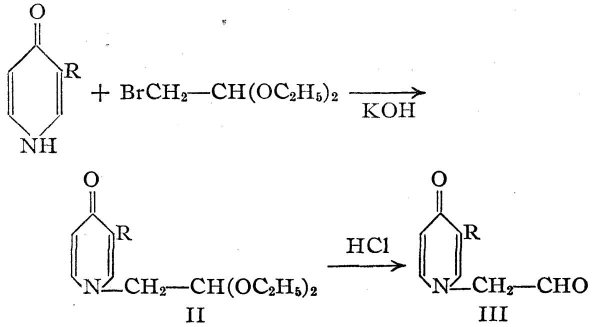
BY A. F. BICKEL[1]

In a number of investigations on the structure of leucaenine[2-6] it has been shown that this amino acid must be represented as β-[N-(3-hydroxypyridone-4)]-α-aminopropionic acid (I).



I

The object of the present investigation was to prepare [N-(3-methoxypyridone-4)]-acetaldehyde (IIIa), a compound which might serve as an intermediate in the synthesis of leucaenine by means of the Strecker reaction. IIIa might be prepared in the following manner.



(a) R = OCH_3 (b) R = H

The starting material for this synthesis, 3-methoxypyridone-4, is not easily available. Hence, in order to become acquainted with the reaction conditions, a similar synthesis, that of (N-pyridone-4)-acetaldehyde (IIIb) was first investigated. IIb was obtained in good yield by the reaction of pyridone-4, bromo-acetal and potassium hydroxide in alcoholic solution. The crude acetal was hydrolyzed to IIIb by boiling with dilute hydrochloric acid. The preparation of [N-(3-methoxypyridone-4)]-acetaldehyde (IIIa) was performed in the same manner. Although this aldehyde was not isolated in the pure state, its semicarbazone was prepared. Preliminary Strecker reactions carried out by the method of Cocker and Lapworth[7] have thus far been unsuccessful.

Experimental

All melting points given are corrected.

4-Hydroxypyridine was prepared according to the method of Königs and Greiner.[8]

(N-Pyridone-4)-acetaldehyde Diethyl Acetal.—A solution of 4.75 g. (0.05 mole) of 4-hydroxypyridine in 10 cc. of ethanol was mixed with 3.3 g. (0.05 mole) of 85% potassium hydroxide in 50 cc. of ethanol and 11.0 g. (0.055 mole) of bromoacetal was added. The resulting solution was heated in a sealed tube at 128–130° for seven hours, filtered from the separated potassium bromide (5.7 g. or 97% of the theoretical quantity), and evaporated *in vacuo*. The sirupy residue was dissolved in 30 cc. of water and rendered neutral with a few drops of concentrated hydrochloric acid.

The acetal was isolated as follows: The neutral aqueous solution was evaporated *in vacuo*. An alcoholic extract of the residue was filtered from a small amount of potassium chloride and concentrated *in vacuo*. On standing exposed to air, the resulting sirup yielded beautiful, colorless crystals of the acetal monohydrate, which were recrystallized from water, m. p., 87–89°. *Anal.*[9] Calcd. for $C_{11}H_{17}O_3N \cdot H_2O$: C, 57.62; H, 8.35; N, 6.11. Found: C, 57.44; H, 8.06; N, 6.18.

On drying over phosphorus pentoxide in a vacuum desiccator, the crystals lose water and revert to a sirup. The picrate was prepared by adding a small excess of picric acid dissolved in ethanol to a solution of the acetal in ethanol. Recrystallization was performed from the same solvent; m. p., 137–139°. *Anal.* Calcd. for $C_{11}H_{17}O_3N \cdot C_6H_3O_7N_3$: N, 12.72. Found: N, 12.49, 12.77.

(N-Pyridone-4)-acetaldehyde Hydrate.—The hydrolysis may be carried out after isolation of the acetal. It is simpler, however, to start with the aqueous solution of the original reaction mixture after neutralization with hydrochloric acid. This solution, treated with 8 cc. of 38% hydrochloric acid and 25 cc. of water, was refluxed for four hours. After evaporation *in vacuo*, a solution of the residue in 15 cc. of water was neutralized with sodium carbonate, a colorless crystalline precipitate of the aldehyde hydrate separating out. The product was collected, washed with small portions of ice-water until free from sodium chloride, and dried in the vacuum desiccator over phosphorus pentoxide. Yield was 4.3 g. (55% calculated on 4-hydroxypyridine). Recrystallization was performed from water. On heating, this compound turns brown above 110°, but does not melt.

Anal. Calcd. for $C_7H_7O_2N \cdot H_2O$: C, 54.19; H, 5.85; N, 9.03. Found: C, 53.98; H, 5.82; N, 8.97.

The picrate was prepared by adding an aqueous solution of picric acid to an aqueous solution of the aldehyde; recrystallization from water, m. p. 182.0–182.5° with decomposition.

Anal. Calcd. for $C_7H_7O_2N \cdot C_6H_3O_7N_3 \cdot H_2O$: C, 40.63; H, 3.15; N, 14.58. Found: C, 40.90, 40.94; H, 3.20, 3.38; N, 14.42.

The semicarbazone was obtained by evaporating an aqueous solution of 155 mg. of aldehyde hydrate, 112 mg. of semicarbazide hydrochloride, and 53 mg. of sodium carbonate on the steam-bath until needles separated. On cooling, the crystals were filtered off and washed with ice-water. Recrystallization was performed from 50% ethanol; m. p. 208–208.5° with decomposition.

Anal. Calcd. for $C_8H_{10}O_2N_4$: C, 49.48; H, 5.19; N, 28.85. Found: C, 49.63; H, 5.38; N, 28.61.

[9] The microanalyses were carried out by Mr. G. L. Stragand of the University of Pittsburgh.

[N-(3-Methoxypyridone-4)]-acetaldehyde.—3-Methoxypyridone-4, bromoacetal and potassium hydroxide were caused to react in the manner described for pyridone-4. More than 90% of the theoretical quantity of potassium bromide was formed. No attempts were made to isolate the acetal; instead, its aqueous solution was refluxed with hydrochloric acid. On neutralizing with sodium carbonate, the liquid turned a dark brown but no aldehyde separated. By reaction of the crude material with semicarbazide, however, a semicarbazone was formed; its yield indicated that the over-all yield of aldehyde, calculated on 3-methoxypyridone-4, was about 40%. The semicarbazone was recrystallized from water and dried over phosphorus pentoxide in the vacuum desiccator; m. p. 188–188.5° with decomposition.

Anal. Calcd. for $C_9H_{12}O_3N_4 \cdot 2H_2O$: C, 41.53; H, 6.20; N, 21.53; H_2O, 13.84. Found: C, 41.86; H, 6.30; N, 21.41; H_2O, 13.76.

The anhydrous compound, which may be prepared by drying over phosphorus pentoxide at 100° (1 mm.), is very hygroscopic.

Summary

(N-Pyridone-4)-acetaldehyde and [N-(3-methoxypyridone-4)]-acetaldehyde have been synthesized.

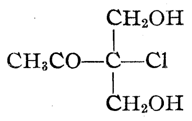
The Condensation of Chloroacetone with Formaldehyde

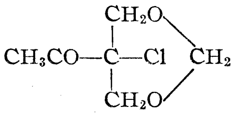
BY CHARLES D. HURD, WARREN D. MCPHEE[1] AND GLEN H. MOREY

While the condensation of formaldehyde with lower ketones has been studied extensively, the reaction of this aldehyde with chloroacetone has not previously been investigated. From the reaction of one mole of chloroacetone with 2.1 moles of formaldehyde, there are obtained three substances: A, a crystalline solid melting at 61–62°; B, a colorless oil distilling at 93.5° (10 mm.); C, a colorless oil distilling at 73–74.5° (10 mm.). From the evidence presented herein, it has been concluded that these substances are respectively 2-chloro-2-acetyl-1,3-propanediol, 2-chloro-2-acetyl-1,3-propanediol formal and 4-hydroxy-3,3-dichloro-2-butanone.



$$\mathrm{CH_3CO{-}\overset{\displaystyle CH_2OH}{\underset{\displaystyle CH_2OH}{C}}{-}Cl}$$

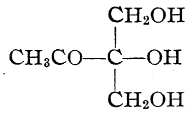
A



B

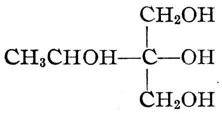
$\mathrm{CH_3COCCl_2CH_2OH}$

C



$$\mathrm{CH_3CO{-}\overset{\displaystyle CH_2OH}{\underset{\displaystyle CH_2OH}{C}}{-}OH}$$

D



$$\mathrm{CH_3CHOH{-}\overset{\displaystyle CH_2OH}{\underset{\displaystyle CH_2OH}{C}}{-}OH}$$

E

In determining the structure of substance A, it is apparent from the empirical formula that two hydroxymethyl groups have been introduced. It is necessary only to ascertain which α-carbon atom carries them. This was done by oxidation of A to acetic acid and by reaction with sodium hypoiodite with the formation of iodoform. ω-Chloroacetophenone is known to give a negative iodoform reaction,[2] and chloroacetone was found to give similar results. In view of these facts, A was assigned the structure shown.

Compound B differs from A only by the presence of one more carbon atom. It seemed logical that B should be the cyclic formal derived from A by reaction with a third mole of formaldehyde. Compound A was converted into B by means of dry formaldehyde in ether in the presence of a trace of acid, thus proving the structure of B. The compound so synthesized was shown to be identical with B.

The high chlorine content of C indicated that it was derived from dichloroacetone, which is generally present in small amounts in chloroacetone. Structure C, analogous to structure A, was selected because this compound gives a positive iodoform test. The formula was confirmed by synthesis of C from α,α-dichloroacetone and formaldehyde.

2-Chloro-2-acetyl-1,3-propanediol, A, was readily converted to its diacetate with ketene and to its dibenzoate with benzoyl chloride. Upon treatment with aqueous or alcoholic alkali, there is obtained a triol believed to be acetylglycerol, D. There is no evidence on the question whether this comes by direct saponification or by way of dehydrohalogenation to an ethylene oxide intermediate,

By the reaction of three moles of formaldehyde per mole of chloroacetone in the presence of one mole of sodium hydroxide, there is obtained substance D. The latter was identical with the triol obtained by alkaline hydrolysis of A. Substance D was reduced by sodium in alcohol to a tetrol, 2-hydroxymethyl-1,2,3-butanetriol, E.

Experimental

Reaction of Chloroacetone and Formaldehyde.—Chloroacetone (containing a little α,α-dichloroacetone) and formalin (40% solution) were mixed in a molar ratio of 1:2.1. The mixture was agitated at 25° for thirty minutes, during which time 2 *N* sodium hydroxide solution was added dropwise till 0.27 mole of the base was added. There was some heat of reaction during this addition, and the two-layer system gradually became homogeneous. The

mixture was shaken three hours longer, then distilled. After the water was removed at 100°, colorless volatile products were collected at 140° (5–10 mm.). A nonvolatile tarry residue (weighing 8–9% of the initial reactants) remained in the flask and the distillate was found to comprise a colorless, sirupy liquid and a crystalline solid which were separated by filtration. The liquid represented 21% of the initial reactants and the solid 33%. The latter was shown to be 2-chloro-2-acetyl-1,3-propanediol. It melted at 61–62° after crystallization from heptane.

Anal. Calcd. for $C_5H_9ClO_3$: Cl, 23.25; mol. wt., 152.5. Found: Cl, 23.36; mol. wt., 149.

Two components, both colorless oils, were separated from the sirupy liquid by distillation: component C, b. p. 73° (10 mm.), d^{20}_{20} 1.371; component B, b. p. 93.5° (10 mm.), d^{20}_{20} 1.286.

Anal. of B. Calcd. for $C_6H_9ClO_3$: Cl, 21.57. Found: Cl, 21.45.

Haloform Reactions.—2-Chloro-2-acetyl-1,3-propanediol (A) was tested as follows:

Five-tenths gram of the substance was dissolved in a solution formed by adding 1.25 g. of iodine to 8 ml. of 10% sodium hydroxide solution, after which 1.25 g. of iodine was added in small amounts with sufficient alkali solution to discharge the brown color. A voluminous white precipitate of iodoform (2 g. or 78%) was formed, m. p. 119°.

In a similar way (A) gave a positive chloroform test by the following procedure: Ten cubic centimeters of 10% sodium hydroxide solution was saturated at 0° with chlorine, followed by addition of 10 cc. more alkali and 1 g. of substance A. The mixture was distilled and the distillate contained an oily layer of chloroform, which was separated and dried; n^{20}_D 1.4458.

4-Hydroxy-3,3-dichloro-2-butanone (C) gave iodoform positively by the above procedure using 1 ml. of C; yield 0.4 g. (25%), m. p. 118.5–119°.

2-Chloro-2-acetyl-1,3-propanediol diacetate (0.5 g.) gave a low yield of impure iodoform by mixing it with 5 ml. of sodium hypoiodite solution prepared by dissolving 2.5 g. of iodine in 16 ml. of 10% sodium hydroxide. The resulting suspension was shaken for fifteen minutes, during which time about 0.1 g. of iodoform melting at 114° was obtained.

Chloroacetone gave a negative iodoform test as follows: 0.6 ml. of chloroacetone was shaken for ten minutes with 8 ml. of sodium hypoiodite solution prepared as above. No iodoform was obtained.

Oxidation of 2-Chloro-2-acetyl-1,3-propanediol.—A sample of the 2-chloro-2-acetyl-1,3-propanediol weighing 1.505 g. (0.00986 mole) was dissolved in 100 g. of water and oxidized quantitatively by means of a chromic acid mixture prepared from 8.8 g. (0.03 mole) of potassium dichromate, 75 g. of water and 22 ml. of concentrated sulfuric acid. The mixture was refluxed in an all-glass apparatus until the evolution of carbon dioxide ceased (thirty minutes). It was then distilled slowly until crystals separated, whereupon 100 g. of water was added, and the distillation was continued. The combined distillate and washings were made up to 500 ml. and two 25-ml. samples were titrated with 0.0651 *N* sodium hydroxide. The ml. of alkali required were 5.36 and 5.34, respectively, representing a total of 0.00697 mole of acid distilled. This is 0.71 mole of acid per mole of 2-chloro-2-acetyl-1,3-propanediol oxidized. The sodium salt, obtained by evaporating the neutralized distillate, was converted into the *p*-bromophenacyl acetate, m. p. 85°.

Duclaux constants were taken on a fresh portion of the distillate: 6.0, 6.4, 6.8. These check fairly well with those for acetic acid, 6.8, 7.1, 7.4.

Conversion of 2-Chloro-2-acetyl-1,3-propanediol into its Formal.—Five grams of dry paraformaldehyde in a 125-cc. flask was heated to 170–180° in an oil-bath while a slow stream of nitrogen (dried with concentrated sulfuric acid) was passed through the flask. The outlet tube (12 mm.) led into a test-tube containing 30 ml. of anhydrous ether at −80°. The heating was continued until nearly all the polymer had disappeared. The gain in weight of the ether solution was 1.3 g., representing 0.04 mole of formaldehyde. To this cold (−80°) solution was added 2.2 g. (0.014 mole) of 2-chloro-2-acetyl-1,3-propanediol (A) and two drops of concentrated sulfuric acid. The solution was kept at −80° for twelve hours, then allowed to come to room temperature. After two days the ether was evaporated on the steam-bath. About 2.3 g. of colorless oil was left. This represents about a 95% yield of the cyclic acetal. The oil was not soluble in water, whereas the starting products were.

The 2,4-dinitrophenylhydrazones of the oil and of substance B (b. p. 93.5° at 10 mm.) both melted at 159–160° after recrystallization from alcohol. Their mixture also melted at 159–160°, but if either was mixed with formaldehyde 2,4-dinitrophenylhydrazone (m. p. 163°), the m. p. was depressed to 139–150°. Hence, the hydrazone is not that of formaldehyde. 2-Chloro-2-acetyl-1,3-propanediol, the starting product, gives no 2,4-dinitrophenylhydrazone when prepared in alcohol, since the hydrazone is soluble in alcohol.

Condensation of α,α-Dichloroacetone with Formaldehyde.—A mixture of 51 g. of α,α-dichloroacetone (55.01% Cl) and 65 ml. of 40% formalin was stirred mechanically while 5 g. of dry sodium carbonate was added slowly. After the initial vigorous reaction (the solution boils) the mixture was stirred at room temperature for eight hours. The lower organic layer was separated, dried with drierite, filtered and vacuum-distilled. The odor of formaldehyde was noticeable. A small forerun (4.5 g.) was obtained, b. p. 78–81° (20 mm.), n^{20}_D 1.4725, after which the main body of 4-hydroxy-3,3-dichloro-2-butanone was obtained, b. p. 81° (20 mm.), 105° (50 mm.), d^{20}_{20} 1.34, n^{20}_D 1.4727. There was no other volatile fraction. This product has the same physical constants as substance C (b. p. 79.5–80.5° (20 mm.), n^{20}_D 1.4724), isolated originally from the experiment with chloroacetone. These directions were modified for runs involving several kg. of product with yields consistently at about 75%.

Anal. Calcd. for $C_4H_6Cl_2O_2$: Cl, 45.21. Found: Cl, 44.96.

The semicarbazone of this substance melted with decomposition at 230–231° after recrystallization from alcohol. The semicarbazone of C, similarly prepared, also melted at 229–230°. The mixed m. p. of the two was 229–230°.

Esters of 2-Chloro-2-acetyl-1,3-propanediol

Diacetate.—This was made by passing a slight excess of ketene into an acetone solution of the diol. From 2 g. of (A), 1.5 g. of 2-chloro-2-acetyl-1,3-propanediol diacetate, b. p. 138–143° (18 mm.), was obtained.

Anal. Calcd. for $C_9H_{13}ClO_5$: Cl, 15.0. Found: Cl, 14.7.

Dibenzoate.—Reaction with boiling benzoyl chloride effected benzoylation in 85% yield. Crystallization was from ethanol or ligroin: m. p., 82–83°.

Anal. Calcd. for $C_{19}H_{17}ClO_5$: Cl, 9.84. Found: Cl, 10.0.

Bis-*p*-nitrobenzoate.—Treatment with *p*-nitrobenzoyl chloride and pyridine (boiling), and crystallization from ethyl acetate (or ethanol) resulted in a 36% yield, m. p. 161°.

Anal. Calcd. for $C_{19}H_{15}ClN_2O_9$: Cl, 7.89. Found: Cl, 8.11.

Acetylglycerol from (A).—Five grams of the solid 2-chloro-2-acetyl-1,3-propanediol was dissolved in 100 ml. of 95% ethanol containing 2.5 g. of potassium hydroxide. A precipitate of potassium chloride formed immediately. The mixture was neutralized with a solution of hydrogen chloride in absolute alcohol. The salt was filtered off and washed with absolute alcohol. The alcohol was removed at 20 mm. by heating in a bath at 60°. The residual yellow sirup was not distillable at 5 mm. from a Claisen flask with a bath temperature of 175°, but it distilled readily from a simple molecular still[3] connected to a pair of mercury pumps and heated by a bath at 120–125°. The colorless, non-viscous, water-soluble distillate (D_1) weighed 1.8 g.

Material possessing the same properties was obtained by treatment with an equivalent of aqueous (6 *N*) sodium hydroxide, removal of water by vacuum distillation, filtration to remove sodium chloride, and distillation from the molecular still. The liquid will be called D_2.

From Chloroacetone.—Five grams (0.055 mole) of chloroacetone and 0.16 mole of formaldehyde (as formalin) were mixed and maintained at 20° while 0.055 mole of 6 *N* sodium hydroxide solution was added little by little with stirring in the course of a day. The mixture was then heated to 60° for ten hours to consume the base. The water was removed by evaporation under reduced pressure up to 90° and sodium chloride was precipitated in quantitative yield. The sirupy material (6.5 g.) was not distillable in an ordinary Claisen flask up to 175° (bath) and 5 mm., but it came over readily from a molecular still with the conditions specified above. The limpid distillate, to be referred to as D_3, weighed 1.5–2 g. There was a red-brown, non-volatile residue in the still.

Anal. Calcd. for $C_5H_{10}O_4$: active hydrogen atoms, 3. Found (Zerewitinoff): active hydrogen atoms from D_1, 3.13, 3.09; from D_3, 3.06, 2.98.

***p*-Bromobenzoic Ester.**—A mixture of 0.5 g. of acetylglycerol, 4 g. of *p*-bromobenzoyl chloride and 30 ml. of dry pyridine was maintained at 0° for thirty-six hours, and subsequently treated with 40 ml. of 5% sodium carbonate solution for eight more hours at 0°. Fifty grams of water was added, and the mixture was filtered. The acetylglycerol tris-*p*-bromobenzoate was digested in ethanol and recrystallized from butyl ether; yield of white needles, 2 g. (79%). D_1, D_2 and D_3 all behaved identically, giving products melting at 215–216°. Mixed melting point determinations of these products were not lowered.

The same product was formed but in lower yield if a reaction temperature of 100–115° was maintained.

Anal. Calcd. for $C_{26}H_{19}Br_3O_7$: Br, 35.1. Found: Br, 35.9.

Reduction of Acetylglycerol.—Four grams of acetylglycerol was dissolved in 17 ml. of ethanol and 3 g. of water. Two grams of sodium was added in small pieces during two hours. At first, the mixture was cooled with ice; when the reaction became less vigorous, it was allowed to proceed at room temperature. After ninety minutes the reaction was very slow, so 10 ml. more of alcohol was added. The solution became a deep red and a yellow precipitate formed. After the sodium had been added, the mixture was neutralized with a saturated solution of dry hydrogen chloride in alcohol. The solution was filtered from the salt which precipitated, the solvent was removed, and the 5 cc. of dark residue was distilled in the molecular still with a bath temperature of 80–85°. The yield of colorless distillate was 0.91 g. or 23%.

Anal. Calcd. for $C_5H_{12}O_4$: active hydrogen atoms, 4. Found (Zerewitinoff): active hydrogen atoms, 3.84, 4.02.

Summary

Formaldehyde condenses with chloroacetone to yield 2-chloro-2-acetyl-1,3-propanediol and its cyclic formal. α,α-Dichloroacetone, similarly treated, gives rise to 4-hydroxy-3,3-dichloro-2-butanone. Various reactions of these compounds are developed.

6-Methoxy-1-tetralone

BY DONALD G. THOMAS AND ALAN H. NATHAN

Of the various methods[1-6] described for the synthesis of 6-methoxy-1-tetralone (V), the one most generally used is that based on the chromic acid oxidation[5] of 6-methoxytetralin (IV), which usually has been obtained from tetralin by sulfonation, alkali fusion and methylation.[7,8] The over-all yield of 6-methoxy-1-tetralone by this method is about 30–35%.

An alternate route to 6-methoxy-1-tetralone is outlined below, and by this procedure we have obtained 6-methoxy-1-tetralone in over-all yields of 40–45%.

The reaction between anisole and succinic an-

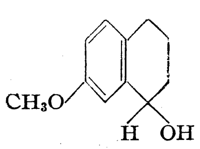
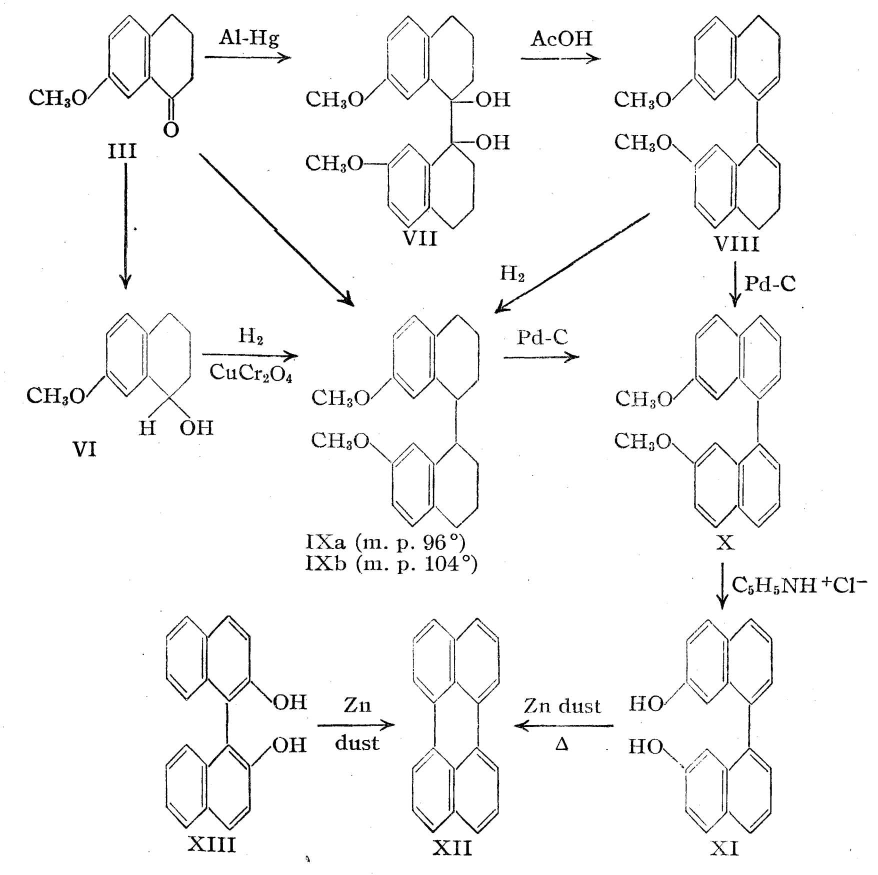
V



VI

hydride was carried out essentially as described,[9] with minor modifications that shortened the time required. Clemmensen reduction of the resultant β-(*p*-anisoyl)-propionic acid (I) was conducted as described.[10] Cyclization of the reduced acid (II) by treatment of the acid chloride with stannic chloride gave 7-methoxy-1-tetralone (III) in excellent yields. Hydrogenation of 7-methoxy-1-tetralone in the absence of solvent with a barium-free copper chromite catalyst up to 200° and under an initial pressure of 200 atmospheres gave practically quantitative yields of 6-methoxytetralin (IV). The success of the hydrogenation was dependent upon the purification of the ketone and the extent of the purification required was related to the amount of phosphorus pentachloride used in making the acid chloride of II. When the ratio of phosphorus pentachloride to acid was 1.1:1, the yield of purified 7-methoxy-1-tetralone was 83%, and it was essential to purify the ketone by distillation, refluxing with Raney nickel, and recrystallization before hydrogenation. Omission of any of these three steps resulted in only 55–70% yields of 6-methoxytetralin which was then accompanied by variable amounts of 7-methoxy-1-tetralol (VI) and occasionally by a crystalline bimolecular reduction product (see below). When the ratio of phosphorus pentachloride to acid was exactly 1:1, the yield of purified ketone was 88% and the treatment with Raney nickel could be omitted although in this case the yield of IV on hydrogenation was lowered to 92–94%.



The hydrogenation of either 7-methoxy-1-tetralone or 7-methoxy-1-tetralol in absolute alcohol with palladium–charcoal at room temperature and three atmospheres gave IV in 92–95% yield; the ketone did not have to be so rigorously purified. Clemmensen reduction of III gave IV in a maximum yield of only 77%.

Chromic acid oxidation of 6-methoxytetralin gave a 62% yield of distilled and recrystallized 6-methoxy-1-tetralone.

Hydrogenation of 7-methoxy-1-tetralol with copper chromite under the same conditions employed for 7-methoxy-1-tetralone gave a 58–62% yield of 6-methoxytetralin and, in addition, a 23–27% yield of a mixture which, by repeated fractional crystallization, was separated into two forms of 7,7′-dimethoxy-1,1′,2,2′,3,3′,4,4′-octahydro-1,1′-binaphthyl (IXa and b), which we conclude are the *cis* and *trans* forms. No attempt was made to determine the configurations of these two forms. The structure of IX was verified by the reactions outlined below.

7-Methoxy-1-tetralone was reduced with aluminum amalgam to the pinacol (VII), which was dehydrated to the diene (VIII).[11] Reduction of the diene with sodium and butyl alcohol gave a mixture from which both IXa and IXb were isolated; only IXb was isolated from the hydrogenation of the diene with Raney nickel. Dehydrogenation of VIII, IXa and IXb gave in each case 7,7′-dimethoxy-1,1′-binaphthyl (X).

The fact that these bimolecular reduction products were joined in the 1,1′-position was proved,

[10] Martin, "Organic Reactions," Vol. I, John Wiley and Sons, New York, N. Y., 1942, p. 167.

[11] This diene was also obtained on distillation of the high-boiling residues from the Clemmensen reduction of 7-methoxy-1-tetralone.

not only by their formation via the pinacol reduction of 7-methoxy-1-tetralone,[12] but also by the formation from the binaphthol (XI) of perylene (XII), which has been previously prepared by a similar reaction from 2,2′-dihydroxy-1,1′-binaphthyl (XIII).[13]

Experimental

β-(*p*-Anisoyl)-propionic Acid (I).—A solution of 560 g. (4.2 moles) of aluminum chloride in 1 liter of 1-nitropropane[14] was added gradually to a mechanically stirred mixture of 216 g. (2 moles) of anisole and 210 g. (2.1 moles) of succinic anhydride in 500 cc. of 1-nitropropane while the temperature was kept at 0–5°. The mixture was kept at 3–8° for approximately twenty-four hours, allowed to reach 15° in about an hour and hydrolyzed with ice and hydrochloric acid. Isolation of the acid as described[9] gave 358–376 g. (86–90%) of almost colorless to cream-colored acid; m. p. (not recrystallized) 144.5–146.5°.

γ-(*p*-Anisyl)-butyric Acid (II).—Clemmensen reduction[10] of the above keto acid in amounts from 350–900 g. gave yields from 90–93.4%; b. p. 152–156° at 0.6 mm.; m. p. (not recrystallized) 59–61° with softening at 56°.

7-Methoxy-1-tetralone (III).—To a mechanically stirred solution of 194 g. (1 mole) of the reduced acid (II) in 1 liter of dry thiophene-free benzene was added 208.3 g. (1 mole) of phosphorus pentachloride while the temperature was kept at 5–10°. The resulting colorless solution was warmed to 50° for a few minutes and then chilled to 0 to −5°. To it was added rapidly (about forty seconds) a chilled solution of 175 cc. of anhydrous stannic chloride in 175 cc. of dry thiophene-free benzene. A blood-red color developed which quickly turned to a dark brown-green and in ten to fifteen minutes the reaction mixture set to a green semi-solid. Hydrolysis and isolation as described for a similar cyclization[15] followed by distillation from 115–120° at 0.6–0.8 mm. (160–165° at 11 mm.) gave 161.4 g. (91.7%) of colorless crystalline ketone. For hydrogenation with copper chromite the product was refluxed for an hour with about 5 g. of Raney nickel in absolute ethanol and then recrystallized from petroleum ether (60–75°) from which it separated as large colorless prisms; m. p. 61–62.5°; yield, 154.9 g. (88%).

6-Methoxytetralin (IV).—7-Methoxy-1-tetralone (70.4 g., 0.4 mole) was hydrogenated in the presence of 7.0 g. of barium-free copper chromite[16] at 200° without solvent and under an initial pressure (at room temperature) of 3000 pounds. Hydrogenation began at 125° and was complete after an hour at 200°.[17] The product was obtained as a colorless liquid; b. p. 121–128° at 11 mm.; yield, 62.2–64.2 g. (96–99%). Hydrogenation of ketone in whose purification the Raney nickel treatment was omitted gave 92–94% yields.

6-Methoxy-1-tetralone (V).—The oxidation of 113.4 g. (0.7 mole) of 6-methoxytetralin with chromic acid was carried out essentially as described[5] except that the tetralin was dissolved in a solvent consisting of 80% of acetic acid and 20% of propionic acid; this mixture prevented solidification when the solution was chilled. After oxidation, the solvent was removed, but instead of distilling the dark viscous residue with super-heated steam it was warmed with 5% sulfuric acid and the ketone was extracted with ether[18] which was then washed with water, 5% sodium hydroxide solution, water and dried. Distillation at 129–133° at 0.7 mm. (a fore-run of unchanged 6-methoxytetralin was collected) and recrystallization from petroleum ether (60–75°) gave V as large colorless prisms; m. p. 77–78.5°; yield, 76.4 g. (62%).

7-Methoxy-1-tetralol (VI).—Hydrogenation of 7-methoxy-1-tetralone in whose preparation 1.1 moles of phosphorus pentachloride was used and which was not subjected to the full purification procedure gave 55–72% yields of 6-methoxytetralin, 10–30% yields of 7-methoxy-1-tetralol and occasionally a bimolecular reduction product (IX) (see below); when IX was obtained little or no tetralol was isolated. 7-Methoxy-1-tetralol is a colorless viscous liquid; b. p. 118–120° at 0.3 mm. (164–166° at 10 mm.); $n^{23}D$ 1.5553.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92. Found: C, 74.05; H, 7.97.

The *p*-nitrobenzoate crystallized from ethanol as pale yellow prisms; m. p. 73.5–74°.

Anal. Calcd. for $C_{18}H_{17}NO_5$: C, 66.04; H, 5.24; N, 4.28. Found: C, 65.95; H, 5.25; N, 4.29.

7,7′-Dimethoxy-1,1′-dihydroxy-1,1′,2,2′,3,3′,4,4′-octahydro-1,1′-binaphthyl (VII).—Eight and eight-tenths grams of 7-methoxy-1-tetralone was reduced with amalgamated aluminum foil in alcohol–benzene according to the procedure described by Newman[12] for 7-methyl-1-tetralone. The pinacol was isolated as a mixture of crystals and an oil which could not be obtained crystalline; both fractions could be converted to the diene (VIII). The crystals, after recrystallization from isopropanol, amounted to 3.9 g. (44%), m. p. 182–184°. After one further recrystallization from benzene–cyclohexane they melted at 183–184.5° and were analytically pure.

Anal. Calcd. for $C_{22}H_{26}O_4$: C, 74.56; H, 7.40. Found: C, 74.67, 74.77; H, 7.39, 7.37.

7,7′-Dimethoxy-3,3′,4,4′-tetrahydro-1,1′-binaphthyl (VIII).—Dehydration of the pinacol (VII) was accomplished by refluxing for two hours in about seven times its weight of glacial acetic acid. The diene crystallized from solution on cooling. Both the crystalline pinacol and the uncrystallizable oil gave the same diene, which was obtained as colorless octahedra from methanol, m. p. 147.8–148.2°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.99; H, 6.97. Found: C, 83.18; H, 7.15.

The pinacol was also converted to the diene by repeated recrystallization from alcohol. A mixed melting point with a product isolated from the Clemmensen reduction of 7-methoxy-1-tetralone was not depressed.

7,7′-Dimethoxy-1,1′,2,2′,3,3′,4,4′-octahydro-1,1′-binaphthyl (IXa and IXb).—Hydrogenation of 71.2 g. (0.4 mole) of 7-methoxy-1-tetralol (VI) under the same conditions employed for the hydrogenation of III gave 40.4 g. (62%) of 6-methoxytetralin and 17.5 g. (27%) of a very viscous yellow oil, b. p. 255–270° at 11 mm., which crystallized rather poorly when triturated in methanol. After a tedious series of fractional crystallizations from methanol two compounds were isolated. One (IXa) formed colorless rhomboidal plates, m. p. 95–96°; the other (IXb) formed colorless hexagonal prisms, m. p. 103–104.5°. Attempts to interconvert these two isomers failed.

Anal. Calcd. for $C_{22}H_{26}O_2$: C, 81.96; H, 8.13. Found: IXa, C, 82.00; H, 8.39. IXb, C, 81.98; H, 8.46.

To a solution of 1.75 g. of the diene (VIII) in 30 cc. of butanol at 60° was added 1.0 g. of sodium; after the reaction had subsided somewhat the mixture was heated until solution was complete. The cooled solution was washed with water until neutral, dried and evaporated. Fractional crystallization of the residue yielded both IXa and IXb.

A sample of the diene (VIII) in absolute alcohol was subjected to hydrogenation over Raney nickel at 50° and 160 atmospheres. The product after one recrystallization from methanol was pure IXb, m. p. 104–105°.

7,7′-Dimethoxy-1,1′-binaphthyl (X).—A mixture of the diene (VIII) with about 2.5% of its weight of palladized charcoal,[19] when heated at 290–300° for fifteen minutes, gave a practically quantitative yield of X which, after recrystallization from ethanol, formed colorless rectangular plates, m. p. 110.5–111.5°.

Anal. Calcd. for $C_{22}H_{18}O_2$: C, 84.08; H, 5.77. Found: C, 83.73; H, 5.64.

Similar treatment of the bitetralyl (IXa and IXb) gave in each case the same compound, identified by mixed m. p.

7,7′-Dihydroxy-1,1′-binaphthyl (XI).—The methyl ether (X) was smoothly demethylated in practically quantitative yield by the method of Prey.[20] A mixture of X with three times its weight of pyridine hydrochloride was heated at 200° for six hours, then poured into water. For analysis, the compound was converted to its diacetate by standard methods, because the free phenol was difficult to purify. The diacetate formed white crystals from ethanol, m. p. 173.5–174.5°. After three recrystallizations the compound gave the following analytical values.

Anal. Calcd. for $C_{24}H_{18}O_4$: C, 77.82; H, 4.90. Found: C, 77.38; H, 4.66.

Perylene (XII).—A mixture of the binaphthol (XI) with five times its weight of zinc dust was heated in a distilling flask with a free flame. A yellow oil distilled out of the mixture and solidified in the cooler parts of the apparatus. This was removed and recrystallized from benzene; it formed yellow leaflets with a bronze luster, melting at 267–268°. This was identified as perylene by comparison with an authentic specimen prepared by heating 2,2′-dihydroxy-1,1′-binaphthyl (XIII)[21] with zinc, zinc chloride and water.[13] A mixture of the two samples melted at 267–268°. The picrate formed dark violet needles from benzene, m. p. 220° (reported[22] m. p. 221°). The sample of perylene obtained from XI gave the following analytical results.

Anal. Calcd. for $C_{20}H_{12}$: C, 95.21; H, 4.80. Found: C, 94.90; H, 4.65.

Summary

1. A procedure for the preparation of 6-methoxy-1-tetralone in 40–45% yields from anisole is described.

2. A by-product from the catalytic hydrogenation of 7-methoxy-1-tetralone or 7-methoxy-1-tetralol has been shown to be 7,7′-dimethoxy-1,1′,2,2′,3,3′,4,4′-octahydro-1,1′-binaphthyl.

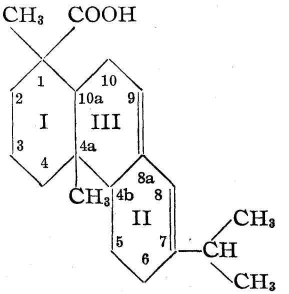
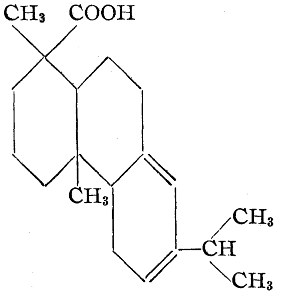
Resin Acids. I. An Improved Method of Isolation of Resin Acids; The Isolation of a New Abietic-Type[1] Acid, Neoabietic Acid

By George C. Harris and Thomas F. Sanderson

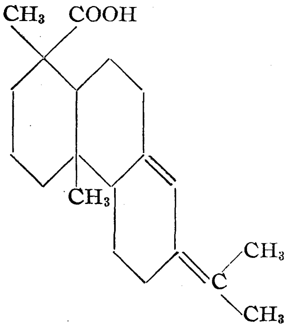
This is the first in a series of papers presenting recent developments made in these laboratories on the isolation and proof of structure of pure resin acids. This paper deals with improved methods of isolation of abietic acid (I)[2] and levopimaric acid (II)[3,4] the most familiar abietic-type acids; the isolation of neoabietic acid (III),[5] a new primary acid of this type, is also described.



I



II



III

Abietic Acid

The difficulty in separating abietic acid from isomeromorphic resin acids has made its isolation from rosin a difficult problem. However, Palkin and Harris[6] were able to obtain a pure abietic acid according to the following procedure: (1) isomerizing rosin by boiling in glacial acetic acid to increase the abietic acid content, (2) concen-

---

[1] We wish to designate by this term that type of resin acid that yields retene, 1-methyl-7-isopropylphenanthrene, upon complete dehydrogenation and has an isopropyl or isopropylidene group at C-7.

trating the abietic acid in the form of "Steele's" acid[7] by crystallizing the isomerized rosin from glacial acetic acid, (3) further concentrating the abietic acid by the preparation and recrystallization of the acid sodium salts ($C_{19}H_{29}COONa\cdot 3C_{20}H_{30}O_2$), and (4) fractionating the regenerated acids by the preparation and recrystallization of the diamylamine salts, a method first employed by Balas.[8] This procedure is effective but somewhat tedious and gives a relatively low recovery (*ca.* 12%) of the pure acid compared with the total abietic acid which can be shown to be present by ultraviolt absorption spectra. We have now found that diamylamine, the amine used by Balas[8] and Palkin and Harris,[6] not only offers a means of purification of abietic acid, $[\alpha]^{24}\text{D}$ −98°, but is specific for the separation of abietic acid from the complex mixture of resin acids in rosin. Addition of a molar quantity of diamylamine to an acetone solution of isomerized rosin precipitates the crystalline amine salts high in abietic acid content from which the salt of abietic acid is readily separated by fractional crystallization. The pure acid, $[\alpha]^{24}\text{D}$ − 106°, m. p. 172–175°, was obtained by decomposition of the salt with a weak acid such as acetic or phosphoric to minimize isomerization of the regenerated acid. The yield amounted to 40% of the weight of the isomerized rosin which is in fair agreement with that indicated by the absorption spectra.

Ultraviolet absorption curves are of great value in determining the amount of abietic acid present in modified or unmodified rosins. Figure 1 shows the ultraviolet absorption spectra of pure abietic acid (curve 1) and isomerized rosin (curve 2) The difference, $\Delta\alpha$, in specific absorption coefficient between the maximum at 241 mμ and the inflection point at 248.5 mμ is a constant value characteristic of pure abietic acid and can well be used as a measure of the abietic acid content of a rosin. The ratio of this difference for isomerized rosin to that for the pure acid is a measure of the amount of pure acid in the isomerized rosin. On the basis of these ratios, isomerized rosin contains 47 ± 2% of abietic acid. This precision does not hold for a non-isomerized rosin which contains neoabietic acid whose most intense band of absorption is at 250 mμ.

The ultraviolet absorption spectrum of pure abietic acid was found to demonstrate its most intense band at 241 mμ, α (specific absorption coefficient)[8a] = 77.0. This value is in good accord with that reported by Sandermann[9] (240 mμ) and that calculated (242 mμ) according to a method postulated by Woodward[10] and in disagreement with the value of 237.5 mμ reported by Kraft.[11]

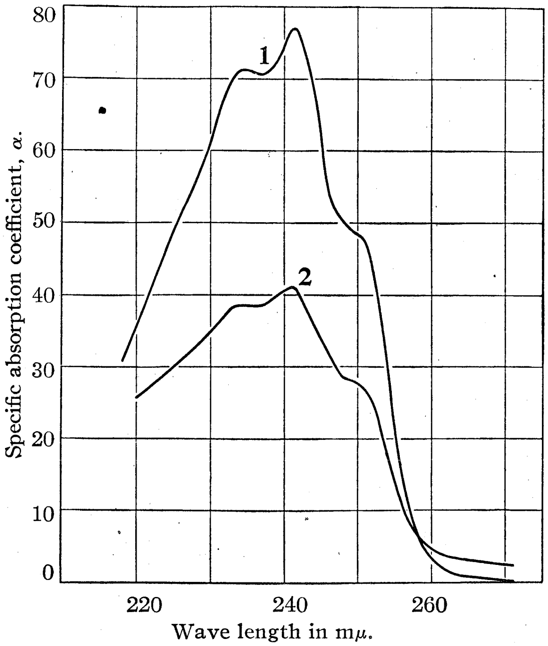

Fig. 1.—Ultraviolet absorption spectra: 1, abietic acid; 2, isomerized rosin.

Levopimaric Acid

Although levopimaric acid is the major constituent of the gum oleoresin of several conifers, its isolation has always been difficult with yields of the order of 1% having been obtained by Ruzicka, *et al.*,[12] and Palkin and Harris[13] from the "galipot"[13a] of *Pinus maritima* and *Pinus palustris*, respectively. The method employed was based on the fractional crystallization of the sodium salts.

The application of the amine salt technique in this instance resulted in the much increased yield of 20% of pure levopimaric acid $[\alpha]^{24}\text{D}$ −276°, from the "galipot" of *Pinus palustris*. The procedure is similar to that used for the isolation of abietic acid from rosin with the exception that butanolamine (2-amino-2-methyl-1-propanol, Commercial Solvents, Inc.) was used since it was found to be more specific for the precipitation of levopimaric acid than any other amine tried.

In the event that the whole oleoresin of *Pinus palustris* is used as the source of levopimaric acid, the total acids can be first separated from the turpentine by precipitation as amine salts. Cyclohexylamine was found most suitable for this purpose, since it results in a nearly quantitative precipitation of resin acids as the very insoluble cyclohexylamine salts from any medium in which they exist with non-resin acid material, *e. g.*, gum oleoresin or tall oil.[14] Formation of the butanol-

(13a) "Galipot" is a term used to describe the crystalline acids which settle out of the oleoresin, which, in turn, is a solution of resin acids in turpentine.

(14) G. C. Harris, U. S. Patent 2,419,211, April 22, 1947.

amine salt and regeneration of the acid as in the previous instance gave a yield of 15% based on the total acids or approximately 50% of the amount reported to be present. Recently, Fleck and Palkin[15] reported a value of 36% of levopimaric acid in the acids fraction of the oleoresin of *Pinus palustris* determined by the quantitative addition of maleic anhydride to levopimaric acid.

The ultraviolet absorption spectrum of pure levopimaric acid was found to demonstrate its most intense band at 272 mμ, $\alpha = 19.2$ (Fig. 2), in good agreement with that reported by Kraft.[11]

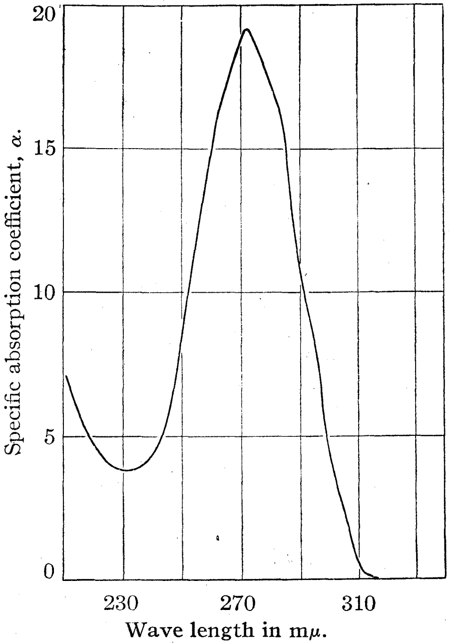

Fig. 2.—Ultraviolet absorption spectrum of levopimaric acid.

Neoabietic Acid

The presence of a dextrorotatory abietic-type acid in gum oleoresin has often been alluded to in the extensive literature on resin acids. The first serious attempt to isolate it was made by Kraft,[16] who was able to obtain only a mixture of acids with a positive rotation, $[\alpha]^{24}\text{D} + 11°$.[17] R. F. Cox, of this Laboratory, also isolated a resin acid with positive rotation, $[\alpha]^{24}\text{D} +83°$. This was obtained by the heat isomerization of abietic acid, $[\alpha]^{24}\text{D} -105°$, at 180° in accordance with a postulation by Ruzicka[18] that dextrorotatory acids are formed in equilibrium with levorotatory acids when the latter are isomerized at elevated temperatures. Cox's method of isolation of the dextro acid consisted of crystallizing the unaltered abietic acid from the mixture to concentrate the former in the residue from which it was fractionally crystallized. It is not surprising that further purification of the dextro acid was not obtained because fractional crystallization of mixtures of resin acids, as pointed out by Duffour,[19] always results in the isolation of mixed crystals rather than pure compounds. It was apparent, then, from the two instances cited above, that the lack of a workable technique for the isolation of pure resin acids from mixtures impeded progress in this direction.

Before employing the amine salt technique for the isolation of the dextrorotatory acid from the gum oleoresin of *Pinus palustris*, it was considered best to attempt its isolation from the simpler mixture of acids obtained in heat-isomerized abietic acid. Abietic acid, for this purpose, was heated[18] at 300° for twenty minutes, and the unreacted abietic acid (76%) separated from the mixture as its insoluble diamylamine salt. In this manner, a highly dextrorotatory residue was obtained which was treated with butanolamine in acetone to obtain two crops of crystalline salts. The first with rotation $[\alpha]^{24}\text{D} +24°$ was discarded, the second with rotation $[\alpha]^{24}\text{D} +100°$ was recrystallized from acetone to a constant rotation, $[\alpha]^{24}\text{D} +102°$. The salt was decomposed with boric acid to obtain a new resin acid, termed neoabietic acid, with rotation $[\alpha]^{24}\text{D} +159°$, and melting point 167–169°. Neoabietic acid, like levopimaric acid, was found to be highly susceptible to mineral acid and isomerizes almost completely to abietic acid in the presence of a trace of strong acid.

This acid was isolated in 5% yield from the resin acids of gum oleoresin by alternate fractional crystallization of the diethylamine and butanolamine salts. Neoabietic acid can also be prepared from commercial gum rosin of any color grade by using the diethylamine salt to obtain initial concentration and butanolamine to effect final purification.

The homogeneity of neoabietic acid was established by preparation and recrystallization of the methy ester, m. p. 61.5–62°, and also of the butanolamine salt, $[\alpha]^{24}\text{D} + 102°$, and regeneration in each case of acid identical with the original in optical rotation and ultraviolet absorption. The ultraviolet absorption spectrum of pure neoabietic acid demonstrates its most intense band at 250 mμ, $\alpha = 80.0$ (Fig. 3).

Experimental[20,21]

Abietic Acid

Acid Isomerization of Wood Rosin.—The extent to which rosin was isomerized to produce the maximum amount of abietic acid was determined as follows: A sample of rosin was heated under reflux in alcohol with concentrated hydrochloric acid. Samples were taken at intervals and the ultraviolet absorption characteristics and specific rotation of each determined. As shown in

[20] All melting points are corrected.

[21] All rotations are of 1% solutions in absolute ethanol.

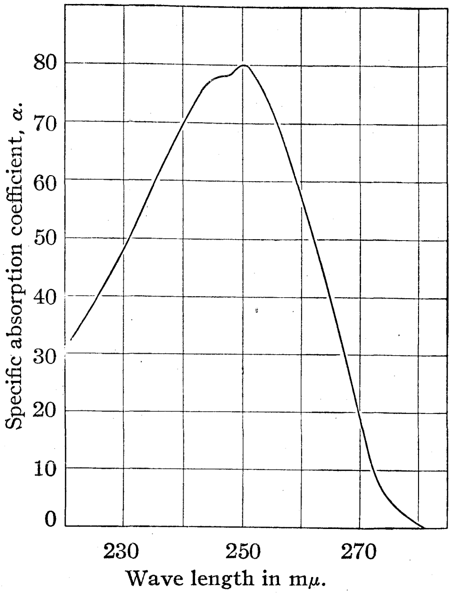

Fig. 3.—Ultraviolet absorption spectrum of neoabietic acid.

Fig. 4, the absorption curves of samples taken at one hour or after were the same and attained the highest value for specific absorption coefficient, α, at 241 mμ, indicating the production of the maximum amount of abietic acid, 47 ± 2%, at the end of one hour. The specific rotation of the samples, Fig. 5, also reached a constant value, $[\alpha]^{24}\mathrm{D}$ −35°, after one hour of heating, again indicating the formation of the equilibrium mixture at the end of this time.

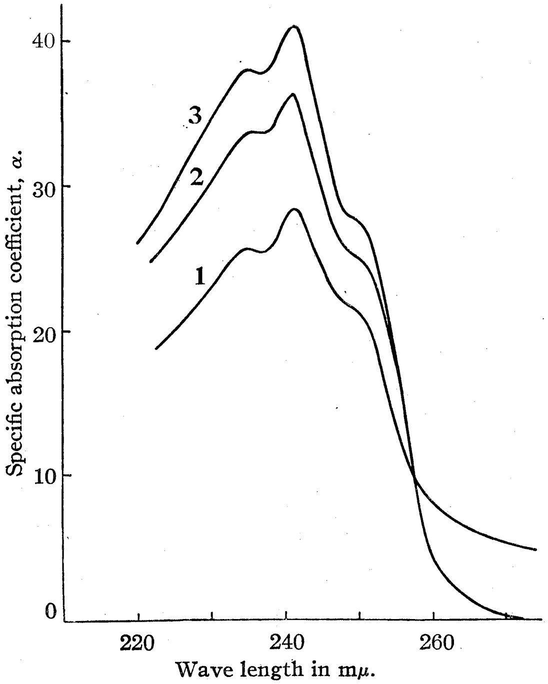

Fig. 4.—Ultraviolet absorption spectra: 1, N wood rosin; 2, rosin isomerized for half an hour; 3, rosin isomerized for one, two and three hours.

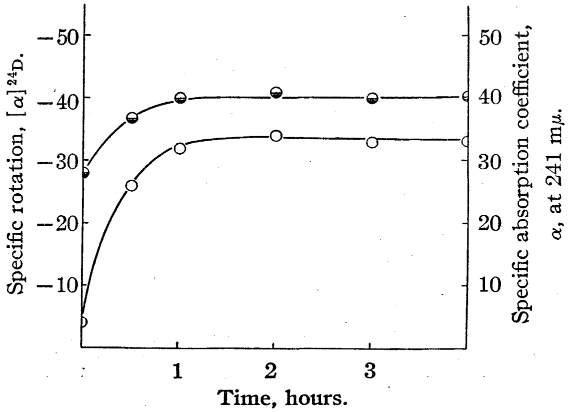

Fig. 5.—◓, Rate of change of specific absorption coefficient of isomerized rosin: ○, rate of change of specific rotation of isomerized rosin.

The sample used was prepared in the following manner. To a hot solution of 250 g. of wood rosin (color grades N to X, acid number 166) in 740 cc. of 95% ethanol was added 42 cc. of concentrated hydrochloric acid and the resulting solution boiled under reflux for one and one-half hours. A stream of carbon dioxide was passed over the surface of the solution during the reflux period and when the solution was being cooled to avoid discoloration due to atmospheric oxidation. At the end of the reaction time, the alcohol and acid were steam distilled, the water decanted, and the residue dissolved in ether. The ether solution was washed free of acid with water, dried over sodium sulfate, and the ether evaporated. The last traces of solvent were removed by melting the rosin in an oil-bath at 180 to 200° under water-pump vacuum. The molten rosin, blanketed continuously with carbon dioxide, was poured into a paper boat for ease of handling, to obtain 245 g. of material with rotation $[\alpha]^{24}\mathrm{D}$ −35°.

Preparation and Purification of the Diamylamine Salt.—To a solution of the isomerized rosin (245 g.) in 375 cc. of acetone at incipient boiling was added 127 g. of diamylamine (Sharples Company, Philadelphia, Pennsylvania) slowly with vigorous agitation. On cooling to room temperature, crystals appeared in the form of rosets. The mass was agitated, cooled in ice and filtered to obtain a cake of salts that was washed with 150 cc. of acetone. The latter was dried in a vacuum oven at 50° to obtain material with rotation $[\alpha]^{24}\mathrm{D}$ −18°. After four crystallizations, using a sufficient amount of acetone (*ca.* 4 liters for 200 g. of salt) to obtain an almost clear solution and evaporating to incipient precipitation (*ca.* 2 liters of solution), 118 g. of the pure amine salt of abietic acid was obtained with rotation $[\alpha]^{24}\mathrm{D}$ −60°. On recovery and recrystallization of the back crops to material with rotation $[\alpha]^{24}\mathrm{D}$ −60°, an additional 29 g. of pure salt was obtained, making a total of 147 g. In obtaining the later crops of salt by concentration of the mother liquors, some amine is lost by evaporation that should be replaced by the addition of a few drops to the concentrated solution.

Isolation of Abietic Acid.—To a cooled solution of the amine salt of abietic acid (147 g.) in one liter of 95% ethanol was added 39 g. of glacial acetic acid at once with stirring and 900 cc. of water slowly at first with vigorous agitation to incipient precipitation and then more freely. The crystals were filtered at once and washed with a liter of water to free them of traces of acetic acid. The acid was recrystallized from 750 cc. of 95% ethanol by the slow addition of 600 cc. of water as above and dried in a vacuum desiccator at room temperature over sodium hydroxide in an oxygen-free atmosphere. Undue exposure to higher temperatures will result in isomerization, and contact with air will result in the oxidation of the material. In this manner, 98 g. (40% by weight of isomerized rosin; theoretical 47%) of abietic acid was obtained with rotation $[\alpha]^{24}\mathrm{D}$ $-106°$. For storage purposes, the acid should be kept in vials under good vacuum.

Absorption Spectra.—The absorption spectrum data were obtained from measurements made with a Beckman ultraviolet spectrophotometer. The formulas employed in making the calculations use the term α, specific absorption coefficient.

$$\alpha = \log_{10} I_0/I/cl$$

I_0 = intensity of radiation transmitted by the solvent (95% ethanol)
I = intensity of radiation transmitted by the solution
c = concentration of solute in grams per liter
l = length in centimeters of solution through which the radiation passes

Levopimaric Acid

Preparation and Purification of the Butanolamine Salt.—To a solution of 125 g. of "galipot" in 250 g. of acetone was added 37 g. of butanolamine (2-amino-2-methyl-1-propanol) in 37 g. of acetone.[22] The suspension was cooled, the salt filtered, and a second crop taken by concentrating the solution to half its volume. The salt was fractionally crystallized from methyl acetate to obtain 31 g. of material with rotation $[\alpha]^{24}\mathrm{D}$ $-218°$.

Isolation of Levopimaric Acid.—The decomposition of the amine salt of levopimaric acid was carried out with boric acid.[23] The salt was suspended in ether and shaken vigorously with a saturated boric acid solution until the amine salt crystals had disappeared. To assure complete decomposition of the salt, the ether solution was washed twice more with boric acid. The ether solution containing the resin acid was washed free of boric acid with water, dried and the ether evaporated.[22] The acid was crystallized by dissolving it in warm ethanol and adding water to incipient turbidity, to obtain, upon cooling to room temperature, 24 g. of levopimaric acid (20% of the "galipot") with rotation $[\alpha]^{24}\mathrm{D}$ $-276°$.

Isolation of Primary Resin Acids from Gum Oleoresin. When the oleoresin is to be used as the source of levopimaric acid, the resin acids are separated from the turpentine according to the following procedure and used as in the following section. To a solution of 200 g. of the gum oleoresin of *Pinus palustris* in 600 g. of narrow-range gasoline (boiling range 90–100°) at 40° was added 41 g. of cyclohexylamine (Monsanto Chemical Co.) in 41 g. of gasoline.[22] The mass of crystalline salts was agitated and the suspension cooled in ice before the salts were filtered and washed with 200 g. of fresh solvent.

The salts were first air-dried overnight to remove the solvent and then decomposed in the same manner as the butanolamine salts taking the usual precautions for complete decomposition and rise in temperature of the concentrated solutions. The last traces of ether were evaporated by puffing the residue to a powder under water-pump vacuum. In this way was obtained 124 g. of resin acids (62% of the total oleoresin) with acid number 185 and neutral equivalent 302.

Preparation and Purification of Amine Salt and Isolation of Levopimaric Acid.—The butanolamine salts of the resin acids fraction (124 g.) were prepared as in the case of "galipot" using the same ratio of amine and solvent. The decomposition of the salts was carried out with the same precautions and the regenerated acid crystallized from ethanol and water to obtain 18.6 g. of pure levopimaric acid (15% of the total oleoresin acids) with rotation $[\alpha]^{24}\mathrm{D}$ $-276°$.

Neoabietic Acid

Heat Isomerization of Abietic Acid; Isolation of Amine Salt of Neoabietic Acid.—A 50.0-g. sample of abietic acid, $[\alpha]^{24}\mathrm{D}$ $-106°$, prepared according to the method described in this paper, was heated at 300° for twenty minutes under a stream of carbon dioxide gas. At the end of this time the molten material was poured in a paper boat to cool, chipped and dissolved in 100 cc. of acetone. Diamylamine (27 g.) was added to precipitate the unreacted abietic acid as its insoluble salt. Two successive crops of salts were obtained, totalling 58.1 g. and corresponding to 76% of unaltered abietic acid. The mother liquor was diluted with 50 cc. of acetone and treated with 3.6 g. of butanolamine to form the butanolamine salts of the residual resin acids combined as diamylamine salts. A first crop with rotation $[\alpha]^{24}\mathrm{D}$ $+24°$ was discarded, and the second, with rotation $[\alpha]^{24}$ $+100°$, obtained by concentrating the mother liquor to half the volume, was recrystallized from acetone to a constant rotation, $[\alpha]^{24}\mathrm{D}$ $+102°$.

Isolation of the New Abietic-Type Acid, Neoabietic Acid.—The butanolamine salt was suspended in ether and decomposed with a saturated solution of boric acid in the usual manner.[23] The ether solution containing the resin acid was washed free of boric acid with water, dried over sodium sulfate, and the ether evaporated.[22] The residue was crystallized from alcohol and water to obtain the pure neoabietic acid with rotation $[\alpha]^{24}\mathrm{D}$ $+159°$, melting point 167–169°, neutral equivalent 302, calcd. 302, in about 1% yield.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.39; H, 10.00. Found: C, 79.46, 79.40; H, 9.97, 9.97.

Isolation of Neoabietic Acid from the Gum Oleoresin.—The resin acids of the gum oleoresin of *Pinus palustris* were separated from the turpentine according to the method described in the previous section on levopimaric acid and used in the following manner for the isolation of neoabietic acid.

To a solution of the total acids, 124 g., in 248 g. of acetone was added 37 g. of butanolamine in 37 g. of acetone. The first three crops of salt, with rotations $[\alpha]^{24}\mathrm{D}$ -218, -210 and $-60°$, highly concentrated with the salt of levopimaric acid, were isolated. Further concentration of the mother liquor, with intermittent addition of small amounts (2 g.) of butanolamine to replace that lost by evaporation, resulted in the isolation of the two dextrorotatory crops, with rotations $[\alpha]^{24}\mathrm{D}$ $+12$ and $+15°$. Since no further increase in dextrorotation could be realized, these salts were combined and decomposed with boric acid in the usual manner. The more specific diethylamine was used to prepare the salts of the regenerated acids. Four recrystallizations from acetone resulted in the isolation of salts with rotation $[\alpha]^{24}\mathrm{D}$ $+70°$, which again could not be increased by further fractionation. These salts were then decomposed with boric acid, the butanolamine salts prepared, and the latter recrystallized from acetone to the top rotation of $[\alpha]^{24}\mathrm{D}$ $+102°$.

The pure salt of neoabietic acid (8.2 g.) was decomposed with boric acid to obtain 6.1 g. (5% of the total oleoresin acids) of pure acid with rotation, $[\alpha]^{24}\mathrm{D}$ $+159°$.

Preparation of the Methyl Ester of Neoabietic Acid.—Five grams of neoabietic acid, $[\alpha]^{24}\mathrm{D}$ $+159°$, was dissolved in 50 cc. of ether; the resulting water-white solution was treated with an excess of an ether solution of diazomethane as evidenced by a permanent yellow coloration. After standing for twenty minutes, the solution was evaporated to dryness.[22] The seed crystal was obtained by cooling a methanol solution of one drop of liquid ester to $-30°$ in an acetone–Dry Ice-bath. The ester, then, was readily crystallized from methanol with the aid of the seed crystal in excellent yield (5.0 g.) with a constant melting point, 61.5–62°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.69; H, 10.19. Found: C, 79.70, 79.65; H, 10.07, 10.17.

The purity and homogeneity of neoabietic acid was established in the following manner. Material with rotation $[\alpha]^{24}\mathrm{D}$ $+159°$ was used to prepare the butanol-

---

(22) The formation of the amine salts is an exothermic reaction and great care must be taken that the temperature does not rise above 50° to alter the levopimaric acid (this applies to neoabietic acid as well) which is highly susceptible to isomerization by heat.

(23) Levopimaric acid (this applies to neoabietic acid as well) is highly susceptible to mineral acid and isomerizes almost completely to abietic acid in the presence of a trace of strong acid. Such precautions against acid isomerization must be taken in regenerating the resin acid from its amine salt. Boric acid, therefore, the weakest acid that can effect the decomposition of the amine salts, is always employed.

amine salt which was recrystallized several times to obtain the constant rotating salt (same as that from which the acid was isolated), $[\alpha]^{24}\mathrm{D}$ +102°. The resin acid was regenerated in the usual manner with the same rotation, $[\alpha]^{24}\mathrm{D}$ +159°, and the same ultraviolet absorption characteristics, particularly the height of the most intense band, 250 mμ, at $\alpha = 80.0$. The methyl ester, prepared with diazomethane as above, was obtained with the same constant melting point 61.5–62°. Saponification in alcoholic alkali with alkali in a sealed tube at 50° for ninety-six hours with subsequent acidification with carbon dioxide and boric acid resulted in the quantitative isolation of neoabietic acid with unchanged rotation, $[\alpha]^{24}\mathrm{D}$ +159°.

Isolation of Neoabietic Acid from Gum Rosin.—A 200-g. sample of gum rosin was dissolved in 400 g. of acetone and treated, at 50°, with 45 g. of diethylamine in an equal weight of acetone. The complete precipitation of salts was allowed to take place over a long period of time (twenty-four hours) at room temperature. No attempt was made to hasten the crystallization by cooling because the necessary fractionation was not obtained in this manner. The salts were fractionated from acetone to a rotation $[\alpha]^{24}\mathrm{D}$ +70° and converted to the butanolamine salts by dissolving in acetone and adding the necessary amount of butanolamine. The latter were, in turn, crystallized to a rotation $[\alpha]^{24}\mathrm{D}$ +102° and the pure neoabietic acid isolated in 5% yield (10.0 g.) with rotation $[\alpha]^{24}\mathrm{D}$ +159°.

Summary

1. An improved method, based on the amine salt technique, for the isolation of abietic acid from acid-isomerized wood rosin and levopimaric acid from the gum oleoresin of *Pinus palustris* is described.

2. The isolation of a new, abietic-type acid, termed neoabietic acid, from heat-isomerized abietic acid, the gum oleoresin of *Pinus palustris* and gum rosin is described.

3. The ultraviolet absorption spectra, utilizing specific absorption coefficients, α, have been determined for each of the three abietic-type acids.

Resin Acids. II. The Structure of Neoabietic Acid

BY GEORGE C. HARRIS AND THOMAS F. SANDERSON

Neoabietic acid[1] has been isolated from the oleoresin and rosin of *Pinus palustris*. It has now been proved that this acid is an abietic-type acid since upon dehydrogenation with palladium–carbon catalyst retene, 1-methyl-7-isopropylphenanthrene, was isolated. The presence of two double bonds was shown by catalytic hydrogenation to the tetrahydro acids and by absorption in the ultraviolet region.[2] The intense band (Fig. 1, Curve 1) at 250 mμ, indicated also that the two double bonds are conjugated between two rings or that one is exocyclic with respect to the other in analogy with the absorption of abietic acid at 241 mμ and in contrast with that of levopimaric acid at 272 mμ. With this information, the structures I–V came into consideration.

From the work of R. B. Woodward[3] predictions can be made concerning the wave length of the most intense band of absorption of this type of conjugated system. These predictions are based on the degree of substitution of the double-bond carbon atoms; they are given below each formula. Since neoabietic acid demonstrates its most intense band at 250 mμ and since the predicted value for abietic acid, I, was so close to that found, 241 mμ, formula IV was at once suspected as that for neoabietic acid.

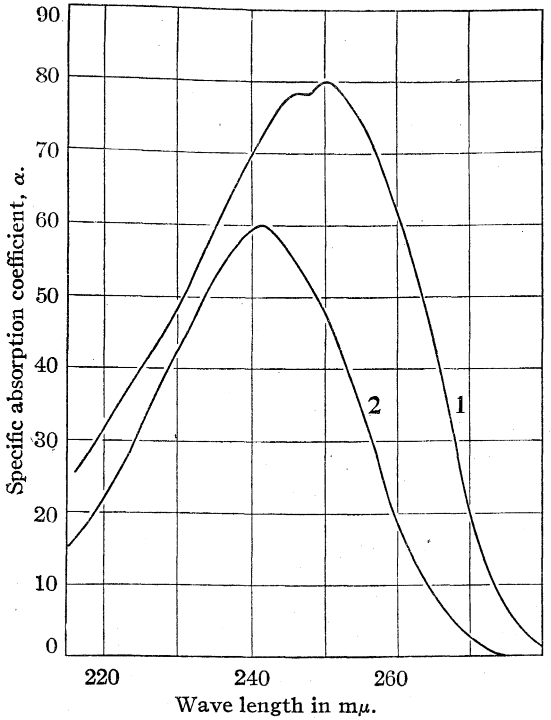

Fig. 1.—Ultraviolet absorption spectra: 1, neoabietic acid; 2, ketone (VI).

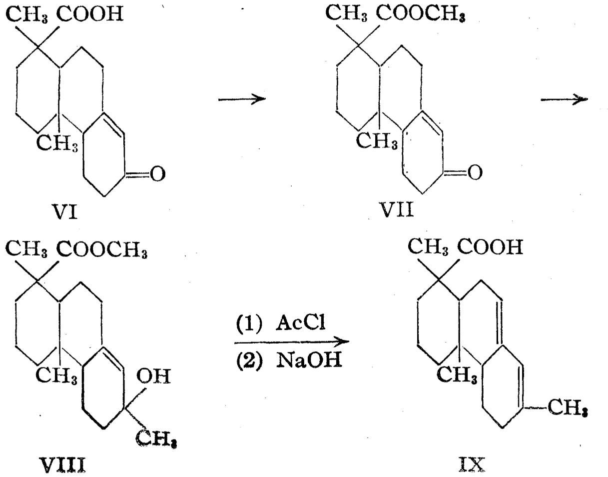
dinitrophenylhydrazone which was shown to be that of acetone after a mixed melting point with an authentic sample. After partial ozonolysis, that is, ozonization of only the exocyclic double bond of the isopropylidene group, in addition to acetone an α,β-unsaturated ketone would be obtained. This was found to be the case in the isolation of the ketone, VI, with melting point 187–188°. The functionality of the α,β-unsaturated keto acid was shown in the following manner. The neutral equivalent of the crystalline compound was 276, theory for the unsaturated keto acid 276. Its methyl ester, VII, was prepared with diazomethane and melted at 127–128°. The presence of the keto group was shown after the preparation of its 2,4-dinitrophenylhydrazone, m. p. 221–222°, and the isolation of the crystalline methyl Grignard addition product of the ester, VIII, m. p. 100–102°. The quantitative absorption of 1.0 mole of hydrogen of the latter in absolute ethanol with Adams catalyst indicated the residual unsaturation. Upon removal of the tertiary hydroxyl group of the Grignard product, VIII, with acetyl chloride or dry hydrogen chloride in benzene, hydrolysis of the ester group with alkali in diethylene glycol and redistribution of the double bonds, an abietic acid analog, IX, was obtained with rotation, $[\alpha]^{24}D$ − 125°, m. p. 187–190°, and specific absorption coefficient, α = 80.0 (Fig. 2).



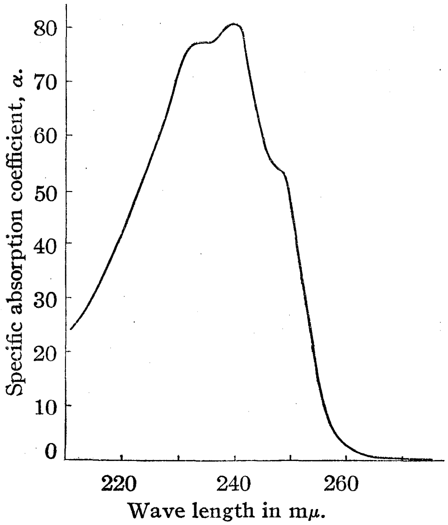


Fig. 2.—Ultraviolet absorption spectrum of an abietic acid analog.

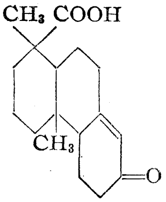
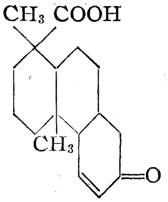
If formula V were that for neoabietic acid (although very unlikely in view of its absorption at 242 mμ), a ketone with formula X would be obtained.



VI



X

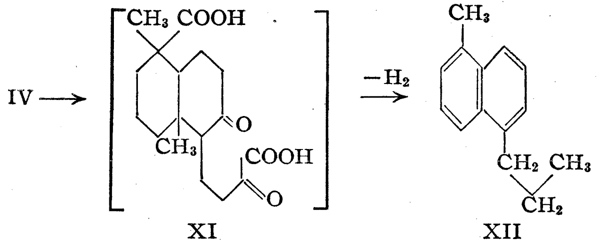
Using Woodward's[4] rules for predicting the most intense band of absorption of substituted α,β-unsaturated ketones, it is a simple matter to differentiate between the two ketones, VI and X. The ketone actually isolated demonstrated a maximum at 242 mμ (Fig. 1, Curve 2), a value that falls well within the limits,[4] 239 ± 5 mμ, set for a system with substitution similar to that of ketone VI and outside of those, 225 ± 5 mμ, set for a system similar to that of ketone X. Therefore

---

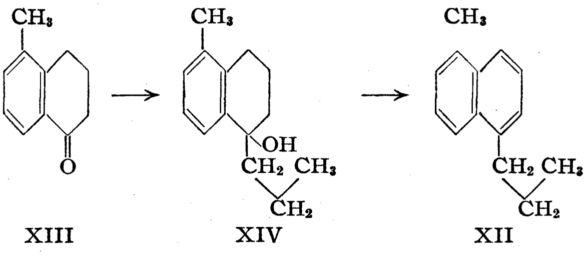
[4] R. B. Woodward, This Journal, 63, 1123 (1941).

formula VI is that for the ketone and formula IV that for neoabietic acid.

Further evidence for formula IV would be the isolation of a dialkylated naphthalene upon complete ozonization and dehydrogenation of the decomposed ozonide. In the case of the other structures, I through III, V having been eliminated, both rings II and III are split to result in the isolation of a substituted benzene nucleus or complete decomposition. Actually a 1,5-disubstituted naphthalene, XII, was isolated as proved by the similarity of the ultraviolet absorption curves of the trinitrobenzolate of this material with that of the synthetic sample and of an authentic sample of 1,5-dimethylnaphthalene[5] (Fig. 3). The hydrocarbon was isolated from the dehydrogenation mixture as its trinitrobenzolate and analyzed as the derivative and as the pure substance. From the analytical data it was determined to be 1-methyl-5-*n*-propylnaphthalene which could be obtained only from a compound with formula IV.



Hydrocarbon XII was synthesized in the following manner. The *n*-propyl Grignard product, of 5-methyl-1-tetralone,[5] XIII, was prepared and dehydrogenated with a palladium-on-carbon catalyst at 250°. The trinitrobenzolate of the hydrocarbon was prepared and found to melt at 82–84°. A mixed melting of the trinitrobenzolate of the hydrocarbon from the dehydrogenation mixture and this authentic sample showed no depression, m. p. 82–84°. The two derivatives also demonstrated identical X-ray diffraction patterns (Fig. 4).



For the sake of completeness and to eliminate the possibility of obtaining acetone from a structure such as that of abietic acid,[6] I, the same experiments were carried out with abietic acid. The failure to obtain acetone or a di- or tri-alkylated naphthalene upon complete ozonization both lends strength to the structure proof of neoabietic acid and eliminates the possibility of formula V as that of abietic acid in view of its absorption at 241 mμ wave length.

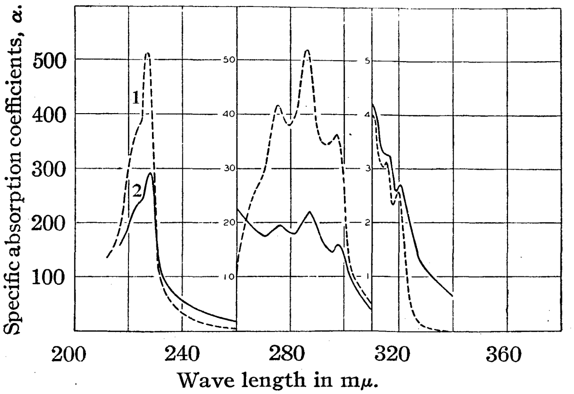


Fig. 3.—Ultraviolet absorption spectra: 1, the hydrocarbon, 1,5-dimethylnaphthalene; 2, the trinitrobenzolates of the isolated and synthetic 1-methyl-5-*n*-propylnaphthalene (identical curves for the two materials).

Experimental[7]

Dehydrogenation and Hydrogenation of Neoabietic Acid.—A 2.0-g. sample of neoabietic acid was mixed intimately with 2.0 g. of 5% palladium-on-carbon catalyst and the mixture heated at 300–330° for four hours. Carbon dioxide gas was passed over the reaction mixture to eliminate the reaction gases. After cooling to room temperature, the reaction products were dissolved in ether and separated from the catalyst by filtration. The oil was dissolved in ethanol and treated with a concentrated ethanol solution of trinitrobenzene to obtain 1.9 g. (65% yield) of constant melting derivative, m. p. 143–144°, that was shown to be that of retene when no depression was observed in a mixed melting point with an authentic sample.

Upon quantitative hydrogenation of neoabietic acid, 1.29% of hydrogen (H_2) was absorbed, calcd. for two double bonds 1.32%.

Ozonization of Neoabietic Acid.—The acid, rotation $[\alpha]^{24}\text{D}$ +159°,[8] was ozonized in 1.0-g. batches in 50 cc. of ethyl chloride at −60° to −70° using an oxygen flow of 20–25 liters per hour to obtain an oxygen solution of 5% of ozone. The gas was passed through the solution[9] until a purple coloration developed (*ca.* two hours) which indicated an excess of ozone. At the end of this time, the excess ozone was swept out with oxygen.

Decomposition of the Ozonide: Isolation of Acetone.—The ethyl chloride solution of the ozonide was added dropwise to hot water in an apparatus so designed that the ethyl chloride was evaporated and the acetone–water

---

[5] We wish to thank Dr. E. W. J. Butz of the Bureau of Animal Industry, U. S. Department of Agriculture, for a pure sample of this material; E. W. J. Butz, THIS JOURNAL, **62**, 2557 (1940).

[6] The structure was proved as that of formula I by L. F. Fieser and W. P. Campbell, *ibid.*, **60**, 159 (1938), and L. Ruzicka, L. Sternbach and O. Jeger, *Helv. Chim. Acta*, **24**, 504 (1941).

[7] All melting points are corrected.

[8] All rotations are of 1% solutions in absolute ethanol.

[9] The subsequent isolation of the hydrocarbon (XII) was indeed difficult until the technique for this type of ozonization was developed. When the solvent in the reaction was not anhydrous. the ozonide was decomposed in the medium and the intermediate ketone (XI) further attacked to form a lactone (A. Baeyer and V. Villiger, *Ber.*, **32**, 3625 (1899); **33**, 858 (1900). The active agent in Caro's acid is ozone). However, when the solvent was anhydrous, the ozonide remained intact during the ozonolysis to result in the formation of the ketone (XI) upon decomposition of the ozonide and the subsequent isolation of the hydrocarbon in good yield upon dehydrogenation.

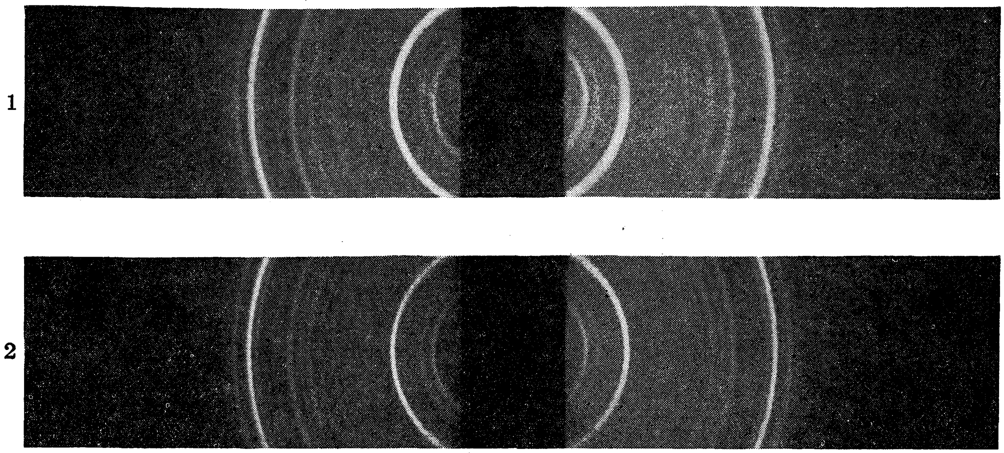

Fig. 4.—X-Ray diffraction patterns of trinitrobenzolates of 1-methyl-5-*n*-propylnaphthalene: 1, isolated; 2, synthesized.

azeotrope refluxed back to the receiver. After two hours of boiling, small portions of distillate were passed periodically for an hour through a saturated alcoholic solution of 2,4-dinitrophenylhydrazine. The alcoholic solution of the reagent (100 cc. of alcohol; 1.0 g. of reagent) was treated with 2 cc. of concentrated hydrochloric acid and boiled until a clear solution was obtained. Upon cooling, in addition to the dark red crystals of reagent, there appeared long, yellow needles which were recrystallized to a constant melting point of 124–126° and were proved to be the 2,4-dinitrophenylhydrazone of acetone when no depression was observed on melting with an authentic sample.

Isolation of 1-Methyl-5-*n*-Propylnaphthalene, XII.—The non-steam-volatile fraction of the decomposed ozonide was dissolved in ether and the bicarbonate-soluble fraction isolated (0.7 g. from 1.0 g. of acid). This was powdered, mixed intimately with 0.7 g. of 5% palladium–carbon catalyst, and dehydrogenated under carbon dioxide gas at 330–350° for four hours. The catalyst was filtered from an ether solution of the dehydrogenation product, the ether evaporated, and the residue dissolved in alcohol and treated with a saturated alcoholic solution of trinitrobenzene. The derivative precipitated and was crystallized to a constant melting point, 82–84°. The molecular weights were determined ebullioscopically, using acetone as solvent.

Anal. Calcd. for $C_{14}H_{16}\cdot C_6H_3N_3O_6$: C, 60.6; H, 4.8; N, 10.6; mol. wt., 199. Found: C, 59.8, 60.3; H, 4.8, 4.6; N, 10.3, 10.0; mol. wt., 201, 203.

The derivative in benzene was passed through a column of alumina to separate the hydrocarbon.

Anal. Calcd. for $C_{14}H_{16}$: C, 91.3; H, 8.7; mol. wt., 184. Found: C, 90.8, 91.0; H, 9.0, 9.2; mol. wt., 185, 188.

Preparation of 1-Methyl-5-*n*-propylnaphthalene, XII.—A 1.0-g. sample of 5-methyl-1-tetralone (XIII), m. p. 49.5–50.5°, was dissolved in dry ether and added to an ether solution of an *n*-propyl Grignard reagent prepared from 0.5 g. of magnesium and 3.3 g. of *n*-propyl iodide. The addition product was decomposed with saturated ammonium chloride and the tertiary alcohol, 1.3 g., isolated in ether. Attempts to crystallize the latter failed.

The oil was mixed intimately with 1.0 g. of 5% palladium-on-carbon catalyst and heated at 250° for two hours. The catalyst was filtered from an ether solution of the dehydrogenation mixture and the trinitrobenzolate of the hydrocarbon prepared in an alcoholic solution of the hydrocarbon using a saturated alcoholic solution of trinitrobenzene and crystallized to a constant melting point, 82–84°. A mixed melting point of the derivative from the dehydrogenation mixture with that of the synthetic sample showed no depression, m. p. 82–84°.

Isolation of Ketone VI.—For the ozonization of only the isopropylidene double bond the experiment was carried out in the same manner as for complete ozonization in respect to solvent, concentration, and temperature, but the time of ozonization was only thirty minutes. The ozonide was decomposed in the same manner and the product isolated in ether. The ketone was crystallized from the mixture from ether, and recrystallized to a constant melting point, 187–188°, and ultraviolet absorption curve with absorption coefficient, $\alpha = 60.2$.

Anal. Calcd. for $C_{17}H_{24}O_3$: C, 74.24; H, 8.72; neut. equiv., 276. Found: C, 74.04, 73.93; H, 8.96, 8.84; neut. equiv., 276.

The methyl ester, VII, was prepared in the usual manner with diazomethane and melted at 127–128°.

Anal. Calcd. for $C_{18}H_{26}O_3$: C, 74.45; H, 9.03. Found: C, 74.49, 74.45; H, 9.27, 9.19.

Derivatives of Ketone VI.—The 2,4-dinitrophenylhydrazone of the pure ketone was prepared in the usual manner in ethanol and recrystallized to a constant melting point, 221–222°.

The Grignard reaction product was prepared in the following manner. The reagent was prepared in a dropping funnel using 1.0 g. of magnesium turnings and 5.7 g. of methyl iodide in 25 cc. of dry ether and added dropwise to an ether solution of 5.8 g. of the ester, VII. A precipitate formed that remained insoluble after one hour of boiling of the mixture. After standing overnight, the reaction product was decomposed with saturated ammonium chloride and the product dissolved in ether. The ether solution was washed well with water, dried and the ether evaporated to obtain, upon recrystallization from ether–hexane, 3.0 g. of material with melting point 100–102°, VIII.

Anal. Calcd. for $C_{19}H_{30}O_3$: C, 74.47; H, 9.87. Found: C, 74.52, 74.43; H, 9.84, 9.87.

Upon quantitative hydrogenation in absolute ethanol with Adams catalyst, the methyl ester of the Grignard addition product absorbed 0.63% of hydrogen, theory for one double bond 0.65%.

Isolation of the Abietic Acid Analog, IX.—A 5.0-g. sample of the Grignard product was dissolved in acetyl chloride at room temperature (same results obtained with dry hydrogen chloride in benzene). After standing for one hour, the reagent was evaporated under vacuum for a period of twenty-four hours. Attempts at crystallizing the ester were not successful; therefore, it was hydrolyzed in the usual manner with alkali (3.0 g.) in diethylene glycol. The acid was readily crystallized from alcohol and water to a constant melting point, 187–190°, $[\alpha]^{24}\text{D}$ − 125°, and specific absorption coefficient, α = 80.0.

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.79; H, 9.55. Found: C, 78.68, 78.69; H, 9.45, 9.50.

Summary

The structure of neoabietic acid has been proved with the aid of Woodward's rules for unsaturated systems, and by the isolation of acetone, a 1,5-dialkylated naphthalene, and a substituted α,β-unsaturated ketone.

N,N'N''-Triacylmelamines

BY WILLIAM S. EMERSON AND TRACY M. PATRICK, JR.

Ostrogovich[1] has reported that treatment of melamine with acetic anhydride gives 96% of diacetylmelamine and with benzoic anhydride gives 100% of tribenzoylmelamine. Diacetylmelamine can be further acetylated with a large excess of acetic anhydride to triacetylmelamine.[1] Triacetylmelamine also can be prepared by acetylating melamine with acetic anhydride in the presence of sodium acetate.[2]

We have found that aliphatic anhydrides above acetic give triacylmelamines as the sole products, and have prepared eleven such compounds by this method in 85–99% yields. We have also prepared diacetylmelamine by Ostrogovich's method.

Attempts to hydrolyze tripropionylmelamine to less highly acylated products were unsuccessful. The compound was unaffected by boiling water but was completely hydrolyzed to melamine by hot aqueous sodium hydroxide or sodium carbonate. Hot aqueous hydrochloric acid not only removed the propionyl groups but also hydrolyzed the melamine to what was probably a mixture of ammeline and ammelide.

Our tribenzoylmelamine melted at 201–203° in contrast to the 142–143° reported by Ostrogovich. His product was probably solvated.

Experimental

Preparation of Triacylmelamines.—These compounds were prepared by heating melamine with the appropriate acid anhydride. In the smaller runs a large test-tube (1 in. by 10 in.) with a thermometer as the stirrer, served as the reaction vessel. The larger runs were conducted in three-necked flasks of suitable dimensions. In all cases the temperature was raised by means of an oil-bath to the value indicated in the table and held there for five to thirty minutes. Upon cooling, the reaction mixture was diluted with some solvent such as methanol, ethanol, acetone or ethyl acetate, and filtered. The solid was washed with additional solvent and dried to obtain the crude yield. Further purification was effected by crystallization from glacial acetic acid or from the anhydride used in the preparation of the compound in question. The compounds prepared are summarized in Table I.

Hydrolyses of Tripropionylmelamine.—When 5 g. of tripropionylmelamine and 100 cc. of water were boiled under reflux for one hour the tripropionylmelamine was recovered unchanged, m. p. 275–276° (282°).

Dielectric Studies. IX. Studies with Gasoline[1]

BY NORMAN C. C. LI AND THOMAS D. TERRY

In earlier papers[2] it was shown that dipole moment studies can be made using solvents of unknown molecular weights, such as gasoline, kerosene and petroleum ether, and that the dipole moment values so obtained are in close agreement with values obtained using non-polar solvents of known molecular weights. The assumption is made, of course, that gasoline, kerosene and petroleum ether are non-polar. In this study this assumption is put to rigorous experimental tests by determining the dipole moment of gasoline and its fractions.

Experimental

The dielectric constants were obtained by determining the capacity difference between rotor positions of a variable cell by means of a heterodyne beat apparatus. It consisted of two oscillators, "The Ferret Model 600" manufactured by the Coastwise Electronics, a Model 200 Signal Tracer manufactured by the Precision Electronics Inc. of Chicago, a precision condenser, Type 722-D, made by General Radio Co. and a dielectric cell. Purified benzene, the dielectric constant of which was assumed to be 2.273 at 25° and 2.254 at 35°, was used in calibrating the dielectric cell.

Refractive indices were measured with an Abbe refractometer with thermostated prisms. Densities were determined by the usual pycnometer method. All such measurements were made in thermostats regulated to 25° and 35°.

For dipole moment determinations the gasoline samples used were taken at random, had a yellowish color and were used without purification. Sample A was separated into eight fractions. The molecular weights of gasoline and the fractions were determined by the usual cryoscopic method in benzene of 5.4° f. p. A summary of the results is presented in Table I.

TABLE I

RESULTS ON GASOLINE AND FRACTIONS AT 25°

Temp., °C.	Mean values aE_1	b	$P_{2(\infty)}$	P_{2D}	$\mu \times 10^{18}$
Gasoline, sample A boiling fraction: below 60	−0.58	−0.34	21.3	21.3	0
60–70	.43	.30	24.8	24.3	.15
70–100	.42	.26	30.8	30.6	.09
100–120	.40	.25	35.1	33.9	.22
120–140	.37	.21	35.7	35.2	.15
140–160	.26	.12	38.2	38.3	0
160–190	.25	.14	39.9	39.3	.17
Above 190	.18	.13	43.3	41.3	.31
Gasoline, sample B, undistilled	.34	.20	43.4	42.8	.17

In Table I the constants a and b are the dielectric constant and density coefficients, respectively, in the expressions

$$E = E_1(1 + aw_2) \qquad (1)$$

$$d = d_1(1 + bw_2) \qquad (2)$$

where E_1 and d_1 are the dielectric constant and density of the pure solvent; E and d are the dielectric constant and density, respectively, of a mixture of gasoline of weight fraction w_2 dissolved in benzene. The weight fractions of the solute, gasoline, vary from 0 to about 0.08. $P_{2(\infty)}$ is the molar polarization at infinite dilution and is given by the equation

$$P_{2(\infty)} = (p_1(1 - b) + CaE_1)M_2 \qquad (3)$$

where p_1 is the specific polarization of the solvent, $C = 3/d_1(E_1 + 2)^2$, and M_2 is the molecular weight of the solute.[3] The values of p_1 and C used in this paper are those for benzene and equal to 0.3412 and 0.1882, respectively.

As shown in Table I, with the exception of the highest boiling fraction which boils above 190°, the fractions from gasoline, sample A, have dipole moments ranging from 0 to 0.2×10^{-18} and are therefore essentially non-polar. The presence of the small apparent moment values in some of the fractions is understandable since the percentage error in $[P_{2(\infty)} - P_{2D}]$ is large when the difference is very small. Traces of polar impurities in the higher fractions, which are colored yellow, may also account for the small moments. In earlier papers where gasoline has been used for dipole moment determinations only the colorless grade was used and the assumption was made that it was non-polar. In this study we have used, for the first time, yellowish samples of gasoline and the result shows that the assumption is essentially correct and justifies the close agreement of dipole moments with those using non-polar solvents of known molecular weights.

The polarity of a compound is also indicated by the difference between the square of the refractive index and the dielectric constant. We have taken at random another sample of gasoline, fractionated it, determined the density, refractive index and dielectric constant of each fraction. The results are shown in Table II.

From the table it is seen that in three cases there is an exact equivalence between n^2_D and E and that the maximum difference between the two quantities is only 0.023 in the highest boiling fraction. This agrees with the results of Table I in

[3] For a discussion of these equations see ref. 1 of this paper.

TABLE II

DENSITY, SQUARE OF REFRACTIVE INDEX, DIELECTRIC CONSTANT OF GASOLINE AT 35°

Temp., °C.	d	n^2_D	E	$E - n^2_D$
Original sample of gasoline	0.7349	2.002	2.012	0.010
Boiling fraction: 60–90	.6782	1.909	1.909	0
90–100	.6933	1.937	1.937	0
100–120	.7164	1.960	1.960	0
120–140	.7257	1.987	1.990	0.007
140–160	.7449	2.008	2.021	.013
160–180	.7619	2.033	2.050	.017
Above 180	.7910	2.074	2.097	.023

that the highest boiling fraction has relatively the highest dipole moment of all fractions, namely, 0.31×10^{-18}. Benzene and carbon tetrachloride have frequently been used as non-polar solvents in dipole moment determinations. The difference in n^2_D and E for benzene and carbon tetrachloride at 25° are, however, 0.037 and 0.114, respectively. According to this criterion, gasoline should be more non-polar than benzene or carbon tetrachloride.

Table III lists the dipole moment values which have been obtained using gasoline and similar solvents of indefinite molecular weights and the values obtained for the same compounds using solvents of known molecular weights.

TABLE III

DIPOLE MOMENT AT 25°[a]

Castor oil	in gasoline 3.62×10^{-18}	in benzene 3.7×10^{-18}
Tung oil	kerosene 2.92	benzene 2.9
Di-*n*-butyl ether	kerosene 1.17	benzene 1.22 toluene 1.13
Ethyl-*n*-butyl ether	kerosene 1.19	benzene 1.24
Acetone	gasoline 2.8	benzene 2.72
Chloroform	gasoline 1.16	benzene 1.15
Acetonitrile	gasoline 3.33 kerosene 3.35 petroleum ether 3.35	benzene 3.37 toluene 3.38

[a] The values for castor oil and tung oil are taken from Li, *J. Chinese Chem. Soc.*, **13**, 8 (1946); the values for the ethers from Li and Hsü, *ibid.*, **13**, 11 (1946); the other values are from Ref. 1 of this paper.

Summary

Dipole moment can be measured using gasoline as solvent, a substance which has no definite molecular weight and whose physical properties may vary greatly with different samples. Experimental results indicate that gasoline and its fractions are essentially non-polar. A summary of the dipole moment values obtained using gasoline and similar solvents of indefinite molecular weights is given and shown to be in close agreement with values obtained using non-polar solvents of known molecular weights.

The Catalytic Decomposition of Ethane and Ethane–Hydrogen Mixtures

BY CHARLES KEMBALL[1] AND HUGH STOTT TAYLOR

The work of Morikawa, Benedict and Taylor[2,3] and of Morikawa, Trenner and Taylor[4] showed that the exchange reactions between the lower hydrocarbons and deuterium on supported nickel catalysts could be brought about at lower temperatures than the decomposition reactions. The energy of activation for the breaking of the carbon–hydrogen bond was some 15 kcal./mole less in the case of propane, than that for the breaking of the carbon–carbon bond. There is little doubt that the exchange reaction involves dissociative adsorption of the hydrocarbon, *e. g.*, as ethyl radical and hydrogen atom, and re-evaporation of the ethyl with a deuterium atom. Much less can be conjectured about the decomposition reaction and it was considered worthy of further study. Morikawa and his co-workers showed that, over a certain range of composition, the rate of production of methane from ethane and hydrogen depended inversely on the 2.5 power of the hydrogen pressure. This point required further investigation because it is difficult to see the kinetic interpretation of such a dependence. Accordingly it was decided to extend their investigation to a wider range of composition for the reacting mixture and further to study the decomposition of ethane in the absence of hydrogen.

Experimental

Analysis.—The reaction was followed by the withdrawal of a sample of gas and analysis by means of a mass spectrometer. The height of the mass 30 peak was determined solely by the ethane concentration and the mass 16 peak was almost entirely due to the methane. A small correction was made for the mass 16 in the ethane pattern; this amounted to 0.004 of the height of the "30 peak." In order to allow for fluctuations in the behavior of the instrument and to avoid the difficulty of using a constant pressure behind the leak of the spectrometer, the ratio of the "16 peak" to the "30 peak" was always measured. A series of known mixtures of ethane, methane and hydrogen were used to obtain calibration curves giving the ratio methane/ethane in terms of the ratio "16 peak"/"30 peak." The curve was linear up to 0.7 for methane/ethane, and was not greatly affected by the presence of hydrogen in the mixture. It was possible to estimate the amount of methane in a mixture to closer than 2% in this manner. A static system was used to follow the reaction and checks were made that the samples withdrawn were representative of the whole reacting gas.

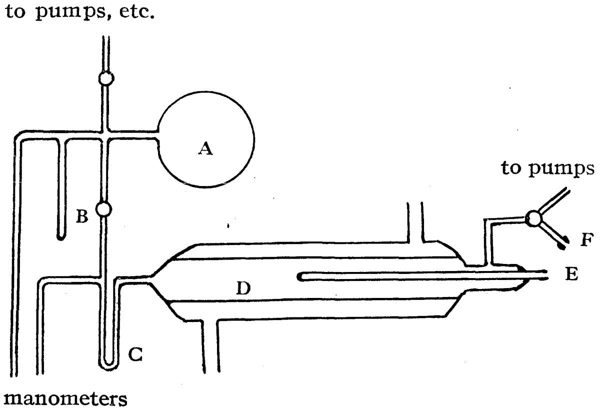

Fig. 1.—The apparatus.

Apparatus.—The essential part of the apparatus is shown in Fig. 1. The gases were allowed to mix in the bulb A. B could be cooled in liquid air to condense ethane during the admission of hydrogen. The trap C, maintained at −80°, prevented mercury out of the manometer from poisoning the catalyst, which was placed in the vessel D. The tube E was large enough to hold a thermometer. Sample bulbs could be fitted on to the ground joint F. The total volume of the reaction vessel was some 100 cc.; it was thermostated by means of the vapor jacket shown. Aniline, and, in the later experiments, naphthalene boiling under reduced pressure, were used for this purpose. The outside of the vapor jacket was wound with resistance wire and well lagged. The resistance unit served as an auxiliary heater and could also be used to bring the catalyst up to a high temperature for reduction or cleaning.

Preparation of Gases.—Cylinder hydrogen was purified by passing over heated copper at 400° and then dried over calcium chloride, Ascarite and finally phosphorus pentoxide. Cylinder ethane was passed over phosphorus pentoxide, condensed in liquid air and after two distillations the middle fraction was stored. Ethylene, which was required in some of the later experiments, was treated like ethane.

Catalyst.—The catalyst contained 15% Ni supported on kieselguhr. It was a specimen no. 330 prepared by the E. I. du Pont de Nemours Co., many years ago and was from the same batch of catalyst that was used by Morikawa[2,3,4]; 2.4 g. was used, being reduced in a stream of hydrogen at 430° and then evacuated. Between each experiment the catalyst was merely evacuated at the reaction temperature.

Experimental Results

Decomposition of Ethane–Hydrogen Mixtures.

A. Normal Kinetics.—The kinetic expression for the rate of production of methane from ethane and hydrogen depended on the composition of the reacting gases. At 182°, provided there was an excess of hydrogen (ratio > 1:1), the rate of reaction depended on $p_{C_2H_6}^{0.7} \times p_{H_2}^{-1.2}$ and the behavior of the catalyst was reproducible. The results of experiments of this type are given in Table I. Whenever the reacting gases were introduced into the reaction vessel there was a decrease in pressure of some 2 mm., taking place mainly in the first fifteen minutes. This was assumed to be due to adsorption of hydrogen but the correction it involved in the calculation of the mean pressures was small. In the last column of Table I the calculated rates of reaction for a given mixture (10 cm. ethane, 15 cm. hydrogen) based on the kinetic expression mentioned above, are listed. The constancy of these figures was the evidence for the expression $p_{C_2H_6}^{0.7} \times p_{H_2}^{-1.2}$. The reactions at 214° followed similar kinetics provided the hydrogen/ethane ratio was maintained at 2 or greater, see Table II. Neglecting the change in density of the gas between the two temperatures the mean rates gave an energy of activation of 52 kcal./mole.

B. Abnormal Kinetics.—With lower ratios of hydrogen to ethane (<1.0 at 182°, <2.0 at 214°) there was an increase in the rate of reaction above that expected from the kinetic expression. The results are tabulated in Table III which can be compared with Tables I and II. The behavior of the catalyst was not as reproducible for mixtures with low hydrogen content. Experiments 41, 42 and 43 showed unusually rapid reaction—this was attributed to the fact that the catalyst had been evacuated at a few degrees above the reaction temperature. Again while experiments 52 and 53 (ratio $H_2/C_2H_6 \approx 1$) showed normal kinetics, experiments 20, 21 and 22 were rapid. The deviation from normal behavior was greater the smaller the ratio of hydrogen to ethane and the smaller the total pressure. A kinetic expression for these reactions would have to contain a factor of the order $p_{H_2}^{-2}$ and it is interesting to note that it was in this region of composition that Morikawa, Benedict and Taylor found the factor $p_{H_2}^{-2.5}$. They worked with hydrogen/ethane ratios varying between 0.5 and 2.0 at 184°.

The Decomposition of Ethane Alone.—In experiments 22 and 24 a slight increase of pressure had been observed. This indicated that some of the ethane was decomposing to give carbon and methane. The rate of reaction of ethane in the absence of hydrogen was then examined. It was clear from the earlier work of Morikawa that the carbon so deposited might poison the surface; however, it was found that the carbon could be removed with hydrogen. The decomposition of ethane was followed by the increase of pressure, and the reaction was found to proceed to completion according to the equation $2C_2H_6 \rightarrow 3CH_4 + C$.

The data for three decompositions at 182° are shown in Fig. 2. Before each reaction the surface had been freed from carbon by hydrogenation as will be described in the next section. The small dip, experimentally observed, at the beginning of each curve was due to the adsorption of ethane. The experiments 27 and 29 were left overnight with little further change in pressure. The ratios of the final to initial pressure were, respectively, 1.49 and 1.51, indicating that the reaction $2C_2H_6 \rightarrow 3CH_4 + C$ was complete. A sample of the gas at the end of experiment 27 was analyzed on the mass spectrometer and the ratio of ethane to methane shown to be approximately 1/3,000. In experiment 31 there was a noticeable decrease in the rate of reaction after the pressure had increased by 2 cm. This was assumed to be due to the covering of surface with carbon and consequent lack of activity. It was found that the shape of the curves corresponded to an expression

$$\mathrm{d}p/\mathrm{d}t = k(p_\infty - p)^{0.7}$$

where p_∞ is the final pressure, *i. e.*, the rate of reaction depended on a fractional power of the unchanged ethane. The plots of $(p_\infty - p)^{0.3}$ *versus* t, the integrated form of the equation, are shown in Fig. 3 and the values of k are listed in Table IV. The poisoning in experiment 31 is easily seen in Fig. 3.

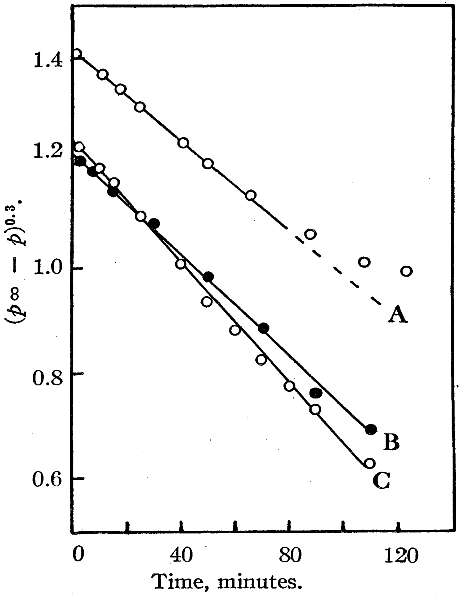

Fig. 3.—Ethane decompositions at 182°: A, Expt. 31, 182.8°; B, Expt. 27, 182.0°; C, Expt. 29, 182.1°.

Three experiments at 192° are recorded in Figs. 4 and 5 and the values of k are given in Table IV. The higher rate of reaction levelled out the dips

due to adsorption which were now only visible as smaller initial gradients. The energy of activation from the mean values of k was 40 kcal./mole.

The Removal of Deposited Carbon by Hydrogenation.—The ethane decompositions were alternated with carbon removal reactions according to the equation $C + 2H_2 \rightarrow CH_4$. The decrease in pressure observed on allowing hydrogen access to the catalyst (subject to a correction for adsorption) was therefore equivalent to the carbon removed and was found to correspond in each case to the rise in pressure in the previous ethane decomposition within the experimental error. This indicated that the carbon deposition was reversible, which was confirmed by the absence of any progressive poisoning. Two reactions are shown in Fig. 6. The decrease in rate of reaction with time was marked and it was not possible to fit a kinetic expression to the curves. The initial part could be fitted to a rate given by $-dp/dt = k(p - p_\infty)^3$, where $(p - p_\infty)$ represents the carbon still to be removed. However, a dependence of rate on the third power of the carbon to be removed is meaningless as regards a physical picture of the mechanism. The plot of $(p - p_\infty)^{-2}$ *versus* t enabled the initial rates of reaction to be estimated. Attempts were made to use rate expressions of the type

$$-dp/dt = k(p - p_\infty)(2p - p_0)^2$$

and

$$-dp/dt = k(p - p_\infty)(2p - p_0)^3$$

but without success; the term $(2p - p_0)$ is a measure of the hydrogen available. The rapid decrease in rate was more likely to be connected with the ease of removal of carbon from a heterogeneous surface.

TABLE IV

DECOMPOSITION OF ETHANE

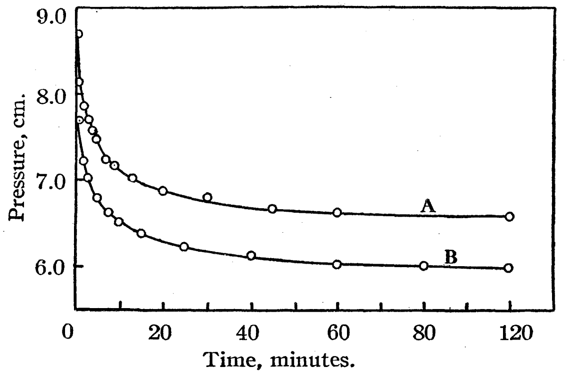

Fig. 6.—The reaction of hydrogen with adsorbed carbon to form methane: A, Expt. 32, 192.0°; B, Expt. 38, 182.1°.

Three experiments were carried out at 182° and four at 192°. There was always some difficulty in obtaining the value for the initial pressure especially at the higher temperature. The estimated initial rates of reaction are shown in Table V. They yielded an activation energy of 18 kcal./mole. However, a graphical comparison of the rates after five minutes indicated zero energy of activation which was further evidence for variation in the ease of carbon removal, *i. e.*, heterogeneity of the surface. These reactions with hydrogen were always left overnight and check experiments over a second night showed no further change in pressure.

TABLE V

REMOVAL OF CARBON BY HYDROGEN

Expt.	Temp., °C.	Initial pressure, cm.	Initial rate of reaction, cm./min.

32	192.5	8.7	.87	0.76
34	192.0	10.2	.59	
36	192.0	11.5	.93	
38	191.7	10.5	.67	

Decomposition of Ethylene.—For reasons which will emerge from the subsequent discussion it was decided to study the formation of methane from pure ethylene. Preliminary experiments indicated that some methane was formed from ethylene, but that a similar amount of ethane would give more methane; the time of these experiments was either thirty or sixty minutes. Analysis with the mass spectrometer showed that the ethylene was converted to saturated hydrocarbons, probably quantitatively. It was difficult to detect traces of ethylene because the "28 peak" of ethane was large. However, by examination of the ratio "28 peak"/"30 peak" it was possible to show that there was little ethylene remaining. The carbon deposited in the early stages of the reaction of ethylene

$$3C_2H_4 \longrightarrow 2C_2H_6 + 2C$$
$$C_2H_4 \longrightarrow CH_4 + C$$

had a considerable poisoning action. Thus, the ethane formed would not decompose to methane nearly as rapidly as in the reactions described in a previous section. Once again the carbon was readily removable by hydrogenation to form methane. It became clear that if there was to be a fair comparison between the reactions with the two gases, the reaction time would have to be short. With longer times, the less poisoned surface under the ethane would lead to a greater yield of methane. The rapid formation of ethane from ethylene might have been accelerated by the hydrogen present on the surface (the surface was not normally pumped out above the reaction temperature and therefore was partially covered with hydrogen). An attempt was made to run some reactions on the catalyst relatively free from hydrogen. Before each of the six reactions in Table VI and Fig. 7 the catalyst was decarbonized overnight with hydrogen and then evacuated for two hours at 425° to remove the majority of the adsorbed hydrogen. The ratio "28 peak"/"30 peak" appeared to vary from day to day for ethane; part of this variation may have been due to the presence of differing amounts of methane. However, it will be observed that, in all three cases, the ratio, "28 peak"/"30 peak," is less for the mixture from ethylene than for the corresponding mixture from ethane. It was therefore most unlikely that there was any unchanged ethylene in the final product. Figure 7 shows clearly how the initial production of methane is faster from ethylene than from ethane. The slight induction period was presumably due to the time taken for the gas to come to reaction temperature and to permeate the catalyst. The greater poisoning of the surface with ethylene is also clear.

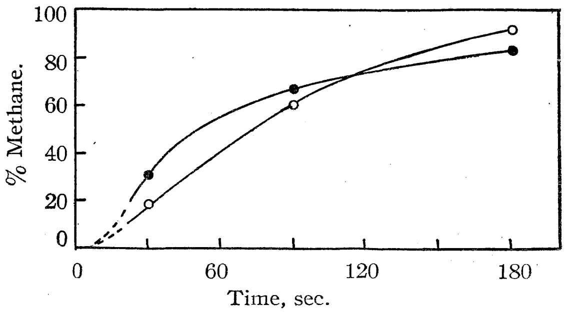

Fig. 7.—The formation of methane from ethane or ethylene: ○, ethane; ●, ethylene.

Interpretation of the Experimental Results

It is assumed that the breaking of the carbon–carbon bond is the slow reaction. In support of this there is the evidence of Morikawa, Benedict and Taylor that the ethane and deuterium exchange reaction proceeds at a temperature of 120°. They also reported 28 and 19 kcal./mole as the energies of activation for the methane exchange and the propane exchange. Thus, the carbon–hydrogen bond is easily broken and reformed and the large energy of activation in the decomposition reaction must be related to the breaking of the carbon–carbon bond. The experiments described in the preceding sections indicate that the equilibrium between methane, adsorbed methyl and methylene groups, etc., on the surface is quickly established. It is unlikely that a van der Waals adsorbed ethane will be sufficiently perturbed by the surface to lead to splitting of the C–C bond. It is possible that an adsorbed ethyl radical might dissociate into a methyl and a methylene group. However, it is more probable that the molecule has to be attacked at both ends, *i. e.*, as an adsorbed ethylene before dissociation can occur. If it is assumed that there will be an equilibrium established between the various species—van der Waals adsorbed ethane, chemically adsorbed ethyls, ethylenes and hydrogen—it is possible to use the device introduced by Temkin and Pyzhev[5] in the ammonia decomposition, namely, the use of a virtual equilibrium pressure.

---

(5) Temkin and Pyzhev, *Acta Physicochimica URSS*, **12**, 327 (1940).

$$\begin{tikzcd}
C_2H_6 \arrow[r, shift left, "\text{Virtual}"] \arrow[d, shift left] & C_2H_4 + {} \arrow[l, shift left] \arrow[d, shift left] & H_2 \arrow[d, shift left] \\
C_2H_{5ads} + H_{ads} \arrow[u, shift left, "\text{Established}"] \arrow[r, shift left] & C_2H_{4ads} + {} \arrow[l, shift left, "\text{Established}"] \arrow[u, shift left, "\text{Virtual}"] & 2H_{ads} \arrow[u, shift left, "\text{Established}"']
\end{tikzcd}$$

If $P^*_{C_2H_4}$ is the pressure of ethylene that would fulfil the gas phase equilibrium, then it would also be in equilibrium with the adsorbed ethylene. Let $\sigma_{C_2H_4}$ be the fraction of the surface covered by ethylene and let A be the fraction of the surface bare. Then

$$p^*_{C_2H_4}A = k_1\sigma_{C_2H_4}$$

Making an assumption similar to that of Temkin and Pyzhev, we write

$$p^*_{C_2H_4} = K\frac{p_{C_2H_6}}{p_{H_2}}$$

It is not possible to express A accurately in terms of the pressures of the gases. However, ignoring the dissociation of the ethane and the hydrogen and using Langmuirian equations of the type

$$p_{H_2}A = k_3\sigma_{H_2}$$
$$p_{C_2H_6}A = k_4\sigma_{C_2H_6}$$

then

$$A = \frac{1}{1 + ap_{C_2H_6} + bp_{H_2}}$$

Hence the rate of reaction, which is assumed proportional to $\sigma_{C_2H_4}$ but not fast enough to interfere with the equilibrium discussed above, is given by

$$\text{Rate} = \frac{kp_{C_2H_6}}{p_{H_2}\,(1 + ap_{C_2H_6} + bp_{H_2})}$$

This means that the rate will depend on some power slightly less than unity, of the ethane, and on some negative power of the hydrogen, slightly greater than unity. This is in good agreement with the observed $p_{C_2H_6}{}^{0.7}p_{H_2}{}^{-1.2}$.

In the decomposition of ethane alone the following equations will hold

$$p_{C_2H_6}(1 - \sigma_{C_2H_5} - \sigma_{C_2H_4} - \sigma_H) = k_1\sigma_{C_2H_5}\sigma_H$$
$$\sigma_{C_2H_4}\sigma_H = k_2\sigma_{C_4H_5}$$

Now there is evidence which will be discussed below to indicate that the surface is well covered with hydrogen and if it is assumed that σ_H is a constant it is possible to show that

$$\sigma_{C_2H_4} = k'p_{C_2H_6}/(1 + k''p_{C_2H_6})$$

which again would account for the rate of the decomposition being dependent on a fractional power of the ethane. It was in order to confirm the mechanism proposed, namely, the formation of methane through the breaking of the C–C bond in adsorbed ethylene that the reactions with ethylene were carried out.

The experiments with ethylene supported the possibility that the mechanism of the ethane–hydrogen and ethane decompositions involved adsorbed ethylene. It will be seen that the rates of reaction with a carefully cleaned surface, experiments 70, 78 and 80 were much faster than the decomposition rates on the "usual" surface, *i. e.*, experiments 27, 29 and 31. This was evidence that the "usual" surface, which was prepared by evacuation of the hydrogen and other gases at 182°, was greatly covered with hydrogen. This had two important results. First, it proved that the surface was definitely heterogeneous with respect to hydrogen adsorption, because the hydrogen could not all be removed by the standard evacuation at 182°. Consequently it is reasonable to suggest that the increase in the rate of reaction with ethane–hydrogen mixtures of low hydrogen content, described as "abnormal kinetics," was due to the uncovering of fresh areas of the surface as the hydrogen pressure was decreased. Second, the fact that the rate was so much faster on a clean surface provided justification for considering σ_H as a fixed quantity when examining the kinetics of the ethane decomposition by itself.

TABLE VI

THE PRODUCTION OF METHANE FROM ETHYLENE AND ETHANE

Expt.	Substance	Pressure, cm.	Temp., °C.	Time, sec.	"16 peak" "30 peak"	"28 peak" "30 peak"	Methane, %
68	C_2H_4	0.87	181.9	90	3.09	3.78	67.0
70	C_2H_6	1.06	182.0	90	2.26	3.85	59.7
76	C_2H_4	1.05	181.0	30	0.663	4.04	30.3
78	C_2H_6	1.12	182.0	30	0.333	4.15	17.9
80	C_2H_6	1.10	181.0	180	17.3	3.98	91.9
82	C_2H_4	1.14	182.1	180	7.82	3.85	83.7

It would be interesting to extend the work of Morikawa in following the decomposition of propane with greater pressures of hydrogen to see if normal kinetics were obtained in that case. Morikawa, Trenner and Taylor reported a rate dependent on $p_{C_3H_8}{}^{0.92}\ p_{H_2}{}^{-2.6}$ but this might turn over to a more normal expression with higher percentages of hydrogen present. If the mechanism was comparable to the present reaction, experiments with propylene would prove interesting.

The energy of activation found in the present work was 52 kcal./mole for the ethane–hydrogen reaction, which is slightly larger than the 43 kcal./mole given by Morikawa. The difference may be due to the region of composition in which the earlier work was done. As expected, the value for ethane decomposition in the absence of hydrogen was lower, being 40 kcal./mole. The decrease of 12 kcal./mole is reasonable when associated with a factor of $p_{H_2}{}^{-1.2}$.

It must be emphasized that little was known about the state of the catalyst except that its behavior was reproducible. It was certainly not yielding its maximum activity as shown by the later experiments with ethane and ethylene. The same sample of catalyst was used throughout and the reproducibility of the results is well illustrated in Table I where the experiments fall into three groups. The last group was carried out after the end of the ethane decomposition reactions and showed no loss in activity. A large fraction of the surface must have been permanently covered with hydrogen except in the last few experiments in which a carefully cleaned surface was used.

It would be interesting to try experiments with acetylene, to see whether it decomposed more readily than ethylene. It may well be that the breaking of the C–C bond would proceed through adsorbed ethylene rather than adsorbed acetylene. For, unless the latter was attached to four nickel atoms simultaneously there would be some double bond character in the C–C bond which should make it more difficult to break.

Acknowledgment.—One of us (C. K.) wishes to express his thanks to the Commonwealth Fund for the generous Fellowship which made this work possible.

Summary

1. The mass spectrometer can be used to follow the reaction of ethane and hydrogen producing methane using the ratio of the "16 peak" to the "30 peak."

2. The ethane–hydrogen decomposition on a supported nickel catalyst obeys the expression Rate = $kp_{C_2H_6}^{0.7}p_{H_2}^{-1.2}$ over a wide range of composition with an energy of activation of 52 kcal./mole.

3. At low ratios of hydrogen/ethane, abnormal kinetics, depending on a high inverse power of the hydrogen pressure, set in. This is ascribed to heterogeneity of the surface.

4. Ethane will decompose quantitatively over this catalyst to methane and carbon with a rate dependent on $p_{C_2H_6}^{0.7}$ and an energy of activation of 40 kcal./mole.

5. The carbon is reversibly deposited and can be converted to methane by hydrogen.

6. The rate-determining step of methane formation must be the breaking of the carbon–carbon bond. Both the ethane–hydrogen and the ethane decompositions can be interpreted by a mechanism involving the presence on the surface of adsorbed ethylene, in equilibrium with adsorbed ethyl radicals and hydrogen. This mechanism was supported directly by showing that the initial rate of production of methane is greater from ethylene than from ethane.

Vapor Pressure of Isobutene over Dioxane as Basis of Manometric Kinetic Studies. The Dissociation of *t*-Butyl Benzoate

BY ROLF ALTSCHUL AND JOANNE HERBERT

This paper has as its primary objective the presentation of an improved method for kinetic measurements of liquid-phase reactions involving isobutene. Such an investigation was relevant to our present effort to expand a previous preliminary study of acid-catalyzed dissociations of tertiary esters.[1] In order to expedite this general project we tested a different analytical procedure, which, with equal accuracy, was to afford identical results with greater facility.

Vapor pressure measurements by a static method served as a basis for this alternate analysis. Two separate problems were involved to adapt this generally useful method to our particular needs: (a) A calibration to establish the vapor pressure of dioxane solutions as a function of their isobutene content. A constant and small amount of sulfuric acid (0.835 mole/liter), necessary to catalyze the subsequent kinetic runs, was included with these standardizations. (b) Application of these data to the reversible dissociation of *t*-butyl benzoate into benzoic acid and isobutene.[1] These manometric rate constants were then matched against parallel experiments resorting to acidimetric analysis by the orthodox procedure.

Since strong mechanical agitation was a prerequisite, a thermostated Van Slyke instrument appeared most opportune for this study.

Experimental

Materials.—Benzoic acid, *t*-butyl benzoate, isobutene, dioxane,[2] and 100% sulfuric acid were prepared, purified, and stored as before.[1] All gave the previous physical constants.

Manometric Determinations.—A Van Slyke instrument was equipped with a thermostated chamber which was maintained at 25 ± 0.05° by means of rapid circulation of water from a constant temperature bath. The detailed directions for this instrument were adapted from manometric analysis of insoluble gases[3] to our problem of measuring saturation pressures of soluble vapor. The optimum procedure described below was checked against pure dioxane, for which the vapor pressure at 25° has been accurately determined.[4] For our description we have adopted the terminology used by Peters and Van Slyke in their detailed outline.[5]

(a) **Calibration.**—Five cc. of 1.670 molar anhydrous sulfuric acid in dioxane is placed in the cup above the chamber, and, with the 3-way cock open and the mercury in the leveling bulb at slight negative pressure, the solution is drawn slowly into the chamber by careful opening and closing of the 4-mm. connecting stopcock. This is followed by the introduction of 5 cc. of an isobutene solu-

[4] p_d = 3.55 cm.: Teague and Felsing, THIS JOURNAL, **65**, 485 (1943).

[5] See ref. 3, pp. 267–280. Figure 37 on p. 272 will be especially relevant to the following discussion. Descriptions of the manometric Van Slyke instrument have also been published in the literature: Van Slyke and co-workers, *J. Biol. Chem.*, **61**, 523 (1924); **73**, 121 (1927).

tion of indeterminate concentration in an identical manner. The 4-mm. cock is closed when the solution has been drained from the cup into the chamber except for a negligible residue remaining in the capillary of the cup. Degassing: after closing of the 3-way cock, the contents of the chamber is evacuated by lowering of the leveling bulb, with the 4-mm. cock open, until the mercury is about 2 cm. below the 50-cc. mark in the chamber. The 4-mm. cock is now closed and the solution is freed of air and some isobutene by rapid shaking for two to three minutes. Mercury is then slowly introduced from the raised leveling bulb by means of partial opening of the 4-mm. cock until the chamber is under very slight excess pressure. The extracted air is immediately expelled through the opened 3-way cock, with the liquid now again filling the capillary of the cup. Vapor pressure determination: the 4-mm. cock is closed, the leveling bulb lowered to slight negative pressure, and a drop of mercury placed into the cup of the chamber. This is slowly drawn into the capillary and into the bore of the 3-way cock by careful opening of the 4-mm. cock, to be turned off instantly when the desired adjustment is attained. With the 3-way cock closed and effectively sealed by means of the mercury, the chamber is evacuated as before, by means of the lowered leveling bulb with the 4-mm. cock temporarily open, until the mercury is again slightly below the 50-cc. mark in the chamber. After a brief period of shaking, the mercury is brought exactly to the 50-cc. mark *from below* by means of careful opening and closing of the 4-mm. cock, to be followed by a manometer reading. Shaking is resumed and the latter procedure repeated in order to assure equilibration of the system.

All our data seemed easily reproducible. The pressures are corrected for the weight of the liquid resting on the mercury in the chamber. The same total volume (10 cc.) was employed for *all* measurements.

Before the bromometric assay for isobutene,[1] the solution is forced back into the chamber by means of the raised leveling bulb with the 4-mm. cock open, until complete re-absorption has occurred. Aliquot samples are then withdrawn and titrated with thiosulfate as described before.[1] The concentrations in Table II are corrected for the constant and small fractions of isobutene present in the vapor phase by simple application of the ideal gas law.

To measure the vapor pressure of dioxane solutions containing varying quantities of sulfuric acid, a similar procedure is followed with these simplifications: Ten cc. of an acid solution is introduced into the chamber. After initial brief degassing shaking becomes superfluous for the measurement of the saturation pressure. Final re-absorption can of course be dispensed with. These preliminary studies are summarized in Table I.

(b) **Kinetic Studies.**—Five cc. of a 1.670 molar solution of anhydrous sulfuric acid in dioxane is introduced into the chamber, to be followed by 5 cc. of an ester solution of known molarity. The subsequent manipulations leading to expulsion of air follow the previous procedure exactly. This short degassing effects an inconsequential shift from the calculated zero point. With the dissolved air extracted and eliminated, the 3-way cock is sealed with mercury as above, and, with the 4-mm. cock temporarily open and the leveling bulb lowered, the mercury in the chamber is adjusted to the 50-cc. mark, or slightly below. Constant shaking is advisable, with brief interruptions for pressure recordings. These are taken on the manometer, at timed intervals, until equilibrium is attained, by careful and slow raising of the mercury to the 50-cc. mark, with the leveling bulb raised and the 4-mm. cock carefully opened until the desired point is reached.

At equilibrium, samples were withdrawn to be analyzed for benzoic acid by titration. They were always in good agreement with the values calculated from the manometric data and also with the known dissociation equilibrium constant.[6]

Acidimetric Runs.—To the *reversible* runs the previous sealed-ampoule technique was applied.[1]

Anhydrous nitrogen was saturated with dioxane vapor by bubbling through 0.83 molar sulfuric acid at 25° and was then passed through the reaction mixture contained in a loosely plugged vessel for the *irreversible* determinations. The stream was regulated to 1 to 2 bubbles per second. One cc. samples of the solutions were withdrawn at timed intervals and analyzed acidimetrically as usual. A blank run, containing 0.202 mole/liter of benzoic acid and no ester, established that the gas stream caused no concentration drifts for at least 2.5 hours, since the acid molarity remained unaltered within the experimental error over this period.

Results and Discussion

Preliminary measurements of the vapor pressure of dioxane, P_d, containing varying amounts of sulfuric acid, are presented in Table I. The values in the last column were computed for an ideal system (Raoult's law); N_d stands for the mole fraction of dioxane. The trend shows a deviation from ideality in the expected direction, emphasizing the formation of oxonium salt.

[a] See ref. 4.

In Table II there are contained the data for solutions of isobutene in 0.835 molar sulfuric acid. The partial pressures of the solute, P_i, were calculated by means of the equation

$$p_i = p_{\text{total}} - p_d \qquad (1)$$

assuming for p_d a constant value over the measured range (3.18 cm.). A simple check shows the error introduced through this approximation to be negative and to remain always below 0.5%. The values of the constant α in the last column illustrate how closely the data adhere to the ideal law

$$p_i = M_i \times \alpha \qquad (2)$$

into which the molarity of isobutene, M_i, rather

(6) Blank tests established that comparable quantities of ester and benzoic acid had no effect on the vapor pressure of isobutene.

than its mole fraction, was substituted as is customary for dilute solutions.

The information above should clearly facilitate the manometric investigation of reactions in which isobutene is a participant, provided the other products and reactants are non-volatile. This surmise was put to the test of a kinetic inquiry. It was applied to the reversible dissociation of *t*-butyl benzoate in anhydrous dioxane solution with 100% sulfuric acid as a catalyst, a system which has been characterized before.[1,7]

$$C_6H_5COOC_4H_9 \underset{k_2}{\overset{k_1}{\rightleftarrows}} C_6H_5COOH + C_4H_8 \qquad (3)$$

The previously derived mathematical function for the dissociation rate constant k_1 can be adapted to the manometric process as follows

$$C + k_1 t = \frac{K_d}{(2p_e/\alpha) + K_d} \ln Q \qquad (4)$$

where

$$Q = \frac{(K_d\alpha) + p_e + p_i}{p_e - p_i} \qquad (5)$$

C is the usual integration constant, K_d is the known dissociation equilibrium constant (K_d = 0.68), and p_e stands for the equilibrium pressure of isobutene. The constant α serves to translate pressure, from cm., into concentration, moles/liter (α = 57.5).[8]

Table III contains the data for two representative manometric runs, while Fig. 1 emphasizes that the linear relationship postulated by Equation (4) is observed over their entire course.

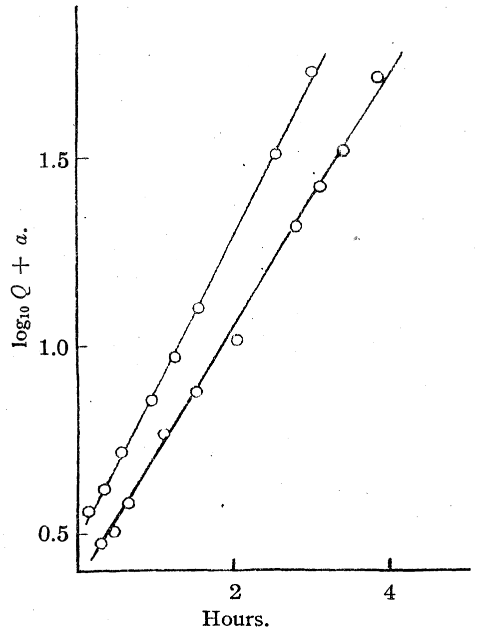

Fig. 1.—Manometric rates of sulfuric acid-catalyzed dissociations of *t*-butyl benzoate in dioxane at 25°: from left to right, no. 2A (a = 0.2) and no. 7 (a = 0).

Three separate approaches substantiated the measurements of the rate constant k_1, and, by implication, justified the manometric procedure. Thus, the ester decompositions were followed either manometrically in a reversible setting, as presented in Table III; or acidimetrically under reversible and under irreversible conditions. The latter was achieved by entraining the volatile olefin in a rapid stream of dry nitrogen, previously saturated with dioxane. The kinetic results obtained with these last experiments were interpreted by plotting the logarithm of ester concentration against the time, as is customary for first-order irreversible reactions. The results are summarized in Table IV. All runs were followed to completion with the exception of no. 4, for which only the initial 20% of its course was measured. Agreement among the diverse methods is obviously satisfactory. The manometric approach is clearly superior, since, with equal accuracy and reproducibility, it is more economic with respect to time and materials, dispensing as

(7) Additional instances of the breakage of the alkyl oxygen-bond in esters have recently been reported: Balfe, Downer, Evans, Kenyon, Poplett, Searle and Tarnoky, *J. Chem. Soc.*, 797 (1946); Balfe, Evans, Kenyon and Nandi, *ibid.*, 803 (1946); Balfe, Kenyon and Wicks, *ibid.*, 807 (1946).

(8) With a small and *constant* fraction of isobutene present in the vapor phase, its molarity in the dioxane solution is somewhat smaller than that of benzoic acid. This required an adjustment of the rate equation. Such a correction is embodied in the factor α, which, as indicated by Equation (2), is based on the concentration of *i*-butene in the *liquid* phase only. See the Experimental Part also.

it does with manipulations of aliquot portions and titrations.

Combined with the previous data at 35°, the new rate constant permits an estimate of the activation energy for the dissociation in 0.835 molar sulfuric acid, ΔE = 17 kcal./mole at 30°.

Summary

The partial pressure of isobutene over dilute solutions in dioxane containing 0.835 molar sulfuric acid was measured by a static method in a Van Slyke instrument at 25°. In its dependence on the concentration, the pressure adheres closely to the ideal law.

The data, applied to the acid-catalyzed reversible dissociation of *t*-butyl benzoate into benzoic acid and isobutene in dioxane solution, provide a basis for manometric kinetic studies and give a first-order rate constant for this reaction. This is in good agreement with the values obtained acidimetrically under reversible and under irreversible conditions.

The activation energy for this reaction is approximately 17 kcal./mole at 30°.

The Salts of Perrhenic Acid. I. The Alkali Metals and Ammonium[1]

BY WM. T. SMITH, JR., AND SELMA HARMON LONG

Although the perrhenates of many of the metals have been prepared, in most cases the physical properties of these salts have been determined only approximately if at all. Of the perrhenates of the alkali metals and ammonium the potassium salt has been most thoroughly characterized, apparently due to the fact that this salt is precipitated in a common method for the recovery of rhenium[2] and that it is easily purified by recrystallization from water. The melting point,[3,4,5,6] boiling point,[6] solubility,[6,7,8,9] heat of solution[9,10] and crystal structure[11] have been reported. The density of the potassium salt was calculated from X-ray measurements of the crystal structure.[11] The density of no other perrhenate of this family has been reported. The only other melting point reported is for sodium perrhenate.[3] The solubilities at room temperature have been reported for all of these salts except lithium perrhenate.[7] The crystal structures of all of the salts except lithium perrhenate have been reported.[11,12,13,14]

Preparation of the Salts.—Rhenium was burned in a stream of oxygen at atmospheric pressure. The finely divided metal ignites under these conditions at approximately 300°. The heptoxide formed was dissolved in water to form perrhenic acid. The acid solution was then neutralized with the C. P. carbonate or hydroxide of the metal.[3] Litmus paper was used as an indicator. The salts so obtained were purified by several recrystallizations from water. They are all white in appearance. Evaporation of water from lithium perrhenate solutions was carried out at room temperature. The vapor from heated solutions of this salt was acidic and contained rhenium which indicated hydrolysis of the salt at elevated temperatures.

After each recrystallization the freezing point of the salt was determined. This was repeated until the same freezing point was observed after successive recrystallizations. The freezing points so obtained are listed in Table I.

The freezing points were obtained by cooling molten samples of 20 to 40 g. at a rate of approximately 2° per minute. The temperatures for the cooling curve for the dihydrate of lithium perrhenate were read on a mercury in glass thermometer while all others were read to 0.2° (0.01 millivolt) on a Brown Portable Potentiometer, Model 1117, using a Chromel–Alumel thermocouple which had been calibrated by direct comparison with a calibrated Iron–Constantan couple furnished by the Brown Instrument Company and guaranteed to give standard voltages corresponding to within 3°F. over the range 0–1200°F. Distinct "arrests" in the cooling curves were noted for each salt which could be melted at atmospheric pressure. The dihydrate of lithium perrhenate does not completely melt at 87.5° but undergoes a transition in which the hydrate decomposes to form a liquid and a white solid which will not completely dissolve in the liquid at 100°. Some of this white solid was separated from the liquid by decantation. The loss in weight of this wet solid on complete dehydration was not so great as the theoretical loss for the monohydrate to anhydrous salt. Apparently the equilibrium is $LiReO_4 \cdot 2H_2O(s) \rightleftarrows$ saturated solution(l) + $LiReO_4(s)$.

The purified salts were analyzed gravimetrically for rhenium as a check on the formula for the salt and its purity. The procedure outlined by Willard and Smith[15] was followed in general. It was found in washing the precipitate of tetraphenylarsonium perrhenate with ice water that precipitation occurred when the wash water was allowed to mix with the original filtrate. Whether this was due to the solubility of the precipitate in the wash water or to the decrease in solubility of the rhenium compound as the salt water filtrate was diluted was not definitely established. The procedure was modified by preparing the reagent, tetraphenylarsonium chloride, already mixed with the specified concentration of sodium

[d] Density of 4.887 previously reported.[11] [e] The values for the solubility of potassium perrhenate are calculated from previously published data.[9] The solubility of this salt in the 50.3° column is the solubility at 49.78°. [f] Roth and Becker[10] report 13.80 ± 0.03 kcal./mole at 21.7°.

chloride and saturated with tetraphenylarsonium perrhenate. The unknown samples were digested with this solution until they were completely converted to the tetraphenylarsonium perrhenate precipitate. During this digestion water was added, if necessary, to maintain the original volume. The precipitate was caught on a Gooch filter, sucked dry and then washed with a saturated solution of tetraphenylarsonium perrhenate. Excellent checks on duplicate samples were obtained in this manner and carefully purified samples of potassium perrhenate agreed with the theoretical rhenium content. The results of these analyses are presented in Table I.

The percentage of water removed from the hydrate of lithium perrhenate in a vacuum desiccator over anhydrous calcium chloride corresponded to the composition of a dihydrate. No further loss of water occurred even above the melting point of the dehydration product. The composition of the monohydrate of lithium perrhenate was established by following the loss in weight of a sample of the dihydrate and the gain in weight of an anhydrous sample of the lithium salt on standing over a 60% sulfuric acid solution in a desiccator at room temperature. After two months both samples were within 0.5% of the theoretical weight for the monohydrate.

Water Vapor Pressures of the Hydrates of Lithium Perrhenate.—In order to determine the conditions under which the hydrates of lithium perrhenate are stable, vapor pressure determinations on saturated solutions and on the solid–vapor systems were made over the approximate temperature range of 25 to 45°. A glass tube containing the sample was sealed to a closed mercury manometer and to a two-way stopcock through which the system was evacuated. The temperature of the sample tube was maintained by a water-bath which was controlled to ±0.05°. When the equilibrium pressure was established readings were made with a depth gage which could be read to 0.05 mm. Water vapor was pumped out of the apparatus after several pressure readings and new pressure readings were made. The pumping was continued periodically until no measurable pressure was found over the sample. The data so obtained are plotted in Fig. 1. Curve I is for the system which contained saturated solution in contact with solid salt. Curve II was obtained on the same samples after pumping off water vapor until lower equilibrium pressures were found. This system contained the two solid hydrates. Curve III was obtained by pumping off more water vapor from the above samples and also by admitting water vapor to anhydrous lithium perrhenate. The two solids in this system were anhydrous salt and monohydrate. The slopes of curves II and III give the following heats of hydration. $LiReO_4(s) + H_2O(v) \rightarrow LiReO_4 \cdot H_2O(s)$, $\Delta H = -13.7$ kcal. $LiReO_4 \cdot H_2O(s) + H_2O(v) \rightarrow LiReO_4 \cdot 2H_2O(s)$, $\Delta H = -12.4$ kcal. $LiReO_4(s) + 2H_2O(v) \rightarrow LiReO_4 \cdot 2H_2O(s)$, $\Delta H = -26.1$ kcal. Using 10.4 kcal. as the molar heat of vaporization of water at the mean temperature of the vapor pressure measurements, the heats of hydration using liquid water instead of vapor in the above reactions are $\Delta H = -3.3$, -2.0 and -5.3 kcal., respectively.

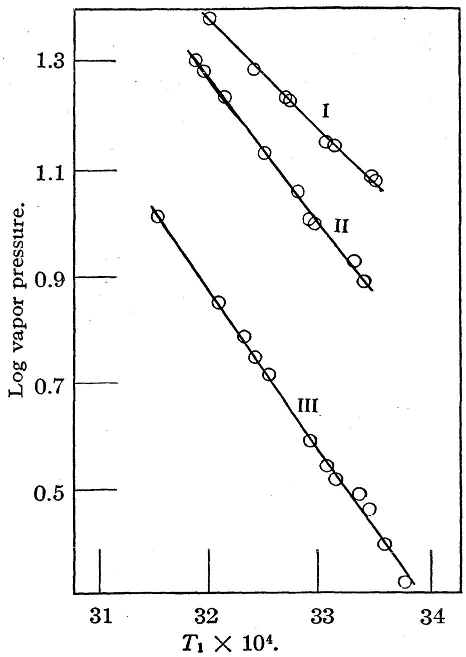

Fig. 1.—Plot of log vapor pressure against the reciprocal of the absolute temperature.

Density Determinations.—The densities of the solid salts were determined at room temperature in a pycnometer using benzene since it does not dissolve these salts and is volatile enough to be effectively removed from the sample without washing. The method was checked using sodium chloride and copper sulfate pentahydrate. The results were 1.4 and 3.5% lower, respectively, than published values[16,17] but duplicate determinations checked within 0.3% of the mean in all cases. Table I lists the densities of these salts.

Solubility Measurements.—The solubilities were determined at 0, 30 and 50.3 ±0.05°, using a method previously described.[9] Lithium perrhenate is so soluble that its solubility was measured only approximately by adding the minimum amount of water necessary to completely dissolve a weighed amount of the salt. Table I includes

(16) Baxter and Wallace, THIS JOURNAL, **38**, 259 (1916).

(17) Andreae, *Z. physik. Chem.*, **76**, 491 (1911).

the solubility of the salts and the heat of solution calculated from the slope of the line obtained when the logarithm of the solubility is plotted against the reciprocal of the absolute temperature. The method of least squares was used to find the best slope.

Microscopic Examination of Crystals.—All of the solid salts prepared were examined with a microscope using polarized light. They are all anisotropic. This has been previously reported[11,12,13,14] for all of these salts except anhydrous lithium perrhenate and its hydrates.

Freezing Point of Ammonium Perrhenate.—Although it was found that ammonium perrhenate decomposes rapidly at 365° at atmospheric pressure, its freezing point can be estimated from other properties. Plots of solubility, molar volume and radius of the cation against the freezing points of the alkali metal perrhenates indicate freezing points of 550, 605 and 580°, respectively, for ammonium perrhenate. The average value, approximately 580°, is predicted as the freezing point of this salt.

Summary

The perrhenates of the alkali metals and ammonium have been prepared and the formulas verified. The densities, freezing points and solubilities from 0 to 50° have been measured. The heats of solution have been calculated. The freezing point of ammonium perrhenate has been predicted.

Studies on the Denaturation of Antibody. III. Kinetic Aspects of the Inactivation of Diphtheria Antitoxin by Urea

BY GEORGE G. WRIGHT AND VERNER SCHOMAKER

Evidence has been presented[1,2] that the inactivation of antitoxin which takes place in urea solutions, as shown by the change in toxin-neutralizing activity, is a first-order reaction in antibody, since the specific rate of inactivation is independent of the initial concentration of antibody. This indicates that a polymolecular complexing reaction of the protein molecules[3-6] is not the mechanism of the inactivation under consideration, even though the occurrence of complexing as a result of the urea treatment could be inferred from the abnormalities of the quantitative flocculation reaction with toxin of the denatured samples.[2] The course of the reaction is not entirely typical of a classical first-order process, however, since the rate decreases more rapidly as the reaction proceeds than is predicted by the first-order law. Similar results have been obtained in the inactivation of antitoxin by heating in the neighborhood of 65°.[7,8] An understanding and a quantitative formulation of these deviations from first-order behavior are essential if the experimental results on antibody inactivation are to yield the maximum information regarding the chemical nature of the reactions and the structure and stabilizing forces of the combining region of the antibody.

In the present investigation we have studied the effects of *p*H, urea concentration, and temperature on the inactivation reaction, in order to explore the influence of these factors on its abnormalities. The experimental results are shown to be compatible with a simple kinetic mechanism.

Materials and Methods

The diphtheria antitoxin was the same globulin preparation used in previous work,[2] and consisted of the water-soluble portion of the protein precipitated from crude horse antitoxin plasma between 1.38 and 1.65 *M* ammonium sulfate. It contained 16% protein and had an activity of about 4000 units per ml. The urea was twice recrystallized from 70% alcohol. The denaturation reactions were carried out in buffered solutions at ionic strength about 0.1; acetate was used in the acid range and borate in the alkaline. The buffers were prepared by mixing various proportions of 0.2 *N* sodium hydroxide and a solution 0.2 *N* in the acid and 0.2 *M* in sodium chloride, so that the ionic strength remained approximately constant at different *p*H values. The *p*H measurements were made with a glass electrode. The buffers were effective in keeping the *p*H change during the experiment to less than 0.1 *p*H unit in practically every case; the recorded value represents the average of the initial and final *p*H measurements. The reactions were carried out in a thermostat constant to within a few hundredths of a degree, at 25.0° except where otherwise indicated.

The solutions for denaturation were prepared by weighing out the calculated amount of urea (using the density data of Dunstan and Mussel[9]), adding

an amount of buffer equal to half the final volume of the solution, and the required amount of water. After the urea had dissolved and the solution had come to temperature in the thermostat, the experiment was started by adding the antitoxic globulin. All the denaturation reactions reported in this paper were carried out at a protein concentration of 0.40%. At the desired intervals, 5-ml. samples were removed, diluted with an equal volume of saline to stop the reaction promptly, placed in cellophane tubing, and dialyzed against several large volumes of saline in the cold to removed the urea. The antitoxin in the samples was assayed by the Römer intracutaneous method in rabbits[10] and corrected for volume changes during the dialysis in accordance with the results of micro-Kjeldahl determinations as described previously.[2] Untreated antitoxin was included in each assay in addition to the partially inactivated samples, and the fraction of the antitoxin activity remaining in the samples was taken as the ratio of the largest amounts of untreated antitoxin and partially inactivated antitoxin which permitted a certain minimal skin reaction when added to the constant amount of toxin.

Experimental

A. The Effect of *p*H.—Previous results had shown that the degree of inactivation of antitoxin after urea treatment for a constant time was influenced markedly by the *p*H.[1] Accordingly, the course of the inactivation was investigated in 8 M urea at a series of *p*H values. Experiments were carried out in acetate buffer at *p*H 4.91, 5.38 and 6.25, and in borate buffer at *p*H 8.85, 9.29 and 9.73. The results are given in Figs. 1–4, where, as in Figs. 5–8, the curves represent the theoretical formulation advanced in the Discussion.

It is possible that specific salt effects may be involved in the variation of the experimental results with change in *p*H, even though the ionic strength was held approximately constant. Exploratory experiments suggested that such variations of ionic strength as did occur could not be of major importance in influencing the rate and course of the reaction. However, further experi-

ments on variation of the ionic strength and on the effects of specific buffer salts and buffer acids would be desirable.

In all of the Figs. 1–8 the fraction of the original antibody activity is plotted on a logarithmic scale and the time on a linear scale, a treatment which reduces the data for a simple first-order reaction to a straight line. Clearly, the reaction deviates from this behavior, and the degree of deviation is influenced markedly by the *p*H. Each of the curves, however, shows a definite tendency to approach linearity after the initial curved portion.

The possibility that the deviation from linearity might be due to some uncontrolled variable in the experimental method has been considered rather extensively. Although it is difficult to exclude this possibility entirely, considerable evidence now supports the conclusion that the deviation is in fact a property of the reaction under consideration. The solutions were adequately buffered, and no significant *p*H change occurred during the reaction. The curves were reproducible and seemed to show an orderly change with *p*H. No change was observed with different urea preparations, and, as noted below, a similar deviation was observed in guanidine hydrochloride inactivation. Perhaps most important, however, was the fact that the shape of the curve was independent of the initial concentration of protein,[2] for if the exhaustion of some contaminant or component of the solution not contributed by the antitoxin solution were responsible for the decrease in specific rate, it should in general occur more rapidly at high protein concentration. The same would be true even if such a substance originated in the antitoxin solution itself.

B. The Effect of Urea Concentration.—The effect of urea concentration was investigated at two representative *p*H values, one in the acid and the other in the alkaline region. Data were obtained for the reaction at 6 and 7 *M* concentrations of urea, and compared with the data already obtained at 8 *M* urea. Since the urea concentration influences the *p*H of the solution, small changes were made in the composition of the buffer used in the 6 and 7 *M* experiments, in order to keep the *p*H constant, as indicated by measurements with the glass electrode. The results are given in Figs. 5 and 6.

It is evident that the effect of increasing the urea concentration is not a uniform increase in the rate of over-all reaction, since the early part of the reaction is greatly speeded up by increase in urea and the latter part of the reaction is speeded up relatively slightly.

C. The Effect of Temperature.—An interesting aspect of the denaturation of proteins in urea is the frequent occurrence of a negative temperature coefficient.[11] Lauffer[12] found that the denaturation of tobacco mosaic virus shows a negative temperature coefficient below room temperature and a positive coefficient above; he advanced a quantitative formulation of this behavior. In a study of the urea denaturation of ovalbumin by measurement of the turbidity after removal of urea by dialysis, however, no negative coefficient was found from 4–40°.[13] It is reasonable that various phases of the denaturation reactions of different proteins with urea should have somewhat different activation energies, so that rather diverse temperature characteristics would be found depending upon the protein and the assay employed for the estimation of extent of denaturation. The results for our reaction, which are recorded in Figs. 7 and 8, show an over-all positive temperature coefficient through the region 0–40°, with, as in the case of ovalbumin, an indication that the reaction may have a minimum rate in the neighborhood of 0° and a negative temperature coefficient at lower temperatures. Although our data are too few and too scattered to demonstrate the existence of such a minimum in the rate of denaturation of antitoxin, they do show that if it does exist it must lie considerably below 25°, the temperature of minimum rate of denaturation of tobacco mosaic virus.[12]

The experiments were carried out under two conditions of urea concentration and *p*H, urea concentrations of less than 8 *M* being necessary because of the reduced solubility of urea at the lower temperatures. In each experiment a single mixture was divided into three parts which were quickly adjusted to the desired temperatures. Accordingly, the three solutions were identical at 25°, but no doubt there were minor differences in *p*H, etc., at the temperatures at which they were allowed to react.

D. Effect of Guanidine Hydrochloride.—The action of guanidine hydrochloride on proteins is generally rather similar to that of urea, but, at equimolar concentration, the denaturing action of the guanidine hydrochloride is considerably greater.[14] A preliminary experiment was carried out to explore the denaturing action of guanidine hydrochloride on antibody activity. Eight *M* guanidine hydrochloride was used, and no buffer or other electrolyte was added; otherwise the methods were the same as in the experiments with urea. The initial *p*H was 6.26, and after forty-eight hours had changed only to 6.28. The results resembled rather closely those for denaturation in 8 *M* urea at *p*H 4.91, but the deviation from linearity was even more extreme. The activity dropped to about 45% of the original in one hour, but after forty-eight hours was still 40%.

Discussion

Although the specific rate of inactivation of antitoxin by urea is independent of the initial concentration of antitoxin,[2] it is clear that the course of the reaction deviates from the typical behavior of a first-order reaction, the specific rate of inactivation decreasing as the reaction proceeds so as to produce a strong deviation from linearity of the log activity *vs.* time plots. The present work shows that this deviation varies greatly with the *p*H and to a lesser extent with the temperature and urea concentration even though it is independent of the protein concentration.[2] The kinetic situation appears in some of these respects to be the opposite of that for the denaturation of tobacco mosaic virus in urea as studied by the disintegration of the virus or by its insolubility on dilution.[12] Nearly straight lines were obtained when the log of the concentration of remaining virus was plotted against the time, but the specific rate varied considerably with the initial concentration of the virus. Preliminary results also suggest that the rate of inactivation of the antibody is less dependent on the ionic strength of the solution than is the rate of denaturation of the virus. It is not clear whether these differences in behavior are due to the very considerable differences in the proteins, or to the different properties of the proteins which were under consideration in the two cases.

It was suggested[1] that the deviation of the inactivation reaction from typical first-order behavior may be due to a heterogeneity of the antibody combining groups in their susceptibility to denaturation by urea. This view was strengthened when it was found to be possible to account quantitatively for the action of simple haptens in inhibiting the precipitin reaction by assuming a normal-error-curve distribution of the free energies of interaction of the antibody molecules with simple hapten.[15] For, although a heterogeneity of

antibody molecules with respect to their interactions with hapten does not require that the molecules be correspondingly heterogeneous in their susceptibility to the denaturing action of urea, such a situation is definitely possible. Attempts were accordingly made to fit the data for antibody denaturation on the assumption, analogous to that adopted for the discussion of the hapten inhibition experiments, that the free energy of activation for the first-order denaturation process is distributed according to a normal-error-curve

$$N(E^*)\mathrm{d}E = \frac{1}{\sigma\sqrt{2\pi}}\, e^{-(E^*-E_0^*)^2/2\sigma_2}\,\mathrm{d}E^*$$

Tables and plots of the resulting expression

$$\text{Remaining fraction of antibody activity} = \frac{1}{\sqrt{\pi}}\int_{-\infty}^{\infty} e^{-k_0 t e^{-bx} - x^2}\,\mathrm{d}x$$

were prepared[16] for comparison with the observed curves. Here t is the time, k_0 is the specific rate of denaturation for antibody with activation energy E_0^* and b is $2^{1/2}\,\sigma/RT$. The fits were often unsatisfactory, since the tails of the plots of this function do not tend to approach straight lines, as seems to be required by the data, and the rapid decline in activity is predicted to amount always to about 50%, in very pronounced disagreement with some of the experimental curves (for example, the upper curve of Fig. 2). Although the shapes of the curves could, of course, be made to fit the data by the assumption of special, non-normal distribution functions for the free energy of activation—as will be seen below, they would indeed need to be simple bimodal distributions—the notion that heterogeneity of the antibody is the main reason for the peculiar kinetics of the reaction was discarded because the values of b required are sometimes greater by an order of magnitude than for the case of hapten inhibitions,[15] and they vary with change in experimental conditions, particularly the *p*H, by what seems to be an unreasonably great amount.

It is, of course, entirely possible that the reaction would proceed by more than one route or mechanism. If each of the mechanisms led independently to inactivation according to the simple first-order law, however, their sum would also follow the first-order law, as has been mentioned by Lauffer[17]; evidently the observed deviation is not to be accounted for in this manner.

A significantly different approach is suggested by the notions that an antibody globulin molecule may undergo denaturation in a number of different ways[18]; that some of these may involve an unfolding of the antibody region, with consequent inactivation, while others may not[18]; and that reactions of this second type can lead reversibly to a product which retains its activity (or regains it when the urea is dialyzed out) but is not susceptible to the inactivation by the first type of reaction. It turns out that the particular, comparatively very simple formulation of these notions

$$\mathrm{I} \xleftarrow{k_1} N \underset{k_3}{\overset{k_2}{\rightleftarrows}} P$$

is consistent with all our data. Here N represents the original, native antibody (or altered antibody not distinguishable from the native antibody in our experiments), I represents the inactivated antibody, and P stands for the postulated active, protected antibody. Transformations among these three molecular species by first-order reactions proceed according to the specific rate constants, k_1, k_2 and k_3, which, although constant in any one experiment, are dependent on the experimental conditions. It is easy to see how this mechanism leads to the correct general results including the straight-line tails of the log activity *vs.* time plots. At the beginning of the reaction the competing transformations of N into I and P predominate, and, although N disappears according to the first-order law, the total activity decidedly does not. Instead, it decays with a rapidly decreasing specific rate, corresponding to an incomplete limiting degree of inactivation. Gradually, however, the reverse action $P \xrightarrow{k_3} N$ becomes important (if $k_3 \neq 0$) and, by providing a continuing source of N such that ultimately a constant fraction of the active material is present as N in steady-state equilibrium with P, leads to ultimate complete inactivation of the antibody according to the first-order law.

It is not difficult to solve the differential equations

$$\begin{aligned} \mathrm{d}[N]/\mathrm{d}t &= -(k_1 + k_2)[N] + k_3[P] \\ \mathrm{d}[P]/\mathrm{d}t &= +k_2[N] - k_3[P] \end{aligned}$$

for this mechanism. The result is

$$\begin{aligned} [N] &= N_1e^{-\lambda_1 t} + N_2e^{-\lambda_2 t} \\ [P] &= P_1e^{-\lambda_1 t} + P_2e^{-\lambda_2 t} \end{aligned}$$

provided that λ_1 and λ_2, the roots (always positive, real numbers) of the determinantal equation

$$\begin{vmatrix} \lambda - k_1 - k_2 & +k_3 \\ +k_2 & \lambda - k_2 \end{vmatrix} = 0; \left\{\begin{matrix} \lambda_1 + \lambda_2 = k_1 + k_2 + k_3 \\ \lambda_1\lambda_2 = k_1k_3 \end{matrix}\right\}$$

are not equal. The constants N_1, N_2, P_1 and P_2 are determined by the general equations

$$\begin{aligned} N_1(\lambda_1 - k_1 - k_2) + P_1k_3 &= 0 \\ N_2(\lambda_2 - k_1 - k_2) + P_2k_3 &= 0 \end{aligned}$$

and the conditions for the initial amounts of N and P

$$N_{t=0} = N_0 = N_1 + N_2 \text{ and } P_{t=0} = P_0 = P_1 + P_2$$

In this way the constants $T_1 = N_1 + P_1$ and $T_2 = N_2 + P_2$ of the expression

$$[T] = [N] + [P] = T_1e^{-\lambda_1 t} + T_2e^{-\lambda_2 t} \qquad (1)$$

for the total activity are also determined

$$N_1 = \frac{(\lambda_1 - k_3)N_0 - k_3P_0}{\lambda_1 - \lambda_2} \quad N_2 = \frac{(\lambda_2 - k_3)N_0 - k_3P_0}{\lambda_2 - \lambda_1}$$

[a] Number of experimental points. Altogether, fifty-six constants were determined from the eighty-eight experimental points of the fourteen curves which were fitted by least squares, leaving thirty-two degrees of freedom for the estimation of error. [b] In reciprocal hours. [c] Data previously reported,[2] not shown in the figures.

$$P_1 = \frac{k_2N_0 + (\lambda_2 - k_3)P_0}{\lambda_2 - \lambda_1} \quad P_2 = \frac{k_2N_0 + (\lambda_1 - k_3)P_0}{\lambda_1 - \lambda_2}$$

$$T_1 = \frac{(k_1 - \lambda_2)N_0 - \lambda_2P_0}{\lambda_1 - \lambda_2} \quad T_2 = \frac{(k_1 - \lambda_1)N_0 - \lambda_1P_0}{\lambda_2 - \lambda_1}$$

For our experiments the values of k_1, k_2 and k_3 were obtained by fitting equation (1) to the data, thereby fixing the values of λ_1, λ_2, T_1 and T_2, and applying the formulas

$$k_1 = \frac{\lambda_1T_1 + \lambda_2T_2}{T_1 + T_2} \quad k_3 = \lambda_1\lambda_2/k_1$$
$$k_2 = \lambda_1 + \lambda_2 - k_1 - k_3 \qquad (2)$$

which may be derived from the above expressions on substituting our initial conditions, $P_0 = 0$ and $N_0 = T_0 = T_1 + T_2$. If the conditions $T_1 + T_2 \cong 1$ (T_1 and T_2 are both positive) and $\lambda_1T_1 >> \lambda_2$ are satisfied, as they are for many of our experiments, k_1, k_2 and k_3 are approximated by the much simpler relations $k_1 \cong T_1\lambda_1$, $k_2 \cong T_2\lambda_1$, $(k_1/k_2 \cong T_1/T_2)$ and $k_3 \cong \lambda_2/T_1$.

Equation (1) was fitted to the data (except for the 40°, 7 M urea, pH 9.23 experiment) by the method of least squares,[19] starting with approximate graphical fits. Equal weights were assigned to all the points of the curves including the initial points, which were not assumed to be necessarily correct inasmuch as the assays of undenatured antitoxin samples were conducted with no greater precision than were the assays of the partially denatured samples. It was assumed that the nominal times of reaction were not in error. The resulting theoretical curves (Figs. 1–8), corresponding to the constants given in Table I and Figs. 9–11, represent the data very well, the root-mean-square of the deviations ($T_{\text{obs.}} - T_{\text{calcd.}}$) for the 88 experimental points being only 0.019, or 1.9% of the initial activity. The corresponding error of the experimental points ($\epsilon = ([v^2]/s-m)^{1/2}$, with $(s-m)$ equal to 32; see ref. 19, p. 245), estimated by the theory of least squares on the assumption that equation (1) is indeed the correct equation for the representation of the data, is 0.031, in good agreement with the accuracy that might be expected from the assay method. This agreement and the generally satisfactory random nature of the deviations provide some additional evidence that equation (1) is an adequate representation of the data. It is true that the average value of $T_1 + T_2$, 0.990, represents a tendency for the curves to pass below the initial assay points, but the discrepancy is not great enough to be regarded as significant.

Although the agreement between the curves and the data is good, the uncertainty in the derived constants is often great because the reactions were not followed intimately enough, particularly at very short and very long times of denaturation, to avoid ambiguity arising from the possibility of approximately fitting data for the intermediate region with different curves having rather different constants. The estimates of standard error of these constants depend on the shape of the particular curves and on the number and distribution of the measured points as well as on the estimated standard error (0.031) of the observations. For T_1, T_2, λ_1 and λ_2 the estimated standard errors are given in the table; for k_1, k_2 and k_3 representative values are perhaps the following for 25° and 8 M urea: at pH 4.91—0.78, 0.87 and 0.0033, respectively; at pH 5.38—0.37, 0.30 and 0.0026; and at pH 9.73—0.09, 0.47 and 0.034. These values, which are so large that only the major trends exhibited by Figs. 9–11 need be regarded as significant, do not tell the whole story, however,

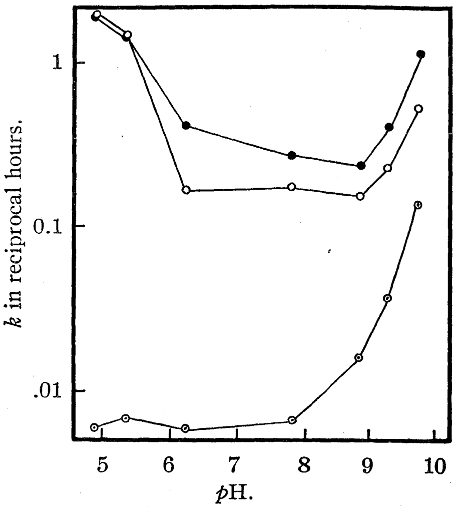

Fig. 9.—The variation of the rate constants discussed in the text with changes in *p*H; plots of log *k* *vs.* *p*H: open circles, k_1; filled circles, k_2; dotted circles, k_3.

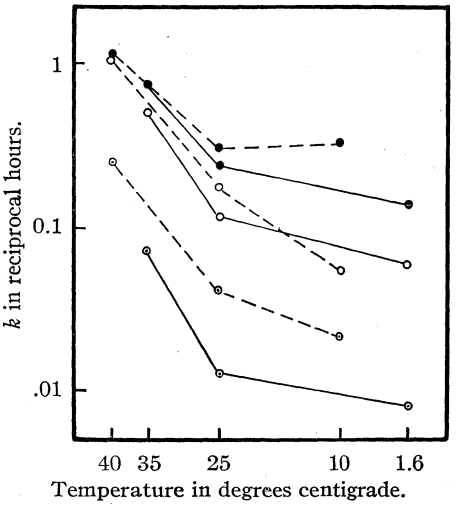

Fig. 10.—The variation of the rate constants with change in temperature; plots of log *k* against the reciprocal of the absolute temperature: open circles, k_1; filled circles, k_2; dotted circles, k_3. Solid lines connect points at *p*H 5.38 and 6 *M* urea; dotted lines, *p*H 9.23 and 7 *M* urea.

because various combinations of the constants may be more or less subject to error, particularly in accordance with their special dependence on the ambiguity just mentioned. This ambiguity is likely to lead to a set of errors such as, $\delta T_1 < 0$, $\delta T_2 > 0$, $(\delta(T_1 + T_2) \simeq 0)$, $\delta\lambda_1 > 0$ and $\delta k_1 > 0$ (increase in initial slope), and $\delta\lambda_2 > 0$, corresponding to $\delta k_2 > 0$, and $\delta k_3 > 0$ as well as $\delta(k_1/k_2) < 0$.

The notable features of the dependence of the *k*'s on *p*H (Fig. 9) are the almost parallel behavior of k_1 and k_2, which decrease with increasing *p*H to about *p*H 6.25 and then increase again beyond *p*H 9.0, and the strikingly different behavior of k_3—hence the great effect of *p*H on the shapes of the log activity *vs.* time curves—which is independent of *p*H below 8 but above *p*H 8 increases rapidly. If it is assumed that the effect of variation of *p*H on the rate is simply one of changing the equilibrium concentration of the critical reaction intermediate (the specific rates of transformation of the intermediate being unaffected by its ionization), these facts may be interpreted in terms of acidic (or basic) ionization constants which are different for the ordinary molecule and the intermediate. If there are *n* such groups, taken as acidic groups, with the same ionization constants *K* and *K** in the ordinary molecule and the intermediate, respectively, the specific rate constant turns out to be given by the expression

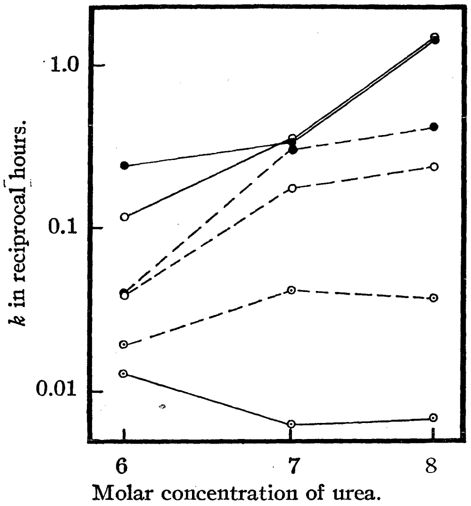

Fig. 11.—The variation of the rate constants with change in urea concentration at 25°; plots of log *k* *vs.* log urea concentration: open circles, k_1; filled circles, k_2; dotted circles, k_3. Solid lines connect points at *p*H 5.38; dotted lines, *p*H 9.26.

$$\log k = \log k_0 + \log([\mathrm{H}^+]^n + K^*) - \log([H^+]^n + K)$$

where k_0 is the specific rate constant at hydrogen ion concentrations so high that the groups are not ionized in either the ordinary molecule or the intermediate. A plot of this expression as a function of *p*H will be seen to consist essentially of two horizontal straight lines and, joining these with short intermediate curves, another straight line of slope $\pm n$. Also, the *p*H values at which the extended straight lines intersect are the values pK^* (*i. e.*, $-\log K^*$) and pK, pK being the greater of the two values if the intermediate line has sloped upward, and *vice versa*. Since the slopes of the steep sections of the curves of Fig. 9 are all essentially unity, one *p*H unit corresponding to a ten-fold change in the rate constant, it may be inferred that in effect only one group of a given kind is coupled with the denaturation reactions; the ionizations are one-step ionizations. It would appear also that only two such groups are strongly coupled with the reactions; regarded as acidic groups, one has $pK \simeq 6.2$ for *P* and the critical intermediates of the reactions $N \rightarrow I$ and $N \rightleftarrows P$ and $pK \geqslant 5$ for N, and the other has $pK \approx 8.8$ for the critical intermediates and $pK > 10$ for P and N. The reaction intermediates and P are accordingly all alike in regard to their reaction-coupled acidic properties in the low pH range (excepting the relatively slight difference that results in the change in the ratio of k_1 to k_2 on going from acidic to basic solutions), but are different at high pH, where P appears to resemble N. With change in temperature the over-all rate of inactivation varies greatly, although the shapes of the log activity *vs.* time curves (Figs. 7 and 8) are not much changed; the same observations are brought out by Fig. 10, which also emphasizes a rather sharp decrease (perhaps not significant) of the ratio k_1/k_2 at the lowest temperature at pH 9.23 and the suggestion, mentioned above, of a minimal over-all rate of reaction in the neighborhood of 0°. The most important point brought out by Fig. 11 is the relative independence of k_3 on urea concentration in contrast to the average eighth-order dependence of k_1 and k_2. In the light of the relatively great probability of errors of the same sign for the k's, particularly for k_2 and k_3, it seems likely that the deviations from these generalizations by the separate results for pH 5.23 and pH 9.26 may not be real.

The substance P is at present hypothetical, and as yet there is no independent evidence of its existence. In addition to the work presented in this paper we have evidence from viscosity studies of the antitoxin system during denaturation that seems to be compatible with the mechanism involving a substance P. Moreover, preliminary experiments in which the denaturation was interrupted by dialysis showed a tendency for the subsequent reaction (when urea was again added) to simulate the original course of reaction with its characteristic plot of log activity *vs.* time. This behavior to us seemed entirely incompatible with the heterogeneity hypothesis. It seems now to be also the sole experimental reason for choosing the scheme

$$\begin{tikzcd} N \arrow[r, shift left, "k_2"] \arrow[dr, "k_1"'] & P \arrow[l, shift left, "k_3"] \\ & I \end{tikzcd}$$

as the basis for our considerations of mechanism rather than the slightly more elaborate scheme

$$\begin{tikzcd} N \arrow[rr, shift left, "k_2"] \arrow[dr, "k_1"'] & & P \arrow[ll, shift left, "k_3"] \arrow[dl, "k_4"] \\ & I & \end{tikzcd}$$

or perhaps its other simplified form with $k_3 = 0$: if the sum of the concentrations of N and P are assumed always to be measured in the assays, the latter scheme gives the same results as the former for the dependence of remaining activity on time of denaturation provided that the rate constants are appropriately adjusted to fit the data. In fact, with $k_3 = 0$, and $\lambda_1 T_1 >> \lambda_2$, the same results are obtained for k_1 and k_2 as before, while for k_4 is found $k_4 = \lambda_2$, in close analogy to the corresponding approximate expression $k_3 = \lambda_2/T_1$ for the first scheme. It should be possible to measure k_3 independently of k_4 by carrying out the crucial interrupted experiment on a quantitative basis with the aid of more data on the denaturation reaction at lower urea concentrations to provide a sounder basis for estimating the rate of reconversion of P to N on dialysis. It should also be possible to gain information about the nature of P by performing interrupted experiments of other sorts, especially with abrupt changes of pH. If these experiments could be performed with enough precision, they, like the crucial dialysis experiment, would also serve to distinguish between our steps in k_3 and k_4, as considerations with the help of the constants shown in Table I and the equations for $k_4 = 0$ with general initial conditions will show.

It is interesting to speculate that from a general chemical point of view P is very similar to I, and that the reactions which form the two products are essentially identical except for the failure in the formation of P of the unfolding of the polypeptide chain to include those regions of the chain which constitute the combining sites[20] of the antibody. The similarity of dependence of k_1 and k_2 on pH, urea concentration, and temperature is in agreement with this view. The partially unfolded globulin molecule (it is known that the unfolding of serum globulin in urea stops far short of the point at which the polypeptide chain is completely extended[21]) may then be stabilized with respect to further unfolding or to refolding. Further processes of refolding and unfolding will no doubt occur, however, and we are particularly interested in the molecule P, which may need to refold into something like its native configuration in order that the antibody combining region may be exposed and thereby again be subjected to the possibility of unfolding and undergoing the detectable change of inactivation. The dependence of the rate constants on urea concentration suggests that the unfolding processes, being highly dependent on urea concentration, may be regarded tentatively as involving actual combination of the protein molecule with several urea molecules—the same number (about eight) for $N \rightarrow P$ as for $N \rightarrow I$—whereas the refolding processes, revealed in the case of $P \rightarrow N$ as independent of the urea concentration, involve dissociation of the protein molecule–urea complexes. According to this interpretation, which certainly cannot be regarded as strictly valid, P may be regarded as a complex formed between a globulin molecule and about eight urea molecules, as may I also if the thesis of general similarity of I and P is correct.

Further studies on the nature of the reactions are in progress. Preliminary experiments with a horse antitoxin against *Staphylococcus* α-hemolysin have indicated that the course of this reaction is closely similar to that of diphtheria antitoxin, and

the simpler technique of the *in vitro* assay for the antitoxin should make the system a favorable one for further kinetic investigations. It is possible that the mechanism proposed for the antitoxin inactivation may prove to be applicable to other denaturations which deviate in a similar way from first-order behavior.

This investigation was carried out with the aid of a grant from The Rockefeller Foundation. The authors are indebted to Professor Linus Pauling for suggestions and discussion, to J. Y. Chien for carrying out preliminary experiments on the effect of temperature, and to Sharp and Dohme, Glenolden, Pennsylvania, for supplying the antitoxin and toxin.

Summary

A study has been made of the influence of *p*H, urea concentration, temperature and certain other factors on the course of the inactivation of diphtheria antitoxin in urea solutions. The reaction is first-order with respect to initial antibody concentration but departs from typical first-order behavior in that the specific rate decreases as the reaction proceeds. The degree of this effect was found to vary greatly with the *p*H of the solution, and somewhat with the urea concentration. No negative temperature coefficient was observed in the temperature studies, although it was clear that the effect of change in temperature is not uniform over the region studied and possibly tends toward a minimum rate of inactivation at or below 0°. The interpretation of the experimental results has been discussed, and a simple kinetic mechanism which accounts for the observed behavior within the error of the measurements has been proposed. The proposed mechanism involves two competing reactions of the protein, one of which leads irreversibly to inactivation of the antibody and the other of which leads reversibly to an active product, more stable in urea solution than the original antibody and subject to inactivation only by way of slow reconversion to the original antibody or its kinetic equivalent.

Tetratriacontanoic Acid and Related Compounds[1]

BY NATHAN L. DRAKE AND SIDNEY MELAMED[1a]

The present research was undertaken with the object of preparing certain aliphatic carboxylic acids and ethers in the C_{20}–C_{40} range. Francis, King and Willis[2] have prepared tetratriacontanoic acid with a yield of 14% from docosanoyl chloride and ethyl sodio-α-acetylbrassylate. More recently dotriacontanoic acid was obtained with a yield of 26% by the reaction of docosanyl zinc iodide and 9-carbethoxynonanoyl chloride.[3] The procedure employed in the present work gave greatly improved yields and is applicable to the preparation of relatively large amounts of material.

The reaction of a dialkyl cadmium with an ω-ester-acid chloride has been extensively studied by Cason.[4] The method has been applied in this work to the preparation of 10-ketohexacosanoic acid from 9-carbethoxynonanoyl chloride and dihexadecyl cadmium and of 18-ketotetratriacontanoic acid from 17-carbethoxyheptadecanoyl chloride and dihexadecyl cadmium; the yields obtained were of 32 and 79%, respectively. The reaction has been further applied to the condensation of an acid chloride and an ω-alkoxyalkyl cadmium compound. In this manner 1-cyclohexoxy-11-ketodotriacontane was obtained from di-(10-cyclohexoxydecyl)-cadmium and docosanoyl chloride and 1-cyclohexoxy-11-ketohexatriacontane was similarly prepared from hexacosanoyl chloride and the same dialkyl cadmium compound. The requisite 1-bromo-10-cyclohexoxydecane was obtained from 1,10-dibromodecane and sodium cyclohexoxide.[5]

The conversion of the keto-acids and keto-ethers to the desoxy acids and ethers, respectively, was accomplished in excellent yield by the application of a recently described modification of the Wolff–Kishner reaction.[6] The only adaptation required was the use of larger amounts of solvent. It is of interest that the method of Clemmensen proved less satisfactory.[7]

The use of the cadmium alkyl reaction for the preparation of these keto-acids is dependent upon the availability of long-chain acid esters. Ethyl hydrogen sebacate[8] is readily obtained by the partial esterification of sebacic acid and can be isolated by fractional distillation. In the preparation of ethyl hydrogen hexadecanedicarboxylate, distillation is not a practicable method of isolation. The partial saponification of the diester[9] leads to

a mixture of the diacid, diester and half ester.[10,11] The diester was removed by extraction from the *dry* sodium salts by hot petroleum ether. The separation of the half-ester from the diacid was accomplished by extracting the mixture of free acids with petroleum ether (b. p. 30–60°), which selectively dissolved the half-ester.

The keto-esters obtained from the cadmium alkyl reaction were found difficult to purify and were therefore isolated as the keto-acids. Two main by-products were formed: the related dibasic acid and dotriacontane. Recrystallization of the crude product from petroleum ether readily removed the hydrocarbon which remained in solution. The separation of the keto-acid from the dibasic acid was accomplished by fractional extraction with sodium hydroxide dissolved in 60% aqueous ethanol.[12] The separation is dependent upon the greater acidity of the dibasic acid and the greater solubility of the sodium salt of the keto-acid in the organic phase.

Similarly in the preparation of the keto-ethers two by-products were formed: the related fatty acid and the diether, 1,20-dicyclohexoxycosane. Docosanoic acid was separated from the corresponding keto-ether by extraction with hot, alkaline 60% aqueous ethanol. In the case of hexacosanoic acid it was found that the sodium salt was completely soluble in hot, wet petroleum ether. The petroleum ether solution was therefore dried and the sodium hexacosanoate, which precipitated as a gel, was removed by filtration.

The dialkyl cadmium reaction is described in detail for the preparation of 18-ketotetratriacontanoic acid. The data for the other condensations are given in Table I. Similarly the modified Wolff–Kishner procedure employed is described for the preparation of tetratriacontanoic acid and the data for the other reductions are given in Table II.

Experimental

Ethyl Hydrogen Hexadecane-1,16-dicarboxylate.—A well-stirred solution of 370 g. (1 mole) of diethyl hexadecane-1,16-dicarboxylate[9] in 500 ml. of dry ethanol was treated dropwise with 400 ml. of dry ethanol containing one mole of sodium ethoxide and one mole of water and allowed to stand overnight. The solvent was removed by distillation and replaced with several liters of petroleum ether (90–100°). The mixture was heated and stirred to suspend the solid and extract the residual diester and finally cooled and filtered. The filtration may be facilitated by the use of a larger volume of petroleum ether or by the addition of ethyl methyl ketone or toluene to the petroleum ether. The sodium salts were extracted with several portions of petroleum ether or mixed solvent as described above and finally washed with ether and dried at 90° to give 271 g. of yellow, granular product; 98 g. of diester resulted from the evaporation of the petroleum ether filtrates.

The dried sodium salts were suspended in 4 liters of warm water (80–90°) and were converted to the free acids by the slow addition of 120 ml. of concentrated hydrochloric acid to the well-stirred suspension. The acids were liquid under these conditions and solidified to a cake when the solution was cooled. The solid cake could be readily separated from the water[13]; further separation of solution was effected by remelting and cooling. The product (252 g.) was powdered and employed in the next step.

The dry mixed acids were extracted in a Soxhlet extractor; 3–4 liters of petroleum ether (30–60°) was used as solvent.[14] The petroleum ether solution deposited 114 g. of ethyl hydrogen hexadecane-1,16-dicarboxylate, m. p. 67–70° (33%). *Anal.* Calcd. for $C_{20}H_{38}O_4$: C, 70.13; H, 11.18; mol. wt., 342. Found: C, 70.45, 70.59; H, 11.32, 11.20; mol. wt. (saponification equivalent), 328.

The material insoluble in the petroleum ether (30–60°) amounted to 85 g.; it melted at 113–119° (27%), and was largely the diacid. A pure sample which melted at 124.5–125.3°, was obtained by recrystallization from methanol. *Anal.* Calcd. for $C_{18}H_{34}O_4$: C, 68.75; H, 10.90. Found: C, 68.82, 68.56; H, 11.13, 10.94.

The petroleum ether filtrate from the crystallization of the half ester was concentrated to give an additional 35 g. of diester. The total quantity of diester recovered was 133 g. (36%); the total of products accounted for 96% of the starting material.

18-Ketotetratriacontanoic Acid.—A Grignard reagent was prepared from 14.9 g. (0.62 gram atom) of magnesium and 214 g. (0.7 mole) of cetyl bromide dissolved in 500 ml. of dry ether. The solution was cooled to 5° and 67.7 g. (0.37 mole) of dry cadmium chloride was added in one portion. The mixture was stirred and heated under reflux until a test for Grignard reagent was negative.[15] The bulk of the ether was removed by distillation and the solid was suspended in 1500 ml. of a mixture of benzene and toluene (2:1).

The acid chloride, 17-carbethoxyheptadecanoyl chloride, was prepared from 141 g. (0.412 mole) of ethyl hydrogen hexadecane-1,16-dicarboxylate by the addition of 85.8 g. (0.412 mole) of phosphorus pentachloride to the molten ester over a period of three to five minutes; the mixture was warmed on a steam-bath for ten to fifteen minutes to complete the reaction. The bulk of the phosphorus oxychloride formed was removed by distillation under diminished pressure; any traces remaining were removed by distilling 100 ml. of dry petroleum ether (60–80°) from the residue. After removal of the last of the petroleum ether, the acid chloride was dissolved in 400 ml. of hot toluene and used without further purification.

The solution of acid chloride in toluene was added over a period of thirty minutes to the well-stirred suspension of the dialkyl cadmium, and the mixture was heated under reflux for six hours and then allowed to stand overnight. A solution of 50 ml. of concentrated sulfuric acid in 1 liter of water was next added, and the mixture was heated to 70° and stirred for a time whereupon the layers were separated while hot. The toluene layer was washed with two 500-ml. portions of hot water and then concentrated to about 400 ml. by distillation. The residue was dissolved in 90% aqueous ethanol, 60 g. of potassium hydroxide was added, and the solution was heated under reflux for two hours to complete saponification of the ester. The well-stirred solution was diluted with 300 ml. of water and acidified with 150 ml. of concentrated hydrochloric acid while being heated under reflux. The hot slurry so formed was diluted with 500 ml. of hot water, cooled and filtered. The solid was melted, cooled and when solid again was removed as a cake from the water

1-Cyclohexoxyhexatriacontane	86.5–87.5	Ethyl methyl ketone	83.37	13.99	82.97 82.88	14.04 14.41	94

[a] Francis and Piper (ref. 17) have recorded the melting point as 87.7°. The cerotic acid obtained by the hydrolysis and oxidation of Chinese Insect Wax had a melting point of 78–80° (ref. 19).

which had separated. The keto-acid was recrystallized from 1 liter of petroleum ether (90–100°). After the acid had been dried at 90–100°, it melted at 98–103°; the yield was 170 g. (79%).

A 10-g. sample of the crude keto-acid was dissolved in 300 ml. of hot petroleum ether (90–100°) and heated and stirred with 200 ml. of 60% alcohol containing 0.004 mole of sodium hydroxide. The layers were separated hot, and the petroleum ether solution was concentrated and cooled; the crystals, after separation by filtration and drying, melted at 103–104°. A small sample, recrystallized twice from acetone for analysis, melted at 104–105°. *Anal.* Calcd. for $C_{34}H_{66}O_3$: C, 78.09; H, 12.72; mol. wt., 522.9. Found: C, 78.30; H, 12.75; mol. wt., (neut. equiv.) 508.

The petroleum ether filtrate from which the crude keto-acid had been isolated was heated and stirred with 700 ml. of 60% alcohol containing 30 g. of potassium hydroxide, the layers were separated, and the petroleum ether solution was washed with two 600-ml. portions of hot 60% alcohol. Acidification of the alkaline solution, filtration, and recrystallization of the solid from petroleum ether (90–100°) yielded 19 g. of impure hexadecane-1,16-dicarboxylic acid which melted at 110–120°. The petroleum ether solution was concentrated to small volume, and the solid which separated was recrystallized twice from absolute ethanol; 13 g. of white needles which melted at 68–70° was obtained. This product is probably dotriacontane. It can also be crystallized from ethyl methyl ketone. *Anal.* Calcd. for $C_{32}H_{66}$: C, 85.24; H, 14.76. Found: C, 84.06; H, 14.43.

1,20-Dicyclohexoxycosane.—The petroleum ether filtrate obtained from the recrystallization of the crude 1-cyclohexoxy-11-ketodotriacontane (see Table I) was concentrated to a small volume and cooled. The precipitate, 40 g. (from 0.2 mole of 1-bromo-10-cyclohexoxydecane), was recrystallized from 250 ml. of ethyl methyl ketone, and the solid so obtained was recrystallized twice from absolute ethanol; 5 g. of 1,20-dicyclohexoxycosane which melted at 54–56° was obtained. *Anal.* Calcd. for $C_{32}H_{62}O_2$: C, 80.26; H, 13.05. Found: C, 80.23; H, 13.28.

Docosanoic Acid (Behenic Acid).—Erucic acid[16] was hydrogenated in alcoholic solution in the presence of Raney nickel catalyst. Under 2000 p. s. i. of hydrogen and at a temperature of 75°, the hydrogenation proceeded rapidly and smoothly. The product, when recrystallized from petroleum ether (b. p. 90–100°), separated as white, shiny plates which melted at 79.5–80.5°. Francis and Piper[17] have recorded a melting point of 79.95° for this acid. *Anal.* Calcd. for $C_{22}H_{44}O_2$: mol. wt., 340. Found: mol. wt. (neut. equiv.), 355.

Tetratriacontanoic Acid.—A mixture of 85 g. of 18-ketotetratriacontanoic acid, 85 ml. of 85% hydrazine hydrate, 85 g. of sodium hydroxide and 3 liters of diethylene glycol was heated in a flask equipped with a stirrer, a thermometer, and an arrangement for the removal or return of refluxing liquid. When the temperature had reached 140–150°, the mixture began to foam, and it was necessary to apply heat less rapidly and to stir vigorously. Foaming stopped when the temperature passed 150°; solvent began to reflux at 175°, and the temperature was held at that point for one hour. Volatile material was then removed over a period of two hours, and the mixture was finally heated under reflux at 215° for an additional hour and a half. When the mixture had cooled to 160–180°, it was poured slowly into a warm (60°), well-stirred solution of 300 ml. of concentrated hydrochloric acid in 3 liters of water. The hot solution was extracted with 3 liters of hot toluene, and the toluene layer washed with hot water and finally with a dilute ethanolic solution of sodium hydroxide (60% aqueous ethanol). The toluene solution was then concentrated and cooled. Tetratriacontanoic acid, which melted at 92–93.5°, was obtained in 82% yield. The time of reaction was insufficient for the large quantities employed; the product contained unreduced keto-acid. Further treatment of the product by the procedure described gave purer material which melted at 95–96°. An analytical sample prepared by recrystallization from acetone melted at 95.5–96.4°.[18]

Anal. Calcd. for $C_{34}H_{68}O_2$: mol. wt., 508.9. Found: mol. wt. (neutral equivalent), 511.

Ethyl Tetratriacontanoate.—A solution of 5.0 g. of tetratriacontanoic acid in 150 ml. of dry alcohol, 250 ml. of benzene and 0.2 g. of *p*-toluenesulfonic acid were heated for two hours under an 18-inch helix-packed column. Distillate was then taken off slowly until 300 ml. had been collected. The residual solution was cooled, and the

precipitate was collected and recrystallized from petroleum ether (90–100°). The white, waxy crystals melted at 76–76.5°.[20] The ester also crystallized well from ethyl methyl ketone.

Anilide of Tetratriacontanoic Acid.—One gram of acid was mixed with 10 ml. of thionyl chloride, allowed to stand for thirty minutes and then heated under reflux for several minutes. Excess thionyl chloride was removed by distillation and the residue, dissolved in 60 ml. of petroleum ether, was added to 5 ml. of aniline. The mixture was stirred thoroughly and evaporated to dryness; the residue was triturated with cold, dilute hydrochloric acid and the crystals were separated by filtration. The product was recrystallized once from a small volume of ethyl methyl ketone and then twice from 100-ml. portions of petroleum ether (90–100°). The anilide, 1.05 g., melted at 110–110.5°. Francis[2] reported a melting point of 113–114°.

Acknowledgment.—We should like to acknowledge the continued interest and suggestions of Dr. Howard Gilbert of the Bureau of Aeronautics, Navy Department. Miss Eleanor Werble performed the microanalyses, and Mr. Herman Sanders aided in the preparation of certain intermediates.

Summary

1. The preparation of hexacosanoic acid and tetratriacontanoic acid is described.

2. The same method has been applied to the synthesis of 1-cyclohexoxydotriacontane and 1-cyclohexoxyhexatriacontane.

3. A convenient synthesis of ethyl hydrogen hexadecanedicarboxylate has been developed. The method depends upon the selective solvent action of petroleum ether which has been shown to be a solvent of useful specificity.
